Mycelial Dry Weight. In the single culture, the dry weight of *Pen. cyaneum* increased until day 10 (115 mg), and decreased slightly thereafter (Figure 1a). In coculture with *Pyt. vexans*, the total dry weight of *Pen. cyaneum* and *Pyt. vexans* increased until day 10 and then became stable (107–108 mg) (Figure 1a). Dry weight in the single culture of *Pyt. vexans* increased from day 4 to 106 mg on day 16 and then decreased on day 18 (Figures 1a and 5a). The *total* dry weight of *Pen. cyaneum* and *Pyt. vexans* in the coculture was not significantly different from that of *Pen. cyaneum* in the single culture (Figure 1a). Since the

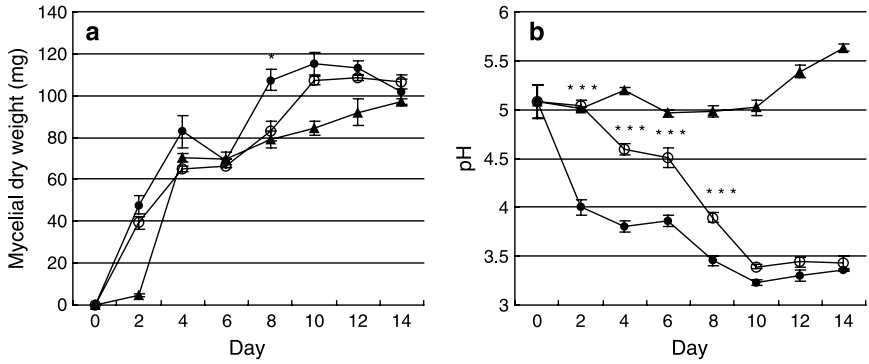

FIG. 1. Single culture of *Pen. cyaneum* and coculture with *Pyt. vexans* (1). (a) Mycelial dry weight. (b) pH. Filled circle: the single culture of *Pen. cyaneum*. Open circle: the coculture of *Pen. cyaneum* with *Pyt. vexans*. Filled triangle: the single culture of *Pyt. vexans*. Statistical analysis was conducted to compare the single culture with the co-culture with *Pyt. vexans*. Bars: ±SE. ***$P < 0.001$, **$P < 0.01$, *$P < 0.05$.

growth of both *Pen. cyaneum* and *Pyt. vexans* was observed in the coculture, the growth of *Pen. cyaneum* must be less in the coculture compared to the single culture.

pH. In the single culture of *Pen. cyaneum*, pH decreased quickly by day 2 and became stable after day 10 (pH 3.23–3.36) (Figure 1b). In the coculture with *Pyt. vexans*, pH gradually decreased until day 10 and became stable thereafter (pH 3.39–3.44) (Figure 1b). pH in the single culture of *Pyt. vexans* was nearly stable until day 10 (pH 4.96–5.19) and increased to 5.63 by day 14 and decreased thereafter to 5.28 (Figures 1b and 5b). pH in the coculture with *Pyt. vexans* was higher than that in the single culture of *Pen. cyaneum* on days 2, 4, 6, and 8 ($P < 0.001$). Thus, the growth of *Pyt. vexans* in the coculture might delay the decrease of pH (Figure 1b).

Antifungal Activity and Amount of Patulin. In the single culture of *Pen. cyaneum*, antifungal activity appeared on day 6, increased until day 10, and became stable thereafter (inhibitory zones; 12.6–13.7 mm) (Figure 2a). Patulin was detected on day 4 and increased rapidly until day 8 (66.8 μg/125 μl), and slightly thereafter (Figure 2b). In the coculture with *Pyt. vexans*, antifungal activity appeared on day 8, increased until day 12 (15.0 mm), and then decreased slightly (13.4 mm on day 14) (Figure 2a). Patulin was detected on day 4, but it increased rapidly after day 6, and the concentration stabilized after day 10 (65.7–70.6 μg/125 μl) (Figure 2b). The antifungal activity and the amount of patulin on days 10, 12, and 14 were not significantly different between the cultures of *Pen. cyaneum* with and without *Pyt. vexans* ($P > 0.05$, Figure 2). On

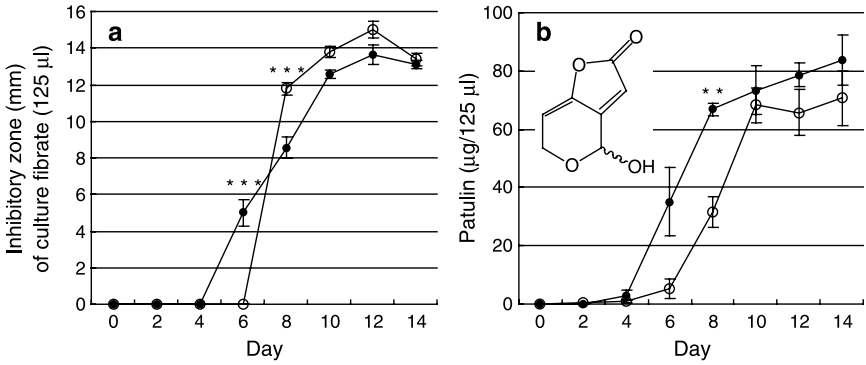

FIG. 2. Single culture of *Pen. cyaneum* and coculture with *Pyt. vexans* (2). (a) Antifungal activity. (b) Amount of patulin. Filled circle: the single culture *Pen. cyaneum*. Open circle: the coculture of *Pen. cyaneum* with *Pyt. vexans*. Bars: ±SE. ***$P < 0.001$, **$P < 0.01$, *$P < 0.05$. The measurement unit µg/125 µl was used in panel b because the inhibitory zones of culture filtrates (125 µl) were examined in panel A. The culture filtrate in the single culture of *Pyt. vexans* did not show any antifungal activity against *Pyt. vexans*. No antifungal compound was detected in the single culture filtrate of *Pyt. vexans*.

day 8, the antifungal activity in the coculture was higher than in the single culture ($P < 0.001$), although the amount of patulin was smaller than that in the single culture ($0.001 < P < 0.01$) (Figure 2). Twenty-five to 100 µg/disk of patulin causes a 14-mm inhibitory zone against *Pyt. vexans* (Yamaji et al., 1999) (the antifungal results using paper disks were not much different from those using cylinders when antifungal compounds in our study were examined). However, the inhibitory zone caused by the culture filtrate of the single culture on day 8 (66.8 µg/125 µl) was much smaller than 14 mm. *Pen. cyaneum* grew more vigorously in the single culture than that in the coculture on day 8 (Figure 1a), suggesting that some metabolites produced in the single culture may have suppressed the activity of patulin. *Pen. cyaneum*, hence, produces patulin even under competitive conditions with *Pyt. vexans*.

Single Culture of Pen. damascenum and Coculture with Pyt. vexans

Mycelial Dry Weight. In the single culture, the dry weight of *Pen. damascenum* increased until day 12 and stabilized thereafter (144 mg) (Figure 3a). In coculture with *Pyt. vexans*, the total dry weight of *Pen. damascenum* and *Pyt. vexans* increased until day 6, fluctuated slightly, then decreased to 102 mg

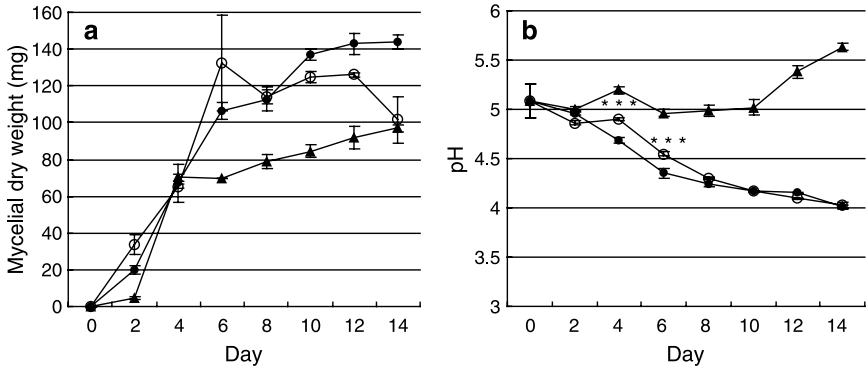

FIG. 3. Single culture of *Pen. damascenum* and coculture with *Pyt. vexans* (1). (a) Mycelial dry weight. (b) pH. Filled circle: the single culture of *Pen. damascenum*. Open circle: the coculture of *Pen. damascenum* with *Pyt. vexans*. Filled triangle: the single culture of *Pyt. vexans*. Statistical analysis was conducted to compare the single culture with the coculture with *Pyt. vexans*. Bars: ±SE. ***$P < 0.001$, **$P < 0.01$, *$P < 0.05$.

by day 14 (Figure 3a). There were no significant differences between *total* mycelial dry weights of the two fungi in the coculture and the dry weight of *Pen. damascenum* in the single culture ($P > 0.05$). Again, as growth of both *Pen. damascenum* and *Pyt. vexans* was observed in the coculture, the growth of *Pen. damascenum* is less in the coculture.

pH. In both the single culture of *Pen. damascenum* and the coculture with *Pyt. vexans*, pH decreased until day 8 and became stable thereafter (Figure 3b). However, pH in the coculture on days 4 and 6 was higher than that in the single culture ($P < 0.001$). The growth of *Pyt. vexans* in the coculture, thus, might delay the pH decrease (Figure 3b).

Antifungal Activity and Amount of Citrinin. In the single culture of *Pen. damascenum*, antifungal activity appeared on day 4 and continued to increase until day 14 (inhibitory zone; 9.4 mm on day 14) (Figure 4a). Citrinin was first detected on day 4, continued to increase until day 8, and became nearly stable thereafter (32.2–39.3 μg/250 μl) (Figure 4b). In the coculture with *Pyt. vexans*, antifungal activity appeared on day 6 and became nearly stable after day 8 (inhibitory zone; 9.4–10.6 mm) (Figure 4a). Citrinin was first detected on day 4 and rapidly increased to its highest value on day 10 (68.9 μg/250 μl). After day 10, citrinin decreased (25.6 μg/250 μl on day 14) (Figure 4b). Antifungal activity in the coculture was higher than that in the single culture on days 6, 8, and 10 but lower on day 4 ($P < 0.001$). However, the amount of citrinin was not different between the two cultures for 14 d except on day 10 (Figure 4b). Although 33 μg/disk of citrinin causes a 9.5-mm inhibitory zone against *Pyt.*

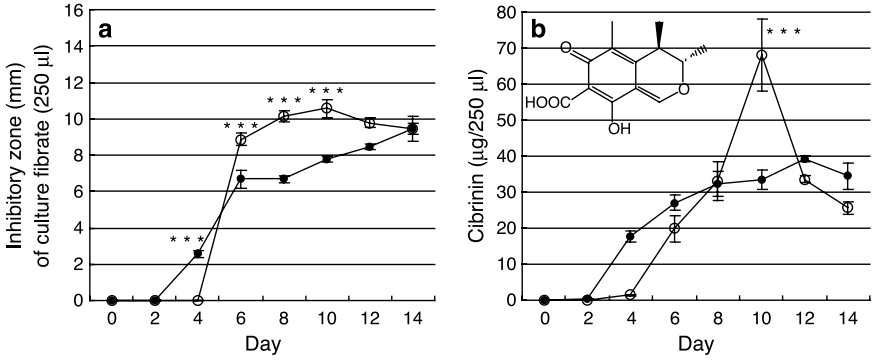

FIG. 4. Single culture of *Pen. damascenum* and coculture with *Pyt. vexans* (2). (a) Antifungal activity. (b) Amount of citrinin. Filled circle: the single culture of *Pen. damascenum*. Open circle: the coculture of *Pen. damascenum* with *Pyt. vexans*. Bars: ±SE. ***$P < 0.001$, **$P < 0.01$, *$P < 0.05$. The measurement unit µg/250 µl was used in panel b because the inhibitory zones of culture filtrates (250 µl) were examined in panel a. The culture filtrate in the single culture of *Pyt. vexans* did not show any antifungal activity against *Pyt. vexans*. No antifungal compound was detected in the single culture filtrate of *Pyt. vexans*.

vexans (Yamaji et al., 1999), the inhibitory zones caused by the culture filtrate of the single culture on day 8 (32.2 µg/250 µl), day 10 (33.5 µg/250 µl), and day 12 (39.3 µg/250 µl) were smaller than 9.5 mm. These results suggest that some metabolites produced in the single culture may have suppressed the antifungal activity of citrinin. The largest amount of citrinin on day 10 (68.9 µg/250 µl) in the coculture did not appear to affect inhibition (10.6 mm, Figure 4a). Our results indicate that *Pen. damascenum* under competitive conditions with *Pyt. vexans* produces citrinin constantly and more abundantly (day 10) than in the single culture.

Single Culture of Pen. implicatum and Coculture with Pyt. vexans

Mycelial Dry Weight. In the single culture, dry weight of *Pen. implicatum* increased until day 10 (115 mg on day 10) and became nearly stable thereafter (98–112 mg) (Figure 5a). In coculture with *Pyt. vexans*, the total dry weight of *Pen. implicatum* and *Pyt. vexans* increased irregularly until day 18 (120 mg on day 18) (Figure 5a). The *total* dry weight of the two fungi in the coculture was heavier than that of *Pen. implicatum* in the single culture on day 4 ($0.001 < P < 0.01$), but was not significantly different thereafter (Figure 5a). The mycelial growth of both *Pen. damascenum* and *Pyt. vexans* was observed in the coculture; therefore, the growth of *Pen. implicatum* is lower in the coculture with *Pyt. vexans*, at least on days 8, 10, 12, and 14.

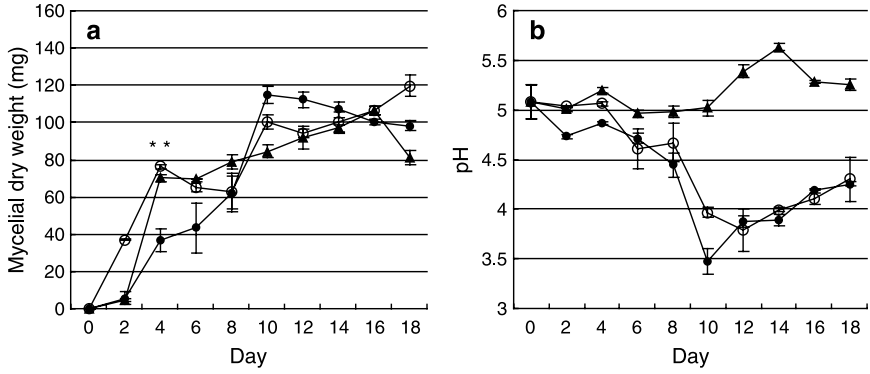

FIG. 5. Single culture of *Pen. implicatum* and coculture with *Pyt. vexans* (1). (a) Mycelial dry weight. (b) pH. Filled circle: the single culture of *Pen. implicatum*. Open circle: the coculture of *Pen. implicatum* with *Pyt. vexans*. Filled triangle: the single culture of *Pyt. vexans*. Statistical analysis was conducted to compare the single culture with the coculture with *Pyt. vexans*. Bars: ±SE. ***$P < 0.001$, **$P < 0.01$, *$P < 0.05$.

pH. Both in the single culture of *Pen. implicatum* and in the coculture with *Pyt. vexans*, pH decreased during the first 10 d and increased slightly thereafter (Figure 5b). On day 10, pH was 3.47 in the single culture and 3.97 in the coculture. There were no significant differences in pH between the single culture and the coculture during the cultural period ($P > 0.05$).

Antifungal Activity and Amount of Palitantin and Frequentin. In both the single culture of *Pen. implicatum* and the coculture with *Pyt. vexans*, antifungal activity appeared on day 10 and increased until day 14 (Figure 6a). Antifungal activity after day 14 was stable in the single culture (inhibitory zone; 11.8–12.0 mm), but decreased in the coculture (inhibitory zone; 8.80–10.1 mm) (Figure 6a). In the single culture, frequentin was first detected on day 8, increased rapidly until day 16 (21.1 μg/125 μl), and decreased thereafter (Figure 6b). Palitantin was detected on day 4, continued to increase until day 14 (10.7 μg/125 μl on day 14), and decreased thereafter (Figure 6c). In the coculture with *Pyt. vexans,* frequentin increased after day 10 until day 16 (15.8 μg/125 μl on day 16), and then decreased thereafter (Figure 6b). The amount of palitantin in the coculture was low during the cultural period (0–3.6 μg/125 μl) (Figure 6c). The antifungal activity in the coculture was not significantly different from or lower (on days 10, 12, and 18, $P < 0.001$) than that in the single culture of *Pen. implicatum* (Figure 6a). In contrast, the pattern of the antibiotic production was different between the single culture and the coculture (Figure 6b and c). The maximum ratio of frequentin to palitantin was 3.67:1 in the single culture, whereas it was 5.87:1 in the coculture during the 18-d culture

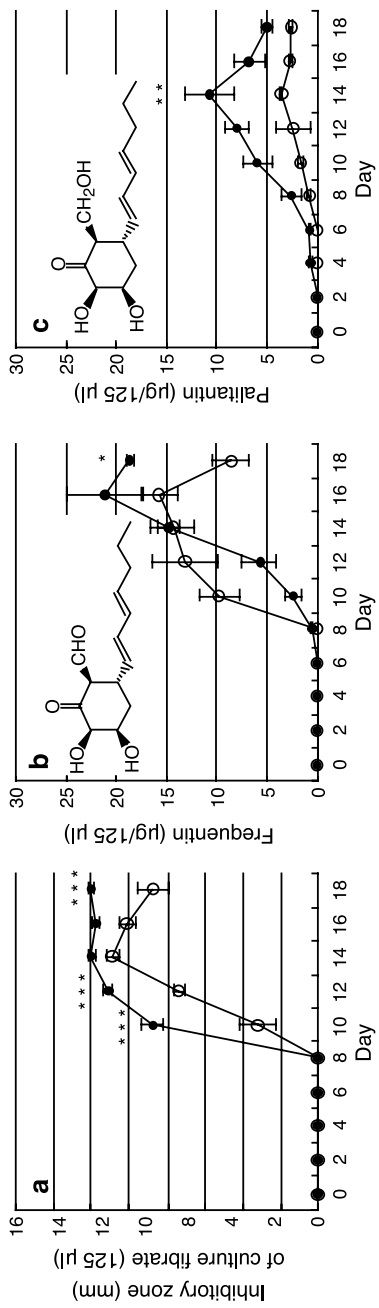

FIG. 6. Single culture of *Pen. implicatum* and coculture with *Pyt. vexans* (2). (a) Antifungal activity. (b) Amount of frequentin. (c) Amount of palitantin. Filled circle: the single culture of *Pen. implicatum*. Open circle: the coculture of *Pen. implicatum* with *Pyt. vexans*. Bars: ±SE. $***P < 0.001$, $**P < 0.01$, $*P < 0.05$. The measurement unit µg/125 µl was used in panels b and c because the inhibitory zones of culture filtrates (125 µl) were examined in panel a. The culture filtrate in the single culture of *Pyt. vexans* did not show any antifungal activity against *Pyt. vexans*. No antifungal compound was detected in the culture filtrate of *Pyt. vexans*.

period. Frequentin shows higher antifungal activity than palitantin against *Pyt. vexans* (Yamaji et al., 2001). *Pen. implicatum* in the coculture produced a larger amount of frequentin than palitantin. *Pen. implicatum*, thus, may maintain high antifungal activity by changing the ratio of antifungal compounds produced.

Each *Penicillium* species in our study showed a particular chemical response to *Pyt. vexans*. Several researchers have reported chemical responses between microorganisms. Coculture of *Lentinus edodes* (Basidiomycete) and *Trichoderma* spp. (a pathogenic fungus against *L. edodes*) showed higher antifungal activity against *Trichoderma* than that of the single culture of *L. edodes* (Tokimoto et al., 1987). *L. edodes* produced two induced antifungal compounds against *Trichoderma* spp. in coculture, and a higher production depended on the kind of medium (Tokimoto et al., 1987). Coculture of *Aspergillus flavus* and *Aspergillus nidulans* produced two induced antibiotics, hydroxyaspergillic acid and an aspergillic acid-like compound, that were not produced when either fungus was grown alone. (Perry et al., 1984). Soil bacteria produced volatile organic compounds (VOCs) that affected the mycelial growth and enzyme activity of several fungi (Mackie and Wheatley, 1999). Fungal response to the bacterial VOCs varied with medium, species, and age of the fungus and the bacteria. These reports and our results suggest that the chemical responses between microorganisms vary with the species, environment, and age.

Pen. cyaneum, *Pen. damascenum*, and *Pen. implicatum* have the ability to produce antifungal compounds and to keep antifungal activity under conditions competitive with *Pyt. vexans*. *Pen. damascenum* can grow vigorously around *P. glehnii* seedling roots and protect seedlings from damping-off when co-inoculated with *Pyt. vexans* (Yamaji et al., 2001). In that report, modified Melin Norkrans Medium (MMN) without glucose was used for seedling growth, thus carbon for fungal growth was supplied from only *P. glehnii* seedlings. *Pen. damascenum* seems to utilize carbon exuded from the seedling roots and to resist *Pyt. vexans* by constant or abundant production of citrinin even under competitive conditions. In contrast, *Pen. cyaneum* and *Pen. implicatum*, which did not protect *P. glehnii* seedlings from damage by *Pyt. vexans* (Yamaji et al., 2001), may not fully utilize the root exudate when grown together with *Pyt. vexans* around *P. glehnii* seedling roots. Composition of root exudates (amino acids and soluble carbon compounds) changes with plant age in trees (Grayston et al., 1996), and this may influence competition between microorganisms in the rhizosphere. When *Pen. cyaneum* and *Pen. implicatum* compete with *Pyt. vexans* for nutrients, *Pen. cyaneum* seems to produce patulin constantly, while *Pen. implicatum* seems to change the proportion of frequentin and palitantin. Both these chemical responses to *Pyt. vexans* may contribute to protection of *P. glehnii* seedlings from damage by *Pyt. vexans*.

Penicillium species are common saprophytes in the soil and have been isolated in significant amounts from the surface of seeds of various plants

(Peterson, 1959; Watanabe, 2002). As well as interactions between symbiotic microorganisms, we should also consider the possible interaction of free-living microorganisms in the rhizosphere. Rhizospheric microorganisms are never independent of other microorganisms and plants. Therefore it is important to clarify the chemical interactions between them.

Acknowledgments—We thank Dr. Kasuya, M.C.M., Vicosa Federal University for supplying *Pythium vexans*.

INTERSPECIFIC VARIATION IN DEFENSE SECRETIONS OF MALAYSIAN TERMITES FROM THE GENUS *Bulbitermes*

CHENG-HOCK CHUAH*

Chemistry Department, University of Malaya, 50603 Kuala Lumpur, Malaysia

(Received August 23, 2004; accepted December 12, 2004)

Abstract—The chemicals of the defense secretions of Malaysian *Bulbitermes*, *B. singaporensis*, *B. germanus*, *B. sarawakensis*, and *Bulbitermes* sp. B, show that *B. singaporensis* is distinct from the other species, which are themselves closely related; the genetic distance between *B. singaporensis* and *B. germanus* is 0.71. *B. singaporensis* contains tetracyclic kempane, and *B. germanus* and *B. sarawakensis* contain tricyclic trinervitene; *Bulbitermes* sp. B contains a mixture of kempane and trinervitene. The mono- and diterpenoid compositions are species-specific.

Key Words—*Bulbitermes*, defense secretions, diterpenes, interspecific variations, Nasutitermitinae.

INTRODUCTION

The genus *Bulbitermes* belongs to the subfamily Nasutitermitinae, whose soldiers possess conical, nozzle-shaped projections on their heads from which defensive secretions are ejected. Behaviorally, *Bulbitermes* species forage under covered trails that run from their arboreal nests up tree trunks; they feed on dead plant material. Only soldiers and workers move in the covered trails; the soldiers protect the trails by positioning themselves at the sides. If the cover is disturbed, the soldiers defend their foraging trail by ejecting a gluey secretion at the predator (Prestwich, 1979a). The Malaysian *Bulbitermes* termites are less studied than the free-ranging *Lecessititermes* (Goh et al., 1990), *Hospitalitermes* (Chuah et al., 1983, 1986), and *Longipeditermes* (Goh et al., 1984), and, in fact,

* To whom correspondence should be addressed. E-mail: chchuah@um.edu.my

even the biology is relatively unknown. This paper presents the compositional and structural variations of the defense secretions of the soldier termites of *Bulbitermes singaporensis* (Prestwich et al., 1981a), *B. germanus*, *B. sarawakensis*, and an unidentified species which will be referred to as *Bulbitermes* sp. B (Tho, 1992).

METHODS AND MATERIALS

Termite Material. Soldier termites used for the present studies were collected from within closed canopy dipterocarp forests from the following localities in Peninsular Malaysia (Figure 1): (1) Gunong Jerai—an upper hill dipterocarp forest in the state Kedah; (2) Muka Head Field Station—a coastal hill dipterocarp forest reserve in Penang; (3) Maxwell Hill—an upper hill dipterocarp forest bordering on the oak montane forest type; (4A) Gombak;

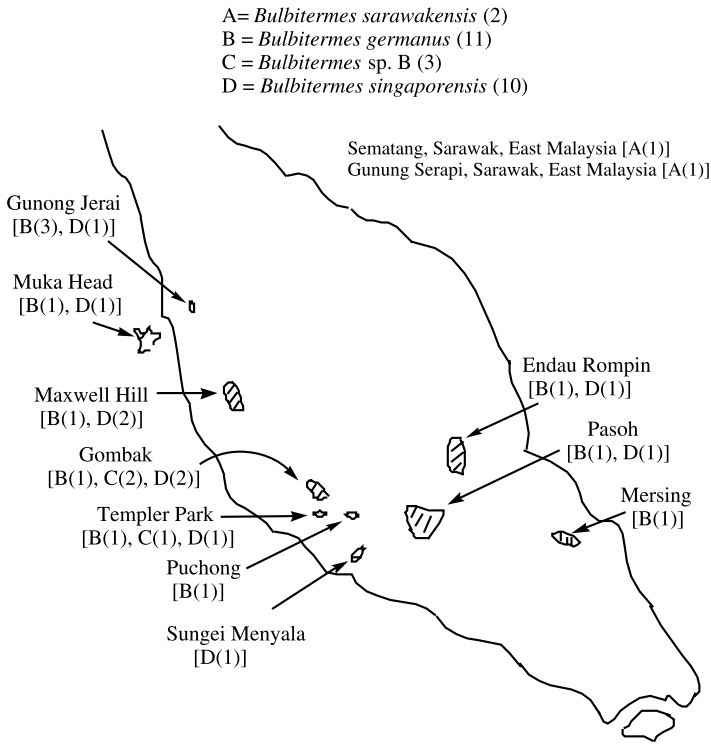

FIG. 1. Distribution of *Bulbitermes* in Peninsular Malaysia.

(4B) Templer Park; (4C) Puchong; 4A–C are hill dipterocarp forests in the state of Selangor; (5) Sungei Menyala—a lowland dipterocarp forest in the state of Negeri Sembilan; (6) Pasoh—a lowland dipterocarp forest in the state of Negeri Sembilan that has been the site for intensive ecological studies under the auspices of the International Biological Program; (7) Endau Rompin—a forest reserve area in the states of Pahang and Johor; (8) Mersing—a lowland dipterocarp forest in the state of Johor; and (9) Sematang and Gunung Serapi—an upper hill dipterocarp forest in the state Sarawak, East Malaysia. The species are labeled as A, B, C, and D, and the number of colonies collected were indicated (Figure 1).

With minimum disturbance, the soldiers were collected in plastic bags and chilled to −10°C, after which they were decapitated and the heads (ca. 20) were crushed and extracted by hexane. The crude extracts were then filtered, and the solvent was partially removed *in vacuo* before analysis (Chuah et al., 1983, 1990).

Analytical Methods. Gas chromatography (GC) analysis of monoterpenes and diterpenes was performed on an HP 5790A instrument fitted with a flame ionization detector. The oven temperature was programmed at 6°C/min from 80 to 150°C and then at 8°C/min to 300°C. Identification of the monoterpenes and diterpenes was performed on an HP 5972A MSD mass spectrometer interfaced with an HP-6890 series GC fitted with an HP-5 5% phenyl methyl siloxane capillary column (30 m × 0.25 mm i.d., 0.3-μm film thickness). The mass spectra were recorded at an ionization voltage of 70 eV with an ion source temperature of 180°C. The monoterpenes (I–V) were characterized by GC-MS spectroscopy and coinjection with commercially available (Tokyo Kasei) standards (Table 1). Similarly, diterpenes (VI–XX, Figure 2) were characterized by MS and NMR spectroscopy (Vrkoc et al., 1978a,b; Prestwich, 1979a,b; Dupont et al., 1981) and by coinjection with compounds previously isolated (Chuah et al., 1983, 1986, 1989; Goh et al., 1982, 1984, 1990). Isolation of

individual compounds from the crude secretion (ca. 30 mg extracted from approximately 1500 soldier termites) was aided by a Waters 440 HPLC instrument fitted with a 25 × 0.64-cm. Ultrasphere silica gel column. Elution of the diterpenes was by a gradient of 2–10% ethyl acetate in petroleum ether (bp 60–80°C). The diterpenes isolated by HPLC were checked for purity by GC and TLC on Merck 5 × 10-cm, 0.25-mm silica gel 60 plates. Proton and carbon NMR spectra were recorded on a Jeol JNM-GSX 270 spectrometer. The isolated known diterpenes (VI–XX) were identified by their ^{1}H NMR, ^{13}C NMR, and MS spectroscopy (Chuah et al., 1983, 1986, 1989; Goh et al., 1982, 1984, 1990).

standards, which were spiked into the chromatograms by coinjection with the samples. The quantification of monoterpenes and diterpenes was made relative to C_{14} and C_{20} *n*-alkanes, respectively. The data are summarized in Tables 1 and 2. The R_f values of diterpenes on silica gel TLC plates, solvent ethyl acetate/dichloromethane (5:95, v/v), are listed in Table 3.

The genetic distance between two species was calculated (Table 4) by using the mean relative proportions of all the mono- and diterpene compounds following the formula of Nei (1972) on the basis of the assumption that the defense chemicals are genetic:

$$D_{XY} = -\mathrm{In}\left[\frac{\sum X_i Y_i}{\sqrt{\left[\sum X_i^2 \sum Y_i^2\right]}}\right]$$

A dendrogram using the unweighted pair-group arithmetic average clustering method was constructed (Figure 3).

RESULTS AND DISCUSSION

The evolution and development of the frontal gland in the subfamily Nasutitermitinae, of which over 500 species have been reported (Tho, 1992), are known to parallel the development of chemicals for the defense of the termite colony against predators (Prestwich and Collins, 1981). The biosynthesis of such chemicals provides the termites with a vast range of chemicals against hostile organisms. Conversely, the distribution of chemicals provides an understanding of the genetic variations among termite species. The chemical variations in the *Bulbitermes* species show differences in the distribution of monoterpenes (Table 1) and diterpenes (Table 2) except for *B. germanus* and *B. sarawakensis*. The species can be differentiated by such variations, which also encompass the presence or absence of certain diterpenes that generally have complex structural types and compositional patterns. Intraspecifically, there are only small, but detectable, quantitative variations in monoterpene and diterpene composition.

The genetic distances between *B. germanus* of Peninsular Malaysia and *B. sarawakensis* of East Malaysia indicate that the two taxa are closely related. In a previous study, Tho (1992) described the separation only in terms of color differences of the head and femur; the shade is somewhat darker for *B. germanus*. In the present study, the genetic distance between *B. germanus* and *Bulbitermes* sp. B is a marginally larger value (0.10), which indicates genetic proximity, as *B. germanus* differentiates morphologically, having a larger and thicker nasus. The dendrogram (Figure 3) provides evidence that *B. germanus* and *B. singaporensis* are distinct (genetic distance = 0.71). Morphologically, the soldier of *B. singaporensis* is generally smaller than that of *B. germanus*. The nasus of *B. germanus* is relatively less broad-based in profile, whereas *B. singaporensis* has a broad-based profile.

Previous studies on the terpenoid distribution among termite species in different parts of the world (Prestwich et al., 1979b, 1981a,b; Braekman et al., 1980, 1983, 1984; Dupont et al., 1981; Baker and Walmsley, 1982; Gush et al., 1985; Valterova et al., 1986) have documented considerable variation; the variation can be used as a chemotaxonomic characteristic (Prestwich, 1983) in establishing interrelationships within the genus. The present investigation of the chemical defense secretions from *Bulbitermes* will eventually contribute toward a better understanding of the taxonomic position of the genus in relation to the other genera in the subfamily Nasutitermitinae. The generic distinction between *Bulbitermes* and *Nasutitermes* is based largely on the constricted head capsule in *Bulbitermes* soldiers. As demonstrated in this study, the major chemical components of the defense secretion of *B. singaporensis* (Prestwich et al., 1981a) is close to that of *Nasutitermes havilandi* (Chuah et al., 1989). On the other hand, *Nasutitermes matangensis* (Prestwich et al., 1981b; Chuah et al., 1989) appears to be distinct from these two species.

DIET-RELATED MODIFICATION OF CUTICULAR HYDROCARBON PROFILES OF THE ARGENTINE ANT, *Linepithema humile*, DIMINISHES INTERCOLONY AGGRESSION

(Received August 3, 2004; accepted November 29, 2004)

Abstract—Territorial boundaries between conspecific social insect colonies are maintained through a highly developed nestmate recognition system modulated by heritable and, in some instances, nonheritable cues. Argentine ants, *Linepithema humile*, use both genetic and environmentally derived cues to discriminate nestmates from nonnestmates. We explored the possibility that intraspecific aggression in the Argentine ant might diminish when colonies shared a common diet. After segregating recently field-collected colony pairs into high or moderate aggression categories, we examined the effect of one of three diets: two hydrocarbon-rich insect prey, *Blattella germanica* and *Supella longipalpa*, and an artificial (insect-free) diet, on the magnitude of aggression loss. Aggression diminished between colony pairs that were initially moderately aggressive. However, initially highly aggressive colony pairs maintained high levels of injurious aggression throughout the study, independent of diet type. Each diet altered the cuticular hydrocarbon profile by contributing unique, diet-specific cues. We suggest that acquisition of common exogenous nestmate recognition cues from shared food sources may diminish aggression and promote fusion in neighboring colonies of the Argentine ant.

Key Words—Argentine ant, cuticular hydrocarbons, diet, invasive ants, nestmate recognition, unicoloniality.

INTRODUCTION

Social insects have evolved a highly developed recognition system that forms the basis of social structure and communication. The signals used in nestmate recognition are primarily under genetic control; however, exogenous cues derived from nest materials (Gamboa et al., 1986; Stuart, 1987) or diet (Jutsum et al., 1979; Obin and Vander Meer, 1988; Le Moli et al., 1992; Liang and Silverman, 2000) may also play a role. Cuticular hydrocarbons have long been considered important mediators of nestmate recognition in ants (Vander Meer and Morel, 1998), with recent evidence supporting a direct role (Lahav et al., 1999; Liang and Silverman, 2000). However, the relative contribution of heritable and environmentally derived cues, including hydrocarbons, to the recognition profile is not known. Irrespective of the source, workers must learn colony-specific cues and must be able to properly evaluate cues present on newly encountered workers. Recognition cues are generally dynamic and may change throughout the life of the colony (Vander Meer et al., 1989) and exhibit seasonal variation (Ichinose, 1991). Therefore a worker must continually update its perception of colony odor in response to endogenous and external changes.

The Argentine ant, *Linepithema humile*, is one of several invasive ants in which the relative loss of territorial behavior is thought to contribute to invasion success. Introduced *L. humile* populations are unicolonial and frequently very large, and they often dominate native ant species (Suarez et al., 1999). Nestmate recognition in the Argentine ant is influenced by genetic (Tsutsui et al., 2000, 2003; Suarez et al., 2002) and environmental (Chen and Nonacs, 2000; Liang and Silverman, 2000) inputs. Holway et al. (1998) and Suarez et al. (2002) reported that aggression persisted between *L. humile* colonies despite maintenance under uniform rearing conditions, whereas Chen and Nonacs (2000) observed a decrease in *L. humile* intercolony aggression following 2 mo of laboratory rearing. Whereas Tsutsui et al. (2000) demonstrated a significant inverse relationship between *L. humile* genetic similarity and intercolony aggression, the colony pairs used by Holway et al. (1998), Chen and Nonacs (2000), and Suarez et al. (2002) were not subjected to genetic analysis. Therefore the observed changes (or lack thereof) in aggression may have resulted from different degrees of genetic similarity, with aggression between the most dissimilar pairs unlikely to change despite similar rearing conditions.

Whereas it has been suggested that loss of genetic diversity is primarily responsible for the unicolonial population structure observed in introduced Argentine ant populations (Tsutsui et al., 2000), the role of shared environmental cues such as diet in promoting unicoloniality is unknown. Shared dietary components, specifically hydrocarbons, for colonies displaying low intercolony genetic differentiation, may mask subtle inherent between-colony distinctions, thereby promoting fusion of adjacent colonies. Liang and Silverman (2000) and

Silverman and Liang (2001) demonstrated the potential of prey hydrocarbons to alter nestmate recognition in the Argentine ant, with worker exposure to specific prey eliciting aggression from colony mates. Of the many different prey exposed to *L. humile* workers, contact with the brown-banded cockroach, *Supella longipalpa*, induced the highest level of intracolony aggression (Liang et al., 2001). *S. longipalpa* has several hydrocarbons that are identical or similar to those of *L. humile*, which may be important in *L. humile* nestmate recognition (Liang et al., 2001). We propose that the opposite process can occur, whereby key *S. longipalpa*-acquired recognition chemicals attenuate differences between *L. humile* colonies, thus diminishing intercolony aggression. We compare intercolony aggression levels before and after continuous exposure to diets including *S. longipalpa*, *Blattella germanica*, or artificial diet and also measure changes in key prey-specific hydrocarbons on *L. humile* cuticle. We hypothesize that diets with *S. longipalpa* will diminish aggression the most. By documenting changes in intercolony aggression following exposure to sources of exogenous recognition cues, we hope to develop a deeper understanding of the dynamic nature of Argentine ant nestmate discrimination and its potential role in structuring populations in this invasive insect.

METHODS AND MATERIALS

Collection and Rearing of Laboratory Colonies. We used 11 colonies of Argentine ants (*L. humile*) from 11 sites in the southeastern USA—North Carolina (six): Chapel Hill (chh), Emerald Isle (emi), Greenville (gnc), Jacksonville (jac), Shallotte (sch), and Winston-Salem (for); South Carolina (two): Greenville (hto) and Greer (gwm); and Georgia (three): Barnesville (bch), Fayetteville (fay), and Griffin (grf). Ants were collected from a variety of habitats, including landscaped residential lots, natural wooded areas, or sand dunes. For each location, we established three large colonies consisting of 5000–10,000 workers, a few hundred queens, and numerous brood. Colonies were maintained in soil-free, Fluon-coated trays. Nests were plastic dishes filled with moist grooved plaster. Colonies were reared on one of three diets, each of which included a 25% sucrose solution *ad libitum* and hard-boiled eggs once a week: artificial noninsect diet (Bhatkar and Whitcomb, 1970), *S. longipalpa* male and female adults, or *B. germanica* male and female adults. All colonies were maintained at 24 ± 1°C, 50 ± 10% RH, and a 12:12 hr light/dark cycle.

Aggression Tests (Nestmate Recognition Bioassay). We assessed the initial level of aggression between 18 colony pairs (listed below) with an assay that measured the level of aggression in single worker introductions into a foreign colony. This behavioral assay has low variance among replicates within the same colony pairing (Roulston et al., 2003). Individual intruder workers were

collected on a toothpick and introduced into rearing trays (52 × 38 cm) containing a resident colony (~10,000 workers). The responses of resident workers toward the intruder were recorded, and aggression was scored using the 0–4 scale of Suarez et al. (1999). The intruder was discarded after each trial, and subsequent trials were conducted when the residents were no longer visibly agitated (5–10 min). Ten replicates per colony pair were performed: five replicates with colony 1 as the resident and five replicates with colony 1 as the intruder. The observer who recorded the aggression level did not know the identity of the interacting colonies and was unfamiliar with the hypothesis being tested. All assays to estimate the initial aggression levels were performed within a week of collection and extraction of ants from the original nesting substrate. Data were analyzed as the maximum score per trial (Roulston et al., 2003).

Our preliminary observations indicated a possible relationship between the initial level of aggression displayed by a colony pair and that colony pair losing aggression over time, with pairs having high initial aggression maintaining it over time and colonies with moderate levels of initial aggression becoming nonaggressive. We define moderate aggression as an average score of 3.0 or lower and high aggression as a score of 3.0 or higher on a 0–4 scoring scale (Suarez et al., 1999). This assignment is based on aggression above level 3 being injurious (biting, stinging), whereas aggression below level 3 is noninjurious (mutual antennation, avoidance). Eight colony pairs were moderately aggressive: gnc–fay, for–emi, chh–bch, for–gnc, chh–grf, chh–hto, gwm–sch, and gwm–fay, and 10 colony pairs were highly aggressive: jac–fay, jac–sch, jac–chh, emi–bch, jac–hto, emi–grf, emi–chh, emi–hto, emi–sch, and jac–bch. Aggression assays and hydrocarbon analyses were repeated 140 d later for all three dietary regimes to assess changes in nestmate recognition patterns and to determine whether behavioral changes were consistent with hydrocarbon patterns. Aggression assays were performed again at day 224 to determine whether aggression had further declined with prolonged laboratory rearing.

Extraction, Isolation, and Chemical Analysis of Cuticular Hydrocarbons. Ants were killed by freezing (−20°C) prior to hydrocarbon extraction. External lipids were extracted from the cuticle by immersing 10 whole thawed ants in 1-ml hexane for 10 min, followed by a brief second rinse. The samples were gently shaken for the first and last 20 sec of the soak period. Hexane extracts were concentrated under nitrogen to ~100 μl and applied to prewetted (hexane) Pasteur pipette minicolumns filled with 500 mg of silica gel (63–200 mesh size, Selecto Scientific, GA, USA). The hydrocarbon fraction was eluted with 6-ml hexane and blown to dryness under nitrogen. The extract was redissolved in 5-μl hexane, and 1 μl was analyzed (two ant equivalents). Gas chromatography (GC) was carried out using an HP 5890 gas chromatograph equipped with a DB-1 column (30 m × 0.25 mm × 0.25 μm film thickness) and interfaced with a G1045A Chemstation (version A05.01). Oven temperature was held at 40°C

for 2 min, then increased to 200°C at 20°C/min, and then to 310°C at 40°C/min. The injector and flame-ionization detector were at 270 and 320°C, respectively. Helium was the carrier gas, and the make-up gas was nitrogen. Quantitative data were obtained by integrating the peaks and calculating the percent area under each peak. Specific peak identity was determined with hydrocarbon standards and by matching diagnostic peaks with those from prior studies (Jurenka et al., 1989; Liang et al., 2001).

Statistical Analyses. The significance of main effects (diet and initial aggression category) and their interaction was tested by using a mixed model ANOVA (PROC MIXED) in SAS 8.1 (SAS Institute, 2002). Upon finding that the effect of diet was not the same in the two aggression categories, we tested for the effect of diet on aggression loss within each of the two aggression categories with colony pairing and diet treated as random and fixed variables, respectively (ANOVA, PROC MIXED). Differences between the three dietary treatments within and across aggression categories were determined with least-squares means. To analyze the magnitude of aggression loss, we used absolute, rather than relative, aggression loss values.

We used linear discriminant analysis (LDA) (Statgraphics Plus, v. 5.1) to examine hydrocarbon divergence patterns between field-collected colonies (Initial) and the same colonies raised on each of the three diets (*Blattella*, *Supella*, and Artificial). The analysis was performed using standardized variables, and an LDA matrix was constructed with 11 colonies, belonging to each of four treatments (Initial, *Blattella*, *Supella*, and Artificial), using 27 peak percentages of the most abundant cuticular hydrocarbons. Significance tests comparing diets used the MANOVA procedure (PROC GLM). The degree of dispersion around the centroids (i.e., the degree of differentiation between colonies within a treatment) was calculated by averaging standard deviations for each of the 11 colonies across all 27 hydrocarbons within each treatment. To test whether Argentine ants acquired key prey-specific hydrocarbons, we first identified key diagnostic hydrocarbons provided by each prey. For *B. germanica*, we selected peaks corresponding to 11-, 13-, and 15-methylnonacosane and 3-methylnonacosane. Both hydrocarbons are relatively abundant in adult *B. germanica*, comprising approximately 14.5 and 10.3% of the total hydrocarbons, respectively (Jurenka et al., 1989). Furthermore, our preliminary analysis indicated that both hydrocarbons were readily acquired by Argentine ants. For *S. longipalpa*, we selected 15,19-dimethylheptatriacontane present in *S. longipalpa* at 19.0% and acquired by Argentine ants from *S. longipalpa* prey (Liang and Silverman, 2000; Liang et al., 2001). To compare changes in individual hydrocarbon levels (average level on day 140 vs. average level on day 0), we used one of two types of *t*-tests, depending on the equality of variances. A parametric *t*-test was used when the variances were homogenous. In cases where the variances were unequal, we used the Welch *t*-test with a Satterthwaite correction (Zar, 1999).

RESULTS

Analysis of the behavioral data revealed that the interaction between diet and aggression was significant (ANOVA, $F_{2,15.1} = 13.38$, $P < 0.001$). Because the diet effects were not the same in the two aggression categories, a separate analysis of diet effects for each aggression category was performed. Colony pairs experienced a significant reduction in initial aggression, irrespective of the diet (Table 1 and Figure 1). The aggression scores in colonies that were initially moderately aggressive and reared on either of the two cockroach diets decreased by ~40% ($P = 0.91$, Table 2). Ants raised on the artificial diet, however, experienced an ~70% loss in initial aggression scores, which was significantly higher than that experienced by ants raised on either *B. germanica* ($P < 0.001$) or *S. longipalpa* ($P < 0.001$). Argentine ants displaying high initial aggression experienced relatively little change in aggression, approximately 8% loss for each of the three dietary regimes. This decrease, although relatively low, was statistically significant for each of the three diets (Table 1), and the magnitude of aggression loss did not differ between dietary categories (Table 2; ANOVA, $F_{2,18} = 0.72$, $P = 0.50$). A comparison of the magnitude of aggression loss between the aggression categories revealed that moderately aggressive colony pairs lost a significantly higher proportion of their initial aggression across all dietary treatments, relative to colony pairs showing high initial aggression (Table 2). Results of aggression tests performed 84 d after the first testing revealed no further aggression loss in any of the aggression/diet categories ($P > 0.05$).

To provide another measure of the magnitude of aggression loss in both aggression categories, we recorded changes in the proportion of injurious/

TABLE 1. INITIAL AGGRESSION LEVELS AND AGGRESSION LOSS IN MODERATELY AND HIGHLY AGGRESSIVE COLONY PAIRINGS REARED UNDER THREE DIETARY REGIMES

Aggression category	Initial aggression level[a]	Aggression loss				
			Change

Artificial	High	0.2 ± 0.1	Artificial	Moderate	2.0 ± 0.2	<0.001

[a]Least squares analysis (SAS Institute, 2002).

significant in each of the two aggression categories, our results indicated that in contrast to pairs displaying moderate aggression, the incidence of injurious fights between highly aggressive pairs remained high. Therefore we question the biological importance of the statistically significant aggression loss between highly aggressive colony pairs. Among moderately aggressive pairs, initially 69 of 80 (86%) encounters resulted in an aggression score of 3 or 4 (three out of 80 had an aggression score of 4). At the end of the study, only 36% of *Supella*-fed ants (corresponding to a 58% reduction in the number of injurious encounters), 36% of *Blattella*-fed ants (58% reduction), and 19% of ants on the artificial diet (78% reduction) displayed level 3 aggression. In contrast, among highly aggressive colonies, initially all encounters (100/100) scored level 4. At the end of the study, 96% of *Supella*-fed ants (4% reduction), 97% of *Blattella*-fed ants (3% reduction), and 98% of ants on the artificial diet (2% reduction) still engaged in injurious aggression. Level 4 aggression remained in 71% of *Supella*-fed ants, 78% of *Blattella*-fed ants, and 79% of ants fed with artificial diet.

Argentine ants acquired significant levels of prey hydrocarbons (Figure 2)—*Blattella*: 11-, 13-, and 15-methylnonacosane ($P < 0.001$), 3-methylnonacosane ($P < 0.001$) and *Supella*: 15,19-dimethylheptatriacontane ($P < 0.001$). Because *S. longipalpa* hydrocarbons overlap the long-chain hydrocarbon profile of *L. humile* (Liang et al., 2001), field-collected colonies of Argentine ants possess relatively high initial levels of hydrocarbons specific to *S. longipalpa* (Figure 2C). However, there are certain qualitative and quantitative differences between *L. humile* hydrocarbons and those provided by *S. longipalpa*. Consequently, providing Argentine ants with *S. longipalpa* prey would likely alter the relative ratio of hydrocarbons already present as well as introduce new hydrocarbons. Furthermore, the results of discriminant analysis revealed marked

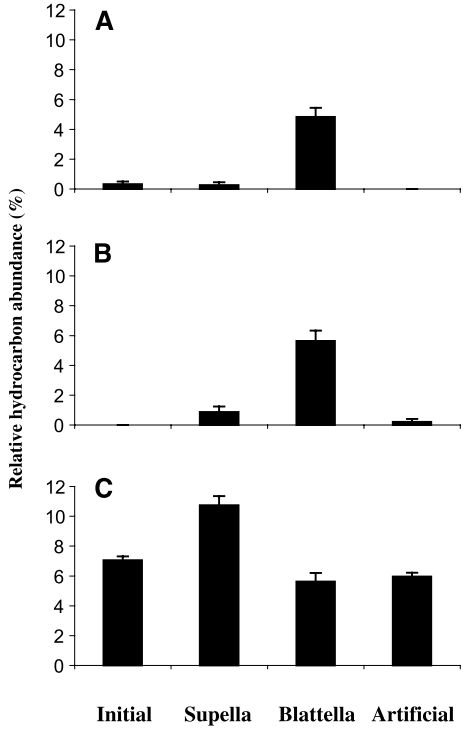

FIG. 2. Relative abundance (% total area) of key prey-derived hydrocarbons in field-collected colonies of *L. humile* (Initial) and colonies provisioned with one of prey diets: *S. longipalpa* (*Supella*) and *B. germanica* (*Blattella*). Hydrocarbons (A) and (B) are *Blattella*-derived and (C) is *Supella*-derived. (A) 11-, 13-, and 15-methylnonacosane; (B) 3-methylnonacosane; (C) 15,19-dimethylheptatriacontane. Means ± SE for 11 colonies are presented.

divergence in cuticular hydrocarbon composition between field-collected colonies (Initial) and colonies raised on either *B. germanica*, *S. longipalpa*, or the artificial diet (Figure 3): Initial vs. *Blattella* (MANOVA, Wilk's lambda = 0.0028, $F_{26,5} = 67.04$, $P < 0.001$), Initial vs. *Supella* (Wilk's lambda = 0.010, $F_{26,5} = 18.16$, $P = 0.002$), and Initial vs. Artificial (Wilk's lambda = 0.010, $F_{26,5} = 18.94$, $P = 0.002$). The divergence between the *Blattella* and *Supella* diets was also significant (Wilk's lambda = 0.0066, $F_{26,5} = 28.88$, $P < 0.001$). Estimates of intracolony variability within treatments revealed that field-collected colonies (Initial) had the lowest variance (1.029), followed by colonies on the artificial diet (1.035), *Supella* (1.147), and *Blattella* (1.209). Changes in the proportions of the 27 most abundant cuticular hydrocarbons are summarized

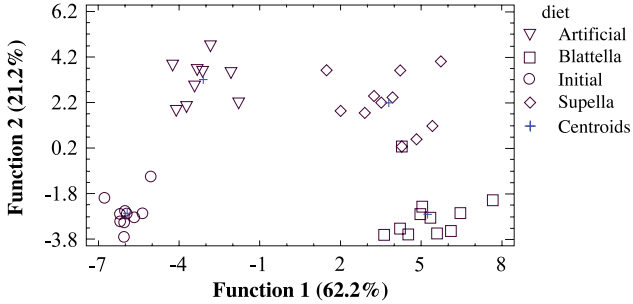

FIG. 3. Linear discriminant analysis of the 27 predictor variables (relative proportions of hydrocarbons) for 11 colonies of *L. humile* each provided a unique diet (*B. germanica*, *S. longipalpa*, and artificial).

in Table 3. Overall, colonies raised on all three diets experienced changes in the proportions of all hydrocarbons. In colonies raised on the artificial diet, six hydrocarbons significantly increased and eight hydrocarbons significantly decreased (52% of hydrocarbons changed significantly). In colonies raised on *Blattella*, five hydrocarbons significantly increased and 12 hydrocarbons significantly decreased (63% change). Colonies raised on *Supella* experienced the greatest change (67%), with seven hydrocarbons increasing and 11 hydrocarbons decreasing over the course of the study.

DISCUSSION

Our results provide further support for Argentine ant nestmate recognition being modulated, in part, by environmental factors (Chen and Nonacs, 2000; Liang and Silverman, 2000), in that rearing under controlled conditions reduces aggression between colonies. Prior studies (Liang and Silverman, 2000; Liang et al., 2001) demonstrated that exogenous hydrocarbons disrupted *L. humile* colony integrity by inducing aggression between fragments of the same colony. Herein, we determined that shared diet reduced intercolony aggression to an extent that might promote fusion of dissimilar colonies.

Changes in aggression were minimal between colony pairs that were initially highly aggressive, despite worker ants acquiring prey hydrocarbons. Therefore limited change in the pattern of intraspecific aggression within the highly aggressive pairings suggests that exogenous recognition cues did not override intrinsic cues, which may help to explain the results of other ant studies in which aggression persisted over time (Le Moli et al., 1992; Heinze et al., 1996; Holway et al., 1998; Stuart and Herbers, 2000; Suarez et al., 2002). contrast, colonies in pairings that were initially moderately aggressive were strongly affected by the imposition of diet-based cues. We predicted that exposure to cockroach prey, especially *S. longipalpa*, would provide abundant hydrocarbons that could minimize between-colony recognition disparities, thereby producing the greatest decline in aggression. However, intraspecific aggression in ants fed with artificial diet diminished further than aggression in ants fed with cockroaches, indicating that the greatest change in behavior may be a consequence of the field-to-lab transition. Hydrocarbon profiles of *L. humile* raised on the artificial diet changed significantly over time; however, the hydrocarbons

(and/or chemical cues) affecting this behavioral change are unclear. Moreover, the difference in the degree of aggression loss between the two prey diets was not significant, an unexpected result given that long-chain hydrocarbons from *S. longipalpa* (33 carbons or more) added to the native *L. humile* cuticular profile induced intracolony aggression, whereas other prey items from diverse insect taxa (including *B. germanica*), having fewer or none of these long-chain hydrocarbons, induced little or no within-colony aggression (Liang et al., 2001). The action of prey hydrocarbons in promoting intercolony unity appears to differ from that inducing intracolony aggression. Perhaps the difference in the way prey hydrocarbons alter nestmate recognition in *L. humile* is related to quantitative differences in hydrocarbon levels needed to affect a behavioral change. Thus, where two antagonistic fragments were created from a single colony (Silverman and Liang, 2001), the acquisition of one or a few key hydrocarbons produced a recognizable shift in an otherwise uniform profile. In the current study, the acquisition of foreign prey hydrocarbons appeared insufficient to completely override intrinsic distinctions between colonies.

Our findings may provide insights into the evolution of unicoloniality in introduced populations of the Argentine ant. Proposed mechanisms for the transition from multi- to unicoloniality include reduced heterozygosity due to genetic drift (Tsutsui et al., 2000) and introduction to new habitats with relaxed ecological constraints (Giraud et al., 2002), with unicoloniality maintained via selection against rare recognition alleles (Tsutsui et al., 2003). Whereas Tsutsui et al. (2000, 2003) and Giraud et al. (2002) demonstrated the importance of genetic, ecological, and behavioral factors in the transition from multicoloniality to unicoloniality, we suggest that shared environmentally derived recognition cues may promote unicoloniality by masking inherent between-colony distinctions, thereby allowing adjacent colonies to fuse. Competing Argentine ant colonies will most likely interact with each other at advancing invasion fronts where they are likely to compete for nesting sites and/or food resources that provide similar nestmate recognition cues. In areas where mutually aggressive colonies exploit a common locally abundant food source, two mechanisms may work independently or together to promote fusion of neighboring colonies: diet sharing and intraspecific "dear enemy" phenomenon, whereby competing animals respond less aggressively to threats by neighbors than strangers (Temeles, 1994; Heinze et al., 1996; Langen et al., 2000). Diet sharing through cooperative use of locally abundant food sources may provide sufficient levels of critical hydrocarbons to alter nestmate recognition and promote fusion of colonies. Argentine ants, like other invasive ants, are generalist feeders (Newell and Barber, 1913; Markin, 1970), tending homoptera and scavenging living and dead arthropods. In addition, shared cues originating from nesting material may diminish intercolony aggression. The "dear enemy" phenomenon may also play a role in the Argentine ant's transition from multicoloniality to

unicoloniality. An increase in the frequency of encounters between aggressive colonies may decrease the frequency of aggression between them, especially in areas where food is abundant and intraspecific competition is limited (Foitzik and Heinze, 1998). Furthermore, repeated interactions in the field were essential for maintaining recognition among spatially isolated nests in the polydomous *Leptothorax longispinosus* with nonaggressive field colonies becoming hostile after 3 mo of laboratory rearing, thereby indicating a possible role for common environment-derived cues and/or contact between colonies in reducing aggression (Stuart and Herbers, 2000). Where Argentine ants interact and compete for resources that provide common recognition cues, cooperation among nests through a reduction in intercolony aggression may be promoted. However, an exception may occur within the native range, where *L. humile* is multicolonial despite neighboring colonies presumably having access to shared environment-derived cues. Native *L. humile* exhibit relatively high genetic diversity and high intercolony aggression (Tsutsui et al., 2000); consequently, environmentally derived recognition cues may be limited in diminishing intercolony aggression. However, colonies from invasive populations having weaker genetic structure (Tsutsui and Case, 2001; Buczkowski et al., 2004) may be more likely to fuse when exogenous cues mask colony distinctions, thereby fostering the development of unicoloniality.

EVIDENCE OF NATURAL HYBRIDIZATION BETWEEN TWO SYMPATRIC SIBLING SPECIES OF *Bactrocera dorsalis* COMPLEX BASED ON PHEROMONE ANALYSIS

SUK-LING WEE[1,3,*] and KENG-HONG TAN[2]

[1]*School of Biological Sciences, Universiti Sains Malaysia, 11800 Minden, Penang, Malaysia*

(Received September 9, 2004; accepted December 8, 2004)

Abstract—*Bactrocera carambolae* and *B. papayae* are major fruit fly pests and sympatric sibling species of the *B. dorsalis* complex. They possess distinct differences in male pheromonal components. In the 1990's, wild *Bactrocera* fruit flies with morphological traits intermediate between those of *B. carambolae* and *B. papayae* were often captured in traps baited with methyl eugenol (ME). Chemical analyses of rectal glands of ME-fed males revealed that the laboratory F_1, F_2, and backcross hybrids possessed ME-derived sex pheromonal components ranging from that typical of *B. papayae* to that of *B. carambolae* without any specific trend, which included a combination of pheromonal components from both parental species within an individual hybrid. ME-fed hybrids without any ME-derived pheromonal components were also detected. Further chemical analysis of rectal glands from wild *Bactrocera* males, after ME feeding in the laboratory, showed a combination of pheromonal components similar to that found in the ME-fed, laboratory-bred hybrids. These findings present circumstantial evidence for the occurrence of a natural hybrid of the two *Bactrocera* species.

Key Words—*Bactrocera carambolae*, *B. papayae* (=*B. dorsalis*), hybrid, methyl eugenol, rectal gland, male pheromone, 2-allyl-4,5-dimethoxyphenol, (*E*)-coniferyl alcohol, 6-oxo-1-nonanol.

INTRODUCTION

Two sibling species of the *Bactrocera dorsalis* complex (Diptera: Tephritidae), *B. carambolae* Drew and Hancock and *B. papayae* Drew and Hancock, are major fruit pests in Southeast Asia, particularly Malaysia, Thailand, and Indonesia. These sympatric species are found readily throughout the peninsular Malaysia, with *B. carambolae* and *B. papayae* being more abundant in the southern and central regions, respectively (Tan and Nishida, 1996).

Following a taxonomic revision by Drew and Hancock (1994), *B. carambolae* can be differentiated morphologically from *B. papayae* by three key traits: (1) wing costal band slightly enlarged at apex of R_{4+5}, (2) the presence of a dark spot on foreleg femora, and (3) the appearance of a bar-shaped pattern of the lateral abdominal band on terga III–V. Subsequently, Iwaizumi et al. (1997) proposed the use of genital characters to differentiate sibling species within the *B. dorsalis* complex. However, identification of wild fruit flies based on these morphological and genitalia traits has been difficult and unreliable because they often show considerable variation (Iwaizumi et al., 1997; Iwahashi, 1999). Nevertheless, distinctive differences were found in volatile components of the male rectal gland, genetic polymorphism in intron sequences, and ribosomal DNA analyses (Perkins et al., 1990; He and Haymer, 1997; Armstrong and Cameron, 2000).

Both species are strongly attracted to and compulsively feed on methyl eugenol (ME), a potent male attractant frequently used in area-wide fruit fly control programs. Males of *B. papayae*, after consuming ME, produced 2-allyl-4,5-dimethoxyphenol (DMP) and (*E*)-coniferyl alcohol (CF) (Nishida et al., 1988; Tan and Nishida, 1996), whereas males of *B. carambolae* produced only CF (Tan and Nishida, 1996; Wee, 2000) in addition to their major endogenous rectal gland component, 6-oxo-1-nonanol (OXO), and other minor components (Perkins et al., 1990). These pheromonal compounds are sequestered and stored in the rectal gland prior to release during courtship at dusk.

Since the early 1990's, wild *Bactrocera* fruit flies with intermediate morphological traits between *B. carambolae* and *B. papayae* (hereafter referred to as intermediates) often have been recovered from traps baited with ME in Malaysian ecosystems where these species are known to coexist (Wee, 2000). This has raised speculation that natural hybridization might have occurred. Nevertheless, the intermediates have been regarded as morphological variants of their respective species (Iwahashi, 1999). Attempts to mate the two sibling species in the laboratory yielded viable hybrids with similar morphological traits to those of the field intermediates (Wee and Tan, 2000a; Wee, 2000). However, to date, there is no conclusive evidence as to whether natural hybridization between the sibling species occurs in the wild.

Here, we report evidence of natural hybrids between *B. carambolae* and *B. papayae* using gas chromatographic analyses of pheromonal components

accumulated in the male rectal glands after ME consumption, involving laboratory-bred hybrids and wild flies, respectively.

METHODS AND MATERIALS

Chemicals. 1,2-Dimethoxy-4-[2-propenyl]benzene (methyl eugenol; >99.8% purity) was obtained from Agrisense-BCS Ltd. (UK). Authentic samples (>96% purity) of CF (96% *trans*), DMP, and OXO were synthesized and supplied by R. Nishida (Kyoto University, Japan).

Insects. Laboratory strains of *B. carambolae* and *B. papayae* were pure-bred lines for more than 30 generations. These fruit fly species possessed the phenotypic traits typical of *B. carambolae* or *B. papayae*, respectively, according to Drew and Hancock (1994). Fruit fly colonies were cultured as described in Wee and Tan (2000b). Male and female flies were segregated by the fourth day after adult eclosion. Virgin males and females of each species were kept in separate cages with food and water in an insectary that had 12 D:12 L regimes with room temperature of 25–29°C and 83–90% RH.

Laboratory Crosses. All crosses were conducted in a screen cage ($40 \times 40 \times 40$ cm^3) placed indoors. Equal numbers (50–100) of sexually mature males of one species and females of the other species were transferred into the experimental cage in the morning and were acclimatized for at least 8 hr before courtship began. At 21:00 hr, under red light, each mating pair was carefully collected in a specimen vial, labeled, and allowed to continue mating until dawn.

The pure-bred lines of *B. carambolae* (BC) and *B. papayae* (BP) were crossed reciprocally to produce F_1 hybrids (BC ♀ × BP ♂ and BP ♀ × BC ♂). Six additional sources of flies, comprising a variety of the three key morphological traits in combination (that is, pattern of wing costal band at R_{4+5} and abdominal band at terga III–V, and absence/presence of a femoral spot on prothoracic legs) between BC and BP, were obtained from the following crosses of flies: (1) reciprocal crosses of F_1 hybrids were self-crossed to produce F_2 generations; (2) F_1 hybrids (from BP ♀ × BC ♂) were backcrossed with the parental species (BP ♀ × hybrid ♂ and hybrid ♀ × BC ♂); and (3) F_1 hybrids (from BC ♀ × BP ♂) were backcrossed with the parental species.

The emerged flies were maintained on artificial diet until sexual maturity (Wee and Tan, 2000b; Wee, 2000) and then allowed to feed on ME. This was performed on 30–74 male flies for each of the above crosses.

Wild Fruit Fly Collections. Wild fruit flies were obtained either by field trapping using ME-baited trap or collecting field-infested fruits from various locations in peninsular Malaysia (northern region: Penang; central region: Perak; and southern region: Johor), which were subsequently reared in the laboratory.

For field trapping, improved and modified clear traps from Tan (1985) (Figure 1) baited with ME were set up at sites located near hillside forests. The trap was designed in such a way as to prevent the trapped flies from feeding on the ME source, thus avoiding regurgitation and anal feeding behavior (Tan, 2000). These traps were used only once (trapping conducted between 08:00 and 14:00 hr) and discarded after use. Trapping was conducted on different dates in July 2000. Occasionally, flies were caught using specimen vials before they could enter the trap. In contrast, male flies raised from rotten fruits were maintained until sexual maturity (20–28 d), and allowed to feed on ME for

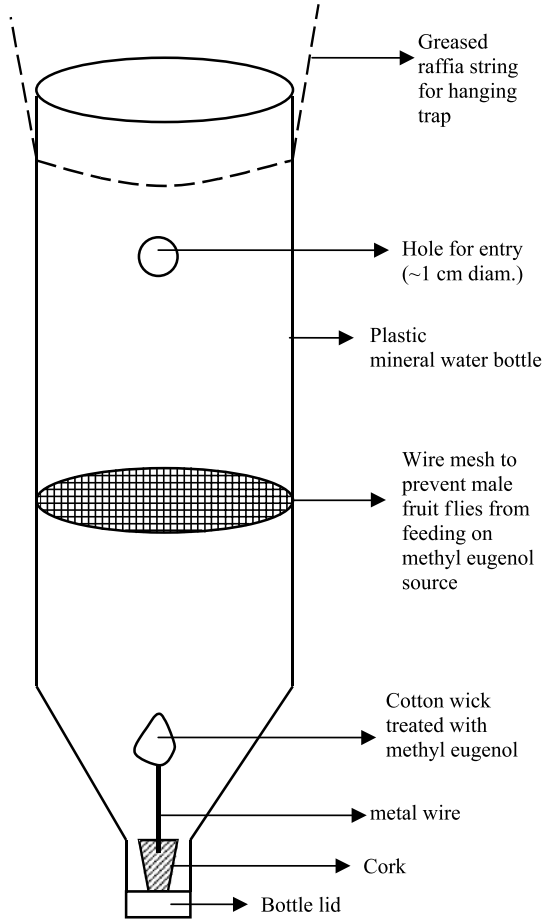

FIG. 1. Methyl eugenol-baited trap used to trap wild *Bactrocera* fruit fly males.

subsequent pheromonal analysis. A total of 167 wild males (Penang, 106; Perak, 11; and Johor, 50) were analyzed for pheromonal components.

Consumption of ME. In the laboratory, each male fruit fly was allowed to feed on 0.1 μl ME dispensed on a small piece of filter paper (1×1 cm^2; Whatman® No. 1) for 10 min during their peak response to ME (10:00–11:00 hr) (Tan, 1985). After 24 hr, male rectal glands were excised and soaked individually in 20–50 μl of redistilled ethanol spiked with an internal standard (1-dodecanol to monitor evaporation of sample solvent and not for quantification) placed in a screw-cap glass vial, and stored at −20°C for further analysis.

Rectal gland samples were obtained from (1) parental males of *B. carambolae* and *B. papayae* ($N = 30$ each), (2) males of laboratory hybrids from F_1 and F_2 generations plus backcrosses, and (3) wild males from both field trapping and male flies raised from field-infested fruits.

Pheromone Analyses. Rectal glands in ethanol (see above) were carefully homogenized with a fine glass rod followed by 5 min sonication. After centrifugation at ~1,000 *g* for 2–3 min, 1 μl aliquots of the supernatant were subjected to gas chromatography (GC) and gas chromatography-mass spectrometry (GC-MS) analyses, respectively.

Analysis of rectal gland volatiles was conducted using splitless injections on a Shimadzu GC-14A gas chromatograph, with an HP Ultra-1 column (Agilent, 25 m × 0.25 mm × 0.33 μm) programmed from 80°C/1 min to 240°C at 10°C/min. The peak areas were calibrated with those of the authentic standard samples using a C-R6A integrator (Shimadzu). Chemical identification was performed by comparison with the retention time, use of authentic internal standards, and mass spectral fragmentation patterns of authentic standards.

GC-MS analyses were performed with an HP 5989B mass spectrometer (electron impact at 70 eV) connected to an HP-5MS column (30 m × 0.25 mm, 0.33 μm film thickness) using the same running conditions as above.

RESULTS

The rectal gland of laboratory-reared *B. papayae* males following ME consumption contained CF and DMP, whereas CF was detected in the rectal gland of *B. carambolae* male along with its endogenously produced rectal gland component, OXO (Figure 2A and B). Identification of the rectal gland components was confirmed by comparison with the mass spectra of authentic standards (Figure 3A, B, and C).

Rectal gland analysis of ME-fed laboratory hybrids revealed the presence of various combinations of components between the two parental species (Table 1). A majority of the ME-fed F_1 hybrid males (68–84%) contained only CF in their

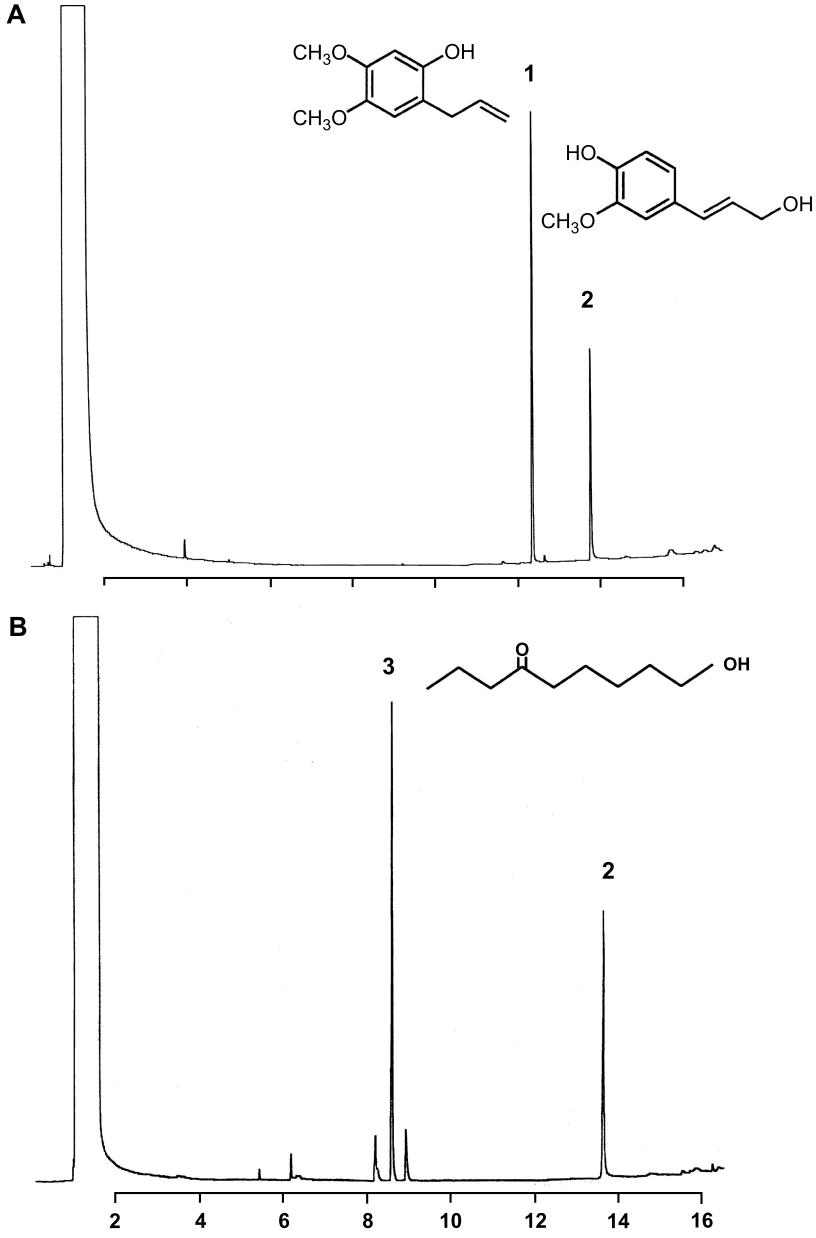

FIG. 2. Gas chromatograms of laboratory male rectal gland of (**A**) *Bactrocera papayae* and (**B**) *B. carambolae*, 24 hr after methyl eugenol consumption. (**1**) 2-Allyl-4,5-dimethoxyphenol, (**2**) (*E*)-coniferyl alcohol, and (**3**) 6-oxo-1-nonanol.

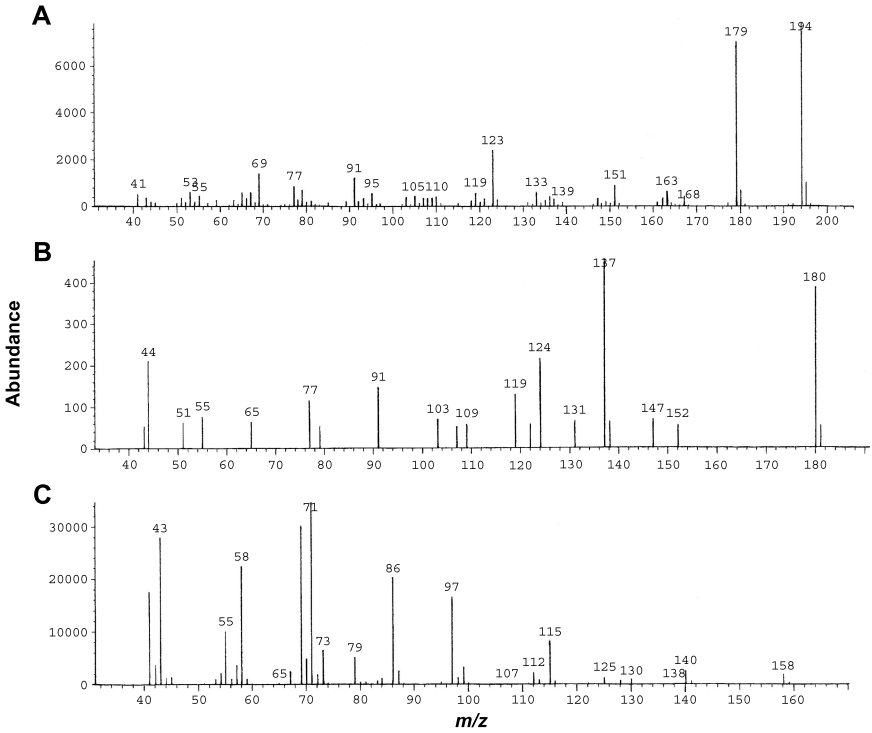

FIG. 3. Mass spectra of (**A**) 2-allyl-4,5-dimethoxyphenol and (**B**) (*E*)-coniferyl alcohol, the methyl eugenol-derived sex pheromonal components in male rectal gland of *B. papayae* and *B. carambolae* (with absence of **A**); and (**C**) 6-oxo-1-nonanol, the major endogenous component of sexually mature male *B. carambolae*.

rectal glands, whereas these percentages showed gradual decrease to below 30% when the respective F_1's were self-crossed (i.e., F_2) or backcrossed to the parental species (Table 1).

Between 14 and 18% of F_1 males possessed both CF and DMP in their rectal gland, which is typical for *B. papayae* males which have consumed ME. Percentages of hybrids that possessed this combination increased when they were subjected to self-crossing (Table 1). Backcrossing F_1 hybrids with parental *B. papayae* further increased the percentages of individuals bearing the *B. papayae* rectal gland blend (Table 1).

Similarly, the occurrence of *B. carambolae* blend (OXO + CF) was low among the F_1 hybrids but showed an increase in the F_2 generation. Backcrossing to the parental *B. carambolae* increased the percentage of hybrids having the *B. carambolae* rectal gland blend (Table 1).

Notes: CF = (*E*)-coniferyl alcohol; DMP = 2-allyl-4,5-dimethoxyphenol; OXO = 6-oxo-1-nonanol; R = hybrid of cross between female BC and male BP; S = hybrid of cross between female BP and male BC.

[a]Combination of rectal gland components typical of a *B. papayae* male after methyl eugenol consumption.

[b]Combination of rectal gland components typical of a *B. carambolae* male after methyl eugenol consumption.

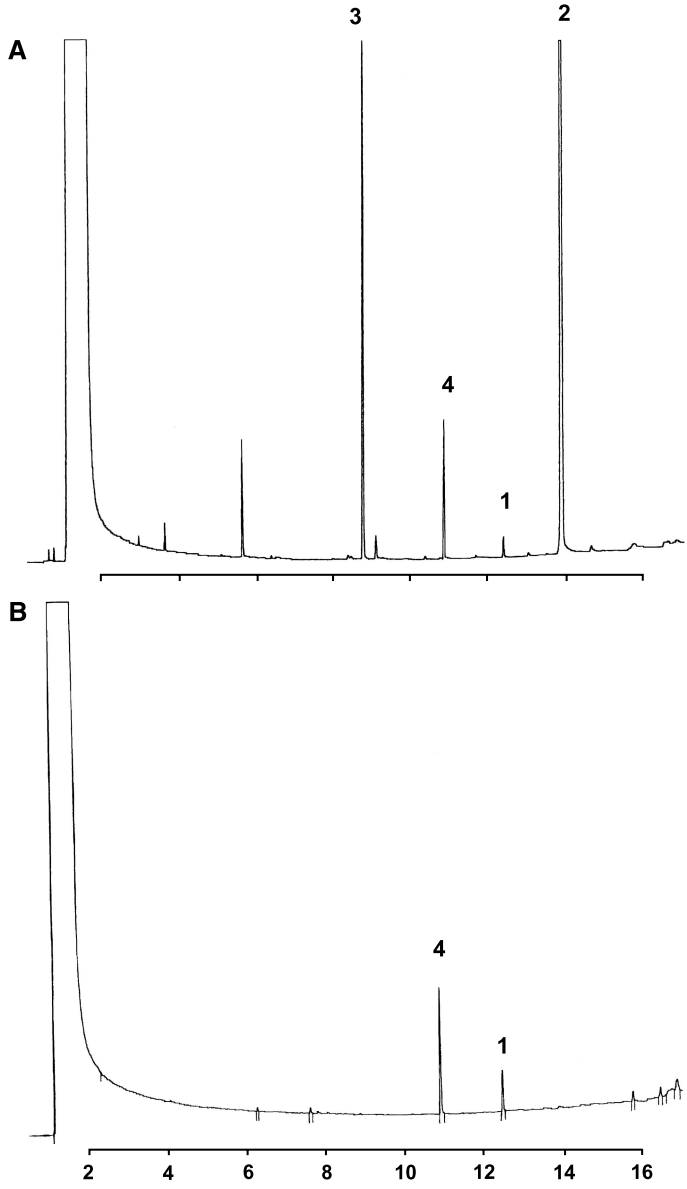

FIG. 4. Gas chromatograms of wild *Bactrocera* male rectal gland, 24 hr after methyl eugenol feeding in the laboratory: (**A**) pheromone profile featuring a combination of both *B. carambolae* and *B. papayae* pheromonal components and (**B**) pheromone profile containing DMP only. (**1**) 2-Allyl-4,5-dimethoxyphenol, (**2**) (*E*)-coniferyl alcohol, (**3**) 6-oxo-1-nonanol, and (**4**) 1-dodecanol as internal standard.

A unique rectal gland blend that featured the combination of both parental species, i.e., OXO + CF + DMP, was detected among the F_1 and F_2 generations as well as when hybrids of *B. carambolae* female and *B. papayae* male were backcrossed with their parental species (Table 1). A low percentage (1–4%) of hybrids possessed DMP only in their rectal glands when *B. carambolae* females interbred with *B. papayae* males, and when their F_1 hybrids were backcrossed to the male parental species (Table 1). Hybrids with OXO component only or without any rectal gland production were not found in F_1 or F_2 generations, but appeared in the backcrossed hybrids of *B. papayae* females and *B. carambolae* males (Table 1).

Rectal gland analyses revealed that several wild males with intermediate morphological traits possessed the unique rectal gland blend from the combination of both *B. carambolae* and *B. papayae* parents, i.e., OXO + CF + DMP (one male each from Penang and Johor; Figure 4A). Apart from this, there were also males detected with DMP only (one male from Perak and two males from Johor; Figure 4B) and without any pheromonal components (three males from Johor).

Interestingly, two wild males collected from Johor of the typical *B. papayae* phenotype were found to possess OXO + CF, which are the typical rectal gland blend of a *B. carambolae* male. In addition, there was a male with the *B. carambolae*-like morphology that contained CF and DMP (typical rectal gland blend of *B. papayae*) in its rectal gland.

DISCUSSION

Among the 52 sibling species in the *B. dorsalis* complex, four (*B. carambolae*, *B. dorsalis*, *B. papayae*, and *B. philippinensis*) have been observed to interbreed in the laboratory. *B. carambolae* interbreeds with *B. dorsalis* (McInnis et al., 1999) and with *B. papayae* (Wee and Tan, 2000a), and *B. dorsalis* interbreeds with *B. papayae* (Tan, 2000). Sexual compatibility was also observed between wild *B. dorsalis* and wild *B. philippinensis* (Medina et al., 1998). However, to date, there is no documented evidence of interspecific mating of these species in the field.

Whereas pheromonal analyses were suggested to be of use in chemotaxonomy of *Bactrocera* flies (Krohn et al., 1992), this paper describes for the first time the use of pheromonal analyses to detect evidence of natural hybrids of the ME-attracted *Bactrocera* species. The distinctive pheromonal components, together with the common phenylpropanoid CF, detected in *B. carambolae* and *B. papayae* were consistent with previous reports (Nishida et al., 1988; Perkins et al., 1990; Tan and Nishida, 1996; Wee, 2000). Therefore, the detection of pheromonal combinations between that of *B. papayae* and *B. carambolae* in a

wild *Bactrocera* fruit fly similar to that of the laboratory hybrids suggests that natural hybridization between *B. carambolae* and *B. papayae* had occurred in the wild.

Wild *Bactrocera* species with intermediate morphological characteristics have been observed regularly since the 1990's (Wee, 2000). Therefore, if natural hybridization happened in the past, some degree of self-crossing among the F_1 or backcrossing to the parental species must have occurred throughout many generations. Laboratory studies have shown that intermediate pheromone combination, such as OXO + CF + DMP, even though at low percentages, persist in F_1, F_2, and backcross generations. Thus, the detection of two wild males with OXO + CF + DMP rectal gland combination in the northern (Penang) and southern region (Johor) of peninsular Malaysia is consistent with the results of our laboratory studies.

The fact that low percentages of captured wild males possessed combinations of pheromonal components may reflect the rarity of the interbreeding that occurs in the wild. However, based on the sample size of trapped wild males, a low capture of those that do interbreed in the field cannot be discounted. Fewer hybrids would suggest higher chances of the hybrid individuals backcrossing with the parental species than among the hybrid themselves. In this study, a higher number of wild males was detected containing DMP only or without any pheromonal components compared with intermediates detected that possess OXO, DMP, and CF. This is also consistent with the laboratory interbreeding results that showed a higher percentage for such occurrence when the F_1 hybrids were backcrossed with the parental species.

The results showed that more hybrids were detected in Johor. Both *B. carambolae* and *B. papayae* are dusk-mating species and exhibit similar mating behavior (Wee, 2000). Although *B. papayae* preceded *B. carambolae* in mating at a slightly higher light intensity (1,000 *versus* 600 lx), their courtship and mating period overlapped (Wee, 2000). A wind tunnel study has shown that females of both species respond by upwind anemotactic flight to conspecific and heterospecific males during courtship period (Wee and Tan, 2000a). In field cages that simulated heterospecific sexual encounters of females, *B. papayae* females showed a much higher prereproductive isolation than *B. carambolae* females (Wee and Tan, 2000a; unpublished data). This suggests that females are able to distinguish between conspecific and heterospecific males at close range/contact during courtship encounters. However, *B. carambolae* females were less discriminating than *B. papayae* females in interspecific encounters (Wee and Tan, 2000a). The fact that *B. carambolae* is more abundant in Johor, and that *B. carambolae* females are nonselective in mate preference may account for natural interbreeding in the field. Moreover, *B. papayae* males are more aggressive in mating behavior than *B. carambolae* males, which could lead to

higher chances of securing a female, be it a conspecific or a heterospecific female (Wee, 2000; Wee and Tan, 2000a). This may explain the higher incidence of wild hybrids captured in Johor.

In contrast, in areas where *B. carambolae* population density is low, high prereproductive isolation in the case of *B. papayae* females may also contribute to the low recovery of hybrids in the wild. However, in the absence of conspecific males, females of both *B. papayae* and *B. carambolae* mate with heterospecific males (Wee, 2000; Wee and Tan, 2000a). In addition, the production of a common ME-derived sex pheromone, in both *B. papayae* and *B. carambolae* males, would further promote and facilitate interspecific encounters and mating in the wild because natural sources of ME are plentiful, especially in the tropics where there are many plant species that contain ME (Tan and Nishida, 2000; Tan et al., 2002; Nishida et al., 2004). ME, as a pheromone precursor (Tan and Nishida, 1996, 1998), enhances male mating competitiveness in *B. dorsalis*, *B. papayae*, and *B. philippinenses* after ME consumption (Shelly and Dewire, 1994; Shelly et al., 1996; Tan and Nishida, 1996, 1998; Hee and Tan, 1998; Shelly, 2000). This may account for the occurrence of the two hybrid flies in the Perak and Penang regions.

Pheromonal analysis also showed that even a wild *Bactrocera* species with the typical phenotype of *B. carambolae* can possess a typical rectal gland blend of a *B. papayae* male and vice versa. Thus, species identification based solely on morphological traits may not be totally reliable, at least in the *B. dorsalis* complex, and especially for the two sympatric species. The discovery of this phenomenon certainly further complicates the existing problem in the taxonomic status of *B. carambolae* and *B. papayae*, the latter of which was recently shown to be neither a distinct biological nor genetic species from *B. dorsalis* (Hendel) (Naeole and Haymer, 2003; Tan, 2003).

Interbreeding between a *B. carambolae* female and *B. papayae* male produced F_1 males with rectal gland blends closer to a *B. papayae* male. However, backcrossing this F_1 male to *B. carambolae* female parent yielded a high percentage (75%) of hybrids having *B. carambolae* rectal gland blend. Therefore, pheromone production in the *Bactrocera* species appears to be a sex-limited trait whereby genes responsible for pheromone production show a 100% penetrance in males only, and although females inherited the same gene, the gene was not expressed in the female progeny.

In contrast, based on these laboratory interbreeding results, backcrossing of the hybrids to the parental species over many generations may produce not only higher percentages of hybrids that resemble the parental species in terms of rectal gland blend, but also, in terms of morphological traits. Therefore, at the time of this investigation, a true hybrid may look like the parental species in all aspects, and, thus, escape any morphological/pheromonal means of screening. Only those minority categories with unique intermediate rectal gland blends

may be detected by pheromone analysis. A more sensitive molecular technique may help in the determination of the hybrids' polymorphism/genetic make-up.

In *B. papayae*, the *in vitro* conversion of ME into its metabolites involves the cytochrome P-450 mixed-function monooxygenases (Lim et al., 1998). Hybridization has resulted in a lower penetrance observed in more than 80% of the F_1 hybrids of the reciprocal crosses, and in some cases, a low percentage of the backcross offspring has been found not to produce either CF or DMP after ME consumption. This lowered and "zero" penetrance may have resulted from the complex interaction between segregated maternal and paternal genes during hybridization of sibling species, causing alteration/deletion or inhibition of the gene responsible for ME conversion, thus disabling the respective gene(s). However, this does not discount other possibilities that may contribute to this lowered penetrance for the sex-limited trait.

Acknowledgements—We are grateful to R. Nishida (Kyoto University, Japan) for providing the various chemical compounds, and we also thank Agrisense-BCS Ltd. (UK) for the supply of synthetic methyl eugenol. This work was funded by Malaysian IRPA grant (NO: 01-02-05-9007) and partly supported by the International Atomic Energy Agency (Contract No. 10570).

Abstract—The sex pheromones of three *Cryptophlebia*, one *Centroxena*, and one *Eucosma* species (Lepidoptera: Olethreutinae) inhabiting mangroves in the Ryukyu Islands, Japan, were studied with coupled gas chromatography-electroantennographic detection, and GC-mass spectrometry (GC-MS). The larvae of each *Cryptophlebia* species are specifically associated with viviparous seedlings from one of three mangrove Rhizophoraceae plants. Whereas three EAG-active alcohol components, (*Z*)-8-dodecen-1-ol, (*E*)-8-dodecen-1-ol, and dodecan-1-ol, in a ratio of 100:12:4, were identified from the pheromone gland extract of female of *C. horii* (host: *Bruguiera gymnorrhiza*), two other sibling species produced the corresponding acetates, i.e., (*Z*)-8-dodecenyl acetate, (*E*)-8-dodecenyl acetate, and dodecyl acetate, in a 100:2:3 ratio from *Cryptophlebia palustris* (host: *Rhizophora stylosa* in Iriomote-jima Island) and in a 100:7:13 ratio from *C. amamiana* (host: *Kandelia candel* in Amami-oshima Island). The double bond positions of the monounsaturated components were confirmed by GC-MS analyses of their adducts with dimethyl disulfide. On the other hand, the larvae of *Centroxena* sp. feed on fruits of *Sonneratia alba*, another mangrove plant in the Sonneratiaceae, and the extract of the female pheromone glands contained (8*E*,10*E*)-dodecadienyl acetate and dodecyl acetate in a ratio of 100:5. The double bond position of

* To whom correspondence should be addressed. E-mail: antetsu@cc.tuat.ac.jp

the diunsaturated compound was confirmed by GC-MS analysis of its adduct with 4-methyl-1,2,4-triazoline-3,5-dione. (*E*)-9-Dodecenyl acetate was exclusively identified in the pheromone gland extract of *Eucosma coniogramma* females reared from seedlings of *B. gymnorrhiza*. Although the roles of minor components have not been revealed by field tests, synthetic lures baited with the main pheromone component of each species successfully attracted the target males, confirming that the sex pheromone is one of the most important factors for their reproductive isolation.

Key Words—Sex pheromones, Tortricidae, Olethreutinae, mangrove, Rhizophoraceae, Sonneratiaceae, reproductive isolation, DMDS, MTAD.

INTRODUCTION

The range of the Ryukyu Islands is approximately 800 km in the East China Sea starting from Tane-ga-shima Island (latitude 30°43′N) near the south end of Kyushu to the Yaeyama Islands (~24°N) near Taiwan. This archipelago includes Amami-oshima Island (28°15′N) and Okinawa-jima Island (26°35′N), and mangroves spread throughout the mouths of the rivers on several islands. In Iriomote-jima Island (24°19′N), one of the main islands among the Yaeyama Islands, mangroves mainly consist of seven plant species in five families such as *Bruguiera gymnorrhiza*, *Rhizophora stylosa*, and *K. candel* in the Rhizophoraceae and *Sonneratia alba* in the Sonneratiaceae. The variety of these plants decreases northward, and mangroves in Tane-ga-shima Island consist solely of *K. candel* (Table 1). To date, 37 lepidopteran species have been recorded from the mangroves in the Ryukyu Islands, including three *Cryptophlebia* spp. in Olethreutinae (Lepidoptera: Tortricidae) (Komai, unpublished). While *Cryptophlebia horii* Kawabe, which is almost exclusively associated with viviparous seedlings from *B. gymnorrhiza*, was newly described in 1987, two other sibling species, *C. palustris* Komai and Nasu and *C. amamiana* Komai and Nasu, the larvae of which feed on *R. stylosa* and *K. candel*, respectively, were recently discovered (Komai and Nasu, 2003). Although *C. amamiana* has not been found in the mangroves with *K. candel* in Iriomote-jima Island, the other two sibling species have been observed there. On this island, viviparous seedlings of *B. gymnorrhiza* were also attacked by another olethreutine species, *Eucosma coniogramma* Clarke (=*E. okubiensis* Kawabe), in addition to *C. horii* (Komai and Nasu, 2003). Furthermore, the fruit of *S. alba* is a host of *Centroxena* sp. in Olethrutinae, known only from Iriomote-jima Island (Komai, unpublished) (Table 1).

Lepidopteran sex pheromones have been chemically identified from adult females of more than 500 species, but information about the species distributed in the tropical and subtropical zones is still limited (Ando, 2005; Ando et al.,

TABLE 1. MANGROVE PLANTS REPRESENTATIVE OF THE RYUKYU ISLANDS, OLETHREUTINE SPECIES ASSOCIATED WITH THEIR VIVIPAROUS SEEDLINGS OR FRUITS, AND MAIN SEX PHEROMONE COMPONENTS IDENTIFIED FROM THE FEMALE MOTHS

Mangrove: host plant		Olethreutine moth: herbivorous insect		Main pheromone component

[a] Data from Komai and Nasu (2003).

2004; Arn et al., 1997; El-Sayed, 2005; Witzgall et al., 2004). Screening tests with synthetic lures baited with known sex pheromones in the Mekong Delta resulted in attraction of males of several lepidopteran species (Hai et al., 2002), but trials targeting olethreutine species have been unsuccessful (Hai et al., unpublished data). Ecological details of the above olethreutine species and damage of mangroves by their larvae are still unknown, and synthetic pheromones are expected to be a useful tool for these investigations. Therefore, we collected seedlings and fruits of mangrove plants infested with olethreutine larvae in the Ryukyu Islands and studied the sexual communication systems of the adults emerging. This paper deals with the identification of the pheromones of the three *Cryptophlebia* and one *Centroxena* species in the tribe Grapholitini and one *Eucosma* species in the tribe Eucosmini in addition to field evaluation of their synthetic pheromones.

METHODS AND MATERIALS

Insects and Pheromone Extracts. In Iriomote-jima Island, young viviparous seedlings of *B. gymnorrhiza* infected by *C. horii* and *E. coniogramma* were collected from January to February, and matured stems of *R. stylosa*, seedlings infected by *C. palustris* were collected in July. Other viviparous seedlings of *K. candel* infected by *C. amamiana* were found in Amami-oshima Island in January. Fruits of *Sonneratia alba* with *Centroxena* sp. were picked in Iriomote-jima Island from July to August. These host plant materials were incubated at 25°C under a 16L:8D cycle. After eclosion, each moth was sexed and kept separately in a glass tube. From 2- to 3-d-old female moths of each species (about 100 females of *C. horii*, *C. palustrism*, and *Centroxena* sp., 10 females of *E. coniogramma*, and 20 females of *C. amamiana*), abdominal tips containing the pheromone glands were removed 2–3 hr after lights off and soaked in *n*-hexane for 15 min to extract pheromone components. Male moths were used for the tests with gas chromatography (GC) equipped with an electroantennographic (EAG) detector (GC-EAD).

Chemicals. The chemical structures of pheromone components and related compounds are abbreviated as follows: Z = (*Z*)-double bond, E = (*E*)-double bond, number before the hyphen = position of the double bond, number after the hyphen = carbon number of the straight chain, OAc = acetate, and OH = alcohol. All dodecenyl compounds and (8*E*,10*E*)-dococadienyl derivatives used as analytical standards and to prepare lures were supplied by Shin-etsu Chemical Co., Ltd. (Tokyo, Japan) with purity levels greater than 98%. Three geometrical isomers of the 8,10-diene (>95% purity) were synthesized according to an established method (Ando et al., 1985).

Derivatization of Pheromone Components. To confirm the double bond position of monounsaturated compounds, crude pheromone extracts of three *Cryptophlebia* spp. were derivatized with dimethyl disulfide (DMDS). Thus, the extract of ca. 10 female equivalents (FE) of each species was dissolved in a mixture of DMDS (50 μl) and a diethyl ether solution of iodine (60 mg/ml, 5 μl) and warmed at 40°C overnight (Buser et al., 1983; Inomata et al., 2000). After the addition of a 5% sodium thiosulfate solution (0.5 ml), crude products were extracted with *n*-hexane and analyzed by GC-mass spectrometry (GC-MS). For the determination of the diunsaturated compound produced by *Centroxena* sp., a crude extract (81 FE) was treated with a CH_2Cl_2 solution of 4-methyl-1,2,4-triazoline-3,5-dione (MTAD, 10 mg/ml, 10 μl) for 10 min at room temperature after removing *n*-hexane (Young et al., 1990). After changing the solvent to *n*-hexane again, the MTAD adduct was analyzed by GC-MS.

GC-EAD Analyses. The EAG activity of the natural pheromone components of each species was measured by GC-EAD (Struble and Arn, 1984), using at least four antennae cut from different 2- to 3-d-old males. The GC was equipped with a DB-23 capillary column (0.25 mm × 30 m, 0.25 μm, J&W Scientific, Folsom, CA), with a temperature program of 80°C for 1 min, 8°C/min to 210°C, 210°C for 10 min. The effluent from the column was split between the flame ionization detector (FID) and EAD at a ratio of 1:1 (Inomata et al., 2005). An antenna was excised at the base from the corresponding male, and a few distal segments were cut off. *Bombyx mori* saline was used for the electrodes, and the airflow carrying eluted compounds to the antenna was at rate of 7.8 cm/min. EAG activities of synthetic pheromone components and their analogs were measured by the GC-EAD using the same conditions as the gland extracts.

GC-MS Analyses. Electron impact GC-MS was carried out on an HP5973 mass spectrometer system (Hewlett-Packard) equipped with a capillary column operating with a mass range of *m*/*z* 50–500. The ionization voltage was 70 eV, and the ion source temperature was 230°C. For analysis of natural pheromone components and DMDS adducts, a DB-23 column (0.25 mm × 30 m) was used under the same temperature program as the GC-EAD. For analysis of the MTAD adduct, an HP-5 column (0.25 mm × 30 m, 0.25 μm; Hewlett-Packard, Wilmington, DE) was used with temperature program of 100°C for 2 min, 15°C/min to 280°C. The analyses of the untreated extracts were repeated in order to confirm the titers of major components and the mixing ratios of minor components, except for *E. coniogramma*.

Field Tests. Lures were white rubber septa (8 mm OD, Aldrich) impregnated with a *n*-hexane solution of the pheromone components. Each septum was placed at the center of a sticky trap (30 × 27 cm bottom plate with a roof; Takeda Chemical Ind. Ltd., Osaka, Japan), which was set at a height of 1.5 m from the ground. The field evaluation for the lures of each olethreutine species

was carried out in the mangrove swamps where the infested seedlings or fruits were collected.

RESULTS

Identification of the C. horii Female Pheromone. A GC-EAD analysis of the *C. horii* pheromone extract (one FE) showed the occurrence of three EAG-active components, as follows: 170 μV at retention time (Rt) 11.2 min [Kováts relative index (RI) 18.9], 900 μV at 11.5 min (RI 19.2), and 830 μV at 11.8 min (RI 19.4) (Figure 1A). This analytical profile was representatively recorded on antennae of *C. horii* males. The chromatographic behaviors of the three components on a DB-23 capillary column coincided with those of authentic samples of 12:OH, E8-12:OH, and Z8-12:OH, which have EAG activity as shown in Figure 1B. The GC-MS data of these natural components also coincided with those of the authentic samples. The mass spectrum at 10.43 min (RI 18.87), which shows the highest ion at *m*/*z* 168 indicating $[M-18]^+$ of 12:OH, was almost the same as that of commercial 12:OH. The mass spectra at 10.75 min (RI 19.15) and 10.97 min (RI 19.35) including the highest ion at *m*/*z* 166, $[M-18]^+$ of dodecen-1-ol, were identical with those of synthetic E8-12:OH and Z8-12:OH. Z8-12:OH occurred as a major component in the pheromone gland extract, and a total ion chromatogram (TIC) of this GC-MS analysis showed a 100:12:4 ratio of Z8-12:OH, E8-12:OH, and 12:OH (Figure 1C). The titer of the main component was ca. 4 ng/female, and its double bond position was confirmed by GC-MS analysis of the crude pheromone extract (nine FE) treated with DMDS. Figure 1D shows the mass spectrum of a DMDS adduct (Rt 23.82 min) derived from the main component. In addition to M^+ at *m*/*z* 278, diagnostic fragment ions at *m*/*z* 175 and 103 confirmed the original double bond at the 8-position of the monounsaturated alcohol.

EAG Responses and Field Attraction of C. horii Males. In GC-EAD studies, antennae of male *C. horii* responded to synthetic pheromone components and their related compounds, as shown in Figure 2. The main pheromone component, Z8-12:OH, showed the largest average value of the EAG activity among the three identified components at a dose of 0.1 ng, whereas the EAG response did not increase dose-dependently and was less than those of E8-12:OH at doses of 1 and 10 ng. Functional derivatives of the pheromonal alcohols also stimulated the antennae, and interestingly monounsaturated aldehydes were more active than the corresponding acetates. Table 2 shows results of the field evaluation of synthetic lures. For the attraction of *C. horii* males, Z8-12:OH was indispensable, but the roles of the other two minor components were at first unclear (Test A-1). However, when the percentage of

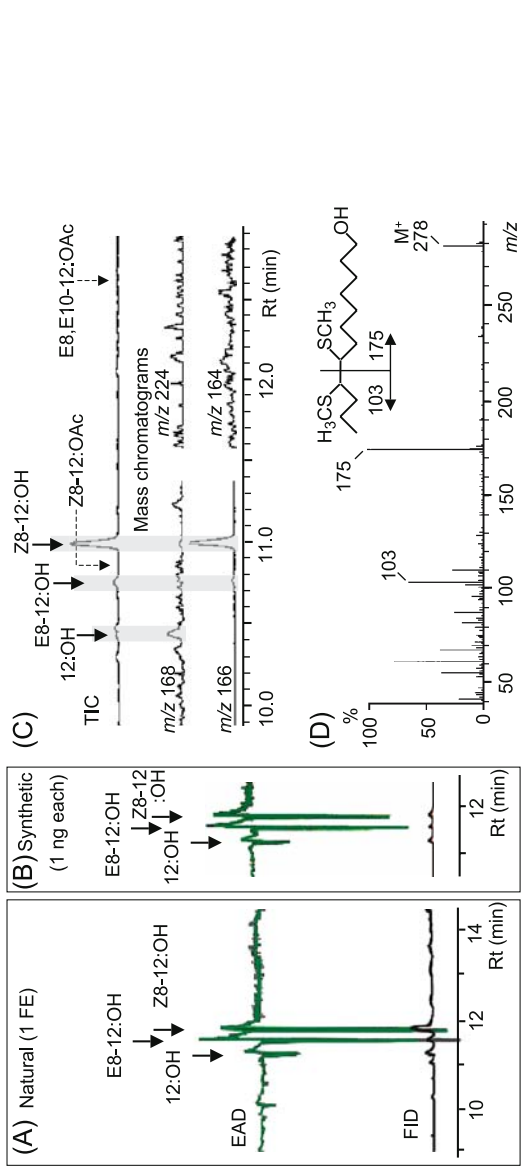

FIG. 1. Analyses of the sex pheromone components of *Cryptophlebia horii* by GC-EAD and GC-MS. (A) GC-EAD of the pheromone extract (one FE) conducted with a flame ionization detector (FID) and an electroantennographic detector (EAD). (B) GC-EAD of synthetic standards (12:OH, E8-12:OH, and Z8-12:OH, 1 ng each). (C) GC-MS analysis of the extract (nine FE); total ion chromatogram (TIC) and mass chromatograms monitoring the diagnostic ions at *m/z* 168 for 12:OH, at *m/z* 166 for E8-12:OH, Z8-12:OH and the corresponding acetates (not detected), and *m/z* 164 and 224 (M^+) for E8,E10-12:OAc (not detected). (D) Mass spectra of a DMDS adduct of Z8-12:OH in the pheromone extract (nine FE).

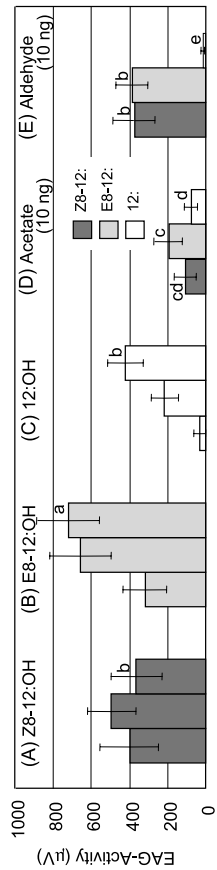

FIG. 2. Electroantennographic (EAG) responses (mean μV ± SE, $N = 10$) of *Cryptophlebia horii* males to synthetic pheromone components (A–C, injection of 0.1, 1, and 10 ng) and some related compounds (D and E, injection of 10 ng). The responses were measured by GC-EAD, which delivered about half of the injected compound to the male antenna. Bars at the dose of 10 ng superscripted by a different letter are significantly different at $P < 0.05$ by Tukey–Kramer test.

[a] Tested in a mangrove with *Bruguiera gymnorrhiza* using three traps for each lure from March 4 to April 6 (Test A-1), from April 6 to May 18 (Test A-2), and from May 18 to June 30 (Test A-3) in 2004.

[b] Mean ± SE. Values within each test followed by a different letter are significantly different at $P < 0.05$ by Tukey–Kramer test.

the (*E*)-isomer was increased, the number of captured males decreased (Test A-2). Furthermore, the activity of Z8-12:OH was greatly inhibited by the corresponding acetate, Z8-12:OAc (Test A-3), which has not been identified from *C. horii* females but has been found from the other two *Cryptophlebia* spp., as described in the following paragraph.

Identification of C. palustris and C. amamiana Female Pheromone Components. A GC-EAD analysis of the *C. palustris* pheromone extract (one FE) showed at least three EAG-active components: 150 μV at 11.1 min (RI 18.8), 190 μV at 11.35 min (RI 19.05), and 830 μV at 11.6 min (RI 19.3) (Figure 3A). Their chromatographic behaviors and mass spectra coincided with those of authentic samples of 12:OAc, E8-12:OAc, and Z8-12:OAc. The mass spectrum at 10.36 min (RI 18.81) showed the highest ion at *m*/*z* 168 indicating $[M\text{-}60]^+$ of 12:OAc. The mass spectra at 10.64 min (RI 19.05) and 10.86 min (RI 19.25)

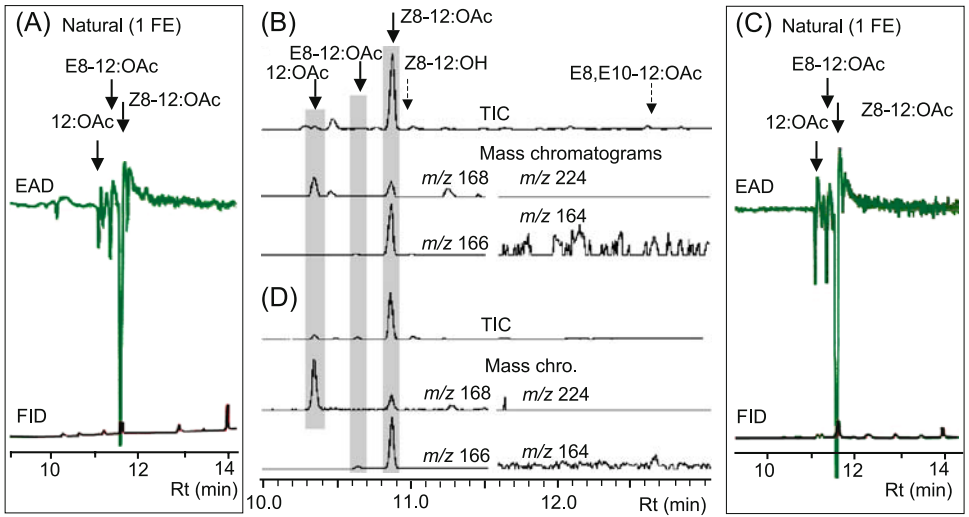

FIG. 3. Analyses of the sex pheromone components of *Cryptophlebia palustris* and *C. amamiana* by GC-EAD and GC-MS. (A) GC-EAD of the *C. palustris* pheromone (one FE). (B) GC-MS analysis of the *C. palustris* pheromone (one FE); TIC and mass chromatograms monitored the diagnostic ions at *m/z* 168 for 12:OAc, at *m/z* 166 for E8-12:OAc and Z8-12:OAc, and the corresponding alcohols (not detected), and *m/z* 164 and 224 (M^+) for E8,E10-12:OAc (not detected). (C) GC-EAD of the *C. amamiana* pheromone (one FE). (D) GC-MS analysis of the *C. amamiana* pheromone (eight FE); TIC and mass chromatograms monitoring the ions at *m/z* 168, 166, 164, and 224.

with the highest ion at *m*/*z* 166, $[M-60]^+$ of dodecenyl acetates, coincided with the spectra of synthetic E8-12:OAc and Z8-12:OAc. Z8-12:OAc occurred as a main component (ca. 4 ng/female), and the chromatogram showed a 100:2:5 ratio of Z8-12:OAc, E8-12:OAc, and 12:OAc in the pheromone gland extract (Figure 3B). The mass spectrum of a DMDS adduct (Rt 22.73 min) with M^+ at *m*/*z* 320, derived from the main component in the crude pheromone extract (three FE), showed two diagnostic fragment ions at *m*/*z* 217 and 103, indicating the original double bond at the 8-position of the monounsaturated acetate.

Similar results were obtained from the analyses of the *C. amamiana* pheromone extract, except for the amounts of the three components (Figures 3C and D). The *C. amamiana* females produced Z8-12:OAc, E8-12:OAc, and 12:OAc in a ratio of 100:7:13, and the titer of Z8-12:OAc was ca. 6 ng/female.

EAG Responses and Field Attraction of C. palustris and C. amamiana Males. Figure 4 shows the EAG dose responses of synthetic pheromone components on male antennae of *C. palustris* and *C. amamiana*, which were measured by a GC-EAD technique. The antennae of both species were most strongly stimulated by the common main pheromone component, Z8-12:OAc, among the three acetates identified. The EAG activity of E8-12:OAc was similar to that of 12:OAc. In *C. palustris* males, the EAG activity of the corresponding aldehyde and alcohol derivatives of the pheromone components was measured, and weak responses of their antennae were recorded.

In a mangrove swamp with *R. stylosa* on Iriomote-jima Island, traps baited with Z8-12:OAc (1 mg/rubber septum) successfully attracted *C. palustris* males; 9 ± 3 males were captured per trap from July 26 to August 22, 2004. However, whereas unbaited traps caught no males, this number was smaller than that expected from a high level of infestation of the viviparous seedlings by the larvae. Although many lures including minor components (E8-12:OAc and 12:OAc) in different ratios have been tested since 2003, no synergistic effects have been observed. In a mangrove swamp with *K. candel* on Amami-oshima Island, a field test for *C. amamiana* was carried out from March 24 to April 6, 2003. Two traps baited with synthetic Z8-12:OAc (1 mg/rubber septum) captured a total of five males, and the minor components showed no synergistic effect.

Identification of the Centroxena sp. Female Pheromone. A GC-EAD analysis of the *Centroxena* sp. pheromone extract (six FE) showed two antennal stimulatory components, as follows: 40 μV at 11.1 min and 380 μV at 13.3 min (RI 20.9) (Figure 5A). Their chromatographic behaviors coincided with those of authentic samples of 12:OAc and E8,E10-12:OAc (Figure 5B). The GC-MS data of these components also coincided with those of authentic samples. The mass spectra at 12.62 min (RI 20.90) with M^+ (*m*/*z* 224) and $[M-60]^+$ (*m*/*z* 164) of dodecadienyl acetate coincided with the spectrum of synthetic E8,E10-12:OAc (Figure 5C). Synthetic standards of its geometrical isomers separately eluted from the DB-23 column [E8,E10-12:OAc 12.57 min (RI 20.85), Z8,Z10-

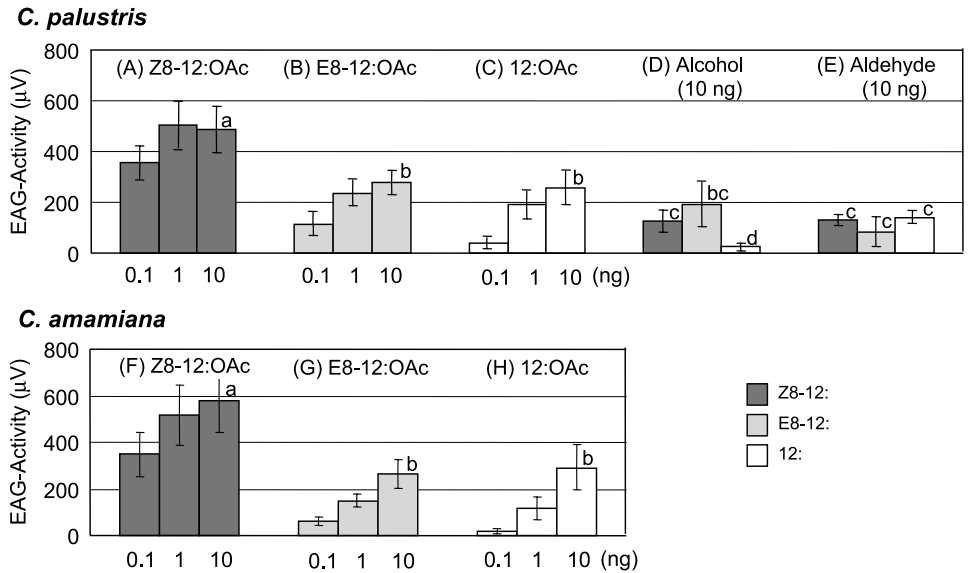

FIG. 4. Electroantennographic (EAG) responses (mean μV ± SE, $N = 10$) of *Cryptophlebia palustris* males to synthetic pheromone components (A–C, injection of 0.1, 1, and 10 ng) and some related compounds (D and E, injection of 10 ng) and those of *C. amamiana* males to synthetic pheromone components (F–H, 0.1, 1, and 10 ng injection). The responses were measured by GC-EAD, which delivered about half of the injected compound to the male antenna. Bars at the dose of 10 ng in each species superscripted by a different letter are significantly different at $P < 0.05$ by Tukey–Kramer test.

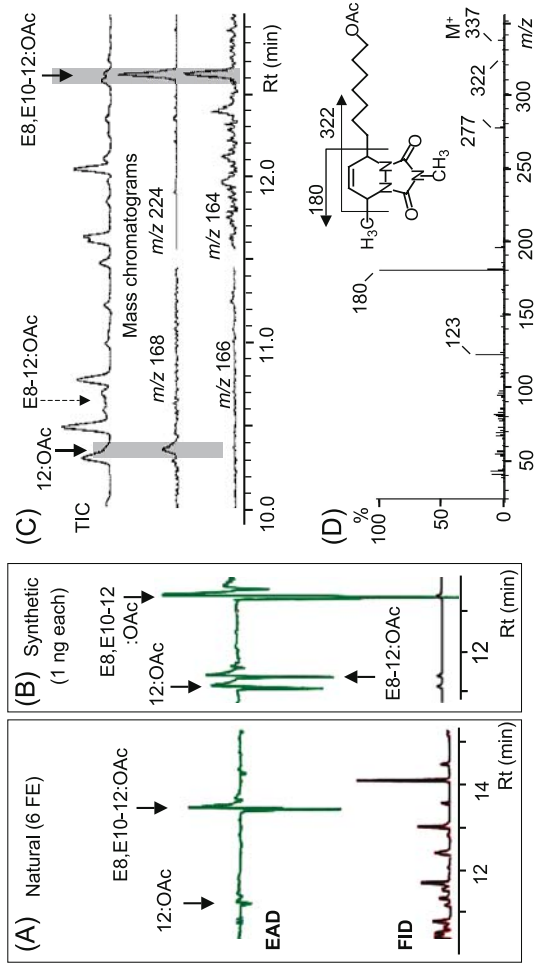

FIG. 5. Analyses of the sex pheromone components of *Centroxena* sp. by GC-EAD and GC-MS. (A) GC-EAD of the pheromone extract (six FE). (B) GC-EAD of synthetic standards (12:OAc, E8-12:OAc, and E8,E10-12:OAc, 1 ng each). (C) GC-MS analysis of the extract (20 FE); TIC and mass chromatograms monitoring the diagnostic ions at *m/z* 168 for 12:OAc, at *m/z* 166 for E8-12:OAc (not detected), and at *m/z* 164 and 224 (M^+) for E8,E10-12:OAc. (D) Mass spectrum of an MTAD adduct of E8,E10-12:OAc in the pheromone extract (81 FE).

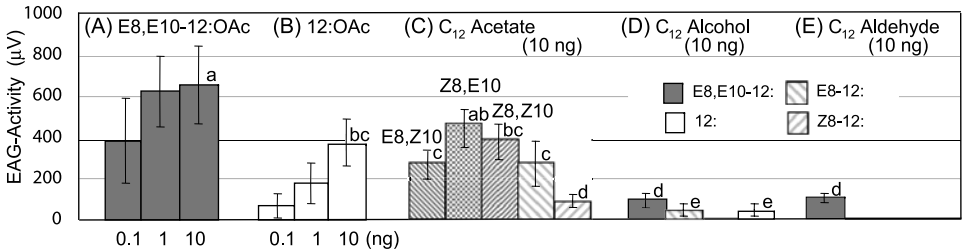

FIG. 6. Electroantennographic (EAG) responses (mean μV ± SE, $N = 10$) of *Centroxena* sp. males to synthetic pheromone components (A and B, injection of 0.1, 1, and 10 ng) and some related compounds (C–E, injection of 10 ng). The responses were measured by GC-EAD, which delivered about half of the injected compound to the male antenna. Bars at the dose of 10 ng superscripted by a different letter are significantly different at $P < 0.05$ by Tukey–Kramer test.

12:OAc 12.80 min (RI 21.07), and E8,Z10-12:OAc 12.82 min (RI 21.09)] and confirmed the 8E,10E configuration of the natural component. The ratio of E8,E10-12:OAc and 12:OAc was 100:5, and the titer of the diunsaturated main component in the pheromone gland extract was ca. 0.6 ng/female. The double bond positions were confirmed by GC-MS analysis of the crude pheromone extract (81 FE) treated with MTAD. The mass spectrum of the MTAD adduct (Rt 14.42 min) derived from the diunsaturated component showed a characteristic base peak at *m*/*z* 180 in addition to $[M\text{-}CH_3]^+$ at *m*/*z* 322 (2%) and M^+ at *m*/*z* 337 (6%) (Figure 5D), proving the original conjugated 8,10-diene structure.

EAG Responses and Field Attraction of Centroxena sp. Males. Figure 6 shows the EAG activity of synthetic standards measured with GC-EAD. Among

[a] Tested in a mangrove with *Sonneratia alba* using two traps for each lure from May 1 to July 15 in 2003 (Test B-1), and using three traps for each lure from October 18 to November 24 (Test B-2), from January 25 to April 6 (Test B-3), May 18 to June 30 (Test B-4) in 2004.

[b] Mean ± SE. Values within each test followed by a different letter are significantly different at $P < 0.05$ by Tukey–Kramer test.

the tested compounds, antennae of male *Centroxena* sp. responded most strongly to E8,E10-12:OAc. The other geometrical isomers also elicited considerable EAG activity. In addition to 12:OAc, the monounsaturated acetate (E8-12:OAc) also showed medium activity. Antennal responses to alcohol and aldehyde analogs were weak. Results of field tests with synthetic lures are shown in Table 3. Traps baited with E8,E10-12:OAc attracted males, but the role of 12:OAc was not clear (Tests B-1 and B-2). Interestingly, three other geometrical isomers of E8,E10-12:OAc also effectively attracted the males (Tests B-3 and B-4). In addition, the diunsaturated acetate attracted a large number of males of another olethreutine species, *Rhadinoscolops koenigianus* Fabricius, the attractant of which had not been reported (Table 3). The host plant of this leafroller species is *Melia azedarach*, which is a deciduous arbor tree and is not found in mangroves.

Sex Pheromone of E. coniogramma. A GC-EAD analysis of the *E. coniogramma* pheromone extract (one FE) showed an EAG-active component: 490 μV at 11.4 min (RI 19.1). This chromatographic behavior on a DB-23 column coincided with that of E9-12:OAc, and the geometrical isomer (Z9-12:OAc) eluted separately at 11.7 min (RI 19.35). On a GC-MS analysis with the extract (five FE), the mass spectrum at 10.71 min (RI 19.12) with the highest ion at *m*/*z* 166 was similar to the spectrum of synthetic E9-12:OAc. The titer of

[a] Tested in a mangrove with *Bruguiera gymnorrhiza* using two traps for each lure from June 9 to July 9 (Test C-1), and using three traps for each lure from July 11 to August 22 (Test C-2) in 2004.
[b] Mean ± SE. Values within each test followed by a different letter are significantly different at $P < 0.05$ by Tukey–Kramer test.

E9-12:OAc was ca. 0.1 ng/female. Results of field tests with synthetic lures are shown in Table 4. Whereas many males of *E. coniogramma* were specifically attracted by E9-12:OAc in the preliminary experiment with single component lures (Test C-1), the evaluation of binary lures revealed that mixing with Z9-12:OAc at 5% effectively increased the activity (Test C-2). E9-12:OH showed no apparent synergistic effect (Test C-2). These results suggest that females secrete the geometrical isomer of E9-12:OAc, but not the alcohol analog, as a minor pheromone component at levels that were undetectable by GC-EAD and GC-MS analyses.

DISCUSSION

Using GC-EAD and GC-MS techniques, the following EAG-active components were identified from the pheromone gland extracts of five olethreutine species collected at mangroves in the Ryukyu Islands: Z8-12:OH, E8-12:OH, and 12:OH (100:12:4) from *C. horii*; Z8-12:OAc, E8-12:OAc, and 12:OAc (100:2:3) from *C. palustris*; the same three acetates (100:7:13) from *C. amamiana*; E8,E10-12:OAc and 12:OAc (100:5) from *Centroxena* sp.; and E9-12:OAc from *E. coniogramma* (Table 1). These compounds are well-known common pheromone components of other olethreutine species. (*Z*)-8-Dodecenyl compounds, the main pheromone components of three *Cryptophlebia* species living in mangroves, have already been identified from several olethreutine species classified into *Grapholita* (subgenus *Aspila*) in the tribe Grapholitini, *Eucosma* and *Proteoteras* in the tribe Eucosmini, and *Hedya* in the tribe Olethreutini. In the genus *Cryptophlebia* (Grapholitini), Z8-12:OAc has been characterized from two species, *C. batrachopa* and *C. leucotreta* (Hall et al., 1984), but both species were recently transferred to the genus *Thaumatotibia* (Komai, 1999). E8,E10-12:OAc has been identified from nine olethreutine species in the genera *Cydia*, *Matsumuraeses*, and *Melissopus* (currently synonymized with *Cydia*) in the Grapholitini and *Epiblema* and *Rhyacionia* in Eucosmini but not in *Centroxena* (Grapholitini). This is the first study of the sex pheromone of any *Centroxena* species.

The tribe Grapholitini is further divided into three groups: the *Grapholita* genus group, the *Cydia* genus group, and the *Dichrorampha* genus group (Komai, 1999). In addition to the sex pheromone, field tests with synthetic compounds have revealed male attraction of more than 90 Grapholitini species (Ando, 2005; Komai, 1999). Males in the *Grapholita* genus group usually were attracted by 8-dodecenyl compounds, suggesting the chemical structures of their real sex pheromones. Conversely, males in the *Cydia* genus group usually were attracted by 8,10-dodecadienyl compounds. The genus *Cryptophlebia* belongs

to the *Grapholita* genus group, and the chemical structures of the pheromones identified from the three *Cryptophlebia* spp. coincide in this respect. The genus *Centroxena* was proposed by Diakonoff in 1971 for a single species *C. ulophora* Diakonoff, and has not been studied much since the original description. This genus also belongs to the *Grapholita* genus group and is closely related to *Cryptophlebia* (Komai, unpublished data). E8,E10-12:OAc identified from *Centroxena* sp. is unusual among this genus group.

E9-12:OAc has been determined as a pheromone component from 10 olethreutine species in *Enarmonia* and *Ancylis* in Enarmoniini, *Gravitarmata*, *Rhyacionia*, and *Zeiraphera* in Eucosmini. This study is the first identification of E9-12:OAc from *Eucosma* species in Eucosmini. In this genus, sex pheromones of two species have been reported, i.e., a mixture of Z8-12:OAc and Z8-12:OH from *E. notanthes* (Hung et al., 2001) and Z7-12:OAc and 7,9-diene derivatives from *E. womonana* (Underhill et al., 1987).

Field tests were carried out in the Ryukyu Islands to evaluate the pheromone components identified from the five species living in mangroves. Although the roles of minor components have not been revealed by this evaluation, each lure baited with the main pheromone component successfully attracted the target males. Four species inhabit Iriomote-jima Island, but their main pheromone components are different, suggesting that diversity of sex pheromones is an important factor in their reproductive isolation. Particularly, male attraction of *C. horii* by Z8-12:OH was strongly inhibited by Z8-12:OAc, which attracted the males of *C. palustris* in the same mangrove swamp mixing with the host plants for both species. Larvae of *C. horii* and *E. coniogramma* bore into seedlings of the same host plant, but male moths of the latter species were attracted by a quite different pheromone component, E9-12:OAc. On the other hand, *C. amamiana* produces the same components as *C. palustris*. *C. amamiana* has not been found in Iriomote-jima Island, and the sexual communication of *C. palustris* is not disturbed by *C. amamiana* on this island (Table 1). The mixing ratios of minor components in their pheromones are interestingly different, but details have not been clarified concerning the sexual communication systems of these two sibling species.

Male moths of *Centroxena* sp. were attracted by not only E8,E10-12:OAc but also by its geometrical isomers, whereas the antennae of male moths showed the highest response to the natural diene among its four geometrical isomers. This result was unexpected, because male moths can generally recognize the geometrical isomer specifically produced by their partners, and are selectively attracted to a synthetic pheromone with the same configuration as the natural component. Isomerization of the diunsaturated compound to the geometrical isomers could possibly occur in the rubber septum used for the formulation and/or after vaporization from the septum (Ideses and Shani, 1988). The septa baited with E8,E10-12:OAc, however, specifically attracted the males of the soybean

pod borer, *Leguminivora glycinivorella* (Matsumura) (Olethreutinae: Grapholitini), in another field test using the same synthetic diunsaturated compounds. *L. glycinivorella* females also produce E8,E10-12:OAc, but its geometrical isomers did not attract male moths (Vang et al., unpublished data). Unspecific attraction of the males of *Centroxena* sp. does not seem to be a result of isomerization. Furthermore, in Iriomote-jima Island, the four isomers attracted many males of *R. koeniganus* (Olethreutine: Enarmoniini). Reproductive isolation between *Centroxena* sp. and *R. koeniganus* would be an interesting subject for future studies.

Whereas *B. gymnorrhiza* (host of *C. horii* and *E. coniogramma*) produces viviparous seedlings all year, seasonal differences in the parasitism rate have been recorded (Kinjo et al., 2001). *R. stylosa* (host of *C. palustris*) bears seedlings from April to August, and *K. candel* (host of *C. amamiana*) bears seedlings from October to May. *S. alba* (host of *Centroxena* sp.) has two main fruit seasons a year beginning in May and October, but the fruits have not been observed in March and April. The host preferences of these olethreutinae species are high, and their seasonal prevalence of occurrence might strongly depend on the foods. However, their life cycles, particularly in a season without food, are not understood. Monitoring by pheromone traps will confirm their habitats and population fluctuations and provide more detail for ecological studies.

(Received February 19, 2004; revised June 14, 2004; accepted December 8, 2004)

Abstract—Our objective was to identify the sex pheromone of *Lymantria bantaizana* (Lepidoptera: Lymantriidae) whose larvae feed exclusively on walnut, *Juglans* spp., in China, and Japan. Coupled gas chromatographic–electroantennographic detection (GC-EAD) analyses of pheromone gland extracts revealed a single EAD-active component. Retention index calculations of this compound on four GC columns suggested that it was a methyl-branched octadecadiene with conjugated double bonds. In GC-EAD analyses of 2-methyloctadecenes, (*Z*)-2-methyl-7-octadecene and (*E*)-2-methyl-7-octadecene elicited the strongest antennal responses, suggesting that the double bond positions were at C7 and C9. In comparative GC-EAD analyses of pheromone gland extract and stereoselectively synthesized isomers (*E*,*E*; *E*,*Z*; *Z*,*E*; *Z*,*Z*) of 2-methyl-7,9-octadecadiene, the (*E*,*Z*)- and (*Z*,*E*)-isomer had retention times identical to that of the candidate pheromone, but only the latter isomer elicited strong EAD activity. Results of field experiments in Japan substantiated that (7*Z*,9*E*)-2-methyl-7,9-octadecadiene is the *L. bantaizana* sex pheromone, a compound previously unknown in the

[$] While this manuscript was in press, a recent taxonomic revision of the world's *Lymantria* spp. proposed that *Lymantria bantaizana* should be more properly referred to as *Lymantria* (*Spinotria*) *grisescens bantaizana* Matsumura, 1933 (Schintlmeister, A. 2004. Taxonomy of the Genus *Lymantria* Hübner (1819) (Lepidoptera: Lymantriidae). *Quadrifina* 7:1–248).

Lepidoptera. Detection surveys in North America for exotic Eurasian forest defoliators could include traps baited with the *L. bantaizana* pheromone.

Key Words—*Lymantria bantaizana*, *Lymantria dispar*, *Lymantria monacha*, *Lymantria fumida*, *Lymantria mathura*, *Lymantria xylina*, (7*Z*,9*E*)-2-methyl-7,9-octadecadiene, sex pheromone.

INTRODUCTION

Lymantria bantaizana Matsumura (Lepidoptera: Lymantriidae) is a little-known species found in Japan, Korea, and northern China (Inoue, 1957; Nam and Kim, 1981; Zhao, 1982). Larvae feed on walnut, *Juglans* spp., in China (Zhao, 1982) and Japan (Gotoh et al., 2004). Unlike all congeners that overwinter in the egg stage, *L. bantaizana* overwinter as caterpillars (Yasunori Kishida, Setagaya-ku, Tokyo, personal communication, August 28, 1997; Gotoh et al., 2004). The flight season of adults is from late June to early August in Japan (Inoue, 1957; Gotoh et al., 2004). Males had not been captured in traps baited with any synthetic pheromone known to date for *Lymantria* spp. When a gravid female was light-trapped in Japan and neonate larvae that hatched from her eggs could be reared to adults, the opportunity arose to identify the pheromone of this unusual *Lymantria* species. We report here the main component of this sex pheromone.

METHODS AND MATERIALS

Laboratory Analyses of Pheromone Extract and General Instrumentation. Abdominal tips with the pheromone gland of calling (pheromone-emitting) 1-day-old virgin female *L. bantaizana* were removed and extracted for 5–20 min in high-performance liquid chromatography (HPLC)-grade hexane. Aliquots of pheromone gland extract and synthetic standards were analyzed by coupled gas chromatographic–electroantennographic detection (GC-EAD; Arn et al., 1975) and coupled GC-mass spectrometry (MS), employing equipment and procedures previously described in detail (Gries et al., 2002a). Relative EAD activities of 2-methyloctadecenes (produced by Wittig reactions from corresponding aldehydes and ylids) with (*E*)- or (*Z*)-double-bond geometry were determined in replicated ($N = 3$) GC-EAD analyses, using for each antennal preparation four isomers [(*E*3,*E*4,*E*5,*Z*7); (*Z*3,*Z*4,*Z*5,*Z*7); (*E*6,*E*7,*E*8,*Z*7); (*Z*6,*Z*8,*Z*9,*Z*7); or (*E*9,*E*10,*Z*10,*Z*7)] injected individually in split mode at 30-sec intervals and chromatographed isothermally (200°C; DB-5 column J&W Scientific). Nuclear magnetic resonance (NMR) spectroscopy of synthetic compounds was conducted on Bruker 300 (at 300 MHz for ^{1}H and 75 MHz for ^{13}C) and Varian AS500

(at 499.77 MHz for ^{1}H and 125.68 MHz for ^{13}C) spectrometers, with chemical shifts reported in ppm relative to TMS (^{1}H, δ 0.00) and $CDCl_3$ (^{13}C, δ 77.00). High-performance liquid chromatography (HPLC) of synthetic compounds employed a Waters LC 626 chromatograph equipped with a Waters 486 variable wavelength UV/visible detector set to 210 nm, HP Chemstation software (Rev.A.07.01), and a reverse phase Nova-Pak C18 column (60 Å, 4 μm; 3.9 × 300 mm, Waters) eluted with acetonitrile (1 ml/min).

Syntheses

(7Z,9E)-2-Methyl-7,9-octadecadiene (4) (Figure 1, Scheme 1). 'A solution (4.80 ml) of butyllithium in hexane (2.5 M, 12 mmol) was added dropwise to a stirred solution of 5-chloro-1-pentyne (**1**) (Aldrich Chem. Co.; 1.06 ml, 10 mmol) in 50 ml of THF under argon at −78°C. After 30 min, the mixture was warmed to −65°C, and 2.70 g (12 mmol) of anhydrous $ZnBr_2$ was added. After 45 min at −65°C, the mixture was warmed to −45°C, and a freshly prepared

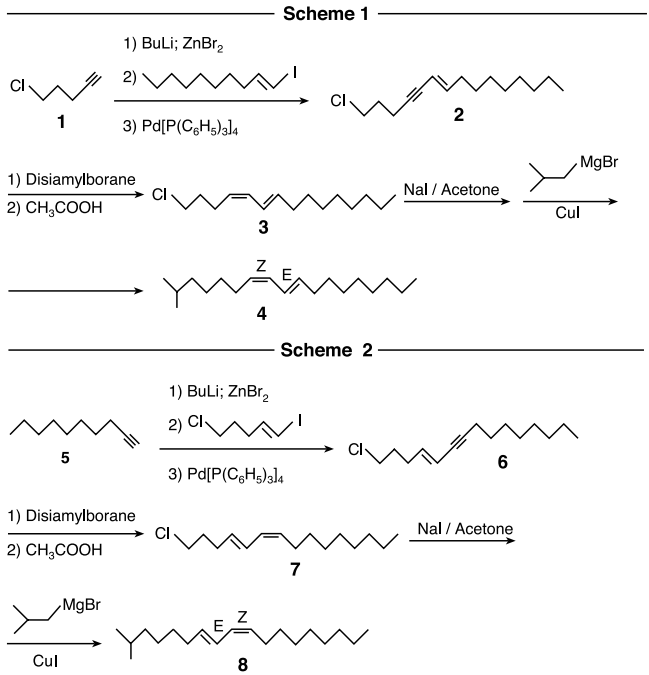

FIG. 1. Syntheses of the (*Z*,*E*)-isomer (Scheme 1) and (*E*,*Z*)-isomer (Scheme 2) of 2-methyl-7,9-octadecadiene.

solution of 6.00 mmol of 1-iodo-(*E*)-1-decene [from 1-decyne, DIBAL and iodine (Gardette et al., 1984)] in 20 ml THF was added, followed immediately by addition in one portion of tetrakis(triphenylphospine)palladium (0.60 g, 0.50 mmol) in 20 ml of THF. After 30 min at −40 to −45°C, the reaction mixture was warmed to and kept at 20°C for 1 hr. The reaction was then quenched with 100 ml of saturated aq. NH_4Cl, extracted with ether (3 × 50 ml), dried overnight with anhydrous Na_2SO_4, and concentrated *in vacuo*. Flash column chromatography (50 g SiO_2, hexane as eluent) afforded 1.42 g (5.28 mmol, 88% yield) of (*E*6)-1-chloropentadeca-6-en-4-yne (**2**). ^{1}H NMR ($CDCl_3$) δ: 0.88 (t, 3H, J = 6.8 Hz); 1.22–1.40 (m, 12H); 1.97 (quint. 2H, H-2, J = 6.7 Hz); 2.07 (q, 2H, H-8, J = 7.3 Hz); 2.48 (dt, 2H, H-3, J = 2.0, 6.7 Hz); 3.65 (t, 2H, H-1, J = 6.7 Hz); 5.43 (td, 1H, H-6, J = 2.0, 15.6 Hz); 6.06 (td, 1H, H-7, J = 7.3, 15.6 Hz). ^{13}C NMR ($CDCl_3$) δ: 14.08, 16.78, 22.65, 28.77, 29.09, 29.22, 29.39, 31.51, 31.85, 32.96, 43.73, 80.18, 86.24, 109.39, 144.09. Anal. calcd. for $C_{15}H_{25}Cl$ (%): C 74.81, H 10.46, found C 74.51, H 10.42.

A solution of **2** (1.32 g, 4.91 mmol) in 50 ml THF was added slowly to freshly prepared (Zweifel and Poiston, 1970) and cooled (−10°C) disiamylborane (6.50 mmol). After stirring for 2.5 hr at 0°C, the mixture was warmed to and kept at room temperature for 5 hr. It was then treated with 6 ml of glacial acetic acid and stirring for 36 hr. Then, 100 ml of water were added, and the reaction mixture was extracted with hexane. Extracts were washed with saturated aq. $NaHCO_3$ and brine, dried with anhydrous $MgSO_4$, and concentrated *in vacuo*. Flash chromatography afforded (*Z*4,*E*6)-1-chloropentadeca-4,6-diene (**3**) (1.22 g, 4.28 mmol, 87% yield, 95% pure by GC). A small sample of **3** was further purified by flash chromatography for spectroscopic analysis. ^{1}H NMR ($CDCl_3$) δ: 0.88 (t, 3H, J = 6.9 Hz); 1.25–1.45 (m, 12H); 1.86 (tt, 2H, H-2, J = 6.6, 6.9 Hz); 2.10 (tdd, 2H, H-8, J = 6.9, 7.5, 1.3 Hz); 2.33 (tdd, 2H, H-3, J = 6.9, 7.5, 1.3 Hz); 3.55 (t, 2H, H-1, J = 6.6 Hz); 5.24 (dt, 1H, H-4, J = 10.8, 7.5); 5.69 (dt, 1H, H-7, J = 15.0, 7.5 Hz); 6.01 (dd, 1H, H-5, J = 10.8, 11.1); 6.30 (dddt, 1H, H-6, J = 11.1, 15.0, 1.3, 1.3 Hz). ^{13}C NMR ($CDCl_3$) δ: 14.09, 22.65, 24.80, 29.22, 29.25, 29.30, 29.44, 31.86, 32.43, 32.85, 44.42, 125.17, 127.24, 130.17, 135.71. Anal. calcd. for $C_{15}H_{27}Cl$ (%): C 74.19, H 11.21, found C 73.85, H 11.02. Without further purification, **3** was dissolved in 50 ml of acetone, and 4.50 g of NaI (30 mmol) were added. After refluxing the mixture for 24 hr, 100 ml of water were added, and the resulting iodide was extracted with hexanes (3 × 50 ml). The combined extracts were washed with 2% aq. $Na_2S_2O_3$ and brine, dried, concentrated, and, at −23°C, added to 50 ml of a THF solution of isobutylmagnesium bromide (13.2 mmol) and CuI (0.25 g, 1.32 mmol). After 20 min, the reaction mixture was allowed to warm to room temperature, quenched with aq. NH_4Cl, extracted with hexane, washed with brine, dried, concentrated *in vacuo*, and filtered through 10 g of silica in hexane. Concentration yielded (7*Z*,9*E*)-2-methyl-7,9-octadecadiene (**4**) (0.81 g, 3.00 mmol, 70% yield based

on **2**, 97% pure based on GC). The (*Z*,*Z*)-isomer contaminant was removed by HPLC, affording >99% geometrically pure **4**. ^{1}H NMR (C_6D_6) δ: 0.93 (d, 6H, J = 6.4 Hz); 0.94 (t, 3H, J = 6.8 Hz); 1.21–1.45 (m, 18H); 1.51 (m, 1H, H-2); 2.14 (td, 2H, H-11, J = 7.1, 6.9 Hz); 2.25 (tdd, 2H, H-6, J = 7.5, 7.5, 1.3 Hz); 5.44 (dt, 1H, H-7, J = 10.8, 7.5 Hz); 5.73 (dt, 1H, H-10, J = 15.0, 7.1 Hz); 6.21 (dd, 1H, H-8, J = 10.8, 10.8 Hz); 6.57 (dddt, 1H, H-9, J = 15.0, 10.8, 1.3, 1.3 Hz). ^{13}C NMR ($CDCl_3$) δ: 14.11, 22.65 (2), 22.68, 27.03, 27.72, 27.95, 29.26, 29.29, 29.42, 29.49, 29.99, 31.89, 32.90. 38.86, 125.59, 128.58, 130.07, 134.68; MS: 41 (42), 55 (25), 67 (100), 81 (95), 95 (66), 109 (36), 123 (23), 137 (8), 208 (5), 264 (13). Anal. calcd. for $C_{19}H_{36}$ (%): C 86.28, H 13.72, found C 86.34, H 13.77.

*(7E,9Z)-2-Methyl-7,9-octadecadiene (**8**).* Compound **8** (Figure 1, Scheme 2) was synthesized analogous to **4**, starting from 1-decyne (**5**), which was coupled in the presence of tetrakis(triphenylphospine)palladium with (*E*)-5-chloro-1-iodo-1-pentene to produce (*E*)-1-chloropentadeca-4-en-6-yne (**6**). Compound **6** was treated with disiamylborane (as above) to yield (4*E*,6*Z*)-1-chloropentadeca-4,6-diene (**7**) which was converted in two steps to (7*Z*,9*E*)-2-methyl-7,9-octadecadiene (**8**) which was purified by HPLC. ^{1}H NMR (C_6D_6) δ: 0.93 (d and t 9H, J = 6.4, 6.8 Hz); 1.20–1.45 (m, 18H); 1.51 (m, 1H, H-2); 2.13 (td, 2H, H-6, J = 7.1, 6.8 Hz); 2.26 (tdd, 2H, H-11, J = 7.5, 7.5, 1.3 Hz); 5.45 (dt, 1H, H-10, J = 10.8, 7.5 Hz); 5.73 (dt, 1H, H-7, J = 15.0, 7.1 Hz); 6.21 (dd, 1H, H-9, J = 10.8, 10.8 Hz); 6.57 (dddt, 1H, H-8, J = 15.0, 10.8, 1.3, 1.3 Hz). MS: 41 (40), 55 (26), 67 (100), 81 (91), 95 (62), 109 (34), 123 (21), 137 (11), 208 (5), 264 (12).

*(7E,9E)-2-Methyl-7,9-Octadecadiene (**12**).* 2,5-Dihydrothiophene-1,1-dioxide (**9**) (Aldrich; 25.0 g, 210 mmol) in 300 ml of dry THF was placed under argon in a three-neck 1-l flask equipped with two dropping funnels. The mixture was cooled to −78°C and stirred vigorously while lithium bis(trimethylsilyl) amide (70 ml of 1 M solution in THF) and 30 ml of THF were added in two portions via one dropping funnel. Via the second dropping funnel, a mixture of 5-methyl-1-iodohexane [5-methyl-1-chlorohexane (available from previous work) was refluxed with sodium iodide in acetone] (16.0 g, 70 mmol), 45 ml of hexamethylphosphoramide (HMPA), and 140 ml of THF was added in 15 min (Yamada et al., 1983). The reaction mixture was then warmed to room temperature, and the reaction was quenched with 100 ml of water and extracted (3 × 100 ml) with ethyl acetate/hexane (1:1). Extracts were washed with water, dried ($MgSO_4$), and concentrated *in vacuo*. Flash column chromatography of the residue with ether/hexane as eluent [gradually increasing (5–30%) the ether content] afforded the pure mono-substituted sulfone (**10**) (6.10 g, 28.2 mmol, 40% yield based on the iodide). The process was repeated with **10** and excess 1-iodooctane (6.32 ml, 35 mmol), 30 mmol of lithium bis(trimethylsilyl)amide, and 26 ml of HMPA, affording after work-up and separation 2,5-disubstituted sulfone (**11**) (3.30 g, 10 mmol, 35.5% yield based on **10**). Sulfone **11** (1 g, 3.0

mmol) was refluxed in 20 ml of 1-propanol with 0.42 g of K_2CO_3 for 2 hr (Yamada et al., 1983) until desulfonylation was complete and (7*E*,9*E*)-2-methyl-7,9-octadecadiene (**12**) had formed. Compound **12** (0.80 g, 89% yield) (Figure 2, Scheme 3) was extracted with hexane from the reaction mixture and purified by flash chromatography. (*E*,*Z*)- and (*Z*,*E*)-isomer contaminants (5%) were removed by HPLC, affording >99% geometrically pure **12**. ^{1}H NMR (C_6D_6) δ: 0.92 (d, 6H, J = 6.4 Hz); 0.94 (t, 3H, J = 6.8 Hz); 1.20–1.48 (m, 18H); 1.51 (m, 1H, H-2); 2.11 (two td, 4H, H-6 and H-11, J = 7.0, 7.0 Hz); 5.66 (m, 2H, H-7 and H-10); 6.20 (m, 2H, H-8 and H-9). MS: 41 (38), 55 (21), 67 (100), 81 (99), 95 (67), 109 (37), 123 (23), 137 (13), 208 (5), 264 (22).

*(7Z,9Z)-2-Methyl-7,9-octadecadiene (**18**)*. To a solution of **5** (3.68 ml, 20 mmol) in 50 ml of THF under argon at −70°C, 9.2 ml (23 mmol) of 2.5 M BuLi in hexane were added, and 3.0 g of paraformaldehyde 30 min later. The mixture was allowed to warm to room temperature; 5 hr later, the reaction was quenched with water. 2-Undecyn-1-ol (**13**) was extracted (2 × 75 ml) with ether hexane (1:1). Extracts were washed with water and brine, dried, and concentrated. Alcohol **13** (93% pure based on GC) was then hydrogenated with P2-nickel catalyst (Brown and Ahuja, 1973) to yield (*Z*)-2-undecen-1-ol (**14**) (3.0 g, 85% yield, 96% pure based on GC). Alcohol **14** (2.15 g, 12.6 mmol) was epoxidized in 25 ml of dichloromethane with *m*-chloroperbenzoic acid (30 mmol, 8.63 g, 60% pure) at 0°C for 5 hr. The reaction mixture was warmed to room tempeature, water (10 ml) was added, and the product was extracted with ether (50 ml). The extract was washed (2N NaOH, water, brine), dried ($MgSO_4$), and concentrated. Flash chromatography of the crude product afforded *cis*-(2,3)-epoxy-1-undecanol (**15**) (2.30 g, 98% pure based on GC). Alcohol **15** (1 g, 5.37 mmol) was added to a stirred mixture (10 min at −60°C) of oxalyl chloride (0.95 ml, 10.8 mmol) and DMSO (1.53 ml, 21.6 mmol; Mancuso et al., 1978). After 20 min, 12 ml of triethylamine were added. After 30 min, the reaction mixture was allowed to warm to room temperature, quenched with water, and extracted with ether. The organic layer was washed (water, brine), dried ($MgSO_4$), and concentrated *in vacuo* to afford the epoxy-aldehyde (**16**). Without further purification, **16** was placed in 50 ml of dry THF and immediately added dropwise to the ylid freshly prepared from 5.02 g (10 mmol) of 6-methylheptyltriphenylphosphonium iodide [synthesized from 6-methyl-1-chloroheptane (available from previous work) by refluxing it with NaI in acetone, and subsequent reflux of the formed iodide with triphenylphosphine in toluene] in 40 ml of THF and 11 ml (11 mmol, 1 M solution in THF) of sodium bis(trimethylsilyl)amide] at −70°C. The reaction mixture was allowed to gradually warm to room temperature, quenched with 100 ml of water–methanol (1:1), extracted with hexane, and purified by flash chromatography (5% ether in hexane) to afford (*Z*)-2-methyl-*cis*-9,10-epoxy-7-octadecene (**17**) [0.89 g, 3.17 mmol, 59% yield based on **15**, with 10% of the (*E*)-isomer]. (7*Z*,9*Z*)-2-methyl-

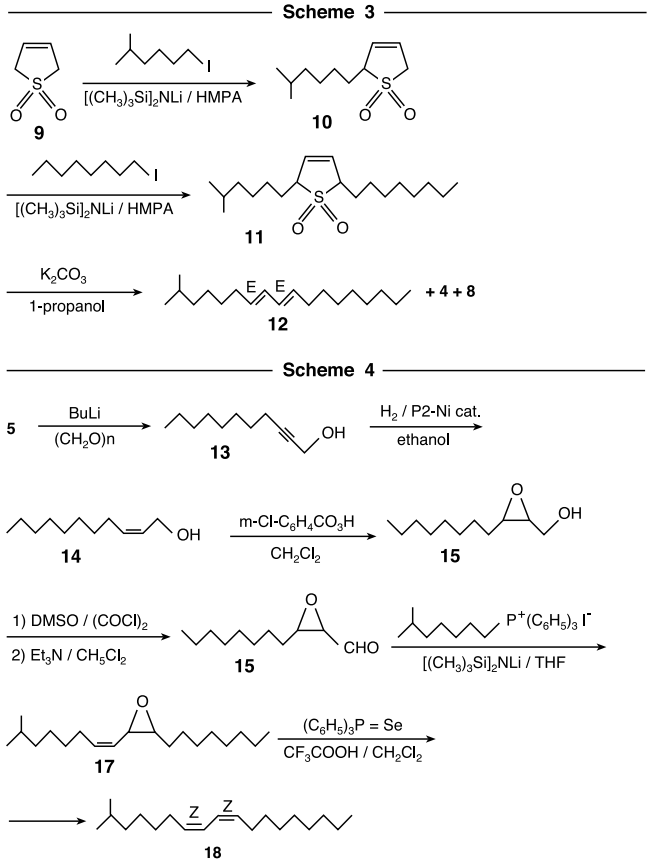

FIG. 2. Syntheses of the (*E*,*E*)-isomer (Scheme 3) and (*Z*,*Z*)-isomer (Scheme 4) of 2-methyl-7,9-octadecadiene.

7,9-octadecadiene (**18**) (Figure 2, Scheme 4) was obtained by treating 0.29 g (1.04 mmol) of **17** with 2.00 mmol of freshly prepared triphenylphosphineselenium in dichloromethane (Clive, 1978) in the presence of trifluoroacetic acid (1 ml) for 20 min. Solvents were removed *in vacuo* from the reaction mixture, and 50 ml of pentane were added. The mixture was filtered through silica (10 g) which was washed with an additional 20 ml of pentane. After concentration, the resulting mixture of **18** (80%, 0.23 g, 83% yield) and some **8** (Scheme 2) was purified by HPLC, affording >99% pure **18**. ^{1}H NMR (C_6D_6) δ: 0.92 (d, 6H, J = 6.4 Hz); 0.92 (t, 3H, J = 6.8 Hz); 1.21–1.45 (m, 18H); 1.50 (m, 1H, H-2); 2.23 (two td, 4H, H-6 and H-11, J = 7.1, 7.1 Hz); 5.56 (m, 2H, H-7 and H-10); 6.50

(m, 2H, H-8 and H-9). MS: 41 (45), 55 (26), 67 (100), 81 (90), 95 (64), 109 (33), 123 (21), 137 (10), 208 (5), 264 (17).

Field Experiments. Candidate pheromone components were field tested in the Iwate University forest (Takizawa Iwate Prefecture; N39°46.5′, E141°9.14′) stocked with mainly oak trees, *Quercus* spp., and some walnut trees, *Juglans* spp., and in the Mizunashi farming valley (N39°53.3′, E141°18.18′) with riparian Siebold walnut trees. At 15- to 20-m intervals, sticky 2-l milk carton traps (Gray et al., 1984) were suspended from trees 1.5 m above ground in complete randomized blocks. Traps were baited with a gray sleeve stopper (The West Co., Lionville, PA, USA) impregnated with test chemicals in HPLC-grade hexane. Experiment 1 tested all four geometrical isomers singly and in quaternary combination, whereas experiment 2 tested the (*E*,*Z*)- and (*Z*,*E*)-isomers of 2-methyl-7,9-octadecadiene singly and combined. Experiment 3 tested the diel periodicity of response by male *L. bantaizana*, by baiting traps ($N = 20$) with synthetic (7*Z*,9*E*)-2-methyl-7,9-octadecadiene (50 μg) and by recording captures of males in 1-hr intervals during the night of July 29, 2001 near Tamayama Village (N39°52.16′, E141°26.16′).

Trap catch data in experiments 1 and 2 were analyzed by nonparametric analyses of variance (Friedman's test) followed by comparison of means by Scheffé test (Zar, 1984; SAS/STAT, 1988). In all analyses, $\alpha = 0.05$.

RESULTS AND DISCUSSION

GC-EAD analyses of pheromone gland extract (Figure 3) on four GC columns revealed a single candidate pheromone component (CPC) that consistently elicited responses from male antennae. CPC occurred at quantities too low to obtain a mass spectrum. Thus, it was identified based on retention time matches and comparative antennal responses of the insect-produced compound and synthetic standards.

Retention indices (RI, relative to alkane standards; van den Dool and Kratz, 1963) of CPC were similar on four nonpolar and polar GC columns (DB-5: RI = 1884; DB-210: RI = 1942; DB-23: RI = 2015; SP-1000: RI = 2002) indicative of a hydrocarbon. Synthetic (*Z*)-2-methyl-7-octadecene (2me-*Z*7-18Hy), a pheromone component of *L. monacha* (Grant et al., 1996; Gries et al., 1996), *L. fumida* (Schaefer et al., 1999), and *L. lucescens* and *L. serva* (Gries et al., 2002b) elicited strong responses from antennae of male *L. bantaizana*, suggesting that it resembled the CPC. The fact that 2me-*Z*7-18Hy elicited the strongest EAD response of all tested 2-methyloctadecenes (Figure 4) substantiated this conclusion. Higher retention indices of CPC than of 2me-*Z*7-18Hy on several GC columns (DB-5: + 42; DB-210: + 82; DB-23: + 138) further

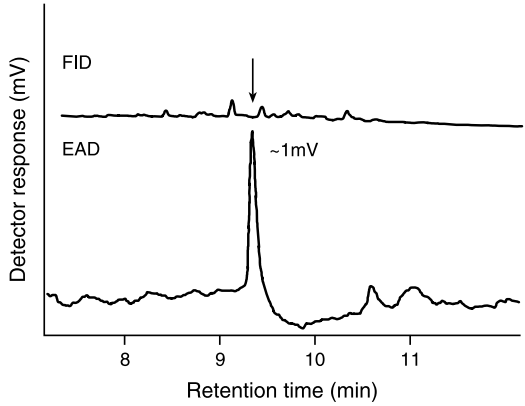

FIG. 3. Flame ionization detector (FID) and electroantennographic detector (EAD: male *L. bantaizana* antenna) responses to one female equivalent (FE) of pheromone extract from female *L. bantaizana*. Chromatography: DB-5 column; splitless injection; injector and FID detector: 240°C; temperature program: 100°C (1 min), then 20°C/min to 190°C (8 min).

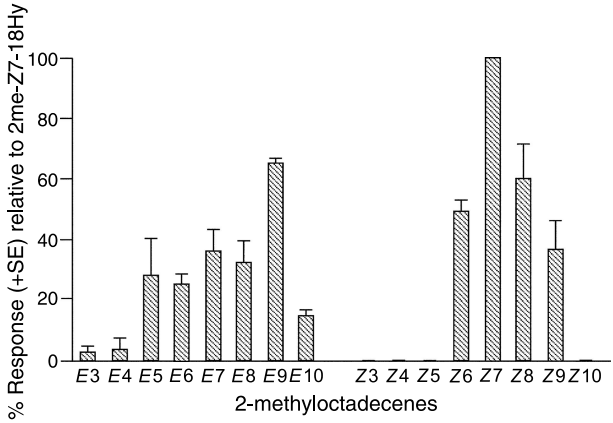

FIG. 4. Relative EAD activity of 2-methyloctadecenes with (*E*)- or (*Z*)-double bond geometry, as determined in replicated ($N = 3$) GC-EAD analyses. For each antennal preparation, four isomers [(*E*3,*E*4,*E*5,*Z*7; (*Z*3,*Z*4,*Z*5,*Z*7); (*E*6,*E*7,*E*8,*Z*7); (*Z*6,*Z*8,*Z*9,*Z*7); or (*E*9,*E*10,*Z*10,*Z*7)] were tested, injected individually in split mode at 30-sec intervals and chromatographed isothermally (200°C; DB-5 column).

suggested that CPC had conjugated double bonds. Taking into account that (*E*)-2-methyl-9-octadecene elicited the second strongest EAD response (Figure 4), we hypothesized that the second double bond was at C9. Strong EAD activity of one geometrical isomer in the 4-isomer (*E*,*E*; *E*,*Z*; *Z*,*E*; *Z*,*Z*) mixture of 2-methyl-7,9-octadecadiene confirmed this hypothesis. In comparative GC-EAD analyses of pheromone gland extract and synthetic 2-methyl-7,9-octadecadienes, the (*E*,*Z*)- and (*Z*,*E*)-isomers had retention times identical with those of the candidate pheromone, but only the latter isomer elicited strong EAD responses.

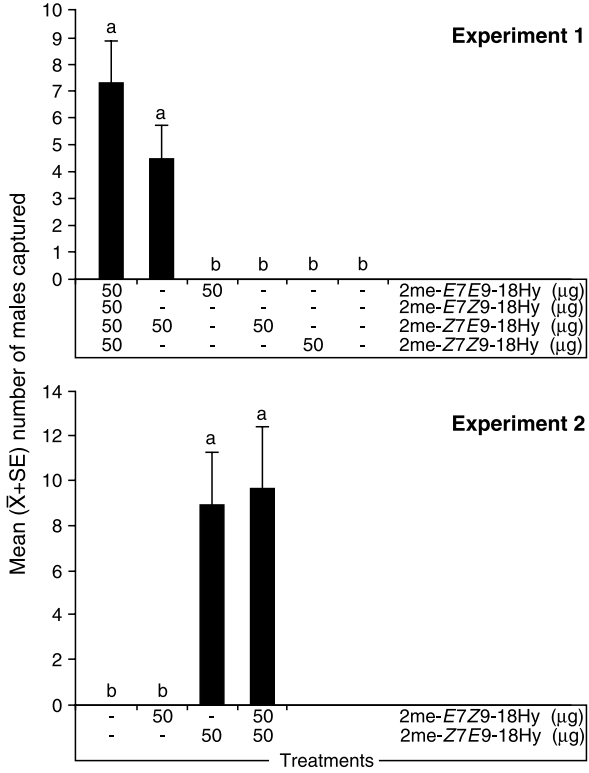

FIG. 5. Mean (+ SE) number of male *L. bantaizana* captured in sticky 2-l milk carton traps baited with geometrical isomers (*E*,*E*; *E*,*Z*; *Z*,*E*; or *Z*,*Z*) of 2-methyl-7,9-octadecadiene. Experiment 1: July 2–August 11, 2003, $N = 6$; Experiment 2: July 5–August 19, 2002, $N = 10$. Bars in each experiment with different letter superscripts are significantly different; nonparametric analysis of variance by ranks (Friedman's test) followed by comparison of means (Scheffé test), $P < 0.05$ (SAS/STAT, 1988).

In field experiments 1 and 2 (Figure 5), only the (*Z*,*E*)-isomer attracted males, whereas other isomers when added to the (*Z*,*E*)-isomer did not inhibit the males' responses. In experiment 3, ten males were captured between 24:00 and 01:00 hr and three males between 01:00 and 02:00 hr. This information about the diel periodicity of sexual communication in *L. bantaizana* will contribute to our ongoing studies as to how communication signals and time of signaling impart specificity to communication channels of five congeners (*Lymantria dispar*, *L. fumida*, *L. lucescens*, *L. mathura*, *L. monacha*) in the complex *Lymantria* communities of Japan.

Following the pioneering discovery of (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadecane [(+)-disparlure] as the pheromone of gypsy moth, *L. dispar* (Bierl et al., 1970; Klimetzek et al., 1976; Cardé et al., 1977; Plimmer et al., 1977), there is mounting evidence that sex pheromones of *Lymantria* spp. are more diverse than previously realized. (7*R*,8*S*)-*cis*-7,8-Epoxyoctadecane serves as a synergistic pheromone component of nun moth, *L. monacha*, in central Europe (Gries et al., 1996), and as the major pheromone component of *L. monacha* in Japan (Gries et al., 2001). (3*Z*,6*Z*,9*R*,10*S*)-*cis*-9,10-Epoxynonadecadiene and (3*Z*,6*Z*,9*S*,10*R*)-*cis*-9,10-epoxynonadecadiene at a 1:4 ratio are sex pheromone components of pink gypsy moth, *L. mathura*, in Japan (Gries et al., 1999a), and (7*R*,8*S*)-*cis*-7,8-epoxyeicosane is the pheromone of Casuarina moth, *Lymantria xylina*, in Taiwan (Gries et al., 1999b). (*Z*)-2-methyl-7-octadecene is a synergistic pheromone component of both *L. monacha* in Central Europe (Grant et al., 1996; Gries et al., 1996) and Japan (Gries et al., 2001) and of *L. fumida* in Japan (Schaefer et al., 1999). The same compound constitutes the pheromone of *L. lucescens* in Japan and *L. serva* in Taiwan (Gries et al., 2002b). Finally, here we show that a methylated diene hydrocarbon is part of the diverse sex pheromones in *Lymantria* spp.

Considering that *L. bantaizana* larvae defoliate walnut trees (an important nut crop in North America) and that *L. bantaizana* is as likely as Asian *L. mathura*, *L. dispar*, and *L. monacha* to be introduced into North America, traps baited with synthetic *L. bantaizana* pheromone could be included in detection surveys for exotic *Lymantria* spp. Commercial trap lures containing a 1:1 mixture of (*E*,*Z*)- and (*Z*,*E*)-isomers will be cheap because such a mixture is readily obtainable from sulfone **11** by desulfonylation at 110°C in a nonpolar solvent rather than the polar solvent shown in Scheme 3 (Yamada et al., 1983).

Acknowledgments—We thank Eberhard Kiehlmann for reviewing the manuscript. The research was supported, in part, by a contract from the State of California, Department of Food and Agriculture (contract #98-0508) and by grants from Global Forest (GF-18-2000-95; GF-18-2000-96) and the Natural Sciences and Engineering Research Council of Canada to G.G. Experimental insects were maintained in SFU's Global Forest Quarantine Facility, the construction of which was completed through financial support from Global Forest (GF-18-2000-SFU-3).

(Received May 10, 2004; revised August 30, 2004; accepted November 20, 2004)

Abstract—Adult male asparagus flies exhibit typical calling behaviors (suggestive of pheromone production) during which they emit a single volatile compound that was identified as isopropyl (*S*)-5-hydroxyhexanoate. In laboratory bioassays, synthetic samples elicited an arrestant response in females, but did not appear to attract females. On the other hand, the synthetic material attracted conspecific males in olfactometer bioassays.

Key Words—*Plioreocepta poeciloptera*, asparagus fly, male-produced volatile, isopropyl (*S*)-5-hydroxyhexanoate.

INTRODUCTION

The asparagus fly, *Plioreocepta (Platyparea) poeciloptera*, is a temperate univoltine monophagous tephritid, the maggots of which are serious pests of asparagus crops in Europe (Lesne, 1913). Adults appear in France in late March to early April (Reulet, 1991). Courtship and mating behaviors of this fly, as observed in both laboratory and field situations (unpublished observations), are similar to those of *Chaestostomella undosa*, wherein males patrol, or remain on the top of the host plant (Steck, 1984). In both of these species, encounters between males lead to agonistic behavior, and encounters between males and

* To whom correspondence should be addressed. E-mail: eric.thibout@univ-tours.fr and oliverj@ba.ars.usda.gov

females occurred without the necessity of lek formation, the females approaching the males perched on their host plant. In the majority of tephritid species (Bateman, 1972; Sivinski and Burk, 1989), the male emits a sex pheromone that attracts females. We earlier described a calling behavior exhibited by adult male *P. poeciloptera*, and described attraction of virgin females to the "calling" males as well as to dissected lateral abdominal pouches, the likely source of pheromone (Seguy, 1951; Thibout and Auger, 1999). We also described experiments with solid-phase microextraction (SPME) fibers, wherein a single volatile compound was collected from calling males and tentatively identified on the basis of its mass and infrared spectra. The structural assignment (Auger et al., 1998) of the presumed pheromone, as demonstrated by synthesis of the proposed structure (Casaña-Giner et al., 2001), turned out to be incorrect, however.

This paper reports our continuing studies of the asparagus fly, including positive identification of the major male-produced volatile. We have determined the optimum age and circadian rhythm of male calling, individually collected male- and female-produced volatiles, and again observed the presence of a major volatile produced exclusively by calling males. Additional gas chromatography-mass spectrometry studies (GC/MS) contributed to a revised structure for this compound, which has now been established as isopropyl (*S*)-5-hydroxyhexanoate. Laboratory behavioral assays and chiral gas chromatography support the assigned structure and stereochemistry of this sex-specific compound.

METHODS AND MATERIALS

Insects. The establishment of laboratory colonies of *P. poeciloptera* (Diptera: Tephritidae) has not been successful (Thibout and Auger, 1999), and test insects were obtained by collecting pupae from asparagus fields in early October. Pupae were collected at the base of spears in the Loire Valley, near Chinon, France, and were maintained in the laboratory at 8 ± 2°C, in a humid atmosphere, until the end of March, after which they were gradually introduced into Petri dishes at a rate of 10–15 pupae per day, in synchronous photoperiod and thermoperiod: 16 hr at 26°C in photophase and eight hr at 17°C in scotophase. About 12 d later, adults (which were isolated by gender) emerged, and were individually maintained in Petri dishes on aqueous sucrose solutions.

Male Specific Volatiles Collection. Collection of volatiles was timed to coincide with the male calling period, determined by hourly observations on 80 isolated males during the 16 hr photophase from day 1 (emergence day) to day 8. The characteristic male calling position (lifted abdomen, protruded abdominal pouches, spread wings) has been previously described (Thibout and

Auger, 1999). SPME-GC was used to trap, transfer, and analyze the collected components of the volatiles. To collect volatiles, a male was placed in a 10-ml glass vial stoppered by a plastic cap with a hole allowing insertion of the SPME fiber. The fiber was positioned a few mm from the abdominal extremity of the immobile male for 1 min. Analysis of the adsorbed sample was carried out within 5 min of sampling by desorption for 2 min in the injection port of the GC. One-, 2-, 4-, and 8-d-old males were used regardless of whether they displayed calling behavior or not. Two- to 4-d-old females were used as controls. Up to seven repetitions were carried out for adults of each sex and age.

Isolation of Male-Specific Volatiles. Volatiles of 4-d-old males and females were trapped on Tenax cartridges (SKC Inc., Eighty-Four, PA). Each adult was introduced into a 20-ml glass vial for aeration. Incoming air (10 ml/min, a rate that did not disturb the flies) was precleaned by passing successively through two Tenax and two activated charcoal cartridges. Exiting air passed through the Tenax cartridge trap (50 mg Tenax). In the morning, a control and a male were aerated for 4 hr. In the afternoon, a female and another male were similarly aerated for 4 hr. This was repeated on 10 consecutive days to obtain four experimental Tenax cartridges, each containing the volatiles from 40 hr of trapping. The entire procedure was repeated a second time with another batch of four cartridges. The two batches of four cartridges were then eluted with pentane at 4°C. Only the two first drops eluting from the cartridge were collected and stored at −20°C until being analyzed by GC/MS.

We first compared the volatiles from females and from a control (vial containing no insects) to those from the two types of male samples (morning and afternoon collections).

Identification of the Male Volatile. ^{1}H NMR spectra were recorded in $CDCl_3$ or C_6D_6 on a Bruker QE-300 spectrometer. In the U.S. laboratory, GC was performed with a Shimadzu Model GC-17A instrument equipped with a 30 m × 0.25 mm SPB-35 capillary column (Supelco, Bellefonte PA) and a flame ionization detector, or on an Agilent 6890N instrument equipped with a 30 m × 0.25 mm HP-5 column (Agilent Avondale PA). Chiral gas chromatography was performed with a 30-m Chiraldex B-DM column (Advanced Separation Technologies, Whippany, NJ). In the French laboratory, solid-phase microextraction-GC (SPME-GC) experiments were conducted with a Varian 3300 instrument with a FID detector equipped with a split–splitless injector, an 80-μl liner for SPME fiber desorption, and a fused-silica HP-1 capillary column (Agilent, 20 m × 0.22 mm I.D., 0.33 μm film thickness). The conditions were as follows: injection temperature 200°C, carrier gas helium, column flow 1.0 ml/min, splitless mode. The column temperature program was 2°C/min from 40 to 200°C.

In the French laboratory, mass spectral experiments were conducted with a benchtop Perkin-Elmer Turbomass system with a split–splitless injector and a 25-m fused-silica HP-1 capillary column similar to that described above. The carrier

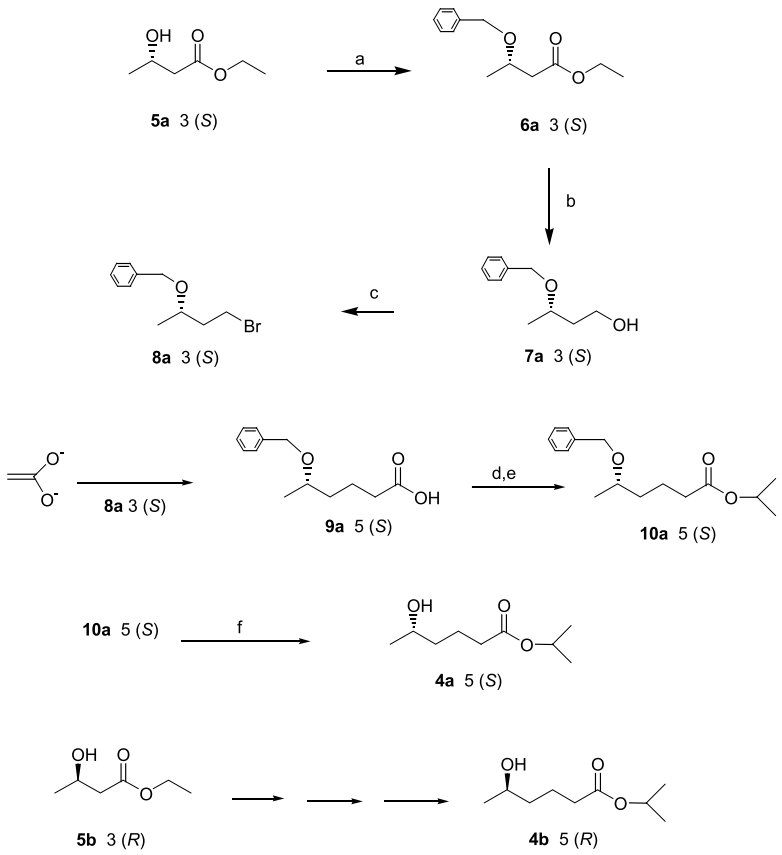
gas was helium at 2 ml/min, and the column temperature program was 5°C/min from 60 to 180°C then 15°C/min from 180 to 280°C. Total ion chromatograms (TICs) and mass spectra were recorded in the electron impact ionization mode at 70 eV. In the U.S. laboratory, mass spectra were obtained from a Shimadzu GCMS-QP 5050A equipped with a 30 m × 0.25 mm DB-5 column (J&W Scientific, Fulsom CA). Chemical ionization spectra were obtained using ammonia as reagent gas. Additional mass spectrometric experiments on the trapped male compound added little to those already published (Auger et al., 1998). Rotations were measured with a Perkin Elmer Model 241 polarimeter.

Syntheses. Described below are a series of reactions leading to the (*S*)-enantiomer of the major volatile, **4a** (Figure 1) An identical series, beginning with the benzyl ether of ethyl (*R*)-3-hydroxybutyrate (Malher et al., 1988), was conducted to prepare the (*R*)-enantiomer **4b**.

*(S)-3-(Benzyloxy)butyric acid ethyl ester **6a*** (Keck and Murry, 1991). To a solution of ethyl (*S*)-3-hydroxybutanoate **5a** (0.9 g, 6.8 mmol) and *O*-benzyltrichloroacetimidate (2.4 g, 7.5 mmol) in 2:1 cyclohexane/dichloromethane (36 ml) was added trifluoromethanesulfonic acid (80 μl). The mixture was stirred at room temperature for 24 hr, then filtered. The filtrate was added to saturated aqueous $NaHCO_3$, and the mixture was extracted with dichloromethane (3 × 8 ml). The combined organic layers were washed with brine, dried over $MgSO_4$, and concentrated *in vacuo*. Flash chromatography (9:1 hexanes/EtOAc) afforded **6a** (1.37 g, 91%) as a light yellow liquid.

*(S)-3-(Benzyloxy)butan-1-ol **7a***. Dry ether (11 ml) was cooled with an ice bath, and $LiAlH_4$ (0.15 g, 3.9 mmol) was added. The mixture was warmed to room temperature and stirred for 30 min, then was again cooled with an ice bath, and a solution of **6a** (1.15 g, 5.18 mmol) in dry ether (3 ml) was added dropwise. After stirring for 1 hr, water (0.15 ml), 15% NaOH (0.15 ml), and water (0.45 ml) were added dropwise in that order, and the mixture was stirred at 20°C for 15 min, then was filtered through Celite. The filtrate was washed with 1:1 brine/sat. $NaHCO_3$, dried over $MgSO_4$, and concentrated *in vacuo* to yield **7a** (0.75 g, 84%) as a light yellow liquid. EI-MS, *m/z* (%): 161 (10), 108 (10), 107 (52), 92 (18), 91 (100), 79 (26), 77 (20), 65 (32), 56 (12), 51 (14), 43 (19), 42 (13).

*(S)-3-(Benzyloxy)-1-bromobutane **8a***. Bromine (260 μl, 5 mmol) in dichloromethane (2 ml) was added dropwise to a solution of triphenylphosphine (1.3 g, 5 mmol) in dichloromethane (5 ml) at about −10°C. The solution was warmed to room temperature and stirred 20 min. After cooling to −30°C, a solution of **7a** (0.75 g, 4.2 mmol) in dichloromethane (2 ml) was added dropwise, then the mixture was stirred at room temperature for 16 hr. After concentration *in vacuo* to near dryness, 10 ml pentane was added. The mixture was filtered and the solids were rinsed with several portions of pentane. The combined filtrates were washed with saturated aqueous $NaHCO_3$ and brine, dried over $MgSO_4$, and concentrated *in*



a. $PhCH_2C(N{=}H)CCl_3$, b. $LiAlH_4$, c. Ph_3PBr_2, d. ClCOCOCl, e. i-PrOH, f. H_2/Pd

FIG. 1. Syntheses of **4a** and **4b** from enantiomers of ethyl 3-hydroxybutyrate.

vacuo. Flash chromatography (9:1 hexanes/EtOAc) afforded **8a** (0.68 g, 67%) as a light yellow liquid. EI-MS, *m/z* (%), 135 (31), 107 (15), 91 (100), 89 (13), 79 (28), 77 (25), 65 (30), 63 (13), 55 (23), 51 (20), 43 (18), 41 (15).

(S)-5-(Benzyloxy)hexanoic Acid ***9a***. Lithium diisopropylamide (LDA) was prepared from diisopropylamine (1.18 ml, 8.46 mmol) and 2.5 M *n*-butyllithium (3.38 ml, 8.46 mmol) in THF (5 ml) at −10°C. The newly prepared LDA was added by syringe to a solution of acetic acid (240 μl, 4.23 mmol) and NaI (2 mg) in THF (5 ml) at −20°C. Hexamethyl phosphoramide (HMPA) (1.47 ml, 8.46 mmol) was added, and after the mixture was stirred at 0°C for 30 min,

it was cooled to −20°C, and a solution of **8a** (0.685 g, 2.82 mmol) in THF (1 ml) was added. The reaction mixture was allowed to warm slowly to room temp and stirred 16 hr, after which time it was added to ice and extracted with ether (2 × 10 ml). The aqueous phase was acidified with 1 N HCl and extracted with 1:1 ether/hexane (3 × 10 ml). The ether/hexane extracts were washed with water and brine, dried over $MgSO_4$, and concentrated *in vacuo*. The crude liquid was filtered through a plug of silica gel to afford **9a** (0.56 g, 89%) as a yellow liquid. EI-MS (of the methyl ester, formed by diazomethane treatment): 135 (19), 91 (100), 79 (19), 77 (16), 65 (28), 55 (16), 51 (13), 43 (12).

*(S)-5-(Benzyloxy)hexanoic acid isopropyl ester **10a**.* Oxalyl chloride (270 μl, 2.8 mmol) and DMF (2 μl) were added to a solution of **9a** (0.57 g, 2.55 mmol) in benzene. After stirring 1 hr, the reaction mixture was concentrated *in vacuo*, redissolved in benzene, and added to a solution of pyridine (270 μl, 3.2 mmol) and isopropanol (490 μl, 6.4 mmol) in benzene (2 ml). After stirring overnight, the mixture was diluted with ether (15 ml) and extracted with 1 N HCl (10 ml). The organic phase was washed with water, then with saturated aqueous $NaHCO_3$, and finally with brine, dried over $MgSO_4$, and concentrated *in vacuo*. Flash chromatography (20:1 hexanes/EtOAc) afforded **10a** (0.345 g, 51%) as a light yellow liquid. ^{1}H NMR (300 MHz, $CDCl_3$), δ 7.36–7.20 (m, 5H), 5.00 (sept, J = 6.43 Hz, 1H), 4.50 (m, 2H), 3.52 (sex, J = 6.05 Hz, 1H), 2.26 (t, J = 6.81 Hz, 2H), 1.78–1.38 (m, 4H), 1.21 (m, 9H). EI-MS: 158 (39), 117 (11), 116 (49), 115 (20), 113 (20), 107 (29), 97 (16), 91 (100), 87 (24), 79 (15), 77 (13), 73 (26), 69 (21), 65 (32), 55 (21), 43 (39), 42 (20), 41 (35).

*(S)-5-Hydroxyhexanoic acid isopropyl ester **4a**.* To a solution of **10a** (0.345 g, 1.3 mmol) in ethyl acetate (10 ml) was added 10% Pd/C (34 mg). The solution was stirred under H_2 for 16 hr, then filtered through Celite and concentrated to provide **4a** (218 mg, 96%) as a colorless liquid. ^{1}H NMR (300 MHz, $CDCl_3$), 4.99 (sept, J = 6.43 Hz, 1H), 3.79 (sex, J = 6.06 Hz, 1H), 2.29 (t, J = 7 Hz, 2H), 1.68 (m, 2H), 1.57 (br s, 1H), 1.46 (m, 2H), 1.21 (t, J = 6.06 Hz, 3H). EI-MS: 115 (23), 114 (13), 99 (20), 97 (23), 89 (12), 88 (27), 73 (18), 71 (19), 70 (20), 69 (39), 68 (10), 60 (75), 55 (36), 45 (75), 44 (12), 43 (100), 42 (62), 41 (65). Under CI-MS conditions, the compound degraded to form 5-caprolactone. CI-MS m/z (%): 132 (54) ($M + NH_4^+$), 115 (100) ($M + H^+$). $[\alpha]_D^{25} = +7$ (c = 2.9, $CHCl_3$). The trimethylsilyl ether of this compound gave only a single peak on a chiral column, for an estimated enantiomeric excess (ee) of >99%.

*Alternate synthesis (Figure 2). (S)-5-Chloro-2-pentanol tetrahydropyranyl ether **12**.* A solution of (*S*)-5-chloro-2-pentanol (Daicel, Inc.; 9.47 g, 77 mmol) in dry dichloromethane (40 ml) and freshly distilled dihydropyran (8 ml, ca. 88 mmol) was treated with pyridinium *p*-toluenesulfonate (PPTS, 210 mg, 0.9 mmol). An exotherm was observed. The solution was allowed to stand undisturbed for 45 min, then most of the solvent was removed with a rotary evaporator and the residue was partitioned between cold aqueous sodium

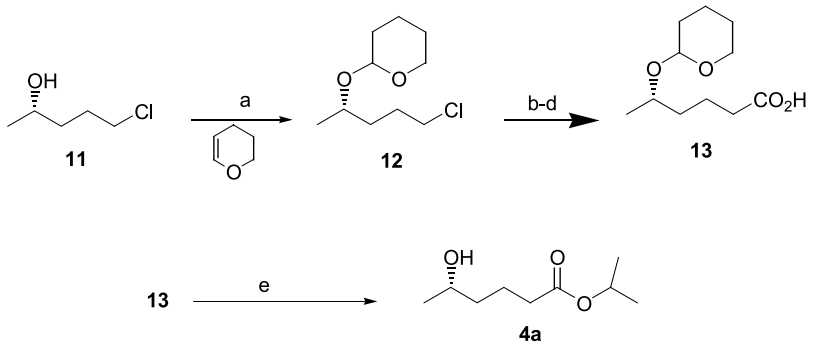


FIG. 2. Alternate synthesis of **4a** from (*S*)-5-chloro-2-pentanol.

carbonate (1 M) and 1:1 ether/hexane. The crude product (17 g) was distilled to give 12.3 g (77%) of **12**, b.p. 56°C, 0.03 Torr. ^{1}H NMR (300 MHz, $CDCl_3$, two diastereomers) 4.67 (m, 1H), 4.61 (m, 1H), 3.83 (m, 2H), 3.54 (m, 4H), 1.99–1.41 (m, ~24H), 1.22 (t, J = 6.43 Hz, 3H), 1.12 (d, J = 6.06 Hz, 3H). This compound has been reported previously (Keinan et al., 1986).

*(S)-5-Hydroxyhexanoic acid tetrahydropyranyl ether **13***. Magnesium (1.56 g, 65 mmol) was covered with dry THF in an argon atmosphere. After activating the metal with a few microliters of 1,2-dibromoethane, THF was heated to reflux and a solution of **12** (6.01 g, 29 mmol) in THF (20 ml) was added dropwise over 0.5 hr. Refluxing was continued an additional 4.5 hr, then the Grignard solution was cooled to room temperature and transferred by cannula onto an excess of powdered dry ice in an argon-flushed flask. After standing about 45 min, ether and water were added, the mixture was acidified with aqueous $KHSO_4$, and the organic products were partitioned into ether. The ether solution was rinsed with water, then extracted with 1 M aqueous sodium carbonate (25 ml, then 2 × 5 ml). The combined extracts were rinsed with ether, then acidified with aqueous $KHSO_4$ and the acidic product was extracted into ether. After rinsing with water and brine, the solution was dried ($MgSO_4$), and concentrated to provide 5.25 g (84%) of **13** as a colorless liquid. ^{1}H NMR (300 MHz, benzene-d_6, mixture of diastereomers) 4.64 (m, 2H), 3.82 (m, 2H), 3.64 (m, 1H), 3.39 (m, 1H), 3.34 (s, 3H), 3.33 (s, 3H), 2.18 (m, 2H), 2.08 (m, 2H), 1.86–1.25 (m, ~22H), 1.22 (d, J = 6.43 Hz, 3H), 0.97 (d, J = 6.05 Hz, 3H). EI-MS: 115 (83), 101 (13), 97 (54), 85 (100), 84 (10), 73 (27), 70 (13), 69 (69), 67 (27), 60 (21), 57 (39), 56 (48), 55 (74), 45 (41), 44 (85), 43 (80), 42 (42), 41 (82).

*Conversion of **13** to **4a***. A 100-ml flask containing a solution of **13** (5.25 g, 24.3 mmol) in 2-propanol (50 ml) plus pyridinium *p*-toluenesulfonate (0.61 g,

2.4 mmol) was fitted with a reflux condenser and introduced into a sonic bath that was operated overnight at room temperature (moderate warming of the water bath occurred during the procedure). The solvent was removed *in vacuo*, and the residue was flash chromatographed on 150 g silica gel, eluting with 10–50% ethyl acetate in hexane. The earlier-eluting fractions provided 1.6 g (38%) of **4a** of 98% purity (GC), identical to **4a** described above. Slightly later-eluting material consisted of mixtures of a little more **4a** and lactone **1** plus some later-eluting (GC) material that appeared to be a dimeric product resulting from intermolecular transesterification of **4a** (or **4a** + **1**) (1.4 g). From chiral GC, the ee of **4a** was estimated to be >98%.

Adult Fly Behavioral Responses to Synthetic Compounds. Behaviors of 4-d-old males and females were observed in an olfactometer similar to that previously described (Thibout and Auger, 1999). Air was passed at 20 cm/sec through a 90 × 9 cm glass cylinder opening into control and test channels. The center of the test channel contained a 4-cm^2 filter paper square treated with 50 μg of a candidate compound dissolved in 5 μl of paraffin oil. One adult was released at the downwind opening of the tube, and its movements and displacements were observed for 2 min. The fly distributions at the end of the observation period were recorded for both sexes, using three classifications: (1) adults moving less than 5 cm; (2) adults moving between 5 and 25 cm; and (3) adults moving more than 25 cm. A second behavior was evaluated in females, that is, the number of flies remaining immobile with spread wings, a posture typically observed when a female is in the proximity of a calling male.

Thirty repetitions were performed, with each fly being used only once. Two similar experiments were carried out, one in 2002 and the other in 2003. In the latter, the *S*-enantiomer **4a** was also tested at a higher concentration (200 μg in paraffin oil). All behavioral data were analyzed, when necessary, with a χ^2 test at $\alpha = 0.05$.

RESULTS

Influence of Male Age on Calling. The study of the number of males that were calling according to the time of day, and of the ages of calling males, showed that 1-d-old males were sometimes able to call, but usually did not (Figure 3). The percentage of 2-d-old males calling was similar to that of older ones (65%). There was a shift in time of calling with age, with young males calling in the middle of the day (mean 8.22 hr in 2-d-old males), earlier than more mature males that called in the early afternoon (9.76 hr in 8-d-old males; $P < 0.001$ using a χ^2 test). All the male distributions were significantly different except between 6 and 8 d.

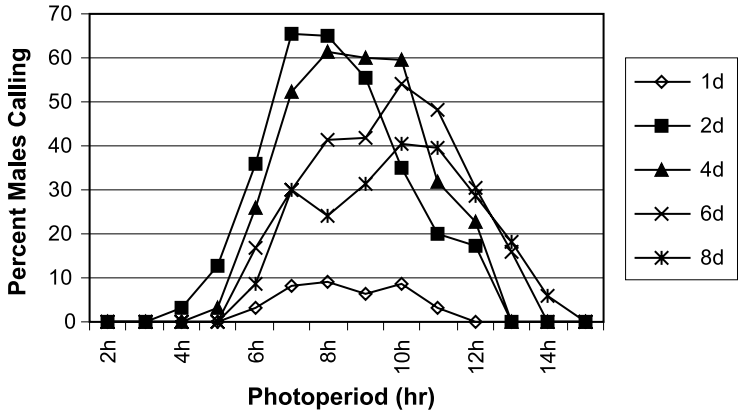

FIG. 3. Calling rhythm of *Plioreocepta poeciloptera* males at various ages. Distributions are statistically different except between 6 and 8 days (χ^2 test).

Identification of the Major Male Specific Volatile. Results obtained by SMPE/GC from individual flies showed that a major GC peak appeared at 13 min only in samples from calling males of 2-d-old or older (Figure 4). This peak was absent from volatiles from females, absent, or nearly so, from samples obtained from 1-d-old males, and absent from volatiles from noncalling males. The GC/MS results of the Tenax trapping of volatiles from males and females paralleled those of the SPME experiments, but reproducibly indicated additional components, particularly one with retention time 7.75 min, present in all extracts including the control (Figure 5). The mass spectra of these components indicated them to be sulfur-containing plant volatiles originating from the asparagus plants, the major being identified as dipropyl disulfide. As had been the case in the SPME/GC study, only one male-specific compound, corresponding to the 13-min eluting peak just discussed, was observed from males aerated in the afternoon, the time at which they were seen calling. In the control, in the female-derived samples, and in the samples from males aerated in the morning (when few or none were calling), no peak with this retention time was observed (Figure 5).

The electron impact ionization mass spectrum of the male-produced unknown was an excellent match for that of δ-caprolactone **1**. A chemical ionization spectrum obtained with methane as reagent gas produced an ion with *m*/*z* 115, consistent with a protonated molecular ion, $M + H^+$, of **1** (MW 114). However, the GC retention time of the unknown was longer than that of **1**, and furthermore, lactone **1** is not consistent with the published infrared spectrum (Auger et al., 1998) that exhibited O–H stretching as well as a carbonyl absorption at 1729 cm^{-1}, more consistent with an aliphatic hydroxy-ester than

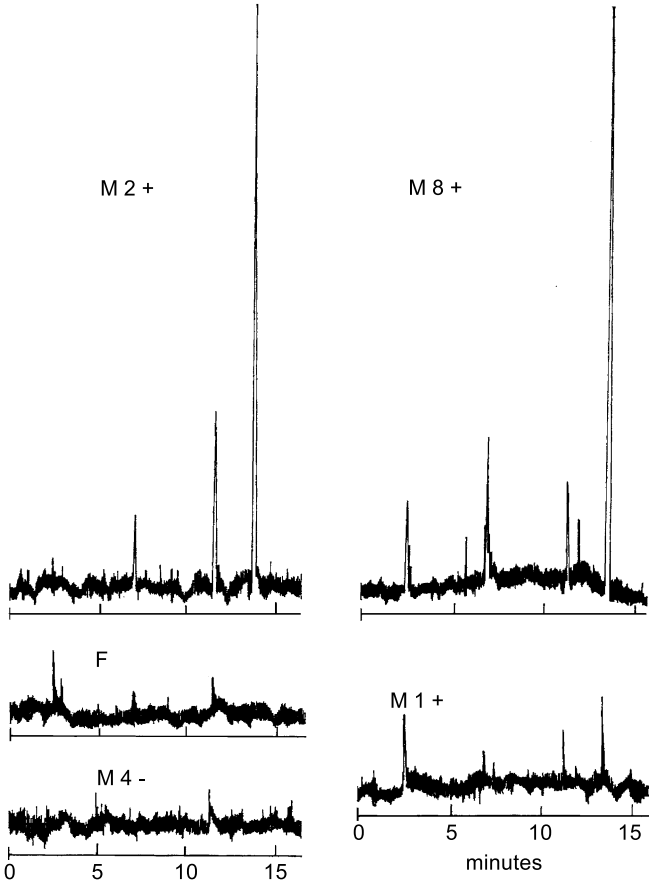

FIG. 4. GC analysis of *Plioreocepta poeciloptera* adult volatiles trapped by SPME at various ages. M1+: 1-d-old calling male; M2+: 2-d-old calling male; M4−: 4-d-old noncalling male; M8+: 8-d-old calling male; F: 4-d-old female.

with a lactone. We postulated that the volatile was possibly a somewhat labile compound that could decompose under MS ionization conditions to provide lactone **1**, but at the same time be stable enough to survive gas chromatography (to produce a retention time longer than that of **1** and a GC–FTIR inconsistent with **1**). We anticipated (incorrectly) that the less energetic CI reagent gas ammonia might improve our chances of determining molecular weight via CI-MS, but the NH_3-CI spectrum consisted cleanly and almost exclusively of ions with *m*/*z* 115 and 132 ($M + H^+$ and $M + NH_4^+$ for **1**, respectively).

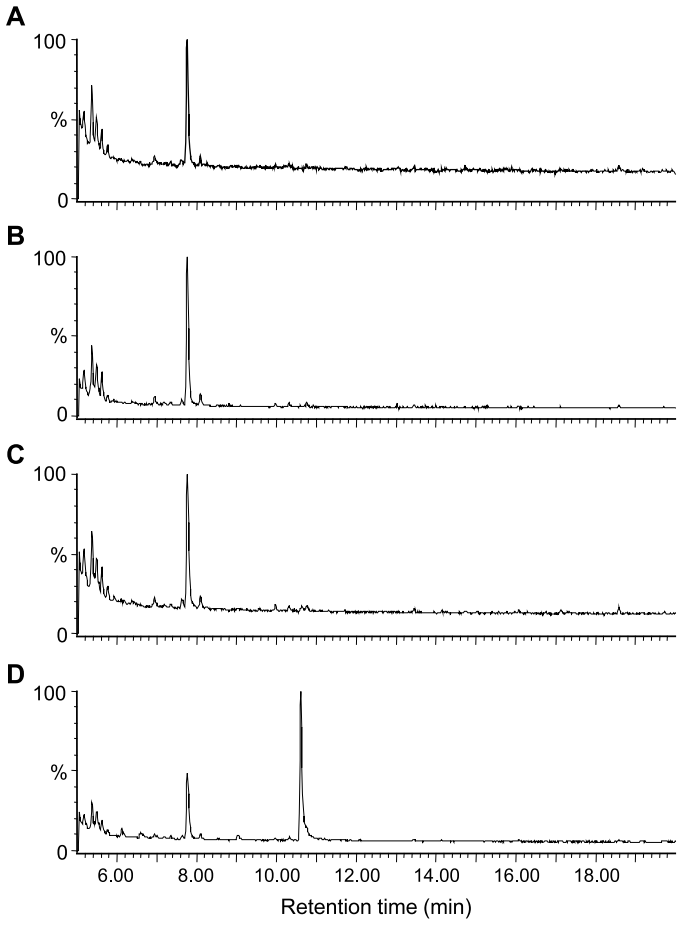

FIG. 5. GC/MS analysis of volatiles from 4-d-old *Plioreocepta poeciloptera* trapped on Tenax cartridges and eluted with pentane. **A** Control without insect; **B** Females, morning collection; **C** Males, morning collection; **D** Males, afternoon collection.

The most conservative explanation seemed to be an ester of 5-hydroxyhexanoic acid that could lose the alcohol component via intramolecular transesterification to form lactone **1**. Accordingly, we prepared ethyl ester **2** (Figure 4) by treatment of **1** with ethanol containing sodium ethoxide (Hernandez et al., 1996). The product **2**, a known compound (Lease and McElvain, 1933), eluted from the GC later than **1**, but still slightly earlier than the unknown; reassuringly, the mass spectra of **2** were also essentially identical to those of **1**. We next converted samples of **1** to the propyl and isopropyl esters **3** and **4**, respectively

(apparently unreported in the literature), and indeed, isopropyl ester **4** proved to be a perfect match for the insect-produced compound.

Racemic **1** was easily prepared by Baeyer–Villiger oxidation of 2-methylcyclopentanone (Hernandez et al., 1996), and opening of the resulting lactone with sodium isopropoxide accordingly produced racemic **4** (Figure 6). By comparing racemate **4** with the insect-produced material by GC on a chiral column (analyses were conveniently conducted on the respective trimethylsilyl ethers, TMS), we established that the latter was a single enantiomer. To assign the absolute configuration of C-5 of the insect-produced compound, we synthesized the enantiomers from precursors in which the stereochemistry was already defined.

*Syntheses of the Isopropyl Ester of (S)-5-Hydroxyhexanoic Acid (**4a**).* Both enantiomers of ethyl 3-hydroxybutanoate are commercially available. The 3-(*S*)-enantiomer **5a** was protected as its benzyl ether **6a** (Keck and Murry, 1991), and **6a** was reduced with $LiAlH_4$ to provide the mono-protected diol **7a** (Figure 1). Treatment with Ph_3PBr_2 converted **7a** to bromide **8a**. Alkylation of the dianion of acetic acid (Pfeffer and Silbert, 1970) with **8a** gave (*S*)-5-hydroxyhexanoic acid benzyl ether **9a**, which was converted to the acid chloride and esterified with isopropanol to afford ester **10a**. Catalytic hydrogenation

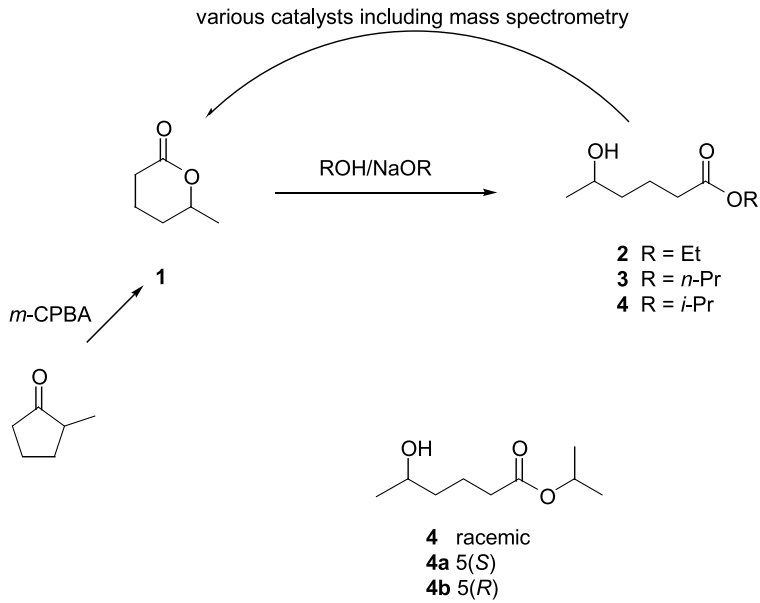

FIG. 6. 5-Hydroxyhexanoates from δ-caprolactone, and the reverse reaction.

removed the benzyl ether and produced the isopropyl ester of (*S*)-5-hydroxyhexanoic acid **4a**.

Repeating the above process beginning with the (*R*)-enantiomer of ethyl 3-hydroxybutanoate **5b**, similarly afforded **4b**, identical to **4a** except for retention time on a chiral GC column and specific rotation ($[\alpha]_D^{25} = -8$ (c = 2.2, $CHCl_3$)).

Comparison by chiral GC proved that the 5-(*S*)-enantiomer **4a** matched the insect-produced compound, and that the insect produced compound gave only a single peak, with no trace of the (*R*)-enantiomer. Better GC results were obtained on the chiral column with TMS ethers of **4a** and **4b** than with the alcohols themselves. The TMS ether of the (*R*)-enantiomer **4b** eluted earlier than the corresponding TMS of the natural (*S*)-enantiomer **4a** from a Chiraldex B-DM column.

At about this time we became aware that (*S*)-5-chloro-2-pentanol **11** was becoming commercially available (Daicel Chemical Industries, Ltd.). Availability of this material suggested a convenient alternative synthesis as outlined in Figure 2. After protection of the secondary alcohol as its tetrahydropyranyl ether **12**, its Grignard reagent was carbonated to give THP acid **13**. Treatment of an isopropanol solution of **13** with Nafion-H™ or with pyridinium *p*-toluenesulfonate resulted in removal of the THP ether and esterification of the carboxylic acid, providing **4a** in a single step.

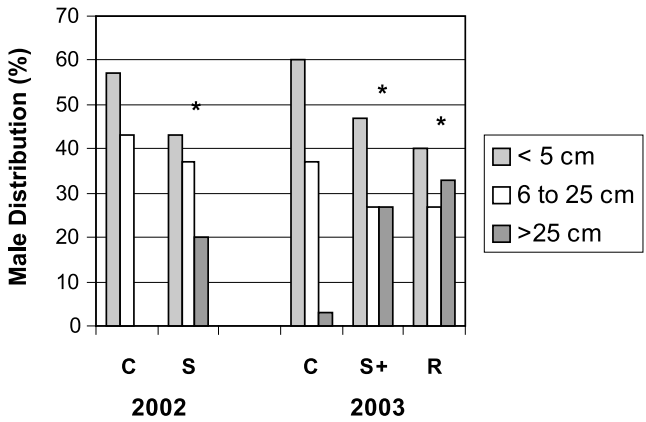

FIG. 7. Distributions in % of *Plioreocepta poeciloptera* males in the olfactometer in the presence of synthetic compounds recorded as distances moved toward the source (in cm). Two years' data are presented. *Distribution is statistically different from the control distribution (χ^2 test). C: Control without volatiles; R: *R*-enantiomer; S: *S*-enantiomer at 50 μg; S+: *S*-enantiomer at 200 μg.

Adult Fly Behavior in the Presence of Synthetic Compounds. The distributions of 4-d-old females and males in the olfactometer, in the presence of a single enantiomer **4a** or **4b**, or the racemate **4**, were compared in 2002 and 2003. The results were similar. Male distributions in response to both the *S*- and *R*-enantiomers were different from the control distributions. Males moved further in the presence of either of the two enantiomers, showing a higher chemo-anemotaxis (Figure 7). Female flies showed no significant upwind movement in response to either enantiomer or the racemate (data not shown).

However, the synthetic compounds were perceived by females and did produce behavioral responses. Females stimulated by the *S*-enantiomer often assumed a position of immobility with spread wings. This behavior was signifi-

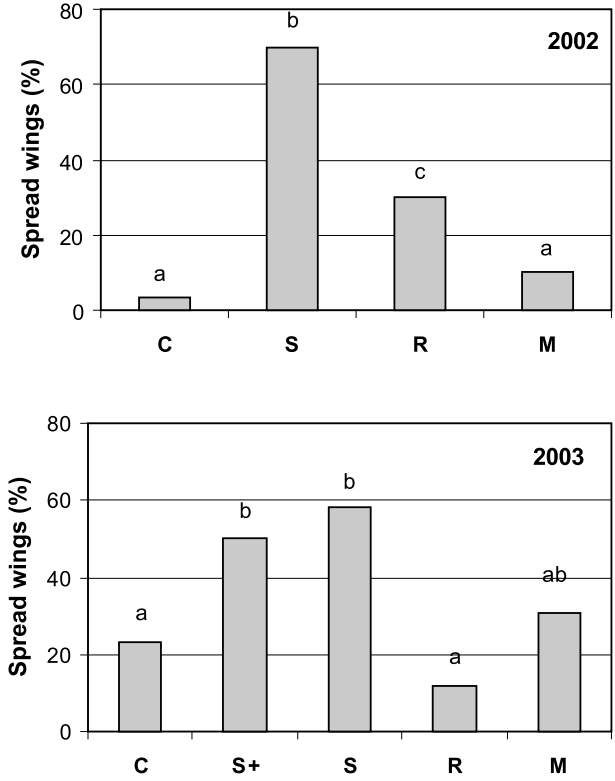

FIG. 8. Percentages of *Plioreocepta poeciloptera* females that spread their wings in the presence of synthetic volatiles in 2002 and 2003. Data with the same letters are not statistically different at $\alpha = 0.05$ (χ^2 test). C: Control without volatiles; M: mixture (racemic); R: *R*-enantiomer; S+: *S*-enantiomer at 200 μg; S: *S*-enantiomer at 50 μg.

cantly more frequent with the *S*-enantiomer than with the control or with the *R*-enantiomer in 2002 (Figure 8). In 2003, females responded more strongly to both doses of the (*S*)-enantiomer than to the control, the (*R*)-enantiomer, or the racemate. Responses to the latter two treatments were no different from responses to the control (Figure 8).

DISCUSSION

As observed previously, male *P. poeciloptera* called in the middle of the day and in the first half of the afternoon (Thibout and Auger, 1999). Calling behavior was rare in 1-d-old males but became frequent from the second d after emergence. The onset of calling and the peak calling time were delayed from age 1 to age 8 d. A time shift in calling corresponding to a time advance has been commonly seen in moth species (Swier et al., 1977; Gemeno and Haynes, 2000), where it was explained as an adaptation of older adults to increase their chances of mating (Swier et al., 1977). The adaptive advantage of delaying calling in mature *P. poeciloptera* males remains unclear.

The major male volatile appeared to be emitted during the afternoon calling period, and release of this compound coincided with eversion of glandular (Dingler, 1934) abdominal pouches (Thibout and Auger, 1999). In contrast to males, females were not attracted by the synthetic compound in the olfactometer. However, females did react behaviorally by spreading their wings, and only in response to the natural (*S*)-enantiomer. The induced wing spreading in females is believed to be a short range arrestant response. This olfactometer result is in contrast to our earlier field and laboratory observations that had indicated that females were attracted to a male pheromone (Thibout and Auger, 1999). The failure to respond in the olfactometer could suggest that factors other than the single compound may be involved in courtship and mating of this fly. We have looked for, but have been unable to find, other noteworthy male-specific volatiles. However, responses may be dose-dependent.

Unexpectedly, males were attracted in the olfactometer by both the *S*-enantiomer and the unnatural *R*-enantiomer. Cases of attraction to a nonnatural enantiomer have been observed in other insects such as cockroaches (Gemeno et al., 2003). However, we have never observed male *P. poeciloptera* attracted to other males or even to females in either the field nor the laboratory (Thibout and Auger, 1999), and the observed attraction of males to the synthetic compounds may result from unnaturally high concentrations, or possibly from some subtlety in the rhythm of emission. One could speculate that wild males could use the emission of invading males to detect their presence and chase them off, or, perhaps more likely, that invading males might exploit the

emission of native males to gain access to already-attracted females. The attraction of males to the male-produced compound, and the absence of attraction by females, can be compared to results previously observed in various tephritid species (Fletcher and Bellas, 1988; Landolt and Heath, 1990; Pike and Meats, 2003).

In summary, in spite of its release as a single, male-specific volatile compound coinciding with typical male calling behavior, and its elicitation of a typical arrestant response in females, isopropyl (*S*)-5-hydroxyhexanoate **4a** has not been established to be a true male sex pheromone of *P. poeciloptera*. Its behavioral effects, at least under laboratory conditions, do not correspond precisely to those observed previously with living males (i.e., lack of demonstrated motility toward a source). However, this volatile compound does attract males, which might be used in management of this insect. Because of the univoltinism of the species, additional studies must be undertaken in future years, particularly to study the activity of isopropyl (*S*)-5-hydroxyhexanoate in asparagus fields.

(Received July 25, 2004; accepted November 20, 2004)

Abstract—Mature larvae of the codling moth, *Cydia pomonella* L. (Lepidoptera: Olethreutidae), exit the fruit and seek sites suitable for pupation. Spinning cocoons in such sites, larvae produce a complex, cocoon-derived blend of volatiles recently shown to attract and/or arrest both conspecific larvae and the prepupal parasitoid *Mastrus ridibundus* Gravenhorst (Hymenoptera: Ichneumonidae). Here we report components of this blend that constitute the pheromone of fifth-instar *C. pomonella* larvae. Thirty-one two-choice olfactometer experiments showed that a blend of synthetic (*E*)-2-octenal, (*E*)-2-nonenal, sulcatone, and geranylacetone, in combination with either 3-carene and/or three saturated aldehydes (octanal, nonanal, decanal), elicited behavioral responses from *C. pomonella* larvae. In on-tree experiments with corrugated cardboard bands as pupation sites for larvae affixed to tree trunks, and with laboratory-reared larvae released onto such trees, more larvae cocooned in those halves of cardboard bands baited with cocoon-spinning conspecific larvae, or with synthetic pheromone components, than in unbaited control halves of the bands. With the larval aggregation pheromone identified in this study, there might be an opportunity to manipulate *C. pomonella* larvae in commercial fruit or nut orchards.

Key Words—Codling moth, larvae, *Cydia pomonella*, *Mastrus ridibundus*, aggregation pheromone, heptanal, octanal, nonanal, decanal, (*E*)-2-octenal, (*E*)-2-nonenal, sulcatone, geranylacetone, (+)-limonene, myrcene, 3-carene.

INTRODUCTION

When mature larvae of the codling moth, *Cydia pomonella* L. (Lepidoptera: Olethreutidae), complete their development, they exit the fruit and seek sites suitable for pupation. While spinning cocoons in such sites, larvae produce an aggregation pheromone that attracts or arrests conspecific larvae (Duthie et al., 2003; Jumean et al., 2004a). Aggregation of fifth-instars prior to pupation may be part of a mating strategy (Duthie et al., 2003) because in laboratory bioassays, eclosed adult males appeared to be arrested by the sex pheromone (*E*,*E*)-8,10-dodecadienol emanating from mature female pupae, which may allow mating as soon as a female ecloses.

Identification of the cocoon-derived pheromone proved challenging because larval antennae were too small to be used effectively in gas chromatographic–electroantennographic detection (GC–EAD) analyses of cocoon volatiles. Testing the hypothesis that *Mastrus ridibundus* Gravenhorst (Hymenoptera: Ichneumonidae), a parasitoid of late instar/prepupal *C. pomonella*, exploits odors produced by or associated with larvae as a kairomone during host-foraging, Jumean et al. (2004b) demonstrated (1) that 10 cocoon volatiles [3-carene, myrcene, heptanal, octanal, nonanal, decanal, (*E*)-2-octenal, (*E*)-2-nonenal, sulcatone, and geranylacetone] elicited responses from female *M. ridibundus* antennae, and (2) that eight of these components [all except myrcene and (*E*)-2-nonenal] were essential for the attraction of *M. ridibundus* in behavioral bioassays. A blend of the same 10 components and (+)-limonene (an abundant compound in cocoon volatiles) as an 11th component also attracted/arrested foraging fifth-instar *C. pomonella* larvae (Jumean et al., 2004b). Here we report that a blend of (*E*)-2-octenal, (*E*)-2-nonenal, sulcatone, and geranylacetone in combination with either 3-carene and/or three saturated aldehydes (octanal, nonanal, decanal) elicited attraction or arrestment of pupation site-seeking fifth-instar *C. pomonella* larvae.

METHODS AND MATERIALS

Experimental Insects. Larvae were shipped in trays of artificial diet from the Sterile Insect Release Program rearing facility in Osoyoos, British Columbia, Canada. Trays containing 1000 larvae were kept in a glass aquarium ($60 \times 31 \times 31$ cm) and stored at 15°C under a 16L:8D photoperiod. Nondiapausing fifth-instar larvae were removed from the diet as needed for experiments.

Acquisition of Volatiles. To acquire naturally emitted volatiles for olfactometer experiments, 300 cocoon-spinning male and female fifth-instars (1:1 sex ratio) were placed in a cylindrical Pyrex glass chamber (15.5×20 cm). An empty chamber served as control. A water aspirator drew charcoal-filtered

air at ~2 l/min through each chamber and through a glass column (14 × 1.3 cm OD) containing Porapak Q (50–80 mesh; Waters Associates, Inc., Milford, MA, USA). After 72 hr, volatiles were eluted from the Porapak Q trap with 3 ml of pentane and ether (95:5). Extracts were concentrated under a nitrogen stream so that 1 μl was equivalent to 10 cocoon-spinning larvae-hour equivalents (10 CSLHE = volatiles released from 10 cocoon-spinning *C. pomonella* larvae during 1 hr). Extracts were stored in darkness at −15°C, and analyzed by coupled gas chromatography–mass spectrometry (GC–MS) in full-scan electron impact mode, using a Varian Saturn 2000 Ion Trap GC–MS fitted with a DB-5 column (30 m × 0.25 mm i.d., J&W Scientific, Folsom, CA, USA).

Olfactometer Experiments. In two-choice Petri dish olfactometers (detailed drawing in Duthie et al., 2003), test stimuli were randomly assigned to one of two 4-ml vials (Table 1), each with a perforated Eppendorf tube to prevent physical contact of experimental larvae with test stimuli. Stimuli were pipetted onto Whatman no. 1 filter paper disks (1 cm diam.), with treatment and control disks receiving the same amount of solvent. For each replicate, one fifth-instar was placed in the center of the olfactometer, and its pupation site was recorded 18–24 hr later. All experiments were conducted at 21–26°C in complete darkness.

To determine whether storage of cocoon volatile extract diminished its attractiveness, experiments 1 and 2 tested the responses of larvae to 180 CSLHE of fresh (1 d old) and aged (8 d old) extracts. In experiment 3, a synthetic blend (SB) of 11 cocoon volatiles [heptanal, octanal, nonanal, decanal, (*E*)-2-octenal, (*E*)-2-nonenal, (+)-limonene, myrcene, 3-carene, sulcatone, geranylacetone] (Jumean et al., 2004b) was tested at 200 CSLHE to determine whether it had a comparable behavioral effect as Porapak Q extract of natural cocoon volatiles. Testing natural vs. synthetic cocoon volatiles, or two blends of synthetic cocoon volatiles, in the same confined olfactometer was attempted but found to compromise the larva's ability to discriminate between volatile blends (Z. Jumean, unpublished data).

Taking the results of experiment 3 into account, experiments 4–7 tested SB at four doses (1, 10, 100, and 1000 CSLHE) to determine the optimal dose for subsequent experiments. To determine essential pheromone components, experiments 8–16 tested SB vs. blends lacking certain classes of organic chemicals (Byers, 1992), such as ketones (experiment 8), monoterpenes (experiment 9), or aldehydes (experiment 10). Experiments 11–16 took a similar approach by deleting from SB either saturated aldehydes (experiment 11), unsaturated aldehydes (experiment 12), or individual components (experiments 13–16). Considering the results of experiments 8–16, experiments 17–26 tested a four-component rudimentary synthetic blend (RSB) [(*E*)-2-nonenal, (*E*)-2-octenal, sulcatone, geranylacetone] alone (experiment 17) or in combination with one of

three monoterpenes [(+)-limonene, myrcene, or 3-carene; experiments 18–20], or with one of four 3-component blends of saturated aldehydes [heptanal, octanal, nonanal, decanal; experiments 21–24]. Considering that only the blend of saturated aldehydes that contained octanal, nonanal, and decanal enhanced the effectiveness of RSB (experiment 22), experiment 25 explored whether decanal could be deleted from this blend without affecting the blend's behavioral activity. Experiment 26 then was designed to confirm that the RSB plus four essential components [3-carene (experiment 20); octanal, nonanal, and decanal (experiments 22, 25)] was attractive to larvae seeking pupation sites. Final laboratory experiments 27–31 explored whether SB at the low and behaviorally inactive dose of 10 CSLHE would become stimulatory upon increasing the amount of 3-carene (experiment 28), or either one or both of (*E*)-2-octenal and (*E*)-2-nonenal (experiments 28–31).

The on-tree experiments (32–36) were conducted at Simon Fraser University (May to October 2003) and employed 4-cm wide corrugated cardboard bands (cut from stock of 0.46 × 76 m single-face corrugated cardboard; Shippers Supply Inc., British Columbia, Canada). Cardboard bands were affixed with metal wire 45 cm above ground to trunks of maple (*Acer* spp.) trees that were 10–16 cm in diam at that height. Bands were divided into two halves, with test stimuli applied to the waxed center (4 cm^2) of each half.

For each replicate in experiments 32–36, 20 fifth-instars were released from a thin circular collar affixed to the tree's main branch crotch (~1.50 m above ground). Experiments were started at 22:00 hr and terminated 10–12 hr later by recording the number of larvae cocooning in treatment or control halves of the cardboard bands.

Experiments 32 and 33 tested whether cardboard band halves baited with 25 1-d-old *C. pomonella* cocoons containing larvae or prepupae (experiment 32), or baited with a synthetic blend at 1000 CSLHE (experiment 33), attracted or arrested more *C. pomonella* larvae than did unbaited cardboard band halves. In

[a] CSLHE = cocoon-spinning larvae hour equivalents.

[b] Solvent consisted of redistilled pentane (20–100 μl).

[c] 10 SB = synthetic blend of 11 components: decanal (1.4 ng) [Aldrich], nonanal (4.1 ng) [Aldrich], octanal (0.94 ng) [Aldrich], heptanal (0.85 ng) [Aldrich], (*E*)-2-nonenal (1.00 ng) [Bedoukian], (*E*)-2-octenal (0.41 ng) [Bedoukian], geranylacetone (0.50 ng) [Aldrich], sulcatone (0.81 ng) [Aldrich], 3-carene (0.95 ng) [Aldrich], myrcene (0.84 ng) [Aldrich], (+)-limonene (10.00 ng) [Aldrich].

[d] 10 RSB = rudimentary synthetic blend of four components: (*E*)-2-nonenal (1.00 ng), (*E*)-2-octenal (0.41 ng), geranylacetone (0.50 ng), sulcatone (0.81 ng).

[e] Fifth-instar larvae were allowed to cocoon in an open-fluted cardboard (CB) strip (4 cm^2).

[f] Female larvae were used as test stimuli, and male larvae were bioassayed to allow recognition and recording of all those larvae that had responded to test stimuli.

experiment 32, female larvae served as test stimuli and male larvae (as determined by testes visible through the dorsal integument) were bioassayed to allow recognition and recording of those larvae that had responded to test stimuli. This experimental design was justified because both male and female cocoon-spinning larvae produce and respond to the same volatile components (Jumean et al., 2004a). Experiments 34–35 determined whether a 10-fold decrease (experiment 34) or a 10-fold increase (experiment 35) in the dose of the synthetic blend affected the response of *C. pomonella* larvae in the field. Finally, experiment 36 explored whether the synthetic blend at the low and behaviorally inactive dose of 100 CSLHE (see experiment 34) would become active by increasing the amounts of (*E*)-2-octenal and (*E*)-2-nonenal as essential blend components.

Statistical Analyses. Numbers of larvae responding to treatment and control stimuli in laboratory olfactometer experiments were analyzed with the χ^2 goodness-of-fit test, using Yates correction for continuity ($\alpha = 0.05$) (Zar, 1999). Numbers of larvae responding to treatment and control stimuli in on-tree bioassays were analyzed with the Wilcoxon paired-sample test ($\alpha = 0.05$) (Zar, 1999).

RESULTS

In laboratory olfactometer experiments, both fresh and aged Porapak extracts of cocoon volatiles at 180 CSLHE attracted larvae (Figure 1; experiments 1, 2), as did a synthetic blend (SB) of 11 candidate pheromone components at 200 CSLHE (Figure 1, experiment 3). SB elicited a behavioral response also at 100 CSLHE (Figure 1; experiment 6), but not at 1, 10, or 1000 CSLHE (Figure 1; experiments 4, 5, 7). SBs lacking ketone or monoterpene components remained moderately attractive (Figure 2; experiments 8, 9), whereas an SB lacking aldehydes was inactive (Figure 2; experiment 10). An SB lacking saturated aldehydes was still active (Figure 2; experiment 11), whereas SBs lacking one or both unsaturated aldehydes [(*E*)-2-nonenal or (*E*)-octenal], or ketones [sulcatone or geranylacetone] elicited no significant responses from larvae (Figure 2; experiments 12–16). A rudimentary synthetic blend [RSB: (*E*)-2-octenal, (*E*)-2-nonenal, sulcatone, and geranylacetone] was not attractive (Figure 3; experiment 17), but the addition of 3-carene, unlike myrcene or (+)-limonene, rendered RSB attractive (Figure 3; experiments 18–20). Addition of the three saturated aldehydes octanal, nonanal, and decanal, unlike other three-component blends of saturated aldehydes, also rendered RSB attractive (Figure 3; experiments 21–24) to a level comparable with that of RSB plus all four saturated aldehydes (= SB minus monoterpenes; experiment 9).

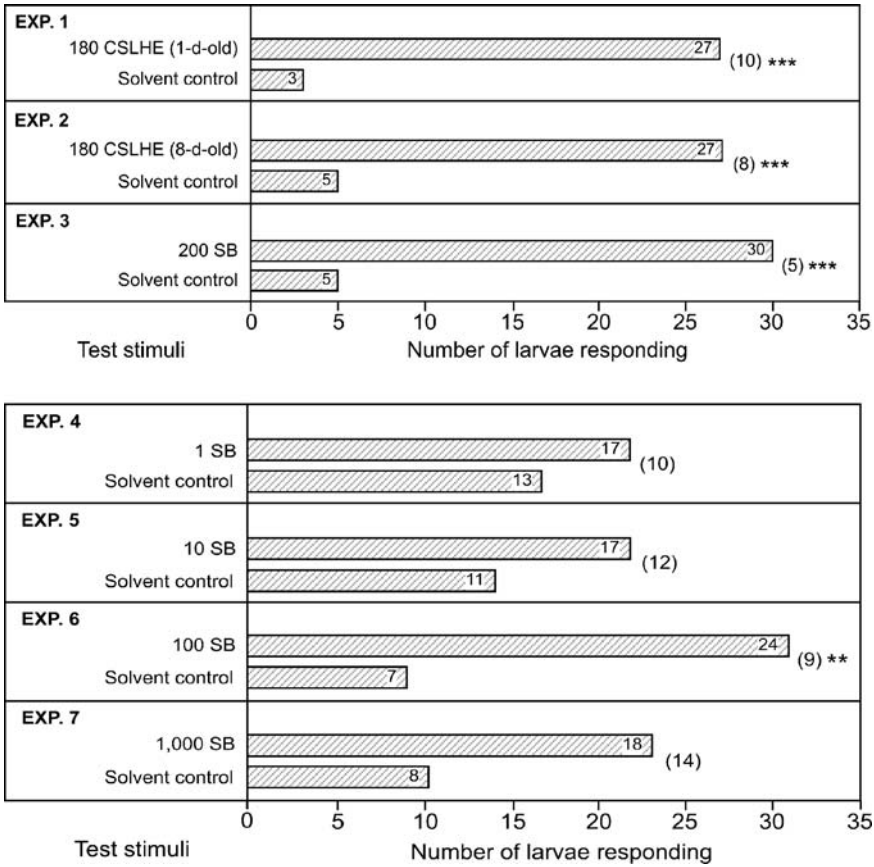

FIG. 1. Response of fifth-instar *Cydia pomonella* larvae in Petri dish olfactometers to extracts of cocoon-derived volatiles and to a synthetic blend (SB) of 11 candidate pheromone components (experiments 1–3), or to varying doses of SB (experiments 4–7). Number of larvae responding to each stimulus is given within bars; number of larvae not responding in each experiment given within parentheses; asterisks indicate a significant response to a particular treatment; χ^2 test with Yates correction for continuity; $^{**}P < 0.005$; $^{***}P < 0.001$. Ten SB consisted of three monoterpenes [(+)-limonene (10.00 ng), 3-carene (0.95 ng), myrcene (0.84 ng)], four saturated aldehydes (heptanal, octanal, nonanal, decanal), two unsaturated aldehydes [(*E*)-2-octenal (0.41 ng), (*E*)-2-nonenal (1.00 ng)], and two ketones [sulcatone (0.81 ng), geranylacetone (0.50 ng)]. Cocoons were 1–3 d old at the time of aeration but Porapak Q extracts were tested before and after aging to determine stability of semiochemicals. Aliquots of 180 or 200 CSLHE (cocoon-spinning larvae hour equivalents) were tested in experiments 1–3. Aliquots of 1, 10, 100, or 1000 CSLHE were tested in experiments 4–7; the same amount (20–25 μl) of pentane was applied to treatment and control stimuli in experiments 1–7.

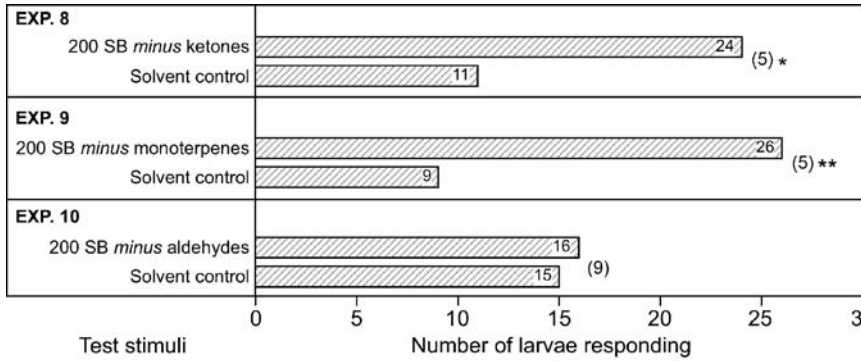

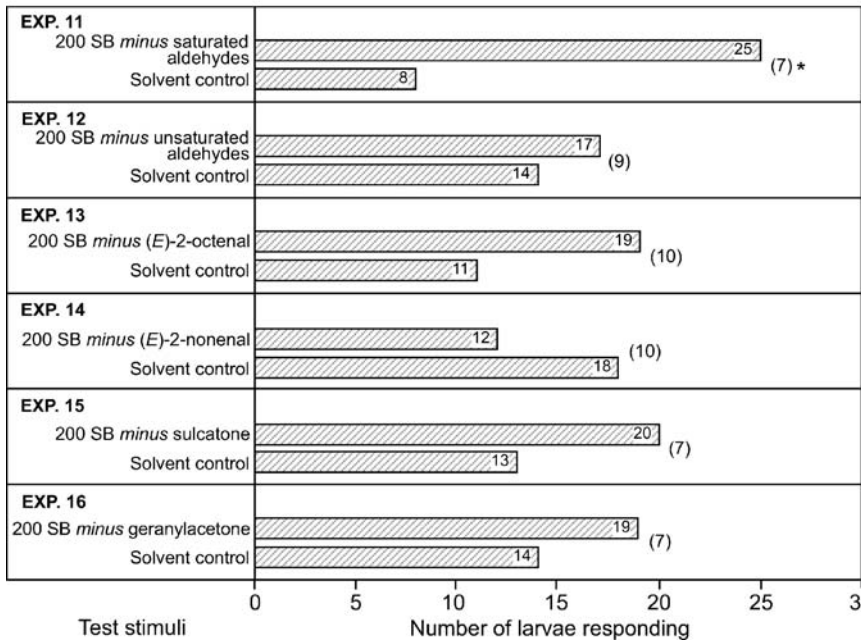

FIG. 2. Response of fifth-instar *Cydia pomonella* larvae in Petri dish olfactometers to synthetic blends (SB) lacking one or more candidate pheromone components. Number of larvae responding to each stimulus is given within bars; number of larvae not responding given in parentheses; asterisks indicate a significant response to a particular treatment; χ^2 test with Yates correction for continuity; $^*P < 0.05$; $^{**}P < 0.01$. Aliquots of 200 CSLHE (see caption of Figure 1) were tested. The same amount (20 µl) of pentane was applied to treatment and control stimuli.

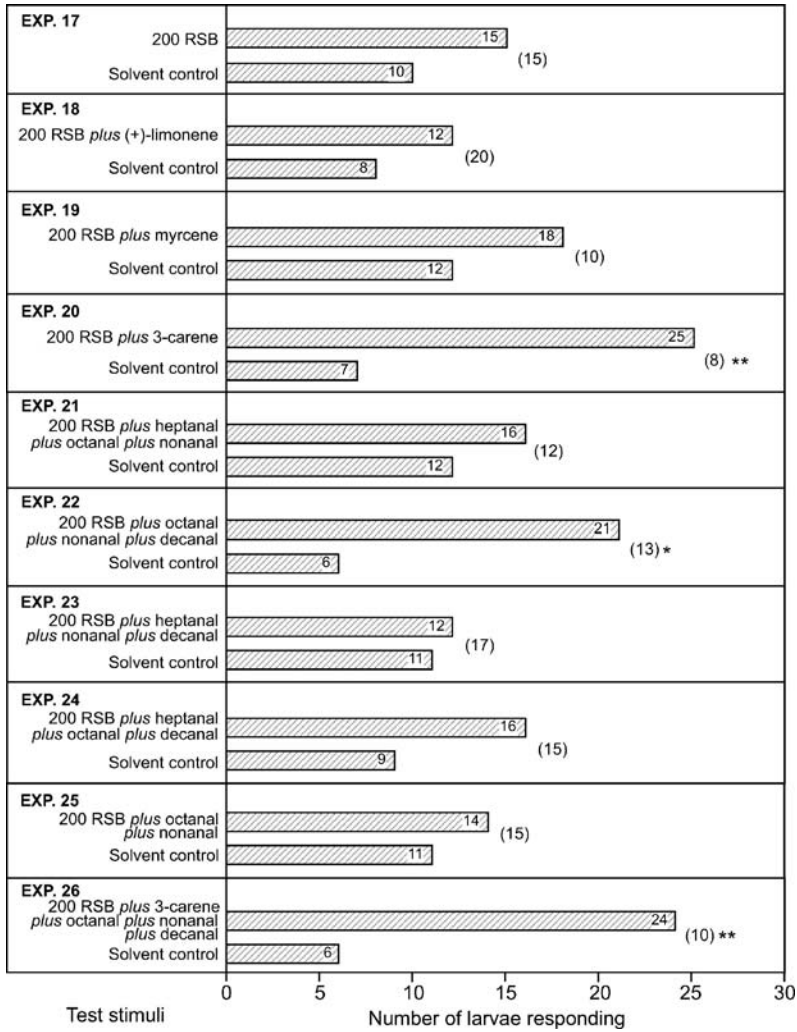

FIG. 3. Response of fifth-instar *Cydia pomonella* larvae in Petri dish olfactometer experiments 17–26 to a rudimentary synthetic blend (RSB) of pheromone components and to RSB plus individual or groups of candidate pheromone components. Number of larvae responding to each stimulus is given within bars; number of larvae not responding given in parentheses; asterisks indicate a significant response to a particular treatment; χ^2 test with Yates correction for continuity; $^*P < 0.01$; $^{**}P < 0.005$. Ten RSB consisted of two unsaturated aldehydes [(*E*)-2-octenal (0.41 ng), (*E*)-2-nonenal (1.00 ng)] and two ketones [sulcatone (0.81 ng), geranylacetone (0.50 ng)]. Aliquots of 200 CSLHE (see caption of Figure 1) were tested. The same amount (20 μl) of pentane was applied to treatment and control stimuli.

Addition of only octanal and nonanal to RSB failed to elicit a response from pupation site-seeking larvae (Figure 3; experiment 25), but RSB plus 3-carene, and octanal, nonanal, and decanal did elicit a behavioral response (Figure 3; experiment 26). SB at the low dose of 10 CSLHE had no effect on larval behavior (Figure 4; experiment 27). Ten-fold increases of either 3-carene, (*E*)-2-octenal, or (*E*)-2-nonenal in that low-dose blend did not modify its attractiveness (Figure 4; experiments 28–30) but a 10-fold increase of both (*E*)-2-octenal and (*E*)-2-nonenal in that blend stimulated a positive response from larvae (Figure 4; experiment 31).

In on-tree experiments, cocoons from conspecifics (experiment 32), and SB at 1000 CSLHE (experiment 33), attracted or arrested *C. pomonella* larvae foraging for pupation sites (Figure 5). In contrast, SB at 100 or 10,000 CSLHE was not active (Figure 5; experiments 34–35). Although the SB had no behavioral effect at 100 CSLHE (experiment 34), a 10-fold increase of both (*E*)-

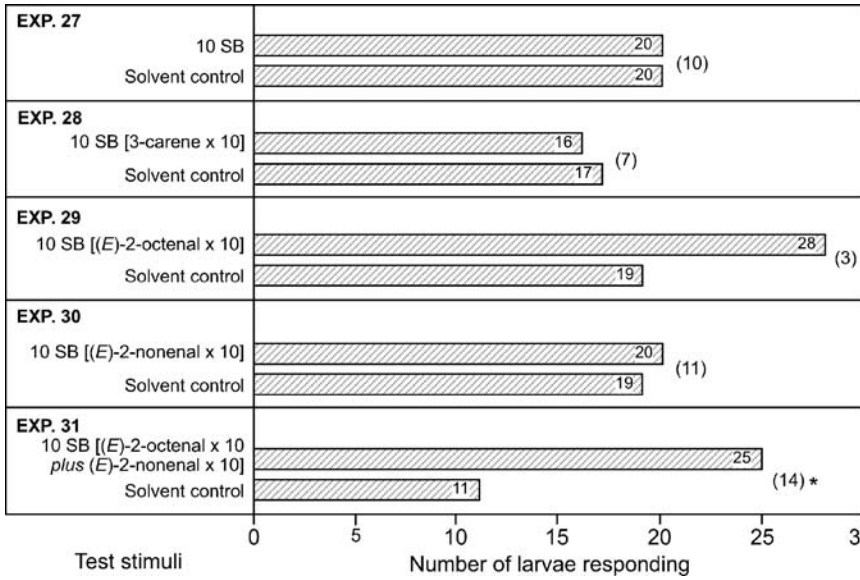

FIG. 4. Response of fifth-instar *Cydia pomonella* larvae in Petri dish olfactometer experiments 27–31 to a synthetic blend (SB; see caption of Figure 1) of 11 components with the relative proportion of 3-carene or unsaturated aldehydes [(*E*)-2-octenal, (*E*)-2-nonenal] increased by 10-fold. Number of larvae responding to each stimulus is given within bars; number of larvae not responding given in parentheses; asterisks indicate a significant response to a particular treatment; χ^2 test with Yates correction for continuity; $^*P < 0.05$. Aliquots of 10 CSLHE (see caption of Figure 1) were tested. The same amount (20 μl) of pentane was applied to treatment and control stimuli.

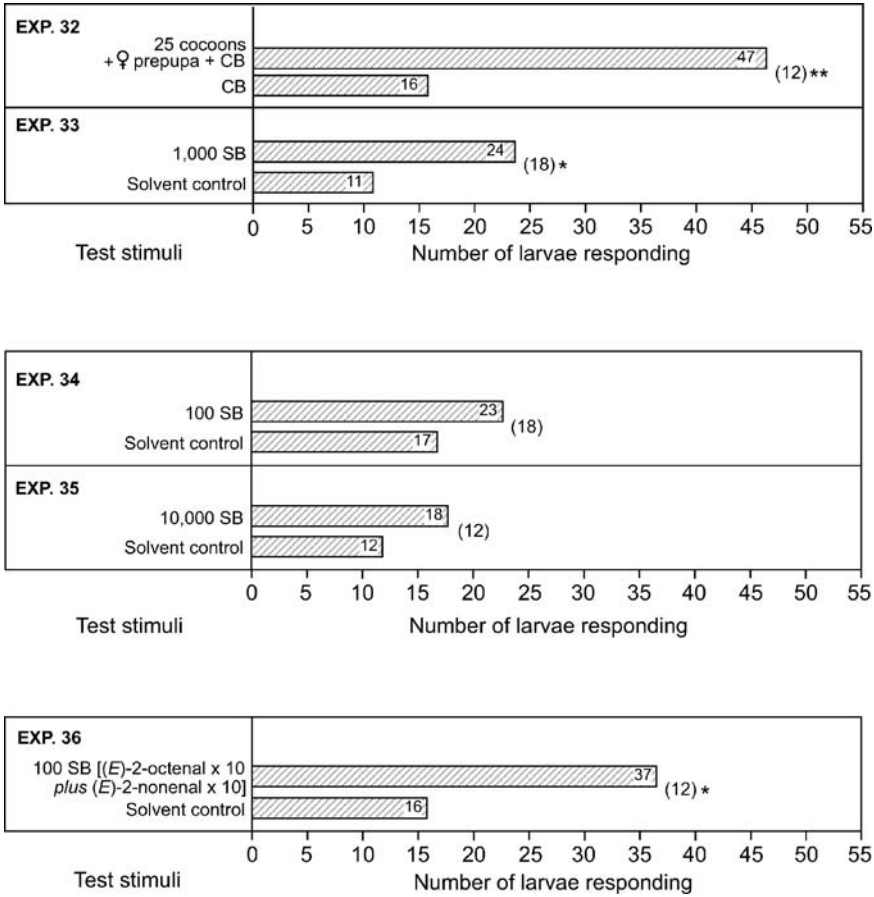

FIG. 5. Response of male (experiment 32), or male and female (experiments 33–36), fifth-instar *Cydia pomonella* larvae in on-tree experiments to stimuli consisting of either 25 cocoons with female larvae (experiment 32), or synthetic blends (SB) of 11 components (see caption of Figure 1) at varying doses and component ratios. Strips of corrugated cardboard (CB) served as a pupation site. Number of larvae responding to each stimulus is given within bars; number of replicates given in parentheses; asterisks indicate a significant response to a particular treatment; Wilcoxon paired-sample test; $*P < 0.01$; $**P < 0.005$. Aliquots of 100, 1,000, or 10,000 CSLHE (see caption of Figure 1) were tested. The same amount (100 µl) of pentane was applied to treatment and control stimuli. In experiment 36 the proportion of (*E*)-2-octenal and (*E*)-2-nonenal in the blend was increased by 10-fold.

2-octenal and (*E*)-2-nonenal in that blend produced responses from larvae (experiment 36).

DISCUSSION

Our laboratory and field data provide evidence that cocoon-spinning *C. pomonella* larvae produce a pheromone that attracts and/or arrests conspecific larvae seeking pupation sites (Duthie et al., 2003; Jumean et al., 2004a).

The cocoon-derived 11 candidate pheromone components that were bioassayed in olfactometer experiments 1–31 were selected based on evidence that they attracted not only *M. ridibundus* parasitoids but also *C. pomonella* larvae (Jumean et al., 2004b). The comparable biological activity of the 11-component synthetic blend and the Porapak Q extract of cocoon volatiles (Figure 1, experiments 1–3) suggested that all essential pheromone components were present in the synthetic blend.

The aggregation pheromone of *C. pomonella* larvae is surprisingly complex and responses were critically dependent on dose and blend composition. Low- or high-dose blends were ineffective (Figure 1), as were blends lacking either (*E*)-2-octenal, (*E*)-2-nonenal, sulcatone, or geranylacetone (Figure 2; experiments 13–16). Synergism between components was also evident when the four-component rudimentary blend of (*E*)-2-octenal, (*E*)-2-nonenal, sulcatone, and geranylacetone failed to affect larval behavior (Figure 3, experiment 17), but addition of either 3-carene (experiment 20) or three saturated aldehydes (octanal, nonanal, decanal) (experiment 23) resulted in attractive blends. Similar positive effects caused by 3-carene, or by saturated aldehydes, suggested redundancy in the blend composition. With five components needed for *C. pomonella* larvae to respond (Figure 3; experiment 20), and eight components needed for *M. ridibundus* parasitoids to respond (Jumean et al., 2004b), it appears that *M. ridibundus* requires a more complex signal to locate *C. pomonella* host prepupae than *C. pomonella* larvae require to communicate among themselves. The fact that the pheromone at low dose but with 10-fold increase of (*E*)-2-octenal and (*E*)-2-nonenal elicited a behavioral response from larvae (Figure 4; experiment 31) suggests that both of these unsaturated aldehydes are major components of the pheromone blend.

Pheromone components are perceived by *C. pomonella* larvae as airborne signals, because baffles in olfactometer experiments prevented physical contact with natural or synthetic pheromone. However, whether the pheromone serves primarily to attract or arrest conspecific larvae is not yet known.

The possible adaptive significance of pheromone-based larval aggregation will be intriguing to investigate. Duthie et al. (2003) proposed that

aggregations of *C. pomonella* larvae are part of a reproductive strategy that facilitates the earliest possible mating of eclosed adults. The proposed fitness advantage, however, may be offset by costs associated with larval aggregations. Host-derived pheromones are reliable indicators of host presence (Wiskerke et al., 1993; Wertheim et al., 2003), and are exploited by foraging parasitoids as illicit receivers of such signals (Stowe et al., 1995; Haynes and Yeargan, 1999; Jumean et al., 2004b). If, however, foraging parasitoids are egg-limited (Bezemer and Mills, 2001), individual *C. pomonella* larvae or prepupae in aggregations may be at a lower risk of parasitism than larvae that cocoon in isolation.

Aggregation of *C. pomonella* larvae as part of a proposed reproductive strategy (Duthie et al., 2003) might explain localized fruit damage in orchards treated with synthetic sex pheromone for *C. pomonella* control. Female *C. pomonella* eclosing from larval aggregations might be mated irrespective of otherwise functional pheromone-based tactics to disorient or attract and kill mate-foraging males. With the larval aggregation pheromone identified in this study, and shown to attract or arrest larvae in on-tree experiments (Figure 5; experiments 32–36), there may be a new opportunity to manipulate *C. pomonella* larvae in commercial fruit or nut orchards. Larval manipulation would be compatible with other biorational tactics of *C. pomonella* control including pheromone-mediated mating disruption and postharvest fruit removal (Judd et al., 1997).

(Received September 21, 2004; accepted December 1, 2004)

Abstract—Headspace extracts obtained from agar plate cultures of two marine bacteria from the North Sea (Germany), *Loktanella* strain BIO-204 and *Dinoroseobacter shibae* strain DFL-27, were analyzed by GC-MS. Several γ-lactones and one δ-lactone were identified, besides pyrazines and some sulfur compounds. The absolute configuration of the major lactone (*R*,*Z*)-dodec-5-en-4-olide, known as buibuilactone, a pheromone of several scarab beetles, was determined by a new catalytic enantioselective synthesis and GC on a chiral stationary phase. Unsaturated lactones in the extracts included (*E*)-dodec-5-en-4-olide and the regioisomer (*Z*)-dodec-6-en-4-olide, previously identified as a component of black-tailed deer urine. The pyrazines 2-butyl-3,6-dimethylpyrazine and 2-isopentyl-3,6-dimethylpyrazine were identified by comparison with synthesized material. The latter compound is a known ant pheromone, as is another identified pyrazine, 2-ethyl-3,6-dimethylpyrazine. The striking similarity between insect pheromones and these bacterial volatiles is discussed, suggesting the possibility of more widespread occurrence of symbiosis between microorganisms and insects than previously thought.

Key Words—Alphaproteobacteria, buibuilactone, coleoptera, headspace analysis, marine bacteria, pyrazines, lactones, *Roseobacter* clade, symbiosis.

INTRODUCTION

Considerable knowledge of intra- and interspecific chemical communication exists for insects, whereas other orders have received less attention. During the last decade, interest in bacterial communication has increased, and it has been shown that many effects, such as formation of biofilms, production of antibiotics, aggregation, expression of virulence factors, and bioluminescence, are mediated through bacterial chemical signals. Nevertheless, much less is known about such signals than about insect semiochemicals (Schulz, 2004, 2005). Whereas some groups of compounds have been intensively studied, such as the *N*-acylhomoserine lactones (e.g., Taga and Bassler, 2003; Daniels et al., 2004), overall, not many compounds have been identified. We, therefore, became interested in the volatile compounds emitted by marine bacteria which occur in biofilms or live associated with dinoflagellates. When these bacteria are cultivated on agar plates with a marine medium, many produce volatile compounds. These compounds have been rarely investigated compared with other bacterial metabolites, predominantly because of their normally low pharmacological activity and the special procedures required for their identification. We report here on the striking structural similarity of some bacterial volatiles to insect pheromones. Our results from the study of agar plate cultures of two marine Alphaproteobacteria from the North Sea (Germany) are reported.

METHODS AND MATERIALS

Bacteria. BIO-204 was isolated from a biofilm grown in the North Sea. Sterilized glass plates were mounted in a biofilm collector and immersed at a depth of 3 m in the channel between the island of Helgoland and the so-called Dune. After 1 wk, biofilms were aseptically scraped off, serially diluted, plated onto seawater agar (autoclaved North Sea water, 15 g/l agar, Difco), and incubated at room temperature for 3 wk. Routine cultivation of BIO-204 was performed on LBSS [25 g/l Luria Bertani broth (Sigma), 14 g/l sea salts (Sigma) in distilled water] at room temperature under ambient day/night cycle. DFL-27 was isolated from cells of the dinoflagellate *Alexandium ostenfeldii*, which were washed several times using artificial seawater and then placed on a solid medium containing 0.04 g/l peptone and 0.008 g/l yeast extract in filtered (0.3 μm) autoclaved North Sea water and incubated at 18°C in the dark. The dinoflagellates were sampled from the culture collection of the Biologische Anstalt Helgoland, culture KO287, after 72-hr growth in the late stationary growth phase. Routine cultivation of DFL-27 used marine broth (MB 2216, Difco); incubation was performed at room temperature. See Allgaier et al. (2003) for

details on sampling and cultivation. For analysis of volatile compounds, strains were incubated on a rotary shaker in liquid culture in LBSS or MB until good growth was obtained. An aliquot of 100 μl was distributed evenly on solid marine media [LBSS or MB; 15 g/l agar (Difco)] in a glass Petri dish using a drygalski spatel and incubated at room temperature at the ambient day/night cycle until the surface was completely covered by the bacteria (between 7 and 10 d).

Sampling of Volatiles. Volatile organic compounds released by cultures of the strains BIO-204 and DFL-27 on agar plates were collected using the closed loop stripping analysis (CLSA) technique as described previously (Dickschat et al., 2004; Schulz et al., 2004).

GC-MS. GC-MS analyses were carried out on an HP 6890 Series GC connected to an HP 5973 mass selective detector (Hewlett-Packard Company, Wilmington, DE, USA) fitted with a BPX5 fused-silica capillary column (25 m $\times$ 0.22 mm i.d., 0.25-μm film, SGE Inc., Melbourne, Australia). Conditions were as follows: inlet pressure, 77.1 kPa; injection volume, 1 μl; transfer line, 300°C; electron energy, 70 eV. The GC was programmed as follows: 5 min at 50°C, 5°C/min to 300°C, and operated in splitless mode (60-s valve time). The carrier gas was He at 1 ml/min. Retention indices (I) were determined relative to a homologous series of *n*-alkanes (C_8–C_{25}). Identification of compounds was performed by comparison of mass spectra to the Wiley 6 Library and the Essential Oils Library (Massfinder) as well as by comparison with synthetic compounds.

Chiral GC. The determination of the absolute configuration of natural **13** was carried out on an HP 6890 Series GC connected to an HP 5973 mass selective detector fitted with a heptakis-(6-*O*-TBDMS-2,3-di-*O*-acetyl)-β-cyclodextrin fused-silica capillary column (15 m $\times$ 0.25 mm i.d., Machery-Nagel, Düren, Germany). The GC was programmed from 100°C, increasing at 1.5°C/min to 180°C, and operated in splitless mode (60-s valve time). The carrier gas was He at 1 ml/min, and the injection volume was 1 μl.

Synthesis (General Methods). Chemicals were purchased from Fluka Chemie GmbH (Buchs, Switzerland) or Sigma-Aldrich Chemie GmbH (Steinheim, Germany) and used without further purification. NMR spectra were obtained using a Bruker AMX400 (^{1}H NMR, 400 MHz; ^{13}C NMR, 100 MHz) spectrometer with tetramethylsilane as internal standard. Optical rotations were determined on a Dr. Kernchen Propol Digital Automatic Polarimeter. Column chroma-tography was carried out using Merck Kieselgel 60. Thin-layer chromatography was carried out using Polygram Sil G/UV_{254} 0.2-mm precoated plastic sheets (Machery-Nagel, Düren, Germany). Solvents were purified by distillation and dried according to standard methods.

*Preparation of 4-(2-Tetrahydropyranyloxy)butan-1-ol (**24**).* A solution of 3,4-dihydro-2*H*-pyran (DHP, 8.40 g, 100 mmol), 1,4-butanediol [**23**] (22.5 g,

250 mmol), and *p*-toluenesulfonic acid (*p*-TsOH, 950 mg, 5.0 mmol) in dry acetonitrile (250 ml) was stirred for 1 hr. Diethyl ether (500 ml) was added. The organic layer was washed with saturated $NaHCO_3$. The aqueous layer was separated and extracted ×3 with diethyl ether. The combined organic layers were dried ($MgSO_4$) and concentrated. The residue was purified by column chromatography on silica gel with pentane/diethyl ether (1:1) to yield **24** (13.1 g, 75 mmol, 75% based on DHP) and 1,4-bis-(2-tetrahydropyranyloxy)butane (2.22 g, 8.6 mmol, 9%) as colorless liquids. 4-(2-Tetrahydropyranyloxy)butan-1-ol **24**. TLC (pentane/diethyl ether, 1:1): R_F = 0.15. GC: I = 1395. ^{1}H NMR (400 MHz, $CDCl_3$): δ (ppm) = 1.47–1.62 (4H, m, 2 × CH_2), 1.63–1.77 (5H, m, 3 × CH_2), 1.77–1.88 (1H, m, CH_2), 3.28–3.30 (1H, br s, OH), 3.38–3.47 (1H, m, CH_2), 3.47–3.55 (1H, m, CH_2), 3.62–3.68 (2H, m, CH_2), 3.73–3.83 (1H, m, CH_2), 3.83–3.90 (1H, m, CH_2), 4.57–4.63 (1H, m, CH). ^{13}C NMR (100 MHz, $CDCl_3$): δ (ppm) = 19.4 (CH_2), 25.3, 25.4 (CH_2), 26.4, 26.4 (CH_2), 29.7, 29.8 (CH_2), 30.5, 30.6 (CH_2), 62.1, 62.2 (CH_2), 62.4 (CH_2), 67.2, 67.4 (CH_2), 98.7, 98.9 (CH). EI-MS (70 eV): *m/z* (%) = 101 (21) $[C_5H_9O_2]^+$, 85 (100) $[C_5H_9O]^+$, 73 (90), 67 (15), 55 (79), 41 (52).

*Preparation of 4-(2-Tetrahydropyranyloxy)butanal (**25**).* A solution of **24** (6.25 g, 35.9 mmol) in dry CH_2Cl_2 (20 ml) was added in one portion to a suspension of pyridinium dichromate (PDC, 20.2 g, 53.9 mmol) in dry CH_2Cl_2 (150 ml). The reaction mixture was stirred at room temperature for 24 hr, concentrated, and then filtered through silica gel. The pure **25** (4.39 g, 25.5 mmol, 71%) was obtained by column chromatography on silica gel with pentane/diethyl ether (1:1) as a colorless liquid. TLC (pentane/diethyl ether, 1:1): R_F = 0.48. GC: I = 1322. ^{1}H NMR ($CDCl_3$): δ 1.45–1.87 (6H, m, 3 × CH_2), 1.95 (2H, quin, J = 6.6 Hz, CH_2), 2.54 (2H, dt, J = 1.6 Hz, J = 7.0 Hz, CH_2), 3.36–3.55 (2H, m, CH_2), 3.72–3.88 (2H, m, CH_2), 4.55–4.62 (1H, m, CH), 9.79 (1H, t, J = 1.6 Hz, CHO). ^{13}C NMR ($CDCl_3$): δ 19.4 (CH_2), 22.6 (CH_2), 25.4 (CH_2), 30.5 (CH_2), 41.0 (CH_2), 62.2 (CH_2), 66.3 (CH_2), 98.8 (CH), 202.2 (CHO). EI-MS (70 eV): *m/z* (%) = 101 (13) $[C_5H_9O_2]^+$, 85 (68) $[C_5H_9O]^+$, 71 (100) $[C_4H_7O]^+$, 57 (17), 41 (53).

*Preparation of 4-Hydroxy-1-(2-tetrahydropyranyloxy)dodec-5-yne (rac-**26**).* A solution of ethylmagnesium bromide (~19.3 mmol) in dry diethyl ether (20 ml) was prepared from magnesium (470 mg, 19.3 mmol) and ethyl bromide (2.10 g, 19.3 mmol). Then a solution of 1-octyne (2.12 and 19.3 mmol) in dry diethyl ether (5 ml) was added dropwise. The reaction mixture was stirred until no more ethane evolved (ca. 1 hr). The resulting solution was added dropwise to a solution of **25** (2.77 g, 16.1 mmol) in dry diethyl ether (100 ml), heated to reflux for 2 hr, and then quenched by the addition of saturated NH_4Cl. The aqueous layer was separated and extracted ×3 with diethyl ether. The combined organic layers were dried with $MgSO_4$ and concentrated *in vacuo*. Purification by column chromatography on silica gel with pentane/diethyl ether afforded *rac*-**26**

(3.86 g, 13.7 mmol, 85%) as a colorless liquid. TLC (pentane/diethyl ether, 1:1): R_F = 0.44. GC: I = 2141. ^{1}H NMR ($CDCl_3$): δ 0.89 (3H, t, J = 6.6 Hz, CH_3), 1.22–1.41 (6H, m, 3 × CH_2), 1.46–1.65 (6H, m, 3 × CH_2), 1.67–1.87 (6H, m, 3 × CH_2), 2.20 (2H, dt, J = 7.1 Hz, J = 1.9 Hz, CH_2), 2.77 (1H, br s, OH), 3.41–3.55 (2H, m, CH_2), 3.75–3.90 (2H, m, CH_2), 4.41 (1H, br s, CH), 4.60–4.63 (1H, m, CH). ^{13}C NMR ($CDCl_3$): δ 14.0 (CH_3), 18.6 (CH_2), 19.3 (CH_2), 22.5 (CH_2), 25.3 (CH_2), 25.5, 25.5 (CH_2), 28.5 (CH_2), 28.6 (CH_2), 30.5 (CH_2), 31.2 (CH_2), 35.4, 35.4 (CH_2), 62.1 (CH_2), 62.3, 62.3 (CH), 67.1, 67.2 (CH_2), 81.1 (C), 85.3, 85.3 (C), 98.5, 98.6 (CH). EI-MS (70 eV): m/z (%) = 223 (1), 195 (1), 179 (4), 151 (3), 121 (8), 101 (8) $[C_5H_9O_2]^+$, 95 (17), 85 (100) $[C_5H_9O]^+$, 67 (25), 55 (25), 41 (35).

*Enantioselective Preparation of (R)-4-Hydroxy-1-(2-tetrahydropyranyloxy) dodec-5-yne [(R)-**26**].* As described by Anand and Carreira (2001), $Zn(OTf)_2$ (700 mg, 1.93 mmol, 0.2 equiv.) was heated to 130°C *in vacuo* for 12 hr to remove traces of water. (+)-*N*-Methylephedrine (380 mg, 2.12 mmol, 0.22 equiv.) was added after cooling to room temperature. The mixture was dried *in vacuo* for an additional 30 min. Dry toluene (10 ml) and triethylamine (0.49 g, 4.83 mmol, 0.5 equiv.) were added. The reaction mixture was heated to 50°C for 2 hr. Then 1-octyne (1.27 g, 11.6 mmol, 1.2 equiv.) was added at room temperature. After stirring for 15 min, a solution of **25** (1.66 g, 9.65 mmol, 1.0 equiv.) in dry toluene (10 ml) was added dropwise by a syringe pump over 2.5 hr. During the first 30 min, the mixture was stirred at room temperature and then heated to 80°C. After the solution of the aldehyde **25** was completely added, the reaction mixture was stirred for additional 15 hr at 80°C and then quenched by addition of saturated NH_4Cl. The aqueous layer was separated, extracted ×3 with diethyl ether, and the combined organic layers were dried with $MgSO_4$ and concentrated. The crude product was purified by column chromatography on silica gel with pentane/diethyl ether (1:1) to yield (*R*)-**26** (1.32 g, 4.67 mmol, 49%) as a colorless liquid. Spectroscopic and physical data corresponded to those of *rac*-**26**. $[\alpha]_D^{21.1}$ = +7.9 (c = 2.1, pentane).

*Preparation of Dodec-5-yne-1,4-diol (rac-**27**).* The alcohol *rac*-**26** (3.12 g, 11.1 mmol) was dissolved in dry methanol (25 ml), and *p*-TsOH (209 mg, 1.1 mmol) was added. The reaction mixture was stirred for 1 hr at room temperature, diluted with diethyl ether (200 ml), and washed with saturated $NaHCO_3$. The aqueous layer was separated and extracted ×3 with diethyl ether. The combined organic phases were dried with $MgSO_4$ and concentrated under reduced pressure. The residue was purified by column chromatography on silica gel with diethyl ether to give *rac*-**27** (1.96 g, 9.90 mmol, 89%) as a colorless liquid. TLC (diethyl ether): R_F = 0.50. GC: I = 1699. ^{1}H NMR ($CDCl_3$): δ 0.89 (3H, t, J = 6.6 Hz, CH_3), 1.23–1.41 (6H, m, 3 × CH_2), 1.45–1.54 (2H, m, CH_2), 1.68–1.85 (4H, m, 2 × CH_2), 2.20 (2H, t, J = 7.1 Hz, CH_2), 2.93 (2H, br s, 2 × OH), 3.65–3.75 (2H, m, CH_2), 4.40–4.47 (1H, m, CH). ^{13}C NMR ($CDCl_3$):

δ 14.0 (CH_3), 18.6 (CH_2), 22.5 (CH_2), 28.4 (CH_2), 28.5 (CH_2), 28.6 (CH_2), 31.3 (CH_2), 35.1 (CH_2), 62.3 (CH), 62.5 (CH_2), 80.9 (C), 85.7 (C). EI-MS (70 eV): *m/z* (%) = 167 (1), 151 (3), 139 (19), 123 (23), 110 (70), 95 (97), 79 (59), 69 (67), 55 (82), 41 (100).

*Preparation of (R)-Dodec-5-yne-1,4-diol [(R)-**27**].* As described for *rac*-**27**, enantiopure (*R*)-**26** was transformed into the corresponding diol (*R*)-**27**. Physical and spectroscopic data as well as the yield corresponded to those of *rac*-**27**. $[\alpha]_D^{22.2} = +11.1$ (c = 3.5, CH_2Cl_2).

*Preparation of Dodec-5-yn-4-olide (rac-**28**).* As described by Bloch and Brillet (1991) and Ley et al. (1994), a mixture of *rac*-**27** (396 mg, 2.0 mmol), *N*-methylmorpholine-*N*-oxide (405 mg, 3.0 mmol), powdered molecular sieve (4 Å, 1.0 g), and tetrapropylammonium perruthenate (TPAP, 35 mg, 5 mol%) in dry CH_2Cl_2 (6 ml) was stirred for 1 hr. Solids were removed by filtration, and the filtrate was concentrated. The residue was purified by column chromatography on silica gel with pentane/diethyl ether (3:1) to obtain *rac*-**28** (264 mg, 1.36 mmol, 68%) as a colorless liquid. TLC (pentane/diethyl ether, 3:1): R_F = 0.18. GC: I = 1714. ^{1}H NMR ($CDCl_3$): δ 0.89 (3H, t, J = 6.9 Hz, CH_3), 1.22–1.43 (6H, m, 3 × CH_2), 1.47–1.54 (2H, m, CH_2), 2.20–2.28 (3H, m, 2 × CH_2), 2.45–2.55 (2H, m, CH_2), 2.59–2.70 (1H, m, CH_2), 5.11–5.14 (1H, m, CH). ^{13}C NMR ($CDCl_3$): δ 13.9 (CH_3), 18.6 (CH_2), 22.4 (CH_2), 27.9 (CH_2), 28.1 (CH_2), 28.4 (CH_2), 30.1 (CH_2), 31.2 (CH_2), 69.6 (CH), 76.4 (C), 88.7 (C), 176.2 (CO). EI-MS (70 eV): *m/z* (%) = 165 (23), 147 (10), 137 (16), 124 (18), 109 (36), 95 (45), 85 (51) $[C_4H_5O_2]^+$, 79 (100), 67 (57), 55 (52), 41 (73).

*Preparation of (R)-Dodec-5-yn-4-olide [(R)-**28**].* This enantiopure compound was prepared as described for *rac*-**28** from (*R*)-**27**. Spectroscopic and physical data as well as the yield corresponded to those of *rac*-**28**. $[\alpha]_D^{23.6} = -20.7$ (c = 3.7, pentane).

*Preparation of Dodec-5-en-4-olide (rac-**13**).* Dodec-5-yn-4-olide (*rac*-**28**) (62 mg, 0.32 mmol) was dissolved in dry methanol (10 ml). The mixture was stirred in a H_2 atmosphere (1 bar) for 30 min after the addition of a catalytic amount of Lindlar's catalyst ($Pd/CaCO_3$/Pb, 10 mg, 10% Pd). Solids were filtered off, and the filtrate was concentrated. Dodec-5-en-4-olide (*rac*-**13**) (57 mg, 0.29 mmol, 94%) was obtained after column chromatography on silica gel with pentane/diethyl ether (3:1) as a colorless liquid. The *Z*/*E*-diastereomers were not separable by column chromatography, and were obtained in a ratio of 8:1. (*Z*)-Isomer (**13**). TLC (pentane/diethyl ether, 3:1): R_F = 0.25. GC: I = 1677. NMR and MS data correspond to those reported by Leal (1991).

(*E*)-Isomer (**14**). TLC (pentane/diethyl ether, 3:1): R_F = 0.25. GC: I = 1691.

*Preparation of (R)-Dodec-5-en-4-olide [(R)-**13**, Buibuilactone].* Buibuilactone was prepared in the same manner as described for *rac*-**13** using (*R*)-**28** as starting material. Spectroscopic and physical data as well as the yield corresponded to those of *rac*-**13**. $[\alpha]_D^{24.0} = -52.2$ (c = 2.0, hexane). The ee of

84% was determined by chiral GC: $t_R(S)$ = 32.4 min, $t_R(R)$ = 33.2 min. Leal (1991) reported an $[\alpha]_D^{24.0} = -61.2$ (c = 0.85, hexane) with 98.4% ee.

*Preparation of 2,5-Dimethylpyrazine-N-oxide (**30**).* As described by Ohta and Ohta (1985), a mixture of 2,5-dimethylpyrazine (**29**) (25.0 g, 231 mmol) and $NaBO_2 \cdot H_2O_2 \cdot 3H_2O$ (42.7 g, 277 mmol) in glacial acetic acid (250 ml) was heated to 80°C for 8 hr. Acetic acid was removed under reduced pressure, and the residue was diluted with 2N NaOH (250 ml). The aqueous layer was extracted ×3 with diethyl ether. The combined organic layers were dried with $MgSO_4$ and concentrated. Crude product was purified by column chromatography on silica gel with diethyl ether/methanol (10:1) to give 2,5-dimethylpyrazine-*N*-oxide **30** (24.3 g, 196 mmol, 85%) as a colorless solid. TLC (diethyl ether/methanol, 10:1): R_F = 0.29. GC: I = 1279. ^{1}H NMR ($CDCl_3$): δ 2.43 (3H, s, CH_3), 2.50 (3H, s, CH_3), 8.07 (1H, s, CH), 8.36 (1H, s, CH). ^{13}C NMR ($CDCl_3$): δ 13.9 (CH_3), 21.1 (CH_3), 132.3 (CH), 141.2 (C), 146.4 (CH), 154.7 (C). EI-MS (70 eV): m/z (%) = 124 (90) $[M]^+$, 107 (53) $[M\text{-OH}]^+$, 93 (2), 80 (95), 66 (30), 52 (20), 42 (43), 39 (100).

*Preparation of 2-Chloro-3,6-dimethylpyrazine (**31**).* As described previously (Inoue et al., 1985; Sato and Fujii, 1994), a solution of 2,5-dimethylpyrazine-*N*-oxide **30** (13.1 g, 106 mmol) in $POCl_3$ (70 ml) was heated to reflux for 3 hr. The reaction mixture was poured onto ice (1 kg), and the resulting aqueous layer was neutralized with NaOH and then extracted ×3 with chloroform. The combined organic layers were dried with $MgSO_4$ and concentrated. Pure 2-chloro-3,6-dimethylpyrazine **31** (12.0 g, 84 mmol, 79%) was obtained as a colorless liquid by column chromatography on silica gel with pentane/diethyl ether (3:1). TLC (pentane/diethyl ether, 3:1): R_F = 0.43. GC: I = 1128. ^{1}H NMR ($CDCl_3$): δ 2.52 (3H, s, CH_3), 2.62 (3H, s, CH_3), 8.25 (1H, s, CH). ^{13}C NMR ($CDCl_3$): δ 20.2 (CH_3), 21.2 (CH_3), 141.0 (CH), 147.5 (C), 149.1 (C), 150.9 (C). EI-MS (70 eV): m/z (%) = 144 (28), 142 (85) $[M]^+$, 107 (100) $[M\text{-Cl}]^+$, 80 (50), 66 (16), 52 (19), 39 (52).

*Preparation of 2-Alkyl-3,6-Dimethylpyrazines (**21** and **22**).* According to the method of Fürstner et al. (2002), a solution of the respective alkylmagnesium bromide in dry THF (10 ml) prepared from magnesium (292 mg, 12 mmol) and the alkyl bromide (12 mmol) was added to an ice-cooled solution of **31** (1.42 g, 10 mmol) and $Fe(acac)_3$ (182 mg, 0.5 mmol) in dry THF (10 ml) and *N*-methyl-2-pyrrolidinone (2 ml). The reaction mixture was stirred at 0°C for 30 min and then quenched by the addition of water. The aqueous layer was extracted ×3 with diethyl ether. The combined organic layers were dried with $MgSO_4$ and concentrated. Purification of the residue by column chromatography on silica gel with pentane/diethyl ether (5:1) yielded the alkylated pyrazines as colorless liquids. 2-Butyl-3,6-dimethylpyrazine (**21**). Yield: 1.12 g (6.83 mmol, 68%). TLC (pentane/diethyl ether, 5:1): R_F = 0.18. GC: I = 1263. ^{1}H NMR ($CDCl_3$): δ 0.96 (3H, t, J = 7.3 Hz, CH_3), 1.43 (2H, sext, J = 7.4 Hz, CH_2),

1.62–1.70 (2H, m, CH_2), 2.49 (3H, s, CH_3), 2.53 (3H, s, CH_3), 2.74–2.79 (2H, m, CH_2), 8.15 (1H, s, CH). ^{13}C NMR ($CDCl_3$): δ 13.8 (CH_3), 21.0 (CH_3), 21.1 (CH_3), 22.7 (CH_2), 30.7 (CH_2), 34.8 (CH_2), 140.5 (CH), 148.3 (C), 149.9 (C), 154.8 (C). EI-MS (70 eV): *m/z* (%) = 163 (1) $[M\text{-H}]^+$, 149 (7) $[M\text{-}CH_3]^+$, 135 (11) $[M\text{-}C_2H_5]^+$, 122 (100) $[M\text{-}C_3H_6]^+$, 107 (4), 96 (2), 80 (4), 66 (2), 53 (7), 42 (11), 39 (12).

2-Isopentyl-3,6-dimethylpyrazine (**22**). Yield: 1.21 g (6.80 mmol, 68%). TLC (pentane/diethyl ether, 5:1): R_F = 0.18. GC: I = 1321. ^1H NMR ($CDCl_3$): δ 0.98 (6H, d, J = 6.6 Hz, 2 × CH_3), 1.51–1.58 (2H, m, CH_2), 1.68 (1H, sept, CH), 2.48 (3H, s, CH_3), 2.52 (3H, s, CH_3), 2.74–2.79 (2H, m, CH_2), 8.14 (1H, s, CH). ^{13}C NMR ($CDCl_3$): δ 21.0 (CH_3), 21.0 (CH_3), 22.4 (2 × CH_3), 28.3 (CH), 33.2 (CH_2), 37.6 (CH_2), 140.5 (CH), 148.3 (C), 149.9 (C), 155.0 (C). EI-MS (70 eV): *m/z* (%) = 177 (1) $[M\text{-H}]^+$, 163 (9) $[M\text{-}CH_3]^+$, 149 (1) $[M\text{-}C_2H_5]$, 135 (15) $[M\text{-}C_3H_7]^+$, 122 (100) $[M\text{-}C_4H_8]^+$, 107 (3), 96 (1), 80 (5), 66 (2), 53 (6), 42 (9), 39 (11).

RESULTS

As part of our studies on volatiles emitted by different microorganisms, we investigated a number of marine bacteria from the North Sea by GC-MS using the CLSA headspace method adapted for agar plates (Dickschat et al., 2004; Schulz et al., 2004). The marine bacteria BIO-204 and DFL-27 have been isolated from biofilms and a toxin-producing dinoflagellate growing in the North Sea, respectively (Allgaier et al., 2003). They both belong to the *Roseobacter* clade of the Alphaproteobacteria subclass of the Proteobacteria. DFL-27 is capable of aerobic anoxygenic photosynthesis. Based on its 16S rRNA sequence, it is distantly related to *Rhodobacter sphaeroides* (92.8% similarity over 1318 nucleotides) and *Jannaschia helgolandensis* (Wagner-Döbler et al., 2003) and is currently being described as *Dinoroseobacter shibae* (Biebl et al., unpublished). BIO-204 is a strain of the recently described genus *Loktanella* (van Trappen et al., 2004).

The results of the analyses of the two species, *Loktanella* strain BIO-204 and *D. shibae* strain DFL-27, are summarized in Table 1. Total ion chromatograms of two characteristic analyses are shown in Figure 1. Both prokaryotic species produce a diverse array of volatiles. The different samples of the bacteria showed some differences in the number of compounds as well as the total amounts of the emitted volatiles. One of the predominant substance classes present in the extracts were lactones (Figure 2). DFL-27 produced a homologous series of unbranched γ-lactones, ranging from 4-hexanolide (**2**) to 4-dodecanolide (**8**), which were identified by comparison of mass spectra and retention times with

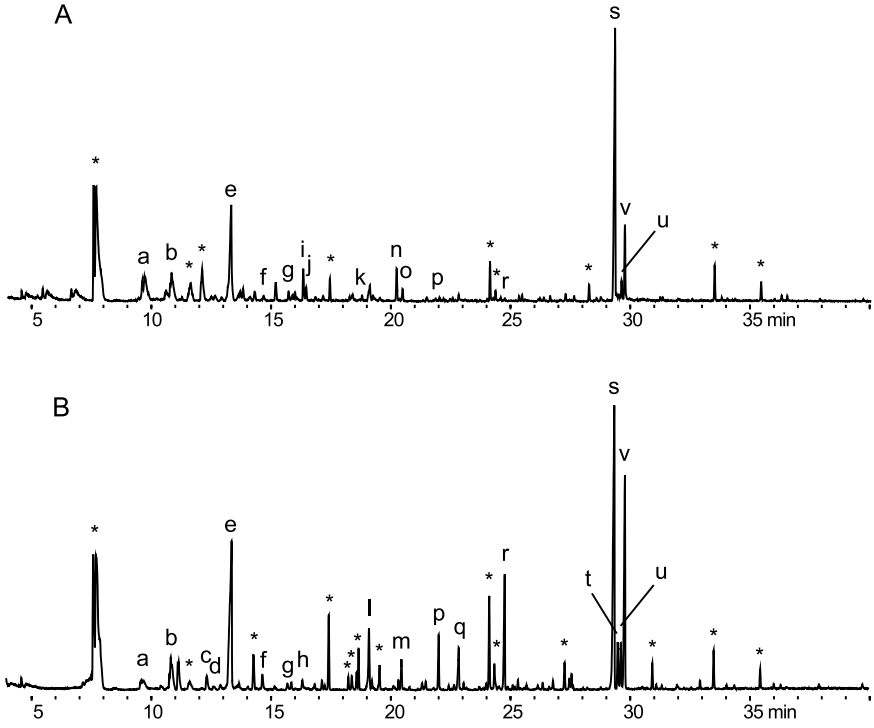

FIG. 1. Total ion chromatograms of the headspace extracts of (A) *Loktanella* strain BIO-204 and (B) *D. shibae* strain DFL-27. Artifacts are marked by an asterisk.

those of authentic reference compounds or mass spectral databases, whereas BIO-204 emitted **1**, **2**, **5**, **6**, and larger amounts of **8**. The branched 3-methyl-4-butanolide (**9**) was only found in one sample of BIO-204, whereas 3-methyl-4-pentanolide (**10**) as well as 2-methyl-4-pentanolide (**11**) was restricted to DFL-27. Additionally, this species produced the δ-lactone 5-nonanolide (**12**). One of the major compounds present in the extracts of both species eluted slightly earlier (I = 1677, I: retention index after van den Dool and Kratz, 1963) than 4-dodecanolide (I = 1699), and its mass spectrum showed a molecular ion at m/z = 196 (Figure 3A). From these data, we inferred the compound to be an unsaturated analog of 4-dodecanolide, which has a molecular weight of 198. Furthermore, the mass spectrum was characterized by a base peak at m/z = 111, as would be expected for dodec-5-en-4-olide. Another compound eluting slightly later (I = 1691) showed a similar mass spectrum (Figure 3B) with the same molecular ion (m/z = 196) and base peak (m/z = 111) and was thus suggested to be the other

diastereomer. The lactone (*R*,*Z*)-dodec-5-en-4-olide is known as an insect sex pheromone, first identified in the scarab beetle *Anomala cuprea* (Coleoptera: Scarabaeidae) (Leal, 1991), and its published mass spectrum (Leal et al., 1993, 1999) was similar to the one obtained by us. To clarify the identity of these two bacterial volatiles, we carried out a total synthesis according to Scheme 1,

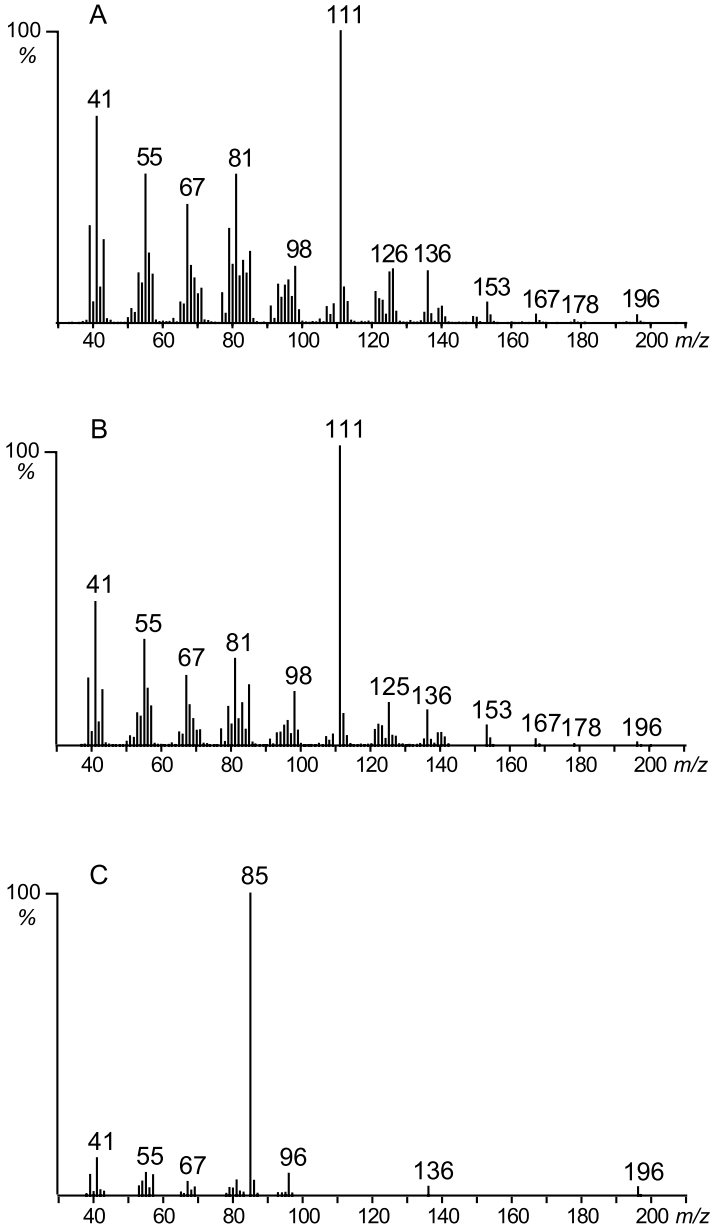

FIG. 3. Mass spectra of (A) (*R*,*Z*)-dodec-5-en-4-olide (**13**), (B) (*E*)-dodec-5-en-4-olide (**14**), and (C) (*Z*)-dodec-6-en-4-olide (**15**).

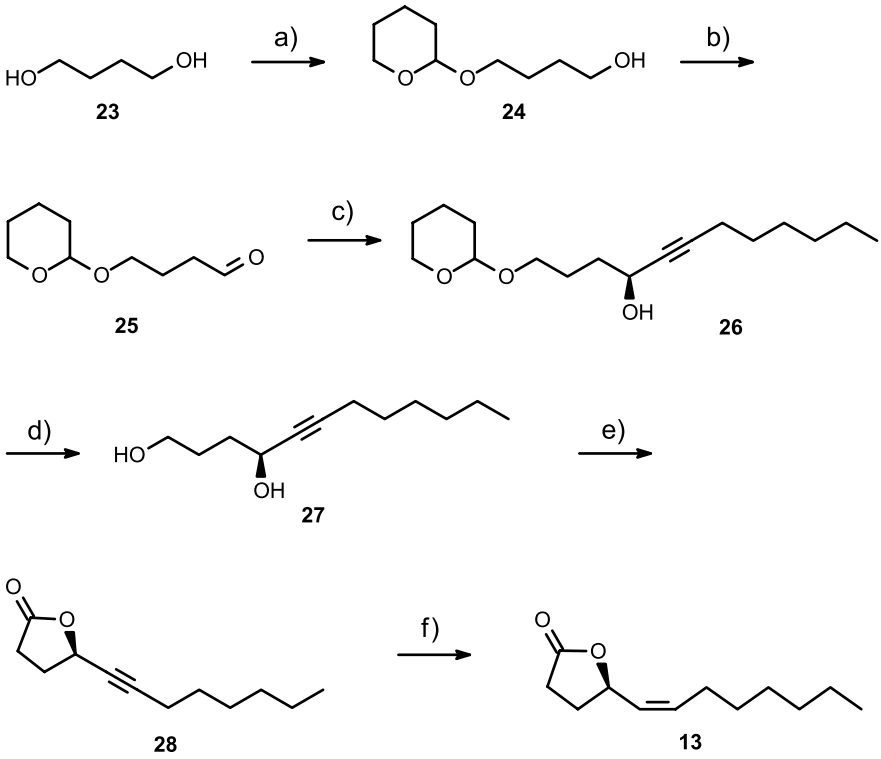

SCHEME 1. Total synthesis of (*R*,*Z*)-dodec-5-en-4-olide (*R*)-**13**. (a) 3,4-Dihydro-2*H*-pyran, *p*-TsOH, CH_3CN, 75%; (b) PDC, CH_2Cl_2, 71%; (c) racemic: octynylmagnesium bromide, Et_2O, 85%, enantioselective: $Zn(OTf)_2$, (+)-*N*-methylephedrine, Et_3N, 1-octyne, toluene, 80°C, 49%, 84% ee; (d) *p*-TsOH, MeOH, 89%; (e) TPAP, NMO, CH_2Cl_2, 68%; (f) H_2, Lindlar's catalyst, MeOH, 94%.

representing a new entry into the enantioselective synthesis of vinyllactones. The synthesis started with 1,4-butanediol (**23**), which was first transformed into its monoprotected THP ether **24** by using an excess of the diol (2.5 equiv.) to reduce the formation of the doubly protected diol. The aldehyde **25** was prepared from **24** by standard oxidation with PDC and used in a Grignard reaction with octynylmagnesium bromide to obtain 4-hydroxy-1-(2-tetrahydropyranyloxy)dodec-5-yne (*rac*-**26**). Deprotection afforded dodec-5-yne-1,4-diol (*rac*-**27**), which was oxidized with tetrapropylammonium perruthenate/*N*-methylmorpholine-*N*-oxide, furnishing dodec-5-yn-4-olide (*rac*-**28**). In this step, we successfully relied on the higher reactivity of the primary compared with the secondary alcohol function and on the formation of an intermediate lactol that would be further oxidized to

give the lactone (Bloch and Brillet, 1991; Ley et al., 1994). The alkyne was then partially hydrogenated using Lindlar's catalyst ($Pd/CaCO_3/Pb$). The product *rac*-dodec-5-en-4-olide (*rac*-**13**/*rac*-**14**) was obtained with a *Z*/*E* ratio of 8:1. The two synthetic compounds confirmed the identification of (*Z*)-dodec-5-en-4-olide as the main component from the bacterial extract and (*E*)-dodec-5-en-4-olide as the minor one. To clarify the absolute configuration of (*Z*)-dodec-5-en-4-olide, we carried out a stereoselective synthesis (Scheme 1) using the Carreira enantioselective alkynylation as the key step (Anand and Carreira, 2001). The stereogenic center was introduced by the enantioselective addition of 1-octyne to the *Si* face of the aldehyde **25** using $Zn(OTf)_2$ and (+)-*N*-methylephedrine as chiral ligand. The yield of this reaction was moderate (49%), and the enantioselectivity (>84% ee) was adequate. The ee of this step was determined by chiral GC of the final product **13**, assuming that no racemization took place during the final steps of the synthesis. Subsequent deprotection, oxidative cyclization, and partial hydrogenation as described for *rac*-**13** yielded predominantly (*R*,*Z*)-dodec-5-en-4-olide [buibuilactone, (*R*)-**13**]. The absolute configuration of natural **13** was detemined by GC on a chiral cyclodextrin stationary phase and found to be exclusively *R* for both bacterial species, identical to the configuration of the scarab beetle pheromone (Leal, 1991). Interestingly, the saturated analog 4-dodecanolide (**8**), present in both strains, showed the same configuration (*S* in this case because of the change of ligand priorities according to the Cahn, Ingold, and Prelog rules), but the other enantiomer was also present in minor amounts. The investigated samples gave *S*/*R* ratios of 92:8 for DFL-27 and 78:22 for BIO-204 (Figure 4). The absolute configuration of the minor compound (*E*)-dodec-5-en-4-olide (**14**) was not clarified because of overlapping peaks under different separation conditions.

Furthermore, strain DFL-27 produced another unsaturated lactone, dodec-6-en-4-olide (**15**), that was tentatively identified from its mass spectrum (Figure 3C). To elucidate the double-bond configuration, we carried out a total synthesis according to the route of Burger et al. (1977). The natural lactone matched both the GC and MS data of synthesized **15**.

Besides the lactones, we identified some sulfur compounds in the headspace extracts. Whereas *S*-methyl methylthiopropionate (**17**) and 4-methylthio-2-butanone (**19**) were only produced by BIO-204 in trace amounts, dimethyl trisulfide (**18**) and *S*-methyl methanethiosulfonate (**20**), one of the major compounds, were emitted by both strains under investigation. The structure of **19** was deduced from its mass spectrum and confirmed by total synthesis from 3-methylthiopropanal which will be reported elsewhere.

Additionally, trace amounts of pyrazines were found in the extracts of the bacteria. Whereas one sample of BIO-204 contained 2-butyl-3,6-dimethylpyrazine (**21**) and 2-isopentyl-3,6-dimethylpyrazine (**22**), only **21** was emitted by one culture of DFL-27. These tentative structures were derived from the mass

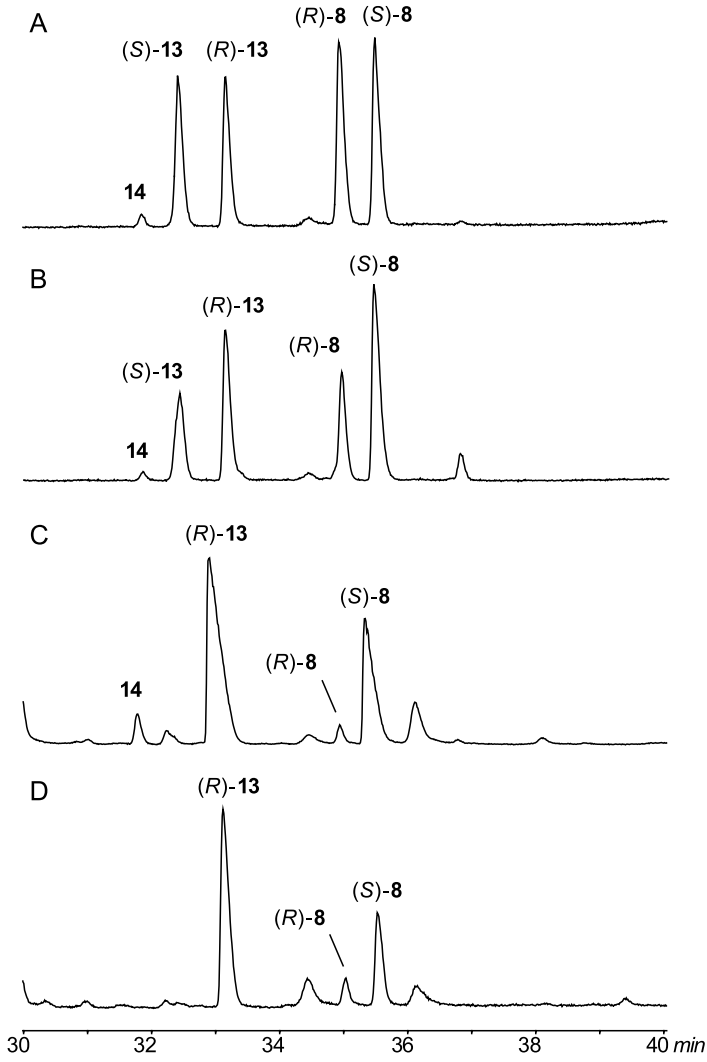

FIG. 4. Total ion chromatogram of (*Z*)-dodec-5-en-4-olide (**13**) and 4-dodecanolide (**8**) on a chiral 15-m heptakis-(6-*O*-TBDMS-2,3-di-*O*-acetyl)-β-cyclodextrin fused-silica capillary column, programmed from 100 to 180°C with 1.5°C/min. (A) Racemate; (B) racemate spiked with (*R*)-**13** and (*S*)-**8**; (C) strain BIO-204; (D) strain DFL-27.

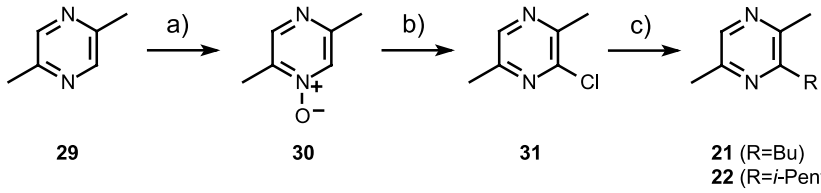

SCHEME 2. Total synthesis of pyrazines **21** and **22**. (a) $NaBO_2 \cdot H_2O_2 \cdot 3H_2O$, AcOH, 80°C, 85%; (b) $POCl_3$, reflux, 79%; (c) RMgBr, $Fe(acac)_3$, THF, NMP, 0°C, 68%.

spectra. The mass spectrum of **21** (I = 1263) showed a molecular ion of m/z = 164 and a base peak at m/z = 122 that originated from the loss of a neutral C_3H_6 fragment by McLafferty rearrangement, showing the presence of a butyl or isobutyl moiety attached to the aromatic ring. The appropriate ions at m/z = 178 (molecular ion) and m/z = 122 (loss of C_4H_8 by McLafferty rearrangement) in the case of **22** (I = 1321) suggested a pentyl, isopentyl, or 2-methylbutyl side chain. Because of the difference between the retention indices of the two compounds (ΔI = 58), we assumed that **21** should contain a butyl group, whereas **22** was likely to be the higher isopentyl homologue. These suggestions were verified by synthesis (Scheme 2). Thus 2,5-dimethylpyrazine (**29**) was oxidized to its *N*-oxide **30** (Ohta and Ohta, 1985), which was transformed into 2-chloro-3,6-dimethylpyrazine (**31**) in boiling $POCl_3$ (Inoue et al., 1985; Sato and Fujii, 1994). This pyrazine was alkylated with butyl and isopentyl magnesium bromides, respectively, with $Fe(acac)_3$ as catalysis (Fürstner et al., 2002). The pyrazines **21** and **22** were identical to the natural compounds. Furthermore, tetramethylpyrazine and 2-ethyl-3,6-dimethylpyrazine were tentatively identified in the headspace extracts. Fürstner's Grignard-iron catalyst method represents an easy access to such substituted alkylpyrazines.

DISCUSSION

The major lactone in the odor bouquet of *Loktanella* strain BIO-204 and *Dinoroseobacter shibae* strain DFL-27 was identified as enantiomerically pure buibuilactone, (*R*,*Z*)-dodec-5-en-4-olide (**13**), accompanied by its diastereomer (*E*)-dodec-5-en-4-olide (**14**), and the regioisomer (*Z*)-dodec-6-en-4-olide (**15**). Buibuilactone was first identified as the sex pheromone of the cupreous chafer beetle, *Anomala cuprea* (Coleoptera: Scarabaeidae) (Leal, 1991). Other scarab beetle species using **13** as a pheromone component, sometimes in combination with other compounds such as (*E*)-2-nonen-1-ol and (*R*,*Z*)-tetradec-5-en-4-olide (**16**, japonilure), include *Anomala daimiana* (Leal, 1993), *A. octiecostata* (Leal

et al., 1994a), *A. albopilosa sakishimana* (Leal et al., 1994b), and *A. solida* (Tóth et al., 2003). Furthermore, (*R*,*E*)-dodec-5-en-4-olide (**14**) was identified as a female-specific component of *A. albopilosa sakishimana*. This compound was also present in the investigated bacterial headspace samples.

Several enantioselective syntheses of buibuilactone have been reported, but the control of the stereochemistry with high enantiomeric purity always proved to be challenging. Different approaches, such as the use of chiral reducing agents and further purification by enantiomeric resolution (Leal, 1991), kinetic resolution by application of enzymes (Fukusaki et al., 1992, 1998), or synthetic routes using chiral pool synthons (Koseki et al., 1993), have been used. Furthermore, structurally related (*R*)-japonilure has been synthesized in high enantiomeric purity (>99% ee) from (*R*)-glutamic acid (Tumlinson et al., 1977). Other syntheses of japonilure using chiral precursors started from D-ribose (Ebata et al., 1992; Koseki et al., 1993), D-glucose (Salas-Reyes, 1995), or (*S*)-glycerol-2,3-acetonide (Chattopadhyay et al., 1990). Several synthetic approaches to japonilure using asymmetric reducing agents for the preparation of chiral propargylic alcohol intermediates have been developed, e.g., BINAL-H (Nishizawa et al., 1981; Senda and Mori, 1983; Noyori et al., 1984; Mori, 1996) or 9-(pinan-3-yl)-9-borabicyclo[3.3.1]nonane (Midland and Tramontano, 1980; Midland and Nguyen, 1981; Baker and Rao, 1982). The optical yields in these reduction steps varied widely and have rarely been satisfactory (74–98% ee). Furthermore, in these procedures, up to three equivalents of the chiral reducing agents were necessary. Other synthetic routes to japonilure used chiral auxiliaries (Nemoto et al., 1990; Hiscox and Matteson, 2000; Papillon and Taylor, 2002). The separation of the enantiomers of a racemic intermediate in the synthesis of (*R*)-japonilure was carried out by kinetic resolution using enzymes (Sugai et al., 1990; Fukusaki et al., 1991) or chiral derivatization reagents for the formation of easily separable diastereomers (Pirkle and Adams, 1979; Sato et al., 1979), thus limiting the yield in these key steps to 50%. In contrast to all these synthetic routes leading to (*R*)-**13** or (*R*)-**16**, respectively, our enantioselective synthesis of (*R*)-**13** was carried out with only catalytic amounts of (+)-*N*-methylephedrine and $Zn(OTf)_2$ in the key step, the enantioselective Carreira alkynylation. The enantiomeric excess of (*R*)-**13** was 84%.

The biosynthesis of buibuilactone in *A. cuprea* has been elucidated (Leal et al., 1999). Hexadecanoic acid is transformed to (*Z*)-9-hexadecenoic acid by the action of a Δ^9-desaturase. The stereogenic center of natural buibuilactone is introduced by an 8-hydroxylase furnishing (*R*,*Z*)-8-hydroxyhexadec-9-enoic acid with high chain length specificity. Two β-oxidation steps and subsequent cyclization complete the biosynthesis of **13** by *A. cuprea*. Analogous enzymes are also known from the Alphaproteobacteria. The Δ^9-desaturase (stearoyl-CoA-desaturase, E.C. 1.14.19.1) is, besides Eukarya, also present in Prokarya such as the fully sequenced bacteria *Rhodospirillum baltica* and *Rickettsia typhi*, which

belong to the Alphaproteobacteria subclass such as the strains analyzed here (KEGG database, http://www.genome.jp/dbget-bin/www_bget?ec:1.14.19.1). The stereospecific enzyme palmitoleic acid hydroxylase belongs to the fatty acid hydroxylase family of enzymes (http://www.genome.jp/dbget-bin/www_bget?ec:1.14.15.3). Although they have originally been described as eukaryotic enzymes, these enzymes have been recently found in some bacteria, especially in *Bacillus* sp. and in Alpha- and Gammaproteobacteria, including an uncultured marine Alphaproteobacterium (de la Torre et al., 2003; accession number Q6UCQ5 in the EMBL database). Thus, buibuilactone may be formed by the bacteria by a similar pathway as present in the beetles.

The isomeric (*Z*)-dodec-6-en-4-olide (**15**), found in the headspace of DFL-27, was previously identified as a constituent of gland secretions of several mammals, including the tarsal gland secretions of the black-tailed deer *Odocoileus hemionus columbianus* (Brownlee et al., 1969; Müller-Schwarze, 1969) and the interdigital gland secretions of the bontebok *Damaliscus dorcas dorcas* (Mammalia: Bovidae) and the blesbok *Damaliscus dorcas phillipsi* (Burger et al., 1977, 1999). It was later shown that this compound does not originate from the tarsal glands but from the animal's urine and is extracted by the tarsal hair tuft (Müller-Schwarze et al., 1977). Interestingly, the aerobic bacterium *Planococcus citreus*, isolated from the secretion of both species, produces **15** when cultured (Burger et al., 1999). Furthermore, **15** was identified in plant extracts of *Polianthes tuberosa* (Maurer and Hauser, 1982), *Morinda citrifolia* (Farine et al., 1996), and in the fungus *Penicillium roqueforti* (Chalier and Crouzet, 1998).

Alkylated pyrazines are known from a number of Hymenoptera (Wheeler et al., 1982), and the occurrence of pyrazines in insects has been reviewed (Brophy, 1989). The two pyrazines, 2-butyl-3,6-dimethylpyrazine (**21**) and 2-isopentyl-3,6-dimethylpyrazine (**22**), respectively, were minor constituents of the headspace volatiles of the bacteria. Compound **22** is an alarm pheromone of the ponerine ants *Odontomachus hastatus* and *O. clarus* (Wheeler and Blum, 1973), and **21** and **22** both occur in the mandibular gland secretions of the ant *Dinoponera australis* (Oldham and Morgan, 1993; Oldham et al., 1994). In more recent investigations on other species of the Ponerinae subfamily, **21** and **22** were found in mandibular and abdominal gland secretions (Morgan et al., 1999, 2003), and **22** was identified in cephalic extracts of two ponerine *Mesoponera* spp. (Fales et al., 1988) and two *Anochetus* spp., respectively (Jones et al., 1999). The isopentyl derivative **22** was also present in the heads of the argentine ant *Iridomyrmex humilis*, now called *Linepithema humile* (Cavill and Houghton, 1974a, b). Furthermore, this pyrazine was found as a trace compound in cephalic secretions of female *Epeolus cruciger* bees (Tengö et al., 1982). The related pyrazine 2-ethyl-3,6-dimethylpyrazine is a trail pheromone of several ant species belonging to the Myrmicinae (Billen and Morgan, 1998).

The structural similarities between the insect pheromones and bacterial volatiles are striking. The co-occurrence of single unsaturated lactones and a range of saturated analogs parallels the situation in some insect pheromone glands in which an active unsaturated compound is accompanied by several inactive analogs. The different enantiomeric purities of the lactones may reflect enzyme specificity targeted toward **13**. Furthermore, we found lactones in only relatively few of the many strains we investigated (Dickschat and Schulz, unpublished). However, we do not know yet the biological function of the lactones in the ecology of these marine bacteria.

Finding identical compounds in two totally independent habitats (marine and terrestrial) raises the question as to whether symbiotic bacteria or other microorganisms might be involved in the formation of the chafer or ant pheromones, as has been shown to be the case for phenol in another scarabaeid, the grass grub chafer, *Costelytra zealandica* (Hoyt et al., 1971). Other examples in which bacteria or other microorganisms appear to be involved in insect pheromone biosynthesis include guaiacol in the locust *Schistocerca gregaria* (Dillon et al., 2000), oxidized terpenes in bark beetles (Brand et al., 1975, 1976; Leufvén et al., 1984), and mellein in a male butterfly (Kunesch et al., 1987). The existence of elaborate symbiotic insect–bacterial relationships has been shown (Boursaux-Eude and Gross, 2000), and, therefore, the possibility exists that the normally tightly regulated pheromone production may nevertheless be performed by symbiotic bacteria, as seems to be the case in the mammal *Damaliscus dorcas* mentioned above.

Contrary to lactones, pyrazines represent one of the major compound classes of bacterial volatiles (Dickschat and Schulz, unpublished), and the same or similar compounds are also relatively widespread as pheromones in ants (Brophy, 1989; Billen and Morgan, 1998). Ants are well known for the presence of multiple endosymbionts (Schröder et al., 1996; van Borm et al., 2002), and, therefore, a bacterial involvement in the production of these compounds may be possible.

Nevertheless, other explanations for the structural similarities exist. The compounds under discussion might be structurally well suited for their tasks, so that convergent evolution in different organisms may have resulted in the formation of identical compounds, which might not interfere because of biological separation. Another explanation might be nonsymbiotic relationships between bacteria and insects, as well as the exchange of genes during evolution, leading to similar biosynthetic options. More research on the biosynthesis and biology of insect pheromones and bacterial volatiles is needed to address some of these questions.

Abstract—In recent years a negative influence of diatom-derived α,β,γ,δ-unsaturated aldehydes (PUA) on the reproductive success of copepods and invertebrates has been suggested. Since adverse chemical properties of diatoms would question the traditional view of the marine food web, this defense mechanism has been investigated in detail, but the PUA-release by test organisms has only been determined in a few cases. The observed effects were nevertheless frequently discussed from a general point of view often leading to contradictory conclusions. We have examined the PUA-production of 51 diatom species (71 isolates) in order to provide a basis for the interpretation of laboratory and field results on the influence of diatom food on the reproductive success of their consumers. PUA-production is species and strain dependent. Thirty-six percent of the investigated species (38% of the cultivated isolates) release α,β,γ,δ-unsaturated aldehydes upon cell disruption in concentrations from 0.01 to 9.8 fmol per cell. *Thalassiosira rotula* and *Thalassiosira pacifica*, major spring-bloom forming diatoms

isolated from Roscoff (Bretagne, English Channel, France) and Puget Sound (Washington, USA) were among the PUA-producing strains.

Key Words—Alga/herbivore interactions, plankton, pentafluorobenzylhydroxylamin, copepod, reproductive success

INTRODUCTION

Diatom-derived α,β,γ,δ-unsaturated aldehydes (polyunsaturated aldehydes, PUA) can interfere with the hatching success and larval development of copepods as well as with the embryonic development of invertebrates (see Ianora et al., 2003 and Pohnert, 2005 for reviews). Diatoms are unicellular algae that contribute substantially to the phytoplankton and are thus an important base of the marine food web. A generally negative impact of diatoms on herbivores would have major implications for the classical concept of plankton ecosystem functioning. Therefore, numerous studies, mainly based on laboratory experiments, have been carried out to clarify this predator-prey relationship. While some authors have proposed a deleterious effect of diatoms (Ianora et al., 2003), others have not found any adverse effects (e.g., Jonasdottir et al., 1998). Moreover, no general negative relationship between copepod egg hatching and diatom biomass was detected in the global field survey by Irigoien et al. (2002). Most of these studies correlated hatching parameters to the presence or absence of diatoms rather than monitoring PUA production of the diet, even if this is the postulated determining factor in these interactions. This is surprising, since only a few marine and fresh water diatoms have been investigated for PUA-production (Pohnert, 2005). Indeed, some of the controversially discussed results on reproductive parameters (Paffenhöfer et al., 2005) might be explained by variability of PUA production in different diatom species. To overcome this limitation and to provide a basis for further ecological and modelling studies, we conducted a survey of volatile PUA-production from representative diatoms of the major classes by using a protocol based on in situ trapping of the reactive metabolites (Wichard et al., 2005).

METHODS AND MATERIALS

Cultivation. Seventy one diatom-isolates from different sources were investigated (Table 1). All isolates were grown in stationary cultures using 250 ml jars containing 100 ml artificial medium (Table 1). Sylvania (Germany) "Cool white deluxe (F36W 840, 4000K)" tubes provided illumination. A light regime of 16:8 (light/dark) with 30–40 $\mu E/m^2/sec$ light intensity was used. Generally, the growth temperature was 15.5°C, except for *Thalassiosira*

aestivalis and *Skeletonema costatum* (CCMP 784), which were grown at 13°C and 23°C, respectively. Cultures reached the stationary phase after 2–3 wk, when 60–90 ml (10^4-10^6 cells/ml culture medium, depending on species) were harvested. The cell morphology of each culture was checked prior to harvest with light microscopy. Cells were counted with a Neubauer-improved haemocytometer in four replicates. The counting variance ranged from 10–35%.

Quantitative PUA Analysis. The cultures were harvested by filtration as described in Wichard et al. (2005). For a first rapid screening of the cultivated isolates, solid phase microextraction was performed with a polydimethylsiloxan fiber after wounding by sonication as described in Pohnert et al. (2002). To quantify PUA release upon cell damage, a protocol based on derivatization of PUA with O-(2,3,4,5,6-pentafluorobenzyl) hydroxylamin hydrochloride

(PFBHA·HCl) and subsequent GC/MS (EI) analysis was applied (Wichard et al., 2005). The limit of quantification for PUA in concentrated diatom cultures was 5 ng/ml. Each analysis was performed in triplicate.

Quantitative Chlorophyll a + c analysis. In cases where PUA were determined, the chlorophyll content of the diatom isolates was quantified as well. The extraction in 90% acetone and quantification was performed in triplicate according to the standardized method No 446.0 (U.S. Environmental protection agency: Microbiological and Chemical Exposure Research and references herein). Jeffrey and Humphrey's trichromatic equations were applied: Chlorophyll a (mg/l) = 11.85 E_{664} – 1.54 E_{647} – 0.08 E_{630} and Chlorophylls $c_1 + c_2$ (mg/l) = −1.67 E_{664} – 7.60 E_{647} + 24.52 E_{630}. Each value was corrected by the absorbance at 750 nm. The ratio of PUA to Chl a + c of identical culture batches was calculated as PUA/Chl (ppm) = PUA (μg/ml)/Chl (μg/ml) × 1,000,000.

Determination of Cell Volume. Living cells were measured microscopically in planar view (minimum: 20 cells). Linear measurements were converted to cell volume using different geometric approximations: a cylinder for *Chaetoceros compressus*, *Guinardia deliculata*, *Melosira* spp., *Skeletonema subsala-*

Footnotes to Table 1

Note. A cross (+) identifies a diatom as PUA-producer. Among those, several strains were selected for quantification (see Table 2).

[a] Applied analytical method.

[b] f_2 = marine enriched medium (artificial seawater) and K = K medium (filtered seawater), see for references Pohnert et al., 2002; WC = fresh water medium; br = brackish water: f_2 medium diluted with Chu-12 medium (2 + 1), see for references Carotenuto and Lampert, 2004.

[c] Only traces of PUA were detected after PFBHA derivatisation.

[d] Strains were isolated from coastal waters off Roscoff in 2004.

[e] Strains were isolated (cruise number of research vessel "C.A. Barnes" in parenthesis) from Dabob Bay, Point Wells or Friday Harbour (Puget Sound and San Juan Island, respectively, Washington, USA) in 2001–2003.

tum, and *Thalassiosira* spp.; a cylinder + 2 half spheres for *Skeletonema costatum* and *Skeletonema pseudocostatum*, and a cone for *Asterionellopsis glacialis*. The carbon content was determined by the carbon to volume relationship based on the equation C (pg/cell) = 0.288 × volume$^{0.811}$ (Menden-Deuer and Lessard, 2000). The PUA to carbon ratio was calculated as PUA/C (ppm) = PUA (fg/cell)/C (fg/cell) × 1,000,000.

RESULTS AND DISCUSSION

Seventy one diatom-isolates were analyzed for PUA-formation upon cell damage by sonication. The diatoms were either obtained from algal collections or freshly isolated from coastal waters off Roscoff (48°45′ N and 3°58′ W, Bretagne, France) and during several cruises to Dabob Bay, Point Wells and Friday Harbour (47° 46.14′N and 122° 50.10′W/47° 44.63′ N and 122° 25.34′ W/48.535° N and 123.005° W, Washington, USA). A total of 50 different species was investigated, with an emphasis on the family Thalassiosiraceae and the species *Phaeodactylum tricornutum*, because these diatoms are widely used in bioassays on the reproductive success of copepods (Miralto et al., 1999; Pohnert et al., 2002; Paffenhöfer et al., 2005). Under defined culture conditions (see Method section), 27 PUA-producers were identified among the 71 isolates investigated (Table 1). Out of the PUA producers, two released the unsaturated aldehydes only in trace amounts. The PUA-production upon wounding of 20 selected isolates (18 marine and 2 freshwater) was quantified during the stationary growth phase. PUA-production ranged from 0.01 fmol PUA/cell (*Thalassiosira nordenskioeldii*) to 9.8 fmol PUA/cell (*Thalassiosira pacifica*) (Table 2). This wide range over four orders of magnitude, as well as the isolate-dependent variability of structurally different unsaturated aldehydes, reflects a high plasticity within the Bacillariophyceae.

Since the calculation of PUA per cell underestimates the aldehyde contribution of species with low cell volume but probably high cell abundance in a typical herbivore diet, the PUA to carbon (PUA/C) and the PUA to chlorophyll a + c (PUA/Chl) ratio were also calculated. With respect to the PUA/Chl and PUA/C ratios, other dominant producers, such as *Skeletonema pseudocostatum* (PUA/Chl = 40,650 ppm) or *Skeletonema costatum* (SAG 19.99, PUA/C = 488 ppm), come to the fore.

Within the Bacillariophyceae, more than half of the investigated species do not produce PUA upon wounding in the stationary growth phase. In the light of the ongoing discussion about the influence of diatoms on herbivores, this result stresses that a general PUA-mediated effect can not be assumed for any given phytoplankton bloom, but that a species and strain-specific analysis is required.

Note. Species sorted by descending total amount of PUA released (fmol/cell). Valuse: mean ± SD.

[a] Traces were detected;

[b] See reference (Carotenuto and Lampert, 2004);

[c] While Pohnert et al. (2002) did not detect any PUA in this strain using solid phase microextraction, the more sensitive PFBHA-derivatisation reveals that this species has to be considered as a weak PUA-producer. Isomeric mixtures of C7:2 = 2,4-heptadienal, C8:2 = 2,4-octadienal, C8:3 = 2,4,7-octatrienal, C10:2 = 2,4-decadienal and C10:3 = 2,4,7-decatrienal were detected.

Recently, the hypothesis that PUA-production could be the reason for poor copepod reproductive success during spring blooms of diatoms was proposed (Ianora et al., 2004). In this context, it is interesting to note that some of the most abundant spring-bloom forming species like *Thalassiosira* spp. (e.g. *Th. rotula* and *Th. pacifica*) release high amounts of PUA. These species were isolated from different habitats, such as the Adriatic Sea (Miralto et al., 1999), the coastal waters off Roscoff (NE Atlantic) and Dabob Bay (NE Pacific).
Because the ability to produce PUA is distributed heterogeneously in the major classes of Bacillariophyceae, one cannot predict the defensive potential of certain species. Moreover, PUA-production within different isolates of one species ranges widely, and thus case-specific chemical investigations accompanying bioassays are required. For example, the different *Thalassiosira rotula* isolates investigated release PUA in a wide range of concentrations from 0.15 to 6.34 fmol/cell. In this study, only cultures in the stationary growth phase were investigated. This culture condition was selected since it is also used in most laboratory investigations. Additional variation of PUA-production during different phases of diatom blooms or growth phases of cultures might have to be taken into account as well.

Based on this survey, we not only recommend performing future bioassays along with chemical analyses, but also urge for a reconsideration of the general conclusions drawn in the past. It is likely, that the observed reduction of hatching success in several studies/regions may not be due to the formation of deleterious PUA, but may have other causes. On the other hand, in regions where major PUA producers are the main constituents of blooms, there might be effects on the reproduction of herbivorous grazers and their population dynamics (Ianora et al. 2004; Halsband-Lenk et al. unpublished). Whether secondary production can be significantly affected by this chemically mediated interaction in such ecosystems requires further investigation.

Acknowledgment—We are grateful to all curators providing for algal collection of scientific usage. The authors acknowledge the financial funding of the Deutsche Forschungsgemeinschaft (T.W., G.P.), the EGIDE-PROCOP exchange program and the French program "Biodeversité et Changement Global". Prof W. Boland is acknowledged for helpful support and discussion during the preparation of this manuscript.

RAPID COMMUNICATION

DIFFERENTIAL UTILIZATION OF PYRROLIZIDINE ALKALOIDS BY MALES OF A DANAID BUTTERFLY, *Parantica sita*, FOR THE PRODUCTION OF DANAIDONE IN THE ALAR SCENT ORGAN

KEIICHI HONDA,* YASUYUKI HONDA, SATOSHI YAMAMOTO, and HISASHI ÔMURA

(Received September 30, 2004; revised December 2, 2004; accepted December 6, 2004)

Published Online December 11, 2004

Abstract—Males of the chestnut tiger butterfly, *Parantica sita*, secrete danaidone as a major component from the alar androconial organ (sex brand). Since danaidone has been postulated to be derived from various pyrrolizidine alkaloids (PAs), which males ingest as adults from PA-containing plants, we conducted oral administration tests of several PAs to examine their availability for danaidone production by *P. sita* males. Males fed with a mixture of intermedine (80%) and lycopsamine (20%) produced danaidone at an average of 25.7 μg per individual, which was comparable to that found in field-caught males. In contrast, a smaller amount of danaidone (5.7 to 7.0 μg/male) was formed when males ingested retronecine or heliotrine, and those fed with an HCl salt of monocrotaline or retrorsine produced only traces of danaidone (<0.5 μg/male). In addition, males showed a strong feeding response to intermedine/lycopsamine, whereas the other PAs elicited no positive feeding behavior. These results indicate that, unlike the arctiid moths, *P. sita* males can only successfully convert limited chemical types of PAs into danaidone, and further suggest that in the field, males selectively ingest particular PAs that are readily transformable into danaidone.

Key Words—Androconial secretion, sex brand, *Parantica sita*, danaidae, pyrrolizidine alkaloids, biosynthesis, danaidone, dihydropyrrolizine.

INTRODUCTION

Males of most danaid butterflies possess characteristic androconial organs, viz. abdominal hairbrushes (hairpencils) and alar patch- or pouch-like glands (sex brand), which secrete a variety of compounds that are thought to serve as pheromones during the courtship behavior (Boppré and Vane-Wright, 1989). Dihydropyrrolizine derivatives such as danaidone, hydroxydanaidal, and danaidal are the components most frequently encountered in danaid secretions (Schulz, 1998). Adults of danaids, particularly males, often gather on withering or dead plants containing pyrrolizidine alkaloids (PAs) to ingest the alkaloids. Plant-acquired PAs are sequestered in the body tissue and used as precursors for pheromone production and also for chemical defense against predators (Eisner and Meinwald, 1987). Similar pharmacophagous acquisition and utilization of PAs have also been reported for many ithomiid butterflies (Schulz et al., 2004) and larvae of some arctiid moths (Hartmann et al., 2003).

Males of *Parantica sita*, an Asian danaid butterfly, have been reported to secrete two dihydropyrrolizines, danaidone (major) and hydroxydanaidal (minor), from both the sex brand and hairpencils (Komae et al., 1983). In some arctiid moths, the biosynthetic pathway of hydroxydanaidal from PA precursors has hitherto been studied intensively (Schulz et al., 1993; Hartmann et al., 2003), while little is known about the mechanisms by which danaid butterflies produce dihydropyrrolizines. Since the finding by Schneider et al. (1975) that danaidone is derived from PAs in *Danaus* butterflies, danaid butterflies are also believed to make use of diverse PAs for the production of dihydropyrrolizines. This study investigated whether PAs containing various structures of necic acids were equally utilized by *P. sita* males for danaidone formation in the sex brand.

METHODS AND MATERIALS

Insects. Males of *P. sita* originated from the population of Hiroshima and its neighbor prefectures of Japan. Larvae were reared on potted *Cynanchum caudatum*, *Tylophora tanakae,* or *Marsdenia tomentosa* plants (Asclepiadaceae) under standard laboratory conditions (16L-8D, 23–24°C). Newly emerged male adults were kept in transparent plastic chambers (25 × 35 cm; height, 21 cm) at 25°C under a 16L-8D regime and fed with 15% aq. sucrose solution once daily throughout the experiments.

PAs. Monocrotaline (Aldrich, purity: 99%), retrorsine (Aldrich, 97%), and heliotrine (Latoxan, 98%) were commercially purchased. Since monocrotaline and retrorsine were sparingly soluble in water, their HCl salts were prepared. Retronecine (98% by GC and NMR) was prepared from monocrotaline

(Bogner and Boppré, 1989). A PA mixture composed of intermedine (80%) and lycopsamine (20%) was isolated from a methanol extract of *Eupatorium chinense* (Compositae) roots collected in Hiroshima prefecture, and purified by ion-exchange chromatography (Accell Plus CM and QMA, Waters). Their structures and purity (95%) were determined by GC-MS and NMR (Roeder, 1990). The chemical structures of these PAs are shown in Figure 1.

Feeding Response to PAs. Ten 7-d-old males were tested. An individual, which had been given 15% aq. sucrose to satiety before the bioassay, was placed on a filter paper strip (20 × 20 mm) impregnated with a 2.5% w/v (net concentration of PA) aq. solution of a PA. One μl of the same solution was applied with a microsyringe to the coiled proboscis. Manifestation of a sequential behavior consisting of proboscis extension and sucking for more than 30 sec was appraised as positive. The response was expressed as the percentage of individuals that responded positively.

Oral Administration of PAs and Quantitative Analysis of Danaidone. After 7 d of eclosion, individual males were fed daily with 0.2 mg (net weight of PA) of any one of the PA samples for 7 d (1.4 mg/male). Several PA samples that

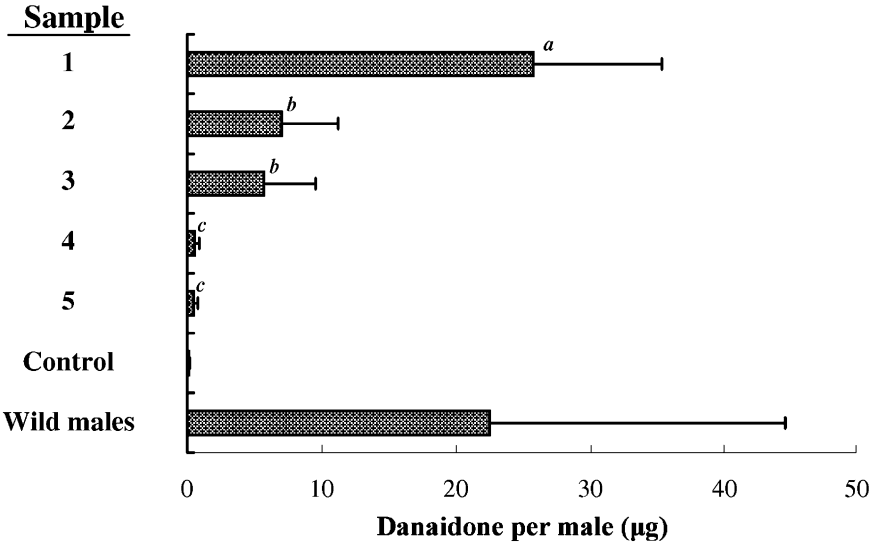

FIG. 2. Amount of danaidone (mean + SD) in the sex brand of *P. sita* males subjected to PA-administration tests or captured in the field. Sample numbers correspond to those of PAs shown in Figure 1. $N = 10$. Different letters represent statistically significant Mann–Whitney rank sum comparisons ($P < 0.001$).

did not stimulate spontaneous feeding were compulsorily given to males together with 15% sucrose solution. Control males were fed with plain sucrose solution only. Ten individuals were used for each treatment. On d 14 of emergence, a pair of sex brands on the hindwings were dissected individually, extracted with 100 μl of purified dichloromethane, and stored at −20°C until use. Quantitative determination of danaidone was performed as described previously (Honda et al., 1995) using benzyl alcohol as the internal standard. Ten wild males collected in the field of Hiroshima prefecture in July, 2001 were also examined for danaidone content by the same method.

RESULTS AND DISCUSSION

Male adults of *P. sita* showed strong positive feeding responses to intermedine/lycopsamine, whereas none of the other PAs stimulated feeding (Figure 1). These results indicate that the males have definite preferences for particular PAs, and also suggest that they selectively ingest certain PAs in the field.

Males that were given intermedine/lycopsamine (**1**) produced the largest amount (25.7 μg/male) of danaidone, which was comparable to that found in wild males (Figure 2). However, uptake of retronecine (**3**) or heliotrine (**2**) resulted in the formation of smaller amounts (5.7 and 7.0 μg/male, respectively) of danaidone, while macrocyclic diester-type PAs, i.e., retrorsine (**4**) and monocrotaline (**5**), were almost ineffective for danaidone formation. Although the number of PA molecules administered differed among the samples depending on their molecular weights, we think that this matters little, because males were given a large excess of PA; the incorporation of compound **1** into danaidone amounted to a low 4% molar proportion.

PAs are undoubtedly the biosynthetic precursors of danaidone, however, it is evident that not all types of PAs are equally utilized for its production. This means that the efficiency of biosynthesis of danaidone, which is apparently derived from a necine base of PAs, depends largely on the chemical structure of the necic acid moieties. At present, however, we cannot determine whether both intermedine and lycopsamine serve as precursors for danaidone.

In contrast, in polyphagous arctiid moths, hydroxydanaidal, which is also a necine base-derived compound, is considered to be formed from diverse plant-acquired PAs, including macrocyclic PAs through their hydrolysis by an unspecific esterase, followed by several characteristic reactions (Hartmann et al., 2003). Therefore, *P. sita*, unlike arctiid moths, may lack a similar esterase that catalyzes the hydrolysis of cyclic or diester PAs and, thus, have a poor ability for processing retronecine. The configuration of a hydroxy group at C-7, however, does not seem to exert a decisive influence on danaidone formation, because heliotrine (7*S*) also afforded danaidone in a small but significant quantity, similar to that produced from retronecine (7*R*). A similar instance has been reported for the arctiid moth, *Creatonotos transiens*, which can utilize 7*S*-heliotrine for the production of 7*R*-hydroxydanaidal (Schulz et al., 1993).

The precursors that *P. sita* males can successfully transform into danaidone seem to be limited to particular PAs, and only those with high availability appear to evoke strong feeding responses. The present findings provide important information on the mechanisms involved in the attraction to and ingestion and utilization of PAs by danaid butterflies in regard to dihydropyrrolizine biosynthesis.

RAPID COMMUNICATION

SHORT AND SIMPLE SYNTHESES OF 4-OXO-(*E*)-2-HEXENAL AND HOMOLOGS: PHEROMONE COMPONENTS AND DEFENSIVE COMPOUNDS OF HEMIPTERA

JARDEL A. MOREIRA and JOCELYN G. MILLAR*

Department of Entomology, University of California, Riverside, CA 92521

(Received November 18, 2004; accepted December 13, 2004)

Published Online December 14, 2004

Abstract—One-step syntheses of 4-oxo-(*E*)-2-hexenal and 4-oxo-(*E*)-2-octenal from commercially available 2-ethyl- and 2-butylfuran are described. A two-step synthesis of the homolog 4-oxo-(*E*)-2-decenal from furan is also reported. These compounds are common components of true bug defensive secretions, and recently have been identified as pheromone components for several species. The simple syntheses reported here will make these compounds readily available for further research.

Key Words—4-Oxo-(*E*)-2-alkenal, true bug, Hemiptera, Heteroptera, allomone, attractant

INTRODUCTION

4-Oxo-(*E*)-2-alkenals of 6, 8, and 10 carbon chain lengths are common components of the defensive secretions of true bugs (Hemiptera) (Aldrich, 1988, 1995; Millar, 2004). More recently, these compounds also have been identified as pheromone components of nymphal (Fucarino et al., 2004) and adult bugs (Innocenzi et al., 2004; Millar, 2004). Several syntheses of these compounds have been reported (e.g., Ward and van Dorp, 1969; Marques et al., 2000; Zarbin et al., 2000), but most have required at least several steps. Because of the increasing interest in these compounds, and in an effort to make them readily available to other researchers, we report here simple, one step syntheses of 4-oxo-(*E*)-2-hexenal and 4-oxo-(*E*)-2-octenal from commercially available 2-

ethyl- and 2-butylfurans respectively, and the two step synthesis of the ten carbon analog from furan. The ready availability of these compounds should also enhance their potential for exploitation for insect pest management.

METHODS AND MATERIALS

Tetrahydrofuran (THF) was distilled from sodium/benzophenone ketyl under argon. ^{1}H- and ^{13}C-NMR spectra (400 and 100 MHz, respectively) were obtained in $CDCl_3$ solutions with a Varian INOVA-400 spectrometer. Mass spectra were obtained with an Hewlett-Packard 5970 (70 eV) mass selective detector interfaced to an H-P 5890 gas chromatograph fitted with a DB5-MS column (25 m × 0.20 mm id × 0.33 μm film) with helium as carrier gas (100 kPa). Products were purified by vacuum flash chromatography on silica gel (E. Merck, 230-400 mesh).

Synthesis of 2-n-Hexylfuran. Butyl lithium (2.5 M in hexanes, 5.9 ml, 14.7 mmol) was added dropwise to a stirred solution of furan (1.00 g, 14.7 mmol) in dry THF (60 ml) at −20°C under argon atmosphere. The resulting mixture was stirred for 3 hr, then 1-iodohexane (3.12 g, 14.7 mmol) in dry THF (8 ml) was added dropwise. The solution was stirred at −20°C for 2 hr and room temperature for 1 hr, then quenched with water. The mixture was extracted with 1:1 ether-pentane (3 × 20 ml). The combined organic layers were washed with aqueous 5% sodium bisulfite solution (2 × 30 ml), water (2 × 50 ml), and brine (2 × 50 ml), then dried over Na_2SO_4 and concentrated. The crude product was purified by vacuum flash chromatography over silica gel eluting with pentane to afford 2.01 g of the product (89.8% yield). ^{1}H NMR δ 0.89 (*t*, 3H, J = 7.0 Hz), 1.24–1.44 (*m*, 6H), 1.63 (quint, 2H, J = 7.6 Hz), 2.62 (*t*, 2H, J = 7.6 Hz), 5.95–5.98 (*m*, 1H), 6.27 (dd, 1H, J = 2.0 and 3.1 Hz), 7.29 (dd, 1H, J = 0.8 and 2.0 Hz). ^{13}C NMR δ 14.31, 22.81, 28.22, 28.24, 29.10, 31.82, 104.71, 110.24, 140.84, 156.87 ppm. MS (*m/z*, rel. intensity): 152 (M^+, 13), 123 (5), 109 (3), 95 (14), 81 (100), 67 (6), 53 (20), 43 (8).

Synthesis of 4-Oxo-(E)-2-hexenal. N-bromosuccinimide (2.72 g, 15.3 mmol, 1.5 eq.) and pyridine (1.61 g, 20.4 mmol, 2 eq.) were sequentially added to a solution of 2-ethylfuran (1.00 g, 10.2 mmol, 1 eq.; Lancaster Synthesis, Pelham, NH, USA) in THF/acetone/water (5:4:2, 22.0 ml) at −15°C. The resulting mixture was stirred for 3 hr at −15° and then warmed to room temperature and stirred overnight. The mixture was poured into aqueous HCl (0.5 M, 20 ml) and extracted with ether (3 × 20 ml). The combined organic layers were washed with brine, dried over anhydrous $MgSO_4$, and the solvent was removed by distillation. The crude product was purified by vacuum flash chromatography over silica gel (ether: pentane, 15:85) to afford 4-oxo-(*E*)-2-hexenal (0.55 g, 48%). ^{1}H NMR δ 1.15 (*t*, 3H, J = 7.2 Hz), 2.73 (*q*, 2H, J = 7.2 Hz), 6.77 (dd, 1H, J = 7.2 and 16.2

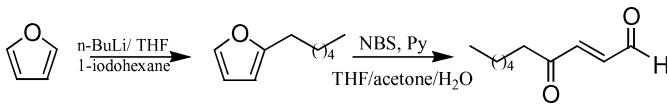
Hz), 6.88 (d, 1H, J = 16.2 Hz), 9.77 (d, 1H, J = 7.2 Hz). ^{13}C NMR δ 7.76, 34.75, 137.51, 144.98, 193.65, 200.59 ppm. MS: *m/z* 112 (M^+, 16), 97 (2), 84 (15), 83 (100), 57 (18), 55 (77), 53 (10).

Syntheses of 4-Oxo-(E)-2-octenal and 4-Oxo-(E)-2-decenal. In the same manner, 2-*n*-butylfuran (0.50 g, 4.0 mmol, Lancaster Synthesis) was converted to 4-oxo-(*E*)-octenal (0.28 g, 50% yield), and 2-*n*-hexylfuran (1.00 g, 6.6 mmol) gave 4-oxo-(*E*)-2-decenal in 56% yield (0.62 g). 4-Oxo-(*E*)-2-octenal: ^{1}H NMR δ 0.92 (*t*, 3H, J = 7.2 Hz), 1.30–1.40 (*m*, 2H), 1.58–1.68 (*m*, 2H), 2.69 (*t*, 2H, J = 7.2 Hz), 6.76 (dd, 1H, J = 7.2 and 16.2 Hz), 6.87 (d, 1H, J = 16.2 Hz), 9.77 (d, 1H, J = 7.2 Hz). ^{13}C NMR δ 14.03, 22.44, 25.93, 41.15, 137.54, 145.17, 193.66, 200.36 ppm. MS: *m/z* 140 (M^+, 1), 125 (7), 111 (39), 98 (46), 97 (13), 83 (53), 70 (40), 57 (28), 56 (15), 55 (100). 4-Oxo-(*E*)-2-decenal: ^{1}H NMR δ 0.88 (*t*, 3H, J = 6.9 Hz), 1.20–1.38 (m, 6H), 1.60–1.70 (*m*, 2H), 2.69 (*t*, 2H, J = 7.2 Hz), 6.77 (dd, 1H, J = 7.2 and 16.2 Hz), 6.87 (d, 1H, J = 16.2 Hz), 9.78 (d, 1H, J = 7.2 Hz). ^{13}C NMR δ 14.23, 22.68, 23.84, 28.98, 31.75, 41.45, 137.54, 145.19, 193.66, 200.38 ppm. MS: *m/z* 168 (M^+, 1), 153 (1), 139 (41), 125 (12), 111 (9), 98 (54), 83 (56), 70 (49), 55 (100), 43 (90).

RESULTS AND DISCUSSION

4-Oxo-(*E*)-2-alkenals were readily prepared from 2-alkylfurans, using aqueous *N*-bromosuccinimide (NBS) to promote oxidative ring opening under mild conditions (Kobayashi et al., 1998). The reaction initially produces 4-oxo-(*Z*)-2-alkenals, which are completely isomerized to the (*E*)-2-isomers after several hours at room temperature in the reaction flask. 4-Oxo-(*E*)-2-hexenal and 4-oxo-(*E*)-2-octenal were obtained in one step from commercially available starting materials in 48 and 50% isolated yields, respectively. 4-Oxo-(*E*)-2-decenal was obtained in two steps, starting from furan. Thus, treatment of furan with *n*-butyl lithium, followed by addition of one equivalent of 1-iodohexane, afforded 2-*n*-hexylfuran in 89.8% yield, which was then oxidized to 4-oxo-(*E*)-2-decenal with aqueous NBS in 56% isolated yield (Scheme 1).

Several methods have been published for the syntheses of geometrical isomers of 4-oxo-2-alkenals. For example, the routes described by Ward and van Dorp (1969), Marques et al. (2000), and Zarbin et al. (2000) furnish



SCH. 1. Synthesis of (*E*)-4-oxo-2-decenal.

stereochemically pure 4-oxo-(*E*)-2-alkenals, but both routes involve multiple steps. During the course of our work, another short synthesis was reported: thus, Fernandes and Kumar (2003) found that under appropriate reaction conditions, homoallylic alcohols react with pyridinium chlorochromate to afford 4-oxo-(*E*)-2-alkenals. This reaction was proposed to proceed by the initial oxidation of the alcohol, followed by double bond migration and subsequent allylic oxidation. However, only a limited number of the homoallylic alcohol precursors are commercially available.

In summary, the short and simple syntheses of 4-oxo-(*E*)-2-alkenals described in this communication should make these compounds readily accessible to researchers. Furthermore, the route can be readily adapted to produce homologs of any desired chain length by the straightforward alkylation of furan with an alkyl halide of the appropriate chain length.

(Received October 14, 2004; accepted January 10, 2005)

Abstract—Phenolic compounds are generally believed to be key components of the oxidative defenses of plants against pathogens and herbivores. However, phenolic oxidation in the gut fluids of insect herbivores has rarely been demonstrated, and some phenolics could act as antioxidants rather than prooxidants. We compared the overall activities of the phenolic compounds in red oak (*Quercus rubra*) and sugar maple (*Acer saccharum*) leaves in the midgut fluids of two caterpillar species, *Malacosoma disstria* (phenolic-sensitive) and *Orgyia leucostigma* (phenolic-tolerant). Three hypotheses were examined: (1) ingested sugar maple leaves produce higher levels of semiquinone radicals (from phenolic oxidation) in caterpillar midgut fluids than do red oak leaves; (2) *O. leucostigma* maintains lower levels of phenolic oxidation in its midgut fluids than does *M. disstria*; and (3) phenolic compounds in tree leaves have overall prooxidant activities in the midgut fluids of caterpillars. Sugar maple leaves had significantly lower ascorbate: phenolic ratios than did red oak leaves, suggesting that phenolics in maple would oxidize more readily than those in oak. As expected, semiquinone radicals were at higher steady-state levels in the midgut fluids of both caterpillar species when they fed on sugar maple than on red oak, consistent with the first hypothesis. Higher semiquinone radical levels were also found in *M. disstria* than in *O. leucostigma*, consistent with the second hypothesis. Finally, semiquinone radical formation was positively associated with two markers of oxidation (protein carbonyls and total peroxides). These results

* To whom correspondence should be addressed. E-mail: rvb@umich.edu

suggest that the complex mixtures of phenolics in red oak and sugar maple leaves have overall prooxidant activities in the midgut fluids of *M. disstria* and *O. leucostigma* caterpillars. We conclude that the oxidative defenses of trees vary substantially between species, with those in sugar maple leaves being especially active, even in phenolic-tolerant herbivore species.

Key Words—Prooxidant, phenolic compound, oxidation, caterpillar, *Malacosoma disstria*, *Orgyia leucostigma*, peroxide, semiquinone radical, protein carbonyl, red oak, *Quercus rubra*, sugar maple, *Acer saccharum.*

INTRODUCTION

The phenolic compounds produced by plants represent a diverse array of over 8000 known structures (Thompson, 1964; Harborne, 1985; Bravo, 1998; Vinson et al., 2001). Along with oxidative enzymes, such as polyphenol oxidases and peroxidases, phenolic compounds are generally considered to be key components of the oxidative defenses of plants against pathogens and herbivores (Duffey and Stout, 1996). The products and byproducts of phenol oxidation include semiquinone radicals, quinones, and reactive oxygen species (e.g., hydrogen peroxide and hydroxyl radicals), each of which can damage nutrients in the gut lumens of insect herbivores or produce cytotoxic effects in their tissues (Gant et al., 1988; Felton et al., 1989, 1992; Canada et al., 1990; Zheng et al., 1997; Thiboldeaux et al., 1998; Galati et al., 2002; Hagerman et al., 2003). Thus, the oxidation of phenolics is believed to be an important step contributing to their biological activity (Canada et al., 1990; Ahmad, 1992; Appel, 1993; Summers and Felton, 1994; Pardini, 1995; Barbehenn et al., 2003b).

The physiological roles played by ingested phenolics vary, however, depending upon their chemical structures and physicochemical environments (e.g., pH, redox potential, and concentrations of oxidases, oxidants, and antioxidants) (Larson, 1995; Metadiewa et al., 1999; Sugihara et al., 1999; Galati et al., 2002; Sakihama et al., 2002; Hagerman et al., 2003). For example, if certain phenolics scavenge free radicals or otherwise function as reducing agents and they have structures that form stable semiquinone or phenoxyl radicals, they can act as antioxidants (Buettner, 1993; Hagerman et al., 1998; Halliwell and Gutteridge, 1999). Indeed, recent evidence has suggested that low molecular weight phenolics may act as antioxidants in some caterpillars (Johnson and Felton, 2001).

In this study, electron paramagnetic resonance spectrometry (EPR) was used to measure the steady-state levels of semiquinone radicals (produced by the one-electron oxidation of di- or trihydroxy phenolics) in caterpillar midgut fluids. In order to distinguish between the overall prooxidant or antioxidant

activities of foliar phenolics, semiquinone radical levels were measured in conjunction with two markers of oxidation (protein carbonyls and total peroxides). We reasoned that if ingested phenolics had an overall prooxidant activity in midgut fluids, a positive association would be observed between levels of semiquinone radicals and markers of oxidation. By contrast, if semiquinone radicals were formed during the protection of other molecules from oxidation, then an overall antioxidant activity would be indicated by a negative association. In support of this rationale, previous work has shown that tannic acid in an artificial diet acts as a prooxidant in the midgut fluids of two caterpillar species: high levels of semiquinone radicals were associated with increased levels of reactive oxygen species and markers of oxidation (Barbehenn et al., 2001, 2003b, unpublished data).

Phenolic compounds have a strong tendency to oxidize at the high pH found in many caterpillar midguts (ca. pH 10) unless there is sufficient ascorbate present to chemically reduce semiquinone radicals (Barbehenn et al., 2001, 2003b). Thus, the potential for foliar phenolics to oxidize in the midgut fluids of caterpillars was predicted by examining the ratio of ascorbate to total phenolics in red oak and sugar maple leaves (Barbehenn et al., 2003b). Based on our previous work on these tree species (Barbehenn et al., 2003a), sugar maple leaves were expected to contain low ratios of ascorbate:phenolics and to produce high levels of phenolic oxidation, while red oak leaves were expected to contain high ratios of ascorbate:phenolics and to produce low levels of phenolic oxidation following ingestion.

The two caterpillar species chosen for comparison were expected to differ in their abilities to handle ingested phenolics. *Malacosoma disstria* Hübner (Lasiocampidae), the forest tent caterpillar, is a phenolic-sensitive species that feeds on the spring foliage of a wide range of deciduous trees in North America (Stehr and Cook, 1968). *Orgyia leucostigma* Smith (Lymantriidae), the white-marked tussock moth, is a phenolic-tolerant species that also feeds on a wide range of North American trees during spring and summer broods (Baker, 1972). The degree of phenolic tolerance ascribed to the two species is based primarily on the extent to which phenolics ingested in artificial diets are oxidized in their midguts and, in the case of *M. disstria*, the formation of pupal deformities (Karowe, 1989). *O. leucostigma* maintains lower levels of phenolic oxidation in its midgut fluids than does *M. disstria* (Barbehenn and Martin 1992, 1994; Barbehenn et al., 2001, 2003b), but little work has been done on the gut biochemistries of these herbivores on their host plants.

This study examined three hypotheses: (1) ingested sugar maple leaves produce higher levels of semiquinone radicals than red oak leaves; (2) *O. leucostigma* maintains lower levels of phenolic oxidation than *M. disstria*; and (3) phenolic compounds in tree leaves have overall prooxidant activities in the midgut fluids of caterpillars.

METHODS AND MATERIALS

Trees. Red oak (*Quercus rubra* L.) (N = 14) and sugar maple (*Acer saccharum* Marshall) (N = 12) were tagged at three sites in Ann Arbor, MI, USA, the University of Michigan campus, the Matthaei Botanical Garden, and the Kuebler-Langford Park. Twigs containing terminal leaf clusters from the sunlit side of trees were cut with a pole pruner. Twigs were selected haphazardly, but damaged or diseased leaves were avoided. They were placed in a flask of water and returned to the lab for feeding experiments or were placed in labeled plastic bags and kept on ice in the dark until extracted 2–4 hr later. Leaves were sampled on the 12th of June and the 10th of July 2003. In addition, preliminary measurements were made on a group of three red oak and sugar maple trees on the 14th of May. Leaf lengths were measured repeatedly in the study trees beginning in May to determine the time when leaf expansion was complete.

A representative leaf (e.g., excluding small or young terminal leaves) was selected from within each leaf cluster. These leaves were cut in half along the length of the midrib, and the thickened portion of the midrib was removed. Leaf halves were immediately weighed (200–800 mg), ground in liquid nitrogen, and extracted in 3.0 ml of 5% (w/v) metaphosphoric acid (containing 1 mM EDTA; ambient oxygen) or nitrogen-purged ethanol (Barbehenn et al., 2003a). Samples were extracted for 30 min (ambient temperature) and then centrifuged (1000 *g*, 5 min). The extraction process was repeated, and supernatant solutions were pooled within samples. Ethanolic extracts were kept under a nitrogen atmosphere, and all samples were stored at −80°C until they were analyzed. A second leaf from each cluster was weighed, after removing the midrib, and dried at 70°C for 3 d in an open glassine envelope. The water content of these leaves was used to estimate the percent dry weight (%DW) of leaves used for chemical analysis.

Insects. The main comparisons between *M. disstria* and *O. leucostigma* were made in mid-June (on recently expanded leaves) and in mid-July (on mature leaves). *M. disstria* normally completes most of its development on expanding leaves, and EPR measurements were done to coincide with this period. *M. disstria* and *O. leucostigma* eggs were obtained from the Canadian Forrest Pest Management Institute (Sault Ste. Marie, Ontario, Canada). The diet for both species was prepared as described previously (Barbehenn et al., 2001), with the exceptions that linseed oil was substituted for wheat germ oil, methyl paraben was omitted, and sodium alginate was included (2.9% dry diet). Larvae were maintained in petri dishes in incubators (primarily at 23°C, 16-hr L, 8-hr D) until the final-instar. Colonies of both species were maintained at 18°C when it was necessary to slow their growth to synchronize their developmental stages. Final-instar larvae were assigned at random to feed on red oak or sugar maple

leaves collected from three trees of each species on the University of Michigan campus. The same trees and leaf-sampling protocol were used for all experiments. Twigs with attached leaves were placed in water in 15-ml centrifuged tubes that were placed inside ventillated plastic boxes (30 × 19 × 10 cm). Leaves in June and July were coated with 200 μl of a 70% acetone solution of sucrose (2% dry weight) to promote feeding. The percent dry weight of the added sucrose was calculated based on the dry weight of untreated leaves. A micropipet was used to dispense the solvent evenly across each leaf, placing the pipette tip parallel to the leaf surface to avoid scratching the leaf. Boxes were replaced in an incubator where larvae were fed for 2 d. Freshly treated leaves were provided on the second day, using the same trees for each caterpillar species (but different trees from the previous day). On the third day of each experiment, midgut fluids were collected from dissected larvae, as described previously (Barbehenn et al., 2001). Gut fluid samples were kept under a nitrogen atmosphere at all times to avoid artifactual oxidation (Johnson and Barbehenn, 1999).

Chemical Analyses. Ascorbic acid was measured in metaphosphoric acid extracts using high-performance liquid chromatography (HPLC) (Lykkesfeldt et al., 1995; Barbehenn, 2003). Samples were stored for 1–2 mo before analysis. Total phenolics were measured in ethanol extracts using the Prussian blue assay (Price and Butler, 1977) as modified by Graham (1992), using gum arabic to stabilize the colored product. This redox assay is based on the formation of a colored complex (ferric ferrocyanide) upon the reduction of iron (Fe III) by phenolic compounds. Samples were stored for 1–3 mo before analysis. Samples were diluted 20-fold with nitrogen-purged ethanol before analysis. Purified tannic acid, composed primarily of tetra- to octagalloylglucose (J.-P. Salminen, unpublished data), was used to construct standard curves. All assays were scaled to 200 μl to fit in a 96-well microplate, and absorbances were read at 655 nm with a Bio-Rad Benchmark microplate reader (Bio-Rad, Hercules, CA, USA). To correct total phenolics measurements for the absorbance caused by foliar ascorbate, a regression between ascorbate concentration and Prussian blue formation was determined. The Prussian blue absorbance contributed by foliar ascorbate in each sample was then subtracted from the total absorbance value for each of the samples. Ascorbate accounted for 30–40% of the "total phenolics" in oak and for 20% of the "total phenolics" in maple. The unknown phenolic compositions of the tree leaves precluded reporting phenolic concentrations on a molar basis, and therefore, all concentrations were expressed on a percent dry weight basis in purified tannic acid equivalents.

To provide a general indication of the accuracy of the Prussian blue assay, total phenolics were analyzed with HPLC or the acid–butanol method (for condensed tannins). A single sample of red oak and sugar maple leaves (including each of the trees used as food plants) was collected in mid-July 2004.

Leaf samples were lyophilized, extracted in 70% aqueous acetone, and the extracts were analyzed with HPLC using a diode array detector (Salminen et al., 1999). Hydrolyzable tannins were calculated in pentagalloyl glucose equivalents (at 280 nm), flavonoids in quercetin equivalents (at 349 nm), chlorogenic acids in chlorogenic acid equivalents (at 315 nm), coumaroylquinic acids in coumaric acid equivalents (at 315 nm), and the remaining phenolics (other than condensed tannin) as gallic acid equivalents (at 280 nm). Condensed tannins were measured with the acid–butanol method (Ossipova et al., 2001), using purified birch leaf-condensed tannins as a standard.

Protein carbonyls were measured in midgut fluids with the 2,4-dinitrophenylhydrazine (DNPH) method (Reznick and Packer, 1994; Quinlan and Gutteridge, 2000). Samples (50–110 mg) were extracted in 400 μl of pH 6.5 phosphate buffer (200 mM, nitrogen-purged) containing 20 mg of hydrated polyvinylpolypyrrolidone (Sigma). Samples were collected from five to 11 replicate larvae from each insect species on each tree species on the 13th of June, and samples from 10 to 15 larvae were collected on the 15th of July (*O. leucostigma*) and 17th of July (*M. disstria*). All samples were stored under a nitrogen atmosphere at −80°C until they were analyzed after 4–4.5 mo. Protein carbonyls were measured in thawed extracts (kept on ice) after treating 200 μl of the supernatant solutions with streptomycin sulfate (22.2 μl; 10% w/v in 50 mM, pH 7.0, HEPES buffer). After centrifugation (8000 *g*, 5 min, 4°C), proteins remaining in the supernatant solution were precipitated with trichloroacetic acid (100 μl, 28% w/v). Protein pellets were treated with 500 μl of 7 mM DNPH (Acros) prepared in 2 M hydrochloric acid (37°C, 15 min). Treated protein pellets were washed free of unbound DNPH and solubilized in a guanidine hydrochloride solution (6 M; Acros) as described by Quinlan and Gutteridge (2000). An extinction coefficient of 22,000/M for the DNPH protein carbonyl adduct at 370 nm was used to calculate protein carbonyl concentrations (Reznick and Packer, 1994; Quinlan and Gutteridge, 2000). Correction for interfering substances was made by running DNPH-free controls from each of the treatments. Protein concentrations in the sample supernatants were measured with the modified Bradford assay and quantified with a bovine serum albumin standard curve (Stoscheck, 1990). Protein carbonyl levels were expressed as nanomoles protein carbonyl per milligram protein.

Total peroxides (hydrogen peroxide and organic peroxides) were measured in methanol extracts with the FOX assay (Nourooz-Zadeh et al., 1994). *M. disstria* midgut contents (25–35 mg from the mid-midgut) were extracted in 1.0 ml of 90% methanol (nitrogen-purged), and the midgut contents of *O. leucostigma* (10–20 mg) were extracted in 0.5 ml of 90% methanol. Following centrifugation (8000 *g*, 3 min), a 35-μl aliquot of the supernatant solution was diluted with 70 μl of 90% methanol. *M. disstria* (N = 14–22/tree species) were examined on the 18th of June and the 11th of July, and *O. leucostigma*

(N = 14/tree species) were examined on the 14th of July. The FOX reagent was prepared fresh daily using ambient oxygen solvents. All assays were scaled to fit in a 96-well microplate, and absorbances were read at 540 nm with a microplate reader. Measurements were made within a period of approximately 1 hr from the time of dissection. A hydrogen peroxide standard curve was used to determine total peroxide concentrations.

Electron Paramagnetic Resonance Spectrometry. Midgut contents (20 mg) were dissected from larvae, alternating between the four caterpillar/tree species combinations. Midgut contents were extracted in 300 μl of pH 10 carbonate buffer (70 mM) containing 10% (v/v) dimethyl sulfoxide (nitrogen-purged). Samples in 2.0-ml microcentrifuge tubes were kept under a nitrogen atmosphere at all times. Samples were centrifuged for 1 min (approximately 10,000 *g*, ambient temperature). Semiquinone radicals in supernatant solutions were measured with a Bruker EMX spectrometer (Bruker Instruments, Billerica, MA, USA), using the instrumental parameters described previously (Barbehenn et al., 2003b). The time between dissecting each caterpillar and starting an EPR scan was recorded. The area of each spectrum was quantified by double integration using WinEPR software (Bruker Instruments). The sizes of semiquinone radical spectra decreased above a threshold phenolic concentration in both midgut fluid samples and in standards, apparently from semiquinone radical disproportionation (unpublished data). Therefore, the EPR spectra from a range of sample dilutions of each sample type were measured to confirm that semiquinone radical intensities increased with increasing sample mass over the full range of sample masses used. Standard curves based on tannic acid were linear over a shorter range than was necessary for quantifying the large radical spectra produced by sugar maple phenolics. Therefore, semiquinone radical intensity was expressed as the double integral area/sample mass, where the double integral area is in arbitrary units determined by instrumental parameters. Semiquinone radical intensities could be compared across all sample types in this and in previous studies because the same instrumental parameters were used in all cases. Radical intensity measured as the double integral area per milligram is directly proportional to, but approximately 10- to 17-fold larger than, measurements of spectrum height per milligram used previously (Barbehenn et al., 2003b). The identity of semiquinone or ascorbyl radicals was based upon the comparison of their spectra with standards and spectra obtained previously under identical conditions (Barbehenn et al., 2003b). As observed previously, semiquinone radical spectra from sugar maple and red oak phenolics had sigmoidal line shapes similar to those of tannic acid standards.

To correct for the decay in radical spectra through time, regressions were plotted of radical intensity vs. time. Samples of the four treatment groups were run in the 15th and 16th of May (Figure 3). These regressions included three to four samples of each type that were rescanned once or twice to extend the time

range over which data were collected. Based on these regressions, semiquinone radical intensities in May, June, and July were adjusted to the levels expected after a period of 5 min. Time periods between extracting a sample and starting an EPR scan averaged 5.0 (±0.2 min) in June and 5.2 (±0.3 min) in July, necessitating only minimal adjustments to these data. Sample sizes in each experiment ranged from eight to 15 replicate larvae for each of the four treatment groups. Midgut fluids from all four treatment groups were examined on the 10th of June, and additional *M. disstria* and *O. leucostigma* larvae were examined on the 11th and the 14th of June, respectively. Midgut fluids from *M. disstria* and *O. leucostigma* larvae were also examined on the 11th and the 14th of July, respectively.

Statistical Analyses. Concentrations of phenolic compounds and ascorbate, and ascorbate:phenolic ratios in red oak and sugar maple were compared using nested ANOVA, with site nested within tree species, and repeated measures on individual trees (PROC MIXED) (SAS, 2000). Significant effects are reported in the results. Semiquinone radical intensities, peroxides, and protein carbonyls were compared using two-way ANOVA, with insect and tree species as main effects. In May, when multiple EPR runs were made through time on the same sample, only the first EPR run on each sample was included in the ANOVA. To compare regressions of semiquinone radical intensity on time in May (Figure 3A, B), entire data sets (including multiple scans per sample) were analyzed with ANCOVA using time as the covariate (SAS, 2000). The normality of residuals was tested using PROC UNIVARIATE (SAS, 2000). If residuals could not be normalized by transformation, the significance of main effects was determined by Kruskal–Wallis tests (Wilkinson, 2000). Pairwise differences between means were examined by differences of least-squares means generated by PROC MIXED (SAS, 2000), or by Kruskal–Wallis tests. No significant differences were observed between days in experiments that were run on more than 1 d, and these data were combined for final analysis. The spatial separation of analytical equipment used in different experiments and the small sample volumes available necessitated performing separate experiments to measure each analyte in caterpillar midgut fluids. Thus, the associations between semiquinone radical formation and markers of oxidation were examined by plotting mean levels (Figure 5A, B). The associations between semiquinone radical intensities and protein carbonyl concentrations in the midgut fluids of *M. disstria* and *O. leucostigma* (Figure 5A) were examined with regressions (Wilkinson, 2000) and by ANCOVA, using semiquinone radical intensity as the covariate (SAS, 2000). Insufficient data were available to examine the association between semiquinone radical intensities and total peroxide concentrations in *O. leucostigma* statistically. However, a visual examination of this relationship in *M. disstria* and *O. leucostigma* (Figure 5B) suggested that a single linear regression for the two species was appropriate and sufficient to

examine whether semiquinone radical intensities are positively or negatively associated with the formation of peroxides.

RESULTS

Sugar maple leaves contained lower levels of ascorbate and higher levels of phenolic compounds than did red oak leaves in mid-June (Figure 1A). Similar results were obtained in mid-July (Figure 1B), with the exception that ascorbate levels were not significantly different between the species. Nevertheless, ascorbate:phenolic ratios remained significantly lower in sugar maple leaves in June (0.045 ± 0.009) and July (0.056 ± 0.007) than in oak in June (0.19 ± 0.02) and

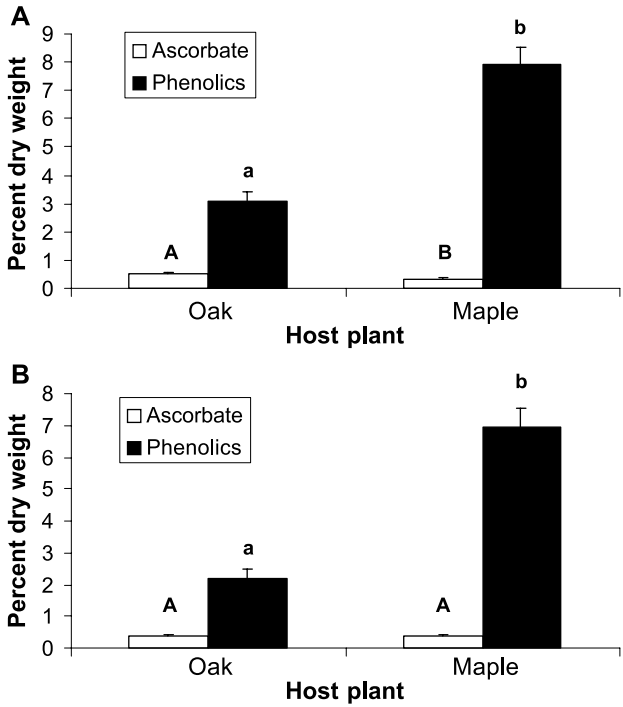

FIG. 1. Ascorbate and total phenolic levels in red oak (*Q. rubra*) and sugar maple (*A. saccharum*) leaves in mid-June (A) (soon after leaf expansion) and mid-July (B). Upper case letters that differ indicate significant differences between tree species for ascorbate ($P < 0.05$). Lower case letters that differ indicate significant differences between tree species for total phenolics.

July (0.25 ± 0.06) ($P < 0.001$). In a preliminary sample of leaves in May, ascorbate levels averaged 0.6% in both species. Total phenolics averaged 2.4 and 3.6% in red oak and sugar maple, respectively, demonstrating that levels of total phenolics doubled as sugar maple leaves matured but remained at lower levels in red oak. Therefore, the early spring foliage of sugar maple used as food in this study also had a lower ascorbate:phenolic ratio (0.17 ± 0.01) than did red oak (0.24 ± 0.02) ($P = 0.050$). Total phenolics in July 2004, expressed as the sum of the individual phenolics, measured 3.4% in red oak and 13.0% in sugar maple. To the extent that year-to-year variation in the experimental trees was negligible, the Prussian blue assay appears to have underestimated total phenolics, but provided a useful estimate of the relative amounts of phenolics in the two tree species.

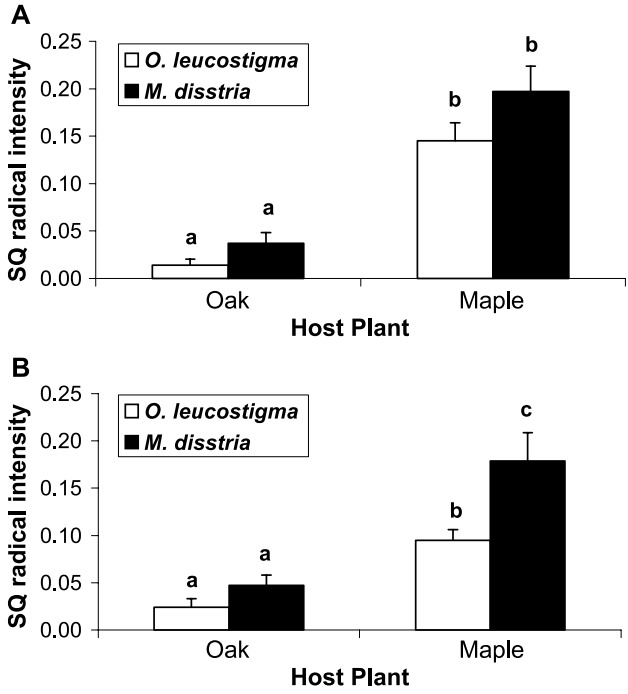

FIG. 2. Semiquinone (SQ) radical intensities in the midgut fluids of final-instar *O. leucostigma* and *M. disstria* larvae that fed on red oak or sugar maple leaves in mid-June (A) or in mid-July (B). Semiquinone radical intensity is defined as the double integral of the EPR spectrum per milligram sample, and all EPR spectra were standardized to a scan time beginning at 5 min after sample extraction. Different letters designate significant differences between the four treatments.

Semiquinone radical intensities were higher in the midgut fluids of caterpillars that were fed on maple than on oak in June and July (Figure 2A, B) ($P < 0.001$ for each month). Although semiquinone radical intensities were greater in *M. disstria* than in *O. leucostigma* in July ($P = 0.056$), they did not differ in June ($P = 0.71$). On early spring foliage, semiquinone radical intensities in *O. leucostigma* and *M. disstria* averaged 0.02 ± 0.002 SE and 0.14 ± 0.02 SE on oak, and 0.18 ± 0.01 SE and 0.30 ± 0.02 SE on maple, respectively. Thus, in May, higher semiquinone radical intensities were formed in maple-feeding caterpillars than in those feeding on oak ($P < 0.001$), and higher semiquinone radical intensities were formed in *M. disstria* than in *O. leucostigma* ($P < 0.001$). Generalizing across all 3 mo, higher semiquinone radical intensities were formed in maple-feeding caterpillars than in those

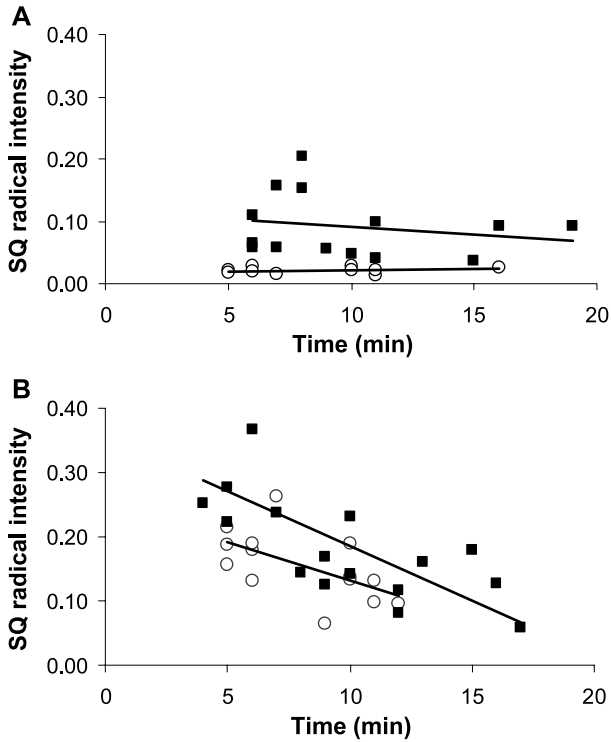

FIG. 3. Changes in semiquinone (SQ) radical intensity through time in the midgut fluids of final-instar *O. leucostigma* (open circles) and *M. disstria* (closed squares) on red oak (A) or sugar maple (B) in mid-May. Times indicate the number of minutes between the extraction of a sample and the beginning of an EPR scan of the sample.

feeding on oak ($P < 0.001$), and they were higher in *M. disstria* than in *O. leucostigma* ($P = 0.002$). Semiquinone radical intensities were higher overall in May than in June ($P = 0.002$) or July ($P = 0.001$). In comparison with semiquinone radical intensities measured previously in *M. disstria* that were fed on an artificial diet containing a mixture of 5% tannic acid and 2.3% ascorbate (Barbehenn et al., 2003b), radical intensities in *M. disstria* on sugar maple were roughly half as large.

Phenolic compounds in red oak leaves formed relatively stable semiquinone radicals in the midgut fluids of *O. leucostigma* and *M. disstria* (Figure 3A). Changes in semiquinone radical levels averaged only +0.0003 and −0.0025 intensity units/min in *O. leucostigma* and *M. disstria*, respectively. By comparison, semiquinone radicals from sugar maple phenolics had decay rates averaging −0.012 and −0.017 intensity units/min in *O. leucostigma* and *M. disstria*, respectively (Figure 3B). Thus, semiquinone radicals from sugar maple

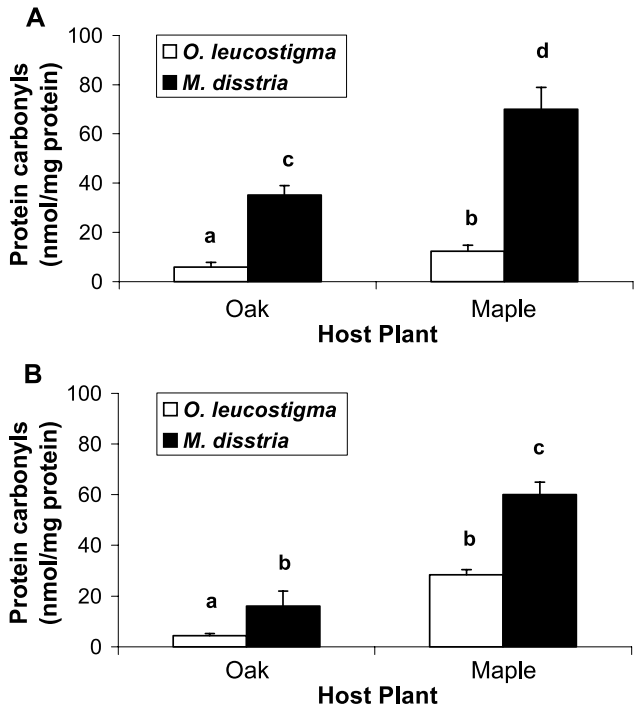

FIG. 4. Protein carbonyl levels in the midgut fluids of final-instar *O. leucostigma* and *M. disstria* larvae that fed on red oak or sugar maple leaves in mid-June (A) and in mid-July (B). Different letters designate significant differences between the four treatments.

decayed more rapidly than did those from oak in *O. leucostigma* ($P < 0.001$) and showed a similar trend in *M. disstria* ($P = 0.086$). Rates of radical decay were not significantly different between the caterpillar species when they each fed on red oak ($P = 0.508$) or sugar maple ($P = 0.792$).

The formation of brown pigments, especially in larvae that fed on sugar maple, suggested that a substantial fraction of the semiquinone radicals oxidized further to form quinones and melanin-like compounds. The gut contents of oak-feeding larvae were commonly bright green, but some browning was observed in *M. disstria* in June and July. Browning was observed in the midgut fluids of many *M. disstria* larvae when they were fed on sugar maple in June and July (and to a lesser extent in May), but the contents of *O. leucostigma* were typically dark green in the spring and summer.

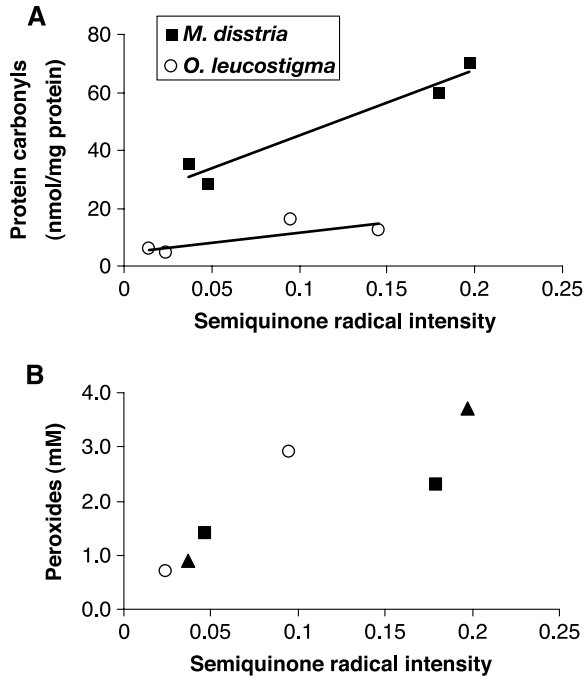

FIG. 5. Association between semiquinone radical intensities and protein carbonyl levels (A) and total peroxide levels (B) in the midgut fluids of final-instar *O. leucostigma* and *M. disstria* larvae that fed on red oak or sugar maple leaves in mid-June or in mid-July. In panel B, closed squares = *M. disstria* in July, closed triangles = *M. disstria* in June, open circles = *O. leucostigma* in July. The lower means plotted for each insect species are from larvae that fed on red oak in June or July.

TABLE 1. TOTAL PEROXIDE CONCENTRATIONS IN THE MIDGUT FLUIDS OF FINAL-INSTAR *O. leucostigma* AND *M. disstria* LARVAE THAT FED ON RED OAK OR SUGAR MAPLE LEAVES[a]

Host plant	Insect species	Date	Peroxides (mM)	*N*
Red oak	*M. disstria*	June 18	0.9 ± 0.1[a]	22
Sugar maple	*M. disstria*	June 18	3.7 ± 0.4[b]	18
Red oak	*O. leucostigma*	July 14	0.7 ± 0.1[a]	14
Red oak	*M. disstria*	July 11	1.4 ± 0.2[b]	15
Sugar maple	*O. leucostigma*	July 14	2.9 ± 0.4[d]	15
Sugar maple	*M. disstria*	July 11	2.3 ± 0.2[c]	15

[a] Data are presented as mean ± SE. Summary statistics followed by different letters (within months) are significantly different ($P < 0.05$).

Protein in midgut fluids was oxidized to a greater extent in caterpillars that were fed on sugar maple than on red oak, both in June ($P < 0.001$) and July ($P = 0.043$) (Figure 4A, B). Protein carbonyl levels were also greater in *M. disstria* than in *O. leucostigma* in June ($P < 0.001$) and July ($P < 0.001$). Protein carbonyls in *M. disstria* were positively associated with semiquinone radical intensities in their midgut fluids ($R^2 = 0.95$, $P = 0.025$) (Figure 5A). In *O. leucostigma*, there was a much weaker association between protein carbonyls and semiquinone radical intensities ($R^2 = 0.63$, $P = 0.21$), although a non-significant result in this case could be due to a small sample size ($N = 4$). ANCOVA provided confirmation that, at a given semiquinone radical intensity, protein carbonyls were formed to a greater extent in *M. disstria* than in *O. leucostigma* ($P = 0.043$). Proteins also appeared to be oxidized at a higher rate in *M. disstria* than in *O. leucostigma*, as indicated by a significant interaction between species and semiquinone radical intensity ($P = 0.046$; Figure 5A).

Total peroxide concentrations were consistently higher in larvae that were fed on sugar maple than on red oak (Table 1). However, peroxide levels in July were higher in *O. leucostigma* than in *M. disstria* on maple, the opposite of the result expected. Nevertheless, total peroxides in both caterpillar species were positively associated with semiquinone radical intensities in their midgut fluids ($R^2 = 0.72$; $P = 0.033$ for both species combined) (Figure 5B).

DISCUSSION

It has been hypothesized that phenolic compounds derive much of their anti-herbivore activities from being "oxidatively activated" (Appel, 1993). However,

few previous studies have clearly demonstrated that ingested phenolics in leaves oxidize in midgut fluids. Phenolic oxidation in the gut lumen has been suggested by studies that have measured (1) the loss of phenolics or increase in their oxidation products in frass (Felton et al., 1989; Barbehenn et al., 1996; Salminen and Lempa, 2002); (2) oxidative damage to the midgut epithelium (Summers and Felton, 1994; Bi and Felton 1995; Bi et al., 1997); or (3) the supression of ingested pathogens (Appel and Schultz, 1994; Hoover et al., 1998). However, in some of this previous work, including our own, it is likely that some fraction of phenolic oxidation occurred in frass after it left the low oxygen conditions in the gut, either from autooxidation or from polyphenol oxidase activity (Johnson and Barbehenn, 1999; Wang and Constabel, 2004). It is also possible that low molecular weight phenolics produce oxidative damage following their absorption into the midgut epithelium. The use of EPR spectrometry provides a direct measure of phenolic oxidation in the midgut fluids of caterpillars. Thus, a major finding in this study is the observation that phenolic compounds ingested in red oak and sugar maple leaves are oxidized in the midgut fluids of caterpillars. The overall prooxidant activity of these mixtures of phenolics is suggested by the positive relationships between semiquinone radical formation and two markers of oxidation in the midgut fluids from *M. disstria* and *O. leucostigma*. Although these results are correlative, it is noteworthy that previous experiments in which levels of phenolic compounds were controlled produced similar results; tannic acid ingested in an artificial diet also oxidized to produce elevated levels of semiquinone radicals, protein carbonyls, and peroxides, particularly in *M. disstria* (Barbehenn et al. 2001, 2003b, unpublished data). The results of the present study are consistent with two additional hypotheses: (1) the oxidation of phenolics and markers of oxidative damage are greater in the midgut fluids of caterpillars feeding on maple than in those feeding on oak; and (2) the levels of oxidation are greater in the phenolic-sensitive species *M. disstria* than in the phenolic-tolerant species *O. leucostigma*.

As expected, sugar maple leaves contain lower ascorbate:phenolic ratios and produce substantially higher semiquinone radical levels in caterpillar midgut fluids than red oak leaves. However, high levels of semiquinone radicals were also produced in the midgut fluids of both *M. disstria* and *O. leucostigma* when they ingested an artificial diet containing an ascorbate:gallic acid ratio of 0.21 (on a %DW basis) (Barbehenn et al., 2003b). Therefore, differences in ascorbate:phenolic ratios alone cannot explain (1) why a similar ascorbate:phenolic ratio in red oak leaves (0.25) produces a low level of semiquinone radicals in midgut fluids, (2) why high levels of semiquinone radicals are produced in larvae that feed on sugar maple in May (ascorbate:phenolics ratio of 0.17), or (3) why semiquinone radicals from sugar maple phenolics decay rapidly, while those from red oak are relatively stable in gut fluids. It appears likely that both the propensity of specific types of phenolics to oxidize and the stability of

the semiquinone radicals formed also affect the extent of oxidative damage in midgut fluids. Sugar maple leaves analyzed from July of 2004 contained high levels of ellagitannins, condensed tannins, and gallotannins, while red oak leaves were rich in condensed tannins, but contained almost no measurable ellagitannins or gallotannins (J.-P. Salminen, unpublished data). This difference in phenolic composition, along with the differences in semiquinone radical intensity and decay rates between the two tree species, leads us to suspect that sugar maple phenolics are more prone to oxidize and to damage other biomolecules than are the phenolics in red oak leaves. Other components of the oxidative defenses of maple and oak leaves, such as their oxidative enzymes, could also contribute to the observed differences in the activities of ingested oak and maple phenolics.

The relatively high levels of semiquinone radicals produced in *M. disstria* and *O. leucostigma* in May compared to June and July suggest that feeding on spring foliage does not necessarily allow these herbivores to avoid the prooxidant activities of ingested phenolic compounds. It is well known that the phenolic compositions of tree leaves change seasonally, even in cases in which there is an apparent lack of change in total phenolic levels (e.g., Salminen et al., 2004). It would be of interest to examine whether the types of phenolic compounds in immature leaves produce higher semiquinone radical intensities than those in mature leaves and to confirm whether biomarkers of oxidation are also higher in May in maple-feeding caterpillars.

As noted above, the observation that phenolic compounds are oxidized more extensively in *M. disstria* than in *O. leucostigma* is consistent with previous work on the propensity of ingested phenolics to oxidize in these species (Barbehenn and Martin, 1992, 1994; Barbehenn et al., 2001, 2003a,b). Therefore, differences in the gut biochemistries of *M. disstria* and *O. leucostigma* that have been observed on artificial diets are relevant to the more complex mixtures of phenolic compounds found in their host plants. A key conclusion of these studies has been that *O. leucostigma* maintains a more efficient ascorbate recycling system than does *M. disstria*, thereby minimizing phenolic oxidation. Higher ascorbate concentrations are found in *O. leucostigma* than in *M. disstria* on artificial diets and on tree leaves in July, but not on immature leaves in the spring (Barbehenn et al., 2001, 2003a). Thus, we are unable to explain the lower levels of semiquinone radicals formed in *O. leucostigma* on the basis of higher ascorbate levels in all cases.

Were levels of semiquinone radicals and markers of oxidation sufficiently low in *O. leucostigma* to suggest that phenolic compounds in oak can act as antioxidants in the midgut lumen? An experiment to determine this, such as one in which phenolic-poor leaves were treated with different levels of oak phenolics and levels of markers of oxidation were negatively correlated with phenolic levels, has not been done. However, the low peroxide levels in the

midgut fluids of caterpillars on artificial diets suggest that peroxide levels in the midgut fluids of *O. leucostigma* on oak were increased, rather than decreased, by oak phenolics. Peroxide levels in midgut fluids of both *O. leucostigma* and *M. disstria* on a phenolic-free diet were on the order of 50–100 μM (using the FOX and red ferrithiocyanate assays) and even peroxide levels measured on a diet containing 5% tannic acid were well below the levels of total peroxides measured in *O. leucostigma* on oak (Barbehenn et al., 2001, unpublished data). Nevertheless, red oak does appear to be a relatively benign host plant in terms of its oxidative defenses for both species of caterpillars tested.

In the case of sugar maple, the oxidative damage it generates in caterpillars could potentially explain its poor host plant quality for *M. disstria* in its northern range (Nicol et al., 1997). Increases in both protein oxidation and peroxides are potentially harmful to insect fitness (Cadenas, 1995; Felton, 1996; Halliwell and Gutteridge, 1999). However, we are unaware of studies that have clearly shown a negative relationship between the oxidation of phenolic compounds in the gut fluids of insects and their performance. Such work is needed to examine the effectiveness of plant oxidative defenses against insect herbivores more closely.

Acknowledgments—We thank Michael M. Martin for suggesting revisions to our manuscript, Juha-Pekka Salminen for analyzing phenolic compounds with HPLC-DAD, Bob McCron for providing insect eggs, and David Borneman, Brian Klatt, and Marvin Pettway for permission to use trees at Kuebler-Langford Park, the Matthaei Botanical Gardens, and the University of Michigan, respectively. This work was supported by NSF grant IBN-9974583 to RVB.

(Received June 15, 2004; accepted January 21, 2005)

Abstract—Linden (*Tilia cordata*) bark was shown to contain an antifeedant effective against the large pine weevil, *Hylobius abietis*. Soxhlet extraction of inner and outer bark resulted in an extract that showed antifeedant activity in a microfeeding assay. The extract was fractionated by chromatography on silica gel using gradient elution with solvents of increasing polarity. The content of the fractions obtained was monitored by thin layer- and gas chromatography. Fractions of similar chemical composition were merged. Two of the 17 fractions showed antifeedant activity in the microfeeding assay. Nonanoic acid was identified in both of these fractions. Subsequent testing in the microfeeding assay showed that nonanoic acid possessed strong antifeedant activity against *H. abietis* adults.

Key Words—Antifeedant, Curculionidae, Coleoptera, deterrent, extract, feeding, fractionation, *Hylobius abietis*, linden, nonanoic acid, outer bark, pelargonic acid, phloem, pine weevil, soxhlet, *Tilia cordata*.

INTRODUCTION

Antifeedants are semiochemicals active in the last step of animal-host selection behavior, limiting the diet for both larvae and adults in insects (Dethier et al., 1961; Beck, 1965; Chapman, 1974) and for higher animals (Jakubas et al., 1994; Epple et al., 1996). Plant derived antifeedants are important as plant protection against predators. The neem tree produces azadirachtin, today a well

known and commercialized compound active against a number of pest insects (Lowery and Isman, 1994; Mordue et al., 1998; Liang et al., 2003). This compound has also shown antifeedant activity against birds (Mason and Matthew, 1996). Other examples of promising plant antifeedant compounds are tryptamine, which harms reproduction in *Drosophila melanogaster* (Thomas et al., 1998), and cucurbitacins that function as feeding arrestants and toxicants against the southern corn rootworm (Barbercheck et al., 1995). Garlic oil, pulegone, and tannins reduce food consumption in birds (Avery et al., 1996; Voltz and Clausen, 2001; Hile et al., 2004) and Scots pine *Pinus sylvestris* contains pinosylvin that suppresses feeding of the snowshoe hare (Sullivan et al., 1992) and (1*S*,2*R*,4*S*,5*S*)-angelicoidenol-2-O-beta-D-glucopyranoside, a moose deterrent (Sunnerheim-Sjöberg, 1992).

This work focuses on the large pine weevil *Hylobius abietis* (L.) (Coleoptera: Curculionidae) and its feeding behavior on linden (*Tilia cordata*) bark extracts. The large pine weevil is a major pest on newly planted pine and spruce saplings in Sweden (Eidmann et al., 1996). If the young plants are left unprotected, the economic losses for the forest industry are severe (Weslien, 1998). Until recently the pyrethroid insecticide Permethrin was used to protect saplings. This insecticide has now been forbidden for use in Swedish forestry and has been replaced by Cypermethrin, which is also a pyrethroid. However, Cypermethrin has shown to be even more toxic than Permetrin (Oliveira et al., 2002). Our approach to this problem is to develop useful antifeedants that act either through smell or taste, or both, and thereby prevent the weevil from feeding. An optimal antifeedant will be an environmentally friendly compound with long-term stability to the conditions it experiences in the field. Thus, the compound should have low volatility and not decompose or be washed away under the influence of environmental factors such as oxygen, UV light, variation in temperature, and rainfall.

We have demonstrated the polyphagous habits of *H. abietis* (Månsson and Schlyter, 2004). When presented to other woody plant species and Scots pine (*P. sylvestris*) in choice tests, *H. abietis* always prefers the latter (Manlove et al., 1977; Månsson and Schlyter, 2004). However, if no choice is given, the weevils will feed on a number of plants, usually not regarded as common food sources. Thus, a broad range of possible food sources are available for the pine weevil in its natural habitat (Samuelsson, 2001). However, there are a number of woody plants on which this insect will not feed, preferring to starve. *Evonymus europaeus* and *Ilex aquifolium* were shown to belong to this group of plants (Månsson and Schlyter, 2004). However, when *Sorbus aucuparia* (L.), *Lonicera xylosteum* (L.), *Viburnum opulus* (L.), *Taxus baccata* (L.), *Syringa vulgaris* (L.), *Populus tremula* (L.), or *Tilia cordata* (Mill.) were used as food sources, another type of feeding behavior was found for the pine weevil. In this group of nonpreferred plants, weevils eat and remove only small amounts of bark and

phloem. We have also identified tree species on which the weevils feed only on the outer bark, but stop feeding once they reach the phloem (Månsson and Schlyter, 2004).

One method to investigate a plant for semiochemical antifeedant activity is to test an extract of the relevant plant tissue for activity against the relevant insect. In this way, the influence of the plant's texture is avoided. Our preliminary tests of bark extracts in microfeeding assays demonstrated that extracts of linden, *T. cordata*, bark displayed the best antifeedant qualities among eight extracted species tested. We have noted that when presented with extracts from some tree species, the weevils do not even approach controls in choice assays. Such results indicate the presence of high amounts of volatile antifeedants and interfere with statistical analysis of choice tests. Because antifeedants of high volatility are less suitable for long-term application in the field, we have focused on identifying nonvolatile antifeedants of *H. abietis* from linden bark. Antifeedant activity was assessed using our previously described microfeeding assay (Schlyter et al., 2004a).

We describe five methods for preparation of linden bark and Soxhlet extraction by different solvents. Furthermore, we describe the isolation of the fractions with the best antifeedant activity, and the identification of one active constituent from these fractions by GC-MS and NMR.

METHODS AND MATERIALS

Insect Collection and Culture. We collected adult *H. abietis* flying in May–June in Southern Sweden using established methods (Klepzig and Schlyter, 1999). Groups of 150 pine weevils were placed into ventilated plastic buckets containing moistened paper towels and *P. sylvestris* branches. To decrease the rate of the metabolism of the weevils, the buckets were stored in the dark in a cold room at 8–10°C prior to the experiments. Before initiation of an assay, the buckets were moved into a growth chamber with the parameters set to conditions similar to those found in the field at the time of weevil collection [24°C, 75% RH, and a photoperiod of 20:4 (L:D)]. Before the assays started, insects were allowed to feed on *P. sylvestris* branches for 1 wk. Thereafter, no food was provided for 6 days, and the last 24 hr before the assays they did not have access to water.

Extractions of T. cordata *Bark.* Linden branches and shoots (diam 5–30 mm) were collected during the summer in southern Sweden. Only young plant materials such as second-year shoots and branches were used. Different methods for preparation and extraction of the plant material were tested (Table 1). To determine the correct amount and concentration to use for each plate in the microfeeding bioassay, the same procedure for the initial prepa-

TABLE 1. THE FIVE EXTRACTION METHODS USED

	Bark	Method	Antifeedant Activity	Further Fractionation	Comments
A	Ground frozen	High pressure soxhlet extraction	Negative	No	Significant attraction
B	Freeze dried	Solvent soxhlet MeOH/CH_2Cl_2, 1:9, at 37°C	No	No	No activity
C	Fresh	Solvent soxhlet increasing polarity: Hexane→ CH_2Cl_2→MeOH	Positive, weak	Yes	Lost activity
D	Ground frozen	Solvent soxhlet MeOH/CH_2CL_2 1:9, at 37°C	Positive	Yes	Active in further fractionation
E	Levigated fresh in blender with MeOH	Solvent soxhlet MeOH	Positive	Yes	Reduced/lost activity

ration of the bark was used for all methods. Prior to removal of the bark from the twigs, the total area of the bark was measured. The outer and inner bark was cut or scraped off the stem and immediately extracted. The resulting extracts were concentrated *in vacuo* and solvent was added. The amount of solvent added was determined on the basis of the total bark area removed. Thus, if the bark area corresponded to, for example, 200 microfeeding assay TLC plates (each with an area of 25 mm^2) solvent was added to the extract until a volume of 200 × 10 μl was reached.

"*Frozen/Pressure*". The bark preparation was frozen in liquid nitrogen, and ground to fibers. The fiber mass was subjected to pressurized Soxhlet extraction using liquid, supercritical carbon dioxide (Rosenblum et al., 2002). In this setup, the extractor consisted of a 5-l vessel that housed a typical Soxhlet glass unit for the extraction of plant material with liquid solvents. The liquid extract was collected under pressure inside the extractor. The liquid solvent was vaporized by water heating of the bottom and sides of the extractor. On the top of the extractor, a refrigerated coil condensed the solvent vapors. The extraction cycle was controlled by monitoring temperature variation. The cycle was ended when the pressure peaked and then dropped, due to the CO_2 evaporation.

"*Freeze-Dried*". Freeze-dried bark was ground and extracted in a solvent Soxhlet apparatus (Furniss et al., 1989) for 4 hr by a mixture of dichloromethane/methanol (9:1) kept at reflux (35–45°C). In the Soxhlet apparatus (also called extractor, or chamber), the sample soaks in solvent that is periodically siphoned off, distilled, and returned to the sample. The resulting extract was concentrated *in vacuo*. To remove residual water, methanol was added to the

condensed extract followed by an additional concentration to dryness *in vacuo*. The dry weight of the extract was recorded and the extract was dissolved in dichloromethane/methanol (1:1).

"*Frozen/Solvent*". Bark was frozen in liquid N_2, then immediately pulverized in a grinder and, thereafter, treated as in the "freeze-dried" method.

"*Fresh*". Fresh bark was pulverized in a grinder, and the same batch was extracted as above with solvent Soxhlet in three steps with increasing polarity. Hexane, dichloromethane, and methanol were used as solvents and accordingly, three crude extracts were obtained.

"*Levigated*". Fresh bark was levigated to fine fiber in a blender with methanol, filtered, and then extracted with solvent soxhlet as above with the methanol from the blender.

The seven crude extracts obtained by the five extraction methods were tested for antifeedant activity in the microfeeding bioassay.

Microfeeding Bioassay. The microfeeding bioassay is a choice test consisting of a treatment and a blank on separate thin-layer chromatography plates [TLC plates (Merck #1.05552) 5 × 5 mm, aluminum sheets covered with a 0.2-mm-thick cellulose layer] (Schlyter et al., 2004b). The treatment is applied on one of the TLC plates as two drops of solution (2 × 5 μl), whereas the same amount of solvent only is added to the control plate. The dry extract was diluted so that the amount per area (10 μl) on the TLC plate (25 mm^2) corresponded to roughly the same amount per area of fresh bark. After evaporation of the solvent from the treatment and control plates, 5 μl of 1 M sucrose in water are added as a feeding stimulant. The two plates are placed together with a pine weevil in a Petri dish (diam 90 mm) and tests are run for 4 hr, $N = 12$. The cellulose layer of the control plate is often consumed within less than 4 hr.

Antifeedant Index. The results from the microfeeding assays are presented as the Antifeedant Index (AFI) (Blaney et al., 1984; Klepzig and Schlyter, 1999):

$$\mathrm{AFI} = \frac{\text{Amount fed on Control} - \text{Amount fed on Treatment}}{\text{Amount fed on Control} + \text{Amount fed on Treatment}} = \frac{\mathrm{C} - \mathrm{T}}{\mathrm{C} + \mathrm{T}}$$

A value of 1.00 corresponds to a total inhibition of feeding, a value of 0.50 a half-effect, and 0 no effect. Negative values (<0) indicate feeding stimuli. Activity was interpreted by comparing the individual 95% confidence intervals ($\alpha = 0.05$) with the theoretical values 0 (no activity) or 1 (full activity).

Fractionation. The Soxhlet extracts obtained from the "fresh," the "frozen/solvent," and the methanol extract from the "levigated" method were concentrated *in vacuo* on silica gel [5.0 g, silica gel 60 (230–400 mesh), Fluka]. The same type of silica gel (25 g) was packed into a column (diam 25 mm) and the

silica gel, impregnated with the extract, was added on top of the column. All solvents used as eluents were distilled prior to use. To elute the compounds, a gradient was used: first cyclohexane (220 ml, four column volumes), followed in order by dichloromethane/cyclohexane (220 ml, 10%, v/v), (220 ml 20%), (110 ml 30% → 90%; after each 110-ml batch, the amount dichloromethane was increased by 10%), and finally 55 ml 100% dichloromethane. The eluent was changed to methanol in dichloromethane. The methanol content was increased in steps: 10%, 15%, 30%, 50%, 80%, and 100%. The same volume of solvent (110 ml) was used in each step. Finally, the column was eluted with 110 ml of acetone. Fractions of 15 ml were collected.

All fractions were analyzed by TLC and some by GC. Those fractions that according to GC or TLC analysis contained roughly the same compounds were combined and were tested via the microfeeding assay.

Chemical Analysis. GC analyses were performed using a Varian 3400 instrument, EC-1 column (Alltech, 30 m × 0.32 mm i.d., 0.25 μm film thickness), temperature program: 40°C, 5 min, (10°C/min) to 250°C, 10 min. GC-MS analyses were carried out using a Varian 3800 GC instrument, CP-sil 5CB low bleed column (Varian, 30 m × 0.25 mm i.d., 0.25 μm film thickness), in series with a Saturn 2000 MS, ion trap detector, EI mode, temperature program as described for GC analyses. NMR analyses were carried out using a Bruker Avance DPX 250 spectrometer operating at 250.13 MHz (^{1}H) and 62.9 MHz (^{13}C), sample temperature 25°C, $CDCl_3$ as solvent, and TMS as internal standard. The reported purities of the compounds are calculated as the relative amount of integrated areas.

RESULTS

Bioactivity of Extracts. The seven extracts obtained by the different methods showed significant differences in antifeedant activity (arcsin-transformed AFI values: ANOVA, $F = 10.54$, $df = 6, 82$, $P < 0.001$). Only "frozen/solvent" fractions (AFI ± SE: Run 2: 0.93 ± 0.07, $N = 7$; Run 3: 1.00 ± 0.00, $N = 7$) showed antifeedant effects after chromatographic separation. The "fresh" method resulted in two extracts with negative AFI (Hexane: −0.64 ± 0.13, $N = 12$; CH_2CL_2: −0.29 ± 0.11, $N = 12$) showing feeding stimulation, and one inactive extract with an AFI overlapping 0 (MeOH: 0.30 ± 0.30, $N = 10$). The "freeze-dried" method yielded an extract with antifeedant activity (0.37 ± 0.14, $N = 10$) that was lost after further chromatographic separation. The "levigated" extract also showed antifeedant activity (0.64 ± 0.19, $N = 10$) that disappeared with further fractionation. The "frozen/pressure" method resulted in an extract with a negative AFI (0.47 ± 0.19, $N = 12$).

In the first set of assays of the "frozen/solvent" extract, only five plates were fed upon, giving a high variance (Figure 1a, Run 1: 0.60 ± 0.89). To allow for statistical comparisons, two additional assay runs were conducted. In both the second and the third run, the solution of extract on the treated plates was allowed to evaporate for 20 hr before testing (instead of the 20 min used before.). We found significant activity in both of these tests (Figure 1a, Run 2: 0.93 ± 0.07, $N = 7$; Run 3: 1.00 ± 0.00, $N = 7$). Out of the tested methods, this was the only one that gave extracts that furnished sufficiently active fractions after further separation by liquid chromatography. A dilution series (1:10 and 1:100) of the merged runs 2 and 3 also was performed in order to test the reliability of the method of measuring bark area as a way to obtain a similar concentration of the extract on the TLC plate as in the bark (Figure 1b). Dilution of the extract resulted in reduced activity with lower dose (Figure 1b, $r_S = 0.701$, $P < 0.001$). Only the undiluted extract had significant antifeedant activity (AFI $\gg$ 1) while the diluted extract (1:10) had an AFI overlapping 0.

Fractionation by liquid chromatography of the "frozen/solvent" extract resulted in 128 fractions. Those containing the same compounds (as judged by TLC or GC) were combined to give 17 fractions. These were tested in the microfeeding assay. Out of 17 fractions, #12 and #13 showed the strongest antifeedant activity (Figure 2, #12: 0.98 ± 0.02, $N = 9$ and #13: 0.83 ± 0.06, $N = 8$). Two fractions showed some, but not significant, antifeedant activity (#8: 0.48 ±

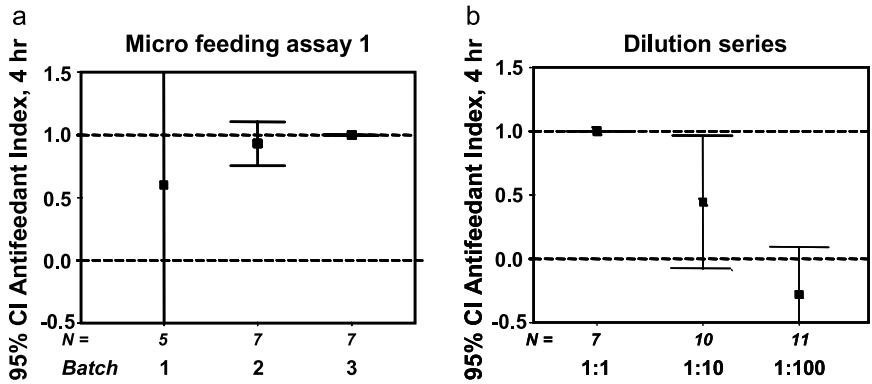

FIG. 1. a. Antifeedant activity of the crude *T. cordata* extract ($N = 12$), replicated twice. Bars show Antifeedant Index (AFI) average area consumed $(C - T)/(C + T)$, ±95% confidence interval from microfeeding assay. The number of responses in the first test was too low for statistical analysis. In the second and third tests, the solvent was allowed to evaporate during 20 hr and then complete feeding inhibition (AFI ≈ +1) was found. b. Dose response of the crude *Tilia* extract from batch 3, ($r_S = 0.701$, $P < 0.001$).

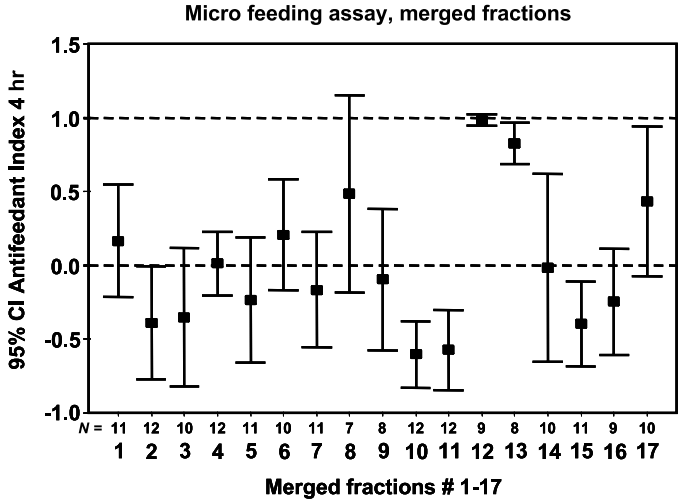

FIG. 2. Antifeedant activity of 17 fractions of *Tilia* extract in the microfeeding assay. Fraction 12 shows complete feeding inhibition (AFI ≈ +1) and 13 shows strong inhibitory tendencies (AFI ≈ 0.70–0.95) while the two fractions collected just before (10 and 11) shows significant attraction (AFI < 0).

0.27, $N = 7$ and #17: 0.43 ± 0.22, $N = 10$), while nine fractions were inactive, with an AFI overlapping 0 (#1: 0.17 ± 0.17, $N = 11$; #3: −0.35 ± 0.21, $N = 10$; #4: 0.01 ± 0.10, $N = 12$; #5: −0.23 ± 0.19, $N = 11$; #6: 0.21 ± 0.17, $N = 10$; #7: −0.16 ± 0.17, $N = 11$; #9: −0.10 ± 0.20, $N = 8$; #14: −0.02 ± 0.28, $N = 10$ and #16: −0.25 ± 0.16, $N = 9$). Four fractions showed a negative AFI not overlapping 0, i.e., feeding stimulation (#2: −0.39 ± 0.17, $N = 12$; #10: −0.60 ± 0.10, $N = 12$; #11: −0.57 ± 0.12, $N = 12$; #15: −0.40 ± 0.13, $N = 11$).

Identification of an Active Compound. The two fractions with the strongest antifeedant activity (#12 and #13, Figure 2) were analyzed by GC. Fraction #13 contained one major compound (84% purity according to GC). By comparison with the spectra of an authentic sample [Fluka], this compound was identified by GC-MS as nonanoic acid. To further verify the identity of the major compound present in fraction 13, ^{1}H and ^{13}C NMR spectra were recorded and found to be identical with those reported for nonanoic acid (Aldrich Library of ^{13}C and ^{1}H FT NMR Spectra). Fraction number 12 was analyzed by GC-MS and also found to contain nonanoic acid as the major constituent together with smaller amounts of unidentified compounds. Commercially available nonanoic acid was tested in the microfeeding assay and displayed high antifeedant activity against *H. abietis* (AFI = 0.99 ± 0.01, $N = 9$).

DISCUSSION

We have reported that *H. abietis* does not feed from the bark or the phloem of some plants including *T. cordata* (Månsson and Schlyter, 2004). We have shown that the bark of *T. cordata* contains nonanoic acid, a chemical constituent that has strong antifeedant activity against *H. abietis*. We also found a suitable method ("frozen/solvent") for extracting the bark and further fractionation of the extract without losing the antifeedant effect.

In order to isolate an active extract that did not lose its activity in the feeding assay after fractionation, we tried several different methods for the extraction of *T. cordata* bark. During the first test of the extract obtained by the "frozen/solvent" method, the number of microassay plates fed upon were only five out of 12. We know from experience that this effect was likely due to a combination of high volatility and high activity of the tested compounds. The vapor from strong repellents or arrestants, present at every position in the Petri dish, stopped the insect from accepting any of the cellulose plates, including the control. To control for this effect, we let the volatiles on the treated plates evaporate for approximately 20 hr before commencing the assays. After this new protocol, the number of plates fed upon increased to seven in both of the two tests performed, a number high enough for statistical analysis.

Nonanoic acid has been identified as minor extractive in some other species that we earlier found to have antifeedant properties (Månsson and Schlyter, 2004), although not in bark and phloem. In the leaves and husks of walnut (*Juglans regia*), for example, it is a common antifeedant against several insects (Cohen et al., 1974; Shaaya et al., 1976; Hwang et al., 1982). The acid has also been shown to occur in almost all species of animals (Fontan et al., 2002), and at low levels in many of our common foods (Jirovetz et al., 2003). Ingestion or inhalation of small amounts of nonanoic acid has no known toxic effects and has been approved as a food additive (http://www.epa.gov). In addition, the compound is degraded rapidly in the environment. Therefore, use of nonanoic acid in pesticide products appears to pose no apparent risks to humans or the environment.

In addition to nonanoic acid in the bark, blossoms from *T. cordata* contain decanoic acid (Vidal and Richard, 1986). The genus *Tilia* contains numerous other compounds, some of them with antifeedant qualities. Eighteen volatile compounds have been identified in linden honey including eugenol, carvacrol, and thymol (Muckensturm et al., 1981; Yano, 1987; Arnason et al., 1989; Blank et al., 1989; Guyot et al., 1998; Moretti et al., 1998; Vasquez et al., 1999; El-Zemity and Radwan, 2001). Essential oil from linden blossoms contain some 100 compounds (Praczko and Gora, 2001) including the antifeedants germacrene-D, limonene, linalool, and *p*-cymene (Maganga et al., 1996; Biavatti et al., 2001; Tripathi, 2002; Halarewicz-Pacan et al., 2003).

Five antifeedants known to be present in *Tilia* spp. affect *H. abietis*. Limonene inhibits the action of α-pinene, a major component responsible for the attraction of *H. abietis* to *P. sylvestris* (Nordlander, 1990). D,L-Linalool is repellent to adult pine weevils (Muller and Haufe, 1991). Apart from being an antifeedant, even low doses of carvacrol cause mortality (Schlyter et al., 2004a). Eugenol inhibits feeding at 10% doses (Schlyter, unpublished data) as does carvone (Schlyter et al., 2004b).

Thus, one single plant species like *T. cordata* provides a rich source of potent antifeedants against numerous insect species. Most likely other promising antifeedant compounds can be found among the plants on which *H. abietis* does not feed.

Nonanoic acid has strong antifeedant qualities against *H. abietis* and is a common naturally occurring plant compound with low environmental persistence and toxicity. It is commercially available and does not have to be extracted from plant material. Although nonanoic acid is commercially available and safe, there is a need to know its activity at different doses and to examine various formulations and heavier analogs. The effects of UV radiation and changes in temperature and humidity have to be evaluated for each compound. The presence of semiochemicals in linden and other woody plants gives a rich library of candidate antifeedants for future plant protection, but they have to be further examined.

Acknowledgments—We are grateful to Fredrik Schlyter for numerous comments and statistical advice, Hans-Erik Högberg for sharing his knowledge in chemistry, Elisabeth Marling for technical assistance, and to Jan Löfqvist for initiation and administration of the research program: "Pheromones and kairomones for control of pest insects," funded by MISTRA, The Foundation for Strategic Environmental Research. We also thank Prof. John Pickett and Prof. Lester Wadhams at Biological Chemistry Division, Rothamsted research, UK, for inviting us to work in their lab. Thanks also to Dr. Hasse Rasmussen and Linda Ireland, Rothamsted, for supervision and sharing their knowledge. Financial support by EU, Objective 1 the Region of South Forest Counties, as well as comments from two anonymous referees is greatly acknowledged.

(Received August 31, 2004; accepted January 24, 2005)

Abstract—A large body of evidence shows that plants release volatile chemicals upon attack by herbivores. These volatiles influence the performance of natural enemies. Nearly all the evidence on the effect of plant volatiles on natural enemies of herbivores concerns predators, parasitoids, and entomophagous nematodes. However, other entomopathogens, such as fungi, have not been studied yet for the way they exploit the chemical information that the plant conveys on the presence of herbivores. We tested the hypothesis that volatiles emanating from cassava plants infested by green mites (*Mononychellus tanajoa*) trigger sporulation in three isolates of the acaropathogenic fungus *Neozygites tanajoae*. Tests were conducted under climatic conditions optimal to fungal conidiation, such that the influence of the plant volatiles could only alter the quantity of conidia produced. For two isolates (Altal.brz and Colal.brz), it was found that, compared with clean air, the presence of volatiles from clean, excised leaf discs suppressed conidia production. This suppressive effect disappeared in the presence of herbivore-damaged leaves for the isolate Colal.brz. For the third isolate, no significant effects were observed. Another experiment differing mainly in the amount of volatiles showed that two isolates produced more conidia when exposed to herbivore-damaged leaves compared with clean air. Taken together, the results show that volatiles from clean plants suppress conidiation, whereas herbivore-induced plant volatiles promote conidiation of *N. tanajoae*. These opposing effects

* To whom correspondence should be addressed. E-mail: hountond@science.uva.nl, f.hountodji@cgiar.org

suggest that the entomopathogenic fungus tunes the release of spores to herbivore-induced plant signals indicating the presence of hosts.

Key Words—Cassava, conidiation, fungal pathogen, GC-MS, herbivore-induced plant volatiles, mite, *Mononychellus tanajoa*, *Neozygites tanajoae*.

INTRODUCTION

Plants can influence the effectiveness of the third trophic level (Price et al., 1980). For example, it is well established that natural enemies are attracted by volatile chemicals released by plants that are attacked by herbivores (Dicke and Sabelis, 1988; Dicke et al., 1990; Turlings et al., 1990). These so-called herbivore-induced plant volatiles (HIPV) help the natural enemies in locating their victims and thereby also help the plant in reducing the impact of herbivory. Whereas much work has been devoted to the effect of HIPV on predators and parasitoids, little is known about the impact on entomopathogens (Elliot et al., 2000). Recently, HIPV from the roots of *Thuja* plants were shown to attract entomopathogenic nematodes (Boff et al., 2001; van Tol et al., 2001), but other classes of entomopathogens, such as fungi, have not yet been investigated for their response to HIPV. One exception is the study by Brown et al. (1995), which suggests that tobacco plants under aphid attack produced volatiles that delay conidial germination by the entomopathogen *Pandora neoaphidis* (Remaudière and Hennebert) until after the conidia come into contact with the aphid integument. The same effect was obtained by exposing conidia to volatiles from mechanically damaged (macerated) leaves and to two alcohol-type components that are part of the blend of green leaf volatiles (GLV) (Brown et al., 1995). Hence it is not yet clear whether there is a separate role for HIPV. In this study, we addressed the question whether the fungal pathogen *Neozygites tanajoae* Delalibera, Hajek, & Humber uses HIPV to tune the production of spores to the presence of its host, the herbivorous mite *Mononychellus tanajoa* (Bondar).

The mite *M. tanajoa* is an important pest of cassava, a staple food crop widely cultivated in Africa. It lives on the underside of cassava leaves which it damages by feeding on leaf parenchyma cells, leaving discolored spots on the leaf, easily recognizable with the naked eye. To control *M. tanajoa*, biological control based on the use of phytoseiid predators and the fungal pathogen *N. tanajoae* has been developed. *N. tanajoae* is specific to *M. tanajoa* and has been found both in the Neotropics (Agudelo-Silva, 1986; Delalibera et al., 1992; Alvarez-Afanador et al., 1993) and in Africa (Bartkowski et al., 1988; Yaninek et al., 1996; Dara et al., 2001a). However, infection rates rarely exceeded 1% in Africa, whereas frequent epizootics were reported in the Neotropics (Delalibera

et al., 1992; Elliot et al., 2002). Brazilian isolates of *N. tanajoae* were, therefore, imported into Benin, West Africa, and released in experimental fields in 1999. Postrelease monitoring showed significantly higher infection rates in fields where Brazilian isolates were released (Hountondji et al., 2002). Annual epizootics have been observed in Benin since then (Hountondji et al., 2003). However, laboratory virulence tests conducted on leaf discs under optimal conditions failed to show significant differences between the indigenous and the imported isolates (Dara et al., 2001b). Given the differential epizootic potential of the indigenous and imported isolates of *N. tanajoae* in the field, we suspect genetic variation among isolates of *N. tanajoae* to play a role, e.g., with respect to climatic conditions or response to HIPV.

Previous studies demonstrated that the phytoseiid predators *Typhlodromalus aripo* DeLeon and *T. manihoti* Moraes respond to volatiles emanating from cassava leaves infested by *M. tanajoa*, as opposed to volatiles from uninfested cassava leaves, mechanically damaged leaves, and *M. tanajoa* females alone (Janssen et al., 1990; Gnanvossou et al., 2001, 2003). These results suggest the release of volatile chemicals upon herbivore attack (HIPV), but definitive proof of their presence is yet to be given. Therefore, we first carried out a GC-MS analysis to identify the compounds in the blends of infested and clean cassava plants.

To assess the sporulation response of the mite pathogenic fungus (*N. tanajoae*) to HIPV, it is important to distinguish among the various kinds of spores produced. Two types are produced during the asexual phase: spherical spores called conidia and almond-shaped spores called capilliconidia (Oduor et al., 1996a). There is also a third type, so-called resting spores, which supposedly arise in the sexual phase. Resting spores are rarely found in the field, even during epizootics (Elliot et al., 2002; Hountondji et al., 2002), but the first two types are commonly observed. Conidia are discharged from infected herbivorous mites that are mummified. Most of these immobile spores end up on the leaf in a halo around the sporulating, mummified mite. Conidia germinate to give rise to capilliconidia, which represent the infective stage of *N. tanajoae*. Production of conidia and their germination into capilliconidia require specific climatic conditions, which are only met during nighttime in certain periods of the year in the tropics: (1) cool temperature, and (2) water-saturated air (Oduor et al., 1996a,b; Elliot et al., 2002). We chose to focus on conidiation because survival—and hence timing—is more critical here than in the capilliconidial phase. Capilliconidia can survive a few days until contacting and infecting a host, but conidia loose their viability within an hour below saturation conditions (Oduor, 1995). If the climatic conditions are not met, they fail to germinate and produce capilliconidia. Therefore, we measured the relation between the production of conidia and HIPV as a potential signal of host presence.

METHODS AND MATERIALS

Fungal Isolates. We used two Brazilian isolates that were successfully introduced in Benin (Altal.brz and Colal.brz) and one isolate found in Benin (Coton.ben). The isolates were preserved as mummified, infected *M. tanajoa* referred to as mummies. Mummies of Altal.brz and Colal.brz were collected from Alto Alegre and Colas das Almas in the state of Bahia, Brazil in 1995, respectively, whereas those of Coton.ben were collected in Cotonou, Benin, in 1997. Mummies of the three isolates were conserved inside tightly sealed photographic film canisters on dry cotton wool over another layer of cotton wool soaked in glycerol (serving as humidity trap) and maintained at 4°C. The stored isolates were cultured *in vivo* at approximately 6-mo intervals to minimize loss of viability. For each experiment, a new batch of mummies was produced for each isolate to be used within a maximum of 2 wk.

Analysis of Volatile Blends. We analyzed the volatile blends from infested and clean young cassava plants (ca. 6 wk old). Plants had the same number (nine) and the same size of leaves, and they were maintained in separate cages at 25°C in climate houses. Two clean plants and four plants infested with *M. tanajoa* were tested for emission of volatiles. Infested plants carried 450–600 adult female *M. tanajoa*. The collection was done following the procedure described by Agrawal et al. (2002). Per plant, volatiles were collected from all nine detached leaves and the plant apex and were put together into a 5-l glass desiccator. Volatiles were trapped on Tenax adsorbent (90 mg) packed in a 160 × 4-mm-ID glass tube (Chrompack) by blowing purified air (ca. 100 ml/min) through the desiccator for 90 min. Incoming air was purified by drawing it through silica gel, activated charcoal, and Tenax. The Tenax tubes were stored at room temperature in the dark until before retrieving the adsorbents through thermodesorption at 250°C for 10 min in a helium flow (10 ml/min). Desorbed products were cold-trapped at −90°C (M-16200, Chrompack) and analyzed with GC-MS. Compounds were identified by comparing the mass spectra obtained with those in the Wiley-Library and our own specialized library of natural products and by comparison of retention times (see Agrawal et al., 2002).

Exposure to HIPV. Two types of experiments were conducted to assess the effect of HIPV on conidiation of *N. tanajoae*. One was conducted in closed Petri dishes to compare conidiation of the three *N. tanajoae* isolates when exposed to volatiles emanating from small, excised leaf discs that were treated in various ways. The second experiment was conducted in a system with a regulated airflow containing either clean air or HIPV emanating from cassava leaves detached from the plant.

Diffusion in Closed Dish Environment. This experiment consisted of four treatments, differing in the sources of volatiles production and clean air as control (Figure 1). Volatiles emanated from leaf discs (2 cm diam) that were

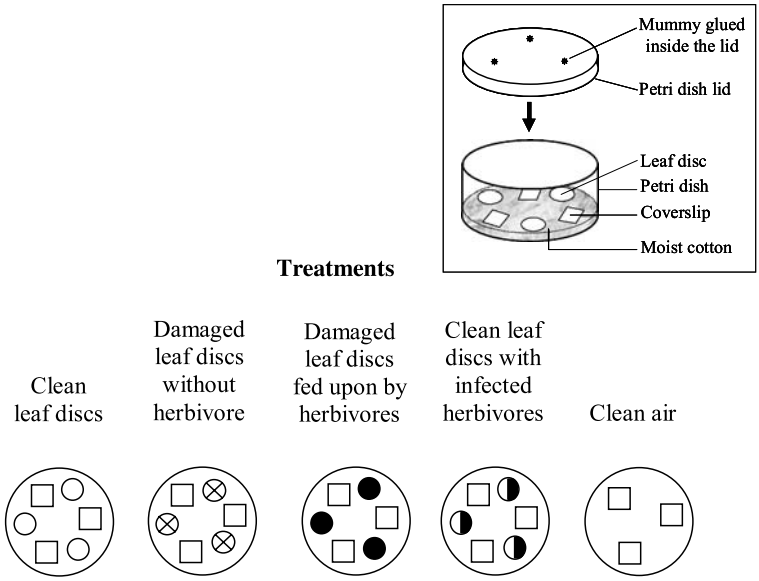

FIG. 1. Arrangement of coverslips to collect conidia (squares) and treated leaf discs (small circles) in a study of the effect of HIPV on conidiation for each isolate of the fungal pathogen *N. tanajoae* in closed dish experiment (large circle = Petri dish; see inset for a three-dimensional view of a Petri dish with mummies of the lid, illustrating the "descending conidia" setup). The volatiles to which the mummies are exposed emanate from the leaf discs, which were treated as follows: clean (open circles), damaged by the herbivore *M. tanajoa*, which were removed just before the experiment (crossed circles), infested with *M. tanajoa* females that were not infected by the fungus (black circles), and clean leaf discs with *M. tanajoa* infected and mummified by *N. tanajoae* (semi-black circles). Control dishes had no leaf discs.

excised from the first fully expanded leaves of intact cassava plants (cv Agric) and that were subjected to the following treatments prior to the experiment:

- Herbivore-damaged leaf discs from which all *M. tanajoa* and byproducts (web and feces) were removed (leaf damage scale rated 4 following the damage evaluation system proposed by Yaninek et al., 1989).
- Leaf discs on which six young adult females of *M. tanajoa*, introduced 2 hr before the experiment (leaf damage scale 2), were feeding.
- Clean leaf discs with six adult females of *M. tanajoa* mummified due to infection by *N. tanajoae* (mummies do not feed; hence no herbivore damage).
- Leaf discs excised from herbivore-free plants ("clean" leaf discs).

The method of "descending conidia" described by Papierok and Hajek (1997) was used to carry out conidiation. Three mummified mites (infected by *N. tanajoae*) were glued upside down using double-sided sticky tape, inside of the lid of a Petri dish (9 cm diam), with the distance between mummies being 4 cm. The conidia ejected from these mummies were shed over 2 × 2-cm coverslips on moist cotton at the bottom of the dish (Figure 1). Cotton inside the Petri dish was soaked with water until it reached the upper two thirds of the dish height, ensuring a maximum distance of 0.5 cm between coverslips and mummies. In between the coverslips, on the moist cotton, each dish had three leaf discs that received the same treatment (one of the four treatments mentioned earlier). Leaf discs were not provided in the control dishes. Each experiment involved five dishes per fungal isolate: four dishes for the different treatments and one for the control (Figure 1). The experiment was repeated three times. Petri dishes were closed with a lid that was fixed with two strips of tape at opposite sides of the lid to keep the mummies above the center of the coverslips. Petri dishes were covered with black cloth to avoid exposure to light (sporulation occurs at night) and incubated at 20 ± 1°C for 6 hr because previous experiments conducted with the three isolates showed that most conidia were produced within 6 hr at these conditions.

After the incubation period, dishes were left open for about 15 min to allow coverslips, covered with water droplets, to surface-dry. Conidia on the coverslips were mounted by turning the coverslips upside down on glass slides with a drop of 0.1% lactophenol blue for staining the conidia. Counts were made under a dissecting microscope (Zeiss, STEMI 2000, 45× magnifications) with inverted light. A piece of cross-ruled transparency was attached under the slide to facilitate counting.

Airflow System. Conidiation experiments were also performed in an airflow box. This was a plastic, cylinder-shaped (12 cm diam, 8 cm high) box with a lid tightly sealed with Teflon and Parafilm. There was an air inlet and an outlet to expose the mummies to an airflow permeated or not with volatile, according to treatment or control (Figure 2). Moistened cotton was placed on the bottom of this airflow box. On top of the cotton layer, there were five sporulation dishes (2.5 cm diam), with a coverslip on a thin layer of cotton on the bottom (inset in Figure 2). A single mummy was glued to the lid of the sporulation dish with double-sided sticky tape, right above the coverslip so that the conidia ejected from the mummy would end up on the coverslip. The conidia on this coverslip were counted following the same procedure as described above. To provide optimal conditions for conidiation, the experiment was carried out in the dark, in a climate room at 20°C, and at high humidity (due to moistened cotton in sporulation dish and airflow box). To facilitate air exchange with the airflow box, each sporulation dish had four equidistant holes (0.4 cm diam) along its lateral side.

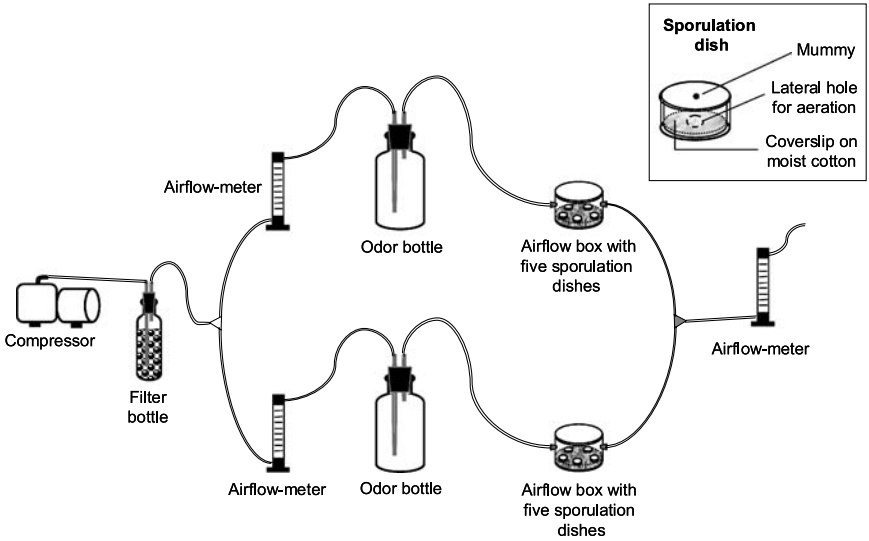

FIG. 2. Diagrammatic view of the airflow system. Air from the compressor was filtered by a bottle containing charcoal before going through airflow meters, the odor bottles (one of which contained herbivore-infested leaves; the other one was empty), the airflow boxes containing sporulation dishes (see inset), and exiting through another airflow meter. Airflow meters served to regulate the flow speed; the exit airflow meter ensures a uniform flow between the two arms of the system. Teflon tubing connected the different parts of the system.

In this experiment, HIPV (treatment) was tested against clean air (control). HIPV emanated from six young cassava leaves (third leaves from the apex) each infested for 3 hr prior to the experiment with 100 females of *M. tanajoa* (that were feeding on the leaves during the experiment) inside one of the two glass odor bottles (Figure 2). Leaves were kept fresh by inserting their petiole through a Parafilm cover into a small vial (1 cm diam, 5 cm high) with water. Airflow in the system was generated by means of a compressor (SERBATOI® AUTOCLAVI, Type ELTO, volume 50 l). The air moved through tubes from the compressor to a bottle containing a charcoal filter to make it clean, then consecutively to the airflow meters, the odor bottles, the airflow boxes, and finally to an airflow meter again (Figure 2). The airflow meters at the beginning and end of the two arms of the system are necessary to maintain a uniform airflow of 1 l/min. in both arms.

Using this setup, we assessed the effect of HIPV from *M. tanajoa*-infested cassava leaves on the conidiation of the two fungal isolates Colal.brz and Coton.ben. The experiment was replicated 10 times for each isolate. Sporulation

was allowed to take place for 24 hr. Before each experiment, airflow boxes and sporulation dishes were washed, whereas cotton wool and coverslips were replaced. Prior to putting the herbivore-infested leaves in the odor bottle and placing the mummies in the sporulation dishes, clean air was allowed to flow through both arms of the system for 2 hr. For successive experiments, allocation of clean air or HIPV was alternated between the two arms in the split tube circuit shown in Figure 2.

Data Analysis. To estimate the original number of conidia produced, it was necessary to calculate the sum of the number of nongerminated conidia, germinating conidia, and capilliconidia that had developed from conidia while ignoring the shriveled remnants of the germinated conidia.

For the closed dish experiment, data for original numbers of conidia were square-root transformed before analysis. A generalized linear model (GLM) procedure (SAS Institute Inc., 1999) was applied to test differences in conidia production between the main factors and their interactions. Isolate and treatments were treated as fixed factors, whereas experiment was treated as a random factor. Tukey's Studentized range test served to separate means at the 5% level.

With respect to the airflow experiment, data were analyzed using replicated goodness-of-fit tests against a 1:1 null hypothesis (Sokal and Rohlf, 1997, p 716). In this way, we assessed the effect of HIPV on conidiation in each replicated experiment, and across the different experiments, to account for heterogeneity among the trials. If heterogeneity was significant, groups of homogeneous replicates were identified using an unplanned comparisons procedure, and a *G*-test on pooled results within homogeneous groups of replicates was subsequently carried out to scrutinize the extent to which heterogeneity affected the validity of the total *G*-statistic based on all the experiments (Sokal and Rohlf, 1997, p 722).

RESULTS

Composition of Volatile Blends. Figure 3 shows histograms of mean chromatogram peak areas for all volatiles that contributed >5% to the total chromatogram peak area. In the blend emanating from clean leaves, five volatiles were produced in relatively large amounts, namely, 2-butanon (2), 3-pentanon (3), (*trans*)-(*E*)-2-hexanal (8), (*Z*)-3-hexen-1-ol (11), and (*E*)-2-hexen-1-ol (12). In the blend emanating from infested leaves, these volatiles were produced in higher or lower quantities, particularly the production of (*trans*)-(*E*)-2-hexanal (eight) was somewhat decreased, and that of (*Z*)-3-hexen-1-ol (11) was increased. Moreover, these blends emanating from infested leaves contained six volatiles that were only present in trace quantities in the blends from clean

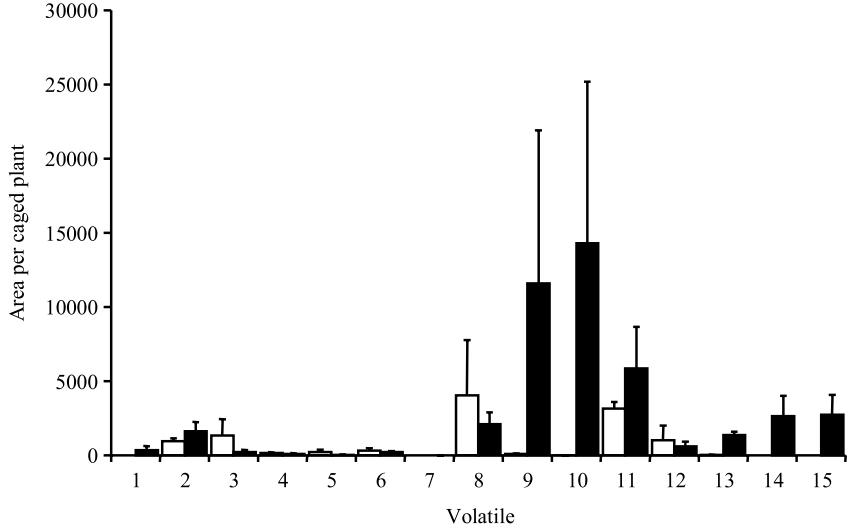

FIG. 3. Quantity of volatiles (expressed in mean peak areas ± SE) produced by leaves and apices from single clean cassava plants (open bars; $N = 2$) or from single cassava plants infested by *M. tanajoa* (closed bars; $N = 4$). The volatiles were identified by GC-MS. Only those that contributed >5% to the total peak area in the chromatograms are shown: (1) *O*-methyloxime-2-methylpropanal; (2) 2-butanon; (3) 3-pentanon; (4) 1-penten-3-on; (5) 1-butanol; (6) 1-penten-3-ol; (7) heptanal; (8) (*trans*)-(*E*)-2-hexenal; (9) (*E*)-(*trans*)-beta ocimene; (10) (3*E*)-4,8,-dimethyl-1,3,7,-nonatriene; (11) (*Z*)-3-hexen-1-ol; (12) (*E*)-2-hexen-1-ol; (13) linalool; (14) methyl salicylate; (15) 4,8,12-trimethyl-1,3(*E*),7(*E*),11-tridecatetraene.

leaves. In decreasing concentrations, these were (3*E*)-4,8-dimethyl-1,3,7-nonatriene (10), (*E*)-(*trans*)-beta ocimene (nine), 4,8,12-trimethyl-1,3(*E*),7(*E*), 11-tridecatetraene (15), methyl salicylate (14), and linalool (13) and, to a lesser extent, *O*-methyloxime-2-methylpropanal (one). Thus we found strong support for the release of volatiles by cassava plant upon herbivory by *M. tanajoa*, thereby confirming earlier inferences from behavioral experiments (Janssen et al., 1990; Gnanvossou et al., 2001). These volatiles are most likely to be herbivore-induced plant volatiles (HIPV) and not byproducts of the feces and the web (Sabelis et al., 1984; Dicke et al., 1990; Gnanvossou et al., 2001).

Closed Dish Experiment. The collective response of all three isolates of *N. tanajoa* to the treatments was close to significance (Table 1). No significant difference was observed between the conidia production of the isolates when all treatments were considered together (Table 1). However, a significant interaction was found between the treatments and the isolates (Table 1) indicating

TABLE 1. EFFECT OF VOLATILES FROM TREATED CASSAVA LEAF DISCS ON CONIDIATION OF THREE ISOLATES (ALTAL.BRZ, COLAL.BRZ, AND COTON.BEN) OF THE FUNGAL PATHOGEN *Neozygites tanajoae*, 6 HR AFTER INTRODUCING MUMMIES OF *Mononychellus tanajoa* INTO THE CLOSED DISH EXPERIMENT

differences in responses to treatments among isolates. To detect trends among the different responses of the isolates, we plotted conidia production under all five treatments for each isolate (Figure 4).

Averaged overall treatments, the isolate Coton.ben produced 292.3 conidia per mummy and showed relatively little variation in response to the different

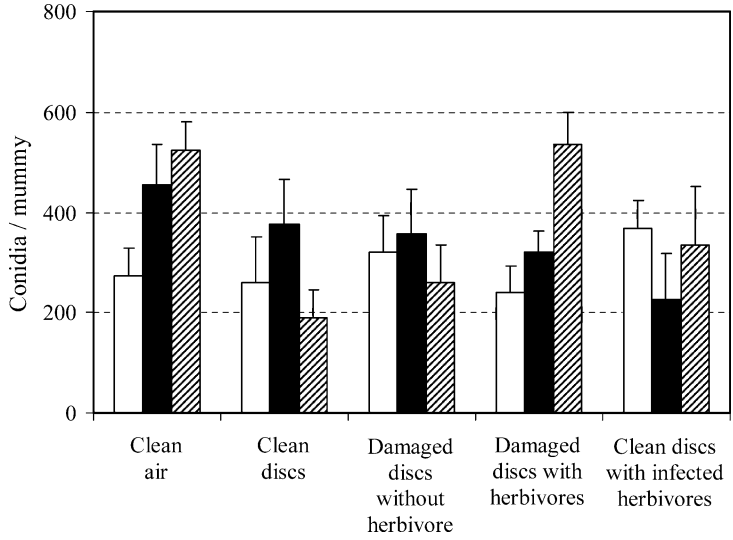

FIG. 4. Conidia production of three isolates (white bars: Coton.ben; black bars: Altal.brz; hatched bars: Colal.brz) of the fungal pathogen *N. tanajoae*, under five different treatments (see Figure 1), 6 hr after introducing mummies of the herbivorous mite *M. tanajoa* into the closed dish experiment.

treatments (coefficient of variation $V^* = 18.9\%$; Sokal and Rohlf, 1997). The isolate Altal.brz produced a mean number of 347.1 conidia per mummy and showed somewhat more variation in response to the different treatments ($V^* = 25.6\%$). Much of this variation can be attributed to the high conidia production under clean air. The isolate Colal.brz produced a mean number of 368.6 conidia per mummy, but the variation in response to the different treatments was much higher than in the other two isolates ($V^* = 44.9\%$). Much of this variation here can be attributed to the strikingly high conidia production under clean air and when exposed to volatiles from leaf discs infested by *M. tanajoa*.

The variation expressed by the isolate Colal.brz in the bar plot points to a trend in responses to clean air as well as to volatiles from leaf discs fed upon by *M. tanajoa*. This trend was also indicated by the nearly significant difference between the treatments (Table 1). To identify potential causes for this trend, a Tukey test was applied following the GLM analysis to separate means between the treatments. This showed a significant difference ($P < 0.05$) between clean air and volatiles from clean leaf discs: 428.8 ± 41.46 conidia per mummy vs. 275.1 ± 47.48 conidia per mummy (mean ± SE), respectively. Furthermore, given the high variability and large differences in the responses to the treatments by the isolate Colal.brz, an ANOVA was conducted for this isolate alone, and significant differences in conidia production were found between the treatments ($P = 0.003$, $F = 4.01$, $df = 4$, $N = 45$). Subsequent Tukey tests to compare the means showed a significant difference between conidia production ($P < 0.05$) under volatiles from leaf discs fed upon by *M. tanajoa* and volatiles from clean leaf discs, but no significant difference between leaf discs fed upon by *M. tanajoa* and clean air (Figure 4).

Airflow System. Given that Colal.brz gave the most striking differences between clean air and volatiles from clean leaf discs and virtually no difference between clean air and volatiles from leaves fed upon by *M. tanajoa*, we decided to challenge the latter result by repeating the experiment with the following modifications: (1) using intact leaves as volatiles sources (instead of leaf discs), (2) starting with a higher infestation of herbivorous mites on cassava leaves (30× more mites than in closed dish experiment), and (3) allowing the herbivorous mites to feed longer on cassava leaves (3 d instead of 2 hr). Using the replicated *G*-test for total *G*-statistics, we found that conidia production was significantly higher in an air stream with volatiles from cassava leaves infested by *M. tanajoa* than under clean air conditions (404.7 conidia per mummy vs. 354.0 conidia per mummy; hence 14% more conidia; total $G = 967.52$, $df = 10$, $P < 0.001$). In total, there were five significant replicates in favor of the control with a difference in conidia production of only 46% (±20.6 SE) of the treatment (Figure 5). There were four significant replicates in favor of the treatment (volatiles from infested leaves), and here the difference was 187% (±71.9 SE) of the control (Figure 5). Indeed, heterogeneity among replicates

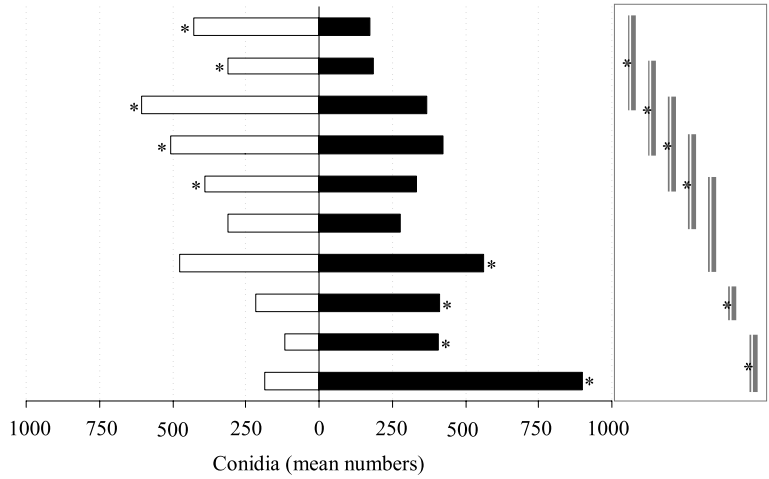

FIG. 5. Conidia production of a Brazilian isolate of *N. tanajoae* (Colal.brz) in the presence (black bars) and absence (open bars) of volatiles from intact cassava leaves infested by the herbivorous mite *M. tanajoa* in the airflow system experiment. Replicates of each treatment were carried out simultaneously with a replicate of the other treatment, and the results are therefore shown pairwise for 10 replicates. Significant differences among simultaneous replicates of the two treatments are indicated by an asterisk. Since replicated *G*-test indicated significant heterogeneity among the replicates, unplanned comparisons were carried out to test for homogeneity among replicates. The right-hand panel shows the groups of homogeneous replicates; significant differences between the two treatments using the pooled *G*-statistic within homogenous replicates are indicated by an asterisk.

was significant (heterogeneity $G = 933.52$, $df = 9$, $P < 0.001$). Unplanned comparisons showed groups of one, two, and more often three replicates that were homogeneous (Figure 5, right-hand panel). Taken together, the comparisons indicated a large variability among replicates (i.e., small homogeneous groups). It should be noted that whenever homogeneous groups showed a significantly higher effect of HIPV on conidia production in the treatment, the numerical difference was more pronounced than when the higher effect was found in the control.

To test whether the absence of a response in the closed dish environment implies the same response under conditions where volatiles come from intact leaves infested by a larger population of herbivorous mites feeding for a longer period, we also assessed conidiation of another isolate, i.e., Coton.ben. We found that conidia production of this isolate was significantly higher in an air stream with volatiles from cassava leaves infested by *M. tanajoa* than under

clean air (251.0 conidia per mummy vs. 183.8 conidia per mummy; hence 37% more conidia). This can be inferred from the replicated *G*-test for total *G*-statistic (total $G = 693.11$, $df = 10$, $P < 0.001$). In total, there were two replicates with significantly more conidia under clean air stream, whereas there were eight replicates with significantly more conidia under an air stream with volatiles from infested leaves (Figure 6). Significant heterogeneity was observed among replicates (heterogeneity $G = 588.93$, $df = 9$, $P < 0.001$). Unplanned comparisons showed that apart from one group of two replicates there were four groups of four replicates that were homogeneous (Figure 6, right-hand panel). Replicated *G*-tests within the latter four homogeneous groups were all significant and all in favor of a higher production of conidia when exposed to HIPV. Note that the homogeneous group size for Coton.ben is somewhat larger than for the other isolate (Colal.brz), indicating a relatively lower level of heterogeneity.

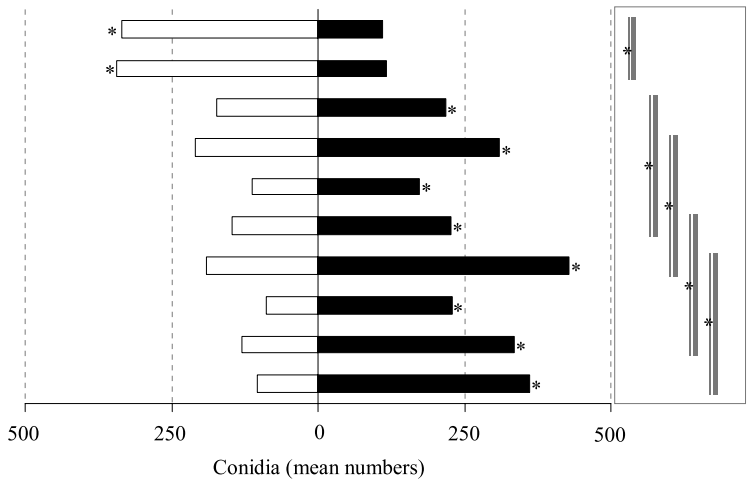

FIG. 6. Conidia production of a Benin isolate of *N. tanajoae* (Coton.ben) in the presence (black bars) and absence (open bars) of volatiles from intact cassava leaves infested by the herbivorous mite *M. tanajoa* in the airflow system experiment. Replicates of each treatment were carried out simultaneously with a replicate of the other treatment and the results are, therefore, shown pairwise for 10 replicates. Significant differences among simultaneous replicates of the two treatments are indicated by an asterisk. Since replicated *G*-test indicated significant heterogeneity among replicates, unplanned comparisons were carried out to test for homogeneity among replicates. The right-hand panel shows the groups of homogeneous replicates; significant differences between the two treatments using the pooled *G*-statistic within homogenous replicates are indicated by an asterisk.

DISCUSSION

Based on the results of our closed dish experiments, we conclude that volatiles from clean leaves (green leaf volatiles; GLV) suppressed conidiation in the two Brazilian isolates (Colal.brz and Altal.brz), whereas volatiles from leaves infested by *M. tanajoa* stimulated conidiation in the Brazilian isolate Colal.brz (Figure 4). Evidence for inhibition by GLV comes from the significantly lower number of conidia produced in the presence of volatiles emanating from excised clean leaf discs than produced with clean air. Evidence for stimulation by HIPV was only found for the Brazilian isolate Colal.brz. It is based on the higher number of conidia produced in the presence of volatiles from *M. tanajoa*-infested leaf discs than produced under exposure to volatiles from clean leaf discs.

It is puzzling that conidia production did not differ between the treatment with clean air and that with volatiles from leaf discs fed upon by *M. tanajoa*. To further analyze this, we carried out a similar experiment, but now following another setup (i.e., the airflow system) in which the amount of volatiles from infested leaves was increased (six intact leaves instead of three excised leaf discs; 30 times more *M. tanajoa* feeding for 3 d instead of 2 hr). This experiment showed that for the Benin isolate (Coton.ben), conidia production is significantly higher when exposed to volatiles from infested leaves than when exposed to clean air (Figure 6). For the Brazilian isolate (Colal.brz), we found much heterogeneity among replicates and apart from a bias in favor of higher conidia production under exposure to HIPV we did not obtain statistical evidence for an effect of HIPV (Figure 5). Possibly, each isolate has a unique optimum in its response to different concentrations of HIPV. The significant effects for the Brazilian isolate (Colal.brz) using the closed dish experiment and that for the Benin isolate (Coton.ben) are consistent with the hypothesis that HIPV stimulates conidiation.

Inhibition of conidiation in response to volatiles from herbivore-free plants has been reported earlier for the aphid pathogen *P. neoaphidis* when exposed to volatiles from macerated tobacco leaves (Brown et al., 1995). Inhibition of growth was also reported in response to isothiocyanate in other insect fungi (e.g., Klingen et al., 2002) and in response to phytoalexins in plant pathogens (Baily, 1970; Fraser, 1970). Some fungi were also found to produce volatiles with a self-inhibiting effect (Chitarra et al., 2004). Whereas evidence for inhibition by volatile chemicals exists, stimulation of conidiation by herbivore-induced plant volatiles is a novel finding. It should be noted that our experiments were done under climatic conditions that are optimal for sporulation, even in the absence of chemical signals (Oduor et al., 1996a). Thus the effects of HIPV and GLV were inevitably of a relative nature. Therefore, it would be worthwhile to repeat them under conditions that are marginal for sporulation.

From a functional point of view, it is in the interest of the entomopathogenic fungus to delay conidiation until HIPV signals that herbivores are nearby. However, this leaves unexplained why conidiation readily takes place in clean air, even more so because inside a mummy the fungus would be able to survive under dry conditions for more than 8 mo (Oduor et al., 1995). We hypothesize that the fungus does not gain by delaying sporulation in an environment without cues from plants, and it may only successfully infect in the event that there is an unlucky herbivore passing by.

Whereas predators and parasitoids are well known to exploit HIPV as a source of information on the location of their victims, entomopathogens have received little attention in this respect. Infochemicals in general have been shown to play a role in this class of natural enemies (baculovirus: Felton and Duffey, 1990; Hoover et al., 1998; entomopathogenic fungi: Brown et al., 1995; entomopathogenic nematodes: Choo et al., 1989; Lei et al., 1992; Lewis et al., 1992, 1993, 1996; Grewal et al., 1993a,b, 1994; Kanagy and Kaya, 1996; Wang and Gaugler, 1998; Boff et al., 2001; Boff and Smits, 2001; van Tol et al., 2001; Cutler and Webster, 2003), but most of these studies concern entomopathogenic nematodes. Among them, recent work by van Tol et al. (2001) and Boff et al. (2001) showed that HIPV from roots of weevil-infested *Thuja* plants attracts the entomopathogenic nematode *Heterorhabditis megidis*. However, fungi are essentially motionless, and attraction cannot, therefore, play a role. Here we showed that HIPV may help to tune conidia production to the presence of herbivores on plants. This paves the way for further tests on the benefits to the plant of releasing volatiles upon herbivore attack.

Another major question for future research is "which components of the volatile blends emanating from herbivore-free and herbivore-infested cassava plants are responsible for inhibition or stimulation?''. It is interesting to note that (*trans*)-(*E*)-2-hexanal, a major component of the blend of volatiles from herbivore-free cassava plants (Figure 3), has been shown to have an inhibiting effect on conidiation of the aphid pathogen *P. neoaphidis* (Brown et al., 1995). As shown by our GC-MS analysis (Figure 3), there are other components of GLV [e.g., (*Z*)-3-hexen-1-ol; (*E*)-2-hexen-1-ol; 3-pentanon; 2-butanon], and HIPV [e.g., (3*E*)-4,8,-dimethyl-1,3,7,-nonatriene; (*E*)-(*trans*)-beta ocimene; 4,8,12-trimethyl-1,3(*E*),7(*E*),11-tridecatetraene; methyl salicylate; linalool], and these are yet to be tested for inhibition or stimulation of conidiation in *N. tanajoae*.

The conidiation responses of the entomopathogenic fungus to HIPV showed much more heterogeneity than the behavioral responses of predatory mites to HIPV (Janssen et al., 1990; Margolies et al., 1997; Gnanvossou et al., 2001; Aratchige et al., 2004). For example, our experiments resulted in mummies yielding 1000 conidia and mummies yielding none, whereas the average number of conidia was about 250. If our hypothesis on the function of HIPV for the

plant and the entomopathogen holds, then why is there so much variability? One explanation may be that we did not sufficiently standardize the conditions of the host and/or the entomopathogen. Whereas we chose adult females as the only hosts under test, we did not select a uniform female size because this is a hard task to carry out with arthropods as small as mites. Variation in host size may cause variation in conidia yield and thereby create noise in our experimental data. Pathogen quality may also have varied in our experiments, for example, because within-host density of hyphal bodies (preceding spore formation) may differ between hosts due to variation in the number of capilliconidia infecting the host or due to variation in host quality. Our current method to propagate the entomopathogen *in vivo* is such that these variations inevitably arise. Development of *in vitro* culturing methods would be a breakthrough in helping to standardize pathogen quality. If further standardization would not substantially reduce variability in the response to HIPV, then there may be a functional reason for its existence. Entomopathogens have a risky life because they are immobile and the infective stages are especially short-lived and sensitive to abiotic conditions. This is why entomopathogens may not use HIPV as the only signal for sporulation, but possibly several other cues related to the presence of potential hosts (e.g., feces, silk). If there are many cues affecting sporulation, and the presence of those cues varies in time and space, then one may either expect entomopathogens to show the full repertoire of responses or a subset if the ability to perceive the cues entails significant costs. In the latter case, variability in responsiveness to the different cues is expected, even among the descendants of a single spore if there is a selective advantage to spreading the risk.

Acknowledgments—We are grateful to Andy Cherry for supporting the realization of this study and Honoré Dossounon, Roland Bocco, and Kevin Yenou for their technical assistance. We also thank Martijn Egas, Michiel van Wijk, Alexis Onzo, and Désiré Gnanvossou for constructive comments on the manuscript. This research was supported by the International Institute of Tropical Agriculture with funds from Danish International Development Assistance (Danida) and the International Fund for Agricultural Development (IFAD), and by the University of Amsterdam. ANTENNAL ELECTROPHYSIOLOGICAL RESPONSES OF THREE PARASITIC WASPS TO CATERPILLAR-INDUCED VOLATILES FROM MAIZE (*Zea mays mays*), COTTON (*Gossypium herbaceum*), AND COWPEA (*Vigna unguiculata*)

(Received October 22, 2004; accepted January 10, 2005)

Abstract—Many parasitic wasps are attracted to volatiles that are released by plants when attacked by potential hosts. The attractiveness of these semiochemicals from damaged plants has been demonstrated in many tritrophic systems, but the physiological mechanisms underlying the insect responses are poorly understood. We recorded the antennal perception by three parasitoids (*Cotesia marginiventris*, *Microplitis rufiventris*, and *Campoletis sonorensis*) to volatiles emitted by maize, cowpea, and cotton plants after attack by the common caterpillar pest *Spodoptera littoralis*. Gas chromatography-electroantennography (GC-EAG) recordings showed that wasps responded to many, but not all, of the compounds present at the physiologically relevant levels tested. Interestingly, some minor compounds, still unidentified, elicited strong responses from the wasps. These results indicate that wasps are able to detect many odorant compounds released by the plants. It remains to be determined how this information is processed and leads to the specific behavior of the parasitoids.

Key Words—GC-EAG, electrophysiology, *Cotesia marginiventris*, *Microplitis rufiventris*, *Campoletis sonorensis*, induced plant odor.

INTRODUCTION

Many plants attacked by herbivorous insects indirectly defend themselves by emitting semiochemicals that act as attractants for natural enemies of the attackers (Dicke and Sabelis, 1988; Turlings et al., 1990; Steinberg et al., 1993; Agelopoulos and Keller, 1994; Geervliet et al., 1994; Röse et al., 1997; Du et al., 1998; Shiojiri et al., 2000; Neveu et al., 2002). At least 12 families of plants produce volatiles in response to herbivory (Dicke, 1999). The compositions of the volatiles produced are variable, but isoprenoids, lipoxygenase-derived volatiles, and aromatics (derived from either the phenylalanine–ammonia–lyase pathway or from other amino acids) commonly dominate the blends released by insect-damaged plants (Whitman and Eller, 1990; Tumlinson et al., 1992; Rutledge, 1996). The emission of volatiles after attack by Lepidoptera is induced by elicitors in the oral secretions of herbivores (Dicke et al., 1993; Turlings et al., 1993; Mattiacci et al., 1995). Two different types of elicitors have been identified, a β-glucosidase from *Pieris rapae* (Lepidoptera: Pieridae) (Mattiacci et al., 1995), and fatty acid derivatives, such as volicitin isolated from *Spodoptera exigua* (Lepidoptera: Noctuidae) (Alborn et al., 1997; Turlings et al., 2000).

Spodoptera spp. (Lepidoptera: Noctuidae) larvae are important pests of various cultivated plants, including maize (*Zea mays mays*), cotton (*Gossypium herbaceum*), and cowpea (*Vigna unguiculata*). In response to larval feeding, these plants emit a particular odor (Turlings, 1990; McCall et al., 1993; Röse et al., 1996) that is perceptible even by humans (Gouinguené, personal observation). These pests can be parasitized by various wasps, including *Cotesia marginiventris* (Hymenoptera: Braconidae), *Microplitis rufiventris* (Hymenoptera: Braconidae), and *Campoletis sonorensis* (Hymenoptera: Ichneumonidae). The induced odors emitted by maize, cotton, and cowpea plants during feeding by *Spodoptera* spp. are attractive to each of these parasitoids (Turlings et al., 1995; Röse et al., 1998; C. Tamó and T. Degen, personal communication). According to the species of plant, the induced odor can vary, although some common substances are present in the different blends (Turlings et al., 1991; Röse et al., 1998; Hoballah et al., 2002). *C. marginiventris* and *C. sonorensis* originate from the new world, while *M. rufiventris* occurs in the old world, in particular in north Africa. These are generalists, although *M. rufiventris* is found more often parasitizing *S. littoralis* feeding on cotton plants (C. Tamó, personal communication). The different hosts of these parasitoids are often generalists, and feed on various plant families, including maize, cotton, and cowpea.

Although the responses of parasitoids to induced plant odors have been intensively studied in terms of behavior, the physiological mechanisms underlying the behavior are largely unknown. Coupled high-resolution gas chromatog-

raphy (GC) and electrophysiology techniques can be used to identify physiologically active compounds from complex natural product extracts (Wadhams, 1990). This approach has been used to determine active components in the odor blend of maize for *C. flavipes*, a parasitoid of the stemborer spp (Ngi-Song and Overholt, 1997). Female *C. flavipes* respond to six compounds (an unidentified C_5 compound, heptanal, (*Z*)-3-hexenyl acetate, (*E*)-ocimene, linalool, and (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT)) in the odor of maize infested with *Chilo partellus* larvae (Lepidoptera: Pyralidae). Using simple EAG recordings, *C. sonorensis* has been shown to respond to green leaf volatiles, monoterpenes (α-pinene, myrcene, limonene), and with lower sensitivity to sesquiterpenoids (gossonorol, β-caryophyllene oxide, β-caryophyllene, α-humulene) (Baehrecke et al., 1989). So far, no data are available on the perception of induced odor by *C. marginiventris* and *M. rufiventris*. EAG recordings have also been used to test the sensitivity of antennal perception in some other parasitoids (Lecomte and Pouzat, 1985; Salom et al., 1991; Jyothi et al., 2002). Only a few studies on parasitoids have been done using coupled GC and EAG systems. Pettersson et al. (2000) found that the bark beetle parasitoid, *Rotrocerus xylophagum* (Hymenoptera: Pteromilidae), did not respond to the major compounds present in the bark oil. More recently, Smid et al. (2002) compared the responses of a specialist and generalist parasitoid of *Pieris* caterpillar to attacked Brussels sprouts, and showed that the two parasitoid species responded similarly to a large number of compounds present in the odor of damaged plants. Interestingly, two compounds were only perceived by the specialist parasitoid (*Cotesia rubecula*) (Smid et al., 2002).

The aim of this study was to use the GC-EAG approach to determine and to compare the antennal perception of compounds in the induced odor blends of maize, cotton, and cowpea for the three generalist parasitoids *C. marginiventris*, *M. rufiventris*, and *C. sonorensis*, which show strong similarities in host range and life cycle.

METHODS AND MATERIALS

Insects. *C. marginiventris*, *M. rufiventris*, and *C. sonorensis* were provided by the Laboratory of Animal Ecology and Entomology, University of Neuchâtel, Switzerland. The rearing of the three parasitoids follows the same procedure. Second instar larvae of *S. littoralis* were exposed to female parasitic wasps for at least 2 hr, then wasps were removed and the larvae reared on artificial diet (Syngenta, Basel, Switzerland). When the parasitic larvae are ready to pupate, they exit the host and form cocoons that can be easily collected. Cocoons were placed in plastic boxes (13.5 × 7.5 × 6 cm) with wet cotton to

maintain humidity and drops of honey for food. Newly-emerged adult parasitoids were sexed, and placed in plastic cups (6.5 × 5.5 cm diam.), and were provided with honey and wet cotton. They were kept in a climate chamber (20°C, 40% RH) and 2- to 3-d-old females were used in experiments.

Collection of Induced Odors. Air entrainment samples of induced odor of cotton, maize (variety Delprim), and cowpea were used, and were prepared at the University of Neuchâtel. Three seeds of cotton, maize, and cowpea were sown in plastic pots, filled with fertilized potting soil (Coop, Switzerland). Plants were grown in a climate chamber at 23°C, 60% RH, and under 50,000 lm/m^2 (16L:8D). Fifteen-d-old plants were used. To induce the plants to emit volatiles, 30 *S. littoralis* larvae (second instar) were allowed to feed on the three plant species for 2 d prior to the first odor collection. The volatile collection system has been described in detail (Turlings et al., 1998) and was modified as follows. It consisted of five vertically placed glass cylinders (7 cm i.d., 43 cm high). The pot with the three plants was placed in a glass pot (7 cm diam., 8.5 cm high), which fits in the vertical cylindrical glass. Purified and humidified air was pushed into each cylinder at a rate of 1 l/min and flowed around the plant. Around the base of each cylinder, an opening served as a port that could hold the collection traps. For collections, air was drawn (0.8 l/min) through a Super-Q adsorbent trap (Heath and Manukian, 1994), while the rest of the air vented through the hole in the top, thus preventing external, impure air from entering. The automated part of the collection system (Analytical Research System, Gainesville, FL, USA) controlled flow through the trap. The climate chamber (CMP4030, CONVIRON, Winnipeg, Canada) in which the collection cylinders were housed was kept at 17.5°C. Due to the heat irradiation, the temperature inside the cylinders was 23 ± 3°C. During the photophase (16L:8D) light intensity was approx. 20,000 lm/m^2.

Two collections were done during the day, starting 2 and 9 hr after the beginning of the photophase. Each collection lasted 6 hr. After each collection, traps were extracted with 250 μl of methylene chloride (Lichrosolv, Merck, Switzerland). The same plants were used for volatile collection the next day. At the end of the 2 d, the samples from the four collections of the same plant species were pooled. To obtain control samples, the same conditions were used to collect volatiles from undamaged plants, pot and soil only, and empty glasses.

Electrophysiology. Electroantennogram (EAG) recordings from 2- to 3-d-old female wasps were made using Ag–AgCl glass electrodes filled with saline solution (composition as Maddrell (1969), without glucose). The insect was anaesthetized by chilling, and the head was excised and inserted in the tip of the indifferent electrode. The tips of the two antennae were inserted into the recording electrode. Signals were passed through a high impedance amplifier

(UN-06, Syntech, The Netherlands) and analyzed by using a customized software package (Syntech, The Netherlands).

Coupled Gas Chromatography-Electroantennography (GC-EAG). The coupled GC-EAG system, in which the effluent of the GC column is simultaneously directed to the antennal preparation and the GC detector, has been described (Wadhams, 1990). Separation of the volatiles was achieved on an AI 93 GC equipped with a cold on-column injector and an FID. The column used was a 50 m × 0.32 mm i.d. HP-1 column (non polar). Oven temperature was maintained at 40°C for 2 min and then programmed at 5°C/min to 100°C and then at 10°C/min to 250°C. The carrier gas was hydrogen (15 psi). The outputs from the EAG amplifier and the FID were monitored simultaneously and analyzed with the software package (Syntech, the Netherlands). A standard stimulation was done at the beginning and at the end of each recording to correct for the loss of sensitivity of the preparation. The stimulus (100 μg of (*Z*)-3-hexenol) was applied on a filter paper strip, inserted in a Pasteur pipette, and a puff of odor was flushed on the EAG preparation. For the correction, we assumed that the decrease in sensitivity is linear with the time. Data were then normalized to the standard as follows:

$$\frac{A}{\mathrm{EAG(std1)} + (\mathrm{EAG(std2)} - \mathrm{EAG(std1)})\dfrac{\mathrm{RT(A)} - \mathrm{RT(std1)}}{\mathrm{RT(std2)} - \mathrm{RT(std1)}}}$$

where A is the amplitude (mV) of the EAG response to compound A; EAG(std1) is the EAG response to standard at the beginning of the recording; EAG(std2) is the EAG response to standard at the end of the recording; RT(A) is the retention time of compound A; RT(std1) is the time when the stimulation at the beginning of the recording was done; RT(std2) denotes the time when the stimulation at the end of the recording was done. For each induced odor tested, responses from 10 females were recorded.

Coupled Gas Chromatography-Mass Spectrometry (GC-MS). GC-MS was used to tentatively identify compounds giving rise to the peaks associated with EAG activity from the induced odor blend of maize, cowpea, and cotton. A capillary GC column (50 m × 0.32 mm i.d. HP-1) fitted with a cold on-column injector was directly coupled to a mass spectrometer (VG Autospec, Fisons Instruments). Ionization was by electron impact at 70 eV, 250°C. The oven temperature was maintained at 30°C for 5 min and then programmed at 5°C/min to 250°C. Peak identities were determined by comparison of the spectra with those of authentic compounds from synthesis or other botanical sources and confirmed by comparison of Kovat's indices.

Statistical Analysis. Normalized EAG responses of the three parasitoids to the different plants odor were compared using nonparametric tests. On each compound that activated a response from the parasitic wasps, a Kruskall–Wallis

comparison was done, when it was shown that the mean responses were different, Mann–Whitney pairs comparisons were realized to determine which parasitoid was different from which. For such comparison, the level of significativity was corrected using the Bonferroni correction, thus $\alpha = 0.017$.

RESULTS

Figures 1, 2, and 3 present representative GC-EAG recordings from the 10 replicates from each wasp species and each induced odor (60 recordings in total). Most of the major compounds elicited EAG responses from the three parasitoids. Some minor compounds also evoked strong responses (Figures 1, 2, and 3). The greatest responses were obtained from the green leaf volatiles (peaks a, b, n), whereas lower responses were recorded later in the GC-EAG analytical traces. This difference may reflect a differences in sharpness of the GC peaks and the number of molecules that hit the antennae at the same time and should not be interpreted as difference in strength of perception. Table 1

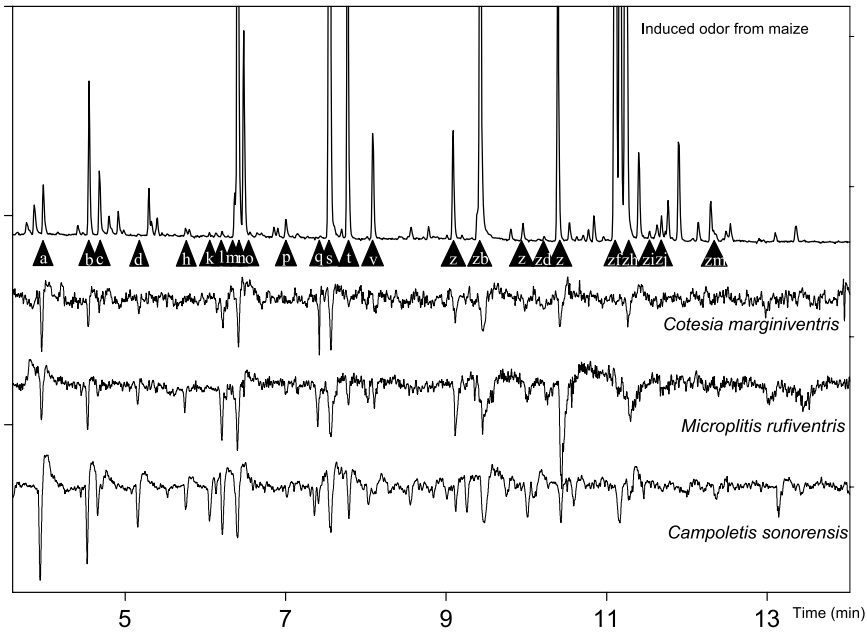

FIG. 1. GC-EAG traces of *Cotesia marginiventris*, *Microplitis rufiventris* and *Campoletis sonorensis* in response to the caterpillar-induced odor from maize.

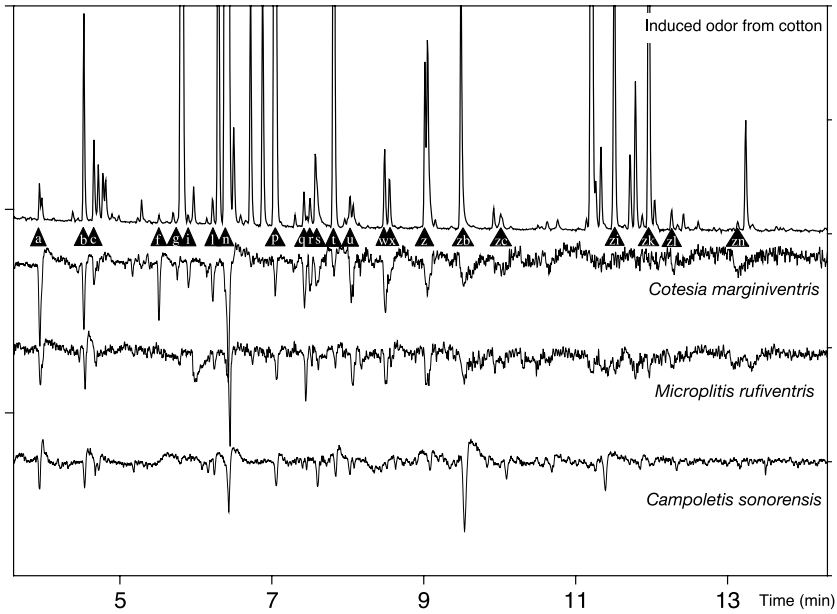

FIG. 2. GC-EAG traces of *Cotesia marginiventris*, *Microplitis rufiventris* and *Campoletis sonorensis* in response to the caterpillar-induced odor from cotton.

gives the identity and normalized EAG value of all the electrophysiologically active compounds in the three induced odor samples tested. The letter in the first column refers to the letters in Figures 1, 2, and 3. Only a few small responses were recorded from the volatile samples from undamaged control plants (Figure 4). For example, in odor from undamaged maize, these responses were associated with the constitutive compounds, like linalool (s).

For maize, a total of 25 compounds in the induced blend gave detectable responses from the three parasitoids combined (Figure 1 and Table 1). EAG responses from *C. marginiventris* were elicited by 24 compounds. *C. sonorensis* females responded to 20 compounds (Figure 1). *C. marginiventris* showed high responses to (*E*)-2-hexenal (b), (*Z*)-3-hexenyl acetate (n), linalool (s), neryl or geranyl acetate (ze), and unknown 5 (l) (Table 1). Normalized responses to (*E*)-2-hexenal (b) were higher than the response of the two other parasitic wasps (comparison with *M. rufiventris*, $P = 0.004$; with *C. sonorensis*, $P = 0.005$), while responses to DMNT were lower ($P = 0.005$ in both comparisons). Neryl or geranyl acetate (ze) gave the highest response (20.6%) from *M. rufiventris* (Table 1), and that response was significantly higher than the one from *C. sonorensis* ($P = 0.007$). *M. rufiventris* responded weakly to unknown 5 (l) as

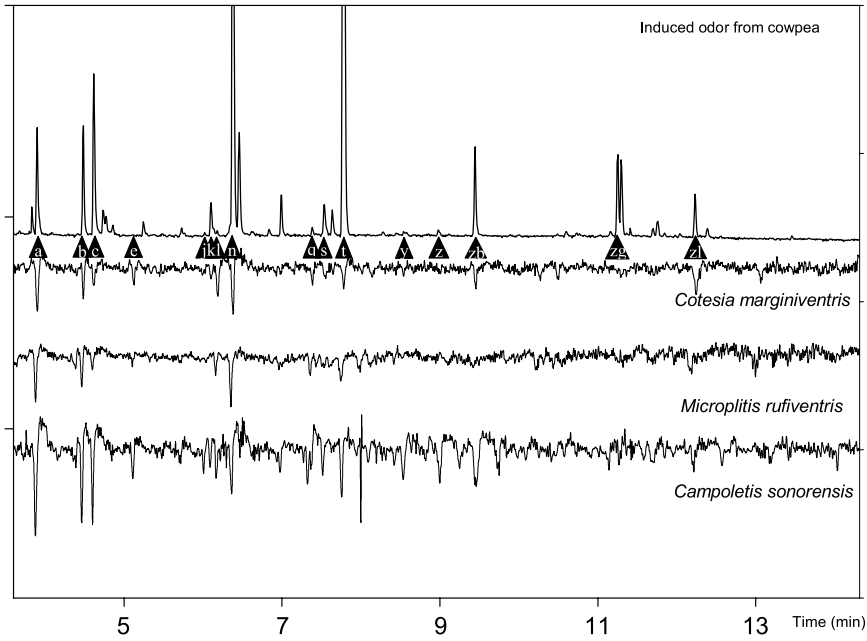

FIG. 3. GC-EAG traces of *Cotesia marginiventris*, *Microplitis rufiventris* and *Campoletis sonorensis* in response to caterpillar-induced odor from cowpea.

compared to *C. marginiventris* ($P < 0.001$) and *C. sonorensis* ($P < 0.001$). *C. sonorensis* showed higher responses to linalool (s), (*Z*)-3-hexenyl acetate (n), (*Z*)-3-hexenol (f), (*Z*)-3-hexenal (a), and DMNT (t). *C. sonorensis* had lower responses than *C. marginiventris* to (*E*)-2-hexenal (b) ($P = 0.005$). Although not statistically different, responses to methyl anthranilate (zc) by *C. sonorensis* tended to be low compared to the ones of the two other parasitoids. Benzyl acetate (v) evoked no responses in *C. sonorensis*. Interestingly, all three parasitoids responded strongly to geranyl acetate (ze).

A total of 23 compounds were perceived in the induced odor of cotton (Figure 2). As in maize plants, some of the minor compounds elicited relatively strong EAG responses in *C. marginiventris* (i and l, Figure 2). *C. sonorensis* and *C. marginiventris* appeared to have similar sensitivity to most of the compounds from induced odor of cotton. These wasps showed a greater sensitivity to green leaf volatiles (compounds a, b, and c) than *M. rufiventris* (Figure 2 and Table 1), which had significantly lower response to (*Z*)-3-hexen-1-ol (c) ($P = 0.015$ and $P = 0.01$, respectively). Compared to the other two wasps, *C. marginiventris* showed particularly strong responses to methyl-(*Z*)-3-hexa-

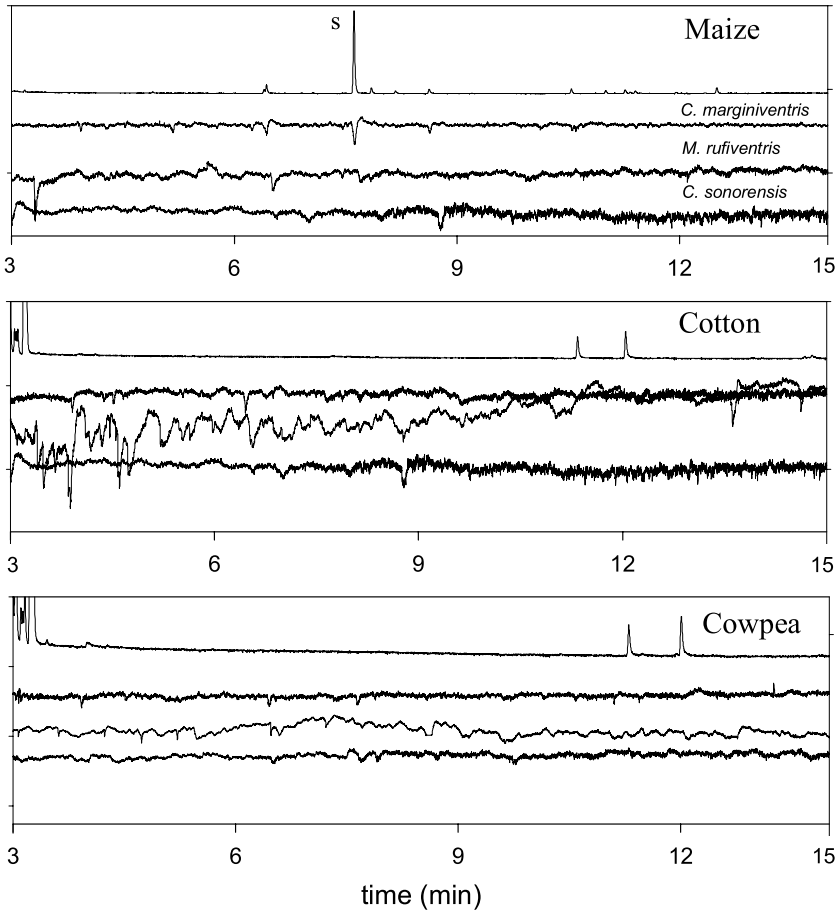

FIG. 4. GC-EAD traces of *Cotesia marginiventris*, *Microplitis rufiventris* and *Campoletis sonorensis* in response to odor from undamaged cotton, maize and cowpea.

noate (f) ($P < 0.001$ both with *M. rufiventris* and *C. sonorensis*), nerolidol (zl), and unknown 8 (zn) (although not significantly different). *M. rufiventris* was less responsive to (*Z*)-3-hexen-1-ol (c), methyl benzoate (q), and DMNT (t) compared to *C. marginiventris* ($P = 0.015$, $P = 0.001$, $P = 0.011$, respectively) and *C. sonorensis* except to DMNT ($P = 0.010$, $P < 0.001$, $P = 0.043$). *M. rufiventris* did not respond to unknown 3 (i), unknown 5 (l), or humulene (zi).

The induced blend of cowpea was less complex than those from maize and cotton (Figure 3). Only 16 compounds elicited EAG responses from the parasitoids (Figure 3). For all parasitoids, responses to green leaf volatiles were

dominant, but *C. marginiventris* also responded relatively well to nerolidol (zl) and methyl benzoate (q) ($P < 0.001$ for both *M. rufiventris* and *C. sonorensis*) (Figure 3). *C. marginiventris* showed a tendency to higher responses compared to the two other parasitoids (Table 1), while *M. rufiventris* and *C. sonorensis* responded similarly to the compounds in cowpea induced odor (Table 1). *C. sonorensis* responded significantly with lower intensity to DMNT (t) ($P < 0.001$), while responses from *C. marginiventris* and *M. rufiventris* were not different ($P = 0.72$). Some compounds did not activate the olfactory receptors, even when released in large amounts. The most striking example was α-pinene (peak between g and i) in the induced cotton odor (Figure 2). Again, all three species were sensitive to some minor compounds (f, g, i, and l), which may be of importance in the recognition of specific host plants. In intact plants, the emission of volatiles was extremely low, which led to no activation of the olfactory receptors on wasps' antennae (Figure 4).

DISCUSSION

The release of volatile compounds when plants are attacked by insect herbivores, and the attractiveness of such induced compounds to natural enemies, have been shown in various studies (Turlings et al., 1990; Steinberg et al., 1993; Geervliet et al., 1994; Dicke and Vet, 1998). In some systems, there are key compounds for the attraction of parasitoids, such as 6-methyl-5-hepten-2-one, which is an indicator of the presence of specific host aphids for the parasitoid, *Aphidius ervi* (Du et al., 1998). In other systems, the role of the various compounds in the induced odor blends appears to be more complex (Dicke et al., 1990; Vet et al., 1990; Turlings et al., 1995; Röse et al., 1998). In this study, we compared the olfactory perception of three female parasitoids to the induced odor of maize, cotton, and cowpea to determine if there are key compounds mediating host location. The results showed that many, but not all, of the compounds in the induced odors were perceived by the parasitoids. There were some differences in the intensity of response to particular compounds, indicating potential differential sensitivity of the parasitoids to the various volatiles. For example, *C. sonorensis* and *M. rufiventris* both responded to linalool, but when the amount of this compound was reduced, as it is in the induced odor of cowpea, no EAG activity was detected, whereas *C. marginiventris* still responded at these concentrations. For an accurate determination of the response threshold of the different parasitoids, dose-response measurements should be made for each compound perceived and for each wasp. The absence of responses from odor blends of control plants indicates that the undetectable amount of odor released in the absence of attack by herbivorous insects may not

be useful at long distance. It cannot be excluded, however, that undetectable amounts of specific plant odors may be detected at short distance. Although it is difficult to distinguish any specific pattern of response from the parasitoids due to the high number of EAG active compounds in the different blends tested, minor compounds may play a more important role than previously thought. The strong EAG responses elicited by these semiochemicals suggests this. While the major compounds are ubiquitous plant secondary metabolites, and may provide general information indicating herbivore-damaged plants, information on the identity of the herbivore doing the damage may be indicated by differences in ratios between the different compounds (De Moraes et al., 1998), and minor compounds may also be key in specific host recognition. Some of these minor compounds were not present in the odor of all three plants, being more plant- than host-specific.

No specific relation between the origin of female parasitoids and their preferred plant/host complex could be detected. For example, *M. rufiventris*, which occurs in Egypt, is more prevalent on cotton plants than the two other parasitoids (C. Tamò, personal communication), but this was not reflected in the antennal responses. It is also curious that, in general, the wasps showed relatively poor responses to DMNT, TMNT, and several sesquiterpenes, which are typical for caterpillar-induced odor blends and have been assumed to be key attractants. This poor perception of these compounds, however, corresponds well with results from behavioral assays designed to pinpoint key parasitoid attractants (Hoballah et al., 2002: M D'Alessandro, M. Held, T. Turlings, personal communication).

A recent study measured the olfactory responses of *C. glomerata*, a generalist parasitoid, and *C. rubecula*, a specialist parasitoid of *Pieris rapae*. No obvious differences were found in the detected range of compounds released by Brussels sprouts when attacked by caterpillars (Smid et al., 2002). This confirms the difficulty of detecting any differences in peripheral perception among parasitoids. As observed for the parasitoids in the present study, *C. glomerata* and *C. rubecula* show a broad olfactory capability responding to 20 compounds in the cabbage volatiles (Smid et al., 2002). The wasps' ability to detect a wide range of compounds in the induced odors of maize, cotton, and cowpea plants suggests that they use a wide range of compounds to identify plants that carry hosts. However, not all detected compounds are expected to have an effect on behavior. The attraction of female parasitoids could be due to a few specific compounds in the blend, or to a specific mixture of compounds. This is testable, as is the relative importance of the minor compounds on parasitoid behavior. Identification of the minor EAG active compounds in the different blends may reveal interesting prospects for application and should improve our understanding of the recognition by female parasitoids of plants attacked by potential hosts. More detailed study should be done at the single sensillum level in order

to determine the specificity of olfactory cells to the different compounds present in the induced blends.

The results show that these parasitic wasps have a wide olfactory capability and that there is little difference among species of parasitoids. Further studies to understand the mechanisms mediating host location by parasitic wasps may help in developing methods to optimize the efficiency of natural enemies as biological control agents.

Acknowledgments—The authors thank Christine Woodcock for her help and advice on the GC-EAG system; Cristina Tamò, Liselore Roelfstra, and Yves Borcard for rearing the parasitoids at the University of Neuchâtel. GRAPEFRUIT OIL ENHANCES ATTRACTION OF MEXICAN FRUIT FLIES TO A SYNTHETIC FOOD-ODOR LURE

DAVID C. ROBACKER* and CIRILO RIOS

Crop Quality and Fruit Insects Research, ARS, USDA, 2413 E. Highway 83, Building 200, Weslaco, TX 78596, USA

(Received October 7, 2004; accepted December 28, 2004)

Abstract—We investigated the attractiveness of grapefruit oil to the Mexican fruit fly. Only high concentrations were attractive in laboratory wind-tunnel bioassays. Attraction of flies to grapefruit oil was not enhanced if they had previous experience with grapefruit. In citrus orchard experiments, undiluted grapefruit oil attracted Mexican fruit flies and enhanced attraction to traps baited with a synthetic food-odor lure emitting ammonia and other nitrogenous chemicals. This is the first demonstration of host fruit odor increasing attraction to another type of attractive blend in Mexican fruit fly. These results indicate differences in the way the flies respond to undiluted grapefruit oil compared with previously tested fruit odors.

Key Words—Diptera, Tephritidae, *Anastrepha ludens*, attractant, grapefruit oil.

INTRODUCTION

It is well known that host plant odors are generally attractive to phytophagous insects. Further, host plant odors often enhance attraction to pheromone in Lepidoptera, Coleoptera, and Diptera (Landolt and Phillips, 1997). In Tephritidae, host fruit odors were commonly demonstrated to be attractive for oviposition, feeding, and mating (Fletcher and Prokopy, 1991; Landolt et al., 1992; Jang and Light, 1996). Additive or synergistic effects from combining host or plant odors with pheromones or bacteria odors were reported for several

* To whom correspondence should be addressed. E-mail: drobacker@weslaco.ars.usda.gov

tephritids including Mediterranean fruit fly (*Ceratitis capitata*) (Dickens et al., 1990), papaya fruit fly (*Toxotrypana curvicauda*) (Landolt et al., 1992), and apple maggot (*Rhagoletis pomonella*) (MacCollom et al., 1994). Combinations of host or plant odors with other types of attractive blends sometimes were less attractive than expected in Tephritidae. For example, traps containing both host fruit and Nulure baits were less attractive than traps with only host fruit bait to protein-fed female Oriental fruit flies (*Bactrocera dorsalis*) (Cornelius et al., 2000).

Combinations of fruit odors with other types of attractants have always been less attractive than the more attractive of the two lure types in the Mexican fruit fly (*Anastrepha ludens* Loew) (Diptera: Tephritidae). Robacker and Garcia (1990) reported that fermented-fruit odor decreased attraction of sexually active females to pheromone, and that pheromone decreased attraction of hungry females to the fruit odor. Robacker (1991) showed that combinations of fermented-fruit chemicals with bacterial odor were less attractive to sugar-hungry flies than fruit chemicals alone. Finally, Robacker and Heath (1997) found that fermented-fruit chemicals decreased attraction to a mixture of ammonia, methylamine, and putrescine (AMPu) tested in a citrus orchard.

In this work, we tested grapefruit oil in laboratory wind-tunnel bioassays to determine the most attractive concentration and to investigate whether attraction of flies to the oil would increase after flies were exposed to grapefruit. Two experiments were conducted in citrus orchards to measure the attractiveness of grapefruit oil by itself and in combination with a synthetic food-odor lure containing ammonia, methylamine, and putrescine.

METHODS AND MATERIALS

Insects and Test Conditions. Mexican fruit flies were obtained from a culture that originated from yellow chapote fruit (*Casimiroa greggii*), a native citrus host of the fly, collected in Nuevo Leon, Mexico, in 2000. Laboratory conditions for holding and testing flies were 22 ± 2°C, 50 ± 20% relative humidity, and photophase from 06:30 to 19:30 hr. Laboratory tests were conducted between 09:00 and 16:00 hr using 3- to 13-d-old flies.

Experiments 1A and 1B: Wind-Tunnel Bioassay of Grapefruit Oil Dose–Response Relationship. The purpose of these experiments was to relate test quantity of grapefruit oil to attractiveness. Grapefruit oil (product code 7553, no lot numbers given by the manufacturer) was obtained from Now Foods (Bloomingdale, IL, USA). Grapefruit oil was tested undiluted, and as serial 1 to 10 dilutions down to 0.01% oil in hexane.

Bioassays were conducted in a Plexiglas wind tunnel with the dimensions of 0.3 × 0.3 × 1.2 m. Each end of the wind tunnel was screened to allow

airflow. The downwind end contained a baffle system to create a uniform airflow through the chamber. Air was pulled through the chamber at 0.4 m/sec by an exhaust fan connected to the downwind end. Air exiting the chamber was directed into an exhaust hose and removed to the outdoors. In addition to the direct exhaust from the wind tunnel, this room contained inlet and outlet vents to bring new air into the room from outdoors and remove air from the room to the outdoors. Air entered and exited the room at the rate of eight complete air replacements per hour. The top of the chamber had two circular openings (12.8 cm diam) with Plexiglas covers, located at each end of the chamber, to allow easy access to the chamber's interior. A 75-W "soft white" light bulb (General Electric Co., Cleveland, OH, USA) in a reflecting lamp was positioned 17 cm above the downwind end of the chamber. The purpose of this light was to minimize random flying into the upwind end of the chamber by using the flies' positive phototactic reaction. Overhead lighting was provided by fluorescent "cool white" lights (F40CW, General Electric).

Bioassays were conducted by using flies of two feeding regimes: (1) sugar-fed, protein-starved (from eclosion) (Experiment 1A) and (2) sugar-starved (for 2 d), protein-starved (Experiment 1B). Mixed-sex groups of 25–40 flies (overall sex ratio was 1:1 but individual cartons varied) were kept in 473-ml cardboard cartons with screen tops until used in tests. To conduct a trial, 100 μl of sample (containing various amounts of grapefruit oil) were put onto a 3 × 3 cm piece of filter paper that was attached to the upwind side (not visible to approaching flies) of a yellow plastic card (10.5 × 15.5 cm) suspended in the upwind end of the wind tunnel. One carton of flies was placed under the downwind opening. Flies were given 5 min to leave the carton, fly or walk upwind, and contact the yellow card. Upwind movement was scored if flies passed a point two-thirds of the distance from the release carton to the card. Seven replications of each experiment were conducted.

Experiment 2: Wind-Tunnel Bioassay of Effect of Experience with Grapefruit on Attraction to Grapefruit Oil. The purpose of this experiment was to determine if attraction of flies to grapefruit oil would increase if the flies had previous experience with grapefruit. The grapefruit oil lure used in this experiment was a 4-ml glass vial containing 1 ml of undiluted grapefruit oil with a cotton wick. The lure was fastened to the upwind side of a yellow plastic card. A plastic card without a lure was used as control for testing both naïve and grapefruit-experienced flies. Bioassays were conducted as in Experiments 1A and 1B.

Test flies were from two groups: naïve flies and grapefruit-experienced flies. Both groups were held in Plexiglas cages (20.5 × 20.5 × 20.5 cm) (200 flies per cage) with screen tops containing a diet mixture of sugar and yeast hydrolysate (U. S. Biochemical, Cleveland, OH, USA) and water supplied separately. Half of the cages were provisioned with a grapefruit (*Citrus paradisi*,

variety Rio Red) from a local orchard beginning when flies eclosed. Grapefruits had a 2-cm-diam piece of peel removed to enhance the release of peel volatiles. All cages were kept in the same laboratory where bioassays were performed, but those with grapefruits were kept near an exhaust fan to vent grapefruit odor to outdoors. Test flies were older than 4 d to allow at least several days for flies to learn the odor of grapefruit. The four treatments (2 fly types × 2 lure treatments) were tested in random order in each replication. Thirteen replications of the experiment were conducted.

Experiments 3A and 3B. Citrus Orchard Evaluation of Grapefruit Oil, Anastrepha Lure, and their Combination. The purpose of these experiments was to determine the attractiveness of grapefruit oil and its combination with nitrogenous food odors in the field. The grapefruit oil lure used in these experiments was a 4-ml glass vial containing 1 ml of undiluted grapefruit oil with a cotton wick. *Anastrepha* fruit fly lures obtained from IPM Tech (Portland, OR, USA) were used as synthetic food odor lure. These lures contain ammonia, methylamine, and putrescine, and are based on an attractant for the Mexican fruit fly reported by Robacker and Warfield (1993).

The experiments were conducted in two citrus orchards located near the laboratory in Weslaco, TX, USA. The first orchard contained several varieties of oranges, lemons, and tangerines. One row of Valencia sweet oranges (*Citrus sinensis*) and one row of Dancy tangerines (*C. reticulata*) were used for tests. The other orchard contained only Rio Red grapefruit from which two rows were used for experiments. Within each row, four linear blocks of four trees each were chosen with one buffer tree between each block. Testing was done during autumn of 2003 in the first orchard and winter–spring of 2004 in the second. All trees were laden with nearly ripe or ripe fruit initially, but fruits were stripped from the grapefruit orchard with three to four replications remaining during spring testing.

Four lure treatments were tested in each experiment: grapefruit oil, *Anastrepha* lure, their combination, and no lure. *Anastrepha* lures were used for the duration of the autumn replications, then replaced with new lures that were used for the duration of the winter–spring replications. Grapefruit oil lures were replaced weekly. One each of the four treatments was tested in each block. Positions of treatments within each block were randomized for the first test of each series. A trial lasted 1 wk, after which flies were counted and traps were serviced as necessary. Positions of treatments in consecutive trials were not randomized but were moved sequentially within each block. Traps were hung one to a tree, north of center, at 1–2 m height. Each week, approximately 2000 flies were distributed uniformly onto rows of trees adjacent to the test rows. Mixed-sex groups of 180–200 flies were kept in 473-ml cardboard cartons under laboratory conditions (described above) until released in the test orchard. Flies were irradiated, due to quarantine laws, with 70–92 Gy (Cobalt 60) 1–2 d

before adult eclosion. Flies were fed sugar and water until they were released in test plots 3–12 d after eclosion.

Experiment 3A was a test of the lures on Intercept AM traps (IPM Tech). Intercept traps are yellow cardboard rectangles (14 × 23 cm) coated with Stickem Special (Seabright Laboratories, Emeryville, CA, USA) on both sides. Lures were fastened onto trap hangers above traps such that the bottom of the lure contacted the top of the trap. Traps were replaced each week. Seventeen replications (weeks) were conducted; eight during autumn in the tangerines section of the first orchard, and nine during winter–spring in grapefruits of the second orchard.

Experiment 3B was a test of the lures in yellow-bottom Multilure traps (Florence Agri Investment, Inc., Miami, FL, USA). Multilure traps are plastic McPhail-like traps with a clear, colorless top and an opaque, colored bottom that serves as a liquid reservoir for drowning captured flies. Grapefruit oil lures were taped inside the tops. *Anastrepha* lures were modified by removing the two plastic bags containing the attractants from the factory supplied mesh bag. The two plastic bags were inserted into the lure basket of the multilure traps. Traps contained water with 0.01% Triton®. (Rohm and Haas Co., Philadelphia, PA, USA) as a wetting agent. The no-lure trap contained only water and Triton. Water was replaced each week in all traps. Fourteen replications (weeks) were conducted; six during autumn in the oranges section of the first orchard, and eight during winter–spring in grapefruits of the second orchard.

Statistical Analyses. All experiments were conducted as randomized complete blocks. For wind-tunnel data, the numbers of males and females that moved upwind or landed on the odor source were divided by the total numbers of males or females in the carton used in the trial. These proportions were transformed by arcsin of the square root for data analyses (Snedecor and Cochran, 1967). Proportions of 0 were replaced with $1/4N$ before transformation (N is the number of males or females in the carton). For field tests, replications over time were treated like replications over space (blocks of trees) for the purpose of statistical analyses. Transformed percentages from the wind tunnel bioassays, and the numbers of flies captured on traps in field tests, were subjected to analysis of variance using SuperANOVA (Abacus Concepts, 1989). Means separations were done by Fisher's protected least significant difference method (LSD) (Snedecor and Cochran, 1967).

RESULTS

Experiments 1A and 1B: Wind-Tunnel Bioassay of Grapefruit Oil Dose–Response Relationship. Sugar-fed flies were not attracted to grapefruit

oil at any test quantity (Figure 1A). Sugar-starved males were attracted to the two highest test quantities of grapefruit oil but not to any lower quantities (upwind movement: $F = 6.4$; $df = 5, 44$; $P < 0.001$; landings: $F = 4.3$; $df = 5, 44$; $P < 0.01$) (Figure 1B). Sugar-starved females showed a similar trend but no individual test quantities were significantly more attractive than blanks or other quantities (Figure 1B). However, single-*df* contrasts of the means for the two

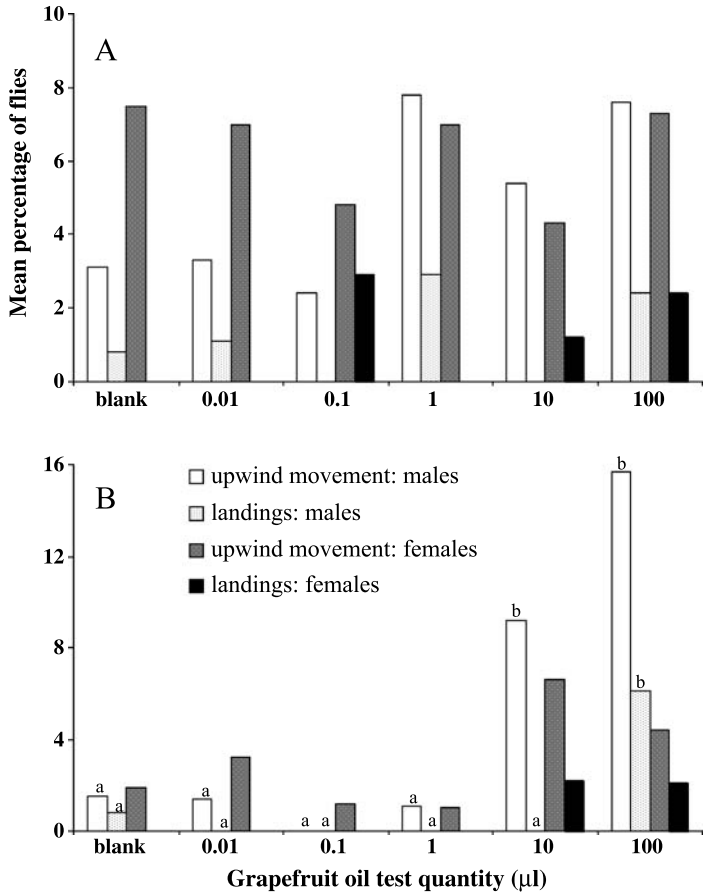

FIG. 1. Attraction of sugar-fed (A) and sugar-starved (B) Mexican fruit flies to various test quantities of grapefruit oil in wind-tunnel bioassays. For sugar-starved males, means in the same data series (upwind movements or landings) with different letters above the bars were significantly different ($P < 0.05$) by Fisher's protected LSD. No individual means were significantly different for sugar-fed males and females, and sugar-starved females.

highest test quantities vs. the blank and lower quantities were significant (upwind movement: $F = 5.6$; $df = 1, 44$; $P < 0.05$; landings: $F = 7.8$; $df = 1, 44$; $P < 0.01$).

Experiment 2: Wind-Tunnel Bioassay of Effect of Experience with Grapefruit on Attraction to Grapefruit Oil. Experience with grapefruit did not enhance attraction of either male or female flies to grapefruit oil. The treatment effect (for the four test sample × experience treatments) was significant only for upwind movements by males ($F = 2.9$; $df = 3, 36$; $P < 0.05$). However, in this instance, the percentage of naïve males to move upwind toward the blank yellow card (12.3%) was significantly greater than response to either of the grapefruit oil treatments (grapefruit oil/naïve males, 2.7%; grapefruit oil/ experienced males, 4.5%) but not significantly greater than response by experienced males to the blank yellow card (7.1%).

Experiment 3A. Citrus Orchard Evaluation of Grapefruit Oil, Anastrepha Lure, and their Combination on Interceptor Traps. Results are shown in Table 1. Analysis of the complete dataset indicated that traps with grapefruit oil were not significantly more attractive than unbaited traps. However, when traps with *Anastrepha* lures and those with the combinations were not included, traps with grapefruit oil were significantly more attractive than unbaited traps to both males ($F = 9.5$; $df = 1, 114$; $P < 0.01$) and females ($F = 7.0$; $df = 1, 114$; $P < 0.01$). Traps with both lures were significantly more attractive than those with only *Anastrepha* lures to males but not to females (complete dataset). Traps with either *Anastrepha* lures or the lure combinations were more attractive than unbaited traps and traps with only grapefruit oil to both males and females. Results from the autumn replications did not differ from those from the winter–spring replications. Also, results from winter–spring replications in which trees had ripe fruit did not differ from those in which trees had no fruit.

Experiment 3B. Citrus Orchard Evaluation of Grapefruit Oil, Anastrepha Lure, and their Combination in Multilure Traps. Results are shown in Table 2. Traps with grapefruit oil were more attractive than unbaited traps to females.

TABLE 1. ATTRACTION OF MEXICAN FRUIT FLIES TO INTERCEPTOR AM TRAPS BAITED WITH GRAPEFRUIT OIL, IPM TECH *Anastrepha* FRUIT FLY LURES, OR THEIR COMBINATION IN A CITRUS ORCHARD

	Males	Females	Total
Blank	0.2 ± 0.05 a	0.2 ± 0.05 a	0.4 ± 0.08 a
Grapefruit oil	0.5 ± 0.08 a	0.6 ± 0.12 a	1.1 ± 0.17 a
Anastrepha lure	1.8 ± 0.22 b	2.0 ± 0.30 b	3.8 ± 0.47 b
Combination	2.7 ± 0.41 c	2.5 ± 0.33 b	5.2 ± 0.65 c

Values are mean flies captured per week (±SE). Means in the same column followed by different letters are significantly different at the 5% level by Fisher's protected LSD (males: $F = 29.4$; $df = 3, 24$; $P < 0.001$; females: $F = 29.3$; $df = 3, 34$; $P < 0.001$).

TABLE 2. ATTRACTION OF MEXICAN FRUIT FLIES TO MULTILURE TRAPS BAITED WITH GRAPEFRUIT OIL, IPM TECH *Anastrepha* FRUIT FLY LURES, OR THEIR COMBINATION IN A CITRUS ORCHARD

	Males	Females	Total
Blank	0.2 ± 0.08 a	0.2 ± 0.08 a	0.5 ± 0.14 a
Grapefruit oil	0.9 ± 0.23 a	1.2 ± 0.21 b	2.1 ± 0.36 b
Anastrepha lure	2.9 ± 0.38 b	3.4 ± 0.40 c	6.3 ± 0.70 c
Combination	3.1 ± 0.41 b	4.3 ± 0.47 d	7.4 ± 0.79 c

Values are mean flies captured per week (±SE). Means in the same column followed by different letters are significantly different at the 5% level by Fisher's protected LSD (males: $F = 29.3$; $df = 3, 21$; $P < 0.001$; females: $F = 42.6$; $df = 3, 21$; $P < 0.001$).

When traps with *Anastrepha* lures and the lure combinations were not included in the analysis, traps with grapefruit oil were also significantly more attractive than unbaited traps to males ($F = 9.4$; $df = 1, 97$; $P < 0.01$). Traps with both lures were significantly more attractive than those with only *Anastrepha* lures to females but not to males (complete dataset). Traps with either *Anastrepha* lures or the lure combinations were more attractive than unbaited traps and traps with only grapefruit oil to both males and females. As in Experiment 5, time of year and presence of fruit did not affect results.

DISCUSSION

Grapefruit oil was only weakly attractive to male and female Mexican fruit flies in wind-tunnel bioassays and citrus orchard experiments. In contrast, fermented chapote fruit and low concentrations of chemicals from the fermented chapote fruit previously proved highly attractive to Mexican fruit flies in laboratory experiments (Robacker et al., 1990a,b; Robacker, 1991) and in one field test (Robacker and Heath, 1996), although chapote chemicals were not very attractive in another field test (Robacker and Heath, 1997). Considering similarities in experimental protocols in at least some of the work with chapote odor and grapefruit oil, the most prudent conclusion is that grapefruit oil is not very attractive to Mexican fruit flies.

Despite its weak attractiveness, grapefruit oil enhanced attraction of both males and females to *Anastrepha* lures in citrus orchard experiments. All previous experiments in which fruit odors were added to either bacterial odors or to a chemical blend similar to that emitted by the *Anastrepha* lures resulted in negative interactions of the odor types (see Introduction).

Grapefruit oil was not more attractive to grapefruit-experienced than to naïve flies. Previous experiments demonstrated that Mexican fruit flies caged

with peel-damaged grapefruits learned the odor of grapefruits and subsequently increased their attraction to low concentrations of grapefruit peel extracts (Robacker and Fraser, 2005). In the current work, the results suggest that flies that learned grapefruit odor did not recognize grapefruit oil as the same odor. The apparent lack of recognition could be due to quantitative differences (low vs. high concentrations) or qualitative differences. The grapefruit oil used in this work probably was qualitatively different from the odor of Rio Red grapefruit to which flies were exposed. The oil was purchased from Now Foods and most likely was not derived from Rio Red grapefruit. However, exposure to grapefruits increased attraction to oranges in a previous work (Robacker and Fraser, 2003) even though the odor of oranges is noticeably different from that of grapefruit.

The nature of the attraction response to grapefruit oil is not known at this time but it appears to be different from the nature of responses of Mexican fruit flies to fruit odors tested in earlier work. To summarize the evidence for this assertion: (1) attraction to grapefruit oil was weak compared with attraction to fermented chapote odor; (2) grapefruit oil enhanced attraction to a blend of attractive nitrogenous chemicals but a combination of chapote-odor chemicals inhibited attraction to the same blend of nitrogenous chemicals; and (3) attraction to grapefruit oil did not increase after exposure to grapefruit whereas attraction to a low concentration of grapefruit-peel extract did increase after exposure to grapefruit.

Although the nature of the attraction is not known, it is interesting that the origin of the attraction is a plant essential oil. The "parapheromone" methyl eugenol, a powerful attractant to males of numerous *Bactrocera* species, was discovered as a minor constituent of citronella oil, another plant essential oil (Howlett, 1915). As recently as 15 years ago, parapheromones such as methyl eugenol were considered by some as "one of the great mysteries of tephritid biology" (Cunningham, 1989). The physiological basis of the attraction to methyl eugenol was not unraveled until the last decade led in part by the efforts of Shelly, Tan, and Nishida (Shelly and Dewire, 1994; Tan and Nishida, 1996). What seemed mysterious attraction just 15 years ago now has been explained as attraction of males to a chemical that serves both as a precursor to a pheromone that attracts females and as an allomone that deters predation (Tan and Nishida, 1998). While the nature of the attraction of Mexican fruit flies to grapefruit oil is very different from the attraction of *Bactrocera* to parapheromones, the possibility exists that the ultimate source of the attractiveness may be a minor component of the oil that may be highly attractive at greater concentrations.

Also relevant to our work is the finding that female papaya fruit flies respond to papaya odor differently depending upon the odor concentration and their mating status (Landolt et al., 1992). Papaya odor, mixed with a constant amount

of pheromone, was most attractive to unmated females at a relatively low concentration but most attractive to mated females at the highest concentration tested. These results suggest the physiological basis of attraction of unmated and mated females to papaya may differ. A similar phenomenon could be occurring in Mexican fruit fly in that attraction to high concentrations of grapefruit odor may have a different physiological basis than attraction to low ones.

We propose three tentative explanations for the results reported here. First, attraction to undiluted grapefruit oil may be an aberrant behavior caused by overloading receptors that normally function to receive lower concentrations of odorants. Second, a minor component of grapefruit oil that has an unknown role in the ecology of Mexican fruit flies may be responsible for the unusual attraction properties. Finally, it is possible that an as yet undiscovered physiological/motivational state may exist in Mexican fruit fly (and other Tephritidae) that causes attraction to fruit odors at high concentrations.

(Received July 5, 2004; revised December 20, 2005; accepted January 4, 2005)

Abstract—*Hyalesthes obsoletus* Signoret (Homoptera: Cixiidae) is a polyphagous planthopper that transmits stolbur phytoplasma (a causative agent of "yellows" disease) to various weeds, members of the Solanaceae, and wine grapes (*Vitis vinifera* L.) in Europe and the Middle East. Planthoppers were collected by hand vacuuming eight native plant species. *Vitex agnus-castus* L., a shrub in the Verbenaceae, hosted the largest number of *H. obsoletus*, although *Olea europaea* L. also served as a host for adults. Using a Y-olfactometer, we compared the planthoppers relative preference for *V. agnus-castus*, *Convolvulus arvensis*, and *V. vinifera*. *V. agnus-castus* was more attractive to both male and female *H. obsoletus* than the other plants. *H. obsoletus* antennal response was stronger to volatiles collected from *V. agnus-castus* than from Cabernet Sauvignon variety of *V. vinifera*. To determine if *V. agnus-castus* would serve as a reservoir for the pathogen, *H. obsoletus* were collected from leaf and stem samples of native *V. agnus-castus*, and were tested by polymerase chain reaction (PCR) for the presence of phytoplasma DNA. While 14% and 25% (2003 and 2004, respectively) of the insects tested positive for phytoplasma DNA, none of the plant samples tested positive. To determine if *V. agnus-castus* could serve as a host plant for the development of the planthopper, we placed emergence cages beneath field shrubs and enclosed wild-caught *H. obsoletus* in a cage with a potted young shrub. We found adult *H. obsoletus* in the emergence cases and planthopper nymphs in the soil of the potted plant. We concluded that *V. agnus-castus* is attractive to

H. obsoletus, which seems to be refractory to phytoplasma infections and warrants further testing as a trap plant near vineyards.

Key Words—EAG, "yellows" disease, spread control, management.

INTRODUCTION

The level of infection of a crop by phytoplasma is dependent on the number and abundance of insect vectors and of alternative/reservoir plants harboring the pathogen, provided that the planting material is not the source of infection. In some cases, such as the aster yellows of carrots, lettuce, and celery in the midwestern U.S., the relationship between the vector and native phytoplasma-infected host plants has been elucidated (Hoy et al., 1992). In other cases, such as the stolbur phytoplasma infection in various crop plants in Europe, the role of alternative host plants in disease epidemiology is not completely understood.

Hyalesthes obsoletus Signoret (Homoptera: Cixiidae), is a polyphagous vector of stolbur phytoplasma to some weeds, plants in the Solanaceae (Brcak, 1979), and wine grapes (*Vitis vinifera* L.) (Maixner, 1994; Sforza et al., 1998) in Europe, and is a suspected vector to wine grapes in Israel (Klein et al., 2001). Grape vines are probably not among the preferred plants of *H. obsoletus*, as it survives poorly on them (Maixner, 1994; Sforza et al., 1998). Brcak (1979) reported that *H. obsoletus* does not leave its primary central and east European host, *Convolvulus arvensis* L., as long as the plant remains suitable for feeding. Furthermore, he reported that as long as the planthopper remained on *C. arvensi*s, a natural source of the phytoplasma, there were no observed incidents of stolbur infection in crops. *H. obsoletus* has been found on other weeds in addition to *C. arvensis*, some of which are also potential phytoplasma reservoirs. In vineyards in Germany, Maixner et al. (1995) demonstrated that *C. arvensis* and *Solanum nigrum* L. were infected with stolbur phytoplasma and could serve as an inoculum reservoir. In contrast, Weber et al. (1997) showed that in vineyards where *Ranunculus bulbosus* L. was the dominant weed, there were fewer infected *H. obsoletus*, and *R. bulbosus* was never found to harbor the phytoplasma. In France, *H. obsoletus* was found to complete its life cycle on *Lavendula hybrida* Reverchon (Moreau and Leclant, 1973), *C. arvensis*, *Lavendula angustifolia* Mill., and *Lepidium draba* L. (Sforza et al., 1999), and was shown to be infected by stolbur phytoplasma (Cousin and Moreau, 1991; Sforza et al., 1998).

Yellows disease was first observed in wine grapes in Israel in the 1980s, and has had a devastating effect. To date, over 50 ha of vineyards have been uprooted due to this disease. Vineyards in affected areas have been surveyed for the presence of phloem feeding insects, such as leafhoppers and planthoppers

(Klein et al., 2001; Orenstein et al., 2003), and several candidate species, including *H. obsoletus*, have been identified.

Alternative plant hosts for the phytoplasmas have not been identified in Israel. During the middle of the growing season (June–August), there are few living plants, and virtually no leafhoppers or planthoppers are captured in vineyards (Klein et al., 2001; Orenstein et al., 2003). Because the last precipitation in wine-grape production areas is in mid-April (Orenstein et al., 2003), by May all nonirrigated areas are dry and only deep-rooted plants remain green throughout summer. Two generations of *H. obsoletus* are found annually in Israeli vineyards; there is a small peak population of adults in May and early June, and another larger peak in September and October (Klein et al., 2001; Orenstein et al., 2003). The goal of this research was to determine the native host plant(s) of *H. obsoletus* and their ability to serve as a reservoir for phytoplasmas.

METHODS AND MATERIALS

Native Plant Screening. This study took place in the Golan Heights at an elevation of 350 m in the south to 800 m in the north. We collected insects from native plants that remained green throughout the summer; *Amaranthus retroflexus* L., *C. arvensis*, *Inula viscose* L., *Myrtus communis* L., *Salix alba* L., *Tamarix* sp., and *Vitex agnus-castus* L. We used a modified leaf blower (Echo model No. PB 1000), in which air intake and exhaust ports were switched, and intake was fitted with a fine mesh nylon bag. Vacuum sampling collects all insects indiscriminately and does not rely on their attractiveness to a trap. In the first year (2003), a minimum of three plants of each species were sampled two to four times in May–June and once in September in the central-southern Golan. During the second year (2004), a minimum of three plants of each species were sampled two to four times in May–June and eight times from September to November; *V. agnus-castus* was sampled in central and northern Golan. *H. obsoletus* were found during spring in an olive (*Olea europaea* L.) orchard, and therefore sampled twice in spring and eight times in autumn.

Captured *H. obsoletus* were counted and recorded by sex when collected in large numbers. Live specimens were maintained at room temperature in screen-covered (50 mesh) boxes containing putative feeding plants until they were used in further trials.

Plant Choice Assay. The host plant preference of *H. obsoletus* was determined by olfactometry. The olfactometer consisted of a Y-shaped glass tube, 2 cm diam. The base was 9 cm long, and the two arms of the olfactometer were each 16 cm in length. Each arm was attached to a flow meter and an odor source container (glass sphere, 12 cm diam) into which test plant branches were

placed. In each case, charcoal-filtered air (1 l min^{-1}) was forced through each arm of the apparatus. There were six replicates of each plant pairing: *V. agnus-castus* vs. *C. arvensis* and *V. agnus-castus* vs. *V. vinifera*. *V. agnus-castus* was used in each pair comparison because of the larger number of planthoppers captured in this species. In Israel, the majority of *V. vinifera* are grafted on Richter 110, but three other rootstocks are also used. We tested Richter 110 and Castel 216. In each replicate (six replicates with females and six with males), a group of five to seven planthoppers was placed in the base tube of the Y-olfactometer and allowed to move upwind towards either of the two arms of the olfactometer. Trial periods were 5 min in length, and the location of each test planthopper was recorded at the conclusion of each trial. To compensate for any positional bias, the olfactometer was rotated 180° after every three replicates. In order to avoid contamination by remaining plant volatiles, the olfactometer was washed with acetone and dried after each experiment.

Volatile Collection. Volatiles were collected from blooming *V. agnus-castus* and Cabernet Sauvignon variety of *V. vinifera*. As noted above, samples of *V. vinifera* from both rootstocks were used. Charcoal purified air was forced through a 500-ml glass sampling jar containing a plant branch, then through a 200-mg SuperQ trap at a rate of 0.2 l min^{-1} to collect organic chemicals released from test plants. Traps were washed with pentane to elute the captured volatiles. The resulting extract was concentrated to a volume of 10 μl and stored at −20°C.

Electroantennograms. In order to examine antennal sensitivity to volatiles of various host plants, electroantennograms (EAG) were recorded from detached antennae of male and female *H. obsoletus* exposed to test volatiles. The base of each antenna was inserted into a glass capillary tube, with a silver electrode lining serving as a grounding probe, while the tip of the antennae was inserted into a second capillary tube, with a silver electrode lining serving as a recording probe. Both glass capillaries were filled with 0.1 N KCl. Antennae were positioned by using a micromanipulator (INR-05, Syntech, Hilversum, The Netherlands). Two microliters of concentrated plant volatiles were applied to an approximately 1 cm^2 piece of filter paper (Whatman No. 1). One microliter of pentane was applied to filter paper to serve as a blank. The filter paper was allowed to air dry for 20 sec to allow the solvent to evaporate, and was then placed inside a glass Pasteur pipette (15 cm long). The pipette tip was inserted through a side hole in a glass tube (0.6 cm diam and 15 cm long) through which charcoal-filtered, humidified air flowed at 0.5 ml min^{-1}. Within each stimulus pipette that contained the filter paper with plant volatiles, 3 ml of air were forced into the constant air stream by a mechanical puffing that delivered puffs of 0.4-sec duration. At least 2-min intervals were maintained between each release of plant volatiles. The presentation order of stimuli for one antenna was randomized within the set (two extracts and one blank). EAG recordings were

made by using a serial data acquisition controller (Syntech IDAC-232, The Netherlands).

H. obsoletus Development on V. agnus-castus. To determine if *V. agnus-castus* serves as a host plant upon which *H. obsoletus* can complete its development, two evaluation methods were used: evaluation of *H. obsoletus* emerging from wild *V. agnus-castus* and development of caged *H. obsoletus* on potted *V. agnus-castu*s. Emergence boxes were made of a 50 × 50 × 40 cm wooden frame covered on five sides with 50 mesh screening. One box was placed, open side down, under the canopy of each of three *V. agnus-castus* plants in the center-south of the Golan at the beginning of May 2003 and again at the beginning of September. One yellow sticky trap was placed in each box to catch any emerging adult insects, and traps were replaced once every 2 wk. In May 2004, one box was placed under the canopy of each of 15 *V. agnus-castus* plants. One yellow sticky trap was placed in each box to catch any emerging adult insects, and traps were replaced once every 2 wk until emergence ceased; this was repeated in autumn starting at the beginning of September and continuing until emergence ceased. Additionally, in spring, 50 mesh screening was draped over the bottom branches of two different shrubs and secured to the ground, encompassing a semicircular area 1.5 m from the trunk. One yellow sticky trap was suspended on a branch from each of these shrubs and changed as described.

In September 2003, 40 adult *H. obsoletus* were vacuum-collected and placed in a 1 × 1 × 1 m cage covered with 50 mesh screening and containing one *V. agnus-castus* plant. The shrub was planted in a 10-l pail: the bottom 2/3 of the potting mix was a mixture of 70:30 peat moss:volcanic gravel, and the top 1/3 was a mixture of 1:1 coconut fiber:perlite. The plant was watered with an automatic irrigation system. Since adults are difficult to discern on the plant through the net, in early May of the next year, when the first adults were observed in the field, the pot was removed from the cage and the soil around the roots was carefully examined for presence of *H. obsoletus* nymphs.

Since *C. arvensis* is a known host in Europe, in May 2003 and 2004, we dug up >50 plants in areas where *V. agnus-castus* were also found, and searched the roots for *H. obsoletus* nymphs.

Phytoplasma Infection in V. agnus-castus. Samples of *H. obsoletus* adult males and females were analyzed individually by polymerase chain reaction (PCR) to determine if they were positive for phytoplasma. Plants on which were they were captured were observed for typical signs and symptoms of phytoplasma infection (proliferation of small leaves, "witches' broom," or yellow leaves) through the duration of the study, and they were analyzed by PCR for presence of phytoplasma at the end of the season (October) in 2003 and 2004.

DNA Extraction and Polymerase Chain Reaction. DNA extracted from phytoplasma-infected *Vinca minor* L. (periwinkle) was used as a positive

control, and DNA extracted from asymptomatic *V. minor* served as a negative control. Insects were homogenized individually in 150 μl extraction buffer, and 1 g of plant tissue was homogenized in a total of 3 ml of extraction buffer (2% cetyl trimethyl ammonium bromide (CTAB), 100 mM Tris–HCl pH 8.0, 1.4 M NaCl, 40 mM EDTA, 0.2% β-mercaptoethanol), then put in a 65°C water bath for 30 min with periodic vortexing. Both insect and plant samples were centrifuged (1500 × *g* for 5 min), the supernatant was mixed with an equal volume of chloroform:isoamyl alcohol (24:1 v/v), and recentrifuged (20,000 × *g* for 5 min). The supernatant was mixed with 0.6 volume of isopropanol for 15 min then centrifuged (20,000 × *g* for 20 min) to pellet the DNA. The extracted DNA was washed twice with 70% ethanol, then resuspended in 60 μl distilled H_2O, and stored at −20°C.

PCR amplification of DNA was performed by using a Tgradient thermocycler (Tamar Laboratory Supplies, Israel). The purified DNA from plant and insect samples was passed through one 30-cycle PCR reaction in the presence of universal primers defined as rU3 and fU5 (Lorenz et al., 1995). Amplification was carried out in a total of 20 μl; 0.1 μl (2.5 units μl^{-1}) *Taq* polymerase (Promega), 16.5 μl amplification buffer (supplied with *Taq* polymerase, and dNTPS), and 5–10 ng test DNA. The PCR reaction began a 5-min 94°C heat shock step followed by a 2-min step at 50°C, a 2-min step at 72°C, 35 cycles of 92°C (30 sec), 55°C (30 sec), 72°C (45 sec). In the last cycle, the 72°C step was extended for 7 min as an elongation step. The amplified PCR products were analyzed by electrophoresis of 12 μl of reaction mixture in 1.5% agarose gel (40 mM Tris–HCl, pH 7.5; 20 mM acetic acid; 1 mM EDTA), stained with ethidium bromide, and visualized with a UV transilluminator. The size standard 100-bp DNA ladder used in gels was obtained from MBI Fermentas.

Statistical Analysis. Comparisons between the numbers of planthoppers caught from the different plant species were analyzed by one-way analysis of variance (ANOVA), and means were separated by the Tukey HSD multiple range test using JMP 5.1 software (SAS software). Results of the olfactometer tests were analyzed by the log-likelihood ratio (*G*-statistic). Kruskal–Wallis test was used to compare the EAG responses to the headspace preparations and the control. Medians were separated by the Median-Notch method. All tests were conducted at $\alpha = 0.05$ level.

RESULTS

Native Host Plants. In the first year, more specimens of *H. obsoletus* were present on *V. agnus-castus* than or any other plant species (df 7, 118, $F = 153.86$, $P < 0.001$) (Table 1). *H. obsoletus* were found on *M. communis* only in autumn.

TABLE 1. SURVEY OF THE NUMBER OF *Hyalesthes obsoletus* FOUND ON NATIVE PLANTS IN 2003

Species	Samplings	Total *H. obsoletus*
Amaranthus retroflexus	13	4 b*
Convolvulus arvensis	18	2 b
Inula viscose	12	0 b
Myrtus communis	15	15 b
Salix alba	12	0 b
Tamarix sp.	12	0 b
Vitex agnus-castus	18	549 a
Vitis vinifera	26	13 b

*Data followed by different letters are significantly different at $\alpha = 0.05$.

Repeated sampling of four wild *V. agnus-castus* shrubs in June yielded 218 *H. obsoletus* individuals with a male:female ratio of 58:42. Vacuuming the same four shrubs in October yielded 564 specimens, with a male:female ratio of 46:54. In spring of the second year, more specimens of *H. obsoletus* were present on *V. agnus-castus*, followed by olives, than for any other plant species ($df = 9, 51$, $F = 87.47$, $P < 0.001$) (Table 2). In autumn, significantly more specimens of *H. obsoletus* were present on *V. agnus-castus* than on all other plants ($df = 10, 210$, $F = 34.04$, $P < 0.001$) (Table 2). *H. obsoletus* were found on olive trees in spring, and only until mid-October in autumn.

TABLE 2. SURVEY OF THE NUMBER OF *Hyalesthes obsoletus* FOUND ON NATIVE PLANTS IN 2004

	Spring		Autumn	
Plant species	Samplings	Total *H. obsoletus**	Samplings	Total *H. obsoletus*
Amaranthus retroflexus	6	2 c	24	1 C
Convolvulus arvensis	6	1 c	18	5 C
Inula viscose	6	0 c	24	0 C
Myrtus communis	6	0 c	24	13 C

Vitex agnus-castus North			21	156 B
Vitis vinifera	9	5 c	18	4 C

*Data followed by different letters are significantly different at $\alpha = 0.05$.

TABLE 3. OLFACTOMETER RESULTS FOR MALE AND FEMALE *Hyalesthes obsoletus* GIVEN A CHOICE BETWEEN *Vitex agnus-castus* (*V. A.-C.*) AND *Convolvulus arvensis* (*C. A.*) OR *Vitex agnus-castus* AND *Vitis vinifera* (*V. V.*)

Sex	Choice	*df*	G-statistic	*P*
Male	*V. a.-c.* × *C. a.*	2	10.66	<0.005
Female	*V. a.-c.* × *C. a.*	2	8.46	<0.025
Male	*V. a.-c.* × *V. v.*	2	22.32	<0.001
Female	*V. a.-c.* × *V. v.*	2	61.76	<0.001

Since *H. obsoletus* was present in large numbers on *V. agnus-castus*, further analysis was possible. Significantly fewer *H. obsoletus* were found on *V. agnus-castus* in the northern Golan (El Rom), and only until the end of October, whereas in the south-center of the Golan, they were abundant until the end of November. In October 2004, the monthly average low temperature in the north was 14.0°C, whereas in the center-south it was 16.5°C. By November, the average low temperature was 7.5°C in the north and 11.3°C in the center-south.

Olfactometer and Electroantennogram Trials. In an olfactometer assay, both sexes of *H. obsoletus* significantly preferred *V. agnus-castus* over grape vines (*V. vinifera*) and *C. arvensis* (Table 3), although the number of females choosing *V. agnus-castus* over grape vines was higher than that of males. Conversely, more males chose *V. agnus-castus* over *C. arvensis*. There was no rootstock effect.

Antennal response of adults (Table 4) was significantly higher to *V. agnus-castus* volatiles than to grape vines (Cabernet Sauvignon) or the blank control ($df = 3, 20$, $F = 9.58$, $P < 0.001$). The antennal response to the grape vine was not different from the response to the blank control. There was no rootstock effect.

TABLE 4. RESULTS OF DETACHED *Hyalesthes obsoletus* ANTENNAE STIMULATED BY VOLATILES ISOLATED FROM *Vitex agnus-castus* AND CABERNET SAUVIGNON VARIETY OF *Vitis vinifera* ON TWO DIFFERENT ROOT STOCKS (CASTEL 216 AND RICHTER 110)

Sample	Number of replicates	Mean (mV) ± standard deviation
Blank	6	390 ± 122 b*
Vitex agnus-castus	6	695 ± 125 a
Vitis vinifera (Richter)	6	455 ± 71 b

2	Drape	37	0	0	0									

H. obsoletus Development on V. agnus-castus. H. obsoletus were caught on sticky traps in emergence boxes placed under *V. agnus-castus* in the field. In the first year (2003) a total of eight adults were caught in May; in autumn, 10 adults were caught from the beginning of September until the middle of October. In the second year (2004), more cages were set up and emergence was monitored in spring and autumn (Table 5). In spring, adults emerged for a maximum of 6 wk, whereas in autumn they emerged over a period of almost 3 mo. In the spring, approximately half the area under each of two shrubs was covered with net; because the entire emergence area was not covered, few planthoppers were caught. Assuming a nonclustered distribution for this species, an estimated mean number of 37 (2 × number captured from 1/2 of each shrub) adult *H. obsoletus* emerged from each shrub. In May, we found 25 third to fifth instar *H. obsoletus* nymphs on the caged *V. agnus-castus* that were exposed to mated females in September. No *H. obsoletus* nymphs were found on any of the 50 + *C. arvensis* plants that were uprooted in spring of 2003 and 2004.

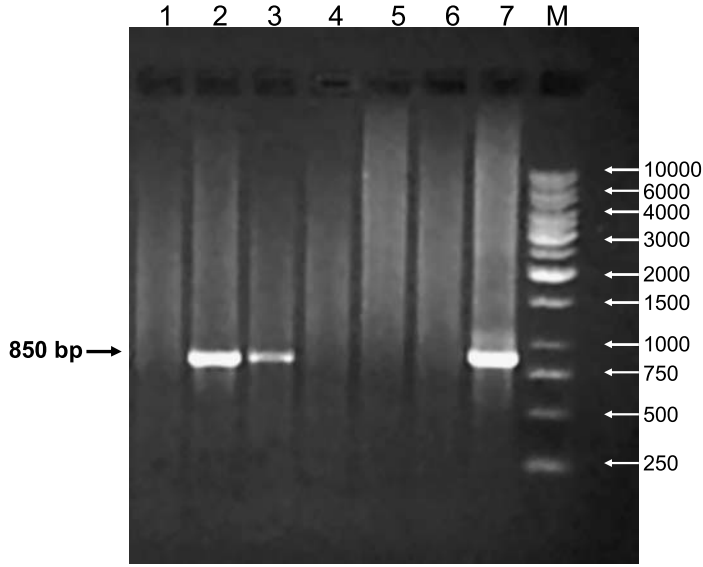

FIG. 1. Photograph of 1.5% agarose gel stained with ethidium bromide, showing amplified products from universal primers rU3 and fU5 for carrots and leafhoppers. Lane: M. molecular markers (in addition to those indicated, 8000, 5000, 4000, 3500, 2500 bp are also present), 1–3 *Hyalesthes obsoletus*, 4–5 *Vitex agnus-castus*, 6 healthy *Vinca minor*, 7 Stolbur-infected *Vinca minor*.

V. agnus-castus Infection with Phytoplasma. V. agnus-castus plants in the field were examined for signs and symptoms of phytoplasma infection. Although no symptoms were observed throughout the entire season, leaf and stem samples were collected from each plant in October and were analyzed by PCR for presence of phytoplasma DNA. Results of these analyses were negative for all 40 *V. agnus-castus* samples and healthy periwinkle, and were positive for phytoplasma-infected periwinkle (Figure 1). Of the *H. obsoletus* collected from these plants, 12.24% of the females (6 of 49 individuals) and 1.92% of the males (2 of 52 individuals) tested positive in 2003, and 17.78% of the females (8 of 45 individuals) and 7.5% of the males (3 of 40 individuals) tested positive in 2004.

DISCUSSION

This is the first study identifying *V. agnus-castus* as the preferred developmental host plant of adult *H. obsoletus* as observed, by vacuum sampling, on *A. retroflexus*, *C. arvensis*, *M. communis*, *O. europaea*, and *V. agnus-castus*. Other than *C. arvensis*, these are native plants that remain green throughout the year. This is consistent with findings of other researchers in Europe (Hoch and Remane, 1986; Maixner et al., 1995; Sforza et al., 1998). In central and eastern Europe, *C. arvensis* is the primary host for the planthopper (Brcak, 1979); however, in Israel aerial portions of this plant are completely dried by May when the first generation of *H. obsoletus* appears, except in irrigated areas where it is usually controlled along with other weeds.

C. arvensis does not appear in the field until after the first rains, usually in November–December, when *H. obsoletus* are usually no longer found (Orenstein et al., 2003). Since the weed and the planthopper are temporally different, it was not surprising that examination of the roots of more than 100 *C. arvensis* yielded no *H. obsoletus* nymphs. Furthermore, based on olfactometer and electroantennagram bioassays with *C. arvensis* and *V. agnus-castus*, the planthopper responded differently to host plant volatiles; response was higher to *V. agnus-castus*. Our results indicate that *V. agnus-castus* is a viable developmental host for the planthopper. When adult *H. obsoletus* were contained in a cage with young potted *V. agnus-castus*, nymphs developed in the same length of time as planthopper development in the field. Differences in the numbers of *H. obsoletus* captured on the shrub in the northern (fewer individuals) vs. central-southern Golan are consistent with previous findings on the distribution of the planthopper in vineyards (Orenstein et al., 2003) and with the distribution of phytoplasma (less incidence in the north) (Orenstein et al., 2001).

Having determined that *V. agnus-castus* is a preferred host plant and supports the complete development of *H. obsoletus*, it was necessary to determine

if the shrub would serve as a reservoir for the pathogen. To date, no signs or symptoms of yellows disease have been observed in *V. agnus-castus* or other wild plants examined in this study. Phytoplasmas can be detected in plants that do not exhibit symptoms of infection, and the part of the plant assayed can be critical to detection (Constable et al., 2003). Asymptomatic plants may be resistant or tolerant to phytoplasma infection. Fourteen percent to 25% of the *H. obsoletus* adults tested by PCR were positive for phytoplasma. Sforza et al. (1998) found between ~28% and 39% of *H. obsoletus* in France were infected with phytoplasma. Since there is a latent period between insect feeding on an infected plant and its capability to transmit the phytoplasma, a positive PCR result does not necessarily mean that the specific insect is capable of transmitting the phytoplasma. However, since these insects were collected in October, at the end of the second peak of *H. obsoletus* activity (Klein et al., 2001; Orenstein et al., 2003), it is reasonable to assume that some were capable of transmitting phytoplasma.

The attraction of *H. obsoletus* to *V. agnus-castus*, as well as the apparent lack of phytoplasma infection in this plant species, suggests that there is potential for using *V. agnus-castus* as a trap plant near vineyards to direct them away from grapevines. Identifying the volatile plant attractants and incorporating them in traps may be effective in protecting crops from inoculation by *H. obsoletus*. We are currently working on identifying the dominant components of the attractant compounds.

Acknowledgments—The authors thank LeAnn Beanland for critical comments on this manuscript. This research was supported in part by a grant from the Chief Scientist, Ministry of Agriculture, State of Israel and the Wine-Grape Growers Board.

(Received November 4, 2004; accepted January 24, 2005)

Abstract—High-pressure liquid chromatography analyses of 73 plant species showed that the nectars of phrygana (East Mediterranean garrigue) mainly contain sucrose, glucose, and fructose, and traces of 10 minor sugars. Although the sucrose/hexose ratio was not related to plant life habit, ecological constraints had a detectable effect in shaping sugar composition. This was detected by distinguishing the phryganic plant species into "spring–summer" and "winter" flowering, with the distinction made on the basis of the water deficit in the study area. Plants flowering in spring–summer had a higher rate of "high sucrose" (i.e., sucrose/hexose ratio $\geq$0.5; 60.8% of the plant species) vs. "low hexose" nectars (i.e., ratio <0.5; 39.2%). The ratio was reversed in winter flowering species (36.4% vs. 63.6% with "high sucrose" and "high hexose," respectively). Sucrose/hexose ratios were associated with plant family. The highest values were those of Lamiaceae, which differed significantly from the "low sucrose" Liliaceae and Apiaceae. Based on recorded plant–pollinator interactions in the community, the present data provide evidence of a partitioning of nectar resources by the existing pollinator guilds within the community, based on the sugar profiles of nectar (all sucrose/hexose ratios for all interactions). Among all major groups, bees and wasps (aculeates) preferred "high sucrose" nectars, which differed significantly from syrphids, anthomyid a.o. flies, and beetles that visited "low sucrose" nectars. Similarly, butterflies visited "lower sucrose" nectars compared to bees. Within families, only Megachilidae could be clearly characterized as "high sucrose" consumers, differing in this respect from all the remaining insect groups including most other bee families. This confirms previous findings that Megachilidae have a key position in Mediterranean

communities where they probably constitute a selective factor for "high sucrose" nectars.

Key Words—Nectar sugars, sugar ratio, sucrose, glucose, fructose, hexoses, sugar preference, evolutionary constraints, bees, Megachilidae, phrygana, Mediterranean ecosystems, pollination ecology.

INTRODUCTION

Among the major rewards to pollinators, floral nectar is unique, and likely subject to selection pressures that result in nectar differences among closely related plants pollinated by different animals (Pyke and Waser, 1981; Baker and Baker, 1982). The literature on floral nectars is considerable. Amount and sugar concentration of nectars are related to pollinator type (Percival, 1961, 1965; Baker and Baker, 1975), especially the hexose/sucrose ratio (Wykes, 1952; Percival, 1961; Baker and Baker, 1979, 1982, 1983, 1990; Southwick, 1982; Stiles and Freeman, 1993; Petanidou et al., 1996). Amino acids in nectars have also received attention, especially their significance to pollinators (Gottsberger et al., 1984; Baker and Baker, 1986; Petanidou et al., 1996; Petanidou, unpublished data).

Several large-scale studies have focused on the relative concentration of sugar components of nectar. In her pioneering, semiquantitative study on nectar of 889 species, Percival (1961) distinguished sucrose-dominant, balanced sugar, and hexose dominant nectars, which she found related to plant family affinity as well as to pollinator type (Percival, 1965). Baker and Baker (1982, 1990) confirmed Percival's results corroborating the correlation between tubular flowers and sucrose richness, and the tendency of open flowers to be hexose-rich. They further placed the sugar profile into a coevolutionary context, by also considering the plant's pollination mode, referred to as the "pollination syndrome." Based on the nectar analysis of 765 species of different origin, they found that the sugar profile [measured in weight as sucrose/hexose ratio: S/(G + F)] could be associated with the plant's pollination syndrome: plants with sucrose-dominant (>0.999) and sucrose-rich (0.999–0.500) nectars are pollinated by hummingbirds, butterflies, and long-tongued bees, whereas plants with hexose-rich (0.499–0.100) and hexose-dominant (<0.100) nectars are pollinated by short-tongued bees and flies. In another study focusing on a wide range of hummingbird-visited plants in Costa Rica, Stiles and Freeman (1993) found that the sucrose concentration of floral nectars decreased with elevation while fructose concentration increased. All the above results were based on the assumption that a plant is pollinated by a certain insect group, and have not been tested by considering the actual response of the pollinators, i.e., all plant–pollinator interactions observed in the community. However, it is commonly

known that actual pollinators may differ from those suggested by the pollination syndrome, and most plants receive visits of a large array of pollinators.

Little is known of the nectar composition of Mediterranean plants, and certainly not at the community level (Dafni et al., 1988; Petanidou et al., 1996, 2000). Due to water shortage in Mediterranean communities, several aspects of pollination ecology are influenced by climate, such as nectar quantity and concentration (Herrera, 1985; Petanidou and Vokou, 1990; Petanidou and Smets, 1995), flower and nectary structure (Petanidou et al., 2000), pollen calorific value (Petanidou and Vokou, 1990), flowering time (Petanidou and Vokou, 1993; Petanidou et al., 1995), and pollinator assemblages (Petanidou and Ellis, 1993, 1996).

In this work, I investigated the role of nectar sugars in phrygana (East Mediterranean garrigue community). In these communities, pollinator assemblages are not as variable as in other arid, tropical, and temperate systems (no birds, no bats, few bumblebees), with the majority of plants being pollinated by wild bees (Petanidou and Ellis, 1993, 1996; Petanidou and Potts, 2005). As this is the first community study from the area, my specific questions were: (1) What sugars dominate in the Mediterranean nectars? (2) What are the major constraints shaping nectar sugar ratios (phylogenetic, ecological, coevolutionary): Are nectar sugar ratios related to plant family (phylogenetic constraints, as found by Percival, 1961) and pollinator assemblages (coevolutionary constraint, as previously concluded by Percival (1965), Baker and Baker (1983), and Stiles and Freeman (1993)), or do plant flowering period and/or life habit also matter (ecological constraints), as it is normally the case with other pollination characteristics in the Mediterranean?

I carried out the investigation in a typical phrygana, and considered all nectariferous plants occurring in the phryganic community (30 ha) for which nectar collection was practical, with flowering times dispersed throughout the year. As all species were native and typical for the phrygana, this allowed me to explore the effect of ecological constraints. In addition, the large number of plants studied (73) allowed investigation within plant families (phylogenetic constraints). Previous studies within the same community allowed me to use a detailed plant–pollinator database to explore any coevolutionary effects. The latter approach, i.e., matching the nectar sugar composition and the response of pollinator assemblages based on plant–pollinator interactions at a community level, is novel.

METHODS AND MATERIALS

Study Site, Plant Species, and Field Measurements. I studied the nectar of 73 phryganic species occurring in the nature reserve of the “I. and A. Diomedes

Botanical Garden of Athens University" located 10 km west of the center of Athens, Greece. The site and the phryganic community have been described in earlier studies conducted by Petanidou and Ellis (1993, 1996) and Petanidou et al. (1995).

Nectar volume, flower depth, and other measurements used in this study were taken from Petanidou and Smets (1995). Nectar for laboratory analyses was collected from flowers selected at random using the same plants from which nectar volume was measured. All flowers used were at their first day of anthesis, covered in bud stage with bridal veil on the eve of the collection day to prevent nectar removal by insects. Nectar was collected the following day, always towards noon to early afternoon (1100–1400 hr) except for *Capparis spinosa* sampled between 0930 and 1000 hr. The nectar of each flower was picked up directly on a Whatman No. 1 small paper wick and fixed on a stainless steel pin that had been cleaned with acetone. The paper wicks, placed on styrofoam blocks, were left to air-dry. They were stored in airtight containers over silica gel until analysis. Touching with the fingers or other possible contaminating means was carefully avoided (Petanidou et al., 1996).

Nectar Analysis. Sugar analysis was carried out with high-pressure liquid chromatography (HPLC) (Dionex, Sunnyvale CA, USA). Before analysis, the nectar content of each wick was dissolved in 1 ml of distilled water in a microcentrifuge tube by intermittent vortexing at room temperature for at least 1 hr. Tubes were centrifuged to remove paper particles (Petanidou et al., 1996). Analysis was made directly on a CarboPac PA1 anion-exchange column, and quantified by a pulsed amperometric detector. Flow rate was 1 ml min^{-1}. The elution conditions were 100 mM NaOH for 4 min, a linear gradient from 0 to 30 mM Na acetate in 100 mM NaOH over 16 min, a linear gradient of 30–100 mM Na acetate in 100 mM NaOH over 30 min, and finally 300 mM NaOH for 10 min. The column was regenerated with 1 M NaOH for 10 min and equilibrated for 20 min with starting buffer after every run. I investigated the presence of 15 sugars, viz. glucose, fructose, sucrose, sorbitol, mannitol, ribose, melibiose, maltose, stachyose, arabinose, mannose, rhamnose, lactose, trehalose, and gentiobiose, all of which have been reported to occur in floral nectars (cf. review by Baker and Baker, 1983). I did not consider xylose, which is present in specific nectars of the South African species of *Protea* and *Faurea* (Nicolson and Van Wyk, 1998). Sugar quantification was performed on the peak areas by comparison with external standards.

Flower Visitors. In order to detect whether pollinator species had a differential response to the different sugar contents of flowers, I used the community data matrix from Petanidou (1991), which was also used as a basis for Petanidou and Vokou (1993), Petanidou and Ellis (1996), and Petanidou and Potts (2005). This matrix contained plant–pollinator interactions for 70 of the 73 plant species analyzed. All flower visitors were considered pollinators if they

visited the flowers repeatedly irrespective of their "quality" (pollinator efficiency). This is normally done in such community studies (Waser and Ollerton, 2005). Excluded from the analyses were *Echinops sphaerocephalus* subsp. *albidus* and *Teucrium chamaedrys* for which there were no pollinator data, as well as *Romulea linaresii*, which was not visited by insects. The 70 plant species were visited by 576 insect species, resulting in 1930 plant–pollinator interactions.

The families Andrenidae, Halictidae, and Colletidae were considered collectively to comprise of short-tongue bee species, whereas the families Anthophoridae, Apidae, and Megachilidae were composed of long-tongue ones (Petanidou and Ellis, 1996; Michener, 2000).

Data Analysis. Values from all laboratory analyses were calculated per flower. This was the average of several separate runs (3–11, except in a few cases), each one on the basis of one flower where nectar secretion was sufficient (e.g., Lamiaceae). In cases where nectar secretion per flower was low, samples were pooled for HPLC analysis.

I used the same sucrose/hexose ratio as Baker and Baker in all their papers: sucrose/(glucose + fructose), all sugar amounts calculated in weights (Baker and Baker, 1983). Differences among plant families in sucrose/hexose ratios were tested using one-way ANOVAs. Seven plant families were considered in the analysis aiming to explore any phylogenetic affinity of nectar composition. Apart from being the most species-rich in the phryganic community (with ≥ 3 plant species), the plant families considered in the data analysis should not be closely related in terms of their phylogenetic history, the independence control based on the plant evolution tree appearing in Dodd et al. (1999), which is enriched with pollination mode data. The families tested were Boraginaceae, Asteraceae, Lamiaceae, Fabaceae, Liliaceae, Apiaceae, and Ranunculaceae, whereas the remaining families were treated as a separate eighth group. The family Dipsacaceae, represented by three species in the study phrygana, does not appear in the tree by Dodd et al. (1999); thus, it was treated together with the remaining species of the eighth group. Similarly, differences among insect groups in their response to flowers was explored by comparing the nectar sugar ratios of the plant species visited by all species of the insect group, considering all ratio values of all plant–pollinator interactions.

In order to investigate the importance of flowering time in shaping nectar composition, I considered the differential water regime (i.e., the relative evapotranspiration vs. rainfall) throughout the year. According to the data taken from ombrothermic curves of the area (cf. Petanidou and Ellis, 1993), two periods were distinguished: (1) April 1–September 15, when evapotranspiration exceeds rainfall, and (2) September 16–March 31, when rainfall exceeds evapotranspiration. Plant species having their midpoint of flowering in either period were assigned as "spring–summer" or "winter" flowering species.

[a] Life forms are: geophytes (geo), therophytes or annuals (ther), herbaceous perennials (herb), frutescent or woody perennials (frut). Life form, flower depth, nectar volume, and midpoint of flowering are after Petanidou et al. (1995) and Petanidou and Smets (1995). Nomenclature used is according to The International Plant Names Index (2004).

Before any statistical application, the data were tested for normality, and if not normally distributed, nonparametric tests were applied (Kruskal–Wallis ANOVA, Spearman *R* correlation). When necessary, Kruskall–Wallis ANOVAs were followed by posthoc Mann–Whitney *U* tests and application of the ultra conservative Bonferroni correction (Pagano and Gauvreau, 1993). Whenever used, mean values are followed by their SEs.

RESULTS

Table 1 contains the list of all 73 plant species, with some floral attributes possibly related to sugars contained in the nectars. All 13 sugars used as references in the HPLC analyses were found in the nectars of phrygana flowers, and some additional unknown peaks were also found (Table 2). As expected, the most common sugars were the "big three": glucose, fructose, and sucrose (Baker and Baker, 1983). The remaining 10 contributed little to the sugar profile of phryganic nectars. Among these, sorbitol had the most significant contribution in a few cases with >1% in total nectar sugars, followed by mannose and melibiose.

Based on the % of sucrose contained in the total nectar sugars (in nmol) and the sucrose/hexose ratios (in weight), the phryganic plant families can be distinguished into three groups: the first with "high sucrose" nectars (Ranunculaceae, Lamiaceae, Fabaceae), a second with "low sucrose" nectars (Apiaceae, Liliaceae), and a third, mixed group, encompassing Asteraceae, Boraginaceae, and the remaining families (Table 3). No plant family has a close phylogenetic relationship to any other family within the same or different group (Dodd et al., 1999).

Plant families differed in their sucrose/hexose ratios (K–W $H_{(7,73)} = 35.6$; $P < 0.001$; Table 3). *A posteriori* comparisons showed that these differences were due to the higher ratios of Lamiaceae (M–W *U* tests after applying Bonferroni correction, $P = 0.006$ and $P = < 0.001$, for the pairs Lamiaceae–Liliaceae and Lamiaceae–other families, respectively). The results are the same if the outlier *Anthyllis hermanniae* is not considered.

The values of the sucrose/hexose ratios were related to flower depth (Spearman rank $R = 0.394$, $P < 0.001$; Figure 1) and nectar volume ($R = 0.383$, $P < 0.001$), especially when the outlier *A. hermanniae* was not considered ($R = 0.441$, $P < 0.001$; $R = 0.426$, $P < 0.001$, respectively). (Being an outlier, this species is considered separately or not at all in the statistical analyses.)

The sucrose/hexose ratio was not time-dependent (Spearman *R* correlation against midpoint of flowering, $P = 0.749$). However, when considering "spring–summer" and "winter" species flowering within different water regimes (see "Data Analyses" in METHODS AND MATERIALS), I found

N is the total number of flowers analyzed by HPLC, the number of runs given in parentheses. Plant abbreviations are given in Table 1.

[a] Data columns are amounts of different nectar sugars (nmol flower^{-1} ± SE); contribution (%) of sucrose and of the minor sugars (=all but the "big three") in the nectar (in nmol); sucrose/hexose ratio (calculated on a weight basis).

TABLE 3. SUMMARY VALUES OF THE PLANT FAMILIES IN THE COMMUNITY[a]

	N	% Sucrose over total sugars (nmol)	S/(G + F) (in weight)
High sucrose families

Other	21	18.0 ± 3.78	0.6 ± 0.14
Dipsacaceae	3	20.3 ± 4.79	0.5 ± 0.15
Low sucrose families			
Apiaceae	4	8.8 ± 3.49	0.2 ± 0.08
Liliaceae	9	9.4 ± 4.60	0.3 ± 0.13

[a] Data columns are: number of plant species per family (N); % sucrose content calculated on the basis of nmoles contained in the nectar; and sucrose/hexose ratio (mean±SE) calculated on the basis of sugar (S, G, F) weights.

significant differences between these two groups in both sucrose/hexose ratio (M–W $U_{(51,22)} = 366.0$; $P = 0.019$) and sucrose content (M–W $U_{(51,22)} = 367.0$; $P = 0.017$). Among the "spring–summer" species, 60.8% have "high sucrose" nectars vs. 39.2% with "high hexose" nectars (Tables 1 and 2). The picture is

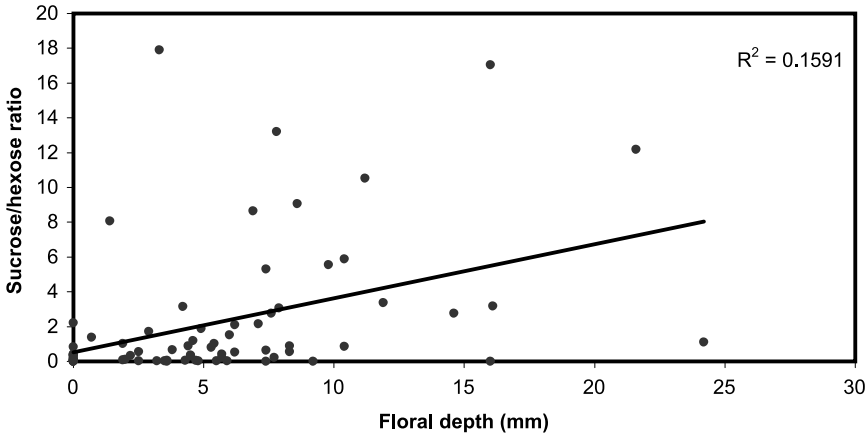

FIG. 1. Sucrose/hexose ratio represented against floral depth of the plant species studied. Best-fitted line and R^2 value are displayed on the chart. *Anthyllis hermanniae* (ratio outlier) and *Crocus cancellatus* (depth outlier) were excluded.

reversed during the wet period of the year, with 36.4% of the "winter" plants having "high sucrose" and 63.6% having "high hexose" nectars. There was no difference in sucrose/hexose ratio among plants of different life habit (K–W $H_{(3,72)} = 6.454$; $P = 0.092$).

The response of pollinator groups to nectar sucrose/hexose ratios is summarized in Tables 4 and 5. The tables give the average value of sugar ratios calculated over the species of plants visited by all insect species on the basis of all interactions observed between them in the community. Among all major insect groups, bees and wasps (aculeates) show the highest preference for high-sucrose nectars. Lepidoptera, a rather heterogeneous group, scored between bees (high) and flies (low). Among bee families, the greatest preference for high-sucrose nectar was shown by the Megachilidae, then by the Anthophoridae, followed by a third group encompassing Halictidae, Colletidae, and Apidae, and finally the Andrenidae family, which has the lowest preference. There was a significant difference in the preference for sugar profiles of nectar among the major insect groups at the level of superfamilies–orders (Table 4; ANOVA, outlier *Anthyllis* excl.: $F_{(6,1917)} = 15.63$; $P < 0.001$). The difference was equally high when major groups are broken down into families of high relevance to pollination (Table 5; $F_{(16,1907)} = 10.64$; $P < 0.001$). *A posteriori* tests (Tukey HSD test) showed that the difference between superfamilies–orders were due to bees (Apoidea–Coleoptera: $P < 0.001$; Apoidea–Diptera: $P < 0.001$; Apoidea–Lepidoptera: $P = 0.048$; Apoidea–Syrphidae: $P < 0.001$) and to aculeates (Aculeata–Coleoptera: $P = 0.001$; Aculeata–Diptera: $P < 0.001$; Aculeata–

TABLE 4. SUCROSE/HEXOSE RATIOS OF THE FLORAL NECTARS VISITED BY THE MAJOR INSECT POLLINATOR GROUPS IN PHRYGANA[a]

	Number of			Sucrose/hexose ratio: S/(G + F)	
Pollinator group	Pollinator species	Plant species visited	p–p interactions	Average value on the basis of p–p interactions	SE
Aculeata	49	29	112	2.85	0.532
Apoidea	224	69 (70)	859 (861)	2.58 (2.86)	0.133 (0.236)
Coleoptera	60	46 (47)	248 (249)	1.28 (1.77)	0.178 (0.515)
Diptera (-Syrphidae)	119	53	288	1.06	0.130
Lepidoptera	30	41 (42)	153 (156)	1.69 (4.00)	0.233 (1.344)
Other	48	27	83	1.43	0.395
Syrphidae	46	39	181	0.66	0.108
All community	576	96 (97)	1924 (1930)	1.90 (2.27)	0.080 (0.172)

Numbers in parentheses are with the outlier *Anthyllis* wherever this is visited.

[a] The preference is given as average S/(G + F) ratio calculated over all interactions of an insect group with the plants visited within the community.

TABLE 5. SUCROSE/HEXOSE RATIOS OF THE FLORAL NECTARS VISITED BY THE POLLINATOR GROUPS BROKEN DOWN TO FAMILIES IMPORTANT FOR POLLINATION IN PHRYGANA[a]

Pollinator group	Number of			Sucrose/hexose ratio: S/(G + F)	
	Pollinator species	Plant species visited	p–p interactions	Average value on the basis of p–p interactions	SE

Other Diptera	25	26	54	0.81	0.211
Coleoptera	60	46 (47)	248 (249)	1.28 (1.77)	0.178 (0.515)
Lepidoptera	30	41 (42)	153 (156)	1.69 (4.00)	0.233 (1.344)
Hemiptera	23	22	43	1.70	0.617
Neuroptera	2	2	2	0.52	0.490
All community	576	96 (97)	1924 (1930)	1.90 (2.27)	0.080 (0.172)

Numbers in parentheses are with the outlier *Anthyllis* wherever this is visited.

[a] The preference is given as average S/(G + F) ratio calculated over all plant–pollinator interactions within the community. The group "anthomyid flies" encompasses the families Anthomyidae, Muscidae, Calliphoridae, Rhinophoridae, Sarcophagidae, Scatophagidae, and Tachinidae.

Syrphidae: $P < 0.001$). Similarly, the Tukey *a posteriori* HSD test showed that Megachilidae was the only insect family that was distinguished by its preference for high sucrose/hexose ratios, contrasting to Syrphidae and "anthomyid flies" preferring low sugar ratios (Tables 5 and 6).

DISCUSSION

The analysis of the phryganic nectars produced no surprises: they contained the most common sugars known for nectars: sucrose, glucose, and fructose (Wykes, 1952; Percival, 1961; Baker and Baker, 1983). Among the remaining minor sugars, none was consistently found within a group or a family of plants, such as

TABLE 6. SUMMARY RESULTS OF THE POLLINATOR RESPONSES TO NECTAR SUCROSE/HEXOSE RATIOS IN PHRYGANA[a]

	P

[a] *P* (Tukey HSD posthoc test) shows the difference between the sugar ratios of the nectars preferred by either insect groups. *P* of empty cells or not appearing pairs was NS. The outlier *Anthyllis* was not considered in the calculations.

xylose was in the nectars of the South African *Protea* and *Faurea* (Nicolson and Van Wyk, 1998). Sugar profiles of the phryganic species are commonly found in nature, with a sugar composition similar to that of most other plants.

When focusing on the two plant groups distinguished by their sucrose content and sucrose/hexose ratios (Table 3), the number of species in "high sucrose" (sucrose-dominant to sucrose-rich, according to the terminology by Baker and Baker, 1983) families exceed those of "low sucrose" (hexose-dominant to hexose-rich) families (59% vs. 41%). Although "high sucrose" species make up only 53.5% of the plant species in the community, it is interesting that most of the species flowering in spring–summer had "high sucrose" vs. "high hexose" nectars (60.8% vs. 39.2%, respectively), whereas the opposite holds for winter (36.4% vs. 63.6% for "high sucrose" and "high hexose," respectively). These differences suggest that under the hot and dry Mediterranean conditions "high sucrose" nectars may be selected against "high hexose" ones. Three explanations seem likely. (1) Hexoses, mostly products of postsecretory phenomena of sucrose hydrolysis, may result in osmotic uptake of water throughout anthesis in order to decrease nectar concentration (% w/w) (Pate et al., 1985; Nicolson, 2002). Therefore, nectars rich in hexoses need more water than nectars rich in sucrose for the same amount (weight) of sugars contained (Nicolson, 1998). This may result in water loss for nectars rich in hexoses, and although nectar volumes in the Mediterranean are generally small, the total mount of water loss per plant bearing hundreds of ephemeral, and

generally open, flowers may be appreciable. Under the extreme water limitations characterizing Mediterranean systems, hexose-rich nectar could be an inappropriate solution. (2) From the calorific point of view, nectar with a high sucrose ratio utilizes less water for the same carbohydrate bait offered to pollinators as reward, therefore contributing to water economy in the system (Nicolson, 2002). What is important for honeybees is calorific value of the reward, not the type of sugars (mono-, disaccharides) in nectars of equal calorific value (Wells et al., 1992). (3) The prevalence of "high hexose" nectars in the "winter" flowering species may be related to adaptation of the insect diet to multiple sugar types. Among the nectar sugars dealt with, only sucrose needs digestion (hydrolysis), whereas monosaccharides and water are rapidly absorbed across the midgut (Nicolson, 1998). It may not be by mere coincidence that insects such as syrphids, anthomyid a.o. flies, and beetles find monosaccharide uptake easier compared to sucrose as a quick drink or as a normal meal (Table 6). Hence, adaptation to easy-to-digest monosaccharides may constitute a differential advantage of hexose-nectars for attracting an extensive array of pollinators, which to a large extent are nonspecialized and most of which are active in wintertime.

Deep flowers have been associated mostly with pollination by specialized pollinators and protection from nectar thieves, enabling the preservation of nectar *quantity* (Baker and Baker, 1983, 1990). What has been underestimated so far is the protection of nectar *quality*, which can result by either open contact with air (evaporation, oxidation) or with a continuous contact with many non-legitimate yeast- or bacteria-bringing insects (fermentation). I argue that deep flowers are the most convenient places for nectars to be preserved. Unless protected, nectar tends to equilibrate with ambient humidity, its concentration being determined by both chemical effects and microclimatic gradients (Corbet et al., 1979; Nicolson, 1998, 2002). On the other hand, deep and closed flowers are efficient in protecting the nectar so that unwanted insects have limited access. In this respect, numerous hairs and stamens are as important as long corollas in restricting air movement and excluding insects, such as *Cistus parviflorus*, *C. salvifolius*, and *Capparis spinosa*, all key species in phrygana, comparable to the South African Proteaceae (Petanidou and Ellis, 1996; Nicolson, 2002). The presence of honey leaves or honey pockets (i.e., petal scales where nectar is accumulated) in bowl-shaped flowers in some phrygana species, probably plays a similar nectar-protective role (e.g., *Nigella arvensis*, *Ranunculus sprunerianus*).

As shown, "high sucrose" nectars prevail in deep flowers vs. "high hexose" nectars that are frequent in open flowers. Thus, plants bearing deep flowers with "high sucrose" nectars are most successful during the difficult period of the year, i.e., between April and mid-September when evapotranspiration exceeds rainfall (Petanidou and Ellis, 1993), allowing open or bowl-shaped "high hexose" flowers to thrive in fall through winter. Yet, this seasonal shift in

flowering time may constitute a potential trade-off for many, albeit unspecialized and illegitimate flower visitors (Petanidou et al., 1995).

Phylogenetic Constraints. That sucrose/hexose ratios were associated with plant family membership in the phrygana community studied was not a surprising result. This confirms previous conclusions by Percival (1961), Baker and Baker (1983), and Stiles and Freeman (1993) that the primary constraints responsible for shaping sugar profiles in the floral nectars of plants are phylogenetic. This is interesting, bearing in mind that Mediterranean communities may differ greatly from other continental communities in this respect. For instance, phylogenetic constraints were not found to play a decisive role in determining plant flowering time in phrygana, as seen elsewhere (Kochmer and Handel, 1986; Petanidou et al., 1995).

Lamiaceae, a key family of the phrygana, is also the top sucrose rewarding plant family in this community (Petanidou and Vokou, 1993; Petanidou, 1996; Petanidou and Ellis, 1996; Petanidou et al., 2000). Interestingly, in all earlier studies, Lamiaceae have been pinpointed for their high rate of sucrose-dominant to sucrose-rich nectars (Percival, 1961; Baker and Baker, 1983), although only in phrygana do all Lamiaceae species have "high sucrose" nectars. This high rate can be explained as an effect of other overwhelming constraints in the Mediterranean, such as climate or a diverse bee fauna (Michener, 1979). With high values in sucrose content, Ranunculaceae follows the Lamiaceae, probably due to its small plant number (3) and the ultra conservative *posthoc* test applied. These findings agree with Baker and Baker (1983), who found sucrose-dominant or sucrose-rich nectars in Ranunculaceae, but not with Percival (1961). Finally, Fabaceae, with very high sucrose values (Table 3) occupies an inferior position, also probably due to the heterogeneity within this group, as confirmed by Percival (1961) and Stiles and Freeman (1993). Apiaceae and Liliaceae, the "low sucrose" families of the community, lie on the opposite side of the scale as found by Percival (1961) and Baker and Baker (1983). It should be noted that all the above families are reasonably phylogenetically independent, being placed far apart in the evolutionary tree (Dodd et al., 1999), which makes convergence/divergence in their sugar ratios meaningful. The results allow for the conclusion that phryganic nectars are, to a large extent, shaped by phylogenetic constraints as found in earlier studies.

Ecological Constraints. That nectar composition (as sucrose/hexose ratio and % sucrose content) is not associated with the plant life cycle, a character resulting from complex ecological factors, is surprising. This, together with the finding that the sugar ratio does not depend on flowering time, may lead one to the conclusion that ecological constraints do not appear to have a detectable effect in shaping nectar composition in the Mediterranean communities. However, when the period of actual water deficit in the system (April–mid-September) is considered, it emerges that plants flowering in the dry period do

differentiate significantly in nectar composition from those flowering in the wet period. This result is notable because it underlines the importance of time, as an expression of water availability within the system, in effectively shaping many pollination-related attributes found in other studies, such as flowering (Petanidou et al., 1995), corolla size of flowers, as well as some nectar and nectary attributes (Petanidou et al., 2000). This study confirms that time constitutes a critical parameter in the Mediterranean, because of the overriding effect of the summer drought that characterizes these communities.

Coevolutionary Constraints. The results also provide evidence of a significant partitioning of nectar resources by the existing pollinator guilds within the community, based on the sugar profiles of the nectars. This confirms Baker and Baker (1983, 1990), but their results were derived from "pollination syndromes" and predominant pollinators alone. My results, in contrast, are based on all plant–pollinator interactions observed in the entire community throughout the year, and they consider not only predominance, but also statistical variation.

The highest preference for nectars of high sucrose content in the phrygana is shown by wasps (aculeates) and bees. The differential preference of bees for visiting flowers with high-sucrose nectars is not only in contrast to beetles, hoverflies, and other flies (as is also the case for wasps), but also includes butterflies, a heterogeneous group (Tables 4 and 5). In this respect, my conclusions do not support those of Baker and Baker (1983) that butterflies prefer sucrose-dominant to sucrose-rich nectars as long-tongue bees do. On the other hand, my data show that bees are a heterogeneous group too, with nectar preferences varying from low- and medium-sucrose (e.g., Andrenidae; Apidae, Halictidae, and Anthophoridae) to high sucrose (Megachilidae; cf. Table 6). The tendency of Megachilidae to exploit such high-sucrose nectars is certainly related to their long-tongue morphology allowing them to obtain nectar from deep flowers. Like bees, wasps are the only group in the community showing a differential preference (vs. beetles, hoverflies a.o. flies, as well as Andrenidae) to visit flowers with "high sucrose" nectars (Tables 4–6). This finding shows that wasps are important as reward consumers and probably as pollinators in these semiarid environments.

Megachilidae are the only group showing a high preference for sucrose-nectars. This family is diverse within the Mediterranean Basin (Michener, 1979), by far the most species-rich in phrygana [32% of the bees and 13% of the anthophilous insect fauna according to Petanidou and Ellis (1993)], and a key family in Mediterranean communities (Petanidou and Ellis, 1996; Petanidou et al., unpublished data). Although little is known of the nectar sugar preferences of solitary bees, experiments on social bees and other animals have shown significant preference differences: honeybees showed no preference for either sugar type of equal calorific value (1 M sucrose vs. 2 M monosaccharides; Wells et al., 1992), but *Melipona beecheii* and *M. fasciata* preferred sucrose to

glucose and fructose (Biesmeijer et al., 1999). Similarly, the peacock butterfly, *Inachis io*, strongly prefered sucrose over fructose, especially over glucose (Rusterholz and Erhardt, 1997). Bearing in mind that sucrose-nectars are advantageous to plant–pollinator relationships in phrygana (see above), I argue that the high rate of sucrose-nectars in the phryganic communities may constitute an ecophysiological response to water constraints, and could be the main driver for floral preferences by their pollinator mutualists. By being the most numerous and representative group in phrygana, the long-tongue Megachilidae can respond to the conditions set above (sucrose-nectars in deep flowers), hence they probably represent the main selecting pollinator group for "high sucrose" nectars in the Mediterranean region.

Acknowledgments—The study was supported by an EC grant (DG VI-contract AIR3-BM92-004). I thank Prof. E. Smets and Prof. A. Van Laere for offering laboratory facilities at the Catholic University of Leuven; E. Nackaerts and V. Goethals for technical assistance on sugar analyses; Prof. Sue Nicolson, Prof. Peter J. Davies, Dr. Ellen Lamborn and an anonymous reviewer for invaluable comments on earlier versions of this manuscript.

NEST PAPER ABSORBENCY, TOUGHNESS, AND PROTEIN CONCENTRATION OF A NATIVE VS. AN INVASIVE SOCIAL WASP

TRACY R. CURTIS,* YAIRA APONTE, and NANCY E. STAMP

Department of Biological Sciences, Binghamton University, State University of New York, Binghamton, NY 13902-6000, USA

(Received October 9, 2003; revised August 17, 2004; accepted December 17, 2004)

Abstract—The amount of proteinaceous food that was allocated to nest construction by a native wasp (*Polistes fuscatus*) vs. an invasive wasp (*Polistes dominulus*) in North America was examined following a field experiment under *natural* and *surplus prey* foraging conditions. Wasps of the *surplus prey* foraging conditions were provided with prey *ad libitum* within an enclosed area, while wasps of the *natural* treatment foraged in an adjacent field-woodland site. At the end of the field experiment, each nest was tested for water absorbency, toughness, and protein concentration. The hypotheses were: (1) When all nests are equally sheltered, the invasive *P. dominulus* (PD) allocates less protein to nest paper construction (for waterproofing and strengthening) and more protein to developing larvae than the native *P. fuscatus* (PF). (2) Nests of *P. dominulus* are more absorbent (less waterproof) and less tough than nests of *P. fuscatus*. Results indicate that *P. fuscatus* nests from surplus prey foraging conditions were more absorbent (less waterproof) to artificial rain drops than *P. dominulus* nests. The toughness of nests was similar between wasp species. However, nests from the natural treatment were tougher than those from the surplus prey treatment. Nests from the natural foraging conditions had half as much protein as those from surplus prey foraging conditions. There was no correlation between nest protein concentration and the number of prey taken, the number of cells, the number of adult offspring produced, or the total wasp biomass produced per colony. For PF under surplus prey conditions, protein concentration and absorbency were negatively correlated, but for PD the correlation was positive. In conclusion, when prey were scarce, *Polistes* wasps allocated less protein to nest construction. Also, the introduced *P. dominulus* may increase production of

* To whom correspondence should be addressed. E-mail: trcurtis@mail.com

offspring by allocating less to nest construction than that of the native *P. fuscatus*, and so more protein to offspring production.

Key Words—Introduced species, proteinaceous food, nest construction, *Polistes fuscatus*, *Polistes dominulus*.

INTRODUCTION

In the construction and maintenance of a nest, many social wasps use an oral secretion to cement together nest material, e.g., plant fibers (McGovern et al., 1988; Espelie and Himmelsbach, 1990; Singer et al., 1992). Nest paper and the nest pedicel are primarily composed of cellulose, derived from plant material and nitrogen most likely derived from the oral secretions of the wasps (Espelie and Himmelsbach, 1990). The protein secreted by wasps may give added strength to the nest, and so the nest pedicel tends to have a higher proportion of protein than the nest paper (Singer et al., 1992). Specifically, because proline is a dominant amino acid in structural proteins, the high proline content of the pedicel protein may help to provide the structural strength required in that part of the nest (Espelie and Himmelsbach, 1990; Singer et al., 1992; Kudo et al., 2000).

The production of a proteinaceous oral secretion for nest construction may be costly, especially for a single foundress, because the foundress has multiple uses for protein: the production of oral secretion, nourishment of her brood, and her own metabolism (Kudo et al., 1998). Kudo et al. (1998) found that 10–20% of total protein resources brought in during the nest founding phase may be devoted to the production of oral secretion. This diversion of protein may prolong the larval period and, thus, the time of emergence of the first workers. Furthermore, the amount of protein allocated to nest construction may depend on environmental conditions. For example, the amount of oral secretion added to paper wasp nest material is positively correlated with exposure to rainfall (Yamane and Itô, 1994; Kudo et al., 1998; Kudo, 2000), and suggests that, in addition to nest strengthening, protein is also a mechanism for nest waterproofing. Nest paper is water-resistant (McGovern et al., 1988). In addition, foundresses that nested at exposed sites produced significantly smaller and fewer immatures than those nesting at sheltered sites (Kudo, 2000), which may reflect a tradeoff between the need for greater waterproofing and the rate of offspring production. Another cost to foraging is that the process requires extensive foraging for prey tissue (Kudo et al., 1998). Specifically, foraging by a lone foundress is risky, for herself and for her unprotected brood (Gibo, 1974, 1978).

A European paper wasp (*Polistes dominulus*) was accidentally introduced to the United States about 20 yr ago (Hathaway, 1981). Since its introduction,

P. dominulus has spread throughout most of the Northeast, seemingly at the expense of the native species, *Polistes fuscatus* (Judd and Carpenter, 1996) and recently has been found on the west coast (Cervo et al., 2000; Pickett, personal communication). Studies in North America have determined that *P. dominulus* has a higher productivity compared to native *Polistes*, including *P. fuscatus* (Pickett and Wenzel, 2000; Armstrong and Stamp, 2003; Gamboa et al., 2004). This higher productivity reflects in part earlier emergence of the first brood.

But other factors may contribute to the differential productivity and, thus, to the success of *P. dominulus* as an introduced species (Cervo et al., 2000; Pickett and Wenzel, 2000). For example, it has been suggested that *P. dominulus* may invest less to waterproof their nests because of this species' long coexistence with human structures in Europe. Specifically, *P. dominulus* has had the opportunity to adapt to nesting in protected human structures for centuries longer than have North American *Polistes* (Pickett and Wenzel, 2000). Correspondingly, *P. dominulus* may allocate less proteinaceous material to nest construction and more to their brood, thereby contributing to increased productivity.

The goal of this study was to compare the absorbency, toughness, and protein concentration of nests of *P. dominulus* (invasive species) and *P. fuscatus* (native species) when wasps had either surplus prey foraging conditions (provided food *ad libitum*) or natural foraging conditions (foraged for themselves in a natural area). We also determined how nest protein concentration corresponded to the number of prey taken, the number of cells in nests, the number of offspring produced, and the total biomass produced per colony.

METHODS AND MATERIALS

Experimental Design. Nests were collected following a 2×2 factorial experiment that was conducted using two levels for wasp species, *P. fuscatus* (PF) and *P. dominulus* (PD), and two levels of foraging conditions, designated *surplus prey* and *natural*. In the field experiment, each nest was placed within a screen cage (dimensions: $1.8 \times 1.8 \times 1.8$ m). The *surplus prey* treatment was supplied with prey (waxworms) *ad libitum*, and foraging was limited to within the cages. Waxworms (*Galleria mellonella*) were obtained from Carolina Biological Supply (Burlington, NC, USA) and reared on an artificial diet. Wasps of the natural treatment, in which cage doors were tied open, had to forage for prey within the adjacent field-woodland area. Within each cage in both foraging treatments, nests were housed in wooden boxes, and the cage frames also provided a supply of wood for making nests. For further details, see

Armstrong and Stamp (2003). Twenty-six nests (8 PD—optimal, 6 PD—natural, 8 PF—optimal, 4 PF—natural) were tested for absorbency, toughness, and protein concentration.

Absorbency. All nests were dried at 50°C to a constant weight and then weighed. Then 10 ml of water were dispensed one drop at a time (to represent rain drops) on the top of each nest (evenly around the pedicel). The nest was suspended so that it was not sitting in the water that had run off the top. After 30 sec, the nest was reweighed. Absorbency was calculated as the amount of mass gained by each nest following the artificial rain divided by the initial mass. Three trials were performed for each nest and the mean determined. Nests were redried between each trial. As nest size varied, the absorbency for each nest was divided by the mass of that nest, and the proportion was multiplied by 100 to obtain percent value. Thus, the *percent absorbency* was used for statistical analysis.

Toughness. Nest toughness was examined using a penetrameter (Sands and Brancatini, 1991). The procedure consisted of determining the grams of sand added to a container attached to a pin that caused the pin to penetrate the nest paper. The procedure was repeated at five equal-spaced locations on each nest, all approximately 1 cm from the pedicel, and mean was taken.

Protein Concentration. A protein microassay (Jones et al., 1989; Bio-Rad, Richmond, CA) was used to measure the concentration of protein for each nest. To avoid protein contamination from wasp silk, exuviae, and/or meconia in the nest protein analysis, nest material was taken from the midsection of the outermost whole cells that had never been used to hold larvae or pupae.

For each nest, 5 mg of nest material were homogenized with 0.1 N NaOH. Then 64 μl of each sample solution were diluted with 96 μl of nanopure water, and 40 μl of dye reagent (Coomassie Brilliant Blue G-250) were added. The absorbency was measured at 595 nm with a Biolinx program (Dynatech Laboratories Inc., version 2.20) on an automated spectrophotometer (MRX, Dynatech Laboratories Inc., Chantilly, VA, USA). The standard was Bovine gamma globulin.

Data Analysis. Two-way ANOVAs were performed using SYSTAT® (version 10) on absorbency, toughness, and protein concentration. The assumptions of ANOVA were met. Tukey tests were used to distinguish between species-foraging condition combinations. In addition, regression analyses were performed on protein concentration vs. nest absorbency, the total number of prey taken (for the surplus prey foraging colonies), the total number of cells, the total number of offspring produced, and the total biomass produced per colony. Data for prey, cells, offspring, and biomass are taken from Armstrong and Stamp (2003). The regression for protein concentration and total number of prey taken was only for the surplus prey foraging condition because under the natural condition we could not determine the number of prey collected.

RESULTS

Absorbency and Toughness. Although there was no effect of species or foraging conditions on nest absorbency (species: $df = 1, 22$, $F = 1.08$, $P = 0.31$; conditions: $df = 1, 22$, $F = 0.61$, $P = 0.44$), *P. fuscatus* (PF) nests from surplus prey foraging conditions were more absorbent (less waterproof) than *P. dominulus* (PD) nests from the same treatment (Tukey test, $P < 0.05$) (Figure 1). Nests from natural foraging conditions were tougher than nests from surplus prey foraging conditions ($df = 1, 22$, $F = 10.42$, $P = 0.004$) (Figure 2). However, there was no effect of wasp species on nest toughness ($df = 1, 22$, $F = 0.51$, $P = 0.48$) (Figure 2).

Protein Concentration. Overall, nests built under surplus prey foraging conditions had a greater concentration of protein in the nest material, about twice that of nests built under natural foraging conditions ($df = 1, 20$, $F = 42.27$, $P < 0.001$). There was no effect of wasp species on the amount of protein allocated to nest construction ($df = 1, 20$, $F = 1.12$, $P = 0.30$). However, PF and PD differed in the amount of protein allocated to nest construction in natural foraging conditions, such that PF nests of that treatment had a nest protein concentration twice that of PD nests (Tukey test, $P < 0.05$) (Figure 3).

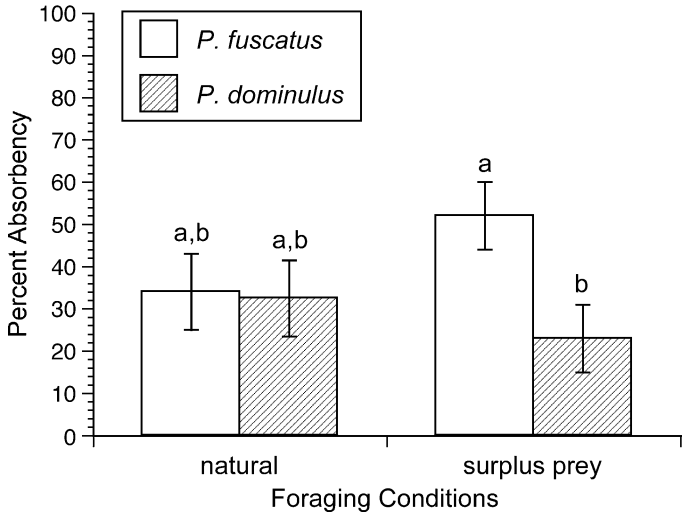

FIG. 1. The percent absorbency of nests for *P. fuscatus* and *P. dominulus* in natural *versus* surplus prey foraging conditions. Means ± SE are shown.

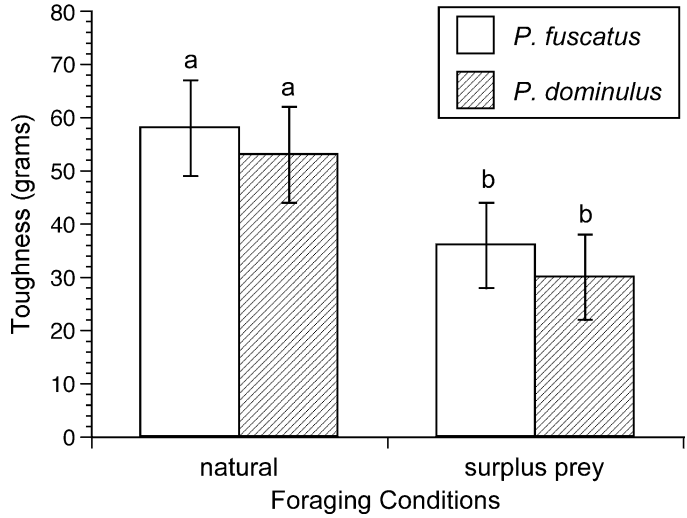

FIG. 2. The toughness of nests of *P. dominulus* and *P. fuscatus* in natural *versus* surplus prey foraging conditions. Means ± SE are shown.

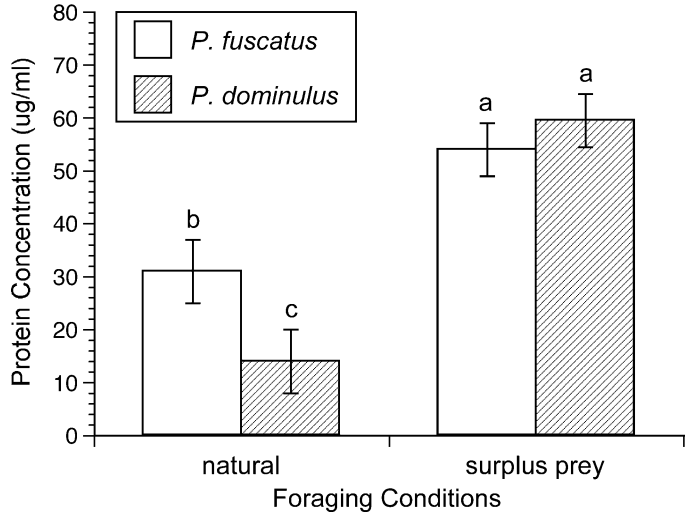

FIG. 3. The concentration of protein in nests of *P. fuscatus* and *P. dominulus* in natural *versus* surplus prey foraging conditions. Means ± SE are shown.

For PF colonies of the surplus prey treatment, there was a *negative* correlation between protein concentration vs. absorbency, such that as protein concentration increased, absorbency decreased (Table 1, Figure 4). In contrast, for PD colonies of the surplus prey treatment, there was a *positive* correlation between protein concentration vs. absorbency, such that as protein concentration increased, absorbency also increased (Table 1, Figure 4). For both PF and PD of the natural treatment, there was no correlation between nest protein concentration and nest absorbency (Table 1).

There was no correlation for either species in either treatment for protein concentration vs. the number of cells per nest, the total number of adult offspring produced per nest, the total biomass produced per nest, or the total number of prey taken (surplus prey colonies only) per nest (Table 1).

DISCUSSION

Although wasps of the natural treatment had to forage for prey in a field-woodland site, they were able to maintain a productivity level similar to wasps of the surplus prey treatment, in terms of the number of eggs, larvae, pupae, and

adult offspring produced (Armstrong and Stamp, 2003), and thus, the lower concentration of protein in nest paper of nests of the natural treatment indicates a tradeoff. Wasps in the natural foraging conditions apparently allocated a greater proportion of proteinaceous material to the brood than to nest construction compared to those in the surplus prey foraging conditions (Figure 3). That nests of the surplus prey foraging conditions had a concentration of protein that was twice that of nests under natural conditions suggests that the wasps of the surplus prey foraging conditions could afford to use more protein for oral secretions. So, in addition to exposure to rainfall influencing protein concentration of nest material (Yamane and Itô, 1994; Kudo et al., 1998; Kudo, 2000), food abundance affects it as well.

If it is not a tradeoff, an alternative explanation for these results is that wasps of the natural treatment were successful at allocating resources to both brood and nest, while wasps of the surplus prey treatment were simply depositing excess protein into their nests. However, the behavioral data from this study suggest that the tradeoff explanation is more likely. For example, wasps of the natural treatment were less often observed checking cells or provisioning larvae and more often foraging than wasps of the surplus prey treatment (Armstrong and Stamp, 2003). These results indicate that wasps of the natural treatment spent a considerable amount of time and energy in the location and capture of prey compared to wasps of the surplus prey treatment to produce a similar brood output. Furthermore, given the substantial predation risks and energetic costs involved in leaving the nest (i.e., foragers may be located by natural enemies that respond visually to moving prey) (Reeve and Gamboa, 1987), it is unlikely that wasps of the surplus prey treatment continued to search for prey after the routine protein requirements of the brood and nest were met.

Under natural foraging conditions, PF wasps used more protein for nest construction than PD wasps. These results suggest that when prey are difficult to find (which they presumably were under the natural foraging conditions in this experiment) and when their nests are similarly sheltered (as in this study), PD uses less protein for oral secretion and so has more for the developing brood than PF. Allocation of more proteinaceous material to the brood would contribute to more offspring and more rapid development of offspring for PD compared to PF.

Based on previous studies (McGovern et al., 1988; Yamane and Itô, 1994; Kudo et al., 1998), we expected a correlation between protein concentration and nest paper absorbency. In the surplus prey foraging conditions, protein concentration of PF nests was negatively correlated with nest absorbency; however, protein concentration of PD nests was *positively* correlated with nest absorbency. Furthermore, in the natural foraging conditions, there was no correlation between protein concentration and nest paper absorbency for either species. These results may reflect in part how environmental conditions influence the

location on the nest where secretion is applied and the amount of secretion applied or reapplied. Also, as colony size increases, there are more workers to apply secretion and also more nest area to maintain, but the timing of brood emergence affects the relationship of those variables, such that there may be more construction at some times and more maintenance (and so, more secretion applied) at other times. Certainly, some nests, especially the top half, look quite "shellacked" compared to others.

The protein secreted by wasps may strengthen nests (Espelie and Himmelsbach, 1990; Singer et al., 1992). However, the results of this study do not support that hypothesis. Probably where protein contributes the most to strengthen the nest is at the pedicel, the stalk that attaches the nest to a surface, which we did not examine. In addition, the oral secretions seem to act as a glue, attaching the pedicel to a surface, yet allowing some elasticity.

For both wasp species, nests of the natural foraging conditions were tougher than nests of the surplus prey foraging conditions. It is possible that wasps of the natural foraging conditions used a different combination of wood types to construct their nests. Wasps of the surplus prey foraging treatment were restricted to using weathered pine for nest construction (from the cage frames and nest boxes). Wasps of the natural foraging treatment, in addition to having the pine in the cages, also had access to other wood types for nest construction, because they foraged freely. Wasps use weathered fibrous material from woody plants for nest paper (Raveret Richter, 2000). Although hardwoods and softwoods differ in composition (e.g., softwoods have a higher lignin content while hardwoods have a higher xylan content), wasps make no distinction between the two (McGovern et al., 1988). The weathering of hardwoods and softwoods for 25–30 yr has been found to result in an 80% loss of lignin and, thus, a loss in fiber connection (Browne, unpublished data). Consequently, nest toughness is likely a function of several factors, including protein concentration, source of plant fiber, and the age or decomposition state of the fiber used. Also, nests built where exposure to weather is greater may be constructed with greater toughness. Because all nests in this study were sheltered in boxes, that was not a source of variation here. However, colonies with abundant food may respond by gathering as much food as possible (Wenzel and Pickering, 1991) and, correspondingly, building cells as quickly as possible, with the result that nest paper is not as tough.

In summary, differences in protein allocation to nest construction between the invasive *P. dominulus* and the native *Polistes* may be a factor in the success of PD as an invasive species. When prey are scarce, PD appears to use less protein for oral secretion for nests and so may have more for the developing brood, thereby contributing to more offspring and more rapid development of offspring for PD compared to native *Polistes*. These results alone do not explain the success of PD; however, it is likely one of several contributing factors.

(Received June 15, 2004; accepted December 26, 2004)

Abstract—We measured electrophysiological responses in the antennae of two predaceous hister beetles, *Platysoma parallelum* and *Plegaderus transversus*, exposed to racemic mixtures of primary aggregation pheromones of scolytid bark beetle prey, ipsenol, ipsdienol, and frontalin. No significant differences were found for either histerid species between male and female antennal responses to any of the three pheromones. Measurement of antennal threshold responses indicated that *Pla. parallelum* has increasing antennal sensitivity to ipsdienol, ipsenol, and frontalin. In contrast, *Ple. transversus* exhibited similar detection thresholds to all three pheromones. *Pla. parallelum* antennae exhibited different response amplitudes to the three pheromones at quantities above the detection threshold, while *Ple. transversus* had similar responses to each. Behavioral responses to the same three pheromones were evaluated for both histerid species using pedestrian olfactometer bioassays. Both species were attracted to frontalin and ipsenol, but not ipsdienol. *Pla. parallelum* was significantly more attracted to frontalin than ipsenol, while *Ple. transversus* showed no significant preference for either compound. Our results suggest that histerids that prey upon pine bark beetles may have different host or host habitat preferences, which could reduce interspecific competition.

Key Words—Scolytidae, Histeridae, *Dendroctonus*, *Ips*, *Platysoma*, *Plegaderus*, bark beetle electrophysiology, hister beetle predators, host location, kairomone, attraction, frontalin, ipsenol, ipsdienol.

INTRODUCTION

Hister beetles (Coleoptera: Histeridae) are important natural enemies of pine bark beetles (Coleoptera: Scolytidae). They comprise approximately 6–7% of total predator abundance for southern pine beetle, *Dendroctonus frontalis* Zimmermann, and *Ips* spp. in the southern United States (Berisford, 1980; Kulhavy et al., 1989). Histerid adults and larvae feed primarily on the early life stages of bark beetles within their galleries, mined into the inner bark of pines (Kovarik and Caterino, 2000; WPS personal observations). They also facultatively prey upon secondary gallery fauna and are considered generalists within a specialized habitat (Erbilgin and Raffa, 2001). Histerids typically arrive at trees within 1 wk of bark beetle colonization (Shepherd and Goyer, 2003). The sympatric histerids, *Platysoma parallelum* (Say) and *Plegaderus transversus* (Say), are associated with both *D. frontalis* and *Ips* spp. infestations in the southeastern United States (Overgaard, 1968; Moser et al., 1971; Stein and Coster, 1977; Dixon and Payne, 1979; Goyer et al., 1980; Riley and Goyer, 1986; Shepherd and Goyer, 2003). These previous studies did not indicate any apparent host specificity for either histerid species.

Histerids exploit bark beetle aggregation pheromones as kairomonal attractants to locate host habitats (Dixon and Payne, 1980; Turnbow and Franklin, 1981; Payne, 1989; Shepherd and Goyer, 2003). Trapping studies have shown that histerids are attracted to the major aggregation pheromones of bark beetles of the southern United States, including frontalin (*D. frontalis*), ipsenol [*Ips grandicollis* (Eichhoff)], and ipsdienol [*Ips avulsus* (Eichhoff) and *Ips calligraphus* (Germar)] (Dixon and Payne, 1980; Turnbow and Franklin, 1981; Shepherd and Goyer, 2003). Variation in responsiveness to prey kairomonal odor cues may indicate that sympatric histerids use different strategies for host location. This could separate arrival times and locations on bark beetle-infested trees and thus reduce interspecific competition.

Our objective in this study was to determine differences in attraction to host pheromones between *Pla. parallelum* and *Ple. transversus* adults. We conducted both electrophysiological and behavioral assays with frontalin, ipsenol, and ipsdienol.

METHODS AND MATERIALS

Insects for Laboratory Assays. We collected adult *Pla. parallelum* and *Ple. transversus* predators from under the bark of loblolly pine, *Pinus taeda* L., logs naturally infested by *Ips* spp. at the Louisiana State University AgCenter, Idlewild Research Station, East Feliciana Parish, LA, USA. Histerids were maintained at room temperature (ca. 23°C) in glass petri dishes lined with moist

filter paper and were fed to satiation with *Ips* spp. larvae twice weekly. We used histerids in experiments up to 60 d after collection.

Electroantennogram (EAG) Recordings. For these analyses, EAG techniques were modified from those used by Visser (1979) and Scholz et al. (1998), and the equipment used was identical to that described in Asaro et al. (2004). We mounted intact head preparations of *Pla. parallelum* and *Ple. transversus* between two glass micropipette/gold electrodes filled with Beadle–Ephrussi Ringer solution and 0.02% v/v Triton X-100 surfactant (Union Carbide, Midland, MI, USA), which improved electrical contact between the antenna tip and the electrode saline. The reference electrode was inserted into the base of the excised head, and the tip of the recording electrode was touched to the intact club of one antenna. The head preparation was enclosed within a brass Faraday cage.

We tested five dilutions (0.0001, 0.001, 0.01, 0.1, and 1 μg/μl) of synthetic racemic [50(+)/50(−)] ipsenol, 97% purity (Bedoukian Research, Inc., Danbury, CT, USA), ipsdienol, 95% purity (Borregaard, Sarpsborg, Norway), and frontalin, 97% purity (BASF, Ludwigshafen, Germany) in redistilled hexane. Dilution series of a single pheromone were delivered in random order to individuals of each sex and species: ipsenol (*Pla. parallelum*—13 M/22 F, *Ple. transversus*—18 M/10 F); ipsdienol (*Pla. parallelum*—16 M/12 F, *Ple. transversus*—18 M/8 F); and frontalin (*Pla. parallelum*—12 M/17 F, *Ple. transversus*—12 M/18 F). The number of replicates differed due to availability of vigorous histerids with undamaged antennae. In addition to the pheromone samples, we puffed a hexane-only control and standard solution (frontalin, *endo*-brevicomin, and verbenone at 0.1 μg/μl in hexane) before and after each puff of a sample dilution. We used a multiple-component standard mixture of *D. frontalis* pheromones because electrophysiological and behavioral responses by *Pla. parallelum* and *Ple. transversus* to individual compounds were not known. This standard elicited consistent, strong EAGs in both sexes and species in pilot trials.

Test solutions (10 μl) were applied to 10 × 0.5-cm strips of Whatman No. 1 filter paper inside glass Pasteur pipettes. We positioned the pipette tip 2 cm upwind of the head preparation in a continuous stream (400 ml/min) of humidified, charcoal-filtered air. Puffs of air (30 ml/min; 3-sec duration) were delivered from a Syntech (Hiversum, The Netherlands) CS-05 stimulus control unit. We recorded the peak voltage amplitude during the puff delivery of each stimulus as the antennal response. An interval of 1 min between puffs was found to be sufficient for complete antennal recovery in both species. We determined the sex of each beetle by dissecting the genitalia.

Y-Tube Olfactometer Bioassays. We tested short-range anemotaxic responses of *Pla. parallelum* and *Ple. transversus* adults in pedestrian bioassays, using a Y-tube olfactometer as described in Sullivan et al. (2000). Individual histerids were

introduced into the stem of a glass Y-tube (6-mm i.d., stem 7 cm, branches 7 cm, and 135° to the stem), and a choice was scored when a beetle walked 5 cm down one branch within 8 min of introduction to the Y-tube. Filtered, humidified air (30 ml/min, 23–24°C, 50–70% RH) carried odors from two bait-holding tubes to each branch of the Y-tube.

Baits were 100 μg racemic ipsenol, ipsdienol, and frontalin in hexane (10 μl) applied to filter paper squares (9 cm^2). The solvent was allowed to evaporate for 20 sec before papers were placed inside the sample tubes. Papers with ipsenol, ipsdienol, frontalin, and hexane only (control) were tested against each other in all possible binary combinations.

We used a total of 60 individual histerids of each species in each test and did not reuse them. Beetles were starved for 5 d prior to introduction to the olfactometer. Between trials, we replaced Y-tubes with clean ones and swapped bait treatments to opposite branches to eliminate directional bias.

Statistical Analysis. We calculated net EAGs by subtracting the mean responses to the controls introduced before and after the sample or standard from the actual sample and standard responses (Scholz et al., 1998). EAG data were standardized by calculating the percentages of the net EAGs relative to the standard solution (Payne, 1975; Dickens, 1978).

We used a Wilcoxon paired signed rank test to compare antennal responses to pheromone dilutions to the average of the contiguous control responses. Detection thresholds were calculated as the lowest concentration of pheromone producing significantly greater responses than the control. We compared histerid EAGs at and above the threshold for each species for sexes combined with a Kruskal–Wallis test and a Dunn's multiple comparison test (SAS Institute, 2001). A *G*-test for goodness of fit with William's correction for small samples was used to identify significant preferences for one olfactometer branch in the Y-tube tests (Sokal and Rohlf, 1995). We set significance levels at $\alpha = 0.05$ for all tests.

RESULTS

EAG Recordings. Mean net responses (±SE) of *Pla. parallelum* to the standard mixture were 2.01 ± 0.07 mV for males ($N = 41$) and 2.49 ± 0.05 mV for females ($N = 51$). For *Ple. transversus*, the mean net responses (±SE) to the standard were 5.45 ± 0.23 mV for males ($N = 48$), and 6.35 ± 0.21 mV for females ($N = 36$). No significant differences were found for either histerid species between male and female antennal responses to the three pheromones at any concentration. Thus, we combined male and female EAG data at and above the detection threshold for each species. *Pla. parallelum* and *Ple. transversus* both exhibited

TABLE 1. EAG DETECTION THRESHOLDS TO SERIAL DILUTIONS OF RACEMIC IPSENOL, IPSDIENOL, AND FRONTALIN FOR *Platysoma parallelum* AND *Plegaderus transversus* HISTERID BEETLES (SEXES COMBINED)

Species	Pheromone	Detection threshold (μg on filter paper)[a]	*P*-value
Pla. parallelum	Ipsenol	1	<0.001
Pla. parallelum	Ipsdienol	10	<0.001
Pla. parallelum	Frontalin	0.1	<0.001
Ple. transversus	Ipsenol	1	<0.001
Ple. transversus	Ipsdienol	1	<0.001
Ple. transversus	Frontalin	1	<0.001

[a]Lowest concentration of pheromone that elicited a significantly greater EAG than average of contiguous control responses ($P < 0.05$: Wilcoxon paired signed rank test).

significant antennal responses to racemic ipsenol, ipsdienol, and frontalin (Table 1). *Pla. parallelum* detection thresholds differed, with antennae exhibiting increasing sensitivity for ipsdienol, ipsenol, and frontalin (Table 1). In contrast, *Ple. transversus* detection thresholds were the same for all three pheromones (Table 1).

Mean percent EAGs for *Pla. parallelum* sexes combined were significantly higher for frontalin than ipsenol ($P < 0.001$) and ipsdienol ($P < 0.001$) and higher for ipsenol than ipsdienol ($P < 0.04$) at both 1- and 10-μg concentrations (Figure 1). For *Ple. transversus* sexes combined, there were no significant

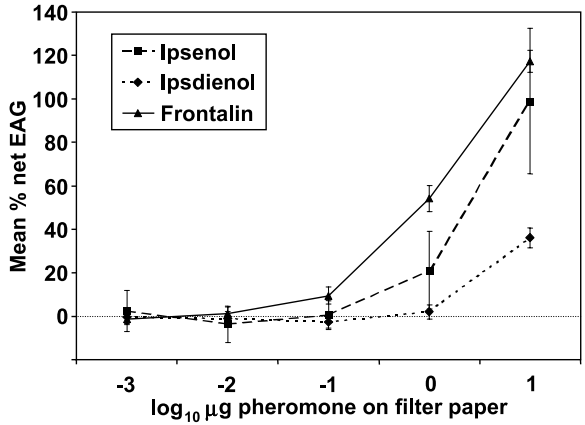

FIG. 1. Mean percent EAGs (±SE) from *Pla. parallelum* adults (sexes combined) to ipsenol ($N = 35$), ipsdienol ($N = 28$), and frontalin ($N = 29$), relative to the standard mixture of *D. frontalis* pheromones.

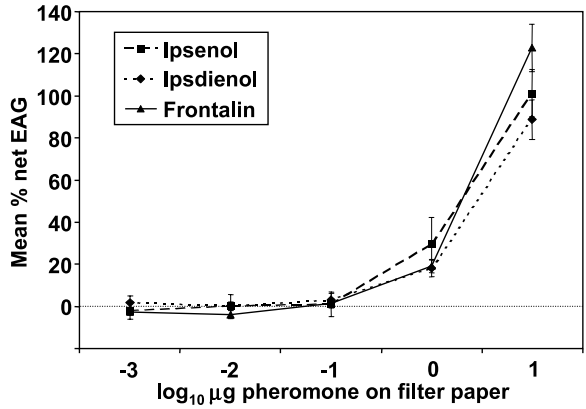

FIG. 2. Mean percent EAGs (±SE) from *Ple. transversus* adults (sexes combined) to ipsenol (N = 28), ipsdienol (N = 26), and frontalin (N = 30), relative to the standard mixture of *D. frontalis* pheromones.

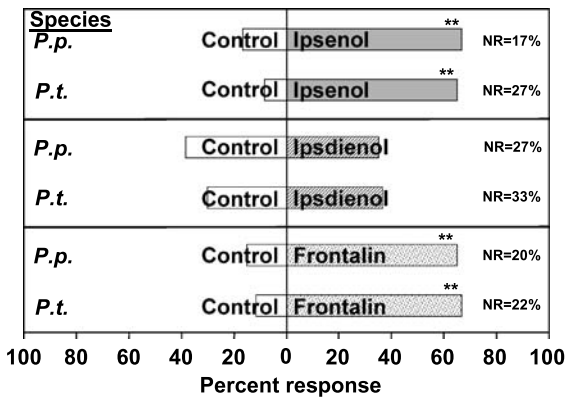

FIG. 3. Percentage of *Pla. parallelum* and *Ple. transversus* adults that walked toward either 100 µg of the pheromone sample or the hexane-only control in six paired choice tests using a Y-tube olfactometer. Asterisks indicate a significantly greater response toward one of the two choices using *G*-tests with William's correction for small samples ($P < 0.001$). *P.p.* = *Pla. parallelum*. *P.t.* = *Ple. transversus*. NR = Percentage of histerids in each test that chose neither the pheromone sample nor the control within 8 min of introduction.

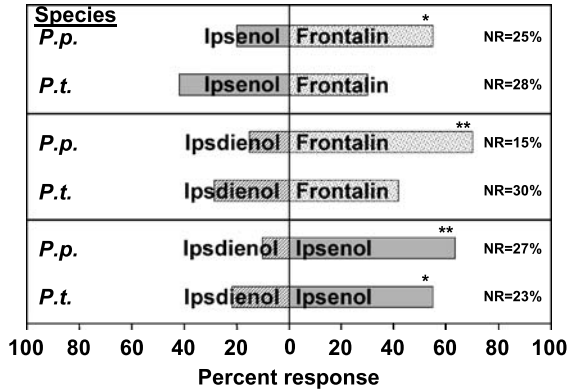

FIG. 4. Percentage of *Pla. parallelum* and *Ple. transversus* adults that walked toward either of two pheromone samples (100 μg each) in six paired choice tests using a Y-tube olfactometer. Asterisks indicate a significantly greater response toward one of the two choices using *G*-tests with William's correction for small samples (*$P < 0.01$; **$P < 0.001$). *P.p.* = *Pla. parallelum*. *P.t.* = *Ple. transversus*. NR = Percentage of histerids in each test that chose neither the pheromone sample nor the control within 8 min of introduction.

differences in responses to the three pheromones at or above the detection threshold (Figure 2).

Y-Tube Olfactometer Bioassays. Both *Pla. parallelum* and *Ple. transversus* were significantly more attracted to frontalin and ipsenol than the control (Figure 3). There was no significant attraction to ipsdienol for either species. Responses to the paired pheromone offerings differed for each species (Figure 4). *Pla. parallelum* was more strongly attracted to frontalin than ipsenol and ipsdienol and to ipsenol than ipsdienol. In contrast, *Ple. transversus* showed no significant preference for either frontalin vs. ipsenol or frontalin vs. ipsdienol when offered as paired choices, but preferred ipsenol over ipsdienol.

DISCUSSION

Different electrophysiological and behavioral responses to three primary bark beetle aggregation pheromones suggest that *Pla. parallelum* and *Ple. transversus* utilize different strategies for host or host habitat finding. The antennae of *Pla. parallelum* responded with increasing sensitivity to ipsdienol, ipsenol, and frontalin, indicating an ability to detect *D. frontalis* attack sites, from which frontalin odor plumes emanate, at greater distances than those of

Ips spp., and *I. grandicollis* colonizations at greater distances than those of *I. avulsus* and *I. calligraphu*s. This histerid likely has a larger antennal receptor population for frontalin than ipsenol and ipsdienol, as we recorded higher intensity antennal responses to frontalin for quantities above the detection threshold (Payne, 1975). We also recorded significantly higher intensity responses to ipsenol than ipsdienol for quantities above the detection threshold, providing evidence for a larger ipsenol receptor population (Payne, 1975). In contrast, *Ple. transversus* exhibited similar detection thresholds and EAGs above the detection threshold for all three kairomones and, thus, may have similarly sized receptor populations for these compounds. Electrophysiological studies of other bark beetle predators found that the clerids, *Thanasimus dubius* (F.) and *Thanasimus formicarius* (L.), also responded to multiple kairomones produced by different prey species (Hansen, 1983; Payne et al., 1984; Tommeras, 1985).

Since both histerid species were attracted to ipsenol and frontalin, but not ipsdienol in the olfactometer bioassays, they may preferentially orient toward portions of trees containing *D. frontalis* or *I. grandicollis*, rather than *I. avulsus* and *I. calligraphus*. The olfactometer preferences of *Pla. parallelum* were mirrored by greater electrophysiological responsiveness to frontalin and ipsenol. Attractive responses and the presence of a larger antennal receptor population suggest specialization for these kairomones. This histerid may be more attracted to trees or portions of trees containing *D. frontalis* than those with only *Ips* spp. In contrast, *Ple. transversus* had fewer odor preferences, differentiating only between ipsenol and ipsdienol when more than one kairomone was offered. Similar to its antennal responses, its attraction to prey kairomones appears less specific than those of *Pla. parallelum*. It may not distinguish between sites colonized by either *D. frontalis* or any of the *Ips* spp.

Differences in attraction patterns between these histerid predators may facilitate niche partitioning, reducing interspecific competition via spatial and temporal separation at sites infested with multiple bark beetle species. These histerids are generalist predators that have not been shown to associate preferentially with any of the four sympatric pine bark beetle species. Different kairomone response profiles may indicate previously unrecognized host preferences, and they may serve to stagger arrival times and separate landing sites at trees infested with multiple host species. In our study, both electrophysiological and behavioral data suggest that *Pla. parallelum* has a preference for frontalin over *Ips* spp. pheromones, while *Ple. transversus* exhibits little or no distinction among these compounds.

Complicating the interactions between these histerid species are the effects of various enantiomeric ratios of prey kairomones on behavior. Studies of histerids associated with *Ips pini* (Say) in Wisconsin have shown that *Platysoma cylindrica* (Paykull) was most attracted to traps baited with 25(+)/75(−)

ipsdienol (Raffa and Klepzig, 1989), and that *Pla. cylindrica* and *Pla. parallelum* were most attracted to traps baited with 3(+)/97(−) ipsdienol (Aukema et al., 2000a,b). In addition to bark beetle pheromones, histerids may use a variety of volatile odor cues derived from other potential prey, host trees, and microorganisms to locate their prey. Any of these compounds, individually or in combination, may provide optimum attractiveness to searching histerid predators.

GENETIC BASIS TO DIVERGENCE OF SEX PHEROMONES IN TWO CLOSELY RELATED MOTHS, *Ostrinia scapulalis* AND *O. zealis*

JUN TABATA* and YUKIO ISHIKAWA

Laboratory of Applied Entomology, Graduate School of Agricultural and Life Sciences, The University of Tokyo, Tokyo 113-8657, Japan

(Received September 16, 2004; accepted December 28, 2004)

Abstract—Crossing experiments between two closely related moths, *Ostrinia scapulalis* and *O. zealis*, were conducted to gain insight into the genetic basis of the divergence of female sex pheromones. The sex pheromone of *O. scapulalis* comprises (*E*)-11- and (*Z*)-11-tetradecenyl acetates (E11 and Z11), and distinct genetic variation is found in the blend of components. This variation is largely controlled by a single autosomal locus with two alleles, $A^{E(sca)}$ and $A^{Z(sca)}$. E-type ($A^{E(sca)}A^{E(sca)}$) females produce a pheromone with a mean E11:Z11 ratio of 99:1, whereas Z-type ($A^{Z(sca)}A^{Z(sca)}$) and I-type ($A^{E(sca)}A^{Z(sca)}$) females produce a pheromone with a mean of 3:97 and 64:36, respectively. *O. zealis* is distinctive in that it has a third pheromone component, (*Z*)-9-tetradecenyl acetate (Z9), in addition to E11 and Z11, and the typical blend ratio is 60:35:5 (Z9:E11:Z11). Our study revealed that Z9 production in *O. zealis* is mainly regulated by an autosomal recessive gene $phr^{(zea)}$, which is suggested to be involved in the chain-shortening of a pheromone precursor fatty acid, and linked to $A^{E(zea)}$, a gene corresponding to $A^{E(sca)}$ in *O. scapulalis*. A few mutations in a gene involved in pheromone production could explain the dramatic shift between a two-component pheromone communication system in *O. scapulalis* and a three-component system in *O. zealis*.

Key Words—Genetics, sex pheromone, reproductive isolation, *Ostrinia scapulalis*, *Ostrinia zealis*, *Ostrinia nubilalis*, communication divergence.

INTRODUCTION

The evolution of animal communication systems is one of the most intriguing themes in the field of evolutionary biology. Communication between individuals is established only when signals from the senders are recognizable by the receivers. Therefore, evolution in the communication traits of senders and receivers must be coordinated (Butlin and Ritchie, 1989). The communication system for mate recognition is a key to premating isolation, and can be an important factor at the beginning of species divergence. Hence, studies on the genetic basis of such communication systems would give novel insights into the mechanism of divergence in communication traits and subsequent species divergence (Monti et al., 1997).

In many moths, mate-finding communication is mediated by sex pheromones produced by females (Cardé and Baker, 1984). The pheromone components and their blend ratios are species-specific, and male response is tuned to the blend of conspecific females (Phelan, 1997). Nevertheless, hybridization between some closely related species does occur under natural or laboratory conditions (for example, Hendrikse, 1988; Foster et al., 1997; Gadenne et al., 1997; Monti et al., 1997). An examination of the sex pheromones produced by hybrid offspring should furnish important information on the divergence of pheromone communication systems.

In the present study, we dealt with two closely related *Ostrinia* species, the adzuki bean borer moth *Ostrinia scapulalis* (Walker), and the burdock borer moth *O. zealis* (Guenée) (Lepidoptera: Crambidae). *O. scapulalis* is found in central Russia, northern India, and eastern Asia, while *O. zealis* is found in eastern Asia, through Japan and China to northern India (Mutuura and Munroe, 1970; Frolov, 1998). *O. scapulalis* is polyphagous and a pest of adzuki bean *Phaseolus angularis* (Leguminosae), and hop *Humulus lupulus* (Moraceae). In contrast, *O. zealis* is oligophagous, specializing in a few Compositae plants such as thistles *Cirsium* spp. and burdock *Arctium lappa* (Ishikawa et al., 1999a). Despite these clear differences in host plant preference, these two species occur sympatrically in several localities in Japan. The sex pheromones, therefore, should play a critical role in premating reproductive isolation.

The sex pheromone of *O. scapulalis* is a mixture of (*E*)-11- and (*Z*)-11-tetradecenyl acetates (E11 and Z11), and three phenotypes have been identified in this species, i.e., E type (96–100% of E11; mean in a typical laboratory culture, 99%), I type (33–95%; mean 64%), and Z type (0–31%; mean 3%) (Huang et al., 1997, 2002; Tabata et al., 2003; Takanashi et al., 2005). These three types are mainly determined by one autosomal locus with two alleles, $A^{E(sca)}$ and $A^{Z(sca)}$: E-type, Z-type, and I-type females have the genotype $A^{E(sca)}A^{E(sca)}$, $A^{Z(sca)}A^{Z(sca)}$, and $A^{E(sca)}A^{Z(sca)}$, respectively (Takanashi et al., 2005).

The sex pheromone of *O. zealis*, on the other hand, is characterized by the presence of a third component, (*Z*)-9-tetradecenyl acetate (Z9), in addition to E11 and Z11 (Ishikawa et al., 1999b). The typical blend ratio is 65:30:5 (Z9:E11:Z11), and no large blend variation has been found to date.

We conducted laboratory crossing experiments using these two *Ostrinia* species, and investigated the female sex pheromone composition in hybrid F1 individuals and F2 or backcrossed progeny. Based on the findings, we discuss the genetic basis of pheromone communication systems in *Ostrinia*, and argue that a few mutations in a gene involved in pheromone production can explain the dramatic shift between a two-component pheromone communication system in *O. scapulalis* and a three-component system in *O. zealis*.

METHODS AND MATERIALS

Insects. Diapausing *O. zealis* larvae were collected from thistles (*Cirsium* sp.) at Irago Promontory (34°34′N, 137°01′E), Aichi Prefecture, Japan on October 24, 2001. To terminate diapause, the larvae were maintained at about 5°C and in darkness for more than 3 mo. These larvae were moved to a rearing room (60% relative humidity; 16 hr light–8 hr dark; 23°C) to facilitate post-diapause development. One to three d after emergence, moths were transferred to a screen cage (20 × 20 × 20 cm) with water-soaked cotton and allowed to mate over a period of 3 d. Mated females were individually housed in 90-ml clear plastic cups with a cotton pad soaked with water, and allowed to lay eggs on the surface of the cups. *O. scapulalis* female moths were collected in Iruma city (35°50′N, 139°23′E), Saitama Prefecture, Japan, on September 8–15, 2001. The field-collected female moths, usually mated, were housed in 90-ml plastic cups individually and allowed to lay eggs. A group of eggs from each female, which we call a "family" in the present article, was reared on an artificial diet (Silk mate™; Nosan Corp., Yokohama, Japan) in a plastic bottle (8 cm diam, 12 cm height), and maintained in the rearing room described above. After pupation, the pupae were sexed, and females and males were separately maintained in 430-ml clear plastic cups.

Crossing Experiments for Genetic Analysis of Pheromone Production. *O. scapulalis* cultures homogeneous in terms of E- and Z-type pheromone production were established from wild populations as follows. The pheromone types of at least 10 female samples per family were determined by gas chromatography as described below, and monomorphic (E or Z type) families were selected. The E or Z cultures of *O. scapulalis* were considered to be established when a monomorphic state continued for three successive generations. Crossing experiments for the analysis of pheromone production were

conducted using the *O. scapulalis* E culture (Sca^E) and Z culture (Sca^Z), and *O. zealis* (Zea). Ten pairs of 1- to 3-d-old moths were housed in a screen cage (20 × 20 × 20 cm) for 3 d with water-soaked cotton. The following crosses (female × male) were carried out: Zea × Sca^E and Zea × Sca^Z to yield F1 hybrids (F1 hybrids are expressed as $ZeaSca^E$ and $ZeaSca^Z$, respectively), $ZeaSca^E$ × $ZeaSca^E$ and $ZeaSca^Z$ × $ZeaSca^Z$ to yield F2 progeny, and eight backcrosses (Zea × $ZeaSca^E$, $ZeaSca^E$ × Zea, $ZeaSca^E$ × Sca^E, Sca^E × $ZeaSca^E$, Zea × $ZeaSca^Z$, $ZeaSca^Z$ × Zea, $ZeaSca^Z$ × Sca^Z, and Sca^Z × $ZeaSca^Z$). In a reciprocal cross for F1 hybrids (Sca^Z × Zea), no fertile mated females could be obtained from more than 50 pairs of Sca^Z × Zea, and we abandoned crossing in this direction.

Sex Pheromone Analysis. The abdominal tip, which includes a sex pheromone gland, was excised from 2- or 3-d-old virgin females during the last 3 hr of scotophase, and tips were immersed individually in hexane (10 μl/female; residual pesticide analysis grade, Wako Pure Chemicals, Kyoto) containing 20 ng of tridecyl acetate (Sigma, St. Louis, MO, USA) as an internal standard. The tip was removed after 30 min, and the extract was kept at −20°C prior to analysis. A gas chromatograph GC-14B (Shimadzu, Kyoto, Japan) equipped with a flame ionization detector, a split/splitless injector, an automatic injector (AOC-20, Shimadzu), and a DB-Wax column (30 m × 0.25 mm i.d.; J & W Scientific, CA) was used for the analysis of extracts. Nitrogen was used as the carrier gas. The injector and detector temperatures were 230 and 270°C, respectively. The column oven temperature was maintained at 120°C for 2 min, then raised to 150°C at a rate of 5°C/min, to 200°C at 3°C/min, and finally to 240°C at 5°C/min. Aliquots (2 μl) of samples were injected into the GC with a splitless time of 1.5 min. The pheromone components were quantified by comparing their GC peak area with that of the internal standard. The authentic Z9, E11, and Z11 were purchased from Pherobank (Wageningen, The Netherlands).

RESULTS

Sex Pheromone Blend Ratios Produced by the F1 Hybrid Females. Sex pheromone compositions of Sca^E, Sca^Z, Zea, and their F1 hybrids ($ZeaSca^E$ and $ZeaSca^Z$) were analyzed based on the proportions of Z9 and E11 in the total (Z9 + E11 + Z11) (Figure 1a and b). Sca^E and Sca^Z produced no Z9, as expected. All of the Sca^E females ($N = 25$) produced only E11, and no Z11 was detected. Sca^Z females ($N = 47$) produced a pheromone with 0–10% E11. Zea females ($N = 36$) produced three components in their pheromone: % Z9 ranged from 50 to 75, and % E11 from 20 to 40 (Figure 1a). It is readily noticeable that proportions of Z9 and E11 are negatively correlated in Zea ($r = -0.99$). In other

words, the proportion of the minor component Z11 was almost fixed (5.97 ± 0.80; mean % ± SD). F1 hybrids ($ZeaSca^E$ and $ZeaSca^Z$; Figure 1b) did not produce Z9 except for two samples, both of which belonged to $ZeaSca^Z$, and the proportion of Z9 was low (<8%). $ZeaSca^E$ produced an E11-dominant blend (>85%), i.e., an Sca^E-like pheromone blend, whereas $ZeaSca^Z$ produced both E11 and Z11, like *O. scapulalis* I-type (Sca^I).

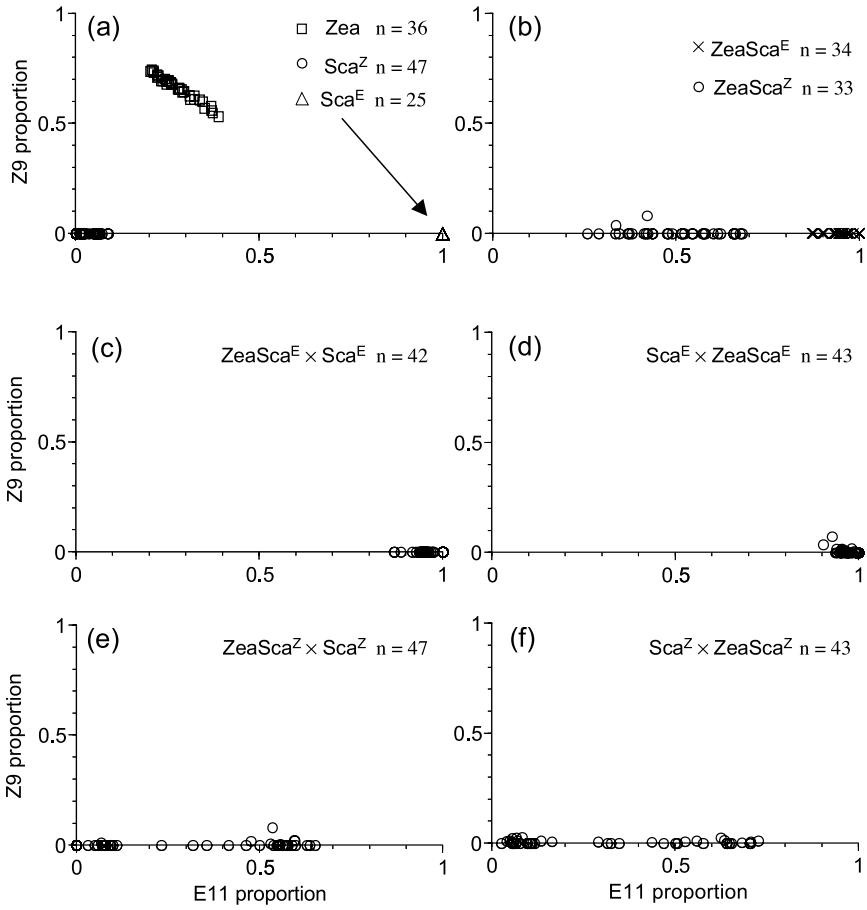

FIG. 1. Distributions of sex pheromone blends in the female progeny of *O. zealis*, E-type *O. scapulalis*, and Z-type *O. scapulalis* (a), their F1 hybrids (b), backcrosses (c–j), and F2 hybrids (k–l). Z: *O. zealis*, SE: E-type *O. scapulalis*, SZ: Z-type *O. scapulalis*. E11: (*E*)-11-tetradecenyl acetate, Z11: (*Z*)-11-tetradecenyl acetate, Z9: (*Z*)-9-tetradecenyl acetate. Abscissa: E11 / (Z9 + E11 + Z11), Ordinate: Z9 / (Z9 + E11 + Z11).

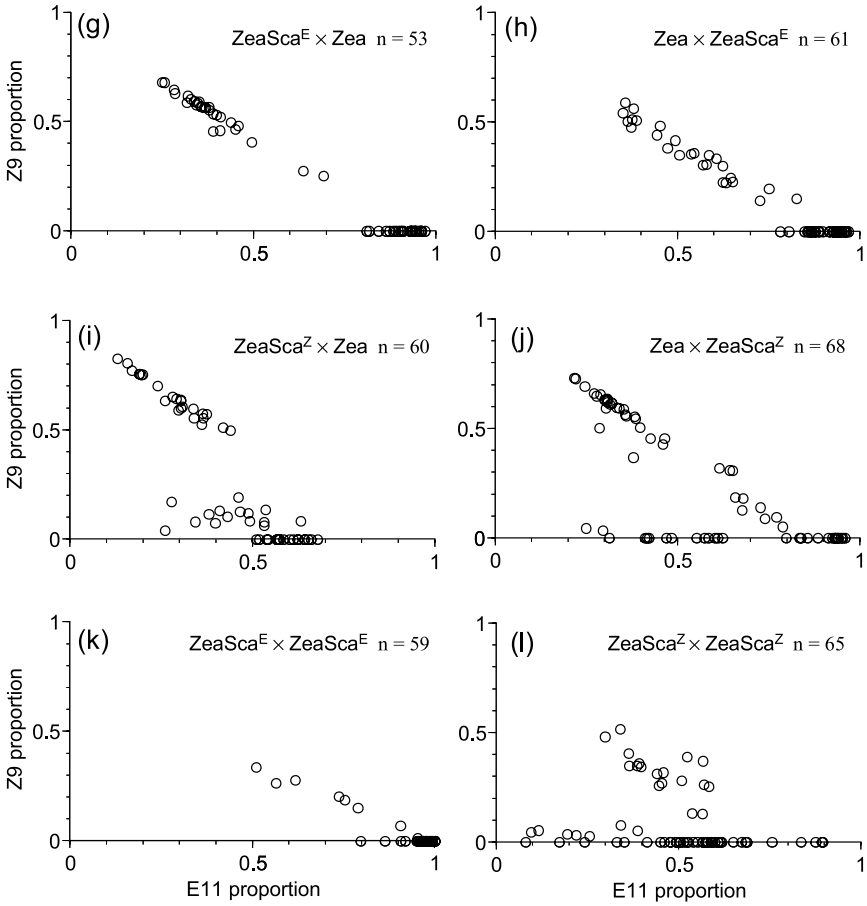

FIG. 1. CONTINUED.

Sex Pheromone Blend Produced by the Backcross and F2 Progeny. The sex pheromone blends of the progeny backcrossed to Sca^{E}, Sca^{Z}, and Zea are shown in Figure 1c–j. The backcrosses to *O. scapulalis* (Sca^{E} and Sca^{Z}), ZeaSca^{E} × Sca^{E}, Sca^{E} × ZeaSca^{E}, ZeaSca^{Z} × Sca^{Z}, and Sca^{Z} × ZeaSca^{Z} yielded five, four, five, and four families, and 42, 43, 48, and 43 female samples, respectively (Figure 1c, d, e, f). Almost all of them produced a two-component pheromone without Z9. The distributions of pheromone blend ratios were unimodal around the Sca^{E}-like blend in the backcross to Sca^{E} (Figure 1c, d), whereas they were bimodal around the Sca^{Z}-like and Sca^{I}-like blends in the backcross to Sca^{Z} (Figure 1e, f). The distributions of E11 proportion in

reciprocal crosses were not significantly different in the Sca^E and Sca^Z directions ($P = 0.31$ and 0.33, respectively; Wilcoxon test).

Two- and three-component-type pheromones were observed in the backcrosses to *O. zealis* (Zea). In the crosses of $ZeaSca^E$ to Zea ($ZeaSca^E \times$ Zea and Zea $\times$ $ZeaSca^E$; total $N = 53$ from two families and $N = 61$ from four families, respectively; Figure 1g, h), the two-component type progeny showed a Sca^E-like pheromone blend (without Z9) in both reciprocal crosses ($N = 25$ in $ZeaSca^E \times$ Zea, and $N = 35$ in Zea $\times$ $ZeaSca^E$), whereas three-component type progeny ($N = 28$ in $ZeaSca^E \times$ Zea, and $N = 26$ in Zea $\times$ $ZeaSca^E$) showed some differences in the proportion of Z9 between the reciprocal crosses ($P < 0.01$; Wilcoxon test). In Zea $\times$ $ZeaSca^E$, the distribution of Z9 proportion was relatively broad (14–59%) in the three-component type progeny, but narrow (41–68%, with two outliers, 21% and 27%) and mostly Zea-like in the reciprocal cross, $ZeaSca^E \times$ Zea. The ratios of Z9 and E11 were negatively correlated in the sex pheromone of the three-component type progeny (Figure 1g, h), as observed in their parent, Zea.

More complex patterns were observed in the backcrosses of $ZeaSca^Z$ to Zea ($ZeaSca^Z \times$ Zea and Zea $\times$ $ZeaSca^Z$; $N = 60$ from two families and $N = 68$ from five families, respectively) (Figure 1i, j). In the cross Zea $\times$ $ZeaSca^Z$, four patterns were clearly distinguishable, i.e., a three-component type high in Z9 (Zea-like type; $N = 29$), a three-component type low in Z9 and high in E11 ($N = 10$), a two-component type with an intermediate proportion of E11 (Sca^I-like type; $N = 14$), and a two-component type high in E11 (Sca^E-like type; $N = 15$). In the reciprocal cross $ZeaSca^Z \times$ Zea, in contrast, only three patterns were observed, i.e., the Zea-like type ($N = 24$), the Sca^I-like type ($N = 21$), and the three-component type low in Z9 and with an intermediate proportion of E11 ($N = 15$). No Sca^E-like type was observed.

In F2 hybrids from the cross of $ZeaSca^E \times$ $ZeaSca^E$ ($N = 58$ from three families), the three-component type had relatively low Z9 (10–37%; $N = 8$), and the two-component type showed a Sca^E-like blend (80–95% E11; $N = 50$) (Figure 1k). On the other hand, the pheromone blend of F2 hybrids from the cross of $ZeaSca^Z \times$ $ZeaSca^Z$ ($N = 65$ from four families) distributed in a scattered manner (Figure 1l). The three-component type could be further divided into a low Z9 type (3–8% Z9; $N = 7$) and an intermediate Z9 type ($N = 18$). The two-component type appeared to be a mixture of Sca^E, Sca^I, and Sca^Z-like blends (8–89% E11; $N = 40$).

DISCUSSION

Genetic Basis of Variations in Pheromone Composition in O. scapulalis and O. zealis. All hybrid F1 females except a few in $ZeaSca^Z$ produced sex

pheromones lacking Z9. This finding indicates the existence of chromosomal recessive genetic factor(s) for the production of the third component, Z9, in *O. zealis*. The involvement of cytoplasmic factors can be excluded, because hybrids did not produce Z9 despite the fact that all the F1 hybrids examined had the cytoplasm of maternal Zea (*O. zealis*), which produces Z9. Moreover, ZeaSca^{E} females produced Sca^{E}-like, and ZeaSca^{Z} females produced Sca^{I}-like pheromone. This suggests that *O. zealis* should have a gene ($A^{E(zea)}$) corresponding to $A^{E(sca)}$ in *O. scapulalis*. The backcross data for Sca^{E} and Sca^{Z} (*O. scapulalis*) support this idea; distributions of the pheromone blend ratios in ZeaSca^{E} × Sca^{E} and Sca^{E} × ZeaSca^{E} are unimodal and Sca^{E}-like, whereas those in ZeaSca^{Z} × Sca^{Z} and Sca^{Z} × ZeaSca^{Z} are bimodal and involve Sca^{Z}- and Sca^{I}-like blends.

The existence of major recessive genes that control production of Z9 is further supported by the finding that the frequencies of two patterns (three-component type and two-component type) were about 1:1 in both reciprocal backcrosses of ZeaSca^{E} to Zea (28:25, in ZeaSca^{E} × Zea; 26:35 in Zea × ZeaSca^{E}; $\chi^2 = 0.08$, $df = 1$ and $\chi^2 = 1.05$, $df = 1$, respectively; chi-square test). It was also demonstrated that these major genes are not linked to the sex chromosome (Z chromosome); the Z chromosomes of the female progeny of these backcrosses differ between the reciprocal crosses (derived from Zea in ZeaSca^{E} × Zea, and from Sca^{E} in Zea × ZeaSca^{E}) because females are heterogametic (ZW) in Lepidoptera. In addition to the major genes, the presence of genetic modifiers for Z9 production was suggested by the difference in distributions of Z9 proportions between the three-component-type females of ZeaSca^{E} × Zea and those of Zea × ZeaSca^{E}. Some of these genetic modifiers appear to exist on the Z chromosome; females of ZeaSca^{E} × Zea, which produced a pheromone high in Z9, have the Z chromosome from Zea, whereas those of Zea × ZeaSca^{E}, which produced a pheromone low in Z9, have that from Sca^{E}.

Significant differences were observed between the reciprocal crosses of the ZeaSca^{Z} hybrid to Zea. The most remarkable difference is the occurrence of the Sca^{E}-like blend (two-component and high E11 ratio) in only one direction of the crosses; 15 samples were Sca^{E}-like in cross Zea × ZeaSca^{Z} ($N = 68$), whereas none was observed in the reciprocal, ZeaSca^{Z} × Zea ($N = 60$). This finding can be explained if the major gene producing Z9, which was shown to be recessive (designated as $phr^{(zea)}$, $PHR^{(sca)}$ being the allele), and the genes regulating the E11 and Z11 ratios in *O. scapulalis* ($A^{E(sca)}$ and $A^{Z(sca)}$) and in *O. zealis* ($A^{E(zea)}$) are on a homologous chromosome (Table 1). When we consider the recombination that specifically occurs in males in Lepidopteran species (Tazima, 1964), the occurrence of two phenotypes (Zea-like and Sca^{I}-like) out of three in ZeaSca^{Z} × Zea, and four phenotypes (Zea-like, Sca^{I}-like, and Sca^{E}-like, and a three-component type with an intermediate E11/Z11) in Zea × ZeaSca^{Z} could be explained based on this hypothesis (Table 1).

TABLE 1. AN EXPLANATION OF THE GENETICS OF FEMALE SEX PHEROMONE PRODUCTION IN THE HYBRIDS OF *Ostrinia zealis* AND *O. scapulalis*

Cross[a]	Phenotype		Number of progenies		Inferred genotype
	Components	Blend type	Observed	Expected[b]	
Zea	3	Zea	36	36	$phr^{(zea)}A^{E(zea)}/phr^{(zea)}A^{E(zea)}$
Sca^E	2	Sca^E	25	25	$PHR^{(sca)}A^{E(sca)}/PHR^{(sca)}A^{E(sca)}$
Sca^Z	2	Sca^Z	47	47	$PHR^{(sca)}A^{Z(sca)}/PHR^{(sca)}A^{Z(sca)}$
Zea × Sca^E	2	Sca^E-like	34	34	$phr^{(zea)}A^{E(zea)}/PHR^{(sca)}A^{E(sca)}$
Zea × Sca^Z	2	Sca^I-like	33	33	$phr^{(zea)}A^{E(zea)}/PHR^{(sca)}A^{Z(sca)}$
$ZeaSca^E$ × Zea	3	Zea-like	28	26.5	$phr^{(zea)}A^{E(zea)}/phr^{(zea)}A^{E(zea)}$
	2	Sca^E-like	25	26.5	$PHR^{(sca)}A^{E(sca)}/phr^{(zea)}A^{E(zea)}$
Zea × $ZeaSca^E$	3	Zea-like	26	30.5	$phr^{(zea)}A^{E(zea)}/phr^{(zea)}A^{E(zea)}$ $phr^{(zea)}A^{E(zea)}/phr^{(zea)}A^{E(sca)}$ [c]
	2	Sca^E-like	35	30.5	$phr^{(zea)}A^{E(zea)}/PHR^{(sca)}A^{E(sca)}$ $phr^{(zea)}A^{E(zea)}/PHR^{(sca)}A^{E(zea)}$ [c]

[a] Zea, Sca^E, and Sca^Z represent *O. zealis*, E-type *O. scapulalis*, and Z-type *O. scapulalis*, respectively. For further details, see text.

[b] The number of phenotypes was expected from our single-major-gene ($phr^{(zea)}/PHR^{(sca)}$) model for Z9 production.

[c] Recombination of chromosomes occurs only in males in *Lepidopteran* species (Tazima, 1964).

In summary, the present study suggests that the production of Z9, the major pheromone component of *O. zealis*, is regulated by a recessive autosomal gene $phr^{(zea)}$and additional genetic modifiers. The $phr^{(zea)}$ gene is suggested to be linked to $A^{E(zea)}$, a gene on the same locus as $A^{E(sca)}$ (or $A^{Z(sca)}$), which controls the blend ratio of E11 and Z11 in *O. scapulalis*.

Biosynthesis of Sex Pheromones in O. scapulalis and O. zealis. Moth sex pheromones are biosynthesized through a relatively simple cascade. Typically, C_{18} or C_{16} saturated fatty acids derived from the fatty acid synthesis cycle are modified by chain-shortening, desaturation, and reduction, and the resultant unsaturated fatty alcohols are further modified to acetate or aldehyde (for review, see Tillman et al., 1999). The pheromones, therefore, are likely to be relatively easily changed by a few mutations in genes coding the enzymes involved in pheromone biosynthesis (Roelofs and Rooney, 2003).

Although few studies have been carried out on pheromone biosynthetic pathways in *O. scapulalis* and *O. zealis*, both the genetics and biosynthesis of

sex pheromone are well understood in a congener, *O. nubilalis*, which is phylogenetically very close to *O. scapulalis* (Kim et al., 1999) and shows pheromone polymorphism (E- and Z-races) similar to *O. scapulalis* in terms of both pheromone components and their blend ratios (Roelofs et al., 1987, 2002; Zhu et al., 1996b). In *O. nubilalis*, two alleles at an autosomal locus, $A^{E(nub)}$ and $A^{Z(nub)}$, are concerned with the regulation of pheromone blend (Roelofs et al., 1987). Zhu et al. (1996b) showed that the large difference in pheromone blend is attributable to the fatty acyl reduction step in the biosynthetic pathway (cf. Figure 2), and suggested that $A^{E(nub)}$ and $A^{Z(nub)}$ are involved in the control of the stereospecificity of fatty acyl reductase. $A^{E(sca)}$ and $A^{Z(sca)}$ in *O. scapulalis* and $A^{E(zea)}$ in *O. zealis* are inferred to be also involved in the control of the specificity of reductase (Figure 2).

In *O. nubilalis*, Z11-14:Acyl and E11-14:Acyl, but not Z9-14:Acyl, are found in the pheromone gland, being consistent with production of Z11 and E11, and nonproduction of Z9. Here, a curious finding was the accumulation of a large amount of apparently unused Z11-16:Acyl in the gland (Linn and Roelofs, 1995; Ma and Roelofs, 2002). Recently, a functional assay of the Δ11-desaturase gene of *O. nubilalis*, *Onu-Z/E11*, using a yeast pYES2 expression system, showed that the desaturase enzyme produces mainly Z11-16:Acyl, along with a mixture of Z11- and E11-14:Acyls (Roelofs et al., 2002). Thus, it appears that in the pheromone gland of *O. nubilalis*, Z11-16:Acyl is produced as a major "byproduct" of Δ11-desaturase (cf. Figure 2). In the present study, production of Z9 in *O. zealis* was suggested to be controlled by a recessive gene, $phr^{(zea)}$. Control of Z9 production by $phr^{(zea)}$ and its allele $PHR^{(sca)}$ can be explained if we assume that this locus is involved in the blockage of chain-shortening reaction of Z11-16:Acyl to Z9-14:Acyl (Figure 2). In *Ostrinia* with a three-component pheromone (*O. zealis*, which carries $phr^{(zea)}$), the chain-shortening reaction is actively occurring, while in species with a two-component pheromone (*O. scapulalis* and *O. nubilalis*, which carry $PHR^{(sca)}$ or its equivalent), Z9-14:Acyl, and hence Z9, is not produced due to blockage of this reaction. Chain-shortening steps in the biosynthetic pathway were demonstrated to be affected in a pheromone mutant strain of *Trichoplusia ni* (Jurenka et al., 1994), and can be important in causing divergence in the pheromone composition.

Divergence of Sex Pheromone Communication Systems in O. scapulalis and O. zealis. For the divergence of communication systems to occur in a species, the signal senders and receivers have to coevolve in the same direction. This is a difficult process because the signal senders' traits and receivers' traits are rarely genetically coupled (Boake, 1991). Sexual communication systems are under strong stabilizing selection (Butlin and Trickett, 1997); individuals who send an outlying signal will be selected away rapidly because no conspecific receivers can recognize it and they fail to mate and reproduce. In

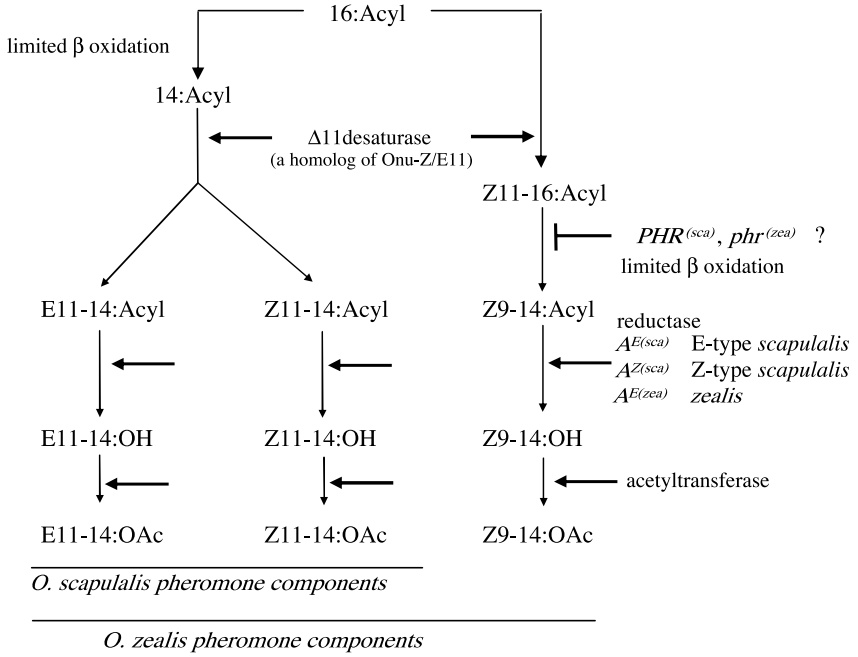

FIG. 2. Biosynthetic pathway and enzymes (genes) involved in the production of pheromone components in *O. scapulalis* and *O. zealis* inferred from the findings of the present study and information available on pheromone biosynthesis in a congener *O. nubilalis* (Roelofs et al., 1987, 2002; Linn and Roelofs, 1995; Zhu et al., 1996b; Roelofs and Rooney, 2003). The symbol resembling a rotated "T" indicates inhibition. The chemical formulae are symbolized as follows: Z = (*Z*)-configuration, E = (*E*)-configuration, the number following Z or E = the position of the double bond, the number before the colon = carbon chain length, Acyl = carboxyl, OH = alcohol, OAc = acetate of alcohol.

this regard, *O. nubilalis*, which shows a distinct sex pheromone variation within a species, has been a good model for studying the evolution of pheromone communication systems (Zhu et al., 1996a; Butlin and Trickett, 1997; Roelofs et al., 2002). Based on detailed genetic analyses of pheromone production in *O. nubilalis*, Zhu et al. (1996a) found that a part of the variations in the pheromone production are hidden due to canalization, and they suggested that these hidden variations played an important role in the divergence of a pheromone communication system.

In the present study, a recessive genetic factor ($phr^{(zea)}$) that alters the signal, sex pheromone composition, was discovered. Recessive gene mutations on signal traits may be able to alleviate selection pressures at a low frequency, because the mutated gene will remain mostly cryptic (Falconer, 1989). If a new

signal trait can be sustained in a population for an extended period, albeit at a low frequency, there would be a chance for this trait to be tracked by receivers with variant preference. Therefore, $phr^{(zea)}$ may explain the divergence of the sex pheromone communication system between *O. scapulalis* and *O. zealis*, i.e., a two-component system (E11 and Z11) and a three-component system (Z9, E11, and Z11). Regarding the male response, our preliminary study showed that variations in male response behaviors in hybrids between Sca^{E} and Zea and their backcrossed progenies could be largely explained by an autosomal locus that determines preference for, or rejection of, Z9 (J. Tabata, unpublished data). Further studies on the genetics of male responses are necessary to clarify the mechanism underlying the divergence of pheromone communication systems in *Ostrinia*.

Despite intensive phylogenetic analyses based on mitochondrial gene sequences, the phylogeny of *Ostrinia* species is not completely determined (Kim et al., 1999; S. Hoshizaki et al., unpublished data). At present, therefore, we cannot conclude the direction of the change, namely, which of the two systems (two-component or three-component) is more ancestral. The genus *Ostrinia* comprises 21 species worldwide (Mutuura and Munroe, 1970; Ohno, 2003). Studies on the sex pheromones of seven species inhabiting Japan have shown that the number of pheromone components alone varies from one to three (Fu et al., 2004). More extensive studies on the sex pheromones of *Ostrinia*, along with studies on the phylogeny of this genus, are needed to clarify the evolution of sex pheromone communication systems in *Ostrinia*.

Acknowledgments—We thank Drs. S. Tatsuki and S. Hoshizaki for advice. Insect samples from Dr. S. Ohno (*O. zealis* larvae on thistles) are acknowledged.

(Received November 5, 2004; accepted January 5, 2005)

Abstract—Stir bar sorptive extraction method was used for investigation of the urinary volatile profiles in male and female *Phodopus campbelli* and *Phodopus sungorus* hamsters. Additionally, female *Phodopus roborowsky* urinary profiles were characterized. A quantitative analytical approach allowed comparisons of 17 selected compounds in urine. Results showed that *campbelli* and *sungorus* species show similar urinary volatile profiles for males and females. Differences appeared only in concentrations. Several unique compounds, such as pyrazine derivatives, were found to be gender- and age-specific. *P. roborowsky* females exhibited a completely different urinary volatile profile from *campbelli* and *sungorus* females, featuring a unique set of substituted quinoxalines.

Key Words—Pheromone candidates, hamster urine, urinary volatiles, *Phodopus campbelli*, *Phodopus sungorus*, *Phodopus roborowsky*, stir bar, sorptive extraction, gas chromatography–mass spectrometry.

INTRODUCTION

Urinary scent marking is an important means of chemical communication in mammals. Examples include rodents (Ralls, 1971; Novotny et al., 1990), canids (Jorgenson et al., 1978; Raymer et al., 1984), and red deer (*Cervus elaphus*) (Bakke and Figenschou, 1990), among others. Urinary scent marks may convey multiple messages, ranging from the species chemosignals and individual-recognition compound patterns to aggression and dominance signaling to various primer pheromone activities. Chemical identification of various scent constituents has become essential in elucidating the physiological and behavioral responses pertaining to olfaction. Such activities have thus far been most successful with investigations in the house mouse (*Mus domesticus*) where distinct chemical compounds have been linked to endocrinology and behavior (for review, see Schwende et al., 1986; Novotny et al., 1990), whereas their direct action on the vomeronasal neurons has also been verified (Leinders-Zufall et al., 2000; Sam et al., 2001).

Hamsters have been yet another frequently studied rodent in terms of olfaction. Here most studies have centered on investigations of flank gland markings (in both genders) and female vaginal secretions. Gland marking behavior of the Syrian golden hamster (*Mesocricetus auratus*) has been well established (Johnston, 1975, 1985), whereas the dense and viscous urine of this desert animal is generally viewed as less important in terms of chemical communication. Vaginal secretions of the Syrian golden hamster are also involved in a distinct communication function (Johnston, 1974; Singer et al., 1976) containing aphrodisin (a protein of the lipocalin family). However, it is improbable that aphrodisin serves a direct pheromonal function (Singer et al., 1987; Singer and Macrides, 1990; Vincent et al., 2001); it is more likely that it functions as a pheromone carrier (Briand et al., 2000).

Among the additional members of the hamster family, such as *Phodopus sungorus* (*P. sungorus*), *P. campbelli*, and *P. roborowsky*, fewer studies have accumulated to date. Secretions of the ventral gland and supplementary sacculi have recently been characterized chemically (Burger et al., 2001a,b). Additional glands and secretions may also be used in chemical communication. Unlike with the Syrian hamster, the *Phodopus* hamsters seem to involve urine odors (Lai et al., 1996). In a recent study of the effects of cross-fostering between *P. campbelli* and *P. sungorus* (Vasilieva et al., 2001), the young hamster appeared to learn quickly the olfactory cues from family members. Whereas we do not know currently the origin of the scent cues used in the adaptation process, the urinary odor (if composed of chemically distinct molecules) would be suggested. Earlier studies (Laska and Hudson, 1995) demonstrated that—at least in the squirrel monkey (*Saimiri sciureus*)—urine contains a considerable amount of information of a potential signal value. Consequently, the purpose of this study

was to characterize the volatile urinary constituents of *P. campbelli* and *P. sungorus* with respect to gender and age. In addition, due to the availability of a few *P. roborowsky* urinary samples, a comparison was also made with this species.

Whereas species and individual recognition may involve quantitative arrays of different chemosignals, it was deemed necessary to employ a highly quantitative technique for the extractions of urinary organic constituents. Based on the previously described stir bar extraction procedure for aqueous media (Baltussen et al., 1999, 2002), we have recently adapted this methodology to quantitative profiling of volatile and semivolatile compounds in biological media (Soini et al., 2005). Its excellent reproducibility has permitted reliable determinations of differences in volatile urinary profiles of different hamster species in this study. Numerous chemically distinct profile constituents were subsequently identified through a combined capillary gas chromatography–mass spectrometry and quantified with an element-specific detector.

METHODS AND MATERIALS

Animals and Age Groups. All three species of the genus *Phodopus* (*P. campbelli*, *P. roborowsky*, and *P. sungorus*) were available; gender, ages, and number of animals are listed in Table 1. Animals were born and raised in captivity and kept in indoor rooms in solid-bottom, polycarbonate cages (30 × 15 × 15 cm) with wood-chip bedding material. For all animals, the bedding material was identical (autoclaved, natural wood chips from pinewood). Bedding material was not subjected to chemical analyses. Since *Phodopus* hamsters are social

TABLE 1. CODES AND AGES FOR THE *Phodopus* HAMSTER GROUPS

Species	Subject groups	Age (months)	Number of animals
Phodopus campbelli female	cf4	4	3
	cf9	9	7
P. campbelli male	cm4	4	4
	cm9	9	3
	cm14	14	3
Phodopus sungorus female	sf1	1	3
	sf10–11	10–11	7
P. sungorus male	sm1	1	4
	sm10–11	10–11	5
	sm14	14	1
Phodopus roborowsky female	rf12	12	4

animals, they were kept in groups (three to five animals) of the same sex or in family units (a pair and its litter) for several weeks. The colony was maintained on a 14-hr light/10-hr dark light cycle with lights off at 10:00 hr; temperature was 21 ± 1°C. All animals had free access to hamster chew and water. Sunflower seeds, fruits, and lettuce were occasionally provided as a dietary supplement.

In *P. campbelli* and *P. sungorus*, the males and females represented different age groups. In *Phodopus* species, sexual maturation is reached between postnatal days 30 and 45. During the first 4 mo of life, animals may be regarded as young adults; animals between 9 and 14 mo-old are in their prime. Life span lasts for up to 2 yr.

Sample Collection. Urine was collected from all three hamster species (University of Tübingen, Germany). To collect urine, animals were removed from colonies and kept individually in small metabolic cages until they produced about 1 ml of urine, or up to 4 hr. If an animal did not produce enough urine in one sampling session, the procedure was repeated the following day. Estrous female hamsters were not subjected to urine collection (estrous state was checked regularly). Samples were kept frozen until analyzed.

Sample Preparation. All glassware was washed with distilled water and acetone and dried at 80°C in the oven. Volatile and semivolatile compounds were extracted from 1.0 ml of undiluted urine by sorptive extraction with a Twister PDMS polymer-coated stir bar (10 mm, 0.5-mm film thickness, 24 µl PDMS volume, Gerstel GmbH, Mülheim an der Ruhr, Germany) for 60 min. Stirring speed was 800+ rpm on the Variomag Multipoint HP 15 stirplate (H+P Labortechnic, Oberschleissheim, Germany). After 60-min extraction time, a stir bar was rinsed with a small amount of distilled water, dried gently on the paper tissue, and was placed in the glass injector liner for mass spectrometry (MS) identification or in the TDSA autosampler tube for a gas-chromatographic (GC) quantification.

Mass Spectrometry. A Finnigan MAT Magnum ion trap gas chromatograph–mass spectrometer (GC-MS) system was used for the compound identification (Finnigan MAT, San Jose, CA, USA). The system was provided with a DB-5 capillary column (30 m × 0.25 mm, i.d., 0.25-µm film thickness, J&W Scientific, Folsom, CA, USA). Helium carrier gas head pressure was 12 psi. At the beginning of the column, a loop of uncoated deactivated silica tubing (30 cm × 0.25 mm, i.d.) was attached by using a universal Press-Tight Connector (Restek Corporation, Bellefonte, PA, USA) as described earlier (Ma et al., 1999). The loop was cooled with liquid nitrogen, while the Twister stir bar was held in the injector liner for 15 min at 250°C for the thermal desorption of the analytes. Subsequently, the desorbed compounds were cryotrapped into the liquid nitrogen cooled loop. After removing liquid nitrogen cooling, the GC temperature was held at 40°C for 5 min and increased to 200°C at the rate of 2°C/min. The final temperature was held for 10 min. The manifold and transfer line temperatures were 220 and

300°C, respectively. The ion trap was operating in the positive electron ionization mode. Spectra were scanned from 40 to 350 msu (1 scan/sec).

Gas Chromatography. Gas-chromatographic (GC) equipment for the quantitative analysis consisted of an Agilent GC Model 6890 with an Atomic Emission Detector (AED) Model G2350A (Agilent Technologies Inc., Wilmington, DE, USA) and a Thermal Desorption Autosampler (TDSA, Gerstel GmbH). The separation capillary was DB-5 (30 m × 0.25 mm, i.d., 0.25-μm film thickness from J&W Scientific Folsom, CA, USA). Samples were thermally desorbed in a TDSA automated system, followed by injection into the column with a cooled injection system CIS-4. TDSA operated in a splitless mode. Temperature program for desorption was 20°C (0.5 min), then 60°C/min to 280°C (10 min). Temperature of the transfer line was set at 280°C. CIS was cooled with liquid nitrogen to −60°C. After desorption and cryotrapping, CIS was heated at 12°C/sec to 280°C with the holding time of 10 min. Temperature program in the GC was 40°C for 5 min, then increasing to 200°C at the rate of 2°C/min. The final temperature was held for 10 min. Carrier gas head pressure was 14 psi (flow rate 1.2 ml/min). The GC unit was operated in the constant flow mode. The emission lines for carbon (193-nm), sulfur (181-nm), and nitrogen (174-nm) were monitored in the atomic plasma emission detection.

Statistical Analysis. Pirouette Lite (Infometrix, Inc., Woodinville, WA, USA) was used for exploratory multivariate analysis to obtain hierarchical cluster patterns for classification of analysis data and for establishment of chemical relations within the subject groups. When appropriate, group comparisons were calculated using the nonparametric Mann–Whitney *U* test.

RESULTS AND DISCUSSION

According to the literature (Sokolov and Vasilieva, 1993; Vasilieva et al., 1990) and the results presented here, *P. campbelli* and *P. sungorus* seem closely related. Yet, they are widely considered as two distinct species. Therefore these two species were compared against each other. *P. roborowsky* will be discussed separately.

I. Campbelli and Sungorus Groups. Campbelli and *sungorus* hamster groups each consisted of 10 males and females (Table 1). Preliminary screening showed that both groups exhibited relatively similar chemical constituents in their profiles. Differences were seen mainly in the levels of compounds within the same age and gender groups. Gender and age inflicted certain profile differences, which will be discussed in more detail below.

The compounds identified by GC-MS in the adult animals are shown in Table 2A. A short list of compounds (numbers 1–17) in Table 2B indicates

[a]Retention index on DB-5 column phase.

substances that have been used for quantitative measurements by TDSA-GC-AED. A typical MS total ion chromatogram (TIC) of the male hamster urine is shown in Figure 1. Peak numbers refer to Table 2B.

Compound identification was made by GC-MS based on retention times, spectra, and known standard compounds. Based on the total ion chromatogram (TIC) profiles (as shown in Figure 1), the compound profiles were quantitatively compared with the GC-AED profiles, whereas the peak identities were assigned for these measurements. Figure 2 shows a typical GC-AED compound profile (carbon 193-nm line) for a male *campbelli* hamster.

TABLE 2B. COMPOUNDS QUANTIFIED BY GC-AED

Compound no.	(min)	Compound name
1	8.82	4-Heptanone
2	10.30	2-Heptanone
3	10.85	2,5-Dimethylpyrazine
4	17.68	A propylpyrazine
5	22.38	Methylaniline
6	22.82	4-Nonanone
7	24.05	A methylpropylpyrazine
8	24.48	An alkenylpyrazine (C-4)
9	25.10	2-Nonanol
10	27.20	Phenylacetonitrile
11	30.17	A dimethylpropylpyrazine
12	30.53	An ethylpropylpyrazine
13	32.80	Formanilide
14	36.33	Geraniol
15	36.43	An alkenylpyrazine (C-6)
16	37.02	An alkylpyrazine (C-6)
17	37.92	2-Undecanol (branched)

Within the complex urinary compound profiles, average levels were calculated for 17 identified compounds (Table 2B). Averages were grouped pertaining to the different species/gender/age groups. Calculations were based on the corresponding integrated peak areas for each compound. Logarithmic ($\log_{10}$) transformations log(peak area + 1) were used to normalize the graphs due to large numerical values of the integrated peak areas (Zar, 1999).

In general, male hamster urine contained higher levels of all compounds in both *campbelli* and *sungorus* species when compared with females. Typically, urinary profiles in *campbelli* and *sungorus* males were closely related. Figure 3 shows average levels of 17 compounds (from Table 2B) for *campbelli* females (9 mo) and males (9 mo) and *sungorus* females (10–12 mo) and males (10–11 mo).

Several quantified compounds were either gender- or age-specific in *campbelli* and *sungorus*. Also, some of the compounds were typical for the particular hamster species. Hamster groups *campbelli* females (cf), *campbelli* males (cm), *sungorus* females (sf), and *sungorus* males (sm) were further divided into subgroups based on their ages. The group codes and number of individuals in each group are shown in Table 1. Summary of the identified species/gender/age-specific compounds is shown in Table 3.

Multivariate hierarchical cluster analysis (HCA) in Figure 4 shows "similarity degrees" of different hamster groups based on the averages of 17 quantified compounds. Clusters connected closest to 1.0 on the *X*-axis mark

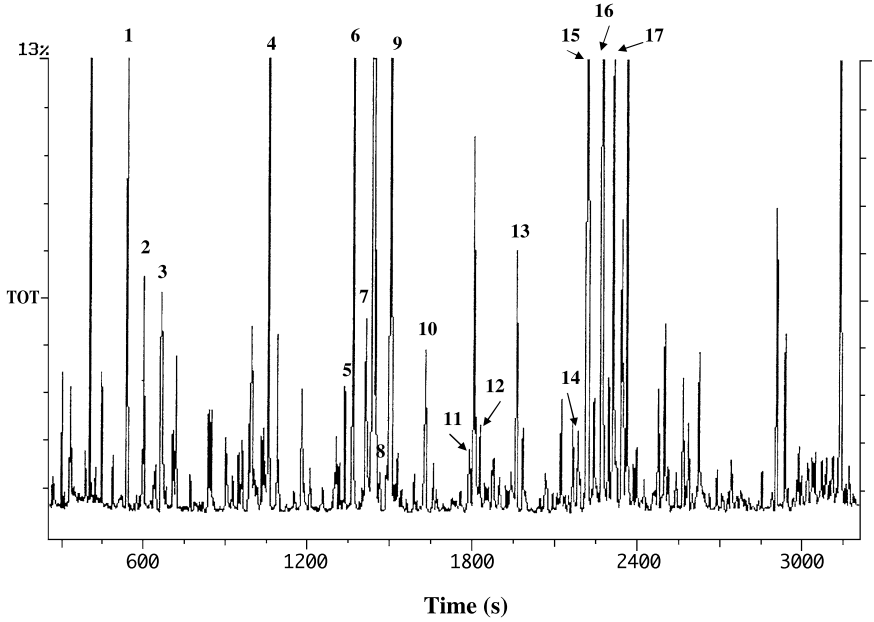

FIG. 1. A GC-MS total ion chromatogram (TIC) of the SBSE-extracted urine of a male *P. sungorus* hamster. Analytical conditions are described in the text. Numbers refer to identified compounds in Table 2B used for quantification by GC-AED.

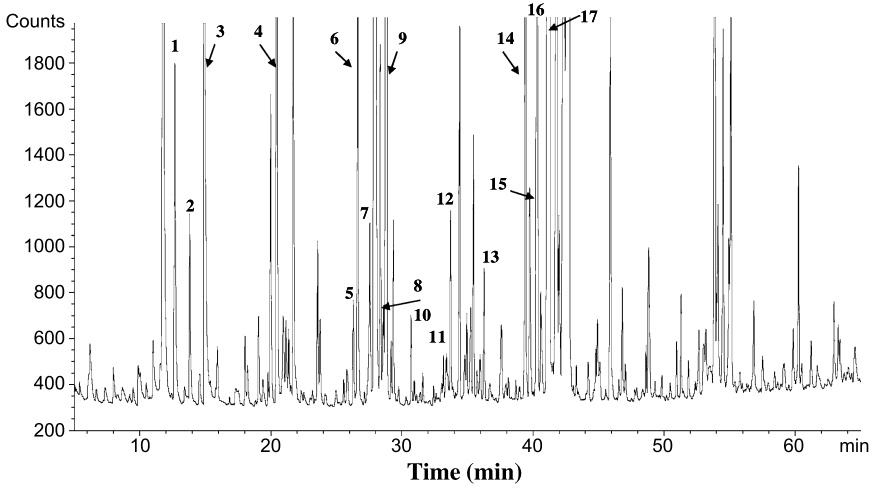

FIG. 2. A urinary volatile profile of a male *P. campbelli* hamster (cm-9) by GC-AED, carbon line 193-nm. Separation conditions are described in the text.

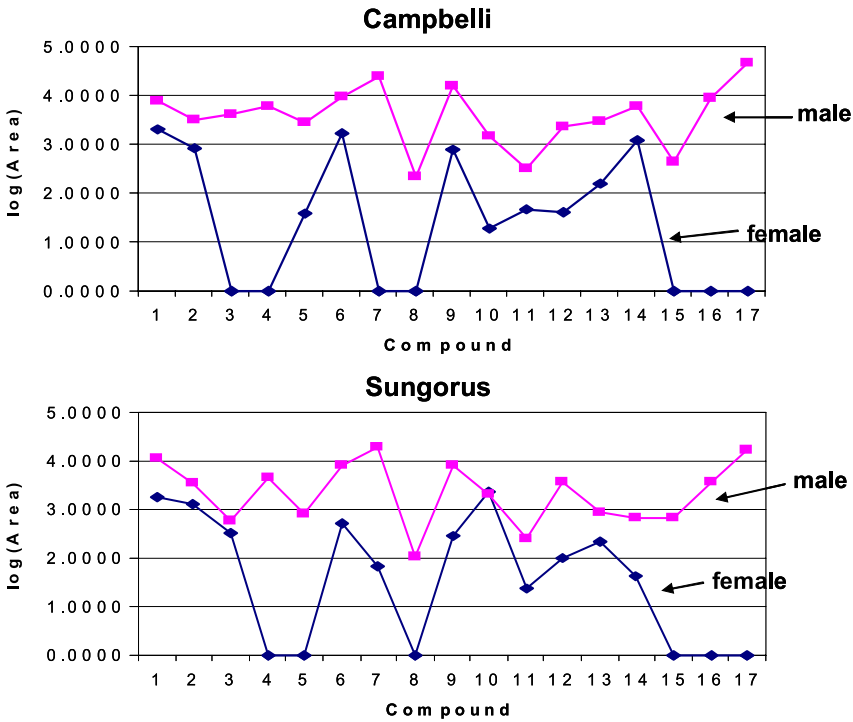

FIG. 3. Averages of levels for compound numbers 1–17 for mature female and male *campbelli* and *sungorus* hamsters. Logarithmic values for peak areas were used [log(peak area + 1)].

the most similar group properties. As shown in Figure 4, volatile profiles of male *campbelli* and *sungorus* hamsters for 17 identified compounds relate closely to each other. Within the corresponding female profiles, relation is not so clear.

Additional comparative qualitative information was obtained from compound profiles by GC-AED sulfur 181-nm line chromatograms (Figure 5). GC-AED facilitated detection of sulfur compound profiles at trace picogram levels (Soini et al., 2005). Characterization by GC-MS was not successful for these compounds due to low levels. As noted for the GC-AED carbon 193-nm line chromatograms (average results in Figure 3), also sulfur-containing, yet unidentified compounds appeared at higher levels in male hamster urine than in female urine.

Method Precision. Reproducibility of extraction and the GC analysis was investigated with the pooled male *campbelli* hamster urine. Four parallel

17	2-Undecanol (branched)	4.7	0	2.9	0	4.2	0	4.6	0

[a]Log (peak area + 1).

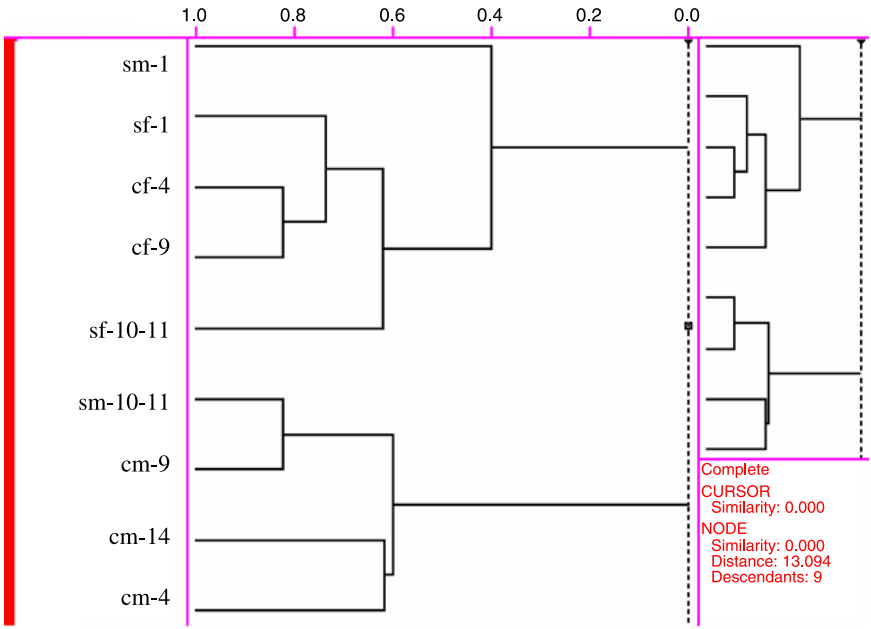

FIG. 4. A hierarchical cluster analysis (HCA) graph for all hamster groups using levels of compounds 1–17 as variables (see Table 2B).

extractions were performed, and the relative standard deviations of peak areas were calculated (RSD). Typical variability for the analytes was between 0.1 and 2.0% (RSD, $N = 4$) as shown in Table 4. A uniform sorptive polymer coating, automated thermal desorption sample introduction, and a constant flow control in the GC-AED system have all contributed to the acceptable reproducibility of the results when no internal standard was deemed necessary.

Role of Pyrazines. In all male *campbelli* and *sungorus* urinary profiles, the presence of pyrazines was a dominating factor, as seen in Table 2A. Compounds with numbers 3, 4, 7, 8, 12, 15, and 16 (Table 2B) appeared to be related to gender and age in both hamster groups. *Campbelli* males showed more *male-specific pyrazines* (2,5-dimethylpyrazine, a propylpyrazine, a methylpropylpyrazine, a C-6 alkylpyrazine, and alkenyl C-4 and C-6 pyrazines). In the *sungorus* group, female urine also contained 2,5-dimethylpyrazine and a C-4 alkylpyrazine, however, with the latter appearing at higher levels in *sungorus* males than in females ($P < 0.02$). Ethylpropylpyrazine (compound 12) levels were significantly higher in both *campbelli* ($P < 0.002$) and *sungorus* males ($P < 0.02$) compared with females. Ethylpropylpyrazine levels were also significantly higher in mature *sungorus* males (10–14 mo) compared with

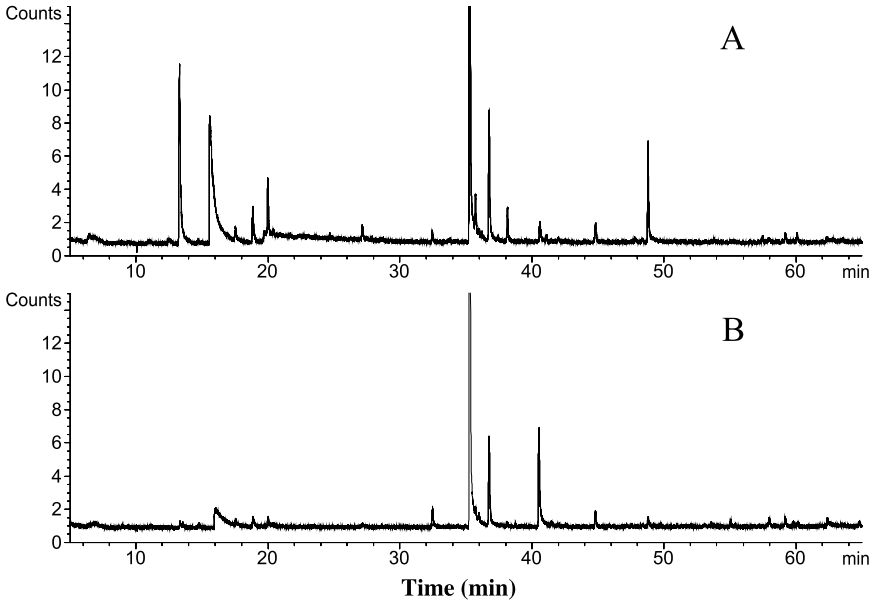

FIG. 5. Comparative urinary volatile profiles for pooled (A) male *sungorus* and (B) female *sungorus* urine by GC-AED sulfur line 181-nm. Compounds were not identified.

juvenile (1 mo) animals ($P < 0.002$). In all *campbelli* and *sungorus* females, the less volatile alkylated C-6 pyrazines (compounds 15 and 16) were absent (below detection limit). Urinary alkenyl C-4 and C-6 pyrazines (compounds 8 and 15) appeared higher in old male hamsters as well as in younger individuals, although the differences were not statistically significant. Figure 6 illustrates average levels of unsaturated alkenyl pyrazines in the *campbelli* male urinary profiles in the different age groups. Large differences in pyrazine levels within gender and age suggest that pyrazines may be under endocrinological control and may thus be an important means of chemical communication for both *campbelli* and *sungorus* hamsters.

Ketones. Relatively small differences of the levels of 4- and 2-heptanone over the age, gender, and species groups were observed. Figure 7 shows that 2-heptanone levels, as an example (compound 2), in *campbelli* (9 mo) and *sungorus* (10–11 mo) males were relatively close to each other. The same applied to *campbelli* (9 mo) and *sungorus* (10–12 mo) females (data not shown). Statistically significant higher levels of 4-nonanone were found in male urine compared with females in both *campbelli* ($P < 0.02$) and *sungorus* groups ($P < 0.002$). These findings suggest that urinary ketones may not carry specific signaling properties as pyrazines do for *campbelli* and *sungorus* hamsters,

TABLE 4. REPRODUCIBILITY OF 17 QUANTIFIED COMPOUNDS BY GC-AED EXEMPLIFIED BY DETERMINATION OF SAMPLES OF POOLED MALE *P. campbelli* URINE ($N = 4$)

Compound no.	Compound	Average log (peak area)	Standard deviation (SD) of log (peak area)	Relative standard deviation of log (peak area) (RSD %, $N = 4$)

17	2-Undecanol (branched)	4.024	0.013	0.3

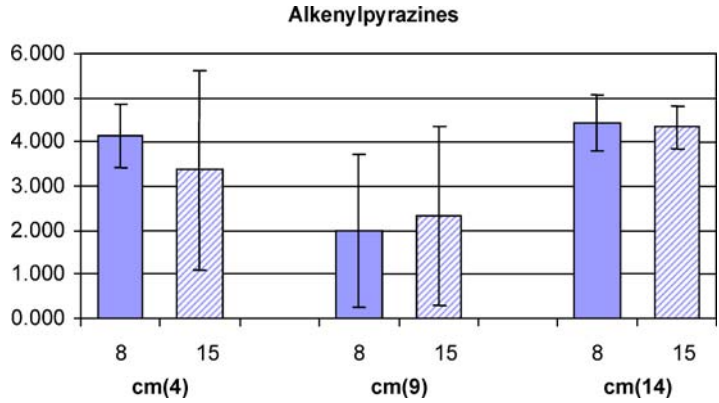

FIG. 6. Averages of alkenyl pyrazine compounds 8 and 15 (see Table 2B) in different male *campbelli* age groups (ages 4, 9, and 14 mo).

although they may be involved in the creation of the baseline scent for the species.

Alcohols. Among the identified alcohols, branched 2-undecanol (compound 17) appeared male-specific in both *campbelli* and *sungorus* species (Figure 3). Surprisingly, branched 2-undecanol levels were already high in the urinary profiles of young *sungorus* males. Levels were declining with age. Geraniol (a terpene alcohol, compound 14) levels appeared somewhat higher in male and female *campbelli* mature hamsters (not a statistically significant

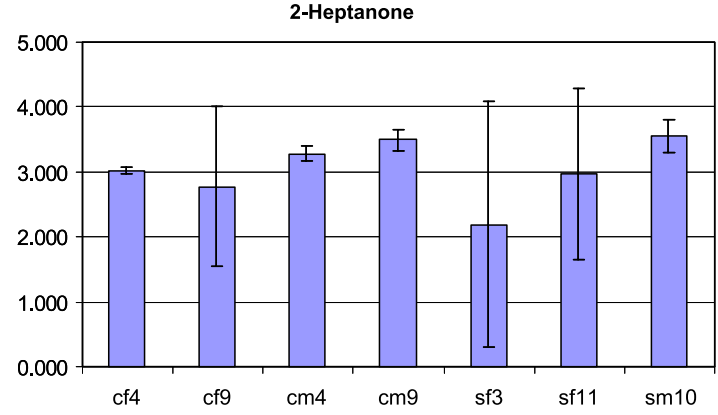

FIG. 7. Average levels of 2-heptanone (compound 2) in different hamster groups.

difference). Only in the *campbelli* group, were geraniol levels higher in males than in females ($P < 0.02$). Young females in both *campbelli* and *sungorus* groups lacked geraniol in their profiles. A branched alcohol, 2-nonanol (compound 9), was found in all age, gender, and species groups. *Sungorus* females showed the lowest levels of 2-nonanol (data not shown) from all groups.

Selected Nitrogen Compounds. Methylaniline (compound 5), phenylacetonitrile (compound 10), and formanilide (compound 13) were independent variables related to each other based on a hierarchical cluster analysis (HCA, data not shown). Within the male profiles, methylaniline was specific for the *sungorus* males only (Figure 3). In the male profiles, methylaniline was shown only in the age group of 9–11 mo (not seen in juvenile and 14-mo-old males). Phenylacetonitrile was not seen in the urine of immature female or male *sungorus* hamsters (1 mo). Among mature *sungorus* males and females, there were no statistically significant differences, whereas the levels in male mature *campbelli* were higher than in females ($P < 0.02$).

Figure 8 shows comparisons of the averages of selected compounds in *campbelli* (9 mo) and *sungorus* (10 mo) male urinary profiles. *Campbelli* average levels tended to be slightly higher than *sungorus* levels. However, the individual variation in their concentrations was clearly larger in the *sungorus* group.

II. P. roborowsky. Within the *roborowsky* group (four female subjects), a completely different urinary volatile pattern was seen. A list of identified or tentatively identified *roborowsky* female urinary compounds is shown in Table 5.

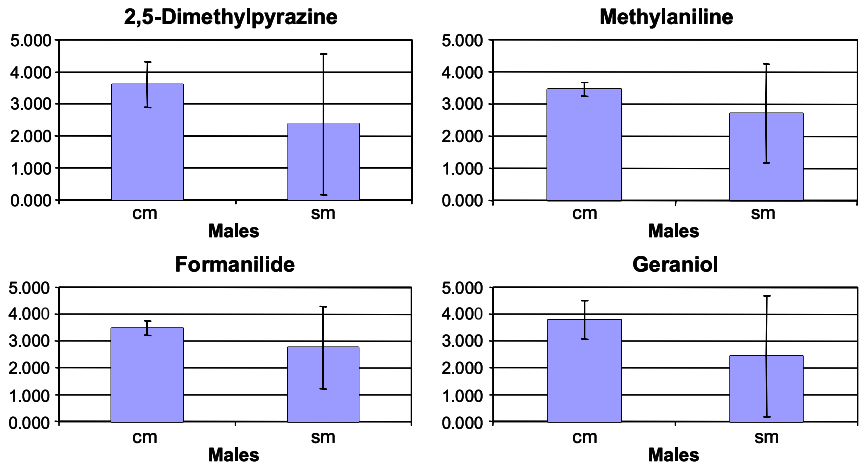

FIG. 8. Comparison of averages and standard deviations of selected compound levels in *campbelli* (cm) and *sungorus* (sm) urinary volatile profiles.

TABLE 5. IDENTIFIED AND PARTIALLY IDENTIFIED COMPOUNDS IN THE URINE OF FEMALE *P. roborowsky* (AGE 12 MO)

An alkylquinoxaline (C-4)	3220	53.67	1538

[a]Retention index.

Screening of urinary profiles of *P. roborowsky* revealed that few compounds were in common with *campbelli* and *sungorus* (Table 2A). A dominant array of alkyl- and alkenylpyrazines was not present in these samples. Instead, the *roborowsky* urine featured a group of higher-boiling alkyl quinoxalines. The presence of ketones, alcohols, and esters was characteristic for the group of 60

identified compounds. The origin of ketones is likely to be β-and ω-oxidation of fatty acids. This suggests that metabolic pathways in *P. roborowsky* hamsters differ markedly from *P. sungorus* and *P. campbelli* hamsters. Also, based on the large difference on the chemical constituent types in urine, the baseline scent properties of the *roborowsky* female hamster are expected to differentiate from those of *sungorus* and *campbelli* females.

In summary, quantitative data were proven highly reproducible using the stir bar sorptive extraction (SBSE) methodology. Typically, relative standard deviations (RSD, $N = 4$) were 0.1–2.0% for normalized peak areas. This analytical feature provided reliability for the urinary profile comparisons. Ultrahigh sensitivity of the atomic emission detection for sulfur-containing compounds provided extra information about comparative urinary volatile profiles.

The chemical characterization data on *P. campbelli*, *P. sungorus*, and *P. roborowsky* verified relatively similar compound profiles in *campbelli* and *sungorus* (males and females), which differed substantially from *P. roborowsky* (females only, males were not available in the screening study). This suggests that metabolic pathways in *campbelli* and *sungorus* hamsters resemble each other but differ substantially from the *roborowsky* species. In *campbelli* and *sungorus*, different substituted pyrazines dominated the urinary profiles. Several pyrazines and branched 2-undecanol were male-specific in both species. Methylaniline and phenylacetonitrile were age-specific in both male hamster species. The individual compound level variability within the *P. sungorus* was clearly larger than in the *P. campbelli* species.

The urinary profiles of *roborowsky* female hamsters were dominated by ketones, alcohols, and esters. Similar pyrazine arrays, as seen in *campbelli* and *sungorus*, were clearly not observed. Instead, low-volatility alkyl quinoxalines were detected.

One could hypothesize that urinary compound classes such as pyrazines, within a certain volatility range (early eluting pyrazines vs. later eluting pyrazines), may classify the overall perception of the urine odor so that a closely related species may learn the scent codes, as reported (Vasilieva et al., 2001) under cross-fostering conditions. The question remains which urinary compounds carry most crucial information and whether concentration level differences play a role in scent recognition between *campbelli* and *sungorus*. At this time, it is not known whether there is any effect of a seasonal variation on the urinary profiles.

Acknowledgments—We thank Mr. Kevin E. Bruce for his help in preparation of the manuscript. This work was supported by a grant no. DC 24 180 from National Institute of Deafness and Other Communication Disorders, National Institute of Health, U.S. Department of Health and Human Resources, and partially by a grant no. RFBR 04-04-49190a to Nina Y. Vasilieva from the Russian Academy of Sciences.

(Received May 6, 2004; revised January 5, 2005; accepted January 18, 2005)

Abstract—Although macrophyte–herbivore interactions in freshwater systems were generally disregarded for many years, recent data suggest that herbivory can be intense and important in structuring freshwater communities. This has led to the hypothesis that chemical defenses should be common among freshwater plants, but few studies have reported such chemical defenses, and no previous studies have assessed the frequency of chemical defenses among a substantial number of freshwater plant species. In a study of 21 macrophyte species co-occurring with the omnivorous crayfish *Procambarus acutus* in a southeastern USA wetland environment, we found that extracts of 11 species (52%) deterred feeding by *P. acutus* when tested in artificial foods at natural concentrations. Of these 11 chemically defended species, one species, *Eupatorium capillifolium*, consistently had a more unpalatable extract following mechanical damage to plant tissue, indicative of an activated chemical defense. Because herbivores are commonly nitrogen-limited and select food based on several plant traits, including plant nutritional value, it might be expected that chemical defenses would be especially important for protein-rich plants. However, we found no relationship between soluble protein concentration and deterrence of plant extracts.

Key Words—Chemical defense, herbivory, freshwater, macrophyte, crayfish, *Procambarus acutus*.

INTRODUCTION

Community structure and plant abundance are strongly influenced by herbivory, with plant–herbivore interactions being well investigated in terrestrial and marine ecosystems (Lubchenco and Gaines, 1981; Fritz and Simms, 1992). Such interactions have been less studied in freshwater systems because it was previously thought that herbivory had minimal impact on freshwater macrophytes (Hutchinson, 1975). However, recent studies show large impacts of herbivory in freshwater ecosystems (e.g., Cyr and Pace, 1993), and this impact should select for macrophyte defenses, as in terrestrial and marine systems (Hay and Fenical, 1988; Rosenthal and Berembaum, 1992). This reasoning led us to investigate the prevalence of antiherbivore chemical defenses among freshwater macrophytes, where only a few specific studies have been conducted, but where no general assessments of many species are available.

Chemical defenses may be constitutive (always present), induced (production up-regulated gradually), or activated (produced immediately) in response to enemy attack (Paul and Van Alstyne, 1992; Karban and Baldwin, 1997). Studies of marine algae indicate that in about 20% of species, greater levels of defense may be activated within seconds of physical damage (Cetrulo and Hay, 2000), but whether activation is rare or common is unknown for freshwater macrophytes. Newman et al. (1990, 1992, 1996) found that in damaged watercress, 2-phenylethyl glucosinolate was enzymatically converted to 2-phenylethyl isothiocyanate, deterring invertebrate feeding. Bolser et al. (1998) found that in the freshwater orchid *Habenaria repens*, the concentration of a deterrent compound, habenariol, increased threefold when cells were lysed.

In this investigation, we asked what proportion of a group of 21 freshwater macrophytes is chemically defended against a co-occurring generalist crayfish, *Procambarus acutus*. We also asked whether mechanical damage to plants led to chemical changes affecting palatability, allowing us to detect some types of activated defenses. We also hypothesized that plants of higher nutritional value to herbivores would be under greater threat of herbivory, would experience greater selection for defenses, and would, therefore, possess more frequent or more potent chemical defenses. To test this, we investigated the relationship between protein content and chemical defenses in this group of plants.

METHODS AND MATERIALS

Study Organisms. We used crayfish as feeding assay organisms because they are generalist feeders, behave well in laboratory assays, and can have great effects on macrophyte biomass in natural systems (e.g., Lodge and Lorman, 1987). The omnivorous crayfish *P. acutus*, commonly found among macro-

phytes, is native to and distributed throughout the southeastern USA, including the Chattahoochee River wetlands in Georgia (Hobbs, 1981). *P. acutus* were collected from wetlands at the Chattahoochee National Recreation Area (Cochran Shoals Unit, near Atlanta, GA, USA) from January to September 2003. Identification of crayfish was accomplished by examination of morphological traits (Hobbs, 1981). They were housed in a water table with recirculating water and were separated by plastic dividers creating 40 chambers measuring 12.5 × 12.5 cm. On days when crayfish were not being used for feeding assays, they were fed with commercial trout pellets.

Multiple sites within the Chattahoochee National Recreation Area wetlands in north Georgia were used for plant collections. Twenty-one freshwater macrophyte species were chosen for study, based on availability from May to October 2003 (see Table 1). We focused on abundant plants and avoided rare plants because of sample size limitations. Identification of macrophytes was accomplished by examination of morphological traits (Godfrey and Wooten, 1979, 1981).

Macrophytes were gently pulled up by the roots, placed in Ziploc bags, and stored on ice for transport to the laboratory at Georgia Institute of Technology. At the lab, plants were gently rinsed, patted dry, weighed, and each collection was sorted into two batches of equal wet mass and volumetric displacement in water. Pressed voucher specimens are stored at the Georgia Institute of Technology.

Chemical Methods. To mimic the shredding action of feeding crayfish and thus simulate herbivore damage, macrophytes were shredded for 45 sec in water using a blender to generate the simulated "grazed" treatment. This method has been used successfully by previous researchers examining activated defenses among macroalgae (Paul and Van Alstyne, 1992; Cetrulo and Hay, 2000). To simulate a nongrazed plant (simulated "nongrazed" treatment), plant material was placed in methanol (MeOH) before blending. This procedure should inhibit enzymatic activity within the plant and prevent activation of chemical defenses. After blending each treatment, plant material and solvent were placed in 1-l flasks, and equal amounts of the opposite solvent were added, resulting in a 1:1 blend of MeOH/H_2O. After extracting for 1 hr at 4°C, extracts were vacuum-filtered, and solvents were removed by rotary evaporation. To maximize both the yield and polarity range of compounds extracted, plant material was further extracted once each with three additional solvent systems: 100% MeOH, then 1:1 MeOH/dichloromethane, and then 1:2 MeOH/dichloromethane. These extracts were combined with the 1:1 MeOH/H_2O extract, dried by rotary evaporation, and stored at −20°C until used in feeding assays.

Feeding Assay Methods. Two types of feeding assays were conducted: (1) tests of extracts from simulated "grazed" treatments were compared to extracts from simulated "nongrazed" treatments, and (2) tests of "grazed" or "nongrazed" treatments were compared to no-extract controls. For each assay,

TABLE 1. FRESHWATER PLANT SPECIES USED IN THIS STUDY, SOME PLANT TRAITS, AND ASSESSMENT OF CHEMICAL DEFENSES FROM THE CURRENT STUDY

Plant species	Common name	Duration[a]	Origin[a,b,c]	Chemical defense	Protein	
					% of dry mass	mg per ml fresh plant tissue
Agrostis scabra	Rough bentgrass	Perennial	US native	None	4.90 ± 0.08	4.41 ± 0.08
Alisma subcordatum	American water plantain	Perennial	US native	Constitutive	Not measured	
Alternanthera philoxeroides	Alligatorweed	Perennial	S. America native	None	Not measured	
Aster sp.		Perennial		Constitutive	3.40 ± 0.13	16.3 ± 0.6
Cabomba pulcherrima	Fanwort	Perennial	US native	None	5.91 ± 0.50	2.95 ± 0.25
Cyperus odoratus	Fragrant flatsedge	Annual/perennial	US native	None	4.95 ± 0.07	8.41 ± 0.12
Eupatorium capillifolium	Dogfennel	Perennial	US native	Activated and constitutive	4.48 ± 0.29	4.48 ± 0.29
Galium tinctorium	Stiff marsh bedstraw	Perennial	US native	Constitutive	8.08 ± 0.17	11.3 ± 0.2
Hydrolea quadrivalvis	Waterpod	Perennial	US native	Constitutive	4.85 ± 0.18	2.91 ± 0.11
Hypericum mutilum	Dwarf St. Johnswort	Annual/perennial	US native	Constitutive	8.80 ± 0.49	10.6 ± 0.6

Ludwigia repens	Creeping primrose-willow	Perennial	US native	None	8.63 ± 0.26	6.04 ± 0.18
Lycopus virginicus	Virginia water horehound	Perennial	US native	None	5.79 ± 0.22	5.21 ± 0.20
Mimulus ringens	Allegheny monkeyflower	Perennial	US native	Constitutive	4.41 ± 0.39	7.93 ± 0.70
Murdannia keisak	Marsh flower	Perennial	Asia native	None	7.63 ± 0.44	2.90 ± 0.17
Myriophyllum aquaticum	Parrot-feather	Perennial	S. America native	None	10.2 ± 0.7	6.14 ± 0.42
Polygonum densiflorum	Denseflower knotweed	Annual/perennial	US native	Constitutive	2.15 ± 0.11	2.15 ± 0.11
Polygonum punctatum	Dotted smartweed	Annual/perennial	US native	None	2.47 ± 0.15	1.98 ± 0.12
Polygonum sagittatum	Arrowleaf tearthumb	Annual/perennial	US native	None	1.24 ± 0.05	2.87 ± 0.16
Sagittaria latifolia	Broadleaf arrowhead	Perennial	US native	Constitutive	7.25 ± 0.63	3.05 ± 0.27
Saururus cernuus	Lizard's tail	Perennial	US native	Constitutive	4.04 ± 0.16	2.83 ± 0.11
Utricularia sp.	Bladderwort		US native	Constitutive	8.50 ± 0.54	5.95 ± 0.38
Broccoli/lettuce control					12.4 ± 0.6	12.4 ± 0.6

Protein content data are also provided for the broccoli and lettuce mixture that was used as the experimental food.

[c] Godfrey and Wooten (1981).

25–40 crayfish were used, and one or two assays were run with each group each day.

Feeding assay foods and experimental design followed procedures of Bolser et al. (1998). Assay food consisted of freeze-dried, finely ground broccoli and lettuce (1:1) in an agar matrix with the addition of plant extracts (either "grazed" or "nongrazed" extracts) or no extracts (no-extract control). For testing of each plant species, we used a quantity of dried broccoli/lettuce corresponding to the plant's dry mass for a 20-ml volume of fresh plant tissue. An aliquot of extract corresponding to 20 ml of fresh plant material was dissolved in acetone/methanol/ethyl ether (1:1:3) and added to the broccoli/lettuce powder. Solvents were then removed on a rotary evaporator, and the extract-coated broccoli/lettuce mixture was suspended in 7.0 ml distilled water, combined with a boiled solution of 0.37 g agar in 12.0 ml distilled water, and quickly poured into a mold beneath which lay window screen. Once cooled, the food adhered to the window screen, and each food patch was cut with a razor blade to contain a total of 63 window screen squares. No-extract control foods were prepared in the same manner, including the solvents described above, but without plant extracts.

To directly contrast the effects of extracts from "grazed" vs. "nongrazed" treatments, each crayfish was independently offered a food strip consisting of one patch of food with "grazed" extract and one patch of food with "nongrazed" extract. For tests of "grazed" or "nongrazed" treatments vs. no-extract controls, each crayfish was offered a food strip consisting of one patch of food with either "grazed" or "nongrazed" extract and one patch of no-extract control food. Each crayfish was allowed to feed until approximately half of the total amount of food on its strip was eaten, typically taking between 1–6 hr, but for some foods up to 24 hr. Once removed from crayfish, the number of food squares missing (eaten) from each treatment patch was counted.

Statistical Analyses. A Shapiro–Wilk test indicated nonnormal distribution of feeding assay results. Therefore, the nonparametric Wilcoxon signed-rank test was used to compare consumption of "grazed" treatments vs. "nongrazed" treatments and to compare consumption of "grazed" or "nongrazed" vs. no-extract controls. The nonparametric Mann–Whitney *U* statistical test was used to compare the amount consumed of the "grazed" treatment from the "grazed" vs. no-extract control assay with amount consumed of the "nongrazed" treatment from the "nongrazed" vs. no-extract control assay (Sokal and Rohlf, 1994). For a few species, uncertain interpretation of results led us to repeat feeding assays at a later date, using extracts from the initial plant collection. A Mann–Whitney *U* test was used to determine whether the data generated from these repeated assays could be combined with the data from the original feeding assays. If the two data sets were significantly different from each other, they were analyzed and presented separately. Linear regression was used to assess

whether a macrophyte's protein content was predictive of the deterrence of its extract. Extract deterrence was calculated for each replicate by subtracting the amount of "grazed" treatment eaten from the amount of the no-extract control food eaten, and dividing this by the total amount eaten, and then averaging across all replicates of one assay (consumption of "grazed" treatment rather than "nongrazed" treatment was chosen for this calculation so that extract deterrence of plants with activated chemical defenses would be evaluated at their activated levels). For plant species that were collected, extracted, and assayed twice, results from both feeding assays were averaged to generate a value of extract deterrence. An extract deterrence value of +1 indicates that only no-extract control food was consumed (i.e., strong deterrence); a deterrence value of 0 indicates that there was no preference between no-extract control food and "grazed" extract food (i.e., no chemical defense). Negative deterrence values suggest feeding stimulation by the plant extract. Data in figures are presented as means ± one standard error. In all analyses, $P < 0.05$ was considered statistically significant.

Plant Nutritional Analyses. Wet mass, dry mass, ash-free dry mass, and volumetric displacement were determined for five separate plants for each macrophyte species. All samples were patted dry and weighed, dried at 45°C until a constant dry mass was achieved (24 hr) and weighed to obtain dry mass, and placed in an oven at 450°C for 4 hr and weighed to obtain ash-free dry mass. To determine the approximate nutritional value of each plant species, soluble protein content was measured according to Bradford (1976) for 19 of the 21 plants species (two plant species were unavailable for recollection at the time of this measurement). Whole plant samples were weighed, freeze-dried, and ground. Three 5-mg samples of each plant were digested in 1.0 ml NaOH (1 mol/l) for 24 hr at 4°C, centrifuged, and 100-µl aliquots of the supernatant were added to 3.0 ml of Bradford reagent. After 15–20 min, absorbance was measured at 595 nm using a Spectronic 21D spectrophotometer against bovine serum albumin (BSA) standards. Five protein standards were used to construct a standard curve (data not shown, $r^2 = 0.997$).

RESULTS

Extracts from 11 of the 21 species tested (52%) significantly depressed crayfish feeding relative to no-extract controls (Table 1, Figures 1 and 2). These chemically defended plants include one floating macrophyte, *Utricularia* sp., and 10 emergent macrophytes: *Alisma subcordatum* (Alismataceae), *Aster* sp. (Asteraceae), *Eupatorium capillifolium* (Asteraceae), *Galium tinctorium* (Rubiaceae), *Hydrolea quadrivalvis* (Hydrophyllaceae), *Hypericum mutilum* (Clusiaceae), *Mimulus ringens* (Scrophulariaceae), *Polygonum densiflorum* (Polygonaceae),

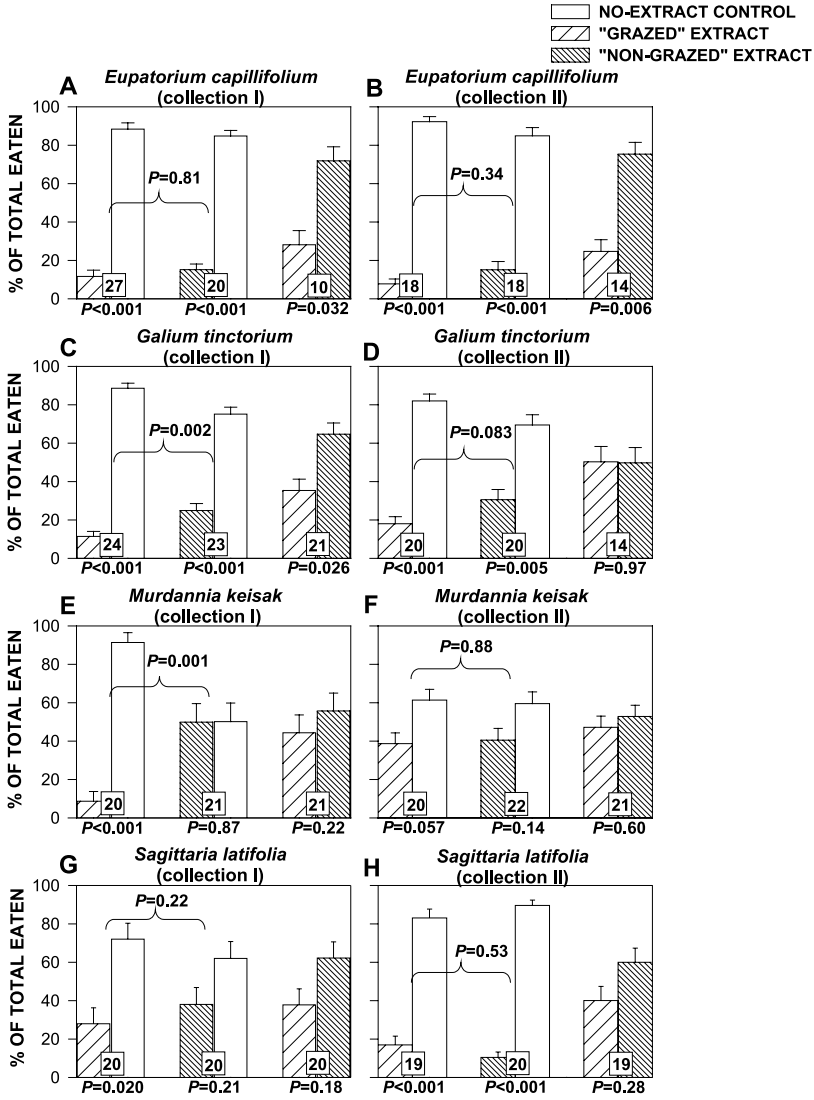

FIG. 1. Effects of simulated "grazed" and "nongrazed" freshwater plant extracts on crayfish feeding behavior: macrophytes found to have activated and constitutive chemical defenses (*E. capillifolium*) and macrophytes with initial data suggesting activated defenses, but upon repeated experiments, found to have constitutive chemical defenses (*G. tinctorium* and *S. latifolia*) or no chemical defenses (*M. keisak*). Histogram pairs represent paired experiments. Sample size is noted in a box at the base of each histogram.

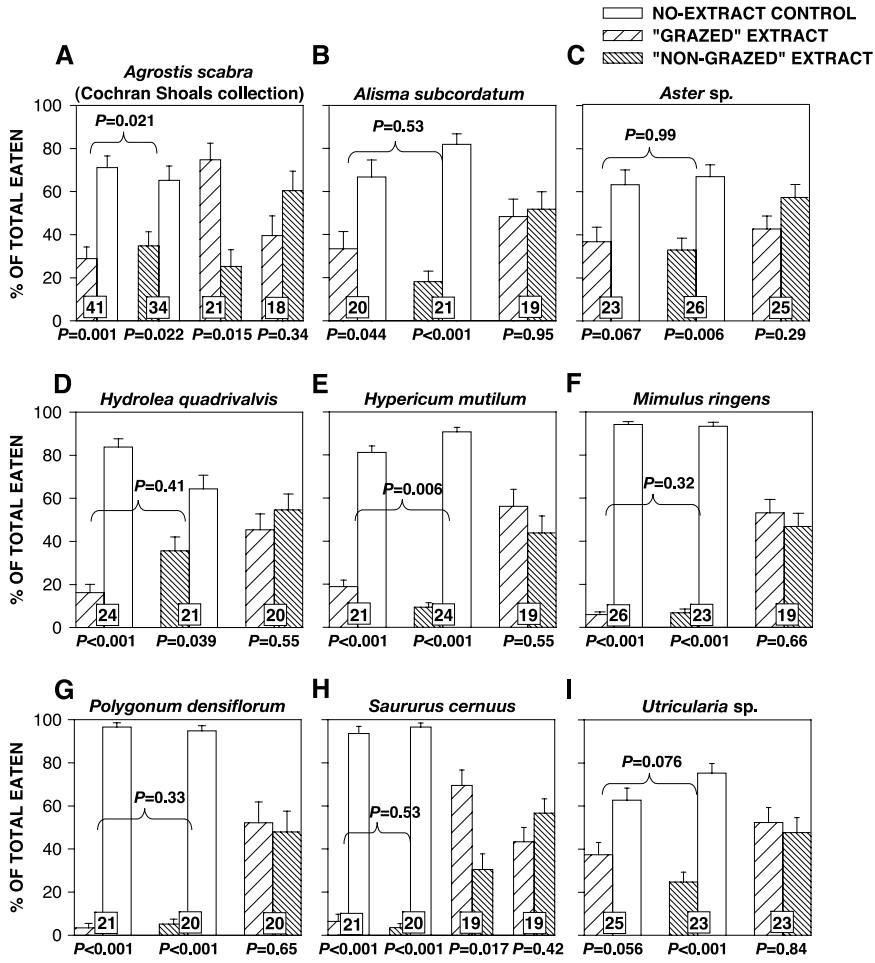

FIG. 2. Effects of simulated "grazed" and "nongrazed" freshwater plant extracts on crayfish feeding behavior: macrophytes found to have constitutive chemical defenses. Analysis and symbols as in Figure 1.

Sagittaria latifolia (Alismataceae), and *Saururus cernuus* (Saururaceae). Collections of one additional emergent species, *Agrostis scabra* (Poaceae), appeared to be chemically defended at one site (Cochran Shoals, Figure 2A), but not at a site 3 mi away (Johnson Ferry, data not shown), although collections were made within 5 wk of each other. The remaining nine macrophytes' crude extracts did not significantly deter crayfish feeding when tested at natural concentrations (data not shown). These nondeterrent plants were one submersed macrophyte

Cabomba pulcherrima (Cabombaceae) and eight emergent macrophytes: *Alternanthera philoxeroides* (Amaranthaceae), *Cyperus odoratus* (Cyperaceae), *Ludwigia repens* (Onagraceae), *Lycopus virginicus* (Lamiaceae), *Murdannia keisak* (Commelinaceae), *Myriophyllum aquaticum* (Haloragaceae), *Polygonum punctatum* (Polygonaceae), and *Polygonum sagittatum* (Polygonaceae).

When originally tested, three macrophyte species (*E. capillifolium*, *G. tinctorium*, and *M. keisak*) appeared to utilize activated chemical defenses because plant extracts generated by the simulated "grazed" treatment (i.e., mechanically damaged prior to extraction) significantly deterred crayfish feeding relative to extracts from the simulated "nongrazed" treatment (i.e., mechanically damaged after treatment with organic solvent had started) (Figure 1A, C, and E). The evidence for activated chemical defenses among these three plants came either from direct comparison of crayfish consumption of foods containing "grazed" vs. "nongrazed" extracts (*E. capillifolium*; $P = 0.032$), or indirectly by comparing data from assays testing consumption of treated foods vs. no-extract controls (*M. keisak*; $P = 0.001$), or by both direct and indirect comparisons (*G. tinctorium*; $P = 0.026$ and 0.002, respectively). Additionally, the "grazed" extract of *S. latifolia* was found to be deterrent relative to no-extract controls ($P = 0.020$), whereas its "nongrazed" extract was not ($P = 0.21$), although there was no significant difference in consumption of foods containing these extracts relative to each other ($P = 0.18$ direct comparison; $P = 0.22$ indirect), so this plant did not appear to possess an activated defense (Figure 1G).

To reassess *S. latifolia*'s mechanism of chemical defense and to test whether the activated defense results for the three plant species were reproducible, these four species were recollected, treated and extracted as before, and new feeding assays were performed. Crayfish again strongly preferred "nongrazed" over "grazed" extracts from *E. capillifolium* ($P = 0.006$; Figure 1B), indicating that this plant utilizes a chemical defense activated by physical damage, although it also possesses a constitutive defense because "nongrazed" extracts were also deterrent. Crayfish were again deterred by extracts of *G. tinctorium*, but for this assay, there was no significant difference in palatability of "grazed" and "nongrazed" extracts ($P = 0.97$ direct comparison; $P = 0.083$ indirect; Figure 1D). Thus, *G. tinctorium* has constitutive chemical defenses, but we could not consistently show activation of a chemical defense. Feeding assays of the second collection of *S. latifolia* also suggested a constitutive chemical defense; both "grazed" and "nongrazed" extracts were unpalatable to crayfish, and their effects were indistinguishable from each other (Figure 1H). Neither "grazed" nor "nongrazed" extracts of *M. keisak* significantly deterred crayfish feeding relative to no-extract controls in the second feeding assay (although nonsignificant trends toward deterrence were observed; $P = 0.057$ and 0.14, respectively, Figure 1F), and the "nongrazed" extract did not deter crayfish feeding in the first assay ($P = 0.87$, Figure 1E), leaving us unable to find

consistent repeatable effects of extracts from this species. Therefore, of the 21 macrophytes studied, only *E. capillifolium* showed consistent changes in extract palatability characteristic of a chemical defense activated by physical damage. Thin layer chromatography analysis showed no obvious chemical difference between "grazed" and "nongrazed" extracts of this plant (data not shown).

In some cases, results of initial feeding assays were difficult to interpret. For example, assays directly comparing palatability of "grazed" and "nongrazed" extracts of *A. scabra* (Cochran Shoals collection) and *S. cernuus* suggested crayfish preference for "grazed" over "nongrazed" extracts (Figure 2A and H), whereas comparisons of palatability of each of these extracts with no-extract controls indicated strong chemical defenses. Because assays directly testing "grazed" vs. "nongrazed" extracts for these plants took up to 24 hr, 4–20 times longer than typical assays, we hypothesized that both "grazed" and "nongrazed" extracts were so unpalatable as to make crayfish preferences between these extracts arbitrary. For these two plant species, feeding assays using extracts from the initial collections were repeated, and crayfish preference for "grazed" extracts was not observed the second time (Figure 2A and H data on far right).

For the 19 plant species for which total soluble protein was measured, positive relationships were identified between: (1) dry mass per volume of fresh plant tissue and soluble protein per volume of fresh plant tissue ($P < 0.001$, Figure 3A); (2) ash-free plant dry mass per plant dry mass and soluble protein per plant dry mass ($P < 0.001$, data not shown); and (3) ash-free plant dry mass per plant dry mass and soluble protein per volume of fresh plant tissue ($P < 0.001$, data not shown). Compared to the 19 plants analyzed, the broccoli/lettuce mixture used as food base for the feeding assays had the highest value of protein per dry mass and the second highest value of protein per volume of fresh plant tissue.

No significant relationship was found between the magnitude of deterrence of plant extracts and plant protein content, neither when protein was expressed as soluble protein per volume of fresh plant tissue ($P = 0.95$, Figure 3B) nor when protein was expressed as a percentage of plant dry mass ($P = 0.67$, Figure 3C). No significant relationship existed between magnitude of deterrence and protein content either when chemically defended plants were grouped together or when nonchemically defended plant were grouped together ($P > 0.13$ and $P > 0.29$, respectively, whether calculated using protein as a proportion of plant volume or of dry mass).

DISCUSSION

Despite the high rate of herbivory in freshwater systems (Cyr and Pace, 1993), and the prediction that selection for antiherbivore defenses, including

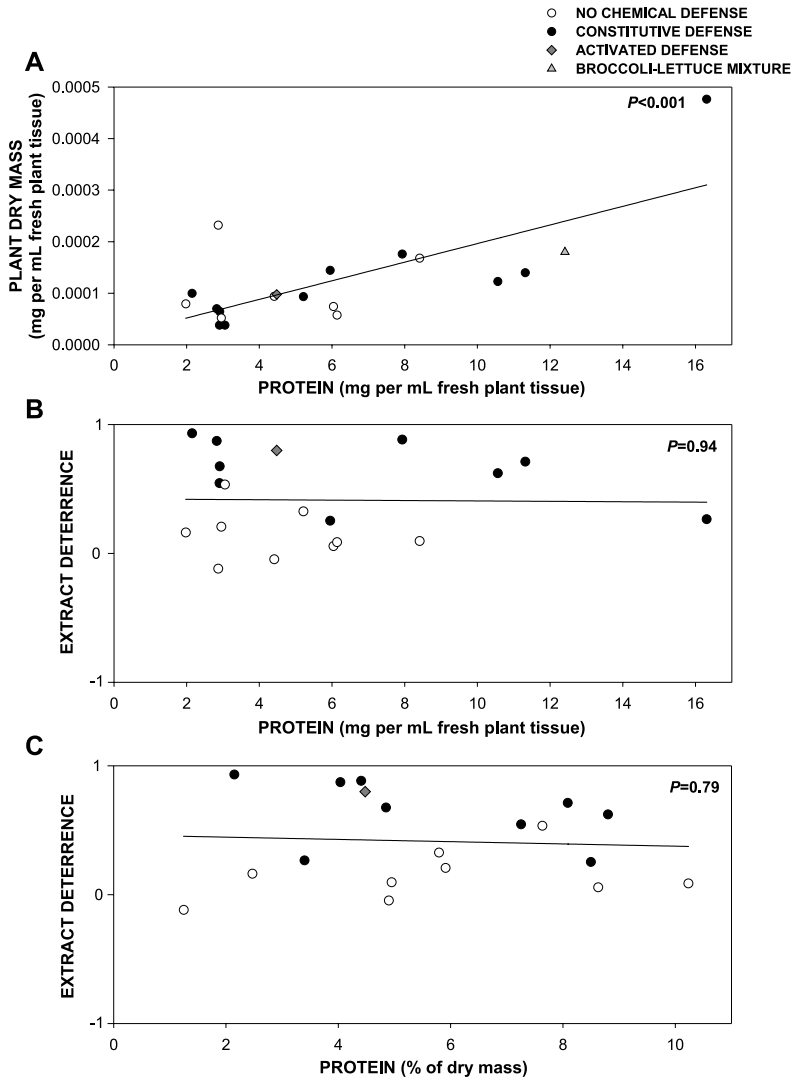

FIG. 3. (A) Relationship between soluble protein concentration and plant dry mass for 19 freshwater plant species in this study and broccoli/lettuce mixture used as experimental food (r^2 = 0.53). (B) Relationship between soluble protein concentration per volume of fresh plant tissue and deterrence of plant extracts for 19 freshwater plant species. A positive extract deterrence value indicates strong deterrence, zero indicates no deterrence, and a negative value indicates feeding stimulation by the extract. (C) Relationship between soluble protein concentration as a proportion of plant dry mass and deterrence of plant extracts.

chemical defenses, should be strong (Lodge et al., 1998), only 14 species of freshwater macrophytes had been examined for chemical defenses prior to this study. The current study provides evidence for 19 previously untested species and predicts that a majority (52% of 21 species in this study; 55% of 33 species tested overall) utilize chemical defenses against generalist herbivores (data from Newman et al., 1992; Bolser and Hay, 1998; Bolser et al., 1998; Cronin, 1998; Kerfoot et al., 1998; Kubanek et al., 2001; Cronin et al., 2002; this study). Because almost all of the freshwater macrophytes chosen for this and previous studies were selected based on availability and not because they were suspected of being chemically defended, it is likely that, in general, freshwater macrophytes are commonly defended chemically.

Studies like ours that use crude extracts to assess deterrence risk overestimating the frequency of chemical defenses, if artifacts of the extraction process contributed to deterrence. Only isolation of deterrent compounds followed by assessment of molecular structures within a biosynthetic framework can remove this risk. Of the 11 plant species predicted in this study to be chemically defended, the deterrence of only one (*S. cernuus*) has been attributed to characterized plant products, in that case, a group of lignans, neolignans, and sesquineolignans (Kubanek et al., 2000, 2001). We advocate caution in suggesting specific deterrent mechanisms for the remaining 10 species, although it is unlikely that artifacts contributed to the observed deterrence of more than a few species.

Including the one freshwater macrophyte species with a probable activated chemical defense from this study (*E. capillifolium*), and the two macrophytes, *Nasturtium officinale* and *H. repens*, found to possess activated chemical defenses in previous investigations (Newman et al., 1992, 1996; Bolser et al., 1998), a total of 9% (3 of 33) of freshwater plant species tested for chemical defenses have been found to display consistent changes in palatability characteristic of activated chemical defenses. In a study similar to ours in which marine macrophytes were sampled based on availability, Cetrulo and Hay (2000) found that 17% (7 of 42) of tropical and temperate seaweed species appeared to use activated chemical defenses. Despite this high frequency, only two seaweed-activated defense mechanisms are well understood: acrylic acid plus dimethyl sulfide, produced by enzymatic action in several seaweeds (Van Alstyne and Houser, 2003), and halimedatrial, a reactive polyaldehyde converted from the less deterrent halimedatetraacetate in *Halimeda* spp. (Paul and Van Alstyne, 1992). Overall, Cetrulo and Hay (2000) suggest that activated chemical defenses may be fairly common among marine plants. In contrast, a relatively smaller proportion of freshwater plants have been shown to possess activated chemical defenses (Newman et al., 1990; Bolser et al., 1998; this study).

In our study, the low frequency of activated chemical defenses (1 of 21 plant species) may be an underestimate of the actual frequency due to

methodological limitations. First, because our feeding assays focused on only one herbivore, we may have missed defenses that deter other herbivores. Second, plants may respond to specific cues or types of damage from herbivores rather than responding simply to physical damage. The most severe limitation of our study may be that volatile or labile activated defenses would have been missed. Our laboratory practices would have removed damage-activated volatile cues like dimethyl sulfide and acrylic acid (Van Alstyne and Houser, 2003), hydrogen cyanide (Conn, 1979), and isothiocyanates and nitriles (Newman et al., 1990). However, none of these groups of volatile compounds are known from the 14 families of plants used in our study, and dimethyl sulfide and acrylic acid are thought to be restricted to marine algae. Extremely labile compounds like oxytonin 2 (Jung and Pohnert, 2001) would have been lost by decomposition. However, some known activated defenses could have been detected in assays like ours, including habenariol (Wilson et al., 1999) and halimedatrial (Paul and Van Alstyne, 1992).

As previously reported (e.g., Cronin and Hay, 1996), we found that chemical defenses can vary by location, time, and environmental conditions. *A. scabra* appeared to be chemically defended at one site (Figure 2A) but not another (data not shown). Extracts of *A. philoxeroides* were palatable in our study (data not shown); yet Cronin et al. (2002) reported that the same species collected in North Carolina was chemically defended against a crayfish congeneric to ours. Four other macrophyte species for which initial data suggested activated defenses (Figure 1) were recollected 1–4 mo later at the same sites, and an activated chemical defense could only be reproduced for one of these (Figure 1B). Results of the second series of experiments indicated constitutive chemical defenses for two plant species (Figure 1D and H) and no chemical defense for one (Figure 1F). This raises the possibilities of type I or II experimental error, that plant defenses varied by location or season, or that defenses were occasionally activated in the field due to physical stress or herbivore attack.

Because herbivores are often nitrogen-limited (Mattson, 1980), protein content should be a good proxy of plant nutritional quality. High protein plants may be desirable to herbivores, selecting for greater defenses in these plants. However, our initial hypothesis that plants with greater nutritional value should be more strongly defended chemically was not supported. We found no relationship between deterrence of plant extracts and protein content (Figure 3).

We chose the conservative strategy of using an artificial food similar in protein content to the most protein-rich of our 21 plant species (Table 1). This avoided a potential artifact of consumers responding to weakly deterrent compounds that would be ineffective within the context of the natural nutritional value of individual plants, but with the risk that some deterrence could have been missed. However, we detected deterrence for 11 of 21 plant

extracts. The 10 species with palatable extracts included some with the highest protein levels. If the high protein content of our artificial food had masked the deterrence of some extracts, this would be expected to have disproportionately affected low protein plants, potentially contributing to a relationship between protein content and deterrence, which was not observed (Figure 3).

In summary, our finding that extracts of 11 of 21 freshwater macrophyte species investigated significantly deterred feeding by a generalist crayfish provides evidence that chemical defenses in freshwater ecosystems are probably common, although chemical defenses activated by mechanical damage were consistently observed for only one of these plant species. When combined with previous studies on freshwater plant chemical defenses, it is clear that many freshwater macrophytes use chemical defenses, particularly constitutive chemical defenses, to defend themselves against generalist herbivores.

Acknowledgments—This research was supported by an NSF IGERT fellowship to A.P. We thank A. Chequer and E. Prince for help with field collections, G. Stanton and J. Parker for crayfish identification, and Z. Hallinan, A. Horner, and T. Watt for initial idea development. Comments from M. Hay, J. Romeo, and two anonymous reviewers improved the manuscript.

(Received December 11, 2003; revised October 5, 2004; accepted January 25, 2005)

Abstract—Intraspecific variation in the composition of three cytotoxic secondary metabolites from the New Zealand marine sponge *Mycale hentscheli* collected at two sites in central New Zealand was quantified by ^{1}H NMR techniques. A total of 275 sponges were analyzed bimonthly over 15 mo to compare intersite (~100 km) and intrasite (~100 m) spatial and temporal variations in the metabolites. Biological and physical characteristics of sponge size, morphology, depth, and temperature were recorded at each site. Metabolite concentrations were found to vary in space and time. Metabolite composition was site-specific; mycalamide A, pateamine, and peloruside A were present at Pelorus Sound, whereas pateamine was absent from sponges at Kapiti Island. Pateamine and peloruside A concentrations in sponges at Pelorus Sound varied seasonally; no such patterns were observed at Kapiti Island. Relationships of compound concentration with volume and depth were complex. High levels of peloruside A in Pelorus Sound sponges from between 8 and 10 m depth coincided with a density boundary layer and chlorophyll *a* maximum.

INTRODUCTION

The endemic marine sponge *Mycale hentscheli* Bergquist & Fromont, (Demosponigiae: Poecilosclerida: Mycalidae) has attracted considerable attention from chemical researchers because its crude extracts are usually potently cytotoxic in biological assays against mammalian cell lines (Perry et al., 1988). Three classes of biologically active compounds with pharmaceutical potential have been characterized from this species over the past 15 years (Figure 1). The mycalamides were the first group of novel cytotoxic compounds to be isolated from *M. hentscheli*. Mycalamides A (**1**) and B (**2**) were first described in 1988 from *M. hentscheli* collected in Otago Harbour on the southeast coast of the South Island (Perry et al., 1988). More recently, we reported the isolation of mycalamide D (**3**) from specimens collected from the northeast coast of the North Island (West et al., 2000a). The mycalamides are potent eukaryotic cytotoxins with IC_{50} values against mammalian cells in the low nanomolar

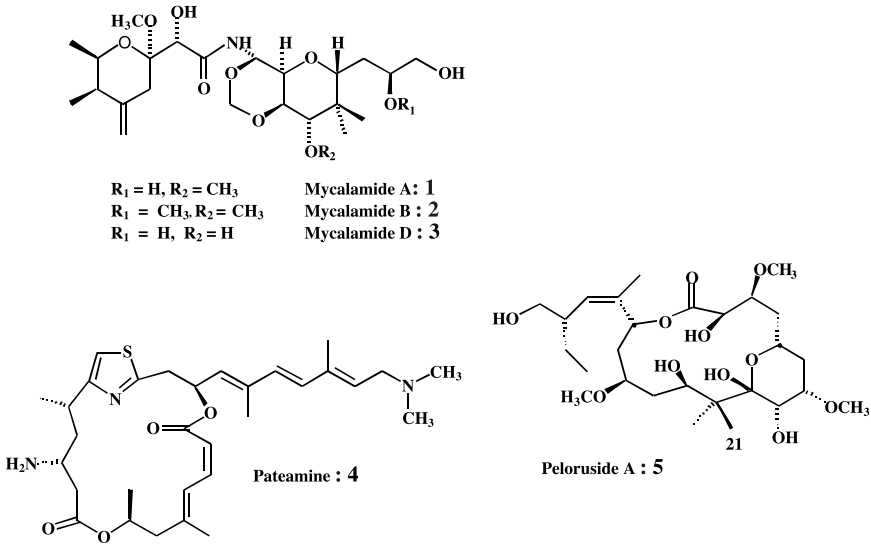

FIG. 1. Chemical structures of three classes of bioactive compounds from *M. hentscheli*: mycalamide A (**1**), B (**2**), D (**3**), pateamine (**4**), and peloruside A (**5**).

range. They have been reported to be potent protein synthesis inhibitors and have recently been found to cause apoptosis (Hood et al., 2001).

The biochemically unrelated macrolide pateamine (**4**) was isolated from *M. hentscheli* collected in Doubtful Sound on the southwest coast of the South Island. Pateamine is also a potent eukaryotic cytotoxin active in the subnanomolar range (Northcote et al., 1991). It has subsequently been found to have immunosuppressive and apoptotic properties (Romo et al., 1998; Hood et al., 2001). Interestingly, no mycalamides were detected in the specimens collected in Doubtful Sound.

The most recently discovered cytotoxic metabolite is peloruside A (**5**), which was isolated from specimens of *M. hentscheli* collected from Pelorus Sound on the north coast of the South Island (West et al., 2000b). Peloruside A is structurally unrelated to either the mycalamides or pateamine, and yet is also a potent eukaryotic cytotoxin. Recently we found that peloruside A is a microtubule stabilizer with potency and mode of action similar to Taxol® and the epothilones. All three classes of *Mycale hentscheli* metabolites show similar profiles of toxicity to a range of organisms and cell lines.

M. hentscheli is a soft, fleshy sponge, sparsely invested with skeletal spicules. It grows as massive to encrusting forms living on subtidal reefs to below 30 m throughout New Zealand (Figure 2). Large variations in relative concentrations of the three compounds are evident in collections of this species made over the past decade, from different geographic regions within New Zealand, and at different times of the year. Intraspecific variability in secondary metabolites through space and time has been studied for few sessile invertebrate taxa (Hay, 1996). Spatial variation is documented for soft corals (Maida et al., 1993; Puglisi et al., 2000), gorgonians (Harvell et al., 1993; Roussis et al., 2000), and sponges (Thompson et al., 1983, 1987; Becerro et al., 1995). Relatively few studies have, however, described long-term quantitative temporal changes in biologically active compounds. Turon et al. (1996) and Duckworth and Battershill, (2003) described such changes using biological assays in the encrusting sponge *Crambe crambe*, and on New Zealand sponges, *Latrunculia wellingtonensis* and *Polymastia croceus*, respectively. These studies measured potential synergistic effects of two or more biologically active compounds, but could not be used to quantify relative concentrations of individual compounds within an organism.

The development of marine compounds with pharmaceutical potential is, however, dependent on a sustainable supply of the desired compounds themselves (Dumdei et al., 1998). Without knowledge of the underlying patterns of production in the natural environment, sustainable supply through wild harvest or aquaculture becomes problematic (Munro et al., 1999).

The primary aim of our study was to describe spatial and temporal patterns of biologically active compounds in *M. hentscheli*.

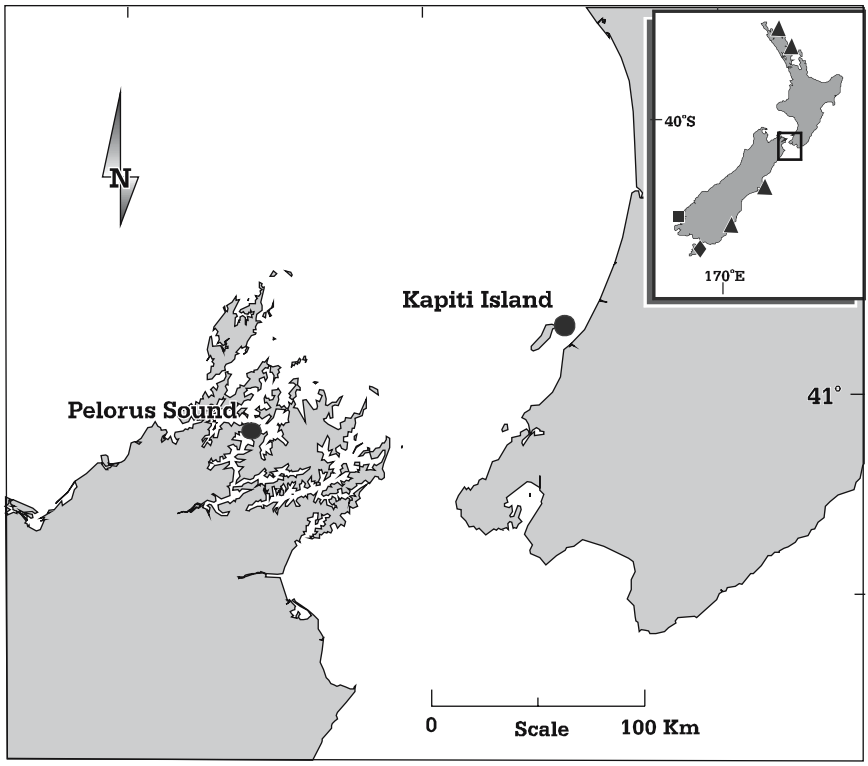

FIG. 2. Pelorus Sound and Kapiti Island study sites, central New Zealand region. The inset shows the geographic distribution of specimens of *M. hentscheli* that yielded compounds isolated in earlier studies: ▲ = mycalamides, ■ = pateamine, and ♦ = mycalamides and peloruside A.

METHODS AND MATERIALS

Study Sites. Sampling was carried out over the entire depth range of *M. hentscheli* at two sites—Pelorus Sound (Pelorus) in the Marlborough Sounds, South Island, and at Kapiti Island (Kapiti) on the southwest coast of the North Island, New Zealand—in 1999–2000 (Figure 2). Sites separated by approximately 100 km were chosen because they represented extremes in known environmental conditions for *M. hentscheli* over a relatively small latitudinal gradient; the site on Kapiti Island is a physically dynamic coastal environment exposed to moderate wave action and tidal mixing. The water is oceanic, and clarity and water quality are high, with low levels of fine suspended sediment.

The physical environment at the Pelorus site, situated in the main channel, is dominated by an almost continuous salinity or thermally induced density stratification, where low-salinity water overlies high-salinity oceanic water (Gibbs et al., 2002). Upper water column current velocities may reach 1–2 m s^{-1}, resulting in horizontal transport of nutrients and phytoplankton above the pycnocline. Suspended sediments are greatest near the seafloor where resuspension by tidal currents occurs (Gibbs, 2001). Hobo® temperature loggers (Onset Computer Corp.) were placed at the top and bottom extent of the sponge populations at each site. Temperatures were recorded at 30-min intervals for 15 mo and plotted as mean daily temperatures.

Sampling Procedure. To examine small-scale intrasite variation in compound concentrations, two populations (A and B) approximately 100 m apart were chosen from each site to contain sponges of similar size and depth ranges. Ten whole sponges were sampled bimonthly for 15 mo (seven sampling periods) from each population (20 samples per site) from August 1999 to November 2000. The sponges were sampled *in situ*, bagged separately for chemical analysis, and the bedrock scraped clean to minimize the chance of resampling the same organism. The depth and size of each sponge collected were recorded. Depth was adjusted to mean sea level (±10 cm), and volume was estimated by using a ruler to measure height, width, and length similar to methods used in other studies e.g., Fell and Lewandrowski, 1981; Meroz and Ilan, 1995.

Taxonomic Identification. Representative subsamples were taken from the 20 sponges collected at each site during December 2000 to confirm taxonomic identity and to describe the morphological characteristics of populations at each site. Sponge tissue was paraffin-embedded and histologically sectioned for light microscopy and spicule mounts prepared for morphometric analysis of mega- and microsclere dimensions, according to the method described in Kelly-Borges and Vacelet (1995).

Extraction and Isolation. Approximately 15 g of each frozen *M. hentscheli* specimen were lyophilized (48 hr) to dryness and ground to a homogenous powder. Approximately 1.5 g of the dry, powdered, sponge material were weighed and extracted with 80% MeOH/H_2O (20 ml) and MeOH (20 ml). Both extracts were loaded onto a 1.0 × 2.0 cm Amberchrom® polystyrene–divinyl–benzene column by dilution with H_2O. The column was washed with H_2O (10 ml) and eluted with 55% Me_2CO/0.2 M NH_4OAc adjusted to pH 4.0 with AcOH (10 ml) into a flask containing 0.2 M NH_4OH (20 ml). The neutralized eluent was desalted on a second Amberchrom® column, and concentrated to dryness under reduced pressure.

^1H NMR Analysis and Quantification. 30 μl (1.8 μmol) of a standard solution of trimethoxybenzene (50 mg) in $CDCl_3$ (5 ml) and 500 μl of $CDCl_3$ were added to the dry concentrated sample. The resulting solution was sonicated (3 sec) in an ultrasonic bath and transferred to an NMR tube (5 mm).

One microliter of pyridine-d_5 was added to the solvent in the NMR tube as a buffer. A ^{1}H NMR spectrum was obtained on a Varian Inova® spectrometer at 300 MHz with the following acquisition and processing parameters: temperature 25°C/298.1 K, relax delay 15.0 sec, pulse width 90.0°, acquisition time 5.0 sec, 64 repetitions, line broadening 0.5 Hz, total time 21 min and 20 sec. The integrals of resonances at δ 7.49(1H), 5.88(2H), and 4.74(1H) of mycalamide A, δ 6.98 (1H), 6.81 (1H), and 6.31 (3H) of pateamine, and δ 4.53 (1H) of peloruside A were compared to the integral of the trimethoxybenzene resonance at δ 6.10 to determine the molar quantities of the three analytes. The concentration of mycalamide A, pateamine, and peloruside A was expressed in $\mu g\ g^{-1}$ dry weight sponge. Ten replications of the analytical protocol on a single homogenous dry sponge sample gave reproducibility of ±5%.

Data Analysis. A partially hierarchical (nested) three-factor mixed-model analysis of variance (ANOVA) was used to compare differences in concentration of each compound among populations within sites and between sites at different times of the year. The factors were time (fixed), site (fixed), and population (random) nested within site. All data were square root transformed prior to analysis, as variances proved heterogeneous in residual plots. Analysis of covariance (ANCOVA) was used to analyze relationships of compound concentrations with depth and volume. Metabolite concentrations over time are described, but not compared statistically with temperature. The GLM ANOVA and ANCOVA were run using SAS statistical software (SAS/STAT, 1990). Two sample Student's *t*-tests were used to test for significant differences in sponge volume between sites. A χ^2 test was used to compare observed with expected peloruside depth–frequency distributions at Capsize Point. The expected frequency of peloruside A occurrence for each depth category was expressed as a percent of the total number ($N = 137$) of sponges sampled for the compound at that site. *t*-Tests and χ^2 tests were computed using NCSS 97 (Hintze, 1997).

RESULTS

Ecological and Environmental Variables. Sponges were distributed between 3 and 15 m at Pelorus Sound and between 10 and 26 m at Kapiti Island, with the shallowest depth at both sites corresponding to the lower extent of the brown macrophytes *Carpophyllum flexuosum* and *Ecklonia radiata*. All sponge samples examined from Kapiti Island and Pelorus Sound conformed to the description of *M.* (*Carmia*) *hentscheli* (Bergquist and Fromont, 1988). Although there was no significant difference in mean volume among sponges at each site ($t_{180} = -0.84$, $P = 0.39$), morphology and spicule size differed. Pelorus sponges had a massive growth form, with thicker subtylostyles and spicule tracts cored

by substantially more nonspecific detritus than sand, whereas Kapiti sponges had an encrusting growth form with thin megascleres, characteristic of low silica content in oceanic waters. A greater abundance of microscopic epibionts were noted on and in each Kapiti sponge, including polychaetes, filamentous algae, a chain-forming diatom, and a hydroid-like filamentous organism that is also present in the holotype from Takatu Point, Northland. Fewer such associations were evident in the Pelorus Sound specimens, but the cellular mesophyl of Pelorus sponges was more grainy and pigmented.

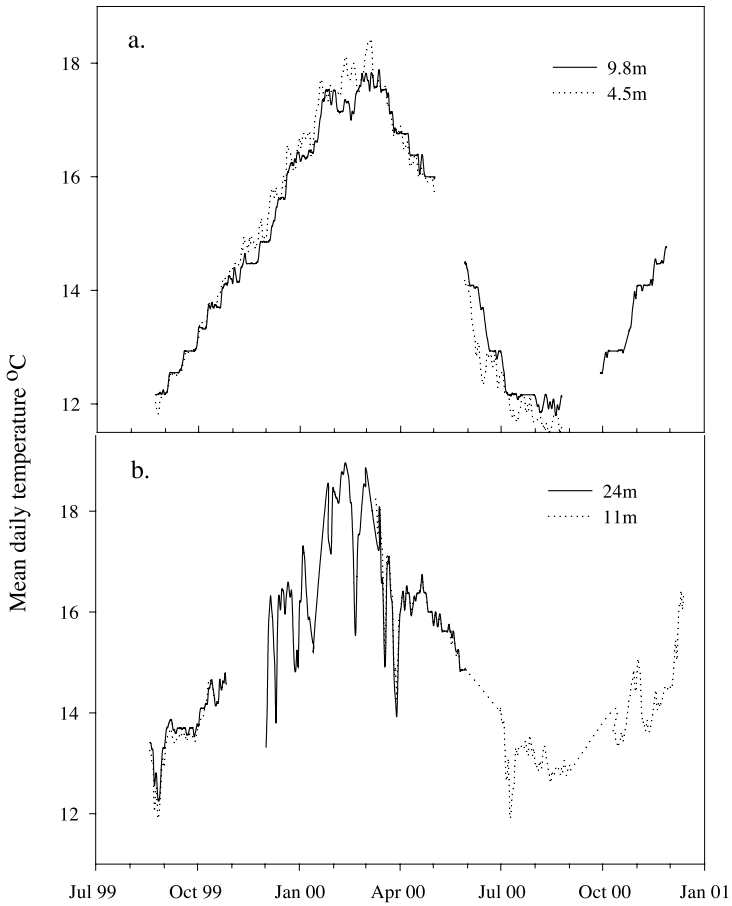

FIG. 3. Seasonal patterns in water temperature recorded by data loggers at the bottom and top extent of the depth range of *M. hentscheli* at each study site: (a) Pelorus Sound; (b) Kapiti Island.

Maximum water temperatures at both sites occurred during February–April 2000 and declined to a minimum in July–August 2000. Summer highs were similar at both sites (17.3 and 16.9°C); however, the water temperature at Pelorus was approximately 1.5°C cooler than at Kapiti Island during winter (Figure 3a and b). Temperature stratification occurred at Pelorus Sound during winter and summer (Figure 3a). Summer temperatures in shallow water were 1°C warmer than for deep water and the reverse occurred during winter.

No temperature stratification occurred at Kapiti Island (Figure 3a). Some data at Kapiti were not recovered due to lost or flooded loggers, although collectively the data showed large within-season variation in water temperatures that occurred at this site. Temperature in both seasons varied as much as ~3°C over 9 d. Both depths showed the same degree of change suggesting that water was well mixed during these events.

Spatial and Temporal Patterns

Mycalamide A. There were significant differences in the relative concentrations of mycalamide A among sites, but not among populations within sites (Table 1a). Concentrations were greater at Pelorus Sound (Figure 4a) than at Kapiti Island (Figure 4b), and differences among populations nested within sites varied over time [i.e., the population (site) × time interaction term was significant, Table 1a]. Generally, the highest concentrations of mycalamide A were recorded in sponges at Pelorus Sound during spring.

Pateamine. Kapiti Island sponges contained no pateamine throughout the study. At Pelorus Sound, however, pateamine was present in sponges, and rela-

Significance of the *F* ratio is abbreviated by $*P < 0.05$ and $***P < 0.001$. All data were square root transformed.

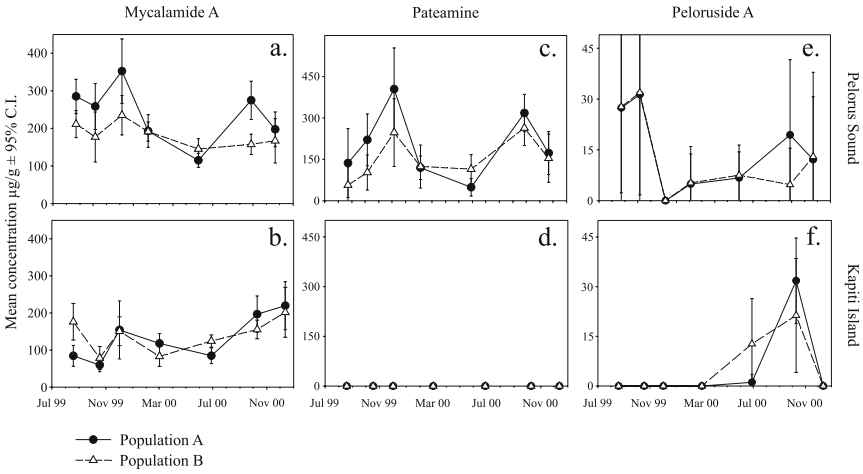

FIG. 4. Temporal patterns in mean concentration of three compounds contained in *M. hentscheli* sampled from two study sites. Circles and diamonds represent data from two populations sampled within each site (N = 10 whole sponges sampled from each population).

tive concentrations of the compound varied significantly over time, although differences among times were not consistent between the two populations within the site (Table 1b). Mean concentrations were greatest in spring, approximately two- to fourfold higher than in winter (Figure 4c). Patterns of change over time at Pelorus Sound were similar for pateamine and mycalamide A (Figure 4a and c).

Peloruside A. Relative concentrations of peloruside A varied significantly between sites, but were not consistent over time (Table 1a). In the first winter,

TABLE 1B. MEAN SQUARES AND F RATIOS FROM A TWO-FACTOR ANOVA (TYPE III SUMS OF SQUARES) OF THE EFFECT OF TIME OF YEAR AND POPULATION ON THE CONCENTRATION OF PATEAMINE IN *M. hentscheli* SPONGES

Source of variation	*df*	MS	Pateamine
Time	6	312.9	3.49**
Population	1	10.6	0.32
Time × Population	6	89.6	2.7*
Error	123	33.1	

Significance of the F ratio is abbreviated by *$P < 0.05$ and **$P < 0.01$. All data were square root transformed.

the compound was present at Pelorus Sound but not at Kapiti Island, but thereafter no clear differences between the two sites were apparent (Figure 4e and f). There was high variability among replicates at each combination of time and population; only a few sponges sampled within a population at any one time contained the compound. At Pelorus Sound, 23% ($N = 137$) of sponges sampled contained detectable amounts of the compound. Although highly variable, peloruside A concentrations appeared to be highest during spring.

Temperature, Volume, and Depth Relationships. At Pelorus Sound, metabolite concentrations increased as water temperatures rose during spring (Figure 4a, c, and e), but declined before temperatures peaked in summer (Figure 3). The timing of successive concentration maxima was not the same in consecutive

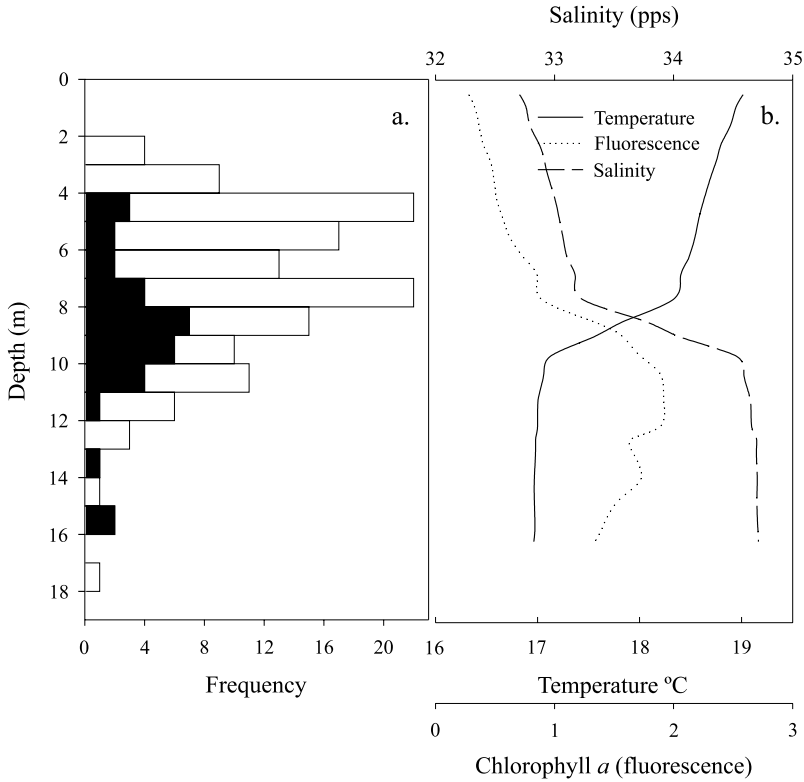

FIG. 5. (a) Frequency of sponges that contained detectable amounts of peloruside A in relation to depth at Pelorus Sound ($N = 137$): □ = total frequency of sponges sampled, ■ = frequency of sponges sampled containing peloruside A; and (b) a vertical temperature, chlorophyll *a* (fluorescence) and salinity profile from the Pelorus site taken on January 28, 2002.

years, nor was any seasonal pattern obvious at Kapiti Island where within-season temperatures were less stable.

There were significant relationships of square-root mycalamide A and peloruside A with volume in the ANCOVA, but these varied with time, i.e., high-order interactions occurred at the volume × population × time level for mycalamide A ($F_{18, 212} = 2.30$, $P = 0.003$), and peloruside A ($F_{18, 212} = 1.81$, $P = 0.025$).

Depth was not a significant covariate for mycalamide A, but there was a relationship with depth for pateamine that varied with time (depth × time, $F_{6, 109} = 2.51$, $P = 0.026$). There was also a highly significant relationship of peloruside A with depth, but this varied among populations at different times (depth × population × time, $F_{18, 219} = 4.45$, $P < 0.001$). Peloruside A at Pelorus Sound was most common in sponges at between 8 and 10 m depth (Figure 5a). No sponges collected above 4 m contained peloruside A, whereas 55% of sponges between 8 and 10 m contained the compound. However, there was no significant difference in the observed *versus* expected frequency of compound occurrence ($\chi^2_{15} = 20.6$, $0.2 > P > 0.1$). This apparent peloruside A maximum was coincident with the depth of the density boundary layer and chlorophyll *a* peak biomass at this site (Figure 5b).

DISCUSSION

The marked spatial and temporal variation in biologically active metabolites of the sponge *M. hentscheli*, as measured at two sites in central New Zealand, suggests that complex ecological and physical factors, largely undetected in this research, are operating within habitats to influence chemical variability in this species. Differences in morphology and chemistry of Pelorus Sound and Kapiti Island sponges may in part be explained by extremes in their physical environment; Kapiti Island represents a high-energy well-mixed coastal environment, whereas Pelorus Sound was a semiestuarine sheltered environment influenced by freshwater runoff. Variations in *M. hentscheli* compounds were, however, not directly correlated to water temperature, depth, or salinity.

Variations in the relative composition of the biologically active metabolites in *M. hentscheli* over time were site-specific. Compounds in sponges at the sheltered Pelorus Sound site were generally higher during spring and summer, and lower in winter. Duckworth (2000) described a similar seasonal pattern in toxicity of the New Zealand sponge *L. wellingtonensis*, suggesting that higher degrees of biochemical activity within the sponge in spring prevented fouling of the surface. Intraindividual cyclic variation in toxicity has also been described in the sponge *C. crambe*. High toxicity evident in the peripheral ectosome of

C. crambe during the boreal summer and autumn correlated with seasonal variation in competitors (Turon et al., 1996). The lack of obvious seasonal variation in *M. hentscheli* secondary metabolites at the exposed Kapiti Island site remains unexplained, and the duration of our study was too short to confirm that temporal variation in metabolite concentrations observed for sponges at Pelorus Sound has annual periodicity, and did not occur by chance alone. The temporal variations in metabolite concentrations observed could also be explained by seasonal changes in skeletal spicule mass relative to metabolite concentrations. However, the gravimetric assay is unlikely to have confounded the interpretation of seasonal patterns in *M. hentscheli*, because spicules in this species are sparse relative to tissue volume and are part of a skeleton that is identical in form in any part of the sponge, new or old growth (unpublished data).

Relatively few studies have documented depth-related variation in secondary metabolites within habitats. Harvell et al. (1993) recorded higher concentrations of diterpenes in deep colonies of the gorgonian *Briarium asbestinim*. Chanas and Pawlik (1997) suggest higher levels of chemical deterrence in deeper *Xestospongia muta* colonies are correlated to depth-specific differences in predation levels. Conversely, higher concentrations of diterpenes found in *Rhopaloides odorabile* in shallow, illuminated conditions may deter surface overgrowth by algae (Thompson et al., 1987). Our results suggest that although there is a complex relationship, depth may be an important factor for peloruside A production in *M. hentscheli* sponges in Pelorus Sound.

The ecological role of secondary metabolites in *M. hentscheli* is unknown. However, the variability of metabolite concentrations between sites and similar temporal patterns in populations within sites suggest that *M. hentscheli* sponges produce secondary metabolites in response to site-specific ecological factors, which have yet to be determined.

Aquaculture experiments on *M. hentscheli* explants transplanted into different environments (unpublished data) further support our hypothesis that the expression of biologically active compounds in this species is determined by site-specific environmental conditions. Therefore, if compounds from this species are of value to harvest then the biological factors triggering metabolite production, as well as seasonal and geographic patterns, need to be considered in the design of any aquaculture program.

Acknowledgments—We thank Pete Notman and Rob Keysers for field support under often trying conditions. Bruce Hartill, Mathew Smith, and Crispin Middleton and Michelle Wilkinson of NIWA Auckland contributed significantly to the taxonomic and morphometric analyses in this study. Many thanks to Drs. Vicky Webb and Alison MacDiarmid, NIWA Wellington, for discussion and comments, and Drs. Don Morrissey and Russell Cole for assistance with statistical interpretation. We also thank the anonymous reviewers for helping to improve our manuscript. This research was funded by Foundation for Science Research and Technology (FRST) research contracts CO1809 and COIX0207 with NIWA.

(Received May 27, 2003; accepted December 24, 2004)

Abstract—We analyzed phenolic compounds and other elements in leaf extracts and compared morphology of three species of the Phytolaccaceae family found in South Korea. To test allelochemical effects of the three *Phytolacca* species, we also examined seed germination and dry weight of seedlings of *Lactuca indica* and *Sonchus oleraceus* treated with leaf extracts. The concentrations of total phenolic compounds were exotic *Phytolacca esculenta* (3.9 mg/l), native *Phytolacca insularis* (4.4 mg/l), and exotic *Phytolacca americana* (10.2 mg/l). There was no significant difference in concentrations between *P. esculenta* and *P. insularis*, but the concentration of total phenolics in *P. americana* was two times higher than either *P. esculenta* or *P. insularis*. Analysis of aqueous extracts by HPLC showed seven phenolic compounds (gallic acid, protocatechuic acid, chlorogenic acid, caffeic acid, *m*-hydroxybenzoic acid, *ρ*-coumaric acid, and cinnamic acid). Total phenolics in *P. americana* were eight to 16 times higher than either *P. esculenta* or *P. insularis*, respectively. *P. americana* inhibited seed germination and dry weight of the two assay species. The phytotoxic effects of the two *Phytolacca* species were different, despite the fact that *P. esculenta* and *P. insularis* had similar levels of total phenolic compounds. We also found that *P. americana* had invaded Ullung Island, which suggested that *P. americana* had excellent adaptability to the environment. The three species of Phytolaccaceae in South Korea can be distinguished by their different allelopathic potentials and morphologies.

Key Words—Allelochemical effects, Phytolaccaceae, total phenolic compounds, seed germination, morphology.

INTRODUCTION

Many plants in the Phytolaccaceae are distributed throughout tropical and subtropical zones. Three species of Phytolaccaceae are found in South Korea: *Phytolacca esculenta*, *Phytolacca insularis*, and *Phytolacca americana* (Lee, 1985). Among these, *P. americana* is native to North America, but is distributed widely in Europe and Asia. It is a perennial weed in the central and southern provinces and Cheju Island. Since 1993, it has become an invasive exotic in South Korea and is threatening native species (Lee et al., 1997; Han et al., 1998; Kim et al., 2000), especially in polluted areas (Park, 1995a; Park et al., 1999). *P. insularis* is native to Ullung Island, and *P. esculenta* is native to China, but occurs rarely in the central province including Cheju Island in South Korea (Lee, 1985; Park, 1995b). There have been several reports of the role of allelopathy in exotic plant invasions and its defense against the spread of invaders to maintain biodiversity of natural systems, community structure, and ecosystem function (Callaway and Aschehoug, 2000; Keane and Crawley, 2002; Kennedy et al., 2002; Bais et al., 2003; Vila and Weiner, 2004). Little is known about the Phytolaccaceae except for a few papers dealing with the invasive threat of *P. americana* in South Korea (Han et al., 1998; Kim et al., 2000). Researchers in South Korea have claimed that *P. esculenta* and *P. insularis* are not morphology distinct, although their distributions are limited to different areas. The opinion of researchers is that *P. insularis* is the same species as *P. esculenta* and that there are no native species of Phytolaccaceae in South Korea. To address this issue, morphological and chemical analyses of these three species were conducted.

Allelopathy is an ecological mechanism operating in natural and managed ecosystems. In competition between exotic and native species, exotic species that produce large amounts of allelochemicals effectively repel other species, and their ability to invade plant communities increases (Pellissier, 1993; Inderjit and Dakshini, 1998; Kim et al., unpublished). There are many secondary metabolites that act as plant allelochemicals including phenolic, terpenoid, flavonoid, and alkaloids. Among these, phenolic compounds are the most abundant under field conditions and are known to affect seed germination, seedling growth, cell division, and fungal activity (Lodhi, 1976; Bhowmik and Doll, 1984; Rice, 1984, 1995; Inderjit, 2003; Kim et al., 2000).

Recently, phenolic-induced oxidative damage was found to be mediated by aluminum (Sakihama and Yamasaki, 2002) and that accumulation of such metals occurs by conjugation with phenolic compounds in various plant organs (Santiago et al., 2000; Lavid et al., 2001). Under field conditions, phenolics interfere with the growth and establishment of competing plant species by releasing water-soluble compounds into the soil. Furthermore, extracts of *P. americana* inhibit seed germination, seedling growth, and exhibit antifungal activity at low concentrations (Lee et al., 1997; Kim et al., 2000).

Phenolic compounds were not studied in the context of physiological responses associated with this family. Therefore the goal of this study was to characterize the three species located in different environments by comparing physioecology of allelochemical effects, heavy-metal accumulation, and morphology in South Korea. The objectives of the present study were to (1) determine the effect of the leaf extracts of Phytolaccaceae (*P. esculenta*, *P. insularis*, and *P. americana*) on seed germination and seedling dry weight of *Sonchus oleraceus* and *Lactuca indica* and (2) differentiate species of Phytolaccaceae according to morphology, phenolic compounds, and allelochemical effect.

METHODS AND MATERIALS

Study Areas. We examined the bioassay of seed germination and seedling growth with the extract of roots, leaves, fruits, and stems. Leaf extract had the strongest effect among these, so we used leaf extracts in this experiment. Plant extracts were made from fresh leaves of 10 individual plants per species (*P. esculenta* V. Houtte, *P. insularis* Nakai, and *P. americana* L.). Leaves were collected from Youngdong (36°10′N, 127°46′E) in Chungcheong Province (*P. esculenta*), Dodong, Ullung Island (37°28′N, 130°54′E) in Kyungpook Province (*P. insularis*), and Suwon (37°16′N, 127°00′E) in Gyeonggi Province (*P. americana*), South Korea, in August 2001. Seeds of *S. oleraceus* L. and *L. indica* Hara were collected in October and November 2000 from old fields in Seoul, South Korea (37°30′N, 127°12′E), and were used for the seed germination bioassay. Youngdong (*P. esculenta*) and Dondong (*P. insularis*) sites are located on rural hillsides with less anthropogenic pollutants. On the other hand, Suwon (*P. americana*) site is at a recently developed suburban hillside, influenced by heavy vehicle traffic. The climate is temperate, with four distinct seasons. June, July, and August, corresponding to the summer season, account for more than half of the total annual rainfall.

Analysis of Phenolic Compounds and Heavy Metals. Chemical standards used for analysis of phenolic compounds were purchased from Sigma Chemical Co. Two hundred grams of fresh leaves of Phytolaccaceae (*P. esculenta*, *P. insularis*, and *P. americana*) were extracted with 1-l distilled water at room temperature for 48 hr and then centrifuged at 15,000 rpm for 30 min (Centrikon T-1045, Kontron Co.). The supernatant was collected and stored at 4°C until used for bioassay and analysis. Phenolic compounds were purified from water extracts by adding 10 ml of saturated NaCl to 40 ml of aqueous extract in a funnel. The pH was adjusted to pH 2 with 1 N HCl. After adding 20 ml of 5% $NaHCO_3$ and mixing, we collected the $NaHCO_3$ solution. This was adjusted to pH 2 with HCl and mixed with 20 ml of ether. After mixing, the ether layer was evaporated under reduced pressure with a rotary evaporator. The residue was

dissolved into 5 ml of acetonitrile. Individual phenolics were analyzed by HPLC (Hewlett Packard Series 1050, USA), with diode-array detection (250, 254, 284 nm). Twenty microliters of extract was injected onto a μBonda-Pak C18 Radial Pak (0.8 × 10 m) column, with a mobile phase of acetonitrile and 0.02 M sodium acetate (pH 4.3) and a flow rate of 1.3 ml/min. Total phenolics were measured using the Folin-Ciocalteu phenol reagent (Swain and Hillis, 1959). Leaf extracts were analyzed for elements B, Al, Co, Cd, Cu, Fe, Mn, Ni, Pb, and As (Agricultural Improving Institute, 1988).

Morphological Comparison of Phytolaccaceae. The morphology of Phytolaccaceae was observed by anatomy microscope (36, EPT, 160T). The anther of *P. esculenta* was observed at 2.5 × 50 and the flower and the fruit at 2.5 × 8.5. The anther of *P. insularis* was observed at 2.5 × 25 and the flower and the fruit at 2.5 × 10, and the anther of *P. americana* at 2.5 × 30 and the flower and the fruit at 2.5 × 10. Those were compared between Phytolaccaceae. Photographs were taken using a Nikon F801 camera, using T-MAX 100 Kodak film (Phillips et al., 2000).

Seed Germination and Seedling Bioassay. Leaf extracts were filtered through Whatman No. 1 filter paper and then diluted to concentrations of 0, 12.5, 25, 50, 75, and 100% for bioassay. After being selected for uniform size, seeds from *S. oleraceus* and *L. indica* were sterilized for 3 min in a solution of 5% sodium hypochlorite and then rinsed with distilled water. Thirty seeds were sown in a Petri dish (diam 90 mm) on filter paper treated with leaf extract solution. The bioassay was repeated four times in a growth chamber set at a constant temperature of 26°C and 80% relative humidity, with an alternating photoperiod of 12 hr light/12 hr dark for 10 days. The germination percentage

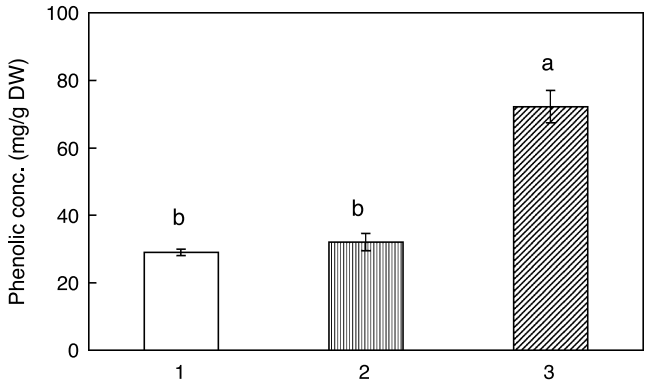

FIG. 1. Comparison of total phenolic compounds from leaf extracts of (1) *P. esculenta*, (2) *P. insularis*, (3) *P. americana*. Means (±SE, $N = 5$) with the same letter are not significantly different (Duncan's multiple range test, $P < 0.001$).

and dry weight for each seedling were measured at each concentration of extract. Seed germination was assessed daily, whereas the dry weight of seedlings was measured after 1 wk. This bioassay was modified from Lodhi (1976).

Statistical Analysis. The data were normally distributed, and significant differences at $P < 0.001$ between the total phenolic compound, treatments, and controls of the bioassay were calculated using Duncan's multiple-range test (SAS Institute 2000, Figures 1 and 4).

RESULTS

Among the species examined, *P. americana* had the highest total phenolic concentrations at 72.2 mg/l, whereas *P. esculenta* and *P. insularis* had concentrations of 29.0 and 32.1 mg/l, respectively (Figure 1, $P < 0.001$). Seven phenolic compounds were identified by HPLC analysis of Phytolaccaceae extracts: gallic acid, protocatechuic acid, chlorogenic acid, caffeic acid, *m*-hydroxybenzoic acid, *ρ*-coumaric acid, and cinnamic acid. Chlorogenic acid in *P. esculenta* and *P. americana* exhibited the highest concentration, whereas *P. insularis* appeared to have none. A small concentration of *m*-hydroxybenzoic acid appeared in *P. esculenta*, but not in *P. americana* and *P. insularis*. An unknown peak was present at Rt = 5.5 min in *P. esculenta* and *P. insularis* that was not observed in *P. americana*. Another unknown peak was observed at 14.5 min in *P. esculenta* that was not present in either *P. insularis* or *P. americana* (Figure 2).

Most of the elements (B, Al, Mn, Ni, Cu, Zn, As, Cd, Pb, except Fe) were found about 3–16 times more concentrated in the leaves of *P. americana* than those of *P. esculenta* and *P. insularis*, respectively (Table 1).

Fruit from the three Phytolacca species had different characteristics. The fruit of *P. esculenta* was berry-like with the ovary separated into eight cells. The number of stamens was eight, the anther was pink, and the stem was pale green (Figure 3A). The fruit of *P. insularis* was also berry-like, the number of stamens was eight, the anther was white, and the stem was green (Figure 3B). The fruit of *P. americana* was spherical, the number of stamens was 10, the anther was white, and the stem was green and reddish (Figure 3C).

Seed germination and dry weight of *S. oleraceus* and *L. indica* were inhibited with increasing concentrations of Phytolaccaceae extract (Figure 4). Germination rates of the two species were greatly reduced in the leaf extracts of *P. americana* in comparison to *P. insularis* and *P. esculenta*, and were slightly stimulated by 12.5 and 25% concentration of *P. insularis* and *P. esculenta* (Figure 4A and C), respectively. The dry weights of *S. oleraceus* and *L. indica* were similar to the germination result, but the dry weights of *S. oleraceus* were slightly stimulated by 12.5–75% leaf extracts of *P. insularis* and *P. esculenta* (Figure 4B). *L. indica* seedling dry weight was stimulated by 12.5–75% of

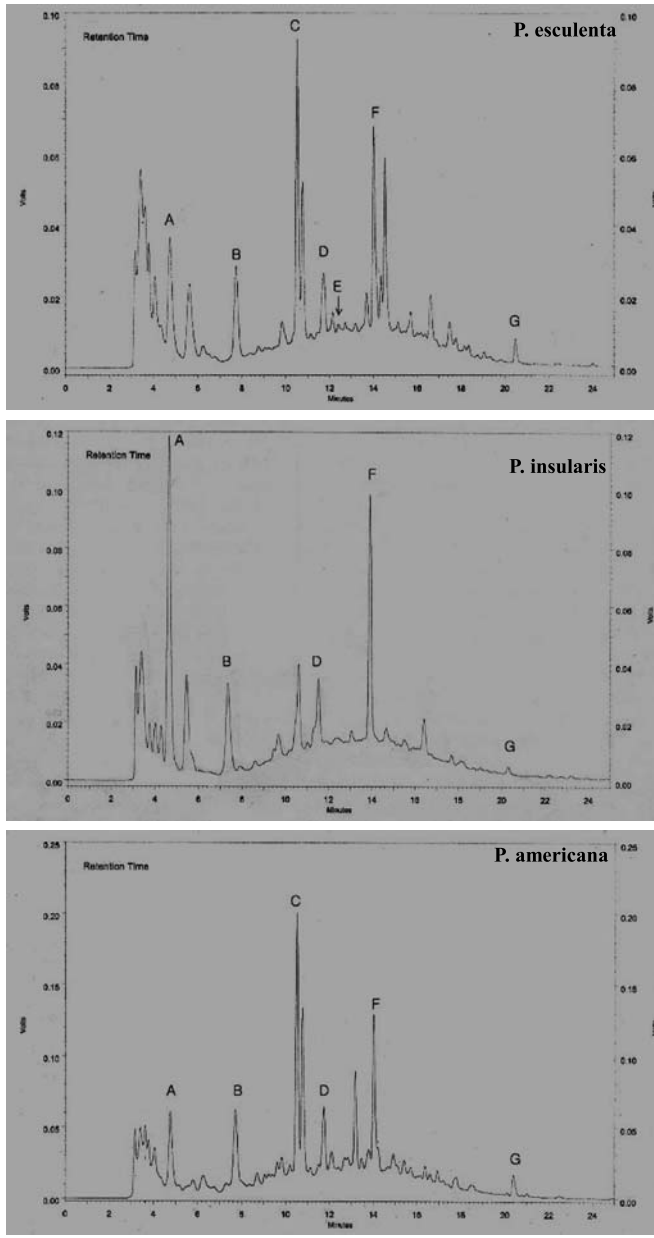

FIG. 2. Analysis of phenolic compounds in leaf extracts of *P. esculenta* (1), *P. insularis* (2), and *P. americana* (3) by HPLC. Identified phenolics are (A) gallic acid, (B) protocatechic acid, (C) chlorogenic acid, (D) caffeic acid, (E) *m*-hydroxybenzoic acid, (F) ρ-coumaric acid, and (G) cinnamic acid.

TABLE 1. HEAVY METAL AND NUTRIENT CONCENTRATIONS OF *Phytolacca* LEAF EXTRACT

	P. esculenta (mg/l)	*P. insularis* (mg/l)	*P. americana* (mg/l)
B	0.39	0.31	**0.81**
Al	1.49	1.32	**35.99**
Mn	8.11	0.42	**66.33**
Fe	2.80	**4.00**	2.32
Ni	0.0	0.0	**0.04**
Cu	0.04	0.03	**0.25**
Zn	0.72	0.05	**3.49**
As	0.04	0.04	**0.20**
Cd	0.0	0.0	**0.01**
Pb	0.0	0.0	**0.02**
Total	**13.59**	**6.17**	**109.46**

Highest concentrations of each element are in bold.

P. insularis (Figure 4D). Leaf extracts of the three species were significantly different (Figure 4, $P < 0.001$). Seed germination of *P. americana* was little affected by extracts of *P. americana* (data not shown).

DISCUSSION

Phenolic compounds have been studied as candidate allelochemicals because they are water-soluble and can complex with ions in the soil (Rice, 1984; Appel, 1993). *P. esculenta* and *P. americana* are exotic species, whereas *P. insularis* is the only native species of the Phytolaccaceae distributed in South Korea. *P. americana* is widely distributed not only in polluted areas, but also occurs in fields throughout South Korea, whereas the distribution of *P. esculenta* and *P. insularis* is limited and is decreasing in South Korea (Lee, 1985; Park, 1995a; Park et al., 1999). This phenomenon may be explained by total leaf phenolic concentration shown in the present study. *P. americana* had a much higher total phenolic concentration (72.18 mg/l) than those of either *P. esculenta* (29.04 mg/l) or *P. insularis* (32.08 mg/l) (Figure 1). The phenolic compounds in leaf extracts of *P. americana* were found to inhibit growth of 35 plant species and nine fungal species (Kim et al., 2000). The quantity and chemical nature of phenolics have important effects on the distribution of plant species and a plastic response that contributes to survival in adverse environmental conditions (Del Moral, 1972; Inderjit and Dakshini, 1998). Wu et al. (1998) isolated 14 phenolic compounds from *Buchloe dactyloides* with the most abundant phenolic compounds being salicylic and cinnamic acids. Among seven phenolic compounds analyzed, chlorogenic acid was the most abundant compound in the exotic species, *P. americana* and *P. esculenta*, whereas the

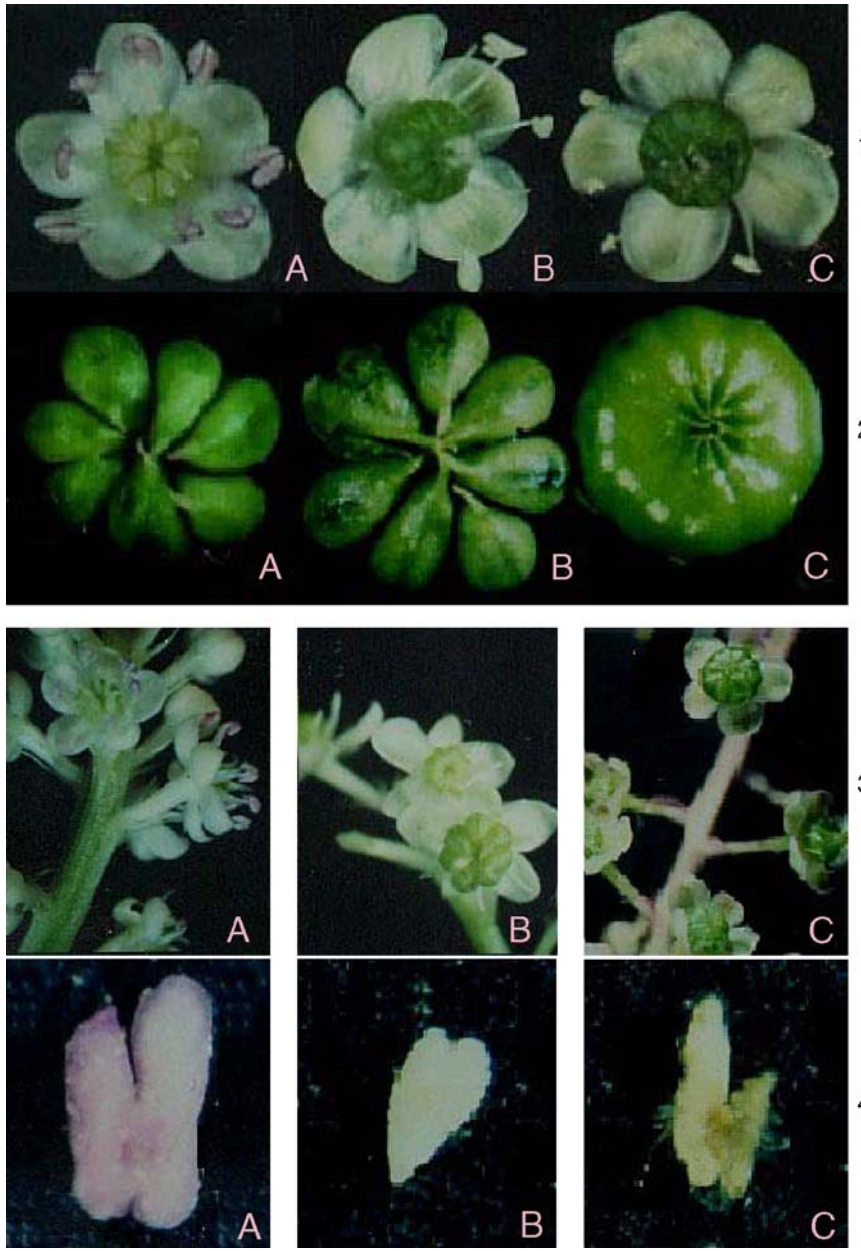

FIG. 3. Morphological comparison of flowers (1), fruits (2), stems and flowers (3), and anthers (4) on *P. esculenta* (A), *P. insularis* (B), and *P. americana* (C).

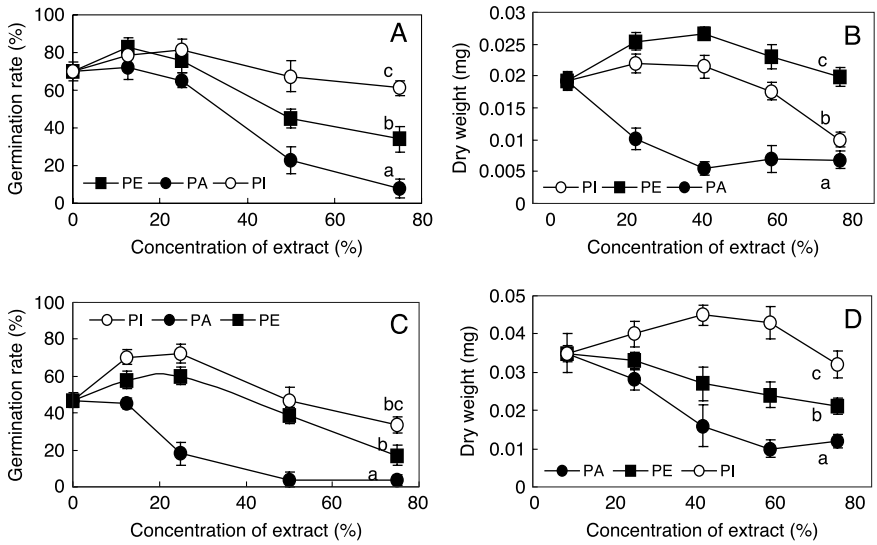

FIG. 4. Effect of the leaf extracts of *Phytolaccaceae* (PA: *P. americana*, PE: *P. esculenta*, PI: *P. insularis*) on seed germination and dry weight of *S. oleraceus* (A and B) and *L. indica* (C and D). Means (±SE, $N = 3$) with the same letter are not significantly different (Duncan's multiple range test, $P < 0.001$).

native species, *P. insularis*, had none (Figure 2). Therefore chlorogenic acid appears to be a candidate phenolic compound that could be used to differentiate between *P. esculenta* and *P. insularis*. Chlorogenic acid is derived from phenylalanine or tyrosine through the shikimic acid pathway and is more widespread in higher plants (Neish, 1964; Rice, 1984). In analysis of phenolic compounds from several plants, the unknown compounds in Figure 2 with Rt = 3.8, 5.5, and 14.5 min were identified as ρ-hydroquinone, gentistic acid, and scopoletin, respectively (Kim et al., 2000; Lee et al., 1997).

P. americana accumulates high concentrations of elements primarily in the leaves, whereas *P. esculenta* and *P. insularis* had lower concentrations (Table 1). Sakihama and Yamasaki (2002) reported that Al, Zn, Mn, and Cd stimulated phenoxyl radical-induced lipid peroxidation. The element concentrations in *P. americana*, especially Al and Mn, were higher than in *P. esculenta* or *P. insularis* (Table 1). *Ruta graveolens* treated with a mixture of Ni, Cu, Co, Cr, Cd, and Pb exhibited both qualitative and quantitative differences in phenolic concentration (Zobel et al., 1999), and phytoremediation plants in field accumulated high concentrations of metals in their foliage (Baker and Brooks, 1989; Raskin et al., 1997). Therefore, the accumulation of elements in the leaves of *P. americana* may be related to the high total phenolic concentration

that was observed in the leaves and may account for the species distribution. *P. americana* is widely distributed in polluted areas throughout South Korea, and its distribution has been correlated with absorption of heavy metals from polluted soil (Park, 1995a; Park et al., 1999).

Lee (1985) and Park (1995b) reported that the only difference between *P. esculenta* and *P. insularis* was the color of the anther. We found that the anther color of *P. esculenta* was pink and *P. insularis* was white and yellow (Figure 3A and B). *P. americana* showed different fruit, flower, stem, and anther color (Figure 3C). Recently *P. americana* has been found around Dodong on Ullung Island, which is visited by many people. This suggests that *P. americana* has invaded Ullung Island, possibly as a result of its high total leaf phenolic concentration and its ability to adapt to this environment. This invasion may threaten the distribution of *P. insularis*, the native species present on the island.

Allelopathic effects typically are the result of an interaction of a mixture of compounds rather than due to a single compound (Veronneau et al., 1997; Inderjit, 2003). Under field conditions, additive or synergistic effects among allelochemicals become more influential, especially at low concentrations (Dalton, 1989; Einhellig, 1995). Thus, we investigated the seed germination and dry weight of *S. oleraceus* and *L. indica* to test physiological effects of leaf extracts. The seed germination and dry weights of *S. oleraceus* and *L. indica* were dramatically inhibited by increasing concentration of *P. americana* extracts. The phytotoxic effects of *P. esculenta* and *P. insularis* were significantly different, although they had similar levels of total phenolic compounds (Figures 1, 2, and 4). We also investigated self-limiting phytotoxic compounds in *P. americana* to confirm if *P. americana* had self-constraining effects on its own seed germination and seedling growth. Seed germination of *P. americana* was little affected by extracts of *P. americana* (data not shown). Consequently, the extract of *P. americana* may decrease the invasiveness of neighbor species more than those of *P. insularis* and *P. esculenta* ensuring survival of their offspring. The phenolic compounds found in leaf extracts have been reported to reduce seed germination, seedling growth, and dry weight (Einhellig, 1995; Inderjit, 2003) as shown in the present study (Figure 4). Since 1993, *P. americana* has become a threat to native species in South Korea (Han et al., 1998; Park et al., 1999; Kim et al., 2000). The overall pattern of seed germination inhibition by leaf extracts containing phenolic compounds corresponds with the findings of previous studies (Pellissier, 1993; Lydon et al., 1997). Species containing abundant phenolic compounds strongly suppressed seed germination of other species. In our study, seedling growth and dry weight was slightly stimulated by 12.5–25% concentration of *P. insularis* and *P. esculenta* extract, but not with *P. americana* extract. Similarly, seed germination is stimulated by low concentrations of phenolic compounds (Heisey, 1990; Inderjit and Dakshini, 1998). Our results showed that *P. americana* also has abundant phenolic com-

pounds that inhibit seed germination and seedling biomass. We suggest that *P. americana* is a successful invader of existing plant communities and may be able to expand its habitats by employing foliar allelochemicals. We also predict that *P. americana* is more adaptable than *P. insularis* and *P. esculenta* to environmental changes through the production of self-defense allelochemicals. Therefore, we need to protect *P. insularis* and *P. esculenta* from *P. americana* to maintain species diversity in South Korea.

(Received September 5, 2004; accepted January 19, 2005)

Abstract—*Salvia leucophylla*, a shrub observed in coastal south California, produces several volatile monoterpenoids (camphor, 1,8-cineole, β-pinene, α-pinene, and camphene) that potentially act as allelochemicals. The effects of these were examined using *Brassica campestris* as the test plant. Camphor, 1,8-cineole, and β-pinene inhibited germination of *B. campestris* seeds at high concentrations, whereas α-pinene and camphene did not. Root growth was inhibited by all five monoterpenoids in a dose-dependent manner, but hypocotyl growth was largely unaffected. The monoterpenoids did not alter the sizes of matured cells in either hypocotyls or roots, indicating that cell expansion is relatively insensitive to these compounds. They did not decrease the mitotic index in the shoot apical region, but specifically lowered mitotic index in the root apical meristem. Moreover, morphological and biochemical analyses on the incorporation of 5-bromo-2′-deoxyuridine into DNA demonstrated that the monoterpenoids inhibit both cell-nuclear and organelle DNA synthesis in the root apical meristem. These results suggest that the monoterpenoids produced by *S. leucophylla* could interfere with the growth of other

plants in its vicinity through inhibition of cell proliferation in the root apical meristem.

Key Words—Allelopathy, *Brassica campestris*, BrdU, camphor, 1,8-cineole, α-pinene, β-pinene, camphene, DNA synthesis, *Salvia leucophylla*, terpenoid, volatile growth inhibitor.

INTRODUCTION

The term "allelopathy" was first used by Molisch (1937) to define the phenomenon that one plant species (donor plant) releases chemicals into the environment and thereby affects the growth and development of other plants. In most cases, however, it remains unclear to what extent allelopathy plays a role in determining the superiority of a plant in natural plant communities because other interfering mechanisms (such as resource competition) may also operate simultaneously.

One of the best known and well-studied examples of allelopathy is the "*Salvia* phenomenon" (Müller et al., 1964). *Salvia leucophylla* is a shrub observed in coastal south California with its Mediterranean climate. It forms soft chaparral vegetation adjacent to areas of annual grassland, showing a characteristic vegetation patterning: annual grasses and forbs are excluded from the interior of the shrub thickets, and the thickets are frequently surrounded by areas of bare soil without grasses, extending 1–2 m beyond the crowns of the shrubs. The third to sixth meters beyond the shrub bear dense, but stunted herbage, and this inhibited vegetation gradually merges with normal grassland 6–10 m beyond the shrubs. The possible involvement of various factors other than allelopathy (for example, activity of small animals, edaphic factors, shading, nutritional conditions, salinity stress, and soil moisture) in this characteristic vegetation patterning was carefully examined and excluded (Müller, 1970, but also see Halligan, 1975).

Because the distance between shrub and inhibited herbs was beyond the lateral spread of the shrub system or crown, the involvement of volatile growth inhibitor(s) was suspected. Five volatile monoterpenoids (camphor, 1,8-cineole, β-pinene, α-pinene, and camphene) were found in *Salvia* leaves (Figure 1), and two of them (camphor and 1,8-cineole) were detected in the air around *Salvia* thickets (Müller, 1965). When added in pure reagent form, these volatile chemicals exhibit inhibitory effects on the seedling growth of test plants; camphor and cineole were most toxic (Müller and Müller, 1964). Müller (1970) also pointed out the importance of the soil as a reservoir of monoterpenoids because soil exposed to vapors from macerated *Salvia* leaves became toxic, and three monoterpenoids (camphor, cineole, and camphene) were detected in soil around *Salvia* shrubs. These results indicate that *S. leucophylla* produces and

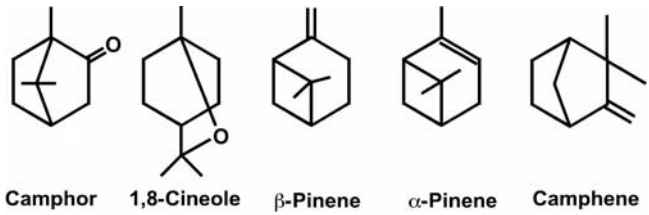

FIG. 1. Structures of monoterpenoids used in this study.

releases monoterpenoids, which adsorb to the soil in its vicinity and inhibit the growth of other plants, resulting in the characteristic vegetation patterning. However, the mode and mechanisms are not fully understood.

Koitabashi et al. (1997) examined the effects of 1,8-cineole on *Brassica campestris*, which was chosen as a test plant because of its rapid seed germination and uniform seedling growth. 1,8-Cineole inhibited growth of *B. campestris* seedlings in a dose-dependent manner, and its inhibitory effects were more severe on root than on hypocotyl growth. Treatment with 1,8-cineole decreased the mitotic index in the root apical meristem. Moreover, indirect immunofluorescence microscopy using an antibody raised against BrdU (a thymidine analog) revealed that treatment with 1,8-cineole decreased cell-nuclear and organelle DNA synthesis activities in root apical meristem. These results suggest that 1,8-cineole may interfere with the growth of other plant species by inhibiting DNA synthesis in the root apical meristem.

In the present study, the effects of five monoterpenoids produced by *S. leucophylla* on the germination and seedling growth of *B. campestris* were examined. The results demonstrated that each of them could act as a growth inhibitor, showing preferential inhibition of root growth. Quantitative analyses of the effects on cell expansion and cell proliferation revealed that they preferentially inhibit cell proliferation in the root apical meristem.

METHODS AND MATERIALS

Plant Material, Chemicals, and Treatment with Monoterpenoids. B. campestris L. var. *lacinifolia* (Bailey) Kitam. Seeds were purchased from Sakata Co., Ltd. (Yokohama, Japan). Seeds were soaked with 8 ml of deionized water on two layers of filter paper wad (Whatman No. 3, diam 55 mm) in transparent, airtight containers (4 cm diam $\times$ 6 cm high, 230 ml, 20 seeds per container) and incubated at 25°C under continuous illumination (80 μmol m^{-2} sec^{-1}). Monoterpenoids (camphor, 1,8-cineole, β-pinene, α-pinene, and camphene) were purchased from Aldrich (Wisconsin, USA). Camphor and

camphene, which are solid at room temperature, were dissolved in dimethylsulfoxide (DMSO) to give final concentrations of 1 M. The monoterpenoids were spotted onto a piece of filter paper (3.5 × 6 cm) hanging from the cap of the container and allowed to volatilize into the airspace within the container (Koitabashi et al., 1997). Concentrations in the airspace within the container were calculated assuming that the spotted compounds volatilize completely without any loss due to adsorption or leakage.

Measurement of Seedling and Cell Sizes. The lengths of hypocotyls and primary roots were measured with calipers. Only individual seeds that successfully germinated were used. For determination of cell size, root tips (5 mm long) and hypocotyls (full length) were excised from 4-day-old seedlings, fixed in an ethanol/acetic acid (9:1) solution overnight, followed by a washing in 90, 70, 50, and 30% ethanol, respectively, and were cleared with a chloral hydrate/glycerol/water solution (8:1:2, w/v/v) as described by Yadegari et al. (1994). Cells were observed under a microscope (BX-60, Olympus, Tokyo, Japan) equipped with Nomarski optics. Cortex cells at the root-hair-forming region of the primary roots and the epidermal cells at the middle region of the hypocotyls were chosen for determination of matured cell sizes. Photographs were taken using Neopan F black and white film (Fuji Film, Tokyo, Japan).

Frozen Sectioning and DAPI-Fluorescence Microscopy. Samples (root tips from 2-day-old seedlings or hypocotyls from 3-day-old seedlings) were fixed with formalin/acetic acid/50% ethanol (FAA, 1:1:18, v/v/v) for at least 12 hr. After fixation, samples were rinsed with 0.1 M sodium phosphate buffer (pH 7.0), dialyzed against 0.1 M sodium phosphate buffer containing increasing concentrations of sucrose (10, 20, and 30%, respectively), immersed in compound for frozen sectioning (O.T.C. Compound, Sakura Finetech, USA), and quickly frozen with liquid nitrogen. Frozen sections (7 μm thick) were prepared using a cryostat (OTE Cryostat, Bright, UK) at −26°C, mounted on gelatin-coated slides, and air-dried as previously described (Tamotsu et al., 1994). Sections on the slides were washed twice (10 min each) with PBS (100 mM sodium phosphate, pH 7.2, 150 mM NaCl), stained with staining solution [1 μg ml^{-1} 4′,6-diamidino-2-phenylindole (DAPI), 12.5% glycerol, 10 mM Tris–HCl, pH 7.6, 0.25 mM EDTA, 3.5 mM β-mercaptoethanol, 0.6 mM spermidine, 0.5% *n*-propylgalate], and the percentages of the cells in mitotic phase were counted using a fluorescence microscope (BX-60, Olympus).

BrdU Labeling and Indirect Immunofluorescence Microscopy with Anti-BrdU Antibody. Labeling of root tip cells with BrdU and indirect immunofluorescence microscopy with anti-BrdU antibody were performed essentially according to Koitabashi et al. (1997). *B. campestris* seedlings were labeled for 12 hr (from 36 to 48 hr after sowing) in the dark with 10 μM 5-bromo-2′-deoxyuridine (BrdU, a thymidine analog) supplemented with 1 μM 5-fluorodeoxyuridine (FldU) to improve labeling efficiency. The root tips (3 mm

long) were excised, fixed with 4% paraformaldehyde, dissolved in sodium cacodylate buffer (pH 7.4), and embedded in Technovit 7100 resin (Kulzer, Wehrheim, Germany) as described by Kuroiwa et al. (1990). Thin sections (1 μm thick) were cut with a glass knife on an ultramicrotome (MT-1, Sorvall, USA), expanded on water drops on a coverslip, and attached onto the coverslip by drying. The samples on the coverslip were first treated with anti-BrdU monoclonal antibody (Becton Dickinson Immunocytometry Systems, California, USA) and then with fluorescein isothiocyanate (FITC)-conjugated second antibody (goat anti-mouse IgGs, Tago, California, USA), and finally counterstained with DAPI, as described previously (Suzuki et al., 1992). The double-stained sections were examined under a fluorescence microscope (BX-60, Olympus). Localization of DNA was visualized as blue-white fluorescence of DAPI under UV excitation, whereas that of BrdU residue incorporated into newly synthesized DNA was visualized as yellowish-green fluorescence of FITC under blue-light excitation. Photographs were taken using color reversal films (Fuji chrome Provia 400, Fuji Film).

Immunodetection Analysis for Measuring DNA Synthesis Activities. To measure the total DNA synthesis activity in the root apical meristem, *B. campestris* seedlings were labeled for 12 hr (from 36 to 48 hr after sowing) in the dark with labeling solution (10 μM BrdU, 1 μM FldU), as described above. Approximately 40 root tips (1 mm long) were excised and collected in a 1.5-ml sampling tube, frozen with liquid nitrogen, ground into powder using a handmade microhomogenizer, dissolved in 125 μl of extraction buffer (50 mM Tris–HCl, pH 8.0, 100 mM EDTA, 300 mM NaCl, 4% SDS, 2% Sarkosyl), and incubated for 5 min at 65°C. Following phenol/chloroform extraction and chloroform extraction, the organic phases were successively re-extracted with 125 μl of HTE (50 mM Tris–HCl, pH 8.0, 20 mM EDTA), and the aqueous phases were combined (total 250 μl). After 5 μg of yeast tRNA was added to the combined aqueous phase, whole DNAs were precipitated with isopropanol and dissolved in 40 μl of TE (10 mM Tris–HCl, pH 8.0, 1 mM EDTA). Concentrations of DNA were determined fluorimetrically using DyNA Quant (Amersham Biosciences, New Jersey, USA). The DNAs were dot-blotted (500 ng DNA/dot) onto nitrocellulose filters (Trans-blot, Bio-Rad, California, USA) using Dot-blot apparatus (Bio-Rad). The BrdU incorporated into DNA was detected with anti-BrdU monoclonal antibody (Becton Dickinson Immunocytometry Systems) using horseradish peroxidase (HRP)-conjugated second antibody (goat anti-mouse IgGs, Cappel, Ohio, USA) and a SuperSignal Substrate Western Blotting Kit (Pierce, Illinois, USA). To compensate for the minor differences in the DNA content of the samples, quantitative Southern blot hybridization was performed. Aliquots of the samples (approximately 20 ng DNA) were electrophoresed in an agarose gel, capillary-blotted onto nylon membrane (Biodine B, Pall, New York, USA), and hybridized with cloned

DNA fragment containing cytoplasmic 26S and 18S rRNA genes from rice (Sano and Sano, 1990) to detect and quantify the amount of cell-nuclear DNA. Detection of the hybridization signals was performed using Alkphos Direct (Amersham Biosciences). In both immunodetection and Southern hybridization experiments, standard curves were generated by blotting a dilution series of a sample. The signal intensities on the X-ray films (X-OMAT AR, Kodak) were measured with a densitometer (Densitograph AE, ATTO, Tokyo, Japan).

RESULTS

Effects of Volatile Monoterpenoids on Growth of B. campestris Seedlings. In the absence of volatile monoterpenoids, seed germination and seedling growth

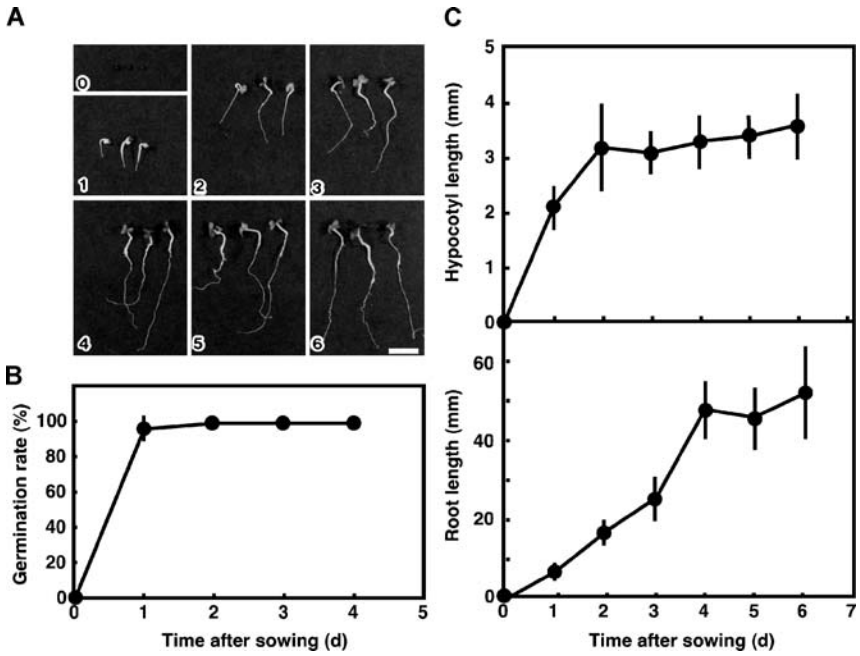

FIG. 2. Germination and seedling growth of *B. campestris* in the absence of monoterpenoids. (A) Photographs of the seeds or seedlings. Numbers represent the days after sowing. Scale bar = 5 mm. (B) Germination rate. (C) Hypocotyl and root lengths. In (B) and (C), average values from nine experiments (180 individuals) are shown. Vertical bars represent standard deviations.

of *B. campestris* proceeded rapidly and synchronously under our experimental conditions (Figure 2). Almost 100% germination was achieved within only 2 days after sowing. Hypocotyl length reached a maximum value (approximately 3.5 mm) on day 2, whereas maximum root length (approximately 50 mm) was achieved on day 4.

The effects of various concentrations of the five volatile monoterpenoids on seed germination were examined on day 4 (Figure 3A). Camphor and β-pinene slightly inhibited seed germination at 400 μM. At 1300 μM, in addition, 1,8-cineole inhibited seed germination. In contrast, α-pinene and camphene did not inhibit seed germination at any concentrations tested (up to 1300 μM), although they slightly delayed the progression of seed germination at high concentrations (data not shown).

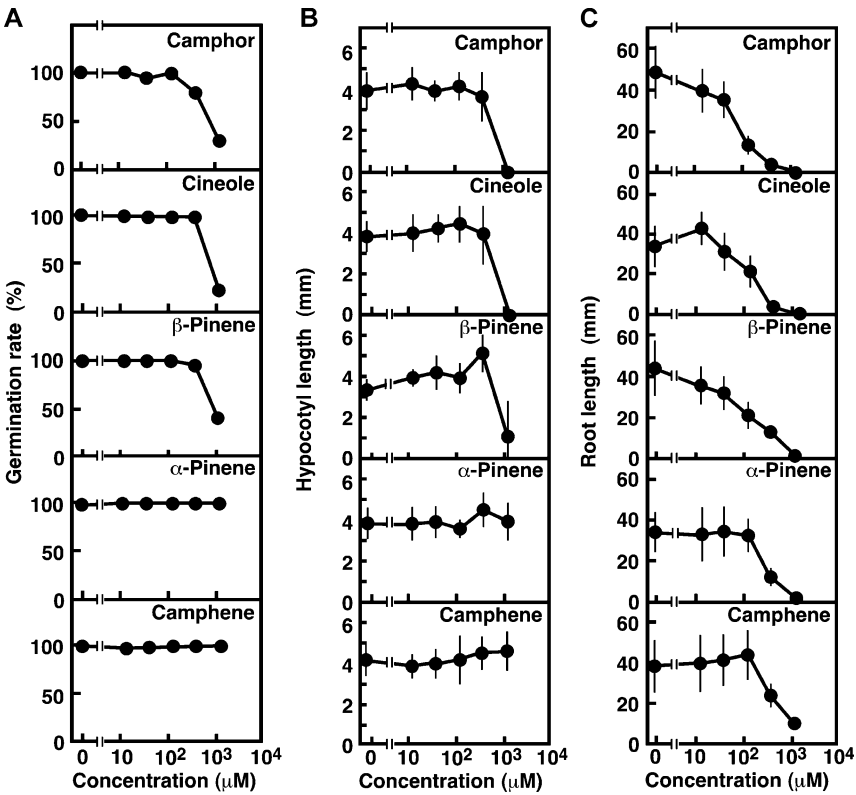

FIG. 3. Effects of the various concentrations of monoterpenoids. (A) Germination rate, (B) hypocotyls length, (C) root length examined on day 4. Each datum represents average values from 20 individuals. Vertical bars represent standard deviations.

The hypocotyl and root lengths of *B. campestris* seedlings that were grown for 4 days in the presence of various concentrations of monoterpenoids are shown in Figure 3B and C, respectively. Hypocotyl growth was relatively unaffected. No inhibition was observed at 400 μM or less for any of the monoterpenoids. At 1300 μM, camphor, 1,8-cineole, and β-pinene inhibited hypocotyl growth severely or partially, but α-pinene and camphene did not at any concentrations tested (up to 1300 μM). Root growth was more sensitive and was inhibited by all five monoterpenoids in a dose-dependent manner. Camphor, 1,8-cineole, and β-pinene shortened the root length even when they were added at low concentrations (130 μM or less). α-Pinene and camphene did not inhibit root growth at low concentrations (up to 130 μM), but did at higher concentrations (400 or 1300 μM). These results show that (1) all five monoterpenoids inhibit root growth more severely than hypocotyl growth or seed germination and (2) the strength of the monoterpenoids as growth inhibitors differs. The concentrations necessary to inhibit root growth to 50% of the control value (IC_{50}) were estimated to be approximately 90, 140, 150, 270, and 570 μM for camphor, 1,8-cineole, β-pinene, α-pinene, and camphene, respectively.

Effects of Volatile Monoterpenoids on Proliferation and Elongation of Shoot and Root Cells. For convenience, and to examine the mechanism of preferential inhibition of root growth by the monoterpenoids, we performed experiments at the concentrations where the root lengths of the 4-day-old seedlings were reduced to 25% of the control value (approximately 200, 300, 500, 750, and 1250 μM for camphor, 1,8-cineole, β-pinene, α-pinene, and camphene, respectively). At these concentrations, monoterpenoids did not affect hypocotyl growth (Figure 4A, also see Figure 3B and C).

The effects of monoterpenoids on the size of matured cells in hypocotyls and roots are shown in Figure 4B. Epidermal cells in the middle region of the hypocotyls and the cortex cells at the root-hair-forming regions of the primary roots were selected for cell size measurements as representatives of matured cells. None of the monoterpenoids decreased the size (length or width) of the matured cells in hypocotyls and roots, indicating that they did not inhibit cell expansion.

The effects of monoterpenoids on the mitotic indices in shoot apex (including both shoot apical meristem and young leaf primordia) and root apical meristem (within 400 μm from the tip of root proper) are shown in Figure 5. The mitotic indices of the shoot apex were scored 3 days after sowing, when the hypocotyl growth had completed and foliage leaves had started developing. The mitotic indices of the root apical meristem were scored 2 days after sowing, when the mitotic index in the root apical meristem of untreated seedlings reached the maximum value (Koitabashi et al., 1997). Monoterpenoids did not inhibit cell proliferation in the shoot apex under our experimental conditions. However, they all decreased the mitotic indices in the root apical meristem to

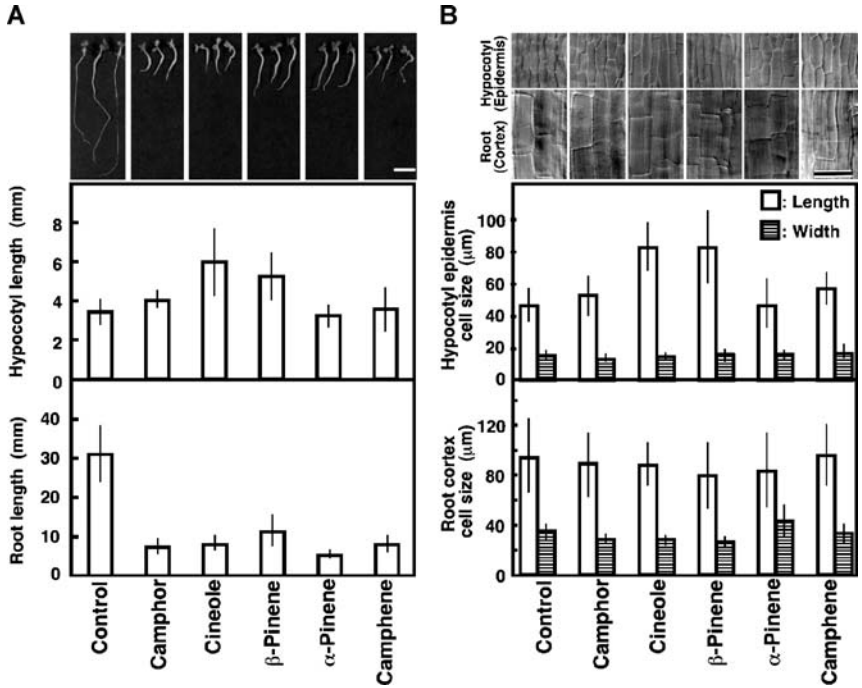

FIG. 4. Effects of monoterpenoids on the mature cell sizes in the hypocotyls and roots. The concentrations of monoterpenoids were adjusted so that root growth was reduced to approximately 25% of the control value. (A) Effects on the length of hypocotyls and roots. Photographs (top), hypocotyl length (middle), and root length (bottom) of the 4-day-old seedlings are shown. Each datum represents an average value from 20 individuals. Vertical bars represent standard deviation. Scale bar represents 5 mm. (B) Effects on the length (open box) and the width (hatched box) of matured cells in hypocotyl epidermis and root cortex. Nomarski images of mature cells (top), cell sizes of the matured hypocotyl epidermis (middle), and those of matured root cortex cells (bottom) are shown. Each datum represents average value from 40 cells. Vertical bars represent standard deviations. Scale bar represents 50 μm.

15–40% of the control value, demonstrating selective inhibition of cell proliferation in the root apical meristem.

Effects of Volatile Monoterpenoids on DNA Synthesis in Root Apical Meristem. In the root apical meristem of untreated seedlings, almost all cell nuclei and organelles were labeled clearly with BrdU (Figure 6a and b), reflecting their high DNA synthesis activities. In monoterpenoid-treated seedlings, by contrast, both labeling frequency and labeling intensity were lowered

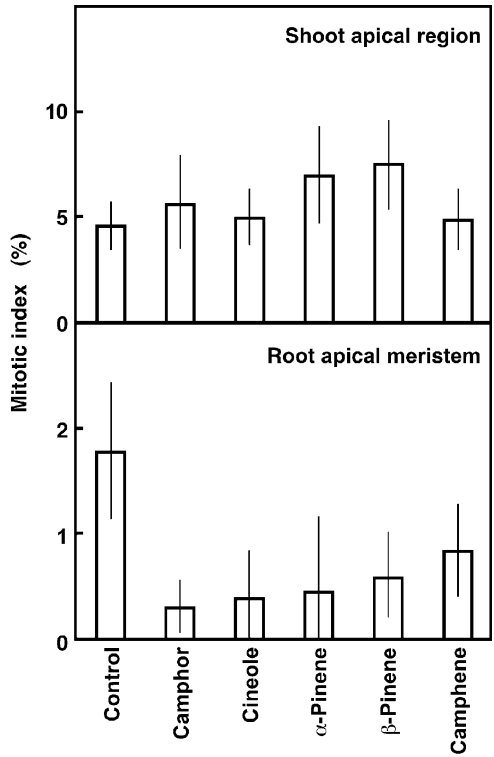

FIG. 5. Effects of the monoterpenoids on the mitotic index in shoot and root apical meristems. Top: Mitotic index of shoot apical region (including both shoot apical meristem and leaf primordia) of 3-day-old seedlings. Bottom: Mitotic index of root apical meristem (within 400 μm from the tip of root proper) of 2-day-old seedlings. Mitotic indices were counted on DAPI-stained frozen sections of the tissue under fluorescence microscopy. For convenience and clarity, only cells at meta- or anaphase were scored in the root apical meristem. Each datum represents average from ≧6 individuals (≧24 sections). Vertical bars represent standard deviations.

(Figure 6c–l), indicating that the monoterpenoids inhibited both cell-nuclear and organellar DNA synthesis within the root apical meristem.

The activity of DNA synthesis was determined quantitatively using an immunoblotting technique (Figure 7). The amount of BrdU residue incorporated into DNA (regardless of cell-nuclear DNA or organelle DNA) per unit cell-nuclear DNA was determined and was regarded as the activity of DNA synthesis per cell. The results demonstrate that treatment decreased the DNA synthesis activity in the root apical meristem to 7–40% of the control.

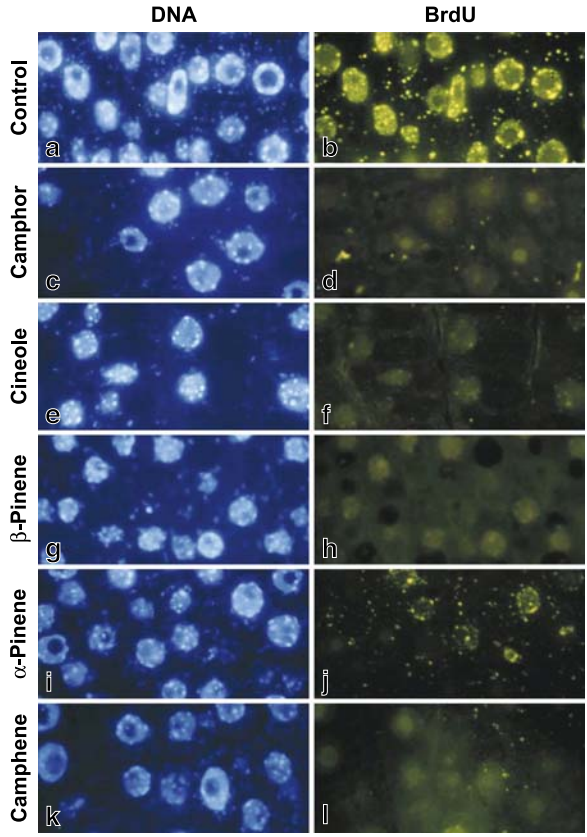

FIG. 6. Effects of monoterpenoids on DNA synthesis in the root apical meristem examined by immunofluorescence microscopy using anti-BrdU antibody. Technovit sections of the root apical meristem of *B. campestris* grown in the absence of terpenoids (a, b) or in the presence of camphor (c, d), 1,8-cineole (e, f), β-pinene (g, h), α-pinene (i, j), and camphene (k, l). *B. campestris* seedlings (1.5-day-old) were labeled with BrdU for 12 hr, embedded in Technovit 7100 resin, cut into thin sections, and examined by DAPI-fluorescence microscopy (a, c, e, g, i, and k) and by indirect immunofluorescence microscopy using anti-BrdU antibody (b, d, f, h, j, and l). Large, ovoid structures are cell nuclei, whereas small dots in the cytoplasm represent organelle nuclei. Dark areas and brighter spots of DAPI fluorescence within the cell nuclei are nucleoli and heterochromatin, respectively.

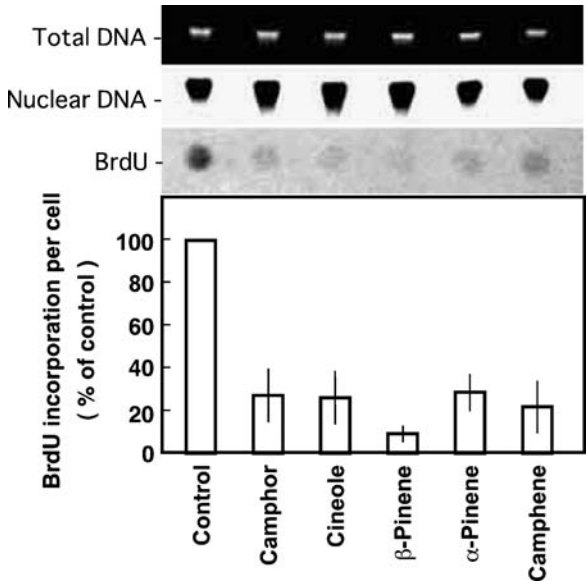

FIG. 7. Effects of monoterpenoids on DNA synthesis in root tips examined by immunodetection of the BrdU-labeled DNA on a nitrocellulose filter. *B. campestris* seedlings (1.5-day-old) were labeled with BrdU for 12 hr. Total DNA was extracted from root tips (1 mm long) and subjected to quantitative Southern hybridization analysis and immunodetection of BrdU residues incorporated into DNA. Shown are as follows: total DNA, EtBr-stained gel showing total DNA extracted from the root tips; nuclear DNA, hybridization signal of cell-nuclear rDNA to standardize the amount of cell-nuclear DNA in the sample; and BrdU, a result of immunodetection. Bottom: Relative amount of BrdU incorporated into unit amount of cell-nuclear DNA. Average values from three experiments (approximately 40 seedlings were used in each experiment) are shown. Vertical bars represent standard deviations.

DISCUSSION

Monoterpenoids as Growth Inhibitors. All five volatile monoterpenoids produced by *S. leucophylla* have the potential to inhibit the growth of *B. campestris* roots in a dose-dependent manner. *B. campestris* was chosen as the test plant because it germinates easily and uniformly and grows relatively quickly (Figure 2); these characters are important for bioassays (Dayan et al., 2000). The order of the strength of the five monoterpenoids as root growth inhibitors based on the IC_{50} values was estimated as camphor > 1,8-cineole > β-pinene > α-pinene > camphene. This order is in agreement with the report by Müller (1970)

that cineole and camphor were most toxic, among the monoterpenoids present in the *Salvia* leaves, to the growth of cucumber seedlings. Vaughn and Spencer (1993, 1996) reported that several monoterpenoids with oxygen-containing functional groups were especially inhibitory to germination of crop and weed seeds. As camphor and cineole have oxygen-containing functional groups while other monoterpenoids present in *S. leucophylla* leaves do not (Figure 1), our results support the argument concerning the relationship between monoterpenoid structure and function.

Mechanism for Root-Specific Growth Inhibition. All monoterpenoids inhibited root growth more severely than hypocotyl growth. One possible explanation is the differences in the actual concentrations of the monoterpenoids around hypocotyls and roots. Under field conditions, volatile monoterpenoids released from *S. leucophylla* are adsorbed to soil and then exhibit inhibitory effects onto other plants (Müller, 1970). Under our experimental conditions, similarly, monoterpenoids can be adsorbed onto a filter paper wad and accumulate to high concentrations, whereas concentrations in the airspace might become lower accordingly. However, we observed that the hypocotyl growth was largely unaffected by monoterpenoids even if they were forcibly associated with small pieces of papers (on which volatilized monoterpenoids should be adsorbed) during seedling growth (unpublished results), suggesting that the different sensitivities of hypocotyl and root growth could not be fully explained by differences in actual concentrations of monoterpenoids around them.

A more plausible explanation is differences in the growth modes of the two organs. Hypocotyl growth is largely dependent on elongation of each cell, which has already occurred in the embryo within the seed (Obroucheva, 1999), whereas root growth requires both proliferation and elongation of cells. The monoterpenoids did not inhibit cell expansion in either root or hypocotyls (Figure 4B), whereas they did inhibit cell proliferation and DNA synthesis in the root apical meristem (Figures 5–7). The observation that monoterpenoids did not inhibit root-hair formation, which depends on cell elongation, supports the opinion that cell expansion is relatively resistant to monoterpenoids (data not shown). Thus we conclude that the root-specific growth inhibition is observed because (1) cell expansion is relatively insensitive, whereas cell proliferation is sensitive, to monoterpenoids and (2) hypocotyl growth depends largely on cell expansion, whereas root growth requires not only cell expansion, but also cell proliferation.

Mechanism for Root-Specific Inhibition of Cell Proliferation. Although root-specific growth inhibition is largely explained by differences in the growth modes of roots and hypocotyls, the reason why cell proliferation in the shoot apical region was not affected by monoterpenoids (Figure 5) should be considered carefully. A decrease in the actual concentrations of monoterpenoids around the shoot apical region, resulting from adsorption, might be responsible.

To examine this possibility, measurement of actual concentrations of monoterpenoids around shoot and root apices is desired. Alternatively, if shoot and root apical meristems are exposed to the same concentrations of monoterpenoids (for example, by growing the seedlings in midair or in liquid culture media), this possibility could be examined easily. Another possibility is that permeability to monoterpenoids may be different between the root and shoot apex. In plants producing essential oils that are mainly composed of various monoterpenoids, production and accumulation of monoterpenoids are restricted to highly specialized structures (Mahmoud and Croteau, 2002). For example, peppermint (*Mentha* × *piperita* L.) stores monoterpenoids in the subcuticular space of the peltate glandular trichomes (Turner et al., 2000a,b), and volatilization of monoterpenoids from the storage sites occurs only at a low rate (Gershenzon et al., 2000). This indicates that the cuticle that covers the surface of aerial parts of a plant can provide a tight barrier against monoterpenoids. Alternatively, in the shoot apical meristem, the metabolic pathway that should be inhibited by terpenoids may be absent or modified to be more resistant to the compounds.

Mechanism for Inhibition of Cell Proliferation. Koitabashi et al. (1997) by using BrdU-immunofluorescence microscopy reported that treatment with 1,8-cineole lowered DNA synthesis activity in the root apical meristem of *B. campestris* seedlings. This procedure is advantageous in that DNA synthesis in cell nuclei and in organelles can be examined separately, but is disadvantageous in that quantitative estimation of the DNA synthesis activity is difficult. In the present study, therefore, a quantitative immunoblotting technique was applied to estimation of the DNA synthesis activity in the root tips. The results demonstrated that the DNA synthesis activity in the root tips of the monoterpenoid-treated seedlings was down to 7–40% of the control value (Figure 7). This is in agreement with the degrees of inhibition of the frequency of the cell division in root apical meristem (Figure 5) and root growth (Figure 4A). This suggests that monoterpenoids inhibit DNA synthesis in the root apical meristem, directly or indirectly, thereby exerting inhibitory effects on cell proliferation in the root apical meristem and, thus, on root growth.

Koitabashi et al. (1997) argued that 1,8-cineole might inhibit DNA synthesis indirectly because DNA replication in cell nuclei and organelles is inhibited simultaneously despite the fact that the nature of DNA synthesis machinery is rather different in nuclei and organelles. Indeed, there are several reports that monoterpenoids inhibit several animal enzyme activities that are not related to DNA synthesis. For example, 1,8-cineole inhibits pentoxyresorufin-*O*-dependentilase, a type of liver monooxygenase (de-Oliveira et al., 1999), and acetylcholinesterase (Savelev et al., 2003). These reports support the opinion that monoterpenoids inhibit some cellular metabolic pathway unrelated to DNA synthesis and ultimately stop DNA synthesis.

Recently, Romagni et al. (2000a,b) reported that 1,4-cineole (an analog of 1,8-cineole) inhibits root growth of test plants, and asparagine synthetase was identified as the primary target site of 1,4-cineole. The apparent similarities in the structures and symptoms suggest that 1,8-cineole may function in a similar way. However, 1,8-cineole did not inhibit asparagine synthetase activity *in vitro* (Romagni et al., 2000b), and root growth inhibition induced by 1,8-cineole could not be reversed by exogenously added asparagine (our unpublished results). Therefore, these two cineoles appear to have different modes of action (Romagni et al., 2000a) despite their similarities. The primary target site of 1,8-cineole and other monoterpenoids produced by *S. leucophylla* is still unclear.

Besides the possibility that inhibition of DNA synthesis is an indirect effect of monoterpenoids, it is also possible that monoterpenoids inhibit DNA synthesis directly. We found that *in vitro* DNA synthesis in the organelle nuclei isolated from BY-2 cultured tobacco cells (Sakai et al., 1999) was inhibited by high concentrations of monoterpenoids (unpublished results). DNA polymerases of plastids and mitochondria in higher plants resemble each other, and both appear similar to bacterial DNA polymerase I (Sakai et al., 1999; Sakai, 2001), suggesting that simultaneous inhibition of organelle DNA synthesis is possible. Moreover, because organelle DNA synthesis before cell nuclear replication is essential for subsequent cell propagation (Suzuki et al., 1996), inhibition of organelle DNA synthesis may result in the cessation of cell-nuclear replication and cell proliferation. The report that camphor induces unfolding of bacterial nucleoids (Harrington and Trun, 1997) also suggests that the target site may be around prokaryotic genetic systems. The primary target site of the volatile monoterpenoids should be examined in the future, taking these various possibilities into consideration.

(Received August 11, 2004; accepted January 10, 2005)

Abstract—An alternative to the use of synthetic pesticides is to exploit the natural defense chemicals produced by cereals. An important class of allelochemicals is cyclic hydroxamic acids and related benzoxazolinones. A prolonged degradation experiment of the allelochemical compound from rye 2-benzoxazolinone (BOA) was carried out for up to 90 d at 15°C at three different concentration levels, 3, 3000, and 30,000 nmol BOA g soil^{-1}, respectively, in a sandy loam soil. Two main degradation products, 2-amino-(3*H*)-phenoxazin-3-one (APO) and 2-acetylamino-(3*H*)-phenoxazin-3-one (AAPO), were identified and quantified by LC-ESI-MS-MS. The half-life of BOA increased with higher levels of BOA added to the soil. Half-lives of BOA, APO, and AAPO were determined by fitting a single first-order model to the degradation data. Half-life of BOA was determined to be 0.6 d in the 3 nmol BOA g soil^{-1} treatment. Half-lives of BOA, APO, and AAPO were 3.1, 2.7, and 2.1 d, respectively, in the 3000 nmol BOA g soil^{-1} treatment. In the 30,000 nmol BOA g soil^{-1} treatment, the half-lives were 31 d for BOA and 45 d for APO. The microbial community structure was not affected by addition of BOA to the soil as investigated by analysis of signature fatty acids. The results suggest that the exploitability of BOA for crop protection is dependent on the existing concentration of BOA in the soil and the timing of incorporation of hydroxamic acid synthesizing crops into the soil.

INTRODUCTION

Cyclic hydroxamic acids (benzoxazinones) and related benzoxazolinones are potential substitutes for synthetic pesticides in crop protection due to their allelopathic activity (Putnam and DeFrank, 1983; Barnes and Putnam, 1986). Several investigations have shown an inhibiting effect on the growth of weeds and reduced infestation by insects and pathogens on cereals producing cyclic hydroxamic acids (Bell and Nalewaja, 1968; Argandoña et al., 1980, 1981; Zúñiga et al., 1983; Pérez, 1990; Pérez and Ormeño-Nuñez, 1991; Niemeyer and Pérez, 1995; Wilkes et al., 1999).

Studies of the degradation kinetics for the benzoxazolinones and their metabolites provide necessary information for estimating the exploitability of these compounds in crop protection, as the weed-reducing effects are dependent on the half-lives in soil. The metabolite 2-amino-(3*H*)-phenoxazin-3-one (APO) has been reported to be more phytotoxic than 2-benzoxazolinone (BOA) (Gagliardo and Chilton, 1992). Soil temperature may influence degradation kinetics. In addition, exploitation of the benzoxazolinones and their metabolites in crop protection requires an estimation of the risk of leaching to aquatic environments, as the risk is likewise dependent on the half-lives of these compounds in soil.

Cyclic hydroxamic acids with the 1,4-benzoxazin-3-one skeleton are secondary plant metabolites found in several grasses (*Gramineae*), including the major agricultural crops rye (*Secale cereale*), wheat (*Triticum aestivum*), and maize (*Zea mays*) (Niemeyer, 1988b). In rye, several allelochemicals have been identified (Chou and Patrick, 1976) with the hydroxamic acid 2,4-dihydroxy-1,4-benxozaxin-3-one (DIBOA) being highest in concentration (Barnes et al., 1987). 2,4-Dihydroxy-7-methoxy-1,4-benzoxazin-3-one (DIMBOA) is the most abundant allelochemical in wheat, whereas both DIMBOA and 2,4-dihydroxy-7,8-dimethoxy-1,4-benzoxazin-3-one (DIM_2BOA) have been found in maize (Cambier et al., 1999). Rye contains minor amounts of the lactam 2-hydroxy-1,4-benzoxazin-3-one (HBOA) (Hofman and Hofmanová, 1969). Hydroxamic acids are chemically unstable in aqueous solutions and are rapidly decomposed to related benzoxazolinones (Bredenberg et al., 1962; Atkinson et al., 1991). Macías et al. (2005) showed an average half-life of 43 hr of DIBOA at concentrations of 1 and 5 mg g $soil^{-1}$ in nonsterilized water-flooded soils. DIM_2BOA hydrolyzes to 6,7-dimethoxy-benzoxazolin-2-one (M_2BOA), DIMBOA to 6-methoxy-benzoxazolin-2-one (MBOA), and DIBOA to BOA (Figure 1).

BOA and HBOA have several metabolites in common, including 2-amino-(3*H*)-phenoxazin-3-one (APO), 2-acetylamino-(3*H*)-phenoxazin-3-one (AAPO) (Figure 1), and *N*-(2-hydroxyphenyl)-malonamic acid (HPMA) (Zikmundová et al., 2002a). Three major classes of degradation products have been identified

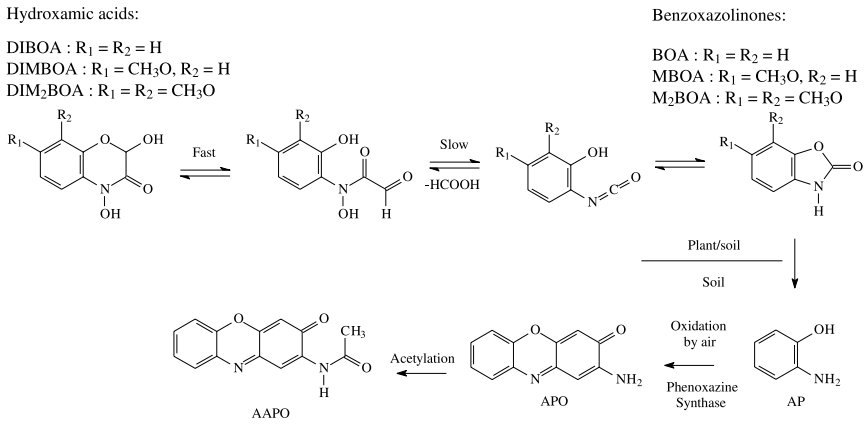

FIG. 1. Chemical transformation of cyclic hydroxamic acids to benzoxazolinones in plants or soils. In soil environments, the benzoxazolinones are degraded to AP. AP may be oxidized abiotically to APO by O_2 or due to catalysis by the enzyme phenoxazine synthase. APO may be further enzymatically acetylated to AAPO (Gents et al., 2005). Further transformation of APO and AAPO can occur as well. Modified after Sicker et al. (2000) and Zikmundová et al. (2002b).

from degradation of BOA and the lactam HBOA. These include aminophenoxazinones (Gagliardo and Chilton, 1992; Friebe et al., 1996; Zikmundová et al., 2002a; Fomsgaard et al., 2004), acetamides (Zikmundová et al., 2002b), and malonamic acids (Friebe et al., 1998; Yue et al., 1998; Vilich et al., 1999; Zikmundová et al., 2002a).

Several of these degradation products such as APO, AAPO, and HPMA have been found to be produced by different species of fungi grown in liquid media (Zikmundová et al., 2002a,b). Degradation of BOA has been reported to be conducted by both bacteria (Chase et al., 1991b; Friebe et al., 1996) and fungi (Friebe et al., 1998; Yue et al., 1998; Vilich et al., 1999; Zikmundová et al., 2002a,b). However, few degradation experiments of benzoxazolinones with identification and quantification of transformation products have been carried out in soil (Nair et al., 1990; Chase et al., 1991b; Gagliardo and Chilton, 1992; Kumar et al., 1993).

Studies of microorganisms in soil pose complex technical problems due to the heterogeneity of soils. Identification of microorganisms by classical methods with cultivation, isolation, and identification of microorganisms in Petri plates is time consuming. Furthermore, the selected medium may favor the growth of certain groups (Bakken, 1985), and the separation of the microorganisms from soil particles may be inconsistent (Schallenberg et al., 1989). An alternative method to estimate the community structure responsible for the microbial

processes taking place in environmental samples is by identification of biomarkers such as signature fatty acids. Biomarkers that are restricted to certain groups of organisms are used to define community structure. The narrow composition of specific signature fatty acids for subsets of the microbial community has been shown (Lechevalier, 1977). Any changes in the signature fatty acid patterns would thus indicate that the microbial community has been affected (Bååth et al., 1998).

The objective of this study was to determine the half-life of BOA at three different concentration levels. The chosen temperature condition at 15°C corresponds to a realistic soil temperature in the northern part of Europe in summertime. Other objectives were to identify degradation products from BOA and to identify changes in the microbial community structure due to addition of BOA by using the signature fatty acid pattern technique.

METHODS AND MATERIALS

Experimental Design. A degradation experiment of BOA was performed in soil by measuring the formation and degradation of the metabolites APO and AAPO. The experiment was performed with two main variables: concentration of BOA and time. The four initial concentrations were 0 (control), 3, 3000, and 30,000 nmol BOA g soil^{-1}. A total of 60 samples for each concentration level of BOA were incubated. At preselected time intervals, the incubation was terminated for sets of six replicates from d 0 to d 15 and for sets of three replicates from d 20 to d 90 for each concentration level. A recovery experiment of BOA, APO, and AAPO was carried out with the same sandy loam soil as used for the degradation experiment.

Soil Data. A sandy loam (Typic Agrudalf, classified according to USDA Soil Taxonomy) (Greve et al., 1998) soil was collected on the 8th of April 2003 from the upper 0–30 cm from a cultivated field near the Research Centre Flakkebjerg, Denmark. The previous cultivated crop in the field was spring-sown barley in 2001, 2002, and 2003. The soil was gently crushed and passed through a 2.00-mm-mesh-size sieve and stored at 4°C at field moisture concentration until start of the experiment. Characteristics of the sandy loam soil are as follows: clay (<2 μm) 18%, silt (2–20 μm) 15%, fine sand (20–200 μm) 40%, coarse sand (200–2000 μm) 24.2%, carbon 1.64%, and pH 6.8 (measured in water).

Solutions and Chemicals. A working standard solution of 40 g l^{-1} BOA (Acros Organics 98%) was prepared by dissolving BOA in MeOH (Ratburn Chemicals Ltd., Walkerburn, Scotland). APO and AAPO were dissolved in dimethyl sulfoxide (DMSO) (Merck, Darmstadt, Germany) at concentrations of 1.5 and 1.1 g l^{-1}, respectively. Gifts of APO were obtained from Professor

Chilton, NC State University, USA, and Professor Igarashi, Toyama Prefectural University, Japan. Later, APO (pure by elemental analysis, TLC, IR, and ^{1}H and ^{13}C NMR spectroscopy; Mp 256–258°C) and AAPO [pure by elemental analysis, TLC, IR, and ^{1}H and ^{13}C NMR spectroscopy; Mp (corr) 298–299°C] were synthesized in another project in our laboratory (Gents et al., 2005). Working standard solutions of BOA, APO, and AAPO for the degradation and the recovery experiments were obtained by serial dilution in MeOH of the stock standard solutions. HPLC-grade solvents hexane and methyl-*tert*-butyl ether were purchased from Ratburn Chemicals Ltd. and acetic acid from Riedel-de-Haën (Seelze, Germany).

Degradation Experiment. Five grams of chemically inert Ottawa quartz sand (particle size 20–30 mesh, Fisher Chemicals) was added to 100-ml Erlenmeyer flasks, and four different concentrations of BOA were added: 0 (control), 3, 3000, and 30,000 nmol BOA g soil^{-1}, respectively. The applied initial concentrations of 3, 3000, and 30,000 nmol BOA g soil^{-1} correspond to 0.4, 400, and 4000 μg BOA g soil^{-1}, respectively. MeOH from the BOA solutions was evaporated under nitrogen. Wet soil, 28.0 g, corresponding to 25.0 g of dry soil was added to the Erlenmeyer flasks and mixed. The soil was moistened evenly by addition of 2.2 ml of milliQ autoclaved water to obtain a water concentration corresponding to field capacity at 17.3%. The Erlenmeyer flasks were closed, and the holes in the stoppers were filled with wads of cotton wool allowing circulation of air. All samples were incubated in the dark at 15°C.

Sampling. The incubation was discontinued for six replicates of each treatment after 0, 1, 3, 5, 7, 10, and 15 d and for three replicates after 20, 30, 40, 50, 60, and 90 d. Each of these samples was stored at −20°C until freeze-drying. Later, the samples were freeze-dried for a period of 12–24 hr in random order. After freeze-drying, the soil was gently crushed and homogenized in the Erlenmeyer flasks and frozen again at −20°C.

Extraction and Chemical Analysis of BOA and Metabolites. The freeze-dried soil materials were transferred to PVC-free polyethylene bags and homogenized. Two times 3.0 g of mixed sand and soil from each of the homogenized samples were weighed out for fatty acid analyses and stored at −20°C in sealed polyethylene bags. The rest of each sample was stored in sealed PVC-free polyethylene bags at −20°C.

Extraction of the compounds from the soil was performed using an Accelerated Solvent Extraction 200 system (ASE) from Dionex. Nineteen grams of soil were added to the 33-ml extraction cell, and a thin layer of Ottawa sand was added to the top of the cell. The eluent was MeOH containing 0.5 vol.% glacial acetic acid. Setup for the ASE 200 was as follows: preheat for 5 min, heat for 5 min, static for 5 min, flush 80%, purge for 60 sec, cycles 2, pressure 1500 psi, and temperature 80°C. Extracts were collected in vials that

were filled to the same volume by addition of MeOH, corresponding to 50-ml solution. Extracts were stored at −20°C. During analysis, extracts were diluted to provide a signal close to the signal from external standards of BOA, APO, and AAPO. A comparison between a standard curve prepared in MeOH and a standard curve prepared in a soil extract showed that no matrix effect influenced the determination of the three compounds.

BOA and the degradation products were analyzed with Applied Biosystems MDS Sciex API 2000 liquid chromatography–tandem mass spectrometry (LC-MS-MS) system in turbo electrospray ionization (ESI) positive multiple reaction monitoring (MRM) mode. The identities of the metabolites were verified by comparison of the fragmentation patterns and retention times with synthetic reference compounds. BOA was detected at *m*/*z* 136/80, APO at *m*/*z* 213/185, and AAPO at *m*/*z* 255/213. The chromatography of the extracts was performed with gradient elution at a flow rate of 200 μl min^{-1} at 30°C. The column was a Hypersil BDS C18 (4.0 × 250 mm, 5 μm). Eluent-A consisted of 10% MeOH and 90% milliQ filtered water (v/v) with 20 mM glacial acetic acid. Eluent-B consisted of MeOH with 20 mM glacial acetic acid. The eluent program was as follows: 1 min 90% A followed by a linear gradient for 7 min to 30% A, which was kept for 7 min followed by a linear gradient in 5 min to 10% A, then back to 90% A in 1 min and 7-min restabilization with 90% A; the total runtime was 28 min.

The detection limits of the analytical method were determined according to Miller and Miller (1993). Two sets of the calibration solutions were prepared, and the linear parts of the calibration curves were used for regression analysis, resulting in detection limits of BOA at 0.2 nmol g $soil^{-1}$, APO at 0.04 nmol g $soil^{-1}$, and AAPO at 0.04 nmol g $soil^{-1}$, respectively.

Recovery Experiment. A recovery experiment was carried out as described for the degradation experiment except that the amount of wet soil was 11.2 g. Samples were not incubated but were placed at −20°C for 24 hr prior to extraction. Spiking concentrations of BOA were 3, 3000, and 30,000 nmol g $soil^{-1}$, whereas recovery experiments with APO were performed at concentrations of 3 and 700 nmol g $soil^{-1}$ and at concentrations of AAPO at 3 and 600 nmol g $soil^{-1}$, respectively. The applied concentrations of APO and AAPO correspond to 0.4 and 150 μg g $soil^{-1}$. In the spiking experiments with APO and AAPO at concentrations of 700 and 600 nmol g $soil^{-1}$, respectively, DMSO could not be evaporated so it was mixed into the soil. Recovery for BOA, APO, and AAPO was 73, 60, and 66%, respectively, in the 3 nmol g $soil^{-1}$ experiment, 75 and 83% for APO and AAPO, respectively, in the 700 and the 600 nmol g $soil^{-1}$ experiment, 75% for BOA in the 3000 nmol g $soil^{-1}$ experiment, and 92% for BOA in the 30,000 nmol g $soil^{-1}$ experiment (Table 1). The recovery estimates have not been used to correct the data from the degradation experiment.

TABLE 1. PERCENTAGE OF RECOVERY OF BOA, APO, AND AAPO FROM SPIKED FLAKKEBJERG SANDY LOAM SOIL

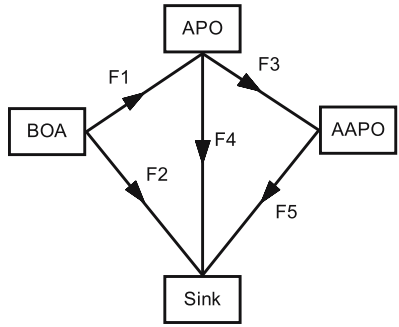
	Concentration of compound added to the soil				
Compound	3 nmol g soil^{-1} (%)	600 nmol g soil^{-1} (%)	700 nmol g soil^{-1} (%)	3000 nmol g soil^{-1} (%)	30,000 nmol g soil^{-1} (%)
BOA	72.9 ± 6.4			74.6 ± 11.2	91.7 ± 20.4
APO	60.4 ± 2.6		74.6 ± 8.3		
AAPO	66.0 ± 2.9	83.4 ± 8.1			

Means and standard deviation ($N = 7$). The molar masses of the compounds are BOA: 135; APO: 212, and AAPO: 254. 3000 nmol BOA corresponds to 400 μg BOA.

Kinetic Modeling. Degradation rates were obtained by modeling data for BOA, APO, and AAPO with ModelMaker 4 (AP Benson). A single first-order model was used, $dM\ dt^{-1} = -kM$ (Eq. 1), where M is the total amount of a substrate present at time t and k is the rate constant. In the flow transformation kinetic diagram (Figure 2), the transformation of BOA (Eq. 2), APO (Eq. 3), and AAPO (Eq. 4) is defined. Formation fraction is the fraction of a substance that is transformed from a precursor into a metabolite (e.g., ff_{APO} is the fraction of BOA transformed into APO) (Boesten et al., 2004). In case of first-order reactions, the formation fraction is equal to the proportion between the two rate constants for the transformation of BOA to APO and BOA to "sink," respectively (Boesten et al., 2004). The term "sink" (Eq. 5, Figure 2) is defined as a pool of nonspecified degradation products, including CO_2 and bound residues. The formation of 1 mol of APO requires 2 mol of BOA.

Extraction and Analysis of Fatty Acids. The extraction of fatty acids from whole cells was performed as a four-step procedure consisting of saponification, methylation, extraction, and wash according to Larsen et al. (2000). The method was followed except for a few modifications in the saponification process. One gram of the mixed sand and soil was saponified in 1.0 ml, 3.75 M NaOH in 50% MeOH and 50% water (v/v) in a screw cap test tube and vortexed for 5–10 sec. The tube was heated at 100°C in a water bath for 1 min, and the lids were tightened again. After an additional minute, the test tube was vortexed for 5–10 sec and returned to the water bath for 28 min followed by cooling on ice. Larsen et al. (2000) described the gas chromatography conditions for analysis of the extracted fatty acid methyl esters. The relative amount of each fatty acid was measured in proportion to the internal standard fatty acid 19:0.

The selected signature fatty acids for gram-positive bacteria were: 15:0I, 15:0A, 16:0I, 17:0I, and 17:0A; gram-negative bacteria: Cy17:0 and Cy19:0ω8; total bacteria: 15:0I, 15:0A, 16:0I, 17:0I, 17:0A, Cy17:0, Cy19:0ω8, 14:0,



Rate equations

$$dBOA \cdot dt^{-1} = -F1-F2 = -k_{BOA} \cdot BOA \cdot ff_{APO} - k_{BOA} \cdot BOA \cdot (1-ff_{APO}) \quad \text{(Eq. 2)}$$

$$dAPO \cdot dt^{-1} = F1-F3-F4 = k_{BOA} \cdot BOA \cdot ff_{APO} - k_{APO} \cdot APO \cdot ff_{AAPO} - k_{APO} \cdot APO \cdot (1-ff_{AAPO}) \quad \text{(Eq. 3)}$$

$$dAAPO \cdot dt^{-1} = F3-F5 = k_{APO} \cdot APO \cdot ff_{AAPO} - k_{AAPO} \cdot AAPO \quad \text{(Eq. 4)}$$

$$dSink \cdot dt^{-1} = F2+F4+F5 = k_{BOA} \cdot BOA \cdot (1-ff_{APO}) + k_{APO} \cdot APO \cdot (1-ff_{AAPO}) + k_{AAPO} \cdot AAPO \quad \text{(Eq. 5)}$$

where

BOA = Total amount of BOA present at time t
APO = Total amount of APO present at time t
AAPO = Total amount of AAPO present at time t
k_{BOA} = Rate constant for degradation of BOA
k_{APO} = Rate constant for degradation of APO
k_{AAPO} = Rate constant for degradation of AAPO
ff_{APO} = Formation fraction of APO
ff_{AAPO} = Formation fraction of AAPO

FIG. 2. Illustration of the flow transformation kinetic diagram between BOA and the metabolites APO, AAPO, and "sink" used in the modeling of the kinetics with definitions for the different rate equations.

10Me16:0, and 17:0; saprotrophic fungi 18:2ω6,9 and 18:3ω6,9,12; arbuscular mycorrhizal fungi: 16:1ω5; and protozoa: 20:4ω6,9,12,15. Nomenclature of the fatty acids is described by Vestal and White (1989).

Levels of significance of main treatments and their interactions were calculated by analyses of variance after testing for variance homogeneity with

Bartlett's test ($P > 0.05$). The statistical analyses were performed with StatGraphics Plus 4.0 (Statistical Graphics Corp.) for Windows.

RESULTS

In the 3 nmol BOA g soil^{-1} treatment, a rapid degradation of BOA was observed within the first 24 hr ($DT_{50} < 1$ d). In contrast to the 3000 and 30,000 nmol BOA g soil^{-1} treatments, no APO or AAPO was observed.

In the 3000 nmol BOA g soil^{-1} treatment, degradation of BOA started within the first 24 hr and was not complete after 30 d, as a background level was reached after 30 d at a concentration of 64 nmol BOA g soil^{-1} (Figure 3). The metabolite APO was already detected 24 hr after start of incubation, and the maximum level of 353 nmol APO g soil^{-1} was reached after 5 d, decreasing toward d 60 to 5.9 nmol APO g soil^{-1}. APO was further acetylated to AAPO. AAPO was detected after 24 hr, and the maximum concentration of 2.4 nmol AAPO g soil^{-1} was observed after 7 d, decreasing toward d 60 to 0.15 nmol APO g soil^{-1}. Half-lives of BOA, APO, and AAPO were estimated as 3.1, 2.7, and 2.1 d, respectively, from first-order fits to the degradation data (Table 2). The transformation of BOA into APO was 23%, and approximately 1% of APO was further acetylated into AAPO.

In the 30,000 nmol BOA g soil^{-1} treatment, the degradation time of BOA increased significantly compared to the 3000 nmol BOA g soil^{-1} treatment (Table 2). Degradation of BOA was incomplete after 90 d when a concentration of 158 nmol BOA g soil^{-1} was measured (Figure 3). APO again was identified within the first 24 hr and reached a maximum of 3950 nmol APO g soil^{-1} after 50 d and a concentration of 1583 nmol APO g soil^{-1} at d 90. At this concentration level of BOA, AAPO was not detected before d 7, and its maximum concentration of 7.6 nmol AAPO g soil^{-1} at d 60 was reached after the maximum concentration of APO had appeared. At d 90, 4.0 nmol AAPO g soil^{-1} was measured. In the 30,000 nmol BOA g soil^{-1} treatment, the estimated half-lives for BOA and APO were 31 and 45 d, respectively (Table 2). Formation fraction of APO was 21%. The decomposition rate for AAPO could not be determined because the maximum concentration was not seen until d 60.

The signature fatty acids for gram-positive bacteria (15:0I, 15:0A, 16:0I, 17:0I, and 17:0A) constituted about 12% of the total fatty acids in the soil samples (Figure 4). The relative value of signature fatty acids for total bacteria, gram-negative bacteria, saprotrophic fungi, arbuscular mycorrhizal fungi, and protozoa varied in proportion to gram-positive bacteria, depending on the existence of these groups of microorganisms in the soil. In general, no significant differences were measured as a function of time. Overall, no

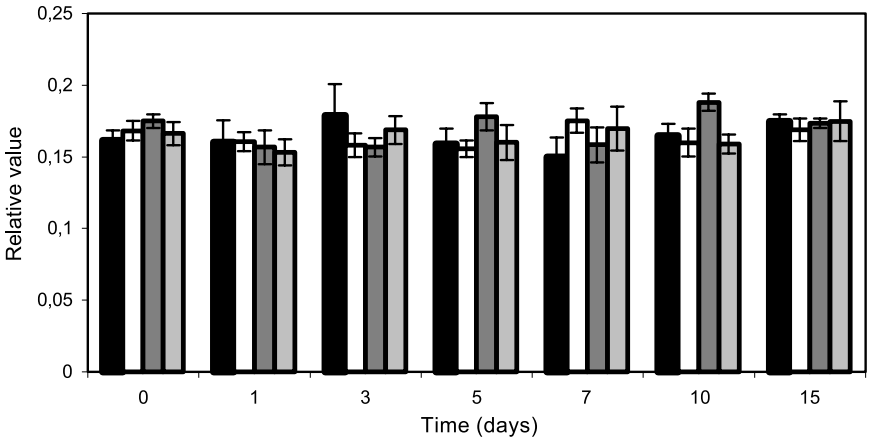

FIG. 4. Time course of changes in relative amount of signature fatty acids for gram-positive bacteria. Bars represent the total amount of the five signature fatty acids 15:0I, 15:0A, 16:0I, 17:0I, and 17:0A. The relative amount of each fatty acid was measured in proportion to the internal standard fatty acid 19:0. Each column represents the mean of five or six replicates, and bars indicate standard error of means. Control (black), 3 nmol BOA g soil^{-1} (white), 3000 nmol BOA g soil^{-1} (dark gray), and 30,000 nmol BOA g soil^{-1} (light gray).

TABLE 3. MULTIFACTOR ANALYSIS FOR EFFECTS OF BOA ON SIGNATURE FATTY ACIDS PATTERNS[a,b,c]

Factor	Gram-positive bacteria	Gram-negative bacteria[d]	Total bacteria	Saprotrophic fungi[d]	VAM fungi	Protozoa[d]
P values						
Time (A)	0.49	0.11	0.43	0.65	0.59	0.13
Concentration (B)	0.67	0.25	0.52	0.43	0.49	0.63
A × B	0.61	0.89	0.48	0.33	0.85	0.42

[a] $N = 5$ or 6.
[b] Significance ($P < 0.05$).
[c] Two factors: time (A), concentration (B), and the interaction (A × B).
[d] Data are log-transformed.

statistically significant differences were observed for the six different groups of microorganisms. Multifactor analysis of variance showed no significant effects ($P < 0.05$) of time or concentration of BOA for any of the six groups of microorganisms (Table 3).

DISCUSSION

This is the first report of quantification of APO and AAPO and the decomposition kinetics for BOA, APO, and AAPO in soil. In accordance with our observations, where unreacted BOA in the 3000 and 30,000 nmol BOA g soil^{-1} treatments was measured even after 90 d, several other investigations have also shown an incomplete transformation of BOA within 10–12 d (Nair et al., 1990; Chase et al., 1991a,b; Gagliardo and Chilton, 1992). Gagliardo and Chilton (1992) found unreacted BOA after 10 d of incubation in a sandy loam soil at an initial concentration of 37,000 nmol BOA g soil^{-1}. Similarly, these authors found that BOA was transformed into APO (Gagliardo and Chilton, 1992). In contrast to our work, a complete transformation of BOA after 3–4 d in a liquid media has been reported, which may indicate a faster transformation of BOA in liquid media compared to soil environments (Friebe et al., 1996). A further transformation of APO to AAPO was similarly reported in liquid media (Friebe et al., 1996; Zikmundová et al., 2002a). The slower degradation of BOA observed in our work might be due to the incubation temperature (15°C), which is lower than the temperatures (23–28°C) used in many degradation studies (Nair et al., 1990; Gagliardo and Chilton, 1992; Friebe et al., 1998; Yue et al., 1998; Vilich et al., 1999; Zikmundová et al., 2002a). Increasing the temperature may affect degradation kinetics, as a higher temperature may accelerate the growth of the microorganisms and thereby the enzyme-catalyzed processes, resulting in a shorter half-life of BOA.

In the kinetic modeling of BOA degradation in soil and ensuing formation and degradation of APO and AAPO, the single first-order model was chosen because this model described the first and dominating part of the curves correctly. Models with a low number of parameters should be used when possible (Boesten et al., 2004), even if the changes in the observed half-lives indicate that we are not dealing with true first-order processes. The decomposition rate and formation fraction of AAPO in the 3000 nmol BOA g soil^{-1} treatment showed a large error due to the low amounts of AAPO formed, making modeling of the data difficult. However, modeling the degradation of AAPO from its maximum concentration, which is the most obvious alternative, resulted in the same half-life. In the 30,000 nmol BOA g soil^{-1} treatment, the decomposition rate of AAPO could not be determined because the maximum concentration was seen at d 60 and only one data point later than d 60 was obtained.

This is the first study of the microbial community structure by whole cell fatty acid (WCFA) signatures after addition of an allelochemical compound to the soil. Measurements of changes in the signature fatty acid patterns showed no significant differences among the treatments. The maximum initial concentration level of 30,000 nmol BOA g soil^{-1} is high compared to a recently measured natural concentration of BOA in soil. Gents et al. (2005) found a maximum concentration of BOA in the soil of 1 nmol BOA g soil^{-1} 7 days after incorporation of rye into the soil. Several investigations have shown differences in the levels of hydroxamic acids and benzoxazolinones in cereals (Niemeyer, 1988a; Burgos et al., 1999). Niemeyer (1988a) found that wheat species differed by a factor of 75 in the concentration of DIMBOA (0.21 mmol kg^{-1} fresh weight to 16 mmol kg^{-1} fresh weight), and Burgos et al. (1999) found that rye species differed by a factor of 10 in the concentration of DIBOA and BOA (137 μg g^{-1} dry weight to 1469 μg g^{-1} dry weight). These considerable differences in the levels of hydroxamic acids in cereals make it reasonable to expect higher concentrations in soil than the 1 nmol BOA g soil^{-1} found by Gents et al. (2005). Higher local concentrations in soil may occur under natural circumstances in the rhizosphere around cultivars with high contents of hydroxamic acids and the ability to exude hydroxamic acids from roots. Even a uniform distribution in the top soil (10 cm) of the 50 nmol BOA estimated in rye residues by Yenish et al. (1995) would lead to a mean concentration of 33 nmol BOA g soil^{-1}. However, when the distribution is not even, concentrations of BOA high enough for initiating the formation of APO and AAPO could easily be imagined. In addition, the concentrations of hydroxamic acids in cereals have been investigated more intensively in wheat species compared to rye species, which makes it realistic to believe that the rye species with the highest concentrations of hydroxamic acids have not yet been identified. Moreover, natural plant breeding or even gene modification may increase the

concentrations of hydroxamic acids in cultivars. Therefore it is relevant to perform degradation studies at higher initial concentrations than 3 nmol BOA g soil^{-1}.

Even at the highest concentration level used in the present study, no observable changes in the microbial community structure could be detected. The soil used had an organic matter (OM) concentration of 2.8%, corresponding to 28 mg OM g soil^{-1}. By addition of 30,000 nmol BOA g soil^{-1}, additionally 14% extra OM was supplied. In the degradation experiments with 3 and 3000 nmol BOA g soil^{-1}, detection of a change in the microbial community structure by WCFA was less likely. The results indicate that BOA, APO, and AAPO have little influence on the amount of biomass for the different groups of microorganisms investigated. The WCFA method does not exclude the possibility that changes have taken place within the different groups, although statistics of the signature fatty acids by principal component analysis showed no such shift. Both bacteria (Chase et al., 1991b; Friebe et al., 1996) and fungi (Friebe et al., 1998; Yue et al., 1998; Vilich et al., 1999; Zikmundová et al., 2002a,b) have been shown to transform BOA, showing that several different groups of microorganisms pose this ability. A natural level of BOA in the soil used might have favored the presence of microorganisms that are adapted to use BOA as a carbon source. In addition, the growth of the microbial population may have been limited by available nutrients (e.g., nitrogen), and the formed APO and AAPO might have lowered the microbial activity at the highest BOA concentration used. Anzai et al. (1960) demonstrated that APO and AP (Questiomycin A and Questiomycin B) had considerable antibiotic effects.

At a concentration of 3 nmol BOA g soil^{-1}, we found a half-life of BOA of 0.6 d, which is in agreement with Gents et al. (unpublished data) who reported a half-life of BOA of less than 0.5 d at the same initial concentration of BOA. The short half-lives of less than 5 d for BOA, APO, and AAPO in soil at concentrations of less than 3000 nmol BOA g soil^{-1} may provide weed control for only a short period once these compounds are released into the soil environment. Therefore production of high hydroxamic acid synthesizing crops by natural plant breeding or even gene-modified cultivars with improved capacities for producing these compounds may provide a prolonged weed control. The fast decomposition rate of BOA is in accordance with the relative high water solubility of 8960 mg l^{-1}, making the compound highly available for degradation by microorganisms, which is also indicated by the low partition coefficient of 14.45 (octanol–water) (Hansch et al., 1995), resulting in a low sorption to soil organic matter. Sakaliene et al. (unpublished data) have found a K_d value for BOA of 3–5 l kg^{-1} in different soil types. A low sorption of BOA in soil increases the risk of leaching of BOA to aquatic environments and groundwater. However, the fast degradation rate reported in this study reduces this risk

substantially. As the concentration of BOA in soil increased, the formation of APO was favored. APO and AAPO have a stronger sorption in the soil compared to BOA (Sakaliene et al., unpublished data), making these compounds less bioavailable and with lower leaching potentials. In spite of a substantial increase in the half-lives of BOA, APO, and AAPO when performing degradation studies at a concentration level of 30,000 nmol BOA g soil^{-1}, the half-lives do not exceed values that would lead to a ban of their use, if we were dealing with conventional pesticides. Combining the key knowledge on the decomposition rate of BOA and its main metabolites with results of ongoing studies concerning the target effects of the compound on weeds (Kudsk et al., 2004; Mathiassen et al., 2004) and studies on nontarget effects on soil organisms (Čoja, 2004; Idinger, 2004) will provide a basis for evaluation whether breeding programs or genetic modification should be initiated for producing rye varieties with substantially higher concentrations of hydroxamic acids as an enhancement of their defense properties.

Acknowledgments—We are grateful to Professor Chilton and Professor Igarashi for providing standards and we thank John Larsen for valuable suggestions and Anne G. Mortensen and Tina Tønnersen for excellent technical support. Published Online April 28, 2005

Abstract—Floral traits such as odor, color, and morphology are important pollinator attractants. Variation in floral traits may influence floral constancy, the tendency of pollinating insects to visit flowers of only one type. We investigated for the first time variation in odor between floral morphs in heterostylous species. We analyzed inter- and intraspecific odor variation in the "pin" and "thrum" floral morphs of sympatric *Primula elatior* and *P. farinosa* (Primulaceae). Floral volatiles were sampled with headspace sorption. Quantitative analysis and chemical identification were performed by gas chromatography coupled to mass spectrometry. The species produced different floral bouquets. *P. elatior* emitted mostly limonene with small amounts of α-pinene, myrcene, and sabinene. *P. farinosa* produced benzaldehyde, 4-oxoisophorone (2,6,6-trimethyl-2-cyclohexene-1,4-dione), benzyl alcohol, and benzyl acetate. These interspecific differences may play a role in promoting floral constancy and maintaining species integrity. Conversely, no differences were detected between the scents of pin and thrum morphs within each species. Heterostyly relies on pollinators visiting both floral morphs. There may be stabilizing selection against divergences in traits that may cause pollinators to develop floral constancy to only one of the floral morphs.

Key Words—Floral odor, heterostyly, *Primula*, pollination, headspace sorption, gas chromatography-mass spectrometry.

INTRODUCTION

Floral traits such as odor, color, and shape are important pollinator attractants and have evolved with the behavior, morphology, and physiology of pollinating animals (Chittka et al., 1999). An intriguing aspect of pollinator behavior is floral constancy, the tendency of an insect to visit flowers of only one type while ignoring other rewarding flowers. Taxa exhibiting floral constancy include honeybees (*Apis mellifera*), bumblebees (*Bombus* spp.) and solitary bees (*Trichocolletes* spp.), moths and butterflies (Lepidoptera), beetles (Coleoptera), and flies (Diptera; Chittka et al., 1999 and references therein). Pollinators use floral traits to discriminate among different flowers. Thus, there may be strong selection upon floral odors, colors, and shapes that encourage constancy if they increase pollen transfer efficiency and/or reproductive success.

Many plant species have variable floral traits and distinct morphs within a population. Heterostyly is a genetic polymorphism in which plant populations comprise two (distyly) or three (tristyly) mating types that differ in the reciprocally arranged female and male reproductive organs (Barrett, 2002). Distylous species have two floral morphs, 'pin' (long style and low anthers) and 'thrum' (short style and high anthers) (Barrett, 2002). Heterostyly occurs in 155 angiosperm genera, including *Primula* (Primulaceae). There are approximately 425 species of *Primula*, 91% of which are distylous (Richards, 2003).

In heterostylous species, pollen is efficiently transferred from the anthers of one plant to the stigma of another plant by its precise placement on the body of the pollinator (Barrett, 2002). Furthermore, self-fertilization is generally prevented by a self-incompatibility system that inhibits germination of pollen from the same floral morph. Successful pollen exchange requires a pollinator to visit both pin and thrum floral morphs during a foraging bout. Therefore, in heterostylous species, fertilization success relies on pollinators failing to distinguish between pin and thrum morphs of a species. Consequently, within a population, pin and thrum morphs are unlikely to differ in traits that may influence floral constancy. Between species, however, significant differences in floral traits are likely to be selected for to reduce pollen wastage and hybridization. Here, we test for low intraspecific and high interspecific variation in floral traits by considering variation in floral odor between floral morphs, and between species, in sympatric populations of heterostylous *Primula elatior* (L.) Hill and *P. farinosa* L. (Primulaceae).

METHODS AND MATERIALS

Floral odor samples were collected from 30 plants of *P. elatior* (15 pin, 15 thrum), 39 plants of *P. farinosa* (23 pin, 16 thrum), and 10 from ambient air

at Klausenpass (1950 m), Switzerland, during July 2004. The odors were collected by headspace sorption by isolating the inflorescence in a polyethylene bag. Air was drawn from the bag and through a filter attached to a pump at ~100 ml/min, for 4 hr. Filters consisted of 5 mg of Porapak Q absorbent material sealed in glass capillaries. Before each use, filters were cleaned with 200 μl of dichloromethane. Filters were eluted with 50 μl of a 9:1 solution of hexane and acetone.

Gas Chromatography. Before analysis, 100 ng of octadecane (Fluka, purity 99.8%) were added as an internal standard to all samples. A 1.5-μl portion of each odor sample was injected splitless into a gas chromatograph (GC) (Agilent 6890N) at 40°C (3 min), followed by opening the split valve and programming to 150°C at a rate of 2.5°C/min, and then 250°C at a rate of 10°C/min. The GC was equipped with an HP-Innowax column [30 m × 0.32 mm (diam) × 0.25 μm (film thickness)] and a flame ionization detector (FID); helium was the carrier gas. Compounds were identified by analyzing samples on a GC coupled to mass spectrometry (MS) and comparing spectra and retention times with reference compounds.

Statistical Analyses. Statistics were calculated by using relative amounts of floral odor compounds. As data were not normally distributed and resisted transformation, nonparametric Mann–Whitney *U*-tests were used to compare the relative amounts of each compound between pin and thrum plants. There was no difference in the compounds produced by pin and thrum plants within each species (Mann–Whitney *U*-tests, all P values > 0.5), so the pin and thrum data were pooled for each species. Between-species comparisons were then conducted, also with Mann–Whitney *U*-tests.

RESULTS AND DISCUSSION

In our study populations, *P. elatior* and *P. farinosa* had relatively simple bouquets composed of common floral odors (Table 1, cf. Gregg, 1983; Knudsen et al., 1993; Knudsen, 2002). The two species produced qualitatively different bouquets. *P. elatior* emitted primarily limonene with small amounts of three other monoterpenes: myrcene, α-pinene, and sabinene (Table 1). *P. farinosa* produced benzaldehyde, 4-oxoisophorone (2,6,6-trimethyl-2-cyclohexene-1,4-dione), benzyl alcohol, and benzyl acetate (Table 1).

Some plant individuals overlapped in scent between the species: five of the 30 *P. elatior* samples contained some benzaldehyde, and two of the 23 *P. farinosa* samples contained a small amount of limonene (Table 1). This overlap may be a part of the natural variation in each species rather than hybridization, since *P. elatior* and *P. farinosa* are classified in different sections

TABLE 1. MEAN (± SEM) RELATIVE AMOUNTS OF VOLATILE COMPOUNDS IDENTIFIED FROM 'PIN' AND 'THRUM' FLORAL MORPHS OF *Primula elatior* AND *Primula farinosa* (PRIMULACEAE)

	Primula elatior		*Primula farinosa*		
Volatile compounds	Pin (n = 15)	Thrum (n = 15)	Pin (n = 16)	Thrum (n = 23)	U (P)
α-Pinene	0.75 ± 0.22	0.74 ± 0.22	0	0	320 (<0.001)
Sabinene	2.71 ± 0.44	2.05 ± 0.45	0	0	180 (<0.001)
Myrcene	2.01 ± 0.50	1.99 ± 0.50	0	0	280 (<0.001)
Limonene	93.9 ± 1.13	94.1 ± 1.34	0.10 ± 0.10	0.31 ± 0.30	0.0 (<0.001)
Benzaldehyde	0.63 ± 0.44	1.10 ± 0.72	34.5 ± 2.46	36.4 ± 2.75	0.0 (<0.001)
4-Oxoisophorone	0	0	27.5 ± 2.28	26.6 ± 1.77	0.0 (<0.001)
Benzyl alcohol	0	0	29.5 ± 2.66	28.4 ± 2.31	15 (<0.001)
Benzyl acetate	0	0	8.41 ± 1.08	8.33 ± 1.00	60 (<0.001)

n = Number of plants sampled. Statistics in final column compare the two species using data pooled from pin and thrum plants. Test statistic U and P values are derived from Mann–Whitney U-tests.

(*Primula* and *Aleuritia*, respectively), and no hybrids between these two species have been reported (Richards, 2003). The quantitative differences in the odor bouquets between the species were also highly significant for all compounds (Table 1).

The different odors emitted by *P. elatior* and *P. farinosa* may attract different pollinators. Limonene and the other monoterpenes emitted by *P. elatior* are produced by many plants with diverse pollinating taxa including bees, Lepidoptera, beetles, and fly species (e.g., Knudsen et al., 1993; Knudsen, 2002 and references therein). The few published observations of visitors to *P. elatior* suggest pollinators include species of bumblebees, Lepidoptera, beetles, and thrips (Schou, 1983). The compounds emitted by *P. farinosa* are often found in Lepidoptera-pollinated flowers (Andersson et al., 2002). Butterflies and day-flying moths reportedly visit *P. farinosa*, but Diptera (Syrphidae, Bombyliidae), bees (*Osmia* spp.), and bumblebees have also been observed (Hambler and Dixon, 2003). Some insect taxa may be attracted to both *Primula* species.

The insects pollinating *Primula* spp. at our study site have not yet been identified, nor has the specific role of floral odor in pollinator attraction been investigated in any *Primula* species. However, odor is a principal pollinator attractant in a wide range of flowering plants and is a major factor promoting floral constancy (Knudsen et al., 1993; Chittka et al., 1999 and references therein). Both *P. elatior* and *P. farinosa* are largely self-sterile and rely heavily on pollinators for fertilization (Richards, 2003).

Even if some pollinator species are shared, cross-pollination between the two *Primula* species seems improbable. Individual insects are unlikely to visit

both *Primula* species during a foraging bout, since the striking quantitative and qualitative differences in the floral bouquets should promote floral constancy to only one of the species. Even minor qualitative differences in floral scent can affect pollinator behavior. For example, trained moths can distinguish between flowers differing by a single volatile compound (Cunningham et al., 2004). Thus, scent differences could contribute to the maintenance of species integrity, and/or provide a selective advantage, e.g., by reducing pollen wastage or clogging of the stigmas with heterospecific pollen.

Intriguingly, we found no intraspecific variation in scent between the floral morphs in either *Primula* species. Even the relative amounts of each compound produced by the pin and thrum morphs were remarkably similar (Mann–Whitney *U*-tests: *P. elatior* all P values > 0.74, *P. farinosa* all P values > 0.58). Similarly, low intraspecific scent variation was detected in two other species: *Cycnoches densiflorum* (Orchidaceae; Gregg, 1983) and *Geonoma macrostachys* (Arecaceae; Gregg, 1983; Knudsen, 2002). As in heterostylous primulas, both *C. densiflorum* and *G. macrostachys* require pollinators to visit two floral morphs for successful fertilization. Thus, in these four species, stabilizing selection might operate against any divergence in scent that would cause pollinators to develop floral constancy to only one of the morphs.

Chittka et al. (1999) argue that floral constancy is rarely strong enough to isolate floral morphs or maintain species integrity. If this is so, some variation in traits between morphs or species may have little impact on pollinator behavior. However, if there are additional factors that limit which individual plants can exchange pollen for successful reproduction (for example, self-incompatibility in heterostylous primulas), then low scent variability that promotes constancy to both floral morphs may provide a significant reproductive advantage.

Acknowledgments—Greg Holwell assisted with field sampling, Hannes Gamper suggested field sites, and Charlotte Salzman and Andreas Jürgens provided laboratory advice and assistance. Two reviewers provided useful comments. This study was supported by the ETH Zürich. Abstract—The sex pheromone of the fir coneworm moth consists of a blend of (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene and (9*Z*,11*E*)-tetradecadienyl acetate. Analogous blends of polyunsaturated, long-chain hydrocarbons with much shorter chain aldehydes or alcohols recently have been discovered in three other moth species in the superfamily Pyraloidea. These combinations of components from two distinct structural classes may represent an important and widespread new pheromone blend motif within the Lepidoptera.

Key Words—Sex pheromone, *Dioryctria abietivorella*, (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene, (9*Z*,11*E*)-tetradecadienyl acetate, Pyralidae, Crambidae

INTRODUCTION

Almost all of the female-produced pheromone blends from the more than 500 species in the lepidopteran suborder Ditrysia for which pheromones have been identified are composed of components with the same or similar chain lengths, structures, and volatilities (Ando et al., 2004; Witzgall et al., 2004). Furthermore, for a particular species, the blend components usually belong to only one of two general structural classes. The first class consists of C_{10} to C_{18} primary alcohols and their corresponding acetates and aldehydes, whereas the second consists of C_{17} to C_{23} polyunsaturated hydrocarbons and epoxides (Ando et al., 2004). Exceptions to this pattern are rare; the pheromone of the tomato fruit borer, *Neoleucinodes elegantalis* (Crambidae: Pyraustinae), a blend of (*E*)-11-hexadecenol and (3*Z*,6*Z*,9*Z*)-tricosatriene, is one such example (Cabrera et al., 2001).

In spring of 2004, we found that the pheromone blends of two pyralid moths, the navel orangeworm (NOW), *Amyelois transitella* (subfamily Phycitinae), and the meal moth, *Pyralis farinalis* (subfamily Pyralinae), contain components of dissimilar structural types. The major component of the NOW blend was identified as (11*Z*,13*Z*)-hexadecadienal (Coffelt et al., 1979), but this single component was only weakly attractive. Using wind tunnel bioassay-directed fractionations and coupled gas chromatography–electroantennography (GC-EAG), we discovered that (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-tricosapentaene and (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene are components of the NOW blend, whereas the meal moth blend contains (11*Z*,13*Z*)-hexadecadienal and (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-tricosapentaene (J.G. Millar, L.P.S. Kuenen, and J.S. McElfresh, unpublished data). Although the pentaenes elicit weak EAG responses, they are critical components of the attractants. The presence of the pentaenes in NOW has been independently verified (Leal et al., 2005).

The fir coneworm, *Dioryctria abietivorella* (Pyralidae: Phycitinae), causes substantial damage in coniferous seed orchards in western North America. The major component of its pheromone [(9*Z*,11*E*)-tetradecadienyl acetate, (9*Z*,11*E*)-14:Ac] had been known since 1985 (G. Grant, unpublished data), but, as with NOW, the single component was minimally attractive in field trials. Here, we report that (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene is a crucial component of the pheromone blend of the fir coneworm.

METHODS AND MATERIALS

Douglas fir cones infested with fir coneworms, collected near Chico, CA, were held in individual containers under ambient laboratory conditions. Emerging moths were segregated by sex and placed in a light box, 16:8 L:D, in an

environmentally controlled room. Pheromone glands of virgin females were clipped off ca. 6 hr after lights off and extracted in pentane. Extracts were analyzed by coupled GC-EAG on DB-5 and DB-WAX columns as previously described (McElfresh and Millar, 1999). An aliquot of a composite extract from 212 females was analyzed by GC-MS (HP-6890 GC interfaced to an HP 5973 mass selective detector, electron impact ionization, 70 eV), using splitless injections with a DB-5MS column programmed from 50 to 250°C at 10°C/min. A second aliquot was treated with 10 μl of a solution of 4-methyl-1,2,4-triazoline-3,5-dione (MTAD, 2 mg/ml in CH_2Cl_2), and the adduct was analyzed by GC-MS (injector 300°C; program 100°C/1 min, 10°/min at 300°C, hold 20 min).

(3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-Pentacosapentaene was synthesized from (5*Z*,8*Z*,11*Z*,14*Z*,17*Z*)-icosapentaenoic acid ethyl ester (Tokyo Kasei Kogo Co., Tokyo, Japan) by reduction with $LiAlH_4$, tosylation of the resulting alcohol, and alkylation with pentyl magnesium bromide with CuI catalysis (Jain et al., 1983). Isomerically pure (9*Z*,11*E*)-14:Ac was prepared by a new synthesis (J.A. Moreira and J.G. Millar, unpublished data). (*Z*)-9-14:Ac was obtained from Bedoukian Research (Danbury, CT, USA).

Field trials were conducted in a seed orchard near Vernon, BC, Canada, during August–September, 2004. Test compounds were loaded onto 11-mm gray rubber septa (The West Co., Lionville, PA, USA) in 100 μl hexane, with 5 mg/ml each of butylated hydroxytoluene (BHT) and Sumisorb 300 added to the hexane solutions as stabilizers. Doses tested are shown in Table 1. Baited sticky traps were hung from branches (~1.5 m above ground), and spaced ~25 m apart.

[a] Trial conducted from August 12–September 14, 2004, with five replicates counted weekly. Trap catch data analyzed by ANOVA followed by Student–Newman–Keuls (SNK) test. Means followed by different letters are different at $\alpha \leq 0.05$. Zero values were not included in the ANOVA or SNK analyses.

[b] Pentaene = (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene.

RESULTS AND DISCUSSION

GC-EAD analyses indicated strong and consistent antennal responses to two compounds in pheromone gland extracts (Figure 1, peaks 1 and 2). The major component was identified as (9*Z*,11*E*)-14:Ac (peak 2) by comparisons of retention times on DB-5 and DB-WAX GC columns, mass spectra, and EAG responses with those of authentic standards. The position of the diene was verified by diagnostic ions (*m/z* 194, base peak, *m/z* 336, 16%) in the mass spectrum of the MTAD adduct. The earlier eluting peak 1 was present in insufficient amounts to obtain a mass spectrum. However, its retention indices on DB-5 and DB-WAX columns matched those of (*Z*)-9-14:Ac, and comparisons with tabulated retention index values of all possible C14 monoene acetates confirmed the position and geometry of the double bond (Marques et al., 2000). However, blends of these two compounds attracted virtually no moths in field trials. In early 2004, our discovery of pentaene compounds in NOW extracts prompted us to carefully examine our composite coneworm extract (212 females) for similar compounds, resulting in the discovery of (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene (Figure 1, peak 3) in an approximately 1:1 ratio with (9*Z*,11*E*)-14:Ac. The identification was confirmed by exact

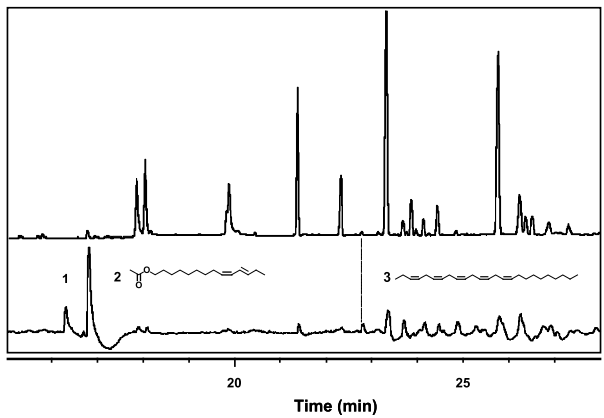

FIG. 1. Gas chromatogram (top trace) and corresponding electroantennogram trace from the antenna of a male *D. abietivorella* moth challenged with an aliquot of pheromone gland extract from female moths. Peak 1, (*Z*)-9-14Ac; peak 2, (9*Z*,11*E*)-14:Ac; and peak 3, (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene. Other EAD responses were to straight- and branched-chain cuticular hydrocarbons. Conditions: DB-5 column (30 m × 0.25 mm ID, 0.25 μm film; 70°C/1 min, 10°/min–275/20 min. Approximately four female equivalents injected splitless.

matches of retention times with those of an authentic standard on polar and nonpolar columns and by its diagnostic mass spectrum characterized by even-mass fragments that unequivocally placed all the double bonds (Underhill et al., 1983, and references therein). In particular, cleavage between C_8 and C_9 with hydrogen transfer from C_5 gave a strong $C_2H_5(CH{=}CH)_3H]^+$ ion (*m*/*z* 108, 38% of base peak), whereas cleavage between C_{10} and C_{11} with hydrogen transfer from C_{14} produced the analogous $C_9H_{19}(CH{=}CH)_3H]^+$ ion (*m*/*z* 206, 9% of base peak) from cleavage and rearrangement from the other end of the chain. Because of the small amounts present, even in a composite sample from 212 moths, it has not been possible to verify that all the double bonds have the *Z* configuration, for example, by GC-FTIR. Nevertheless, the exact retention time and mass spectral matches, coupled with the strong biological activity (see below) provide strong evidence that the natural compound is the all-*Z* isomer.

(3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-Pentacosapentaene elicited unexpectedly weak responses from male moth antennae in GC-EAD analyses (Figure 1, peak 3). However, field trials demonstrated that this compound is a key component of the pheromone blend (Table 1). Although (9*Z*,11*E*)-14:Ac (Table 1) and (3*Z*,6*Z*,9*Z*,12*Z*,15*Z*)-pentacosapentaene (second trial, data not shown) were not active as single components, a 5:1 ratio of the pentaene:acetate was attractive to male moths. When added to the 5:1 blend, (*Z*)-9-14:Ac decreased attraction at the rate tested, despite being present in pheromone gland extracts (Table 1).

These recent examples of pheromone blends from four related species in the superfamily Pyraloidea, consisting of one or more polyunsaturated long-chain hydrocarbons in combination with much shorter-chain aldehydes, alcohols, and acetates, suggest that these combinations represent a new and possibly widespread motif in lepidopteran pheromone chemistry. These examples also suggest a possible reason (i.e., missing long-chain components) why the pheromone blends of some other moths (e.g., the sugar cane borer, *Diatraea saccharalis* (Crambidae)) have proven so elusive.

These blends have other remarkable features. First, their dissimilar components almost certainly arise from two independent pheromone biosynthesis pathways, with the shorter chain components probably being synthesized in the pheromone gland and the longer chain hydrocarbons possibly being synthesized in oenocyte cells and transported to the gland through the hemolymph (see Jurenka, 2004). Second, it is unclear how calling female moths successfully emit optimal blends of compounds with such substantial differences in vapor pressure. Third, it is surprising, but not unprecedented (e.g., Cabrera et al., 2001), that the polyunsaturated hydrocarbon components elicit relatively weak responses from male antennae, despite their being crucial to eliciting behavioral responses. Answers to these and other questions may be forthcoming from ongoing explorations of these novel pheromone blends.

SOIL MICROVARIATIONS AS A SOURCE OF VARIABILITY IN THE WILD: THE CASE OF SECONDARY METABOLISM IN *Origanum dayi* POST

G. N. AMZALLAG,[1] O. LARKOV,[2] M. BEN HUR,[3] and N. DUDAI[2,*]

(Received July 13, 2004; accepted February 26, 2005)

Abstract—The volatile components of *Origanum dayi* Post were analyzed in 10 wild populations grown in a limited area. ANOVA tests showed no significant differences among the compositions of plants that grew in different locations, which suggests that differences in composition are of genetic origin and do not spring from environmental variation. However, the use of new statistical methods (such as use of the correlation coefficient, *r*, as a parametric value) revealed that, despite their reduced range of variation, most of the 22 soil properties (SPs) measured correlated with the composition of the volatile components. This analysis also indicated that the main volatile components were modified in parallel in response to SP variations. It is concluded that variations in soil properties affected the composition of volatile components in *O. dayi*, and that the main influencing factors were soil microelement contents and texture. This study highlights the need for highly sensitive statistical tools to determine the actual influence of environmental factors in natural environments, especially when their range of variation is small.

Key Words—Canalization, plasticity, secondary metabolism, essential oil, *Origanum dayi*, analysis of variability, ANOVA, nongenotypic effects, soil microvariation effects.

INTRODUCTION

Variations in soil composition and structure may influence the composition of essential oils in plants. For example, soil fertility was shown to affect the composition of the essential oils in *Mentha arvensis* (Singh et al., 1989), *Origanum syriacum* (Omer, 2000), *Daucus carota* (Schaller and Schnitzler, 2000), and many other species (e.g., Adler et al., 1989; Piccaglia et al., 1989; Thomas and Cracker, 1991; Dragar and Menary, 1995; Khan et al., 1999). Variations in micronutrient contents and soil sodicity also affect the essential oil composition (Ram et al., 1999; Singh and Misra, 2000).

However, in all these cases, the observed changes in essential oil content or composition resulted from wide variations of a single soil parameter that were imposed to evaluate its influence. However, such a mode of variation does not necessarily match the conditions encountered in natural habitats. In the wild, many soil properties vary simultaneously over narrow ranges, even within an apparently homogeneous area. In such a case, it is not clear whether low amplitude variations of soil properties affect plant secondary metabolism. The present study used highly sensitive statistical tools to evaluate the effects of soil microvariations on the composition of plant volatile components, specifically in *Origanum dayi* Post (Lamiaceae). This endemic subshrub, a copious producer of volatile components (Dudai et al., 2003), grows wild in the Northern Negev and Judean Desert in Israel (Feinbrun-Dothan, 1987). Most of the individuals belonging to this species grow in a small area in the southeastern Judean Mountains (a north–south strip, 15 km long and ~5 km wide), at the boundary between the Mediterranean and the desert land flora. This area is relatively uniform in altitude, between 700 and 900 m above sea level (asl), with annual mean rainfall ranging from 250 to 350 mm. It was chosen for testing the influence of microvariations in soil properties and structure on the accumulation of the volatile components in plants.

METHODS AND MATERIALS

Plant and Soil Sampling. Ten sites were selected. In each, the vegetative shoot was harvested from each of six individuals that were randomly sampled within a 15-m radius. Sampling was conducted between 6:00 and 8:00 A.M. on July 18, 2002, when most of the upper parts of the plant stem were still vegetative.

One soil sample from 0.05- to 0.2-m depth was taken in the middle of each sampling site. Soil samples were dried in a ventilated oven at 70°C and ground by hand. The gravel (fragments up to 7.5-cm diam) content in the soil samples was determined by dry sieving. Crushed soil was sieved through a 2-mm sieve

and stored pending further analysis. Values of soil properties (SPs) at the 10 sampling sites and their coefficients of variation (CV) are presented in Table 1. Calculation of the coefficient of variation (CV) of each SP revealed that nitrogen, phosphorus, zinc, manganese, gravel, and $CaCO_3$ were the most variable (Table 1).

Chemical and Physical Analysis. Essential oil was extracted from a 2-cm segment of the upper part of a nonflowering shoot of each plant sample. A mixture of methyl *tert*-butyl ether (MTBE) and 10 μg/ml of isobutyl benzene (as internal standard) were combined with the shoot segment at 5 ml MTBE per gram (fresh weight) of shoot, according to Lewinsohn et al. (1993). This was shaken gently for 2 hr at room temperature. The resulting extract was purified by passage through a Pasteur pipette containing anhydrous Na_2SO_4 and silica gel 60 (230–400 mesh, Merck). This purification was to dry the sample and to remove polar substances of high molecular weight that would interfere with the GC-MS analyses (Dudai et al., 2001).

Methyl *tert*-butyl ether extracts were analyzed on an HP-GCD apparatus equipped with an Rtx-5SIL MS (30 m × 0.25 mm i.d. × 0.25 μm) fused-silica capillary column (Restek). The carrier gas was helium flowing at 0.8 ml/min. Samples were injected in both split and splitless injection modes. The injector temperature was 250°C, and the transfer line temperature was 280°C. Column conditions were 50°C for 1 min, 50–260°C at 5°C/min, and 10 min at 260°C. The mass range was acquired by working in the EI mode (70 eV), over an *m*/*z* range of 41–350. Compounds were identified by comparing their relative retention indices and spectra with those of authentic standards or with those reported in the literature (Adams, 2001) and by using the NIST 98 and QuadLib 1607 GC-MS libraries.

For all soil samples, the mechanical composition was determined with a hydrometer (Day, 1956), the organic matter (OM) content by the Walkley–Black method (Allison, 1965), and the $CaCO_3$ content by a volumetric method (Allison and Moodie, 1965). The pH, electrical conductivity (EC), sodium adsorption ratio (SAR), and potassium adsorption (PAR) values and the Cl^-, Na^+, Ca + Mg, and K^+ concentrations were determined in saturated soil paste. The SAR and PAR were calculated according to Equations (1) and (2), respectively.

$$\mathrm{SAR} = \frac{(\mathrm{Na})}{(\mathrm{Ca} + \mathrm{Mg})^{0.5}} \tag{1}$$

$$\mathrm{PAR} = \frac{(\mathrm{K})}{(\mathrm{Ca} + \mathrm{Mg})^{0.5}} \tag{2}$$

where the cations concentration are expressed in mmol/l.

$N–NO_3$ concentration in the soil samples was determined by extraction with 1 M KCl (Keeney and Nelson, 1982) and the available $P–PO_4$ concentration by extraction with 0.5 M $NaHCO_3$ (Olsen and Sommers, 1982). The available micronutrients, Fe, Zn, Mn, and Cu, in the soil samples were determined by extraction with diethylenetriaminepentaacetic acid (Lopert and Inskeep, 1996).

Statistical Analyses. The statistical tools used in this study were based on comparison of r values (the correlation coefficients for linear correlation) considered as parameters. However, since the r coefficients are not normally distributed, their comparison is only possible after a z-transformation, which converts them into parameters with near normal distributions (Sokal and Rohlf, 1981), according to Equation (3):

$$z = 0.5 \times \ln\left[(1 + r)/(1 - r)\right] \tag{3}$$

As previously shown by Amzallag (1999a,b, 2000), such a conversion enables the r coefficients to be used as parameters that quantify the level of linkage between a pair of variables.

For each soil property (SP), an influence index was calculated as follows:

$$\ln\,(\mathrm{SP}) = 1/(m-1)\sum z\left(\mathrm{SP}, Y_j\right) \tag{4}$$

where Y_j are the $m-1$ components other than SP considered to be representative of the essential oil (m = 21; see Results and Discussion).

For a volatile component Y, the coefficient of variation, $\mathrm{CV_L}(Y)$, in a location L is defined in Equation (5)

$$\mathrm{CV_L}(Y) = 100 \times \mathrm{SD_L}(Y)/\mathrm{AVG_L}(Y) \tag{5}$$

where SD and AVG are the standard deviation and the mean value, respectively, of the parameter Y for the population considered (L). Canalization of a parameter quantifies the level of uniformity of expression of a character among plants exposed to the same soil conditions (the same location). For a volatile component Y, the canalization $[C(Y)]$ is determined according to Debat and David (2001) as the inverse value of the mean of the within-localities values of the CV of Y:

$$C(Y) = n \times 1\Big/\left[\sum \mathrm{SD_{L}}i(Y)/\mathrm{AVG_{L}}i(Y)\right] \tag{6}$$

where $L_1, \ldots, L_n$ are the n localities considered.

Plasticity quantifies the influence of environmental variations on the composition of the volatile components. For each component Y, the plasticity $[P(Y)]$ was calculated as the coefficient of variation between mean values of Y (each determined at one location):

$$P(Y) = 100 \times \mathrm{SD}[\mathrm{AVG_{L1}}(Y), \ldots, \mathrm{AVG_{L}}n(Y)]\Big/\tilde{Y}, \tag{7}$$

[a]Mean and SD values of 52 main volatile components of *O. dayi* from the 10 locations. Quantity of each component was calculated as the percentage of the total volatile compounds. Mean and SD values were calculated on the basis of six samples harvested from each of the 10 locations.

where $\tilde{Y}$ is the overall mean value of Y, calculated by Equation (7)

$$\tilde{Y} = 1/n \times \sum \mathrm{AVG}_{\mathrm{L}i}(Y) \tag{8}$$

RESULTS AND DISCUSSION

Volatile Components of O. dayi. The volatile components of *O. dayi* were analyzed separately for each of the six individual plants sampled from each of 10 localities, and an average composition was determined for each location by pooling data from the six related individuals. About 52 volatile components were separated, of which the most abundant were 1,8-cineole, (*E*)-sabinene hydrate, α-terpineol, and (*E*)-sabinene-hydrate acetate (Table 2).

TABLE 3. CHARACTERISTICS OF THE 21 VOLATILE COMPONENTS SELECTED FOR FURTHER ANALYSIS[a]

[a] The *Y* components are ordered according to their quantitative importance. Mean, maximal, and minimal values were calculated (as % of the total components) on the basis of the whole population of 60 samples. The *P* value was calculated for difference among the 10 defined populations (ANOVA).

Only 21 of the 52 compounds were subjected to further analysis: they included all the compounds present at more than 1%, but also some of those with the longest retention times (Table 3). These 21 components (designated as Y) account for about 92% of the total volatile components that form the average composition of the 60 *O. dayi* samples analyzed; all of them varied considerably in their abundance, as indicated by the minimum and maximum values presented (Table 3).

In spite of this wide variation, between-population variation was similar to within-population variation (Table 3), which suggests that the samples taken from the 10 locations belong to the same population of *O. dayi*. Moreover, no significant difference ($P < 0.05$ one-way ANOVA test) could be found among the 10 populations for any individual *Y* component, except for caryophyllene oxide, which accounts for less than 1% of the total compounds (Table 3). These results suggest that variations in soil structure and composition (Table 1) had no real influence on the composition of Y, so that variations in the composition of *Y* could be attributed to genetic variation inherent to the sampling of a wild population.

Reinterpretation of the Observed Variability. If most of the observed variations in composition were of genetic origin, it would be expected to exhibit similar amplitudes in all locations, and no relationship would be expected between within-location variability (i.e., the variability of each volatile component, among the six samples analyzed in each location) and between-population variability (i.e., the variability among mean values calculated for each population). For each of the 21 components of *Y* (Table 3), the CV calculated for each one of the 10 populations (Table 2) was averaged, and this value (mean of CV values) was plotted as a function of the CV calculated between the 10 mean

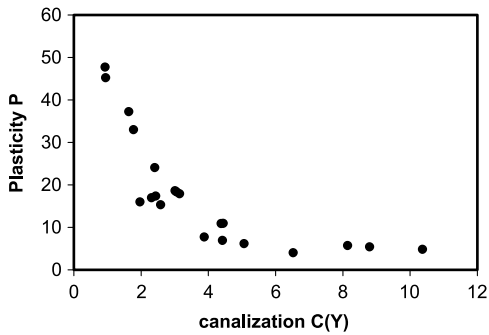

FIG. 1. Relationship between plasticity and canalization in representation of the 21 main components of the essential oil from *O. dayi*. For each volatile component *Y*, canalization and plasticity [respectively $C(Y)$ and $P(Y)$] were calculated as described in Methods and Materials.

[a] The significant correlations ($P < 0.05$ for $|r| > 0.632$, $df = 8$) are indicated in bold characters. For each SP, the influence index was calculated as described in Methods and Materials.

values presented in Table 2 (CV of the mean values). A significant and positive relationship was observed ($r = 0.904$, $df = 19$, $P < 0.001$, not shown), which indicates that the variability observed cannot be considered simply as noise. Rather, the CV of the 10 mean values reflects the level of *plasticity* of each component of Y. The significant relationship observed (Figure 1) between plasticity and canalization (calculated as defined in Methods and Materials) suggests that the levels of variation within and between populations are not determined mainly by genetic variability. Therefore, more detailed analysis of any links between soil properties and essential oil composition is required.

Linkage between Soil Parameters and Volatile Components. For each soil property (SP_i) ($1 \leq i \leq 22$), a numerical value $SP_i(l_k)$ was designated for each location l_k ($1 \leq k \leq 10$) (Table 1). In parallel, for each volatile compound Y_j ($1 \leq j \leq 21$), a numerical value $Y_j(l_k)$ was designated for each location l_k (Table 2). Thus, for each pair (SP_i, Y_j), a correlation coefficient (termed r_{ij}) could be determined on the basis of variation of these variables among the 10 locations.

The *r* coefficients were calculated for the 462 possible (i, j) pairs presently defined (Tables 4 and 5). This analysis revealed an influence of many SPs on *Y* values. For example, the percentage of 1,8-cineole, the most widely represented volatile component in the essential oil of *O. dayi* (Table 3), appears to be correlated with the percentage of calcareous components in the soil (Table 4A),

[a] The significant correlations ($P < 0.05$ for $|r| > 0.632$, $df = 8$) are indicated in bold characters. For each SP, the influence index was calculated as described in Methods and Materials.

but also with the concentrations of microelements, especially iron and manganese, in the soil (Table 5B).

Not all the SPs exhibited the same influence on the volatile compounds. For example, Na content and SAR showed no significant correlation with any *Y* component. In contrast, the percentage of organic matter in the soil and the zinc and potassium contents were each significantly correlated with three *Y* parameters (Tables 4 and 5).

To estimate the precise influence of each SP on essential oil composition, the *r* coefficients were converted into *z* values by Equation (3). For each SP_i, the *influence index* [$In(SP_i)$] of its effect on essential oil composition was calculated by Equation (4), as described in Methods and Materials. Calculation of this index indicated that the soil factors that most influenced the essential oil composition are iron content, delta F, PAR, Zn content, and pH (Tables 4 and 5).

Nature of the Nonsignificant Correlations. Less than 10% of the correlations presented in Tables 4 and 5 were statistically significant ($P < 0.05$ for $r \geq 0.632$, $df = 8$). Indeed, such a result is not surprising because the analysis was applied to wild populations for which genetic and environmental variations (even microvariations in soil properties between surface and deep soil layers) are constitutive. In such a context, attention should be given not only to significant correlations, but also to the trends in variations of low *r* values. For this reason, we have considered the *r* values (after their *z*-transformation) as parameters that quantify the linkage between a soil property and a volatile component. Before performing such an analysis, it is necessary to verify whether variations in *z* values really reflect the strength of the relationship between a soil parameter and a volatile component.

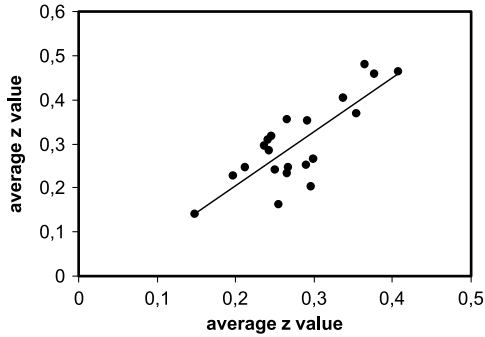

FIG. 2. Relationship between influence of structural and composition parameters of soil on representation of the 21 main components of the essential oil of *O. dayi*. The influence index (determined as the average value of *z*-transformed absolute *r* values) was calculated separately for structural parameters (from Table 4) and for composition parameters (Table 5). A highly significant correlation ($r = 0.805$, $df = 19$, $P < 0.001$) is observed.

TABLE 6. CLASSIFICATION OF SOIL PARAMETERS ACCORDING TO THEIR EFFECT ON BETWEEN-POPULATION VARIABILITY IN COMPOSITION OF VOLATILE COMPONENTS IN *O. dayi*

	Significant correlation	Nonsignificant correlation
Soil structure	Calcareous (0.570)	Sand (−0.216)
	Clay (0.601)	Silt (−0.227)
	Gravel (0.517)	
	Org. (−0.761)	
Soil properties	Satur (−0.431)	Delta F (−0.04)
	Conduct. (−0.456)	PAR (0.204)
		SAR (−0.161)
		PH (0.055)
Macroelements	Na (−0.556)	Cl (−0.007)
	Ca + Mg (−0.491)	N (−0.335)
		P (−0.339)
		K (−0.108)
Microelements	Fe (−0.669)	
	Zn (0.487)	
	Mn (−0.672)	
	Cu (0.440)	

For each soil parameter SP, the *r* correlation between CV of the *X* component and its $z_{sp}(X)$ value was calculated. The *r* values are indicated in parentheses. Significant correlations ($P > 0.05$, $df = 19$) are observed for $|r| > 0.43$.

For each *Y* component, all the *z*-transformed absolute values of the *r* coefficients for relationships with the SPs listed in Table 4 were averaged. A similar calculation was performed for the SPs listed in Table 5. Thus the corresponding average *z*-values calculated from Tables 4 and 5, respectively, were plotted against one another, and a highly significant correlation was observed ($r = 0.805$, $df = 19$, $P < 0.001$, Figure 2). This suggests that components with low average *z* values may be considered to be stable, and those with high *z* values to be highly dependent, for their production, on the various soil characteristics.

Before drawing conclusions about fluctuations in *z* values, it is also necessary to verify whether variations in *r* coefficients reflect a real influence on the composition of the essential oil in *O. dayi*. For example, if the highest r_{ij} values coincided with the most widely variable SPs, one might conclude that the strength of the relationship was biased by the range of SP variation. To test this point, the coefficient of variation of each SP was calculated from the data in Table 1 and plotted as a function of the corresponding influence index (Tables 5 and 6). The very low *r* value obtained for this correlation ($r = 0.13$, $df = 20$, $P > 0.05$ not shown) indicates that the differences in the amplitude of SP variations did not significantly influence the strength of the relationship with *Y* parameters.

Linkage Between z Values and Canalization. Networks are characterized by buffering properties with regard to perturbations (Amzallag, 2001). For this reason, and to test whether low *r* values may also be considered to reflect a phenomenon, we investigated the relationship between canalization of a Y_j character calculated by means of Equation (6) and the *z*-transformed r_{ij} value calculated for the relationship with an SP_i. We tested this link for the organic matter content in the soil (abbreviated as *org*), a soil property with wide variations in *r* values (Table 4). When the canalization of a volatile component

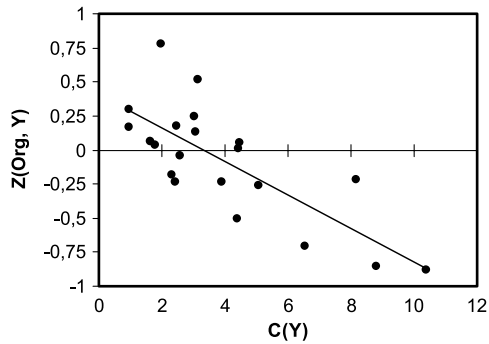

FIG. 3. Relationship between canalization of a volatile component and the influence of the percentage of organic matter in the soil on its variation. A highly significant correlation ($r = -0.761$, $df = 19$, $P < 0.001$) is observed.

TABLE 7. PARALLELS IN THE INFLUENCE OF MACROELEMENTS ON COMPOSITION OF THE VOLATILE COMPONENTS IN *O. dayi*[a]

[a]Upper half: r coefficient of correlation between $z(\mathrm{SP}, Y)$ of two SP variables; lower half: r between two SP variables. Upper half: The correlations (indicated in bold characters) are significant ($P < 0.05$) for $r \geq 0.433$ (upper half, $df = 19$) and for $r \geq 0.632$ (lower half, $df = 8$).

Y was plotted as a function of $z(org, Y)$, a highly significant negative correlation was found (Figure 3). This confirms that the z values may be considered as parameters *per se*, independently of the statistical significance of the r coefficients. Moreover, it reveals that the main components of the essential oil of *O. dayi* behave as a globally integrated system, which suggests that there is a network of relationships among the metabolic pathways.

A similar relationship was studied for the other soil properties. Of the 22 properties that were measured (Table 2), 11 showed a significant correlation between the CV and the $z_{sp}(X)$ value of the X component (Table 6). Therefore, we suggest that all the microelements and soil texture parameters directly affect the secondary metabolic network as a whole. Concerning the other 11 soil properties, they may also influence the secondary metabolic network, but their influence cannot be revealed by simple analyses of the r correlation coefficient.

Redundancy in Data. A parallel between the $z(\mathrm{SP}, Y)$ values of two soil properties may be a consequence of a correlation between their variations in the soil samples. To test this point, the relationships between the contents of the

TABLE 8. PARALLELS IN THE INFLUENCE OF MICROELEMENTS ON COMPOSITION OF VOLATILE COMPONENTS IN *O. dayi*[a]

Mn	**0.941**	−0.569		**−0.549**
Cu	−0.350	**0.954**	−0.441	

[a]Upper half: r coefficient of correlation between $z(\mathrm{SP}, Y)$ of two SP variables; lower half: r between two SP variables. Upper half: The correlations (indicated in bold characters) are significant ($P < 0.05$) for $r \geq 0.433$ (upper half, $df = 19$) and for $r \geq 0.632$ (lower half, $df = 8$).

various macroelements in the soils were calculated. A significant correlation was observed only between the variations of Cl and Ca + Mg concentrations in the soil solution (lower half of Table 7). In contrast, seven of the 15 correlations between the z(SP, Y) values of two SP variables calculated for macroelements were significant (upper half of Table 7). This indicates that the parallels observed in the influence of the various macroelements on Y values were not trivial, but that they reflected their common influence on these metabolic pathways. A similar analysis was performed for the microelements, and real parallels were found between the influence of copper and zinc contents in soil and between those of iron and manganese contents (lower half of Table 8). For this reason, it is impossible to determine which of the microelements in each of these pairs (Cu or Zn, Fe or Mn) actually influences this secondary metabolism. However, nontrivial antagonistic interactions between the effects of Fe and Mn, and between those of Cu and Zn, were revealed by the significant negative correlations between their z values (upper half of Table 8). Again, the significant correlations observed between z values (upper half of Tables 7 and 8) confirm that they should be considered as parameters that quantify the influence of soil properties on the composition of the essential oil in *O. dayi*.

Conclusions and Implications. Analysis of variance (ANOVA) is generally used to test the importance of fluctuations of a variable on parameters of a system. The present study reveals a more complex situation. The fact that a one-way ANOVA test does not reveal significant differences does not always imply that the observed variability is noise that is inherent to the environmental and genetic heterogeneity (Figure 1). In the present case, many soil factors have a real influence on the abundance of certain volatile components in *O. dayi* (Tables 4–6, Figure 3). It is even difficult to point to a soil property (except perhaps the SAR) that is devoid of influence on the secondary metabolism in these natural conditions.

The inability of ANOVA tests to reveal such an influence may arise from one or more of many causes, which are not mutually exclusive: (1) opposing influence of various soil parameters prevents the emergence of a significant trend; (2) the range of variation of the SP is too small to generate significant differences large enough to be evaluated by tests based on comparison of mean values; (3) the influence of soil properties is partly buffered by the metabolic network; (4) the wide range of genetic variability inherent in the wild population hides any clear trend.

To overcome these problems, in laboratory experiments, the range of variation of SPs is generally increased artificially. However, it is not always possible to extrapolate the effects of amplified variations to the responses of plants exposed to natural conditions. For example, macronutrients are considered to be the main soil factors influencing production of the volatile components (Dudai, 2005). However, calculation of the indices of influence

(Tables 4 and 5) for all the soil properties indicated the K, P, and N contents to be secondary factors; they were ranked 10th, 16th, and 17th, respectively, in order of importance, among 22 factors. In the present study, we found that the most important soil factors in influencing composition of the essential oil in *O. dayi* were microelements (Table 6 and Figure 3), which are generally ignored in studies of the influence of soil nutrients on secondary metabolism.

Until now, *r* correlation coefficients have been used to test the significance of the linkage between two variables. This leads to an all-or-none segregation of the linkages into significant and nonsignificant ones: a segregation which classifies the *r* value *per se* as devoid of significance. The importance of variations in *r* values to the understanding of physiological processes has already been highlighted (Amzallag, 1999a,b, 2001), and the present study confirms that *r* values, after being *z*-transformed, may reflect the strength of the influence of a soil factor on the composition of the essential oil. As shown by the highly significant correlations observed (e.g., Figures 2, 3, and Tables 6–8), even low values of *r* are of importance in such a representation. In that sense, we should also consider *r* as a variable and not only as a parameter.

In many cases, the $z(\mathrm{SP}, Y)$ values calculated for two soil properties are interrelated (e.g., Tables 7 and 8), which indicates that variations in at least some of the soil properties (e.g., the iron, manganese, copper, and zinc contents) affect the secondary metabolism as a whole (Table 6). This "integrated effect" in the influence of some of the soil properties suggests that the processes that produce the main components of the essential oil in *O. dayi* are not controlled independently, but that they behave as a part of an integrated metabolic network. It also suggests that genetic variability is not necessarily reflected in the variability in the composition of the essential oil. A similar conclusion arose from a comparison between populations of *Pistacia lentiscus*, with respect to their genetic variability and variations in their essential oil composition (Barazani et al., 2003). It seems, therefore, that the chemical composition of the essential oil reflects discrete stable states of the metabolic network, rather than strict genetic control over the production of each volatile component.

The influence of environmental factors on the biosynthesis of essential oil in *O. dayi* is not the only highly networked process to be found in plants. Meristems and differentiating tissues are also organized in a complex regulation network of communication, through the plant growth regulators they produce (Amzallag, 1999a). The source–sink relationships also generate a complex network that involves both sugars and PGRs as information-carrying substances (Gibson, 2000), and even gene expression in plants is now understood to be regulated as a network of interactions (Finnegan, 2001). This suggests that the quantitative use of statistical parameters as variables should not be restricted to our understanding of the factors influencing production of essential oils of commercial value. Rather, these parameters may be useful tools in elaborating

our oversimplified representation of the relationships between organisms and their natural environments.

EXPRESSION OF CONSTITUTIVE AND INDUCIBLE CHEMICAL DEFENSES IN NATIVE AND INVASIVE POPULATIONS OF *Alliaria petiolata*

DON CIPOLLINI,* JEANNE MBAGWU, KATHRYN BARTO, CARL HILLSTROM, and STEPHANIE ENRIGHT

Department of Biological Sciences, Wright State University, 3640 Colonel Glenn Highway, Dayton, OH 45435, USA

(Received December 3, 2004; accepted February 4, 2005)

Abstract—The Evolution of Increased Competitive Ability (EICA) hypothesis posits that invasive plants in introduced habitats with reduced herbivore pressure will evolve reduced levels of costly resistance traits. In light of this hypothesis, we examined the constitutive and inducible expression of five chemical defense traits in *Alliaria petiolata* from four invasive North American and seven native European populations. When grown under common conditions, significant variation among populations within continents was found for trypsin inhibitors and peroxidase activity, and glucosinolates and trypsin inhibitors were significantly jasmonate-inducible across populations. Across populations, constitutive levels of glucosinolates and trypsin inhibitors were negatively correlated with their degree of induction, with three North American populations tending to have lower constitutive levels and higher inducibility of glucosinolates than the seven European populations. Alliarinoside and isovitexin 6″-*O*-β-D-glucopyranoside levels were both higher in North American plants than in European plants, but levels of these compounds were generally increased by jasmonate in European plants and decreased by the same treatment in North American plants. Aside from the tendency for invasive populations to have reduced constitutive glucosinolate levels coupled with increased inducibility, little support for the predictions of EICA was evident in the chemical defenses that we studied.

Key Words—*Alliaria petiolata*, defense proteins, evolution, glycosides, herbivory, induced defenses, invasive plants, jasmonic acid.

INTRODUCTION

Explaining the apparent increased vigor of invasive plant species in novel habitats has received a great deal of attention recently. One hypothesis that has motivated a number of studies is the Evolution of Increased Competitive Ability (EICA) hypothesis (Blossey and Nötzold, 1995). Among a broader suite of predictions, the EICA hypothesis posits that invasive plant populations in introduced habitats with reduced herbivore pressure will evolve lower levels of costly herbivore resistance traits and higher fitness than populations from the native range, given enough time. The expression of resistance traits by plants is costly to growth and fitness (Cipollini et al., 2003a), and relaxation of herbivore pressure can quickly select for reduced expression of resistance traits in plants (Mauricio and Rausher, 1997). Increased growth rates due to reduced expression of unnecessary resistance traits may be one explanation for the success of some invasive species.

Comparisons of invasive and native plant populations in common garden studies have revealed mixed support for EICA thus far. In *Lythrum salicaria*, plants from one invasive North American population grew larger in a European garden and were less resistant to a root-feeding weevil than plants from one native European population (Blossey and Nötzold, 1995). However, performance of a leaf-feeding beetle did not vary. Willis et al. (1999) found that native *L. salicaria* populations were no more resistant to herbivores than invasive North American and Australian populations, despite having higher phenolic contents. In *Solidago gigantea*, invasive European populations incurred more ambient herbivore damage than native North American populations in a North American garden (Meyer et al., 2001). In *Solidago canadensis*, however, invasive European populations were less fit than plants from native North American populations in a North American garden and were equally responsive to simulated herbivory (van Kleunen and Schmid, 2003). Siemann and Rogers (2001) showed that invasive North American populations of *Sapium sebiferum* grew faster and had lower levels of tannin in a North American garden than native Chinese populations, but were equally susceptible to herbivory. In *Alliaria petiolata*, Bossdorf et al. (2004a) demonstrated higher feeding rates by a specialist weevil on invasive North American populations than on native European populations in the laboratory, but no variation in susceptibility to a generalist caterpillar or in tolerance to simulated herbivory. Bossdorf et al. (2004b) also showed that, while similar in the absence of competition, invasive populations were less fit than their native counterparts when in competition with them, challenging the notion of improved competitive ability in invasive populations.

Although the EICA hypothesis makes clear predictions about the evolution of resistance traits in plants, few tests of EICA have examined defense chemistry. In those that have (e.g., Willis et al., 1999; Siemann and Rogers, 2001), comparisons have been restricted to a single compound, which did not explain patterns of resistance among native and invasive populations. In addition, no

tests of EICA have examined variation in inducibility among populations or the relationship between constitutive and induced defense expression. We examined the degree to which the expression of five chemical defenses in *A. petiolata* conformed to predictions of the EICA hypothesis. *A. petiolata* is an aggressive invader of deciduous woodlands throughout North America (Nuzzo, 2000). In Europe, *A. petiolata* is consumed by as many as 70 different herbivores (including five monophagous specialists) and seven pathogens, while only 11 total herbivores (no monophagous specialists) and few pathogens have been reported to consume it in North America (Blossey et al., 2001). Some information on the defense chemistry of this plant is available (e.g., Haribal and Renwick, 2001; Renwick et al., 2001; Cipollini, 2002b), but no comparisons of defense expression in native and invasive populations have been reported.

We first examined the expression of glucosinolates, peroxidase, and trypsin inhibitor activity in several native and invasive populations of this plant. We selected these defenses because they are known to be expressed by *A. petiolata* (Cipollini, 2002b), they are associated with resistance to generalist insects and/or pathogens in other mustards (e.g., Traw et al., 2003; Cipollini et al., 2004), and they are associated with fitness costs in other mustards (Mauricio and Rausher, 1997; Cipollini, 2002a). Each of these defenses has also been shown to be inducible by wounding, insect feeding, and/or jasmonic acid (JA) application in *A. petiolata* or other mustards (Cipollini and Bergelson, 2000; Cipollini, 2002b; Cipollini et al., 2003b, 2004). Second, we examined the expression of alliarinoside and isovitexin-6″-*O*-β-D-glucopyranoside, two glycosides in *A. petiolata* that are known to deter feeding by the mustard specialist *Pieris napi oleraceae* (Renwick et al., 2001), but for which little other information is available. Since *A. petiolata* both lacks monophagous specialists and supports fewer generalist herbivores in North America (Blossey et al., 2001), we predicted that North American populations would show reduced constitutive expression of each chemical defense, assuming that the expression is costly (Cipollini et al., 2003a). According to defense theory, the maintenance or increased inducibility of defenses should accompany reduced constitutive defense expression in populations where this is observed, lest plants be rendered defenseless (Koricheva et al., 2004). As plant defenses vary in their costs, and herbivores are differentially responsive to them, examination of a broader suite of defenses and their modes of expression may help to explain the varying support for EICA that has been detected thus far.

METHODS AND MATERIALS

Study System. A. petiolata. [(M. Bieb) Cavara and Grande; Brassicaceae] is a self-fertile Eurasian biennial, first recorded on Long Island, NY, in the 1860s,

that is spreading rapidly in North America (Nuzzo, 2000). *A. petiolata* flourishes in moist woodlands with moderate exposure to light, but it can grow in a diversity of habitats (Byers and Quinn, 1998; Meekins and McCarthy, 2000). It exhibits remarkable morphological plasticity to local environmental conditions (Byers and Quinn, 1998), it can exude allelopathic chemicals (e.g., Roberts and Anderson, 2001, but see McCarthy and Hanson, 1998), and it produces numerous seeds (Cavers et al., 1979).

Experimental Design. We used seeds from four North American populations from Ohio and Pennsylvania, USA, and seven European populations from the UK and the Netherlands (Table 1). These populations represent only a portion of the native and introduced ranges of garlic mustard, but we have considered population a random factor in our statistical analyses to broaden the generality of our results. Within each population, several mature seeds were collected from at least 10 widely spaced individuals and pooled. Seeds of each population were stratified on moistened filter paper at 4°C until germination, and seedlings were grown in a greenhouse as in Cipollini (2002b). Briefly, germinated seeds were transplanted in Pro-Mix BX potting medium in 500-ml pots and grown under ambient light supplemented with fluorescent lights timed to be on for 13 hr each day. Greenhouse temperatures averaged 22 ± 5°C. Plants were watered with distilled water as needed and were not fertilized in addition to the starter nutrients present in the potting medium. After 35 days of growth, half of the plants in each population were treated with a foliar spray of jasmonic acid (JA) as in Cipollini (2002a). Jasmonic acid is a wound-related hormone that mediates the expression of several chemical defenses in plants (e.g., Cipollini

et al., 2004). Induction of defenses by exogenous application of this hormone reasonably mimics induction by herbivore damage (e.g., Thaler et al., 1996). Use of jasmonic acid allows the careful control of the level and timing of induction, and it removes the potentially confounding effects of differential population susceptibilities and herbivore-derived elicitors that would limit generalizations extending from the use of an actual herbivore for induction. In preliminary experiments, we found that exogenous application of this hormone induces trypsin inhibitors in *A. petiolata* in a manner similar to wounding (C. Hillstrom and D. Cipollini, unpublished data). Uninduced plants in each population received an aqueous control spray. Four days after treatment, samples from the fourth true leaves of all plants were harvested for chemical analysis. For each population, levels were assessed in 5–10 replicate plants in each treatment.

Chemical Analyses. Total glucosinolates were assessed in methanol extracts of leaves using the glucose release method as in Siemens and Mitchell-Olds (1998), as modified in Cipollini (2002b). Due to sampling error, the Cedar Falls population was not included in the glucosinolate analysis. Peroxidase activity was assessed in soluble protein extracts of leaves using a spectrophotometric assay as in Cipollini et al. (2004). Trypsin inhibitors were assessed in soluble protein extracts using a radial diffusion assay as in Cipollini and Bergelson (2000). Levels of alliarinoside and isovitexin 6″-*O*-β-D-glucopyranoside were assessed in water-soluble fractions of ethanol extracts of leaves by HPLC, as in Haribal and Renwick (2001), with the following modifications. Compounds were extracted from two to three plants from each population receiving each treatment in boiling ethanol for 10 min, then diluted with water before a solvent change to pure water. Glycosides were isolated using a Phenomenex Luna C18 (150 × 4.6 mm, 5 μm) column attached to a Waters 2690 HPLC system equipped with a photodiode array detector. A water/acetonitrile gradient from 5 to 30% acetonitrile over 10 min was used. We identified the two glycosides by their retention time and UV absorption spectra. Peak areas at 218 nm were used to quantify the expression of each compound. We verified the identity of these two compounds by electronspray ionization (ESI)/MS and MS/MS on an liquid chromatography quadrapole (LCQ) ion-trap mass spectrometer (ThermoQuest, USA).

Statistical Analysis. Mean chemical defense levels were analyzed with mixed-model nested analysis of variance (ANOVA) with continent, population nested within continent, and JA treatment as main effects, including all interactions. Population and its interaction with other factors were considered random factors, and continent and JA treatment fixed factors. The generalized linear model procedure (PROC GLM) using the random statement in SAS V. 8.02 (SAS Institute, Cary, NC, USA) was used to complete these analyses. Type III expected mean squares were used in all tests, which utilized Satterthwaite

F values. The approximate degrees of freedom in the denominator of each *F* statistic have been rounded to the nearest whole number. While most populations were still represented, the population factor was excluded in the analysis of alliarinoside and isovitexin 6″-*O*-β-D-glucopyranoside due to lack of replicate samples within some populations. Thus, only continent, JA and their interaction were included in the fixed effect ANOVA for these two defenses. Pearson correlations were performed among and between constitutive and induced levels of trypsin inhibitor, peroxidase, and glucosinolates using the treatment means for each population. In addition, Pearson correlations were performed between constitutive levels of each of these defenses and the percent difference between their constitutive and induced levels (their *degree* of inducibility), again by using population means. All data were transformed as needed to meet the assumptions of ANOVA. All analyses were conducted using SAS V. 8.02 (SAS Institute, Cary, NC).

RESULTS

Total glucosinolate levels were similar among continents overall and among populations within continents, but were significantly induced by JA treatment by about 26% overall (Table 2, Figure 1A). While no significant interaction was detected in the ANOVA, North American populations tended to have lower constitutive and higher induced levels than European populations.

TABLE 2. *F*-VALUES FROM MIXED-MODEL ANOVA EXAMINING THE EFFECT OF CONTINENTAL ORIGIN, POPULATION WITHIN CONTINENT, AND JASMONIC ACID (JA) TREATMENT ON CHEMICAL DEFENSE LEVELS IN FOURTH TRUE LEAVES OF GARLIC MUSTARD FROM NATIVE EUROPEAN AND INTRODUCED NORTH AMERICAN POPULATIONS *P*-VALUES ARE IN PARENTHESES

Source	TI	GS	POD
Continent	$F(1,11) = 0.03$ (0.867)	$F(1,9) = 0.01$ (0.908)	$F(1,11) = 2.02$ (0.182)
Population (Cont)	$F(9,9) = 4.50$ (<0.018)	$F(8,8) = 0.53$ (0.809)	$F(9,9) = 4.79$ (<0.014)
JA treatment	$F(1,23) = 88.73$ (<0.001)	$F(1,25) = 4.93$ (0.036)	$F(1,19) = 0.24$ (0.631)
Continent × JA	$F(1,24) = 0.37$ (0.550)	$F(1,27) = 2.73$ (0.110)	$F(1,20) = 1.19$ (0.288)
Pop (Cont) × JA	$F(9,183) = 1.10$ (0.364)	$F(8,168) = 1.27$ (0.263)	$F(9,183) = 1.41$ (0.187)

TI = trypsin inhibitor, GS = glucosinolates, POD = peroxidase.

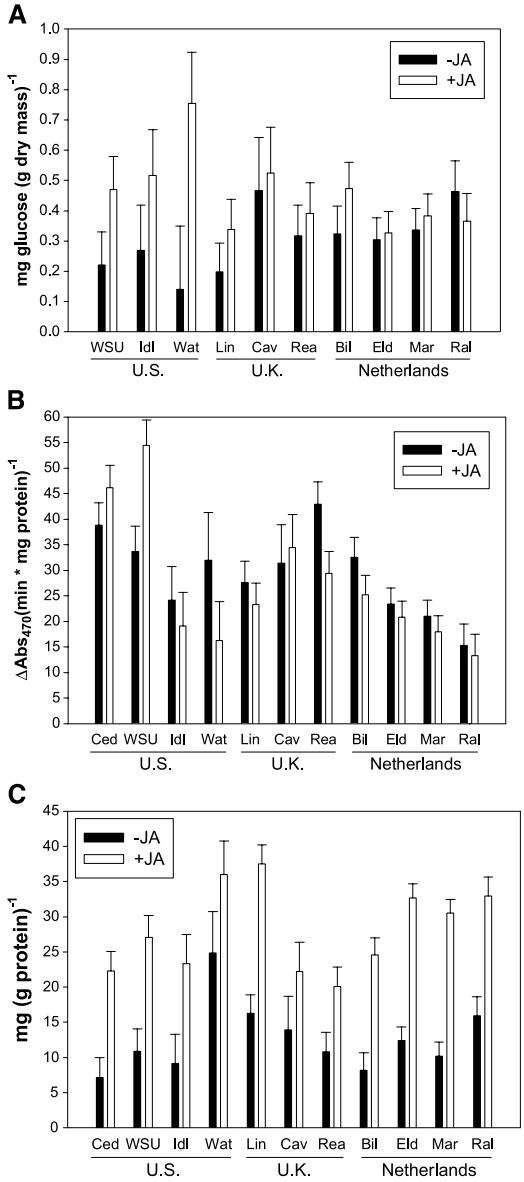

FIG. 1. Constitutive and jasmonic acid induced levels of chemical defenses in leaves of 39-day-old *Alliaria petiolata* from native European and introduced North American populations. (**A**) Glucosinolate content. (**B**) Peroxidase activity. (**C**) Trypsin inhibitor content. Bars represent the mean ± 1 SE, N = 5–10. See Table 1 for population abbreviations.

No variation among continents in peroxidase activity was found, but populations varied within continents by as much as 112% (Table 2, Figure 1B). Although not significant, an interesting pattern was present in the response of populations to JA treatment. Two North American populations displayed higher peroxidase activities after JA treatment, and two populations displayed lower

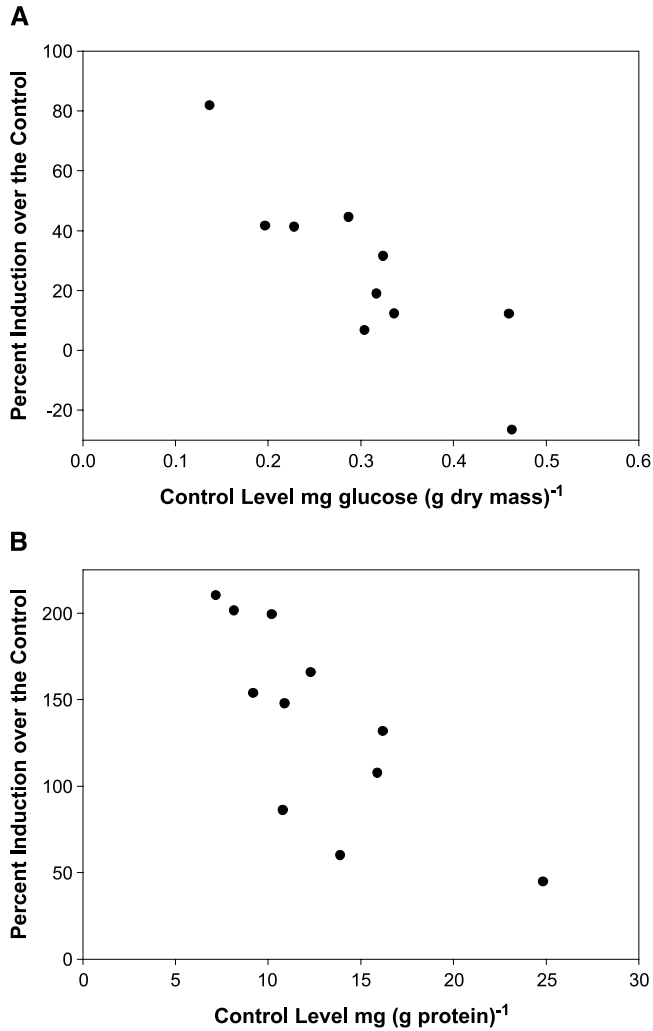

FIG. 2. Correlations between mean constitutive defense levels for each population and mean percent induction by jasmonic acid over control levels. (**A**) Glucosinolates. (**B**) Trypsin inhibitors. Each point represents the mean of 5–10 plants for one population.

peroxidase activities. Six of seven European populations displayed lower peroxidase levels after JA treatment.

No differences among continents were detected in trypsin inhibitor content overall, but populations varied within continents by as much as 300% (Table 2, Figure 1C). JA treatment significantly increased trypsin inhibitor expression by an average of 130% across populations.

Only two significant correlations among and between constitutive and induced *levels* of chemical defenses were detected. Constitutive and induced levels of peroxidase were positively correlated ($r = 0.637$, $P = 0.035$, $N = 11$), and constitutive and induced levels of trypsin inhibitor were positively correlated ($r = 0.697$, $P = 0.017$, $N = 11$). However, constitutive levels of both glucosinolates ($r = -0.867$, $P = 0.001$, $N = 10$; Figure 2A) and trypsin inhibitors ($r = -0.764$, $P = 0.006$, $N = 11$; Figure 2B) were negatively correlated with their degree of induction across all populations. In particular, constitutive glucosinolate levels were 36% lower on average in the three North American populations than in the seven European populations, but were four times more inducible on average.

Neither continent [$F(1,31) = 0.202$, $P = 0.657$] nor JA treatment [$F(1,31) = 0.009$, $P = 0.926$] affected alliarinoside levels independently. However, the response of alliarinoside to JA treatment varied by continent [$F(1,31) = 7.17$, $P = 0.013$]. Constitutive levels of alliarinoside were high in North American plants and decreased by JA, but were low in European plants and increased by JA (Table 3). Levels of isovitexin 6″- *O*-β-D-glucopyranoside varied by continent, being higher overall in North American plants than in European plants [$F(1,31) = 10.81$, $P = 0.003$, Table 3]. The effect of both JA treatment [$F(1,31) = 3.387$, $P = 0.076$] and the interaction of continent and JA treatment [$F(1,31) = 3.077$, $P = 0.09$] on levels of this compound approached significance. The response to JA treatment of this compound by continent was similar to that of alliarinoside (Table 3).

TABLE 3. MEAN (± 1SE) ALLIARINOSIDE AND ISOVITEXIN 6″-*O*-β-D-GLUCOPYRANOSIDE CONTENTS IN FOURTH TRUE LEAVES OF 39-DAY-OLD *Alliaria petiolata* PLANTS FROM NATIVE EUROPEAN AND INVASIVE NORTH AMERICAN POPULATIONS TREATED WITH JASMONIC ACID (JA) OR A CONTROL SOLUTION UNITS ARE IN AU_{218} PER GRAM LEAF EQUIVALENT ($\times 10^5$).

North America	JA	4.81 (3.88)	10.2 (1.78)

DISCUSSION

We examined the degree to which the expression of five chemical defenses in young *A. petiolata* plants conformed to predictions of the EICA hypothesis in a subset of populations from the introduced and native range of this plant. Our population sampling was relatively restricted, so our results should be interpreted cautiously, but little evidence for the predictions of EICA was found in this study.

Although few continental differences were detected among the populations, significant variation among populations within continents was found in the expression of trypsin inhibitor and peroxidase, and both trypsin inhibitor and glucosinolates were jasmonate-inducible. Jasmonate regulation of these two defenses is consistent with findings in other mustard species including *Arabidopsis thaliana* (Cipollini et al., 2004). There were no negative correlations among or between constitutive or induced levels of any of these compounds, but constitutive levels of glucosinolates and trypsin inhibitor were negatively correlated with their degree of induction across all populations. This finding is in accordance with plant defense theory (e.g., Koricheva et al., 2004), suggesting that there are tradeoffs between constitutive expression and inducibility of these two defenses in this plant. In particular, the three North American populations included in the glucosinolate analysis generally displayed lower constitutive expression and increased inducibility of these chemicals relative to the European populations, a pattern that supports the predictions of EICA. Continental patterns in the expression of trypsin inhibitor and peroxidase activity do not support the predictions of EICA.

Expressing low constitutive levels and high inducibility of a defense, such as glucosinolates vs. high constitutive levels and low inducibility, may be a cost-saving strategy resulting from reduced selective pressure by herbivores (Koricheva et al., 2004). However, either strategy may result in the same benefits for resistance. If so, our results could explain the finding of no differences in susceptibility to the generalist caterpillar, *Spodoptera littoralis*, in the invasive and native populations of *A. petiolata* studied by Bossdorf et al. (2004a). Performance of a related caterpillar on *A. thaliana* is negatively related to glucosinolate and trypsin inhibitor content and is reduced by jasmonate (Cipollini et al., 2004). It is unclear how our results might explain the variation in susceptibility to the monophagous specialist weevil, *Ceutorhyncus scrobicollis*, among the populations studied by Bossdorf et al. (2004a), since it is unknown how it responds to the defenses that we measured. This herbivore is currently absent from the North American fauna and is being considered for release as a biocontrol agent (Blossey et al., 2001). Understanding its response to variation in host defense chemistry could inform biocontrol efforts.

Although variation among populations and correlations with other defenses could not be assessed due to a restricted sample size, North American plants of *A. petiolata* displayed higher constitutive levels of alliarinoside and isovitexin 6″-*O*-β-D-glucopyranoside than European plants, in stark contrast to the predictions of EICA. This finding suggests that invasive North American populations may be as well or better defended than native populations from herbivores that are sensitive to these compounds. Although *A. petiolata* has escaped many European herbivores (Blossey et al., 2001), herbivore pressure in North America may be sufficient to select for high levels of these defenses in invasive populations. Benefits to resistance against North American mustard specialist herbivores, such as *P. napi oleracea*, may have favored the maintenance of constitutively high levels of these glycosides. Slugs are one of the more important generalist herbivores of this plant in North America (Blossey et al., 2001; D. Cipollini, personal observation) and may also produce enough damage to select for the maintenance of certain chemical defenses. Why glycoside levels declined in response to jasmonate in North American populations, but generally increased in response to jasmonate in European populations is unknown.

Despite the focus on costs of defense as an impediment to competitive ability, expression of chemical defenses may be a critical part of the invasiveness of *A. petiolata*. Although monophagous specialists may be lacking, *A. petiolata* has retained a substantial degree of resistance to herbivores in its introduced range, as some North American mustard specialists and several generalist herbivores either perform poorly or cannot survive on it (Renwick et al., 2001; D. Cipollini, personal observations). Although presumably physiologically costly, expressing high levels of resistance by *A. petiolata* could benefit individual plants if high defense levels force herbivores to consume more palatable interspecific neighbors, favoring competitive release of *A. petiolata*. In addition to their interactions with herbivores, some chemical defenses may also have alternative benefits that could contribute to invasiveness and select for their maintenance in the invasive range. For example, glucosinolates have been associated with allelopathy in *A. petiolata* (e.g., Roberts and Anderson, 2001) and may confer competitive ability to this plant in species mixtures. Expression of allelopathic chemicals with multiple roles in resistance contributes to the invasiveness of plants such as *Centaurea maculosa* (Bais et al., 2002). In addition to defense against herbivores and pathogens, peroxidase has numerous roles in plant development and stress tolerance (Campa, 1991). Alternative benefits may be provided by the more recently discovered flavonoid glycosides, including allelopathy or protection from photooxidation, but they have been little studied to date.

In summary, analysis of five chemical defenses of *A. petiolata* revealed little support for the predictions of EICA, although population variability and jasmonate regulation was demonstrated for some defenses. Variation in the

constitutive and induced expression of chemical defenses with multiple roles in stress resistance may explain the idiosyncratic results that have accumulated in tests of EICA in this and other invasive plants, but most studies have failed to fully consider chemical defenses. The finding that some chemical defenses may be expressed as highly or more in invasive genotypes as in native genotypes suggests that some chemical defenses may contribute to invasiveness and that the general expectation that they will trade off with competitive ability in an ecological context may not always hold true.

Acknowledgments—We thank Paul Hatcher, Adrian Goodman, and Nicole van Dam for seeds of garlic mustard. We thank Meena Haribal for advice on Mass Spectrometry and HPLC analyses, and Wayne Carmichael and Jerry Servaites for access to equipment and assistance with our procedures. Comments by Oliver Bossdorf and two anonymous reviewers substantially improved this manuscript. We thank Moucon Yuan for help with identification of compounds by mass spectrometry. This project received financial support from Wright State University, the Ohio Board of Regents, and the NSF-UMEB program.

CHANGES IN THE COMPOSITION OF PHOSPHOLIPID FATTY ACIDS AND STEROLS OF MAIZE ROOT IN RESPONSE TO MONOTERPENES

MARÍA P. ZUNINO* and JULIO A. ZYGADLO

Instituto Multidisciplinario de Biología Vegetal (IMBIV), CONICET, Cátedra de Química Orgánica, Facultad de Ciencias Exactas Físicas y Naturales, Universidad Nacional de Córdoba, Ciudad Universitaria, Av. Vélez Sarsfield 1600 (X5016GCA), Córdoba, Argentina

(Received June 24, 2004; revised December 10, 2004; accepted February 23, 2005)

Abstract—Terpenes are thought to be important in plant–plant interactions because of their phytotoxic action on seed germination and growth. Herein, the effects of five volatile monoterpenes on root sterols and phospholipid fatty acid (PLFA) composition have been studied during maize seedling germination. The investigated monoterpenes (camphor, 1–8 cineole, geraniol, menthol, and thymol) were applied at their respective IC_{80} (concentration causing 80% inhibition). They quantitatively affected free sterols and PLFA composition, thus producing an increase in the percentage of unsaturated PLFAs, stigmasterol of the free sterol fraction, and saturated steryl ester fatty acids. Alcoholic and nonalcoholic monoterpenes appeared to have different modes of action. The former affected unsaturated fatty acid and stigmasterol to a greater extent, and accordingly they could interfere in seedling growth by changes in the membrane lipids.

Key Words—Allelopathy, fatty acid, monoterpenes, sterol, *Zea mays*, geraniol, 1,8-cineole, menthol, camphor, thymol, phytotoxicity, membrane.

INTRODUCTION

Monoterpenes are toxic towards vascular plants (Vaughn and Spencer, 1993, 1996; Scrivanti et al., 2003). An extensive study by Vaughn and Spencer (1993) showed that 18 volatile monoterpenes are inhibitory to the germination and growth of nine different plant species. They were generally phytotoxic to corn, wheat, and alfalfa. Notwithstanding, the mode and mechanism by which these

* To whom correspondence should be addressed. E-mail: pauzun@gtwing.efn.uncor.edu

compounds affect the growth of other plant species have been poorly examined at chemical levels (Abrahim et al., 2000; Romagni et al., 2000).

In recent years, the lipid composition of various plant tissues has been shown to influence a number of factors crucial to growth and development (Grandmougin-Ferjani et al., 1997; Borst et al., 2000; Hellgren and Sandelius, 2001; Harker et al., 2003). Phospholipids are more than just structural components of membranes; they can be cofactors for membrane enzymes, signal precursors, or signaling molecules themselves (Laxalt and Munnik, 2002). Plant sterols, like other sterols, are primary components of cellular membranes where they regulate fluidity and permeability. This structural role is often described as "bulk" function. Additionally, sterols can participate in the control of membrane-associated metabolic processes; their involvement in signal transduction events has been reported in mammalian cells (Hartmann, 1998). It is known that free and esterified sterols participate in the formation of biomembranes, and during plant development the sterol content is not static (Huang and Grunwald, 1988; Grandmougin et al., 1989; Izzo and Navari-Izzo, 1993; Moreau et al., 1998).

Since monoterpenes are lipophilic compounds, the question arises whether they act on plant growth by affecting lipid composition. This investigation was conducted to evaluate how monoterpenes affect the most abundant free and esterified sterols, i.e., sitosterol, stigmasterol, and campesterol (Dyas and Goad, 1993; Hartmann, 1998) and phospholipid fatty acid (PLFA) composition of roots during maize seedling growth.

METHODS AND MATERIALS

Chemicals. The monoterpenes used were 1,8-cineole, thymol, menthol, geraniol, and camphor. Previous studies indicated these were the most active compounds (Asplund, 1968; Vaughn and Spencer, 1993, 1996; Koitabashi et al., 1997) They were obtained from ICN Pharmaceuticals Co. (Costa Mesa, CA, USA) and were of high purity.

Plant Material. Maize seeds (*Zea mays* L.) were rolled in the upper 3 cm of a 20-cm-long paper towel scroll. Individual scrolls were moistened with 25 ml of distilled H_2O and placed upright in 3 l flasks. The scrolled seeds were germinated for 3 d at 27 ± 1°C in the dark. At the end of this period, the length of the roots was 6 ± 1 cm, and the seedlings were harvested and transferred to bioassay.

Bioassay. Three-d-old seedlings (0 hr of treatment) were placed in 3 l desiccator flasks on Whatman No. 1 filter paper wetted with 15 ml of distilled water, and a 5-ml glass beaker was placed in the center. A sample of 2 ml of liquid (1,8-cineole and geraniol) or 2 g of solid (thymol, menthol, and camphor)

monoterpenes (volatile source) was added to the beaker. No direct physical contact occurred between the compounds and the seedlings. These amounts saturated the headspace, reaching concentrations of 21.7, 2.0, 1.9, 2.5, and 7.4 mg l^{-1} of 1,8-cineole, thymol, geraniol, menthol, and camphor, respectively. These concentrations corresponded to the inhibitory concentration 80 (IC_{80}), defined as the concentration that inhibited 80% of root growth at 96 hr of treatment compared with the control (Zunino and Zygadlo, 2004). Flasks were placed in the dark at 27 ± 1°C and atmospheric pressure for 24, 48, and 96 hr. Then, the plants were harvested, the roots dissected, and the different experimental parameters were measured. The central beakers were left empty in the controls.

Analysis of Volatile Compounds. Volatiles from headspace of glass desiccators were trapped by using a 10-ml gastight syringe and were analyzed by gas chromatography (GC) and GC/mass spectrometry (MS). A gas chromatograph (Shimadzu R1A) equipped with a flame ionization detector was used. A split inlet (split ratio 200:1) was used to inject volatiles into a DB-5 capillary GC column (30 m × 0.25 mm i.d., and 0.25 μm film thickness), and ramped column temperature conditions (60°C for 3 min, increased to 240°C at 4°C min^{-1}) were used. Detector temperature was 280°C. The carrier gas was He, and it was applied at a constant flow of 0.9 ml min^{-1}. Individual peaks were identified by using a mass selective detector (Perkin-Elmer Q700 gas chromatograph–mass spectrometer) and co-injection with standards. GC-MS was performed under the same conditions. The ionization potential of MS was 70 eV. The quantity of monoterpenes in the headspace was determined by the external standard method (Vaughn and Spencer, 1993). Standard curves were generated by analysis of known concentrations of each compound dissolved in *n*-C_6H_{14}.

Lipid Extraction and Analysis. Lipids were extracted from the roots (20 ± 5 g fresh weight) with $CHCl_3$:methanol (87:13) in a Soxhlet apparatus for 12 hr. Extracts were dried on dry Na_2SO_4, taken to dryness under vacuum, and chromatographed on preparative silica gel thin-layer plates (silica gel 60 G F254) using hexane–ether (4:1 by volume) as the developing system. Sterols were visualized under UV light. Three fractions were eluted corresponding to steryl esters (SE), free sterol (FS), and phospholipids (PL). Cholesteryl myristate, sitosterol, and phosphatidylcholine were used as markers, respectively. The FS fraction was scraped off and eluted in dichloromethane, filtered to remove the residual silica, dried in a rotatory evaporator, and then purified by a bidirectional thin-layer chromatography (TLC; hexane–ether 4:1 and benzene–ether 4:1 as developing system) (Rohmer et al., 1972). SE and PL fractions were saponified with 1 N methanolic KOH to obtain the respective fatty acids. Fatty methyl esters from SE and PL were prepared by transesterification through treatment with 1 N H_2SO_4 in dry methanol for 30 min (Grosso et al., 1994) and analyzed by GC. Quantitative determinations of total PLFA were made with

heptadecanoic (C17:0) methyl esters as an internal reference. Analytical GC was performed on a Shimadzu GC-R1A gas chromatograph (FID) fitted with Supelcowax-10 capillary column (30 m × 0.25 mm i.d.). Column temperature was programmed from 180 to 240°C (4°C min^{-1}). Injector and detector temperature was 250°C, and N_2 was used as the carrier gas at a flow rate of 20 ml min^{-1}. The injection volume was 2 μl.

SE fraction sterols were recovered from unsaponifiable matter and together with FS were subjected to GC analysis. Qualitative and quantitative analysis were carried out using a Shimadzu GC-R1A gas chromatograph (FID) fitted with DB5 capillary column (30 m × 0.25 mm i.d.). Column temperature was programmed from 240°C to 290°C (4°C min^{-1}). Injector and detector temperature was 300°C, and N_2 was used as the carrier gas at a flow rate of 1 ml/min. The injection volume was 2 μl.

Sterol identities were confirmed by comparison with authentic compounds under identical conditions using a GC mass-selective detector.

Statistical Analyses. Experimental values are means and SDs of three independent experiments. A two-way analysis of variance (ANOVA) was used to evaluate treatment time (T) and monoterpenes (M) effects together with their interaction (T × M). Significance (at $P \leq 0.05$) was assessed using DGC multiple range test (Di Rienzo et al., 2002).

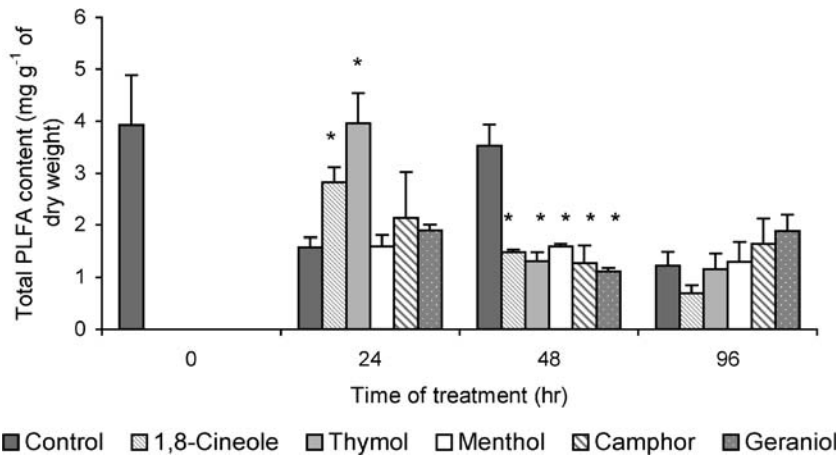

FIG. 1. Effect of monoterpenes on total PLFA content in maize roots. Values are means and SD. *Denotes significant differences between treatment and control for each time of treatment, according to DGC multiple range test at $P \leq 0.05$ ($n = 3$).

RESULTS

Effect of Monoterpenes on Phospholipid Fatty Acid Content. Each treatment and the control reduced the total PLFA content of roots during the period that goes from 0 to 96 hr (Figure 1). Control roots and roots treated with menthol, camphor, and geraniol showed a decrease of total PLFA at 24 hr, but soon after a recovery occurred in control roots at 48 hr (but not with treatments). Otherwise, roots treated with 1,8-cineole and thymol showed a decrease of the total PLFA from 48 hr. Nonetheless, the total PLFA of each treatment and control at 96 hr was lower than that observed at 0 hr (Figure 1).

In maize roots, the FAs 16:0, 16:1, 18:0, 18:1, 18:2, and 18:3 were the main contributing ones (Grandmougin et al., 1989; Bohn et al., 2001). The percentage of FA 18:2, 18:1, and 16:0 was higher than the other FAs, 16:1, 18:0, and 18:3 (Table 1). Saturated FAs did not show any significant changes

with treatments with the exception of FA 18:0 that increased from 48 to 96 hr in control roots. At 24 hr, roots treated with 1,8-cineole, thymol, geraniol, and camphor showed lower percentage of FA 16:0 than controls. For each monoterpene, the percentage of FA 18:0 was lower than controls at 96 hr. Among unsaturated FAs, there was a decrease from 0 to 96 hr in the percentage of 18:2 for controls, 1,8-cineole, and camphor. Compared with the untreated control, the composition of 18:2 at 96 hr was higher in each treatment, except in the 1,8-cineole and camphor treatments where their composition was similar to that of the controls (Table 1). A significant increase in the FA 18:1 was observed at 96 hr in the control and camphor treatments. This was not observed with the other treatments, which showed lower percentages of 18:1 than those at 96 hr. At 24 hr, 1,8-cineole and thymol treatments showed higher values of 18:1 than controls. FA 18:3 showed changes neither in time nor with treatments. Whereas FA 16:1 increased only with camphor during treatments (showing

higher values than controls at 48 and 96 hr), 1,8-Cineole also produced higher values of 16:1 than controls, occurring at 24 and 48 hr (Table 1).

Regarding the unsaturated to saturated FA ratio, a decrease from 0 to 96 hr was shown in control roots and the 1,8-cineole treatment. Nevertheless, the rest of the monoterpenes did not show changes over time but showed higher unsaturated to saturated ratio values than controls at 96 hr (Table 1).

Effect of Monoterpenes on Composition of Sterol Ester Fatty Acids. The main FA of SE, like PL, were 16:0, 18:1, and 18:2 (Table 2). The saturated FA 16:0 showed higher values than controls at 48 hr with 1,8-cineole, and at 48 and 96 hr with menthol, geraniol, and camphor. FA 18:0, on the other hand, increased with geraniol at 48 and 96 hr, and with camphor treatment at all time points studied (Table 2). Among unsaturated FAs, 16:1 and 18:3 showed increases preferentially with menthol and geraniol monoterpenes. With camphor, FA 18:3 increased at 48 hr. In contrast, the percentage of the major compounds FA 18:1 and 18:2 showed lower values than controls: 18:1 at 24 hr with monoterpenes thymol, menthol, and camphor, and FA 18:2 with 1,8-

cineole (at 48 hr), menthol (at 96 hr), geraniol (at 48 and 96 hr), and camphor (at all times). These changes in FA composition are shown in the unsaturated to saturated ratios, which were lower than controls at every time studied for all monoterpenes—with the exception of 1,8-cineole at 96 hr and thymol at 48 and 96 hr (Table 2).

Effect of Monoterpenes on Composition of Free Sterols. The main FS constituent in the FS maize root fraction was stigmasterol (36.5–67.8%), as observed in the control and all monoterpene treatments (Table 3). Treatment with 1,8-cineole and menthol showed an increase in campesterol at 96 hr, whereas at 48 hr it decreased with 1,8-cineole and thymol monoterpenes. Stigmasterol values increased from 0 to 48 hr, decreasing at 96 hr with controls and 1,8-cineole and thymol treatments. At 24 and 96 hr, there were increases in stigmasterol with the menthol and geraniol treatments. With camphor, this FS increased at 96 hr, too (Table 3). In the control and every monoterpene studied, sitosterol decreased through time. At 96 hr, only with thymol were there no significant differences from control, and at 48 hr this FS was unchanged with

ANOVA with interaction. Values having different letters are significantly different from each other according to DGC multiple range test at $P \leq 0.05$.

1,8-cineole, geraniol, and thymol treatments. The rest of the studied monoterpenes showed lower sitosterol values than those of control. This is shown especially with menthol treatment, which produced the small value of 8.19% (Table 3).

Effect of Monoterpenes on Composition of Sterols of Sterol Esters. The main sterol in the SE maize root fraction observed in all treatments and controls was sitosterol (43.5–70.8%; Table 4), which is in accordance with the levels expected for this sterol in maize roots (Kemp et al., 1967). Sitosterol increased with time, reaching a maximum level at 48 hr in the control experiment, as well as in the 1,8-cineole, thymol, and menthol treatments. It decreased significantly

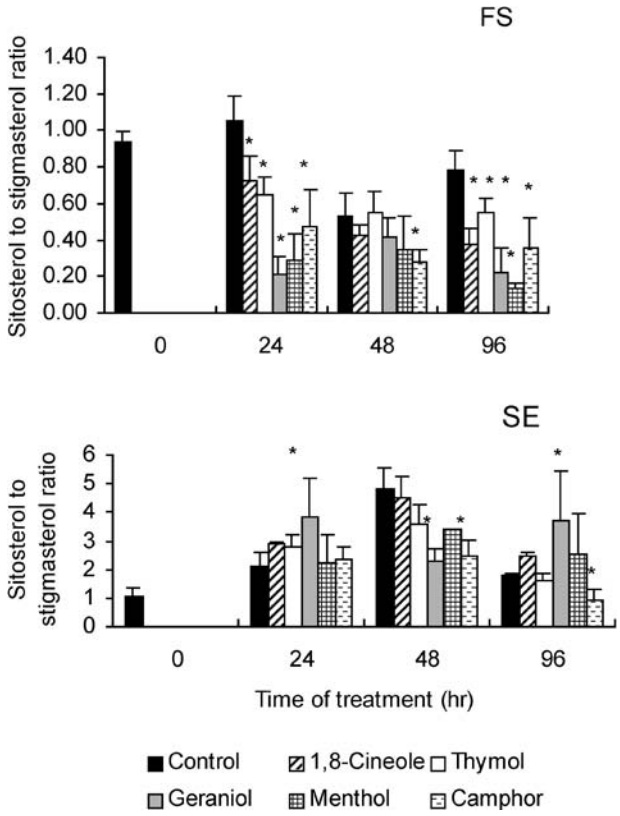

FIG. 2. Effect of monoterpenes on sitosterol to stigmasterol ratio of free sterol (FS) and steryl ester (SE) fractions in maize roots. Values are means and SD. *Denotes significant differences between treatment and control for each time of treatment, according to DGC multiple range test at $P \leq 0.05$ ($n = 3$).

in only the thymol and camphor treatments to levels of 45.99% and 34.94%, respectively, at 96 hr (Table 4). A different result was observed with geraniol treatments. It showed maximum values at 24 and 96 hr (64.32% and 66.14%, respectively) that were higher than controls.

Meanwhile, stigmasterol decreased from 0 to 96 hr in controls, and with all monoterpene treatments showed no significant differences. Only with camphor did this sterol increase at 96 hr—similarly to 0 hr (Table 4).

Geraniol treatment increased campesterol at 48 hr and decreased later (Table 4).

Effect of Monoterpenes on Sitosterol to Stigmasterol Ratio. The SE fraction presented a higher sitosterol to stigmasterol ratio (values >1) than that of FS fraction (values <1) (Figure 2), which is in agreement with previously

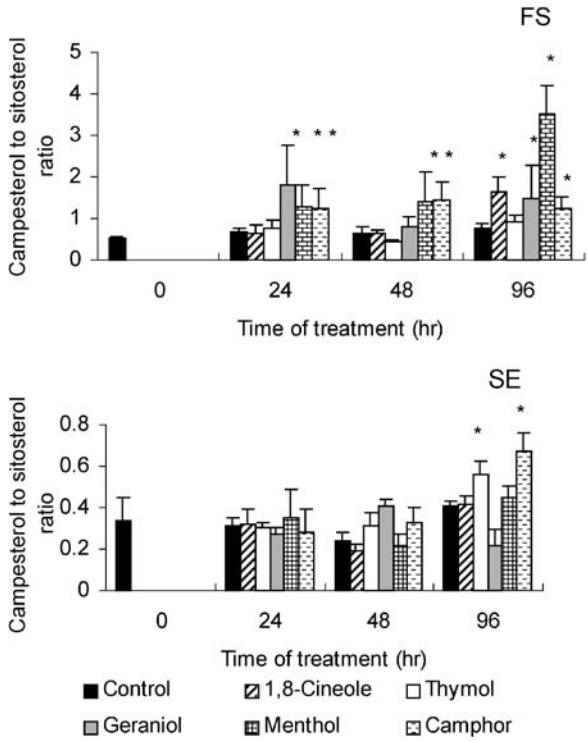

FIG. 3. Effect of monoterpenes on campesterol to sitosterol ratio of free sterol (FS) and steryl ester (SE) fractions in maize roots. Values are means and SD. *Denotes significant differences between treatment and control for each time of treatment, according to DGC multiple range test at $P \leq 0.05$ ($n = 3$).

published data and documents the discriminating character of sterol esterification in plants (Kemp et al., 1967, 1968; Dyas and Goad, 1993). The sitosterol to stigmasterol ratio was more affected by monoterpene treatments in the FS than in the SE fraction. In the FS fraction, this ratio decreased in the studied monoterpenes, mainly at 24 and 96 hr due to an increase in stigmasterol and decrease in sitosterol percentages (Figure 2). In the SE fraction, monoterpenes produced a different result, only geraniol and camphor treatments showing significant differences from controls (Figure 2).

Effect of Monoterpenes on Campesterol to Sitosterol Ratios. The FS fraction produced a higher campesterol to sitosterol ratio than that of the SE fraction (values <1) (Figure 3). Only thymol and camphor treatments increased this sterol ratio in the SE fraction at 96 hr, whereas in the FS fraction it was increased mainly by geraniol, menthol, and camphor. These terpenes increased by about 166%, 92%, and 84%, respectively, at 24 hr. Menthol treatment at 96 hr caused a 351% increase in that sterol ratio (Figure 3).

DISCUSSION

The growth of seedlings in darkness could explain the low content shown in the total PLFA fraction of the untreated control roots (Figure 1) because lipid biosynthesis slows in the dark (Somerville and Browse, 1991). Moreover, plants growing in prolonged darkness reactivate the β-oxidation cycle necessary for carbohydrate synthesis from fatty acids (Poirier et al., 1999). The fluctuation observed in control roots, in which the total PLFA content decreased at 24 hr and then increased to almost the original level at 48 hr (Figure 1), could be explained by the stress that the plant suffers when transferred to the bioassay.

Monoterpenes, which are lipophilic compounds, could alter the packing, fluidity, and/or physical arrangement of phospholipids in the membrane (García et al., 1995; Sikkema et al., 1995; Perillo et al., 1999; Turina and Perillo, 2003). Plants treated with monoterpenes showed an increase in the unsaturated to saturated PLFA ratio at 96 hr, with the exception of 1,8-cineole. This increase is mainly due to the high percentage of FA 18:2 and reduction of FA 18:0 (Table 1). Variations in PLFA unsaturation may produce drastic effects on physical and functional membrane properties, and membrane fluidity may increase (Stubbs and Smith, 1984; Karp, 1987; Borst et al., 2000).

Monoterpenes increased the total unsaturated FA of maize root (Zunino and Zygadlo, 2004). In contrast, saturated FAs of the SEFA fraction were increased at 96 hr, mainly in the menthol, geraniol, and camphor treatments (Table 2). This increase might be related to the specificity and increased activity of the acyltransferase enzyme, which esterifies sterols (Dyas and Goad, 1993).

Most of the higher plant sterols are found as FS, which serve as membrane components and reside predominantly in the plasma membranes (Hartmann and Benveniste, 1987; Schaller, 2003), whereas the greatest amount of SE in *Z. mays* roots are located in mitochondrial and microsomal fractions and in the nucleus (Dyas and Goad, 1993). The SE could operate as a supply of FS, as a transport form of sterols in terms of both intracellular movement and movement between tissues, and as a stored form in which sterols present in amounts greater than immediately needed by the plant are sequestered. There is a freely interconvertible pool of FS and SE (Dyas and Goad, 1993; Gondet et al., 1994).

In both the FS and the SE fractions, there was a high negative correlation between sitosterol and stigmasterol in time (see values in Tables 3 and 4). This is indicative of the biosynthetic relationship of these sterols (Kemp et al., 1967; Benveniste, 1986; Izzo and Navari-Izzo, 1993). The major changes observed in the sterol fraction corresponded to the FS fraction, which produced a decrease in the sitosterol to stigmasterol ratio (Figure 2) and an increase in the campesterol to sitosterol ratio (Figure 3). These changes were shown principally with geraniol, menthol, and camphor monoterpenes.

From the "membrane environment" point of view, an appropriate composition of sterols in the cell membranes is crucial for optimal enzymatic activity, ion and metabolite transport or channeling, protein–protein and protein–lipid interactions, signal transduction, and finally to face fluctuating environmental conditions (Schaller, 2003). It is known that membrane fluidity and permeability is regulated by the relative proportion of lipids, as well as by the length and the unsaturation of fatty acids, and that sterols can also participate in the control of membrane-associated metabolic processes (Ros et al., 1990; Schuler et al., 1991; Hartmann, 1998; Hellgren and Sandelius, 2001). Our results indicate that the treatment of maize roots with monoterpenes induces a modification of the sterol proportions, mainly in the FS fraction, and a change in the unsaturation of fatty acids. So it can be suggested that alcoholic monoterpenes (geraniol and menthol) together with camphor would be the most important monoterpenes affecting membrane permeability and fluidity according to the lipid changes shown, i.e., increased percentages of unsaturated PLFA at 96 hr (Table 1) together with an increase on stigmasterol of FS fraction (Table 3).

It has been shown that during senescence the stigmasterol to other sterols ratio increases (McKersie et al., 1978; Lees and Thompson, 1980), and several environmental stresses alter the FS composition as well (Hellgren et al., 2001). Equally, the sitosterol to stigmasterol and/or the stigmasterol to campesterol ratios are modified (Navari-Izzo et al., 1989; Mansour et al., 1994; Hellgren et al., 2001). The central role of campesterol as a precursor of the plant-growth regulators, called brassinosteroids, has been established (Yokota, 1997; Schaller, 2003). The ratio of campesterol to sitosterol is associated with growth and development modifications and with the activity of the enzyme sterol

methyltransferase 2 (SMT2) (Schaeffer et al., 2001). The campesterol to sitosterol ratio in our FS fraction of menthol, geraniol, and camphor treatments increased two times, mainly at 24 and 96 hr (note that this ratio in menthol treatment increased 4.5 times compared to controls) (Figure 3). Thus, the activity of the enzyme SMT2 might be reduced with the above-mentioned treatments. Additionally, the synthesis of 24-ethyl-sterols (sitosterol and stigmasterol) is kinetically favored over 24-methyl-sterols (campesterol) at some stages of corn development (Guo et al., 1995), and, thus, the first sterols are the principal ones. At 96 hr, the campesterol percentage was higher than that of sitosterol with every monoterpene studied, except thymol (Table 3). It may be that the reduced activity of SMT2 is favorable to the seedlings to support some physiological concentration of campesterol.

In summary, from the results obtained, it appears that every monoterpene affects the maize root lipid composition in a different way.

(Received July 2, 2004; revised January 28, 2005; accepted February 16, 2005)

Abstract—The effect of disturbed root nodulation on the quantitative and qualitative composition of the main isoflavonoid glucoside–malonates, glucosides, and aglycones in the leaves of *Trifolium pratense* L. grown under waterlogging conditions was investigated. Isoflavonoids are involved in the regulation of root nodule activity and the establishment of the mycorrhizal association. Isoflavonoid determination was performed using reversed-phase liquid chromatography coupled to mass spectrometric and UV absorbance detection. In response to waterlogging, the concentrations of biochanin A and biochanin A–7-*O*-glucoside–malonate, biochanin A–7-*O*-glucoside, and genistein–7-*O*-glucoside in the leaves increased two- to threefold after a lag period of 3 wk because of disturbed root nodulation. The other isoflavones detected—formononetin, formononetin–7-*O*-glucoside–malonate, and formononetin–7-*O*-glucoside—did not show any significant changes related to waterlogging. After restoring normal soil water conditions, the concentrations of biochanin A and its glucoside and glucoside–malonate rapidly returned to the initial values, whereas the concentration of genistein–7-*O*-glucoside remained high.

Key Words—*Trifolium pratense* L., glucoside–malonates, isoflavones, Leguminosae, mass spectrometry, red clover, nodulation, waterlogging.

INTRODUCTION

Because of their importance for the conservation of biodiversity, the restoration of wetlands is a goal in many countries worldwide. Restoration activities include changes in grassland management and rewetting dry (polder) areas and can have great impact on ecological processes, especially affecting those plant species that are sensitive to waterlogging and/or flooding. Flood-resistant plants can easily acclimatize to wet conditions, but in nonflood-resistant species, flooding may cause metabolic problems because of oxygen deficiency and enhanced availability of reduced metals (Lupwayi et al., 1997).

Red clover (*Trifolium pratense*, Leguminosae) is a nonflood-resistant species that commonly occurs in moist grasslands. Trifolium species are known symbiotic nitrogen-fixating crops that are used in sustainable agriculture to restore N fertility of a soil (Warembourg et al., 1997; Kumar and Goh, 2000). In symbiotic plant–rhizobium interactions, flavonoids play a role as signal transducing compounds. The isoflavonoids, for example, are involved as nodulation inducers (Edwards et al., 1997). In a variety of leguminous plants, they can influence the early stages of the establishment of biological nitrogen fixation in root nodules after infection by *Rhizobium* bacteria (Paiva, 2000).

In *T. pratense*, over 40 flavonoids have been identified (Klejdus et al., 2001; de Rijke et al., 2001, 2004a). They constitute one of the most important groups of natural products found in plants—in total, more than 6000 flavonoids have been identified and documented (Harborne and Baxter, 1999). In plants, they are usually present as glycosides, i.e., provided with one or more sugar groups such as glucose, galactose, or rhamnose. The sugars are often further substituted by acyl residues, such as malonate, acetate, 4-coumarate, caffeate, or ferulate (Stumpf and Conn, 1981). Glycosylated compounds, rather than free aglycones, are accumulated in plants; they are better stored within plant vacuoles and are less reactive towards other cellular components than aglycones. They are often thought of as detoxification products or as physiologically inactive plant storage forms (Stumpf and Conn, 1981). From a physiological point of view, flavonoids are of interest because of their various biological activities: as screens against elevated UV-B radiation (Rozema et al., 1997; Olsson et al., 1998; Logemann et al., 2000), infection resistance to microorganisms (Bednarek et al., 2003), protection from herbivore attack (Wang et al., 1999), and adaptation to water stress (Francis and Devitt, 1969; Stafford and Ibrahim, 1992). Flavonoids—and isoflavonoids in particular—are also involved in the induction of the expression of *Rhizobium* nodulation genes in leguminous plants (Smit et al., 1992; Gagnon and Ibrahim, 1997).

The aim of this study was to investigate the effect of disturbed root nodulation on the concentrations of the main isoflavones of *T. pratense*, including aglycones, glucosides, and glucoside–malonates. To that means *T. pratense*

plants were subjected to two different soil water regimes to study the effect of disturbed root nodulation in response to waterlogging on the levels of the main isoflavonoids (for structures and abbreviations, see Table 1). The study focuses on isoflavonoids in the leaves because isoflavonoids are known to respond to environmental disturbances (Edwards et al., 1997), and the leaves of *T. pratense* have the highest concentrations. In roots, the flavonoid concentrations are lower, and less root mass is available for analysis. To study isoflavonoid profiles and their changes due to environmental effects, a sensitive method is needed. Therefore, a previously reported reversed-phase liquid chromatographic (RPLC) procedure was used, coupled to negative atmospheric pressure chemical ionization mass spectrometry (NI APCI-MS) and UV absorbance detection (de Rijke et al., 2001, 2003).

METHODS AND MATERIALS

Flooding Studies. Flooding experiments were performed using *T. pratense* plants grown from commercially obtained seeds (Duchefa, Haarlem, The Netherlands). Seedlings were grown in a greenhouse for 4 mo. Plants were grown in a controlled-environment greenhouse maintained at 25/20°C day/night temperatures and 60–70% relative humidity. Light conditions were those of the

natural glass-filtered (UV B) radiation in the period from 1 May to 24 June. Plants were approximately 25 cm high, with about 120 leaves per plant and an area of approximately 3 cm^2 per leaf. During the experiments, they were in the flowering stage. Plants were placed in PVC cylinders filled with potting compost containing 22 wt.% organic material (Jongkind, Aalsmeer, The Netherlands) and a wire mesh bottom. The cylinders were placed in plastic pots to enable soil water management. As sampling and extraction can affect flavonoid concentrations (de Rijke et al., 2001), sampling was considered destructive. Therefore, 10 separate *T. pratense* plants were placed in each pot. At each sampling date, fresh plants were sampled. Plants were removed from the experiment after sampling. Because all plants in one pot were subjected to the same environmental conditions, they are considered as one block that was sampled repeatedly over time.

The experimental setup followed a single-factor ANOVA design with two levels, waterlogged (W) and normal (N) conditions, and seven replicates per level. At t = 1 day, the soil water level of the W plants was raised to ensure complete waterlogging of the soil, i.e., water reached the soil surface. Throughout the study, the N plants were watered daily to field capacity. Plants were sampled at t = 0, 7, 14, 21, 35, and 42 days, and the flavonoid composition of their leaves was determined as described below. At t = 35 days, the soil water level of the W plants was changed to the level of the N plants and kept at this level until the end of the study.

Materials. Biochanin A and biochanin A–7-*O*-glucoside were purchased from Indofine (Somerville, NJ, USA), and genistein–7-*O*-glucoside, formononetin, and formononetin–7-*O*-glucoside from Roth (Karlsruhe, Germany). Methanol and formic acid were from J.T. Baker (Deventer, The Netherlands), and ammonium formate and white quartz sand were from Aldrich (Steinheim, Germany). Tris(hydroxymethyl)aminomethane (TRIS) was purchased from Merck (Darmstadt, Germany). Ultrapure water was prepared with a Millipore-Academic system (Etten-Leur, The Netherlands).

Extraction. Extraction of *T. pratense* leaves was performed as described earlier (de Rijke et al., 2003). Fresh leaves (1 g) were ground with 3 ml of aqueous 350 mM TRIS solution, pH 7.9, for 2 min. One gram of white quartz sand and 10 ml of methanol–water (9:1, v/v) were added, and the extract was stirred for 1 min. The extract was filtered over a Büchner funnel, and 10 ml of methanol–water (9:1, v/v) were added to the residue. The procedure was repeated once, and the combined extracts were filtered over a 0.45-μm filter and stored at −20°C until use.

Care must be taken during the extraction procedure, as the isoflavone–glycoside–malonates are readily converted to their corresponding glycosides and aglycones when the plant material is crushed (e.g., Saloniemi et al., 1995; Edwards et al., 1997). This is caused by high enzyme activity (β-glucosidase) in

the plant parts; because they are not substrate specific, hydrolysis easily occurs. In our study, TRIS solution, which functions as an inhibitor of these enzymes (Larner and Gillespie, 1956; Dale et al., 1985), was added to prevent this hydrolysis. In a previous paper (de Rijke et al., 2001), the suitability of this approach was demonstrated: we tested the stability of the isoflavone–glucoside–malonates in the extract under the extraction conditions described above; at room temperature, conversion of glucoside–malonates to their corresponding glucosides was only observed upon prolonged storage (ca. 8% after 1 wk of storage). In the current study, the extracts were prepared in a few minutes, directly stored at −20°C (which slows down the hydrolysis even further), and analyzed within a day; under these conditions, no measurable loss of the glucoside–malonates occurs.

Instrumentation. LC–DAD UV. Liquid chromatography was performed on an HP 1050 LC system (Hewlett Packard, Waldbronn, Germany) with a photodiode array UV detector (DAD) set at 250 nm. For separation, a 250 × 4.6 mm I.D. 5 μm Zorbax SB-C18 LC column was used, with a methanol–10 mM ammonium formate buffer (pH 4.0) gradient at a flow rate of 1.0 ml/min (see (de Rijke et al., 2003)). Before use, all solvents were filtered over a 0.45-μm filter and degassed with helium. Sample injection (10 μl) was performed with a Midas autosampler (Spark Instruments, Emmen, The Netherlands).

LC–APCI-MS. For LC–MS, a Shimadzu (Princeton, NJ, USA) LC system was used consisting of two LC-10A pumps, a SCL 10A controller unit, a DGU-14A degasser, a SIL-10AD autoinjector, and a SPD-10A UV detector (set at 250 nm). The autosampler was cooled to prevent hydrolysis of flavonoid glucoside–malonates in the extracts. The setup was coupled to a Thermo Quest Finnigan (San Jose, CA, USA) LCQ deca ion trap mass spectrometer. The injection volume, column, and gradients were the same as in LC–DAD UV. Atmospheric pressure chemical ionization spectra were obtained in the negative ionization mode in the *m*/*z* 150–650 range. Capillary and vaporizer temperatures were 250 and 450°C, respectively. Capillary voltage was set at −12 V, and the corona discharge current was 10 μA (see (de Rijke et al., 2003)). The sheath-gas (nitrogen) flow rate was approximately 200 l/hr, and the auxiliary gas (nitrogen) flow rate was approximately 50 l/hr. The LC flow was directed to the mass spectrometer without stream splitting.

Statistical Data Analysis. A single-factor repeated-measures ANOVA was performed to test for effects of soil water level, time of exposure, and their possible interaction on isoflavone concentrations, i.e., to test whether soil water level and time of exposure are independent parameters. Data requirements for the multivariate analysis concerning equality of the covariance matrix were checked using Box's *M* test. To test whether isoflavone concentrations decreased to the level of the control after restoring the original soil moisture conditions, isoflavone concentrations of both treatments were compared at

t = 42 days using an independent samples t-test. Data were checked for normality using Shapiro–Wilk's test. All analyses were performed using the program SPSS version 10.1.0.

RESULTS

LC–UV/APCI-MS. Figure 1 shows typical LC–UV and LC–MS chromatograms of an extract of *T. pratense* leaves. The advantage of an ion-trap MS instrument is that full-scan (FS) and time-scheduled selected ion monitoring (TS SIM) can be performed simultaneously. Full scan is used to scan the extracts and TS SIM for quantification of selected (see below) isoflavones. To select the masses to be used in SIM, a 10-mg/l standard mixture of five isoflavone

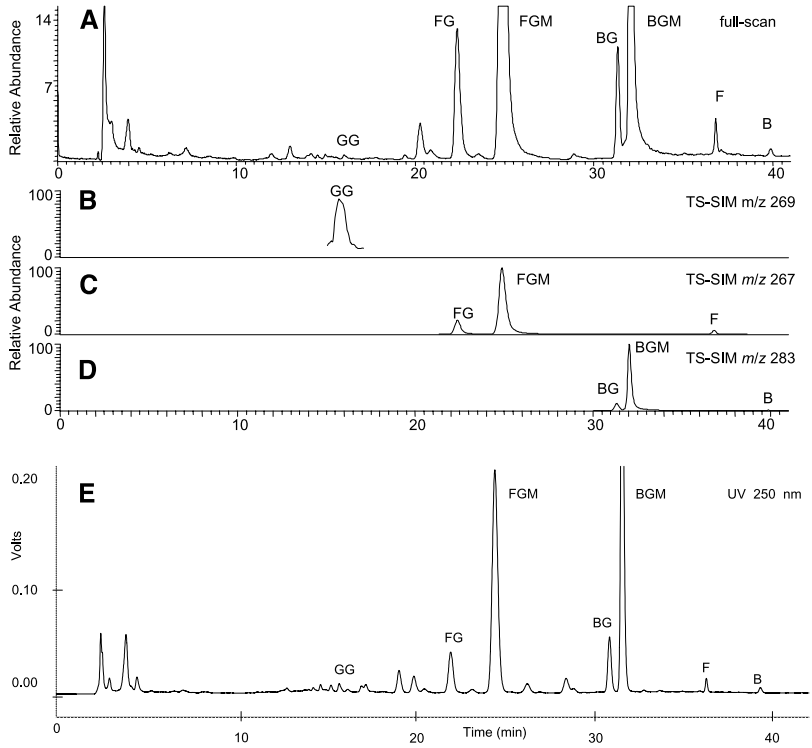

FIG. 1. Reversed-phase LC with **(**A**)** full-scan and **(**B–D**)** TS SIM (*m*/*z* 269 for GG, *m*/*z* 267 for F, FG, and FGM, and *m*/*z* 283 for B, BG, and BGM) NI APCI-MS and **(**E**)** UV_{250} of a *T. pratense* leaf extract, recorded at t = 35 d. For details, see text.

aglycones and glucosides [formononetin–7-*O*-glucoside (FG), biochanin A–7-*O*-glucoside (BG), genistein–7-*O*-glucoside (GG), formononetin (F), and biochanin A (B); cf. Table 1] was analyzed in the FS MS mode (*m*/*z* 150–650). This enabled us to attribute five of the main peaks that show up in Figure 1 to FG, BG, GG, F, and B, based on their mass spectra and retention times. In addition, the strong peaks at 25 and 32 min can be attributed to formononetin–7-*O*-glucoside–malonate (FGM) and biochanin A–7-*O*-glucoside–malonate (BGM), respectively (de Rijke et al., 2003). Compounds were identified based on their aglycone mass and their characteristic fragmentation pattern, using TS SIM (Figure 1B–D) and FS chromatograms (Figure 1A), respectively. The main ions that were generated in NI APCI-MS were the pseudomolecular ions $[M–H]^-$, formic acid adducts $[M + 45]^-$, $[M–Glc]^-$, and, when the analytes were glucoside–malonates, $[M–Mal]^-$ and $[M–Glc–Mal]^-$ ions. In all cases, the aglycone ions were selected for TS SIM because they had the highest intensities with the MS settings used. In an independent study, the structures of these compounds were confirmed by means of LC–UV–NMR and stand-alone COESY and NOESY NMR experiments of LC-separated fractions (de Rijke et al., 2004b).

In a previous paper (de Rijke et al., 2003), four ionization modes (PI and NI APCI; PI and NI ESI) were compared using a *T. pratense* extract and optimized LC conditions. In the PI modes, background signals were higher than in the NI modes. Overall, the analyte responses were best in the NI APCI modes. In the mass spectra, differences in relative intensities of the fragment ions were observed depending on the ionization mode and eluent composition.

Analyte detectability was the same for the simultaneous FS–TS SIM method and the conventional TS SIM method, whereas the gain in sensitivity of TS SIM compared with FS was about 100-fold. Detection limits (LODs; $S/N = 3$) in the TS SIM mode were found to be 1–45 μg/l (R^2 values of calibration plots, 0.993–0.999 in all cases). Because no standards of FGM and BGM—the malonates of FG and BG—are available, their concentrations were calculated based on the calibration curves of FG and BG, assuming equal MS response of the aglycone ions in SIM. This was confirmed on the basis of LC–UV standard curves; the molar extinction coefficients of the glucosides and the glucoside–malonates are identical (de Rijke et al., 2004a). With UV detection, LODs were higher than in TS SIM MS (40–530 μg/l; R^2 values 0.998–0.999); for that reason, TS SIM MS was used to identify and quantify the isoflavone aglycone, glucoside, and acylated glucoside peaks in the extracts. The simultaneous FS and TS SIM method was used throughout the study.

Flooding Studies. Leaves and roots of the two series of full-grown plants (4 mo-old) under N and W conditions were compared during the experiment. After 3 wk, the areas of the leaves of the W plants were slightly smaller (ca. 2 cm^2) than leaves of the N plants (ca. 3 cm^2), and some leaves of the W plants

had turned yellow. We also observed that the roots of W plants were gradually reaching the soil surface, and that the amount of root nodules on the submerged roots of W plants was decreasing over the course of the study. These qualitative observations are summarized in Table 2. After 35 d, an approximately twofold decrease was observed. At t = 42 d, the root nodule level was approximately restored to its initial value. N plants did not show any changes.

Concentrations of the seven isoflavone aglycones, glucosides, and acylated glucosides during the experiment are displayed in Figure 2. As expected, at t = 0 d, the concentrations of all isoflavones in the N and W plants were the same and, therefore, the two groups were pooled together (N = 14). Concentrations of all isoflavones varied in a compound-specific way. For F, FG, and FGM, the changes were essentially independent of water level conditions, with a constant increase in FG during the experimental period. For B, BG, BGM, and GG, a significant increase of the concentrations was observed. Biochanin A–7-*O*-glucoside and GG remained virtually constant up to 21 d, then, between 21 and 35 d, they increased two- to threefold in the W plants. In contrast, B and BGM differences occurred already after 10 d. The data set was evaluated with repeated-measures ANOVA. The results are shown in Table 3. The level of significance is displayed for the effects of soil water level, time of exposure, and their interaction. Soil water level significantly affects B, BG, BGM, and GG concentrations over the period up to 35 d. Time significantly affects BG, BGM, FG, and FGM concentrations, whereas for B and GG, a minor effect is observed. The effects of soil water level hardly interact with effects of time. In other words, a change of soil water level does not change the response over time and vice versa. A low significance tells us that most variation in the data is accounted for by the separate effects of soil water level and time.

At t = 35 d, normal soil water conditions were restored for the W plants, and at t = 42 d, the concentrations of all isoflavone aglycones, glucosides, and

TABLE 2. ROOT NODULE LEVEL OF *T. pratense* ROOTS AFTER NUMBER OF DAYS EXPOSED TO WATERLOGGING

Time (days)	Root nodule level
0	++
7	+

21	−
35	−−
42	++

The root nodule level of the roots of the *N* plants remained ++ during the course of the study.

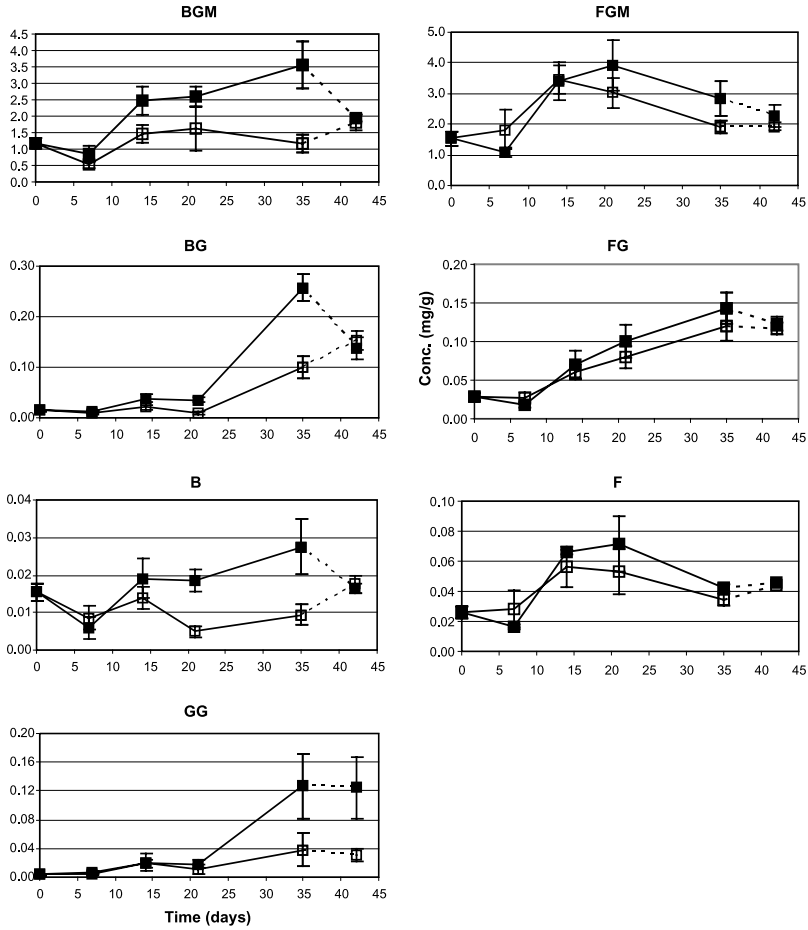

FIG. 2. Effects of waterlogging (□ = normal; ■ = waterlogged) over time on the concentrations (mg/g fresh wt) of seven isoflavone aglycones, glucosides, and glucoside–malonates in *T. pratense* leaves in LC−TS SIM MS, corrected for weight of leaves. Mean values and standard deviations of the mean are given ($N = 7$; 0 d, $N = 14$). Soil water levels were raised at $t = 1$ d and restored to normal at $t = 35$ d.

glucoside–malonates except GG had returned to values equal to those for the N plants (cf. Figure 2). In all cases, except for FG and BG, these values were equal to the values of $t = 0$ d, and even for these two analytes, the differences were not large. The results of the independent samples *t*-test to check whether isoflavone concentrations decreased to the level of the control treatment after restoring the original soil moisture conditions confirm this. There was a significant difference

***$P \leq 0.001$.

between the W and N plants only for GG, which means that at t = 42 d, the effect of waterlogging on the concentration of GG continued. For B, BG, and BGM, there was no significant difference at t = 42 d between the W and N plants: the concentrations of the W plants decreased to the level of the N plants.

DISCUSSION

The observed changes in the roots and color of the leaves between W and N plants indicate that the W plants suffered from oxygen shortage. Nonflood-resistant plants—such as *T. pratense*—under water stress can avoid oxygen shortage, either by having their lateral roots close to better oxygenated soil surfaces or by developing superficial adventitious roots in response to flooding. Flood-resistant plants can tolerate the stress because they have morphological and anatomical features, e.g., aerenchyma, which allow internal oxygen transport to satisfy the needs of root respiration and also the oxidation of chemically reduced toxins (Etherington, 1983; Gibberd et al., 2001).

The increase in isoflavone levels in *T. pratense* under waterlogged conditions is comparable to the behavior of three Australian clover species (Francis and Devitt, 1969). Because the processes in roots such as *Rhizobium* infection and formation of root nodules are disturbed in response to waterlogging, it is likely that the isoflavones that are usually involved in the nodulation process and in the arbuscular mycorrhizal symbiosis accumulate in the leaves of the plant. Earlier studies with *Trifolium semipilosum* (Lupwayi et al., 1997) and *T. repens* (Pugh et al., 1995) also show that processes in the roots are affected under waterlogged conditions. Flavonoids are involved in response mechanisms to stress conditions in plants (Etherington, 1983; Stafford

and Ibrahim, 1992; Reuber et al., 1996; Strack, 1997; Rozema et al., 1997; Olsson et al., 1998; Wang et al., 1999) and in biological interactions of clover species with microorganisms. In the symbiosis of clover with arbuscular mycorrhizal fungi, flavonoids can stimulate spore germination and hyphal growth (Chen et al., 2001; Fracchia et al., 2003). Bacterial nodulation (*nod*) genes are essential for infection of the host root and the establishment of the nodule. The expression of these genes requires the presence of flavonoids as signal compounds, released from the host plant roots, and the *nodD* regulatory protein (Rossen et al., 1987). Several authors report the involvement of flavonoids in the induction of the expression of *Rhizobium* nodulation genes from leguminous plants, e.g., *T. pratense* (Janczarek et al., 1997), *Galega orientalis* (Suominen et al., 2003), and *Lupinus albus* (Gagnon and Ibrahim, 1997).

Edwards et al. (1997) studied the effect of nodulation on isoflavonoid concentration in red clover. Red clover plants that were inoculated with *Rhizobium trifolii* were compared with noninoculated plants. In the leaves of noninoculated plants, the concentrations of BGM and FGM increased with age, and the accumulation of BGM in the leaves was suppressed by nodulation, whereas FGM remained constant. In their study, a 3-wk lag period was observed. These observations are in accordance with our findings: because of waterlogging, nodulation decreases, and this coincides with accumulation of BGM, BG, B, and GG, whereas the concentrations of FGM, FG, and F remain virtually unaffected. The observed changes of isoflavonoid accumulation are most likely caused by signals from the roots that are indicative of the extent of root nodulation.

After restoration of normal soil water conditions, oxidation processes are stimulated, and processes in the root zone such as mycorrhiza infection and root nodule formation are restored. As Figure 2 suggests, this regeneration process is much faster than the initial response of the isoflavone aglycones, glucosides, and glucoside–malonates, viz., about 1 vs. over 3 wk. After 1 wk, the concentrations of all isoflavones except GG returned to the values found for the N plants. For GG, the concentration remained higher: there was no decrease after restoring the normal soil water conditions. An explanation for this may be that GG is biosynthetically the simplest of the isoflavonoids and, therefore, a key intermediate in the biosynthesis of more complex isoflavonoids (Dixon and Ferreira, 2002). Whereas the other isoflavones may be used to restore the nodulation processes in the roots, the production of G and GG may remain high for the formation of other isoflavonoids such as coumestans and pterocarpans.

As regards the much faster recovery of oxygenation of the soil when restored to normal conditions compared with the change because of waterlogging, it takes some time before all the oxygen is removed from the soil (Pugh et al., 1995). Apparently, after 3 wk, the soil is completely anaerobic, and processes in the roots and in the rhizosphere are being disturbed. When the soil

water level is restored to normal, the diffusion of oxygen into the soil will be relatively fast, and the processes in the roots are restored within 1 wk. A rapid recovery of rhizobial nitrogen fixation was found earlier in soybean (Sung, 1993). The activity of rhizosphere microorganisms may strongly increase as well (Ozan et al., 1997).

INCREASED SULFUR PRECURSORS AND VOLATILES PRODUCTION BY THE LEEK *Allium porrum* IN RESPONSE TO SPECIALIST INSECT ATTACK

SEBASTIEN DUGRAVOT, NATHALIE MONDY, NICOLE MANDON, and ERIC THIBOUT*

Institut de Recherche sur la Biologie de l'Insecte, UMR CNRS 6035, Faculté des Sciences, Université F. Rabelais, Avenue Monge, Parc Grandmont, 37200 Tours, France

(Received September 27, 2004; accepted January 24, 2005)

Abstract—To defend themselves against herbivory, plants use a variety of direct and indirect strategies involving induced increases in secondary substances. Species of the *Allium* genus (Alliaceae), such as the leek *Allium porrum* (L.), produce nonprotein sulfur amino acids derived from cysteine, i.e., alk(en)yl-cysteine sulfoxides that are precursors of volatile thiosulfinates and disulfides. These defend most species including the specialist leek moth, *Acrolepiopsis assectella*. We determined by measuring the increase in the sulfur precursor propyl-cysteine sulfoxide (PCSO) if production of this precursor is induced in response to moth attack and mechanical wounding. The concentration of PCSO was determined by HPLC in 2- or 6-mo-old leeks after attacks of various intensity either by the specialist leek moth or by a generalist moth, *Agrotis ipsilon*. Injury-induced release of sulfur volatiles was measured by GC/MS after the attacks. Results showed an increase in the production of sulfur compounds in both the precursor and volatile form, occurring only in association with intensive attacks by leek moths. The increase in sulfur precursors also led to an increase in the release of sulfur volatiles. This induced response may provide an effective defense strategy against the plant's main natural enemy, both directly and indirectly by attracting entomophagous insects.

Key Words—*Acrolepiopsis assectella*, *Allium porrum*, constitutive defenses, induced defenses, sulfur compounds, disulfides, thiosulfinates, propyl-cysteine sulfoxide, specialist insect, tritrophic interactions.

INTRODUCTION

Through evolution, plants have developed various defense strategies against pathogens or herbivores. Most are based on production of defensive chemicals (Karban and Baldwin, 1997) with possible toxic or repellent effects on insects (Fraenkel, 1959). In some cases, production is constitutive and occurs independently of injury to the plant. However, an abiotic or biotic wounding such as a herbivore damage often triggers increased defensive chemical production (Karban and Baldwin, 1997; Constabel, 1999). Injury can also modify secondary metabolic processes resulting in increased production of nonvolatile toxic compounds such as nicotine in tobacco plants (Baldwin, 1988a) or glucosinolates in crucifers (Agrawal and Kurashige, 2003). These strategies can be classified as induced direct defense systems, and can lead to increased release of volatile substances such as terpenes in corn (Turlings et al., 1990) that attract entomophagous insects (Turlings et al., 1995; Paré and Tumlinson, 1999). Although direct and indirect induced defense systems have been observed in numerous species, it is not possible to conclude that they occur in all plants.

Plants of the *Allium* genus (Alliaceae), such as the leek *Allium porrum* (L.), produce nonprotein sulfur amino acids derived from cystein, i.e., alk(en)yl-cysteine sulfoxides (Virtanen, 1965; Block, 1992). These amino acids are considered precursors of sulfur volatiles because their contact with the enzyme alliinase produced after the rupture of plant tissue cells leads to the formation of sulfur volatiles mainly in the form of thiosulfinates that subsequently break down and rearrange into disulfides and trisulfides (Auger et al., 1989; Jaillais et al., 1999). This complex involving alk(en)yl-cystein sulfoxides–alliinase–thiosulfinates and di- or trisulfides is probably involved in the plant's defense strategy. Tests in confined spaces have demonstrated that these products are highly toxic for various species (Auger and Thibout, 2002). One, dimethyl disulfide, interferes with the cytochrome oxidase mitochondrial complex involved in the production of ATP, thus causing a loss of neuronal activity and death in some species (Dugravot et al., 2003). Moreover, tests in natural settings on crucifers (Chew, 1988) have shown that sulfur compounds can act as chemical repellents against herbivores (Auger et al., 1989).

In leeks, constitutive concentrations of sulfur precursors appear to provide an effective defense against nonspecialized insects. The main pest for field-produced leeks is the specialist leek moth *Acrolepiopsis assectella* (Zeller) (Lepidoptera: Acrolepiidae) (Arnault et al., 1986), which is particularly well adapted to the organosulfur chemistry of the host plant (Dugravot et al., 2004). The biosynthesis of secondary products in leek may change when damaged. To ascertain this possibility, the response induced in leeks damaged by the specialist herbivore moth was characterized by measuring the concentration of

sulfur compounds in both the nonvolatile precursor form, i.e., mainly propyl-cysteine sulfoxide (PCSO), and the volatile form, i.e., mainly thiosulfinates and disulfides. Response was studied in plants of various ages under several damage conditions inflicted by the moth and compared with responses elicited by mechanical wounding or by damage of the generalist moth *Agrotis ipsilon* (Lepidoptera: Noctuidae).

METHODS AND MATERIALS

Insects. A. assectella and *A. ipsilon* were reared on leek plants in the laboratory with a photoperiod of 16-hr light/8-hr dark at 25°C during the photophase and 16°C during the scotophase with 60–80% relative humidity. The *A. ipsilon* stock was obtained from the UMR Santé Végétale, INRA Bordeaux, France. The *A. assectella* stock was renewed every year in July by collecting caterpillars and chrysalids in leek fields around Tours, France.

Plants. In a first experiment, healthy leeks with no evidence of attack and damaged leeks with visible evidence of attack by leek moth caterpillars were picked in the field of a local grower practicing organic farming near Tours. The intensity of attack and time lapse since its end (more than 2 wk) could not be determined precisely. In other experiments, leek plants (Parlton variety) used were obtained from the Centre Technique Interprofessionel des Fruits et Légumes at Carquefou, France. When 4-months-old, they were transplanted to 10-cm diam pots and maintained in a greenhouse for 6–8 wk. Plants were randomly assigned to control or experimental groups. Most experiments were performed on 6-mo-old leeks, but smaller 2-mo-old leeks were also used to study the effect of plant age on the induced response.

Experimental Setup. All experiments were carried out on whole plants. Leaves or other plant parts had no other injuries than those inflicted for experimental purposes as described. Herbivore attacks were realized by placing third instar leek moth caterpillars on plants in the greenhouse. Caterpillars that escaped or underwent nymphosis were replaced.

The effect of attack intensity was studied by varying the number of caterpillars used and the duration of their presence on the plant: five caterpillars for 8 d, 15 caterpillars for 3 d, and 15 caterpillars for 8 d. Plants submitted to attacks under these three conditions were compared with plants submitted to mechanical wounding and healthy controls.

Mechanical wounding consisted of 10 1-cm incisions on 6-mo-old leek plants twice a day for 8 d on a new leaf everyday. This technique was not intended to reproduce an attack by *A. assectella* but to demonstrate the possible effect of a stress induced by abiotic cell destruction.

The systemic reaction of the leek plants was studied using 6-mo-old plants as follows. Fifteen *A. assectella* caterpillars were confined for 8 d in a transparent, ventilated chamber containing a portion of a green leaf. In this way, caterpillars were forced to consume only the available part of the green leaf. The response of the damaged green leaf was compared with the response on healthy green leaves on the same leek plant and healthy green leaves on control plants.

The specificity of leek plant response to herbivory was determined by comparing the effects of damage by *A. assectella* caterpillars to damage by generalist *A. ipsilon* caterpillars. These experiments were also performed using chambers to confine the caterpillars to certain parts of the plant. Unlike *A. assectella*, *A. ipsilon* is highly mobile with a tendency to consume only leaf tips and then leave the plant. Because of their larger size, five second-stage *A. ipsilon* caterpillars caused as much (or more) damage to the plant as 15 *A. assectella* caterpillars in 8 d.

To study the persistence of the response to damage, results in undamaged control leeks were compared with results in three batches of injured leeks immediately after and 2 or 4 wk after damage by 15 *A. assectella* caterpillars for 8 d. The number of caterpillars used, duration of damage, and number of replications in each experiment are indicated in figures.

Measurement of Sulfur Precursor. The level of PCSO, the main sulfur precursor in leek (Freeman and Whenham, 1975), was measured on a 10-cm segment of the stalk using the Waters Pico-Tag technique (Bidlingmeyer et al., 1984). The sample was weighed and ground in methanol for 40 sec at atmospheric pressure. The resulting mixture was filtered first through Whatman 114V paper and then through 0.45-μm Millex. Ten μl of the resulting extract was used for UV detection of all derived amino acids. Phenylisothiocyanate was used as the derivatization reagent. The HPLC system consisted of a Waters (Milford, MA, USA) chromatograph with a two-pump delivery system (Waters 600E) and a UV detector with the wavelength set at 254 nm (Waters 488). The column was a Waters Novapack C18 (3.9 × 300 mm). The solvent consisted of two Waters eluents, and the flow rate was 1 ml/min. Precise amounts of PCSO synthesized in the laboratory (Auger and Thibout, 1981) were added to allow quantification by comparing retention time and peak areas. Concentrations were expressed in nmol/mg of fresh leek.

Measurement of Sulfur Volatiles. Sulfur volatiles released by damaged leek were studied using a specially designed dual technique (Mondy et al., 2002). In the first step, the leek either undamaged or that had undergone an 8-d attack by 15 caterpillars was placed for 30 min under light conditions in an air-conditioned chamber (26°C, 70% relative humidity). A leaf was placed inside a glass tube (20 cm long × 2.6 cm in diam) closed at both ends using cotton to avoid damaging the plant. The tube had two side openings. Through one side

opening, 10 1-cm incisions were made in the leaf. Through a Teflon membrane placed over the other side opening, a polyacrylate solid phase microextraction (SPME) fiber (85-μm diam; Supelco, Bellefonte, PA, USA) was introduced and used to trap odors released in the headspace for 15 min. The second step used an electric crusher to grind the preceding leeks to compensate for natural degradation of some sulfur volatiles on the SPME fiber (Jaillais et al., 1999; Arnault et al., 2000). The resulting liquid was filtered through a blutter cloth. After a 60-min standing period, a 5-ml specimen was collected, extracted in 1 ml of ether, and centrifuged at 8000 $\times$ *g* for 5 min. The ether phase was passed through a 0.4-μm filter, dried with NaCl, and injected directly into the GC/MS to quantify all volatiles produced by the leek during the crushing process. GC/MS analyses were carried out using a Perkin-Elmer Turbomass benchtop system (Perkin-Elmer, Norwalk, CT, USA) fitted with a split–splitless injector and a fused-silica capillary column (10 m $\times$ 0.32 mm) with a 4-μm methylsilicone coating. Helium (99.999%) was used as carrier gas, and the column temperature rate was programmed for 5°C/min from 70 to 250°C. The injection port temperature was 200°C. Total ion chromatograms and mass spectra were recorded in the electron impact ionization mode at 70 eV. The transfer line and source temperature were maintained at 150°C. Dipropyl disulfide was used as the external calibration standard for quantification. Data processing was performed using the full-screen mode for the SPME fiber and the selected ion recorded (SIR) mode for ether extracts. Compound identification was based on retention time and comparison with spectra of available authentic compounds or with published data (Arnault et al., 2000; Mondy et al., 2002).

Statistical Analysis. Data recorded for sulfur precursors and compounds trapped by the SPME fiber were compared in pairs using the nonparametric Mann–Whitney *U*-test for independent samples ($P < 0.05$). Means of more than two specimens were compared using a nonparametric Kruskal–Wallis one-way analysis of variance ($P < 0.05$) followed if necessary by a classification test (Dunn test). For each chromatographic profile, the relative value of each identified peak with respect to the total was calculated and expressed as a percentage. Peaks of volatiles were analyzed with principal component analysis (PCA).

RESULTS

Evidence of Propyl-Cysteine Sulfoxide Production. Concentration of PCSO under natural conditions was significantly higher in damaged than healthy leeks (Mann–Whitney *U*-test, $P = 0.012$; Figure 1). Concentration was almost three times higher in damaged than in healthy leeks: 0.21 ± 0.09 vs. 0.59 ± 0.15 nmol/mg (means ± SE).

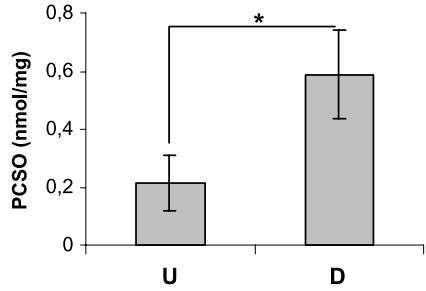

FIG. 1. Mean (±SEM) propyl-cysteine sulfoxide concentration (PCSO) in undamaged and damaged leek *A. porrum* collected in the field. U: undamaged leeks ($N = 6$); D: leeks damaged by *A. assectella* ($N = 6$); *$P < 0.05$ (Mann–Whitney *U*-test).

Mechanical Injury and Intensity of Attack. Cutting the leaves daily did not induce a significant change in PCSO concentration (Figure 2). Only damage by 15 caterpillars for 8 d triggered an increase in PCSO concentration threefold higher than in undamaged leeks (Kruskal–Wallis test, $P < 0.001$; Figure 2). Damages of lower intensity, i.e., by five caterpillars for 8 d or 15 caterpillars for 3 d, caused no significant increase in PCSO concentration (Figure 2).

Plant Age. In 2-mo-old leek plants, damage by three caterpillars for 8 d was sufficient to induce a significant increase in PCSO concentration (Mann–Whitney *U*-test, $P < 0.001$; Figure 3). In this case, PCSO concentration was also three times higher in the stalks of the damaged than undamaged leeks.

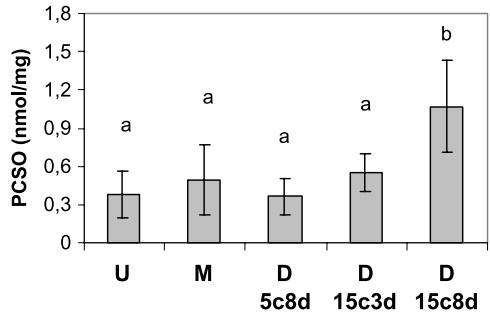

FIG. 2. Mean (±SEM) propyl-cysteine sulfoxide concentration (PCSO) in 6-mo-old undamaged leek *A. porrum* or damaged leek that had undergone mechanical wounds or attacks of various intensity by *A. assectella* caterpillars. U: undamaged ($N = 22$); M: mechanically wounded ($N = 12$); D 5c8d: damaged by five caterpillars for 8 d ($N = 12$); D 15c3d: damaged by 15 caterpillars for 3 d ($N = 12$); D 15c8d: damaged by 15 caterpillars for 8 d ($N = 15$). Equal letters indicate no significant differences among treatments ($P < 0.001$, Kruskal–Wallis test).

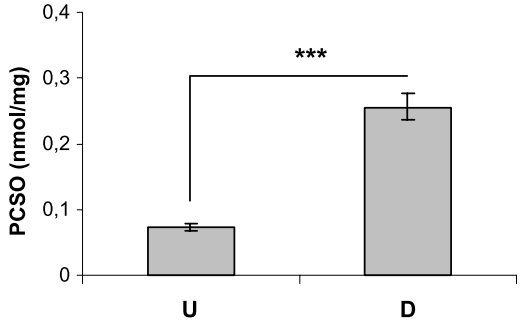

FIG. 3. Mean (±SEM) propyl-cysteine sulfoxide concentration (PCSO) in undamaged and damaged 2-mo-old leek *A. porrum*. U: undamaged ($N = 12$); D: damaged by three *A. assectella* caterpillars for 8 d ($N = 12$). ***$P < 0.005$ (Mann–Whitney *U*-test).

Furthermore, PCSO concentration was nearly four times lower in 2-mo-old leeks than in the older leeks (0.07 ± 0.01 and 0.37 ± 0.18 nmol/mg in healthy leeks vs. 0.26 ± 0.02 and 1.07 ± 0.35 nmol/mg in damaged leeks; Figures 2 and 3). However, low-intensity damage with no effect on 6-mo-old leeks sometimes caused a response in younger, smaller leeks.

Systemic Response. Green leaves from undamaged leek showed significantly lower PCSO concentrations than healthy or wounded leaves from damaged leeks (Figure 4). However, healthy leaves from damaged plants also showed significantly lower PCSO concentrations than leaves directly damaged by caterpillars (Figure 4). The PCSO concentration was 0.09 ± 0.01 nmol/mg in

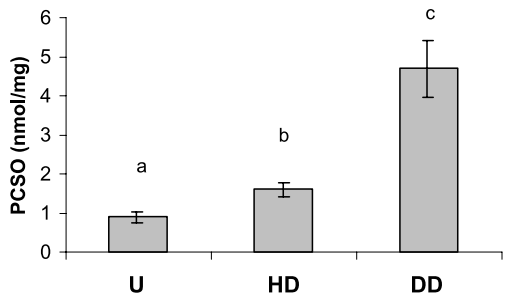

FIG. 4. Mean (±SEM) propyl-cysteine sulfoxide concentration (PCSO) in leaves from undamaged and damaged 6-mo-old leek *A. porrum*. U: healthy leaves from undamaged leeks ($N = 12$); HD: healthy leaves from leeks damaged by 15 *A. assectella* caterpillars for 8 d ($N = 12$); DD: damaged leaves from leeks attacked by 15 *A. assectella* caterpillars for 8 d ($N = 12$). Equal letters indicate no significant differences among treatments ($P < 0.001$, Kruskal–Wallis test).

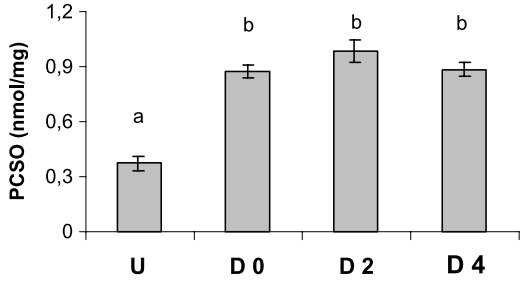

FIG. 5. Mean (±SEM) propyl-cysteine sulfoxide concentration (PCSO) according to the time in undamaged and damaged leek *A. porrum*. U: undamaged (N = 22); D0: immediately after end of attack by *A. assectella* caterpillars (N = 12); D2: 2 wk after end of attack by *A. assectella* caterpillars (N = 12); D4: 4 wk after end of attack by *A. assectella* caterpillars (N = 12). Equal letters indicate no significant differences among treatments ($P < 0.001$, Kruskal–Wallis test).

the leaves from undamaged plants as compared with 0.16 ± 0.02 nmol/mg in healthy leaves from damaged leeks and 0.47 ± 0.07 nmol/mg in the wounded leaves from the same damaged plants (Kruskal–Wallis test, $P < 0.001$).

Persistence of Plant Response. Regardless of the interval between the end of damage and date of measurement, PCSO concentrations were significantly higher in damaged than in undamaged control leeks (Figure 5). The concentration, i.e., 0.37 ± 0.04 nmol/mg in undamaged leeks, rose sharply immediately after the damage and remained between 0.9 and 1.0 nmol/mg for at least 1 mo (Kruskal–Wallis test, $P < 0.001$).

Specificity of Plant Response. Mean PCSO concentration in leeks damaged by *A. ipsilon* caterpillars was 0.28 ± 0.04 nmol/mg of fresh leek (N = 12) and was not significantly different from the mean PCSO concentration in undamaged leeks, 0.38 ± 0.06 nmol/mg of fresh leek (N = 12; Mann–Whitney U-test, $P = 0.064$).

Effects on Release of Sulfur Volatiles. An undamaged 6-mo-old leek gave off no detectable odor under the experimental conditions used (data not shown). In contrast, leeks damaged by *A. assectella* caterpillars or submitted to mechanical wounding released general green leaf volatiles, mainly *trans*-2-hexenal, *cis*-2-hexen-1-ol, and *cis*-3-hexenyl-acetate, as well as sulfur volatiles that broke down mainly into dipropyl disulfide and propyl-propenyl disulfide on the SPME fiber.

The ether extraction technique allowed identification of substances actually produced by leeks during damages prior to their breakdown into disulfides. A total of seven sulfur volatiles were identified: methyl-propyl thiosulfinate (and its isomer propyl-methyl thiosulfinate), methyl-propenyl thiosulfinate, dipropyl

thiosulfinate, propyl-propenyl thiosulfinate, and two *cis* and *trans* isomers of zwiebelanes. The last two compounds resulted from rearrangement of dipropyl thiosulfinate. There was no significant qualitative difference between undamaged and damaged leeks when crushed. Principal component analysis performed on these seven sulfur volatiles showed three principal components with eigenvalues higher than 1, explaining 80.9% of the total variance. On the basis of their proportions of sulfur volatiles, undamaged leeks were clearly distinguished from damaged leeks (Figure 6).

In addition, different degradation compounds of thiosulfinates and zwiebelanes were affected by insect attack. These compounds trapped by SPME were mainly dipropyl disulfide (DPDS) and propyl-propenyl disulfide (PPeDS) (Figure 7). During the formation of disulfides, the propyl moieties came from both the thiosulfinates and the zwiebelanes. After being cut, leek plants that had been damaged 8 d earlier released around twofold more disulfides than leek plants that had not been damaged (Mann–Whitney *U*-test, $P_{\mathrm{DPDS}} = 0.015$; $P_{\mathrm{PPeDS}} = 0.004$; Figure 7).

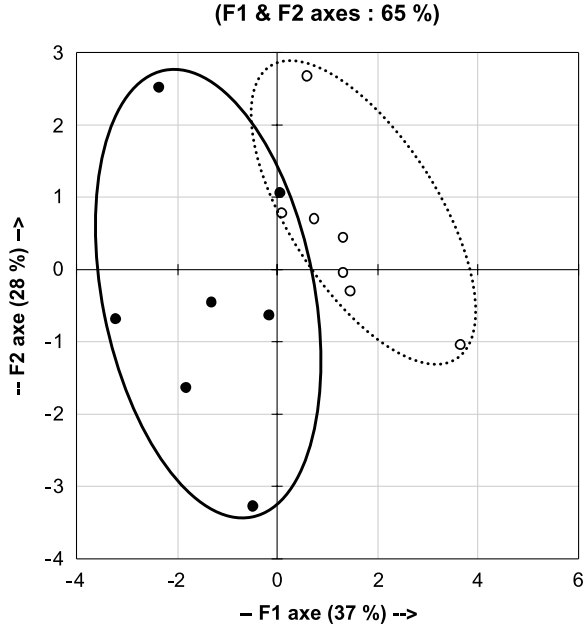

FIG. 6. Principal components analysis (PCA) of all sulfur volatiles released by undamaged leek *A. porrum* (black dots, $N = 7$) and by leek damaged by 15 *Acrolepiopsis assectella* caterpillars for 8 d (white dots, $N = 7$).

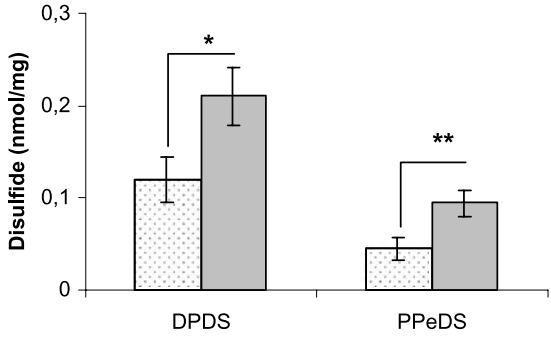

FIG. 7. Mean (±SEM) disulfide concentration released by mechanically wounded leek *A. porrum* that had or had not been previously damaged by 15 *A. assectella* caterpillars for 8 d. Dark bars: undamaged ($N = 7$); light bars: attacked ($N = 7$); DPDS = dipropyl disulfide; PPeDS = propyl propenyl disulfide. *$P < 0.05$; **$P < 0.01$ (Mann–Whitney *U*-test).

DISCUSSION

This study shows that the concentration of PCSO in leek plants increases in response to damage by the herbivore *Allium* specialist *A. assectella*, and that this increase is followed by a characteristic profile of sulfur volatile release.

In preliminary experiments using another liquid chromatography technique (Arnault et al., 2003), the concentrations of three sulfur precursors in leek plants were determined. Results showed that in addition to PCSO, the only precursor studied here, methyl-cysteine sulfoxide and propenyl-cysteine sulfoxide also increased sharply after intensive damage by *A. assectella* caterpillars (Auger and Arnault, personal communication). Without excluding possible repercussions on other biosynthetic pathways, these findings indicate that the concentration of all sulfur precursors in the leek increases in response to damage by *A. assectella* caterpillars.

The induced increase in the production of sulfur precursors depends on several factors including the intensity of attack. Under our study conditions, no response was observed after damages involving a small number of caterpillars or attacks of short duration. Similar findings have been reported in cotton *Gossypium hirsutum* in which the induced response to attack by *Spodoptera littoralis* depends on the extent of damage (Anderson et al., 2001). In *Brassica napus*, the increase in concentration of glucobrassicine (but not the other 13 glucosinolates analyzed) depends on the intensity of the damage inflicted by *Delia floralis* larvae (Hopkins et al., 1998).

The sensitivity of leeks to damage also varies with age. Young 2-mo-old plants respond to damages of lower intensity than 6-mo-old plants. This finding

suggests that production of sulfur precursors occurs only if the stimulus resulting from *A. assectella* caterpillar activity is sufficient. It seems that because of the possible metabolic costs involved, as observed in various plant species (Simms, 1992; Rausher, 1996), and the abundance of constitutive defenses, leeks invest in production of sulfur precursors only in cases of intensive attack. This may be especially true for older leeks that are less sensitive to attack than younger leeks because the same damage intensity from leek moth represents a lower threat in old leeks.

Repeated mechanical wounding did not trigger an induced response. This suggests that herbivore-specific cues may be involved in the leek response to caterpillar damage. Similar findings have been reported in the wild radish *Raphanus raphanistrum* in which response is induced by insect herbivory but not by mechanical wounding (Agrawal, 1998, 1999). Further experiments demonstrated that elicitors in larval oral secretions or feces were responsible for inducing the plant response (Turlings and Tumlinson, 1992; Turlings et al., 1993; Mattiacci et al., 1995; Alborn et al., 1997; Neveu et al., 2002).

The response induced in leek plants by *A. assectella* appears to be systemic. Healthy leaves on damaged leeks have higher PCSO concentrations than healthy leaves on undamaged plants. However, the PCSO concentrations observed in healthy leaves from damaged plants were not as high as those observed in injured leaves. Systemic induction of secondary compounds has been reported in numerous other plants (Green and Ryan, 1972; Baldwin, 1988b; Turlings and Tumlinson, 1992; Potting et al., 1995; Cortesero et al., 1997; McAuslane et al., 1997; Mattiacci et al., 2001; Neveu et al., 2002).

In leeks, a sustained induced increase in sulfur precursors persists for at least 1 mo after the attack. Neobiosynthesis can require a long time. In leeks, an 8-d damage is required to induce the response. Similar findings have been observed in tobacco in which the peak increase of nicotine production occurs 7–8 d after the beginning of the attack (Baldwin, 1989). In cotton, attack by *S. littoralis* induces a strong response 5–10 d after the beginning of the attack but not after only 1–3 d (Anderson and Alborn, 1999; Anderson et al., 2001). Previously attacked leeks may present higher precursor levels than never-attacked plants for a long time after injury. As a result, previously damaged plants can be better protected against herbivory and against the offspring of the insects that inflicted the first damage (Dugravot and Thibout, unpublished data). This type of protection is comparable to an immune response (Agrawal, 1998) that once induced would allow the plant to be better protected in case of further damage. Induced protection may persist for months or more. In the birch tree *Betula pubescens*, protection persists from 1 yr to another (Haukioja and Neuvonen, 1985; Haukioja et al., 1985). However, long-term protection is not consistently observed in all species. In tobacco, the concentration of nicotine returns to normal 14 d after induction (Baldwin, 1989), and induced resistance

in *Glycine max* soybean disappears 20 d after the end of damage by *Epilachna varivestis* (Underwood, 1998). These findings could indicate that duration of the induced resistance may be correlated with the life cycle of the plant. In annual species such as tobacco and soybean, the response lasts only a few days, whereas in pluriannual tree species such as the birch, the response lasts several months. We suggest that in biennial leek plants, the response duration of at least 1 mo could be intermediate between annual and pluriannual plants. In addition, the greater the number of generations that the attacking insect may develop, the longer the induced response could last.

In experiments involving a generalist herbivore, *A. ipsilon*, PCSO concentration in leek plants did not increase even after intense damage. This finding implies that the elicitors of the induced response to *A. assectella* caterpillars in leeks are not present in *A. ipsilon* caterpillars. Constitutive levels of sulfur precursor concentrations may be sufficient to protect the plant against this type of generalist herbivore. In the field, *A. ipsilon* caterpillars consume mainly the tips of old leek leaves, i.e., the site where the concentration of sulfur metabolites is the lowest (Dugravot, personal observations). The finding concerning the response of leeks to generalist attack is in contradiction with findings reported in the herbacean *Hypericum perforatum* that increases production of secondary compounds in response to attack by generalist insects, i.e., *Spilosoma virginica*, *S. congrua*, and *Spodoptera exigua*, but not in response to attack by the specialist *Chrysolina quadrigemina* that causes more extensive damage (Sirvent et al., 2003). Schultz (2002) reported that it was exceptional for herbivore insects not to trigger a response in the consumed plant. It cannot be ruled out that attack by *A. ipsilon* caterpillars induces a response using biosynthetic pathways other than those producing sulfur precursors.

Gas chromatography studies showed that healthy leeks release no detectable odor under our experimental conditions. Conversely, leeks that have been attacked by leek moth or mechanically wounded release volatiles, including numerous thiosulfinates and zwiebelanes, compounds previously identified in analytical conditions (Auger et al., 1989; Jaillais et al., 1999). The lack of qualitative difference between volatiles released after herbivore damage and mechanical wounding has also been reported in Solanaceae such as tomato and potato (Bolter et al., 1997) and in crucifers (Mattiacci et al., 1994). Like leeks, these plants generally exhibit nonvolatile secondary compounds that can be used for effective direct protection against herbivores (Dicke, 1999). In corn or bean plants that do not produce nonvolatile secondary compounds for direct defense (Dicke, 1999), the spectrum of volatiles released in response to herbivores is different from that released after mechanical wounding (Dicke et al., 1990; Turlings et al., 1990; Tumlinson et al., 1999). The differences observed between undamaged and damaged leeks suggest that the insects living on *Allium* plants will be able to distinguish between the two plant categories.

This study has also demonstrated that the increase in nonvolatile sulfur precursor production following a damage by *A. assectella* caterpillars leads to a different chemical profile from that of another attack or wound event. The main difference consists of a significant increase in breakdown disulfides and rearrangement of all released sulfur volatiles products. This response by leek plants to *A. assectella* damage persists for at least 1 mo and could be considered as a direct induced defense strategy involving substances that can act on the metabolism and behavior of the damaging insect as well as its offspring.

Acknowledgments—This research was supported in part by a grant from the French Ministry of Research to one of the authors.

(Received October 13, 2004; revised December 14, 2004; accepted February 24, 2005)

Abstract—Levels of (−)-epicatechin in tea cultivars resistant to blister blight leaf disease were significantly higher than those in susceptible cultivars, while the reverse was true for (−)-epigallocatechin gallate, suggesting that epicatechin was involved in the resistance mechanism. The content of the methylxanthines, caffeine and theobromine, in the leaf increased in the initial translucent stage of the disease, probably as a defense response to fungal attack. Epicatechin and epigallocatechin levels were less than in healthy tissues at this stage, but increases in the corresponding gallate esters suggested that they were being converted into esters. Although epicatechin and epigallocatechin levels decreased from translucent to mature blister stages, the decrease was not significant. The decrease in levels of epicatechin, epigallocatechin, and their esters on infection and the formation of cyanidin and delphinidin on oxidative depolymerization of the blisters suggests that proanthocyanidins may play a role in the defense mechanism. The high resistance of a purple green leafed cultivar is attributed to the additional catechin source provided by the high levels of anthocyanins present.

Key Words—Tea, *Camellia sinensis*, blister blight, *Exobasidium vexans*, resistance, catechins, proanthocyanidins, caffeine, theobromine.

INTRODUCTION

Blister blight caused by *Exobasidium vexans* Massee is a leaf disease in tea, *Camellia sinensis* (L.) O. Kuntze, that is important in tea-growing areas of Asia (Arulpragasam, 1992). *E. vexans* is an obligatory biotrophic fungus that com-

* To whom correspondence should be addressed. E-mail: isarathb@yahoo.co.uk

pletes its life cycle of 11–28 d in the tea leaf (Gadd and Loos, 1948; Agnihothrudu and Moulli, 1991). The initial symptoms of the disease are lime green translucent spots, which appear 6–9 d after the infection. These spots develop into blisters that are ruptured releasing spores at the completion of the life cycle.

Tea cultivars have been categorized as resistant and susceptible to blister blight (Balasooriya et al., 1996), and some morphological and anatomical characters have been correlated with resistance (Martosupono, 1991). Little attempt has been made to correlate resistance with the chemical composition of tea leaf, although changes in saccharide metabolism (Pius et al., 1998) and increased activity of polyphenol oxidase and peroxidase, and decrease in chlorophylls and carotenoids (Rajalakshmi and Ramarethinam, 2000) induced by blister blight infection have been shown. A preliminary report (Nagahaulla et al., 1996) discusses the formation of phytoalexins, probably polyphenolic in nature, on blister blight infection. The variation in chemical composition and the quality of tea with increasing severity of blister blight has also been studied (Gulati et al., 1999).

Polyphenols are the major chemical constituents of tea, with the catechins being predominant. The role of phenolic substances in disease resistance is well documented(Vidhyasekaran,1988; Nicholson and Hammerschmidt, 1992). Polyphenols are fungitoxic and antibacterial, with varying levels of toxicity to spore germination, mycelial growth, and fungal enzyme production (Vidhyasekaran, 1988). Caffeine has been shown to play a role in the resistance of tea to attack by the shot-hole borer, *Xyleborus fornicatus* (Kumar et al., 1995).

The present study was initiated to investigate the role, of flavan-3-ols (catechins) and methylxanthines on preformed or induced chemical resistance of tea leaf against *E. vexans*.

METHODS AND MATERIALS

Plant Material. Tea plants were grown in experimental plots at the Tea Research Institute of Sri Lanka, Talawakelle, Sri Lanka. The plants were raised by vegetative propagation using standard procedures (Kathiravetpillai and Kulasegaram, 1986). Tender tea leaves (two apical leaves and the bud) from each tea cultivar, which belong to *E. vexans* resistant (DT1, TRI777, TRI2043, N2, TRI4067, TRI4052, NAY3, and TRI3073) and susceptible (TRI2025, TRI2024, TRI2023, TRI62/5, TRI3015, TRI3014, and TRI62/1) groups, were used for comparison of catechin and caffeine contents.

Plants selected for the infection study were those in an experimental plot that contained about 50 plants. They were naturally infected with *E. vexans* during the rainy season. About 100 leaves were randomly harvested, imme-

diately brought to the laboratory, and sorted into those that were healthy and those in the three stages of infection-translucent spot stage, mature blister stage 1 (convex lesions which are green in color), and mature blister stage 2 (convex lesions which are white in color due to sporulation). Leaf discs cut from each of the stages or leaves, depending on the requirement, were transferred to glass tubes and stored at −20°C until use within 48 hr.

Extraction and HPLC Analysis of Catechin and Methylxanthines. Analysis was carried out according to ISO procedure (ISO/TC34/SC8; ISO, 1999). Tender tea leaves (10 g) from each cultivar or leaf discs (1 g) from infected material were plunged into boiling 70% aqueous methanol and boiled for 10 min. The extract was cooled and homogenized for 3 min using a top-drive macerator (Ultra-Turrax, USA). The homogenate was centrifuged (4000 rpm × 15 min), and the supernatant was decanted into a volumetric flask (100 ml). The residue was reextracted with the solvent (40 ml), centrifuged, and the supernatant was transferred to a volumetric flask. The volume of the pooled extract was increased up to 100 ml with 70% aqueous methanol. After tenfold dilution, the sample was filtered through 0.45-μm filter, and 10 μl of this were injected into the high-performance liquid chromatography (HPLC) system (Waters Alliance 2690XE Separation module coupled to a Waters 996 photodiode array detector (PDA) and Waters Millennium 32 data system). The analysis was replicated eight times. Standards of caffeine, theobromine, (+)-catechin, (−)-epicatechin, (−)-epigallocatechin, (−)-epigallocatechin gallate, and (−)-epicatechin gallate (Sigma, St. Louis, MO, USA) were prepared. A phenomenex phenyl hexyl column (4.6 × 250 mm) and a linear gradient with mobile phases A (9% acetonitrile containing 2% acetic acid) and B (80% acetonitrile) were used for the separation.

Histochemical Staining of Infected Leaf Tissues. A tea leaf infected with *E. vexans* was rinsed with distilled water and soaked in ethanol/glacial acetic acid (3:1 v/v) for 30 min. The decolorized leaf was stained with vanillin (5% vanillin in ethanol/4 N HCl; Broadhurst and Jones, 1978) and 4-dimethylaminocinnamaldehyde (0.3% DMACA in methanol/6 N HCl, Li et al., 1996) for 20 min at 25°C. Excess stains were washed away with distilled water, and the leaf was observed for color changes. The staining was replicated eight times, and a suitable specimen was chosen for photographic record.

Determination of Proanthocyanidins in Infected and Healthy Leaf Material. Oxidative cleavages were carried out as described by Porter et al. (1986) using leaf discs (1 g) from healthy tea leaves and the infected area of three stages of blister blight infected leaf tissues. The leaf tissues (1 g) were homogenized with 70% acetone (containing 0.1% ascorbic acid). The extract was centrifuged and the volume of the supernatant was increased up to 10 ml with the extracting solvent. To an aliquot of the above extract (1 ml), BuOH/concentrated HCl (95:5 v/v, 5 ml) and iron reagent [2% $NH_4Fe(SO_4)_2 \cdot H_2O$ in

2 M HCl, 0.2 ml] were added. The resultant solution was placed on a water bath and heated at 95°C for 40 min, cooled, and decanted into a volumetric flask, and the volume was increased up to 10 ml with BuOH/HCl (95:5 v/v). A small aliquot was filtered through 0.45-μm filter (Millipore, USA), and 10 μl were injected into the HPLC system. The experiment was replicated twelve times. Calibration curves were constructed using standards of cyanidin and delphinidin (Carl Roth Gmbh, Germany).

Determination of Moisture Content. The moisture content of leaf samples was determined by drying at 103°C for 6 hr (ISO 1573, 1980).

Identification of Anthocyanidins in TRI2043. Tender leaves (50 g) from the cultivar TRI2043 were homogenized with methanol containing 0.01% HCl (100 ml). The extract was centrifuged (4000 rpm, 10 min), and the volume of the supernatant was increased up to 100 ml with the extracting solvent. To an aliquot (5 ml) of the above homogenate, 2 N HCl (5 ml) were added, and the mixture was heated on a water bath at 95°C for 2 hr. The acid hydrolyzate obtained was analyzed initially by thin-layer chromatography (TLC) and paper chromatography and then by HPLC. An aliquot (50 μl) was chromatographed on analytical cellulose TLC plates (20 × 20 cm, E. Merck, Germany) and on Whatman no. 3 paper (Whatman Inc, USA) using acetic acid/water/HCl (30:10:3, Forestal solvent system, Harborne, 1967) as eluent in both cases. The chromatographic bands were separately removed, dissolved in methanol containing 0.01% HCl, and spectroscopically analyzed (Cintra-5-UV–Visible Spectrophotometer, GBC, Australia). An aliquot (10 μl) of the acid hydrolyzate was filtered through a 0.45-μm filter (Millipore, USA) and injected into the HPLC system. The anthocyanidins, cyanidin and delphinidin, were detected at 520 nm.

Statistical Analysis. Student's *t*-test was performed to identify the difference between the two means against the critical difference (LSD) using Statistical Analysis System Software, USA. GLM procedure was conducted to identify any significant difference among healthy, translucent, and mature blister stages for the catechins and methylxanthines, and Duncan's multiple-range test was used for the mean separation.

RESULTS AND DISCUSSION

A study of the flavan-3-ol and caffeine content of resistant and susceptible tea cultivars showed that significantly higher levels of (−)-epicatechin (22.4 mg/g) were present in cultivars of tea resistant to blister blight compared with those in susceptible cultivars (11.3 mg/g) (Tables 1 and 2). A significantly higher level of (−)-epigallocatechin gallate was present in susceptible cultivars compared with resistant cultivars. No significant differences were seen among

cultivars in (+)-catechin, (−)-epigallocatechin, (−)-epicatechin gallate, or caffeine. Resistant cultivars with higher levels of epicatechin had lower levels of epigallocatechin gallate.

The resistance of apple cultivars (Treutter and Feucht, 1990) to *Venturia inaequalis*, and avocado (Prusky et al., 1996; Prusky, 1996) to anthracnose have been attributed to high levels of epicatechin, suggesting that epicatechin may be directly or indirectly involved in the resistance mechanism of tea against blister blight.

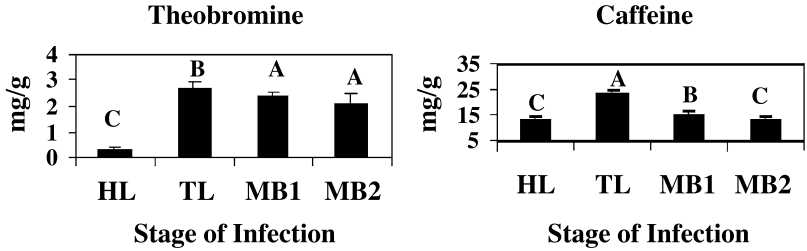

FIG. 1. Changes of theobromine and caffeine content (on dry weight basis) upon *E. vexans* infection, $N = 12$. HL, Healthy; TL, Translucent stage; MB1, Mature Blister 1; MB2, Mature Blister 2. Bars with the same letter are not significantly different.

Analysis of leaf material for flavanols and methylxanthines showed that significant changes occurred in flavan-3-ol and methylxanthine during infection. No significant difference was observed in catechin and methylxanthine between a disc sample (1 g) cut from fresh leaf and a similar sample from the same leaf stored at −20°C for 48 hr. The methylxanthines, caffeine and theobromine, increased significantly during the translucent stage of the disease, but the increase was not significant thereafter (Figure 1). The increase in methylxanthine at the first stage of infection could be the initial defense response of the plant to fungal attack, as reported to occur in infestation of tea by the shot-hole borer beetle, *Xyleborus fornicatus*, (Kumar et al., 1995) and in fungal attack on cocoa leaves (Aneja and Gianfagna, 2001).

Epicatechin and epigallocatechin significantly decreased upon infection (Figure 2). Epicatechin levels decreased in the translucent stage when compared with healthy tissues. A twofold reduction of epigallocatechin levels (from 42 to 21 mg/g) was observed in the translucent stage of the infection. However, the observed decrease in epicatechin and epigallocatechin content from the translucent stage to the mature blister stage was not significant. The content

of epicatechin gallate and epigallocatechin gallate increased at the translucent stage of infection, but the increase was significant only for the former. The content of the gallate esters, however, decreased significantly during the mature blister stage (Figure 3).

Histochemical staining of tea leaves with vanillin reagent (Broadhurst and Jones, 1978) and 4-dimethylaminocinnamaldehyde (DMACA) reagent (Li et al., 1996) gave evidence for the accumulation of proanthocyanidins in the infected areas of the leaf tissue. Vanillin reagent produced the deep red color characteristic for flavan-3-ols or proanthocyanidins, and the blue green color shown by DMACA (Figure 4) indicated that proanthocyanidins were formed on infection. DMACA has been shown to be more sensitive to soluble proanthocyanidins (Joseph et al., 1998), reacting only with the terminal units of proanthocyanidins (Rohr, 1999).

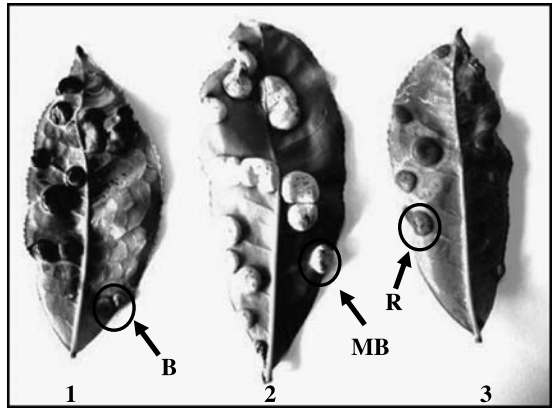

FIG. 4. Histochemical staining of tea leaves with mature *E. vexans* blisters. (1) Stained with DMACA, B = blue green in color. (2) Without staining, MB = mature *E. vexans* blisters. (3) Stained with vanillin, R = red in color.

Acid-catalyzed oxidative depolymerization of proanthocyanidins to the anthocyanidins, cyanidin, and delphinidin has been used to detect proanthocyanidin levels in plants (Porter et al., 1986). Depolymerization of infected tissue gave higher levels of cyanidin and delphinidin compared with healthy tissue (Figure 5).

It has been suggested that catechins condense with flavan-3,4-diols to give proanthocyanidins, which are known to be fungitoxic (Rao and Rao, 1986; Winkel-Shirley, 2002). The observed reduction in catechin levels and increase in proanthocyanidin levels on infection suggest a possible role for proanthocyanidins in the defense mechanism.

Of the cultivars studied here, TRI 2043 is the most resistant cultivar to blister blight. Substantially higher amounts of cyanidin and delphinidin were formed during the acid hydrolysis of the extract of the purple green leaf of this cultivar when compared with other cultivars. The identities of the anthocyanidins were confirmed by comparing their ultraviolet (UV)–visible spectra, paper chromatography, TLC, and HPLC values (Harborne, 1958, 1967) with those of standards. The color of the leaf was, therefore, attributed to the presence of high levels of anthocyanins. The higher tolerance of this cultivar may be explained as being due to the enhanced levels of catechins, which are proanthocyanidin precursors formed from the anthocyanins.

The increase in epicatechin gallate at the translucent stage could be due to the conversion of epicatechin into its gallic acid ester upon infection, since the translucent stage is accompanied by a significant decrease in epicatechin content. Similar observations were seen with epigallocatechin gallate and epigallocatechin content, although the increase in the former at the translucent stage was not significant (Figure 3). The increase in gallic acid esterification is important, as gallic esters of catechins have higher antibacterial, antiviral, and antioxidant activity than catechins (Kajiya et al., 2001, 2002). The decrease in

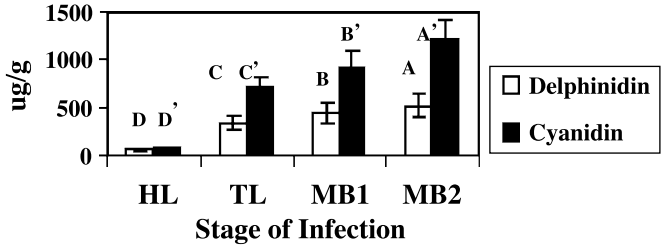

FIG. 5. Contents (on dry weight basis) of cyanidin and delphinidin liberated from proanthocyanidins upon acid-catalyzed oxidation of *E. vexans* infected leaf tissues, $N = 12$. HL, Healthy; TL, Translucent stage; MB1, Mature Blister 1; MB2, Mature Blister 2. Bars with the same letter are not significantly different.

catechin observed in the mature stage may be ascribed to the utilization of catechins for the formation of proanthocyanidins.

Epicatechin appears to play an important role in the resistance mechanism of tea against blister blight disease, while methylxanthines may play a role during initial attack by the fungus, *E. vexans*. The high resistance of the cultivar TRI 2043 is attributed to the high level of anthocyanins present.

SOURCES OF CHEMICAL SIGNALS WHICH ENHANCE MULTIPARASITISM PREFERENCE BY A CLEPTOPARASITOID

BRUNO JALOUX, CHRISTINE ERRARD, NATHALIE MONDY, FABRICE VANNIER, and JEAN PAUL MONGE*

Institut de Recherche sur la Biologie de l'Insecte (UMR CNRS 6035), Avenue Monge Parc de Grandmont, 37200 Tours, France

(Received December 1, 2004; accepted February 15, 2005)

Abstract—The cleptoparasitoid *Eupelmus vuilleti* recognizes and prefers laying on hosts parasitized by *Dinarmus basalis* to unparasitized hosts. This recognition is based on the perception of a chemical substance deposited on the surface of the seed. Dufour's gland secretion and cuticular hydrocarbons of *D. basalis* are attractive and may mediate the host discrimination. This activity is linked to a mixture of linear and methyl alkanes whose source is apparently the Dufour's gland.

Key Words—*Eupelmus vuilleti*, *Dinarmus basalis*, hymenoptera, eupelmidae, pteromalidae, cleptoparasitoid, interspecific discrimination, Dufour's gland, venom gland, cuticle, hydrocarbons.

INTRODUCTION

Interspecific competition between two species exploiting the same resource induces negative interactions that reduce the fitness of each competitor. Some behaviors are selected for these species that reduce the negative effects of competition. More often than not, competing species position themselves on temporally or spatially distinct portions of the resource gradient and thus avoid competition (Price, 1971). Some species, in contrast, have selected indirect strategies that allow them to take advantage of interspecific competition. Individuals of competing species can, for example, physically eliminate a competitor (intraguild predation; Polis et al., 1989) or promote intervention of

* To whom correspondence should be addressed. E-mail: jean-paul.monge@univ-tours.fr

natural enemies (apparent competition; Holt, 1977). One of the most common strategies that allows a species to take benefits from interspecific competition is to "rob" resources foraged by a competitor (cleptoparasitism; Furness, 1987; Ronquist, 1994). These resources could be food or laying site.

In the parasitoid hymenoptera, hosts represent both a laying site and a food stock for the developing offspring. With the species named solitary parasitoid, hosts can allow the development of a unique parasitoid larvae, which induces an intensive competition both with conspecific and heterospecific females to gain access to these hosts. Some studies of parasitoid species mention a behavior that can be considered as cleptoparasitism (Arthur et al., 1964; Spradbery, 1969; Price, 1970; van Alebeek et al., 1993). Females of a species recognize the hosts parasitized by the competing species, reuse the hole drilled by the ovipositor, destroy the heterospecific egg, and lay their own egg instead. The stimulus implicated in the interspecific host recognition has never been identified. Potentially, this behavior is damaging for the challenged species, which would be expected to select adaptations to avoid the recognition of the hosts by the cleptoparasitoid.

How can a female recognize hosts parasitized by another species? Is the interspecific discrimination based on the diversion of an intraspecific signal or on the perception of exploitation cues left unintentionally by the competitor? Arthur et al. (1964) suspected that the cleptoparasitoid perceived the intraspecific marking pheromone of the competitor. In most species where the origin of the marking pheromone has been studied, the active product is produced by the Dufour's gland, one of the two accessory gland of the female genital apparatus (Guillot and Vinson, 1972; Mudd et al., 1982; Harrison et al., 1985; Hubbard et al., 1987). This gland produces an oily secretion containing mainly hydrocarbons, nearly identical to the cuticular secretion of the female (Syvertsen et al., 1995; Howard and Baker, 2003). After the laying, this secretion is deposited on the surface of the host or of the plant structure containing the host, during a typical marking posture (Salt, 1937; Bosque and Rabinovitch, 1979).

Eupelmus vuilleti (CRW.) (Hymenoptera: Eupelmidae) and *Dinarmus basalis* (ROND.) (Hymenoptera: Pteromalidae) are two larval and nymphal solitary ectoparasitoids. They have for hosts several bruchid species (Coleoptera: Bruchidae), including *Callosobruchus maculatus*, which at larval stages destroys *Vigna unguiculata* (Fabaceae) seeds (Monge et al., 1995). They are sympatric in West Africa, and they compete with each other for unparasitized hosts. In the presence of seeds containing unparasitized and hosts parasitized by *D. basalis*, *E. vuilleti* females prefer laying their egg on parasitized hosts (van Alebeek et al., 1993; Lévêque et al., 1994; Jaloux et al., 2004). The recognition of the host seems to be attributable to the female perception of a stimulus, present on the surface of the seed, and linked to the host exploitation by the *D. basalis* female (Jaloux et al., 2004).

The research reported here was designed to determine the nature, origin, and chemical composition of the stimulus produced by the *D. basalis* parasitized host and recognized by cleptoparasitoid *E. vuilleti* female.

METHODS AND MATERIALS

Parasitoid Rearing. E. vuilleti and *D. basalis* populations originated from the area of Dapaong, an important cultivation area of *V. unguiculata* in the North of Togo. These two populations were reared separately in the laboratory. Rearing and experimentations were run under the same conditions: 35°C:25°C; L–D 12:12 hr; RH 70% (Jaloux et al., 2004).

Choice Tests. A choice test was done to determine the preference of *E. vuilleti* females for the hosts treated with different substances. A two-days-old mated *E. vuilleti* female was placed in a Petri dish containing two hosts: a control and a treated one fixed at the bottom of the dish. The position of the female was recorded periodically for 30 min (at 10 sec, 1, 2, 3, 4, 5, 6, 8, 10, 12, 15, 20, 25, and 30 min) in order to build a preference index. The position of the female at each observation time was encoded: 0 at the bottom of the Petri dish, 1 on the treated host, and −1 on the control. The average position of one female gave an individual preference index (PI_i), between −1 and 1. For each experiment, 60 *E. vuilleti* females were tested, leading to calculation of the mean preference index (PI). This index value, obtained in test conditions, was compared to the one obtained in control conditions, presenting a choice between two identical healthy hosts. In the control condition, 0 was encoded when the female was observed at the bottom of the Petri dish, 1 on the first host, and −1 on the second host (the position of the first and second hosts was determined randomly before the experience). Statistical analysis required a nonparametric Mann–Whitney *U* test ($\alpha = 0.05$) under Xlstat 6.1.9.

Stimulus Nature. In order to check that the stimulus involved in the interspecific recognition was chemical, we studied its transfer through dichloromethane. The hosts used were contained in artificial systems, transparent capsules 2 cm long and 0.6 cm in diam. These capsules were modified to create a lodge in which a *C. maculatus* nymphae was introduced (Jaloux et al., 2004). Sixty capsules containing a host were placed in Petri dishes with 60 mated and experienced *D. basalis* females. Forty-eight hours later, *D. basalis* females were removed, and the parasitism was verified. The upper parts of parasitized capsules were taken and plunged about 10 sec into 2 ml of dichloromethane. A control extract was carried out immersing the upper parts of 60 clean capsules containing healthy hosts into 2 ml of dichloromethane. Five microliters of each extract were deposited on the surface of 60 capsules containing a healthy host. Sixty *E. vuilleti* females were submitted to a choice test between a capsule

treated with parasitized capsules extract and a capsule treated with clean unparasitized capsule extract (Exp. 1).

Stimulus Origin. In order to determine the role of *D. basalis* accessory glands and cuticular secretions in the interspecific recognition, we studied the preference of *E. vuilleti* females in choice tests for hosts treated with extracts of these structures. For these experiments, we used a simpler artificial system, a capsule without lodge or host. This system allowed us to study the activity of *D. basalis* secretions regardless of plant and host stimuli. First, 120 *D. basalis* females were sacrificed and dissected into saline solution (0.9% NaCl). Accessory glands of 60 females were removed and crushed on the surface of 60 clean capsules. The rest of the genital apparatus was deposited on the surface of a second group of 60 clean capsules. The Dufour's gland of the 60 other females was isolated from the venom gland-reservoir complex. Dufour's and venom gland extracts were carried out by crushing 60 glands into 2 ml of dichloromethane. These extracts were evaporated at 25°C and then taken up again into 5 ml of dichloromethane. Sixty *E. vuilleti* females were submitted to a choice test between a capsule on which were crushed *D. basalis* accessory glands (Exp. 2) or the rest of the genital apparatus (Exp. 3), and a capsule on which was deposited an equivalent quantity of body fat taken in the abdomen during the dissection. Sixty *E. vuilleti* females were submitted to a choice test between a capsule on which were deposited 5 µl of Dufour's gland extract (Exp. 4) or 5 µl of venom complex extract (Exp. 5), and a capsule on which were deposited 5 µl of pure dichloromethane. Second, 20 other emerging *D. basalis* females were placed separately into Petri dishes without hosts for 3 days. The 4th day, these females were plunged directly into 5 ml of dichloromethane for 10 sec. Five microliters of this extract were deposited on the surface of 60 clean capsules. These capsules were then presented in a choice test to 60 *E. vuilleti* females with 60 clean capsules on which were deposited 5 µl of pure dichloromethane (Exp. 6).

Chemical Analysis. In order to avoid contamination by the plant or the host, *D. basalis* females were placed into capsules for larval development, first containing a host, then without the host for nymphal stage. Five cuticular extracts were carried out with five groups of 10 *D. basalis* females, each into 100 µl of pentane (GC grade, 99.9%) for 10 sec. Females were removed and dissected. Five Dufour's gland extracts were prepared by crushing the glands of 10 females into 50 µl of pentane. Two microliters of each extract were injected on-column into the GC/MS Perkin-Elmer Turbomass system equipped with a capillary column (BP, 1.25 m long, 0.32 mm ID) that was temperature-programmed from 50 to 280°C at 10°C per min, maintained at 280°C for 10 min. The compounds were identified by using their retention times compared with reference products and by matching their mass spectra at 70 eV to the US National Institute of Standards and Technology (NIST) spectrum library.

RESULTS

Stimulus Nature. In experiment 1, *E. vuilleti* females preferred the capsules on which were deposited an extract of a capsule exploited by *D. basalis* to the clean capsules. The preference index was significantly different from the one obtained in the control experiment (Figure 1; PI = 0.24; *U*: $P < 0.001$). The stimulus can be transferred from a parasitized host to an unparasitized one through dichloromethane, and, therefore, can be considered a chemical substance.

Stimulus Origin. In experiment 2, *E. vuilleti* females preferred capsules on which were crushed the accessory glands of *D. basalis* to the ones on which were deposited an equivalent quantity of body fat (Figure 2) even though these capsules did not contain any host. The preference index obtained in this experiment was positive and significantly different from the one obtained in control experiment (PI = 0.33; *U*: $P < 0.01$). Experiment 3 showed that the rest of the genital apparatus was not active (Figure 2). The preference index obtained in this experiment, although positive, did not differ from the one observed in the control (PI = 0.09; *U*: $P = 0.06$). The ovaries, oviducts, collateral glands, and spermatheca do not seem to be involved in synthesis or in storage of chemical substances recognized by *E. vuilleti* females. In experiment 4, *D. basalis* Dufour's gland secretion was active and apparently caused the preference of *E. vuilleti* females for capsules on which it had been deposited. The preference index differed from the control (PI = 0.23; *U*: $P < 0.001$). *D. basalis* Dufour's gland seems to be involved in the production of or in the

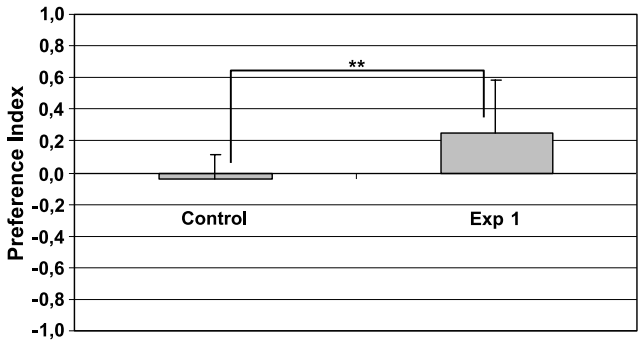

FIG. 1. Mean preference index (±SEM) of *E. vuilleti* females in choice condition between two clean capsules containing a healthy host (Control) or between a capsule on which were deposited 5 µl of an extract obtaining by washing capsules exploited by *D. basalis* in dichloromethane and a capsule on which were deposited the same quantity of pure dichloromethane (Exp. 1). * : Highly significant (*U*; $P < 0.001$).

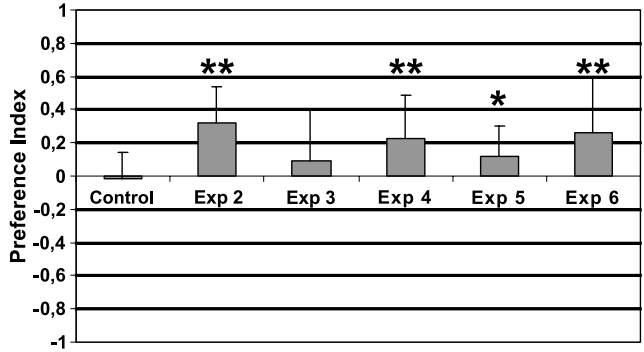

FIG. 2. Mean preference index (±SEM) of *E. vuilleti* females in choice condition between two empty clean capsules (Control); between a capsule on which were crushed *D. basalis* accessory glands and a capsule on which was deposited fat body (Exp. 2); between a capsule on which was crushed the rest of the genital apparatus and a capsule on which was deposited fat body (Exp. 3); between a capsule on which were deposited 5 µl of a Dufour's gland extract and a capsule on which were deposited 5 µl of pure dichloromethane (Exp. 4); between a capsule on which were deposited 5 µl of a venom gland extract and a capsule on which was deposited 5 µl of pure dichloromethane (Exp. 5); between a capsule on which were deposited 5 µl of a cuticular extract and a capsule on which were deposited 5 µl of pure dichloromethane (Exp. 6). ** : Highly significant (U; $P < 0.001$); * : Significant (U; $P < 0.05$).

storage of the substance perceived by the *E. vuilleti* female. Venom gland secretion was also active (Exp. 5: PI = 0.12; U: $P < 0.05$). However, the corresponding preference index was weaker than the one obtained with the Dufour's gland secretion extract. In experiment 6, *E. vuilleti* females showed a preference for the capsules treated with a cuticular secretion extract (PI = 0.27; U: $P < 0.001$). The preference index was similar to the one observed with Dufour's gland extract.

Chemical Analysis. The *D. basalis* Dufour's gland secretion is made up of saturated hydrocarbons, linear, mono, or dimethyl branched alkanes, and of three esters in low amount (3% of the total) including the decylpalmitate (Figure 3, Table 1). The *n*-alkanes (C_{21} to C_{34}) are the most common hydrocarbons (74%), followed by the methyl branched alkanes (2% of the total) in position 2-, 3-, 10-, 11-, 12-, 13-, 15-, and 17-, and by the dimethyl branched alkanes (1%) in position 3,9-, 9,13-, 10,12-, 11,15-. No unsaturated hydrocarbon were detected. The cuticular profiles are similar to those of Dufour's gland (Figure 4). Cuticular secretion is mainly made up of *n*-alkanes (73%), and contains monomethyl branched alkanes (8%), dimethyl branched alkanes (3%), and esters (3%). The compounds identified in Dufour's gland secretion and on the cuticle are the same. No compound was identified as characteristic of the

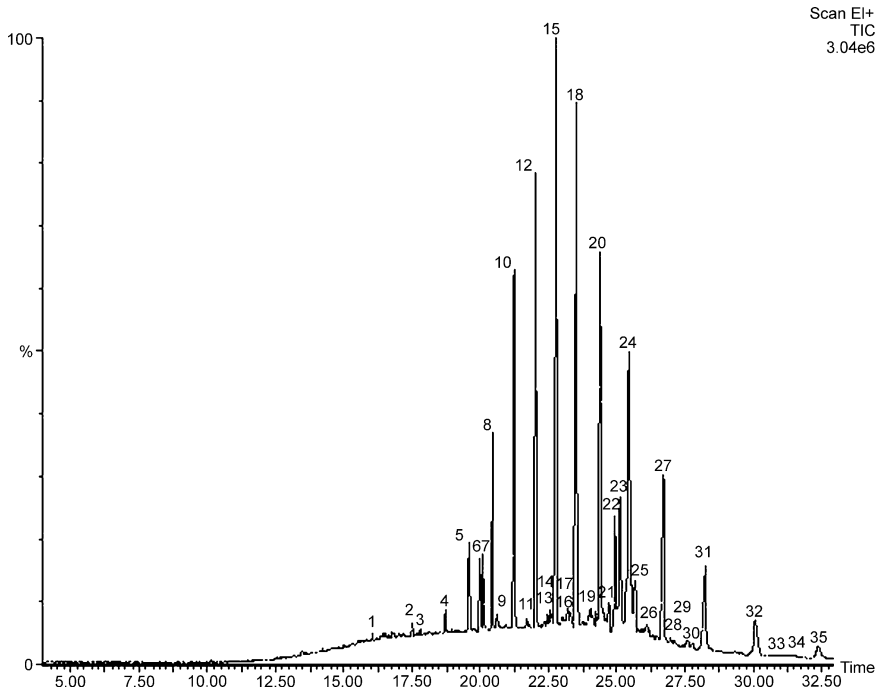

FIG. 3. Gas chromatogram of Dufour's gland secretion of *D. basalis* females. The peak numbers refer to compounds identified in Table 1.

cuticle or of the Dufour's gland. Only slight quantitative differences in the relative amounts of some compounds between the cuticular profile and the Dufour's gland profile were found (Table 2). Dufour's gland extracts are characterized by a significantly higher amount of the compounds corresponding to the peaks 7 (unidentified), 14 (decylpalmitate), and 19 (unidentified) (U; $P < 0.05$). Cuticular extracts are characterized by a significantly higher amount of the compounds corresponding to the peaks 17 (3-MeC_{27}), and above all the most heavy alkanes, 28 (11-+13-+15-MeC_{31}), and from 30 to 35 (3-MeC_{31}, C_{32}, C_{33}, 11-+13-+15-+17-MeC_{33}, 11,15-+13,17-DiMeC_{33} and C_{34}).

DISCUSSION

The stimulus allowing *E. vuilleti* females to recognize hosts parasitized by *D. basalis* is a dichloromethane-soluble chemical substance deposited by the *D. basalis* female on the surface of the seed during the exploitation of the host. Our results show that the *D. basalis* accessory glands are likely to be, at least, one of

the production sites of the substance(s) involved. The rest of the genital apparatus is not significantly active. The slight preference observed when the rest of the genital apparatus was crushed on the surface of a capsule could be attributable to the contamination of the vagina by accessory gland secretions that naturally pour through a thin duct at the junction of the vagina and the ovipositor. Above the two accessory glands, the Dufour's gland seems to be the main production or storage site of the active substance. The venom gland secretion also induces a preference by *E. vuilleti* females, even though weaker than the Dufour's gland. This activity could be due to contamination during the dissection and the isolation of the two very close glands. It could also be a result of an additional signal (Höller et al., 1991) produced independently by the venom gland.

The deposit of a cuticular extract of *D. basalis* females on the surface of a capsule induces a comparable preference to the one observed with a Dufour's gland extract. The rubbing of the *D. basalis* female's abdomen on the surface of the system could be enough to allow the perception and the recognition by the

E. vuilleti female. The identical activity of the cuticular and Dufour's gland secretion is linked to the similarity in their hydrocarbon composition. This similarity seems to be widespread in Hymenoptera (bumblebees, Oldham et al., 1994; polist wasps, Dani et al., 1996; *Apis mellifera*, Gozansky et al., 1997). With hymenoptera parasitoids, the Braconidae *Cardiochiles nigriceps* (Syvertsen et al., 1995), the two Bethylidae *Cephalonomia tarsalis* and *C. waterstoni*, and the two Pteromalidae *Anisopteromalus calandrae* and *Pteromalus cerealellae* (Howard and Baker, 2003), wherever a joint analysis of the cuticular and Dufour's gland secretion has been performed, such similarity has been described. In the Pteromalidae, the composition in hydrocarbons of the two secretions in *D. basalis* is similar, even though slight differences between the relative amounts of some compounds were observed. Some heavy alkanes were present in higher amounts in the cuticular secretions. The production of cuticular hydrocarbons may involve another or several different production sites.

The kind of compounds, their diversity, the carbon number range, and the absence of any unsaturated hydrocarbons in *D. basalis* profiles are quite similar to those of two other Pteromalidae where analysis has been performed, *A. calandrae* and *P. cerealellae* (Howard and Baker, 2003). On the other hand, the presence of even-numbered alkanes in the same amount as odd-numbered alkanes is unusual. In all parasitoid species where the composition of the Dufour's gland secretion has been studied, odd-numbered alkanes are the only ones present (Mudd et al., 1982; Marris et al., 1996) or are in the majority (Syvertsen et al., 1995; Howard and Baker, 2003).

The location on the system and the origin and nature of the stimulus recognized by *E. vuilleti* agree with the marking pheromone characteristics described by Guillot and Vinson (1972). Marking pheromones are used by many phytophagous and parasitoid species to avoid laying their eggs in already exploited hosts or plants, which are of lower quality for the larval development of their offspring (Hofsvang, 1990; Nufio and Papaj, 2001). This pheromone is generally produced by the Dufour's gland and is deposited on the surface of the host after laying during a marking posture. *D. basalis* females are able to avoid laying on hosts already parasitized by a conspecific (Gauthier and Monge, 1999a). However, even though the marking posture is frequently observed, this intraspecific discrimination does not seem to involve the perception of an external mark. Superparasitism avoidance is performed after ovipositor insertion into host lodge, and perception of an internal signal which is transferred from the living egg to the parasitized host (Gauthier and Monge, 1999b). The possible deposit of Dufour's gland secretion on the surface of the seed would not be involved in intraspecific discrimination and, thus, could not be considered a pheromone. Furthermore, the *D. basalis* marking posture does not seem to be efficient: it is not systematic, only 71% of laying is followed by this posture, and no drop or deposit linked to this posture has been observed.

D. basalis marking does not seem to be necessary for the start of the *E. vuilleti* cleptoparasitic behavior. The recognition of the hosts parasitized by *D. basalis* could only involve external cuticular cues left unintentionally by the *D. basalis* female during the exploitation of the host. The *D. basalis* marking posture could constitute a relic behavior of an external marking system, now discarded because of disadvantageous competition conditions with *E. vuilleti* (Gauthier et al., 2002), which uses this mark to locate and destroy *D. basalis* eggs. A more discreet internal marking system would then have been selected for in *D. basalis* females. The similarity between Dufour's gland secretion and cuticular secretion could have allowed the adaptation of *E. vuilleti*, by changing from discrimination based on the external mark to discrimination based on the perception of exploitation cuticular cues.

CONFIRMATION OF POTENTIAL HERBICIDAL AGENTS IN HULLS OF RICE, *Oryza sativa*

ILL-MIN CHUNG, SANG-JOON HAHN, and ATEEQUE AHMAD*

Department of Applied Life Science, College of Life and Environment Science, Konkuk University, KwangJinKu HwaYangDong, Seoul, 143-701, South Korea

(Received July 2, 2004; revised December 8, 2004; accepted February 23, 2005)

Abstract—An ethyl acetate extract of *Oryza sativa* (rice) hulls yielded seven compounds: hentriacontane, 1-tetratriacontanol, β-sitosterol, momilactone A, momilactone B, tricin (a flavonoid), and β-sitosterol-3-*O*-β-D-glucoside. The structures of these compounds were elucidated with 500 MHz nuclear magnetic resonance (NMR), using 1D and 2D spectral methods, aided by electron ionization mass spectrometry (EI–MS), fast atom bombardment mass spectrometry (FAB–MS), infrared (IR), and ultraviolet (UV) spectrophotometry. The complete ^{1}H NMR assignments for momilactone A and B and ^{13}C NMR assignments for tricin are discussed. To the best of our knowledge, hentriacontane, 1-tetratriacontanol, and β-sitosterol-3-*O*-β-D-glucoside were identified for the first time in rice hulls. In biological activity tests using these identified compounds, momilactone A and B showed potent inhibitory activity against duckweed (*Lemna paucicostata*). 1-Tetratriacontanol and β-sitosterol-3-*O*-β-D-glucoside also showed about 13–20% inhibitory activity based on chlorophyll reduction. Hentriacontane and β-sitosterol did not show any herbicidal activity. In a germination assay of three weed species (*Leptochloa chinenesis* L., *Amaranthus retroflexus* L., and *Cyperus difformis* L.) in culture tubes both momilactones A and B had high inhibitory effects. Momilactone B completely inhibited germination of all three weed species at 20 ppm. Germination of *L. chinensis* L. was completely inhibited by a 4 ppm solution of momilactone B.

Key Words—*Oryza sativa* L., Gramineae, rice hull composition, hentriacontane, 1-tetratriacontanol, β-sitosterol, momilactone A, momilactone B, tricin, β-sitosterol-3-*O*-β-D-glucoside, herbicidal activity, *Lemna paucicostata* Hegelm 381, germination assay in culture tube.

INTRODUCTION

Rice (*Oryza sativa* L.) is the principal cereal food in Asia and the major staple of the majority of the population. It generally occurs as two types, with white and colored hulls, although the white hulled variety is more common (85%). The germination of rice seed is of great agricultural importance, and it has long been known to be influenced by compounds present in the seed coat (hull) (Dutta, 1973). The compounds momilactone A and B from rice hulls cause germination and growth inhibition in the roots of rice (Kato et al., 1973, 1977; Takahashi et al., 1976). They were later found in rice leaves and straw as phytoalexins (Cartwright et al., 1981; Kodama et al., 1988). A putative growth inhibitor was isolated from rice root exudates and identified as momilactone B (Kato-Noguchi et al., 2002), and it was recently reported that rice seedlings release momilactone B into the environment (Kato-Noguchi and Ino, 2003). The antioxidant activities of methanol extracts (Ramarathnam et al., 1988) and the compound isovitexin (a *C*-glycosyl flavonoid) from methanol extracts (Ramarathnam et al., 1989) of rice hulls have been described. The growth inhibitor sakuranetin, a flavanone phytoalexin from ultraviolet (UV)-irradiated rice leaves, has also been isolated (Kodama et al., 1992). Little information is available on the influence of rice hull compounds on rice yield. However, it has been suggested that rice hulls, the most abundant agricultural by-product in rice growing areas, possess phytotoxic substances that could serve as natural herbicides by inhibiting seed germination and the growth of weeds. This study has implications for the use of agricultural residues because farmers in Korea have always left rice hulls in the field after harvesting. Such information might indicate the potential of inhibitory substances contained in rice hulls as natural herbicides that could control weeds in an environmentally acceptable and sustainable manner. Because there are few reports in the literature about the chemical constituents of rice hulls, identification of bioactive constituents with growth or germination inhibitory properties is required. Thus, the objectives of our research were: (1) to isolate and identify bioactive constituents from rice hulls, and (2) to examine the bioactivity of these compounds including momilactone A and B. Although use of synthetic herbicides is increasing around the world, little information is available on the development of natural herbicides. The isolation of compounds from rice hulls and their inhibitory activity, based on germination assays in culture tubes, are discussed in this paper.

METHODS AND MATERIALS

Plant Material. The hulls of *O. sativa* were collected from the Konkuk University Experimental Farm, Seoul, South Korea, in October 2002. The

voucher specimen (no. KKU 96, HOCHOKJINDO) has been dried and deposited in the herbarium of our department.

Preparation of Extracts. Dried hulls of *O. sativa* (10 kg) were immersed in methanol (MeOH) for 1 wk at room temperature and concentrated under vacuum to produce an extract (150 g), which was suspended in water and extracted successively with ethyl acetate (EtOAc) and *n*-butanol (*n*-BuOH).

Fractionation of the Ethyl Acetate Extract. The EtOAc extract (35 g) was subjected to normal-phase column chromatography over silica gel and yielded 40 fractions with the following eluants: fraction 1 in hexane, fractions 2–5 in hexane:EtOAc (9:1), fractions 6–11 in hexane:EtOAc (8:2), fractions 12–15 in hexane:EtOAc (7:3), fractions 16–20 in hexane:EtOAc (1:1), fractions 21–22 in EtOAc, fractions 23–28 in EtOAc:MeOH (9.5:0.5), fractions 29–32 in EtOAc:MeOH (9:1), fractions 33–34 in EtOAc:MeOH (7:3), and fractions 35–40 in MeOH.

Isolation and Identification of Compounds from the Fractions. Fractions 1 and 5, with further column chromatography and thin-layer chromatography (TLC) over silica gel with hexane:EtOAc, yielded two pure compounds: hentriacontane (100 mg) and 1-tetratriacontanol (50 mg). Fraction 6 was crystallized and, after purification by column chromatography, yielded β-sitosterol (1 g). This was confirmed by comparison with an authentic sample from Sigma. Fraction 11, which was further purified by column chromatography over silica gel with methylene chloride and methanol, produced two pure compounds: momilactone A (150 mg) and momilactone B (100 mg). Fraction 12, after column chromatography over silica gel and Lichroprep RP-18 [octadecyl silica (ODS)], yielded one yellow compound as a powder. This was identified as tricin (a flavonoid). Fraction 23, after column chromatography over silica gel with chloroform and methanol, yielded one pure compound: β-sitosterol-3-O-β-D-glucoside. All isolated compounds (Figure 1) were identified with different spectroscopic techniques as described in Results and Discussion.

General Experimental Procedures and Instrumentation. Melting points of isolated compounds were determined on an electrochemical engineering apparatus. Thin-layer chromatography (TLC) was carried out on precoated silica gel plates (Merck) with a layer thickness of 0.5 mm, unless otherwise indicated. Spots were detected under UV light (254 and 366 nm) before and after the plates were dipped in a chamber containing 1% vanillin–sulfuric acid (ethanol solution). Column chromatography was carried out on silica gel (70–230 mesh; Merck) and optical rotations were measured on an AA-10 model polarimeter. Both nuclear magnetic resonance spectra—^{1}H NMR (500 MHz) and ^{13}C NMR (125 MHz)—were measured with a Bruker Avance (DRX-500) spectrometer using deuterated chloroform ($CDCl_3$), methanol (CD_3OD), and pyridine (C_5D_5N) as solvents. Electron ionization mass spectrometry (EI–MS) spectra were recorded with a JEOL JMS-SX 102A spectrometer and fast atom

FIG. 1. Structures of β-sitosterol (**3**), β-sitosterol-3-*O*-β-D-glucoside (**7**), momilactone A (**4**), momilactone B (**5**), and tricin (**6**).

bombardment mass spectrometry (FAB–MS) were recorded with a JEOL JMS-AX 505 WA instrument. Infrared (IR) spectra were recorded with a Thermo-Mattson 60-AR spectrophotometer, and ultraviolet (UV) spectra were measured with a TU-1800_{PC} UV–VIS spectrophotometer.

Chemical Elucidation of the Allelopathic Compounds. The details of the compounds isolated from rice hull are given in Appendix 1 (available online at www.springerlink.com; search for DOI: 10.1007/s10886-005-5290-5; Electronic Supplementary Material can be found at the end of the article).

Bioassay of Phytotoxicity (Lemna Assay). Test compounds were dissolved in acetone, which contained the nonionic surfactant Tween-20, and were then mixed with 1/2 Hunter medium. The final concentrations of acetone and Tween-20 were 1 and 0.01%, respectively.

The technique used to analyze the bioactivity of the identified compounds was based on the method of Hong et al. (2000). The test solution (2 ml) and one duckweed (*Lemna paucicostata* Hegelm 381) frond were added to each well of a 24-well plate. The plate was incubated in a growth chamber (26°C, 14-hr photoperiod, 50 μmol m^{-2} sec^{-1}) for 5 d. Herbicidal activity was then rated by visual scoring and by measuring chlorophyll content. The chlorophyll was extracted with dimethyl sulfoxide (DMSO) and analyzed using a UV–VIS spectrophotometric method (Hiscox and Israelstam, 1979). Visual injury symptoms were recorded on d 5 on an injury symptoms scale of 0 to 100 (0 = no effect, 100 = complete death). Other measurements included:

- Chlorophyll content (μg ml^{-1}) = $2.367 \times (\text{absorbance})^2 + 6.299 \times \text{absorbance} + 0.169$ ($r = 0.999$);
- Inhibition of chlorophyll content (%) = [(control − treatment) / control] × 100

Germination Assay in Culture Tubes. The compounds used in the experiment were isolated from rice hulls, and included hentriacontane, 1-tetratriacontanol, β-sitosterol, β-sitosterol-3-*O*-β-D-glucoside, momilactone A, momilactone B, and tricin. This test was applied to detect any inhibitory activities. Three weed species were used for the test: *Leptochloa chinensis* L., *Amaranthus retroflexus* L., and *Cyperus difformis* L. Both *L. chinensis* and *C. difformis* can be found growing in rice paddies, whereas *A. retroflexus* prefers the area around paddies. Weed seeds were collected in October 2002 and after debris was removed from the seeds by flotation in distilled water, the seeds were stored at −35°C until used for bioassays. The seeds were surface sterilized in a 1:10 (v/v) dilution of commercial hypochlorite bleach for 10 min and rinsed several times with distilled water.

A modified bioassay technique developed by Choi et al. (2002) was applied. Sea sand (650 mg) was placed into disposable culture tubes (12 × 75

mm) with the isolated rice hull compounds, which had been dissolved in acetone to obtain the following concentrations: 4, 20, 100, and 1000 ppm. Weed seeds from the three species (2 mg) were added to the tubes, which were then put in the growth chamber under the following conditions: 25°C, 12 hr daylight, 20 μmol m^{-2} sec^{-1}. Percentage germination was determined after 7 d, and the inhibitory effects of identified compounds on germination and growth were evaluated using the equations:

- Germination inhibition (%) = [(control − treatment) / control] × 100; and
- Growth inhibition (%) = [(control − treatment) / control] × 100.

Statistical Analysis. Analysis of variance for all data was undertaken using the general linear model (GLM) procedure of the SAS program (SAS Institute, 2000). All of the aforementioned experiments were replicated three times using a completely randomized design. The pooled mean values were separated based on least significant difference (LSD) at the 0.05 probability level.

RESULTS

Identity and Phytotoxicity of Compounds From Rice Hulls. Seven constituents of rice hulls were isolated, including hentriacontane (**1**), 1-tetratriacontanol (**2**), β-sitosterol (**3**), momilactone A (**4**), momilactone B (**5**), tricin (a flavonoid) (**6**), and β-sitosterol-3-*O*-β-D-glucoside (**7**). These were identified using 500 MHz NMR with ^{1}H, ^{13}C, ^{1}H–^{1}H correlation spectroscopy (COSY), and ^{1}H–^{13}C heteronuclear chemical shift correlation (HETCOR) spectra, together with EI–MS, FAB–MS, IR, and UV spectrophotometry. In earlier published work, momilactone A, momilactone B (^{1}H NMR), and tricin (^{13}C NMR) values were incompletely described. Hentriacontane, 1-tetratriacontanol, and β-sitosterol-3-*O*-β-D-glucoside are reported for the first time from rice hulls.

Hentriacontane (**1**) was isolated as a colorless white solid from the first fraction of the ethyl acetate extract. It exhibited a peak *m/z* of 436 on EI–MS (calculated for $C_{31}H_{64}$). The FAB–MS data of compound **1** gave a positive-mode $[M + H]^{+}$ ion peak at 437 and a negative-mode $[M - H]^{-}$ ion peak at 435, which suggested a molecular ion peak $[M]^{+}$ of 436. The IR spectrum displayed intense absorption bands at 2920, 1464, 1215, and 760 cm^{-1}. The 500 MHz ^{1}H NMR spectrum in $CDCl_3$ showed protons at δ 0.88 (6H, t, $J = 7.0$ Hz) for two methyls and at δ 1.25–1.31 for all 58 methylene protons. The 125 MHz ^{13}C NMR in $CDCl_3$ gave only six signals for all carbons at δ 14.33 for two methyls and at δ 22.91–32.15 for methylene carbons. The above evidence established the structure of **1** as hentriacontane.

Tetratriacontanol (**2**) was isolated as white granular crystals with a melting point of 83–86°C. It exhibited a peak at *m/z* 476 $[M - H_2O]^+$ on EI–MS, and FAB–MS gave a positive-mode $[M + H]^+$ ion peak of *m/z* 495 and a negative-mode $[M - H]^-$ ion peak of *m/z* 493, suggesting a molecular weight of 494. The IR spectrum displayed intense absorption bands at 3450, 2917, 1465, 1215, and 757 cm^{-1}, with the band at 3450 cm^{-1}, indicating the presence of a hydroxyl group. ^1H NMR of compound **2** in $CDCl_3$ gave signals that appeared as a triplet at δ 0.88 (3H, t, $J = 6.7$ Hz) for methyl protons, a multiplet at δ 1.55 for methylene protons of CH_2CH_2OH, and a triplet at δ 3.64 (CH_2OH). All remaining methylene protons appeared as a broad singlet at δ 1.25–1.33. ^{13}C NMR in $CDCl_3$ produced 15 carbon signals at δ 63.34, 33.04, 32.15, 29.92, 29.88, 29.84, 29.83, 29.66, 29.58, 29.47, 29.30, 25.96, 24.98, 22.91, and 14.33 for methylene attached to hydroxyl group, all methylenes, and one methyl carbon, respectively. Analysis of compound **2** by ^1H, ^{13}C, and 2D NMR (COSY, HETCOR) supported the assigned structure **2** as 1-tetratriacontanol.

β-sitosterol (**3**) was isolated as colorless needles that exhibited an *m/z* of 414 $[M]^+$ (possible $C_{29}H_{50}O$). The IR spectrum showed absorption bands at 3429, 2936, 1644, 1462, 1376, and 1057 cm^{-1}, with the band at 3429 cm^{-1} characteristic of a hydroxyl group. The ^1H NMR of compound **3** displayed a one-proton broad multiplet at δ 3.51, which was assigned to a carbinol 3α-proton. Two three-proton broad signals at δ 0.63 and 0.94 were ascribed to the tertiary C-18 and C-19 protons, respectively. Three doublets at δ 0.92 ($J = 7.4$ Hz), 0.81 ($J = 7.5$ Hz), and 0.91 ($J = 7.15$ Hz), which integrated for three-protons each, were attributed to secondary C-21, C-26, and C-27 methyl groups, respectively. Another triplet at δ 0.88 ($J = 7.5$ Hz) was attributed to the C-29 methyl protons, and a one-proton broad multiplet at δ 5.56 for one vinylic proton was attributed to C-6. The remaining methine and methylene protons resonated between δ 2.29 and 1.13. The ^{13}C NMR spectrum of compound **3** showed the presence of 29 carbon signals. The signals at δ 140.72 and 121.71 were ascribed to vinylic carbons at positions C-5 and C-6. Other carbon signals appeared at δ 37.31 (C-1), 31.57 (C-2), 71.80 (C-3), 42.19 (C-4), 31.87 (C-7, 8), 50.10 (C-9), 36.48 (C-10), 21.11(C-11), 39.81 (C-12), 42.33 (C-13), 56.79 (C-14), 24.32 (C-15), 28.26 (C-16), 56.11 (C-17), 11.87 (C-18), 19.39 (C-19), 36.17 (C-20), 18.82 (C-21), 33.95 (C-22), 26.13 (C-23), 45.85 (C-24), 29.18 (C-25), 19.48 (C-26), 19.07 (C-27), 23.09 (C-28), and 12.32 (C-29). Based on the above results, the structure **3** was determined to be β-sitosterol, and confirmed by comparison with data from the literature.

Momilactone A (**4**) was isolated as colorless crystals that exhibited an *m/z* of 314 on EI–MS. A FAB–MS of compound **4** gave a positive-mode molecular ion peak $[M + H]^+$ at *m/z* 315 and a negative mode at *m/z* 313 $[M - H]^-$, suggesting a molecular weight of 314. The IR spectrum of compound **4** gave absorption bands at 2932, 1765, 1700, 1386, and 1181 cm^{-1}. The bands at 1765

and 1700 cm^{-1} suggested lactone and ketone groups, respectively. The ^{1}H NMR ($CDCl_3$) spectrum of **4** displayed three singlets at δ 0.89, 1.52, and 0.99 for C-17, C-18, and C-20 tertiary methyl groups, respectively, and two multiplets at δ 2.60–2.64 and δ 1.89–1.91 for C-1 and C-2 methylene groups, respectively. Signals at δ 2.31 (d, J = 5.0 Hz), δ 4.85 (t, J = 5.0 Hz), and δ 5.71 (d, J = 5.0 Hz) were assigned to the C-5 to C-7 protons for two methine and one olefinic groups. The multiplets at δ 1.80 and 1.60 were assigned to C-9 and C-12 methine and methylene protons, and the double doublets at δ 1.32, 1.74 and δ 2.06, 2.21 were assigned as the C-11 and C-14 methylene protons. Finally, other signals in the downfield region including double doublets at δ 5.85 (J = 17.5 and 10.7 Hz) for the C-15 proton and δ 4.94 (J = 10.8 and 1.2 Hz) and 4.98 (J = 17 and 1.2 Hz) for the two protons on C-16 were ascribed to olefinic protons. The ^{13}C NMR spectrum of **4** showed resonances for all 20 carbons (δ 35.08, 31.41, 205.37, 53.76, 46.66, 73.36, 114.23, 148.22, 50.39, 32.66, 24.19, 37.44, 40.32, 47.73, 149.15, 110.36, 22.16, 21.66, 174.51, and 21.99), which included three methyl, six methylene, five methine, and six quaternary carbons. The ^{13}C NMR spectrum suggested the presence of both a ketone and lactone group from signals at δ 205.37 and 174.51, respectively. Olefinic carbons were assigned to 149.15, 148.22, 114.23, and 110.36. Analysis of compound **4** by ^{1}H, ^{13}C, and 2D NMR (COSY, HETCOR) confirmed the structure as the known momilactone A.

Momilactone B (**5**) was isolated as colorless crystals with m/z of 330 on EI–MS. A FAB–MS of compound **5** gave a positive-mode molecular ion peak at m/z $[M + H]^+$ of 331 and a negative mode m/z at 329 $[M - H]^-$. This suggested a molecular weight of 330. The IR spectrum gave bands at 2939, 1735, 1670, 1233, 1129, 1037, and 932 cm^{-1}, with the band at 1735 cm^{-1} suggesting a lactone. The ^{1}H NMR ($CDCl_3$) spectrum of **5** displayed 3H singlets at δ 0.86 and 1.40 for the C-17 and C-18 tertiary methyl groups. There were two multiplets at δ 1.52–1.56 and δ 2.09 for the C-1 and C-2 methylene groups, respectively, and a singlet at δ 4.13 for the hydroxyl proton. Signals at δ 2.20 (dd, J = 7.1 and 2.1 Hz), δ 4.94 (dd, J = 7.1 and 4.5 Hz), and δ 5.67 (d, J = 4.5 Hz) were assigned to the C-5, C-6, and C-7 protons (all methine groups), respectively. Other double doublets were at δ 1.44 for C-9 (methine) and 1.22 and 1.66 for C-11 methylene protons, respectively. A multiplet at δ 1.55 was for protons on C-12 (methylene) and a doublet at δ 2.01 (J = 12.0 Hz) and double doublet 2.13 (J = 12.0 and 1.8 Hz) were for the C-14 methylene protons. Double doublets at δ 5.82 (J = 17.6 and 10.7 Hz), δ 4.92 (J = 10.5 and 1.2 Hz), and δ 4.94 (J = 17.6 and 1.2 Hz) were for the C-15 and C-16 olefinic protons. Two more double doublets at δ 3.56 (dd, J = 9.1 and 3.2 Hz) and δ 4.06 (dd, J = 9.1 and 1.9 Hz) were for the C-20 methylene protons. The ^{13}C NMR spectrum of this compound showed resonances for all 20 carbons (δ 29.00, 26.63, 96.78, 50.53, 43.17, 73.93, 114.19, 146.88, 44.87, 30.93, 24.97, 37.41, 40.17, 47.72,

149.02, 110.40, 22.06, 19.16, 180.64, and 72.90), which included two methyl, seven methylene, five methine, and six quaternary carbons. The ^{13}C NMR spectrum confirmed the presence of a ketone at δ 180.00, and a hydroxyl carbon at δ 96.7 shifted downfield due to being attached to another oxygen in the hemiketal. The methylene carbon for C-20 also was shifted downfield due to being attached to an oxygen. Analysis of compound **5** by ^{1}H, ^{13}C, and 2D NMR (COSY, HETCOR) supported confirmation of the structure as momilactone B.

Tricin (**6**) was isolated as a yellow powder with a molecular ion peak on EI–MS at *m*/*z* of 330 $[M]^+$. A FAB–MS gave a positive-mode molecular ion peak at *m*/*z* $[M + H]^+$ of 331 and a negative-mode molecular ion peak $[M - H]^-$ at *m*/*z* of 329. This suggested a molecular weight of *m*/*z* 330. The IR spectrum of compound **6** gave intense absorption bands at 3468, 2928, 1647, 1506, 1359, 1166, and 830 cm^{-1}. The bands at 3468 and 1647 cm^{-1} suggested hydroxyl and ketone groups, respectively. The ^{1}H NMR showed a singlet at δ 7.27, which was assigned to aromatic H-2′ and H-6′. Another two singlets at δ 6.16 and 6.62 were assigned to H-6 and H-8, respectively. Moreover, a singlet at δ 3.95 was assigned to two methoxy groups. The ^{13}C NMR spectrum showed 15 discrete signals for the 17 carbons in the molecule. Analysis of compound **6** by ^{1}H, ^{13}C, and 2D NMR (COSY, HETCOR) confirmed the structure as tricin.

β-Sitosterol-3-*O*-β-D-glucoside (**7**) was isolated as a colorless powder that exhibited a fragmentation ion peak at *m*/*z* 414 $[M - \text{glucose}]^+$. The IR spectrum gave absorption bands at 3429, 2933, 1635, 1376, and 1073 cm^{-1}, with the absorption band at 3429 cm^{-1} characteristic of a hydroxyl group. Compound **7** is a glucoside of compound **3**; other than the glucose protons and carbons, the ^{1}H and ^{13}C NMR values of **7** were almost the same as those of **3**. A one-proton doublet at δ 4.97 (J = 11.1 Hz) was attributed to anomeric H-1. Four one-proton doublets at δ 4.16 (J = 9.3 Hz), δ 3.92 (J = 4.45 Hz), δ 3.85 (J = 4.85 Hz), and δ 3.56 (J = 4.85 Hz), and two one-proton multiplets at δ 3.83 and 3.60, were assigned to the remaining glucose protons. In ^{13}C NMR, the H-1 anomeric carbon appeared at δ 103.09, and other glucose carbons appeared at δ 79.11, 78.80, 75.84, 72.22, and 65.58. Based on the above evidence, compound **7** was confirmed as β-sitosterol-3-*O*-β-D-glucoside.

Inhibitory Effects of Compounds on Plants. The inhibitory activity of the compounds against duckweed, and the results of the germination assays in culture tubes on three weed species, *C. difformis*, *L. chinensis*, and *A. retroflexus*, are shown in Tables 1 and 2. Momilactone A and B had high inhibitory activity against duckweed. The other compounds had lower or no inhibitory activity (Table 1). Momilactone A and B showed reduction of chlorophyll content (85.8, 52.3, and 27.0%, and 98.3, 91.9, and 33.9%, respectively) at the concentrations of 10, 3.3, and 1 ppm. At concentrations of 100 and 33 ppm, momilactone A reduced chlorophyll content by 98.9 and 95.6%, respectively.

TABLE 1. INHIBITORY EFFECTS OF SEVEN IDENTIFIED COMPOUNDS AGAINST *Lemna paucicostata* HEGELM 381

Compounds	Concentration (ppm)	Inhibition of chlorophyll content (%)[a]	Visual injury symptoms (%)
Hentriacontane	100	0	0
	10	0	0
1-Tetratriacontanol	100	14.3 ± 9.5	0
	33	13.1 ± 3.5	0
	10	12.8 ± 4.1	0
	3.3	0	0
	1	0	0
β-Sitosterol	100	0	0
	10	0	0
Momilactone A	100	98.9 ± 1.0	95
	33	95.6 ± 1.2	90
	10	85.8 ± 3.7	70
	3.3	52.3 ± 3.0	50
	1	27.0 ± 4.4	20

	10	19.4 ± 7.6	0
	3.3	0	0
	1	0	0

[a] Data represent mean ± SD of three replicates.

Visual injury due to momilactone A and B was 70, 50, and 20%, and 98, 70, and 20%, respectively, at concentrations of 10, 3.3, and 1 ppm. The momilactone A caused visual injury symptoms of 98.9 and 95.6% at concentrations of 100 and 33 ppm, respectively (Table 1). This result is similar to that of Kato et al. (1977), who showed that momilactone A and B and their derivatives inhibited the germination of lettuce seeds.

1-Tetratriacontanol reduced chlorophyll by 12.8, 13.1, and 14.3% at the concentration of 10, 33, and 100 ppm, respectively (Table 1). β-Sitosterol-3-*O*-β-D-glucoside reduced chlorophyll by 19.4, 20.5, and 21.3% at 10, 33, and 100 ppm respectively (Table 1). Hentriacontane, β-sitosterol, and tricin did not show any inhibition of chlorophyll nor any visual injury symptoms at concentrations of 10 and 100 ppm.

Germination Assay in Culture Tube. Momilactones A and B inhibited germination of seeds of three weed species (Table 2), whereas hentriacontane, 1-tetratriacontanol, β-sitosterol, tricin, and β-sitosterol-3-*O*-β-D-glucoside did not inhibit germination or growth of the three weed species at the concentrations of 4, 20, 100, and 1000 ppm tested (data not shown). Increasing concentrations of test compounds appeared to be generally correlated with inhibitory effects on germination and growth and showed 100% inhibition at concentrations equal to or greater than 20 ppm. Momilactone A inhibited germination from 0 to 20% at 4 ppm and between 30 and 100% at a concentration of 100 ppm, depending on weed species. Momilactone B had an inhibitory effect on weed growth (~12.5–23.3%) at 4 ppm, whereas momilactone A had no effect at this concentration. Momilactone B inhibited growth completely for all three species at 20 ppm, whereas momilactone A only showed 100% inhibition at 1000 ppm (Table 2).

DISCUSSION

In a search for growth-regulating substances in higher plants, Kato et al. (1973) identified momilactones A and B from the seed hulls of *O. sativa*, and determined that these compounds inhibited the growth of roots of rice at less than 100 ppm. Kato et al. (1977) further reported that momilactones A and B, especially the latter, inhibit the germination of lettuce seeds and growth of roots of rice. In order to establish the functional groups in the momilactones necessary for activity, several derivatives were prepared and assayed for inhibitory activity. It was found that all derivatives that inhibited lettuce seed germination had activity against rice root growth.

Momilactones A and B also were isolated from UV-irradiated, dark-grown rice coleoptiles (Cartwright et al., 1981). The same compounds were also produced in blast-infected, WL 28325-treated rice leaves. They appear to be the first clearly identified cereal phytoalexins. Furthermore, rice seedlings (Kato-Noguchi et al., 2002) inhibited the growth of cress (*Lepidium sativum*) and lettuce (*Lactuca sativa*) seedlings when the cress and lettuce were grown with rice seedlings. The putative compound causing the inhibitory effect of rice seedlings was isolated from their culture solution and identified as momilactone B.

Momilactone B was found recently in root exudates of rice, and 3-d-old rice seedlings were transferred to hydroponic culture and the level of momilactone B released into the environment from the seedlings was measured (Kato-Noguchi and Ino, 2003). The concentration at which momilactone B is released and its effectiveness as a growth inhibitor suggest that it may play a role in rice allelopathy.

There are no reports in the literature for growth or germination inhibition of 1-tetratriacontanol and β-sitosterol-3-*O*-β-D-glucoside. Song et al. (2004) reported that allelochemicals from root exudates of rice varieties at various growth stages were different and caused growth inhibition in barnyard grass. These compounds may be used to control barnyard grass, i.e., weed management based on allelopathy, to reduce labor cost and use of synthetic agricultural chemicals for weed management.

The inhibitory effects of the compounds varied between weed species. In general, germination and growth of *C. difformis* was more inhibited by momilactone A than the other weeds, whereas germination and growth of *L. chinensis* was the most susceptible to momilactone B. *Amaranthus retroflexus* was the least affected at 100 ppm. Momilactone A inhibited germination and growth of *C. difformis* by 97.5 and 100%, respectively, at 20 ppm, whereas *L. chinensis* was not inhibited at the same concentration (Table 2).

Our results were similar to those of Kato et al. (1977), who reported that momilactone B was more inhibitory than momilactone A on lettuce seed germination at 10, 100, and 1000 ppm. This result might suggest that momilactone B has more potential of being used as a natural herbicide than momilactone A. If these compounds are used to contribute to the control of weed species, they might also be used as genetic markers for identifying allelopathic varieties by analyzing hulls before sowing seeds into the field.

CHEMICAL PROFILES OF SCENT GLAND SECRETIONS IN THE CYPHOPHTHALMID OPILIONID HARVESTMEN, *Siro duricorius* AND *S. exilis*

GUENTHER RASPOTNIG,[1,2,*] GUENTER FAULER,[2] MATTHIAS LEIS,[2] and HANS-JOERG LEIS[2]

[1]*Institute of Zoology, Karl-Franzens-University, Universitaetsplatz 2, 8010 Graz, Austria*
[2]*Department of Biochemical Analysis and Mass Spectrometry, University Children's Hospital, Auenbruggerplatz 30, 8036 Graz, Austria*

(Received December 15, 2004; accepted February 1, 2005)

Abstract—Gas chromatographic–mass spectrometric analyses of the scent gland secretions of *Siro duricorius* and *S. exilis* (Opiliones, Cyphophthalmi, Sironidae) revealed a set of 24 components, comprising a series of saturated and unsaturated methyl ketones (C11–C15) and four naphthoquinones. Whereas the scent gland secretions of *S. duricorius*, collected in Austria, and *S. exilis* from USA were qualitatively nearly indistinguishable (with the exception of acetophenone that was specific to *S. duricorius*), they distinctly differed in their relative quantitative compositions: major components of the secretion of *S. duricorius* were 7-tridecen-2-one, tridecan-2-one, undecan-2-one, 1,4-naphthoquinone, 6-methyl-1,4-naphthoquinone (tentatively identified only), and 4-chloro-1,2-naphthoquinone. In contrast, in *S. exilis* a compound tentatively identified as 6-methyl-4-chloro-1,2-naphthoquinone was present in large amounts (in *S. duricorius* a trace component), whereas undecan-2-one only occurred in minor quantities. Secretion profiles of juveniles and adults (both sexes) of each species showed high correspondence.

This is the first report on the chemistry of scent gland secretions of the opilionid suborder Cyphophthalmi. 4-Chloro-1,2-naphthoquinone was identified as a new exocrine product of arthropods, whereas 1,4-naphthoquinone and the tentatively identified 6-methyl-1,4-naphthoquinone are known constituents of exocrine secretions from one species of palpatorid opilionids, *Phalangium opilio*. In contrast, all ketones identified were new for opilionid scent glands, although similar ketones are characteristic of scent gland secretions of palpatorid genera *Leiobunum* and *Hadrobunus*. With regard to the near-basic position of Cyphophthalmi in currently proposed phylogenetic

trees of Opiliones, naphthoquinones and ketones from *Siro* may represent the condition ancestral to the (derived) naphthoquinone- and ketone-rich secretions in phalangid Palpatores.

Key Words—*Siro*, Cyphophthalmi, Opiliones, scent glands, naphthoquinones, methyl ketones.

INTRODUCTION

The arachnid order Opiliones (also known as harvestmen or daddy longlegs) is estimated to comprise about 5,000 species (Shear, 1982). All possess large scent glands in the prosoma (Juberthie, 1976; Martens, 1978). These glands constitute paired hollow sacs that are surrounded by secretory tissue, each sac opening to the body surface via one single pore at either of the lateral margins of the cephalothorax (Juberthie, 1961; Clawson, 1988). Glandular openings may be developed as oblique slits (Acosta et al., 1993) or, as is the case in the opilionid suborder Cyphophthalmi, they may be located atop conspicuous tubercles, so-called ozophores that dorsolaterally protrude from the carapace (Juberthie, 1961). With regard to biological roles, opilionid scent glands are considered to serve mainly for chemical defense: their secretions, discharged as fine sprays or administered by so-called "leg-dabbing" behavior, have been shown to deter ants and other predatory invertebrates (Juberthie, 1976; Martens, 1978; Holmberg, 1986). In addition, pheromonal roles, such as for territorial marking, have been suggested (Juberthie et al., 1991), and recently, the scent gland secretion of a laniatorid opilionid has been reported to possess alarm pheromonal properties (Machado et al., 2002).

Opilionid scent glands not only represent sources of diverse natural products with interesting biological functions, but also may prove useful in chemosystematic studies. Several authors have already alluded to the chemotaxonomic potential of these secretions (Roach et al., 1980; Ekpa et al., 1985), particularly as the taxonomy of this group is in a state of flux (Shultz and Regier, 2001; Giribet et al., 2002). In fact, in Laniatores, benzoquinones and phenols seem to characterize the scent gland secretions of the superfamily Gonyleptoidea (Eisner et al., 1971, 1977; Roach et al., 1980; Duffield et al., 1981; Gnaspini and Cavalheiro, 1998) whereas from one representative of the laniatorid superfamily Travunioidea, terpenes, bornyl esters, and nitrogen-containing products have been reported (Ekpa et al., 1984). In Palpatores, acyclic compounds have been found in representatives of the genera *Leiobunum* and *Hadrobunus*, and naphthoquinones have been found in scent glands of *Phalangium* (overview in Ekpa et al., 1985). In contrast, nothing is known about the scent gland chemistry of the mitelike representatives of the third classical suborder of Opiliones, the Cyphophthalmi. This small group of Opiliones, so far

comprising about 115 species (Giribet and Boyer, 2002), holds a key position in the phylogenetic systematics of Opiliones, possibly representing the most basal opilionid group (e.g., Giribet et al., 2002).

In the present paper, to address this gap in opilionid scent gland chemistry, we investigated the scent gland secretions of two species of cyphophthalmid opilionids from two continents, *Siro duricorius* (mainly distributed in Southeastern Europe) and *S. exilis* (from the United States).

METHODS AND MATERIALS

Specimen Collection. *S. duricorius* (Joseph, 1868) was collected from soil samples at two different localities in Austria. Collection site I was South Carinthia, near Waidischbach (= first collection: 30 adult and 7 juvenile individuals). Collection site II was South Carinthia, Sattnitz (= second and third collection: 27 adults, 9 juveniles and 38 adults, 3 juveniles, respectively). *Siro exilis* Hoffman (1963) was collected from two soil samples from West Virginia, USA (= fourth and fifth collection: 12 adults, 1 juvenile and 14 adults, 8 juveniles, respectively).

Sample Preparation. Scent gland secretions were either directly collected from ozophores or indirectly by whole-body extraction. For direct sampling from ozophores, a specimen was grasped by a leg with forceps, which usually led to the immediate extrusion of a yellowish or brownish droplet of scent gland secretion. The droplet was absorbed on a small piece of filter paper (2 × 2 mm), then extracted for 5 min in hexane (100 μl). Alternatively, whole specimens were extracted in 100 μl of hexane for about 15 min, expelling their secretions directly into the solvent. Extracts were separated from filter paper pieces or bodies, respectively, and frozen until analysis. Each extract contained the exudate from one individual.

Chemical Analysis. Aliquots of crude extracts, in most cases 1 μl, were analyzed by gas chromatography–mass spectrometry (GC-MS), using a Fisions MD 800 GC-MS (Thermo-Quest, Vienna, Austria). The GC column (ZB-5, 30 m × 0.25 mm × 0.25 μm film thickness, Phenomenex via HPLC Service, Vienna, Austria) was directly connected to the ion source of the MS. The splitless Grob injector was held at 260°C with helium carrier gas (1.5 ml/min). The electron impact (EI) ion source of the MS was kept at 200°C and the transfer line at 310°C. The following temperature program was used: initial temperature 50°C/1 min, 10°C/min to 200°C, then 15°C/min to 300°C and hold for 5 min. Dimethyldisulfide (DMDS) derivatives, to determine the positions of double bonds, were prepared according to Vincenti et al. (1987). Methyloxime derivatives of the DMDS-derivatized alkanones were prepared by concentrating 20 μl of the solution containing the DMDS adducts under a stream of N_2

and then adding 50 μl of *O*-methylhydroxylamine hydrochloride (Pierce Biotechnology Inc., Rockford, IL, USA) in pyridine (2%, w/w). The mixture was heated at 75°C for 1 hr. After cooling, 0.5 ml of water was added and the methyloximes were extracted with hexane (2 ml). The solvent was removed under nitrogen and the residue was dissolved in 100 μl ethyl acetate for GC-MS analysis.

Reference Compounds. Undecan-2-one, dodecan-2-one, tridecan-2-one, 1,4-naphthoquinone, and 2-methyl-1,4-naphthoquinone, were purchased from Aldrich (Vienna, Austria). 4-Chloro-1,2-naphthoquinone was prepared as described by Perumal and Bhatt (1980) and Paquet and Brassard (1989): 800 mg lead tetraacetate were added to a solution of 200 mg of 2,4-dichloro-1-naphthol (Aldrich) in 12 ml benzene. The mixture was stirred under nitrogen for 10 hr at room temperature, then poured into 50 ml of water and extracted with ether. The product was purified using silica gel chromatography and $CHCl_3$:hexane (1:2) as eluent.

Scanning Electron Microscopy. For scanning electron microscopy (SEM), specimens were fixed in glutaraldehyde, dehydrated, and mounted on small dishes before sputtering with gold. Micrographs were prepared at the Research Institute for Electron Microscopy, Technical University of Graz, Austria.

RESULTS

Extraction, Separation, and Identification of Scent Gland Components. GC analyses of scent gland secretions of *S. duricorius* and *S. exilis*, either collected directly after discharge from ozophores (Figure 1) on filter paper pieces or indirectly by the technique of whole-body extraction in hexane, led to the same spectrum of 24 gas chromatographically separable compounds (Figure 2, peaks A–X). Chromatographic and mass spectrometric data for the identification of compounds are summarized in Table 1. Generally, the compounds fell into two chemical groups, ketones and naphthoquinones. Among ketones, a homologous series of 20 saturated to triply unsaturated ketones was present. However, peak A (a minor component exclusively present in the secretion of *S. duricorius*) was identified as acetophenone (M^+ at *m*/*z* 120).

Ten compounds of this series (peaks B, C, D, F, J, K, M, N, Q, and W) appeared to be saturated C11–C15 methyl ketones, showing characteristic mass spectra that generally exhibited a prominent fragment ion at *m*/*z* 58 (arising from McLafferty rearrangement). The compounds displayed molecular ions of weak intensity along with M-15, M-18, M-43, and M-58 fragments (see Table 1). The identities of major components of this series (peak B: undecan-2-one; peak D: dodecan-2-one; peak J: tridecan-2-one) were confirmed by comparison of retention times with those of authentic standards. Peaks C and F, with

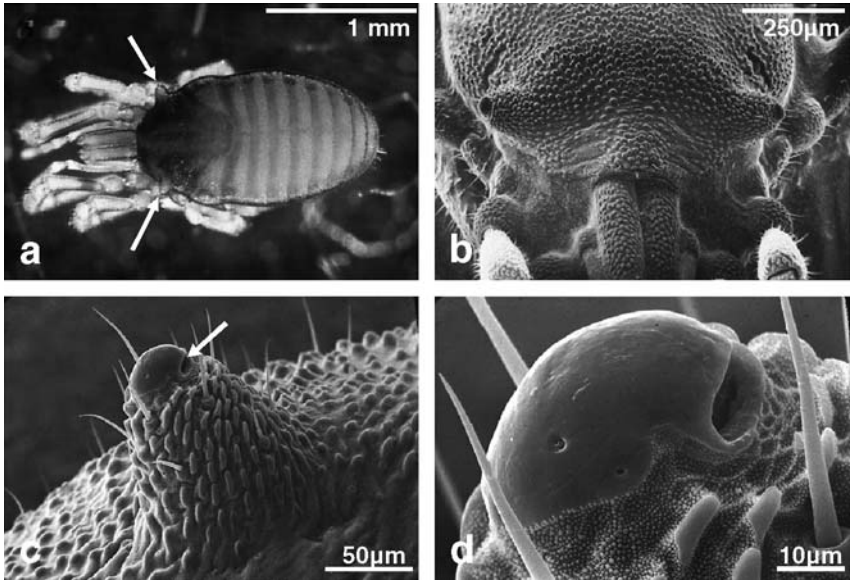

FIG. 1. Topography and external morphology of scent glands in *S. duricorius*. (a) Dorsal view of an adult specimen; arrows point to tubercles of scent glands (ozophores). spectra nearly identical to dodecan-2-one and tridecan-2-one) are tentatively proposed as branched-chain isomers of those compounds, with branch points unknown. All other components of this series (four isomeric tetradecanones: peaks K, M, N, Q, and a pentadecanone: peak W) were of minor abundance and were tentatively identified on the basis of their mass spectra (Table 1).

Five components (peaks G, H, O, P, and U) exhibited mass spectra typical of monounsaturated C13–C15 methyl ketones. Peaks G and H, the major components of this series, were identified as isomeric tridecen-2-ones (M^+ at *m*/*z* 196). The double bond positions were determined by derivatization with dimethyldisulfide. The adducts appeared as one large peak at RT = 20.05–20.15 min. This peak obviously consisted of two components, both with a molecular ion at *m*/*z* 290 as expected, but differing in fragmentation patterns. The larger of the two components (thus derived from larger peak H) showed prominent ions at *m*/*z* 159 and *m*/*z* 131, being consistent with either a 5-tridecen-2-one (fragment at *m*/*z* 131 bearing the carbonyl group) or a 7-tridecen-2-one (fragment at *m*/*z* 159 bearing the carbonyl group). In spectra of the DMDS adduct after *O*-methyl-oximation, adding 29 amu to the carbonyl-group-bearing

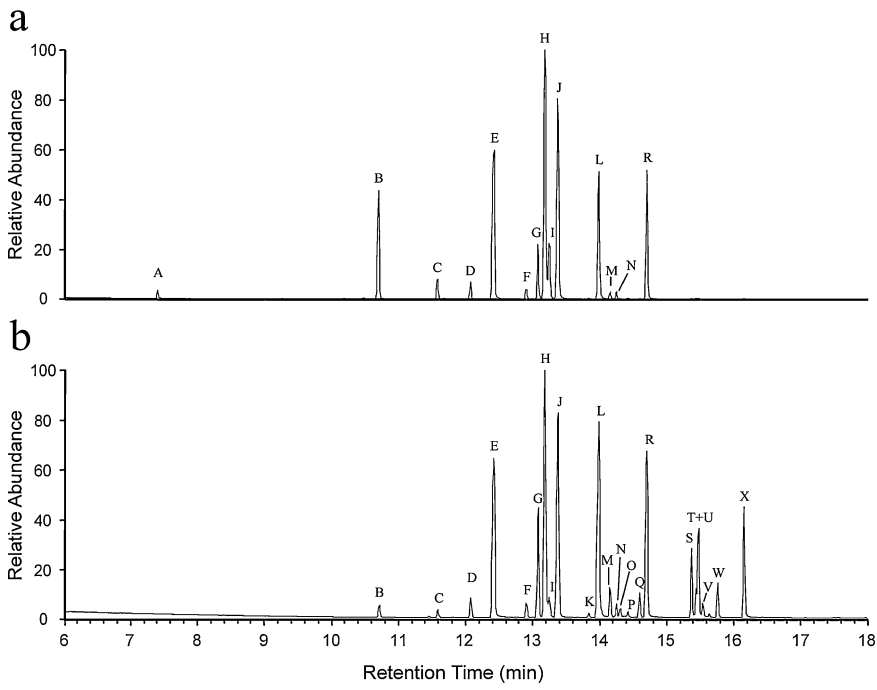

FIG. 2. Gas chromatographic profiles of scent gland secretions of *S. duricorius* (a) and *S. exilis* (b). Peaks marked with an asterisk have been conclusively identified. All other identifications remain tentative. Peak A* (acetophenone), B* (undecan-2-one), C (branched dodecan-2-one), D* (dodecan-2-one), E* (1,4-naphthoquinone), F (branched tridecan-2-one), G* (6-tridecen-2-one), H* (7-tridecen-2-one), I (tridecadienone), J* (tridecan-2-one), K (tetradecan-2-one isomer 1), L (6-methyl-1,4-naphthoquinone), M (tetradecan-2-one isomer 2), N (tetradecan-2-one isomer 3), O (tetradecenone isomer 1), P (tetradecenone isomer 2), Q* (tetradecan-2-one isomer 4), R* (4-chloro-1,2-naphthoquinone), S (pentadecadienone), T (pentadecatrienone), U (pentadecenone), V (unknown), W* (pentadecan-2-one), X (6-methyl-4-chloro-1,2-naphthoquinone).

fragment, the fragment at *m*/*z* 131 remained unaffected whereas the fragment at *m*/*z* 159 disappeared along with the formation of a new fragment at *m*/*z* 188. Thus, the carbonyl group could clearly be classed with the fragment at *m*/*z* 159 in the original DMDS adduct, consistent with the structure of a 7-tridecen-2-one for compound H. The DMDS adduct of the minor compound originating from peak G exhibited a single prominent ion, the base peak, at *m*/*z* 145, indicating a hydrocarbon fragment, and a carbonyl-group-bearing fragment of equal mass. This result is consistent only with the structure of a 6-tridecen-2-one. The remaining monounsaturated ketones (peaks O, P, and U) were present in minor or trace amounts and could only be tentatively identified by their mass spectra

as isomeric tetradecenones and a pentadecenone, respectively (Table 1). Positions of double bonds in these compounds remained undetermined.

Another four components of this series (peaks I, S, T, and V), all of them of minor abundance, were tentatively identified as further homologous C13 and C15 ketones, their spectra indicating double or triple unsaturation. Peak V may possibly represent a mixture of doubly and triply unsaturated C15 ketones (presumed molecular ions at *m*/*z* 220 and *m*/*z* 222).

Naphthoquinones. A second, chemically distinct group of compounds was represented by naphthoquinones (peaks E, L, R, and X). Peak E was identified as 1,4-naphthoquinone by comparisons with an authentic sample. Peak L appeared to be a methylated homolog of 1,4-naphthoquinone, exhibiting a molecular ion at *m*/*z* 172 (base peak), and showing the loss of a methyl group at *m*/*z* 157, together with double neutral loss of CO leading to ions at *m*/*z* 144 and *m*/*z* 116, and loss of CO and COH (fragment at *m*/*z* 115). Prominent ions at *m*/*z* 118, *m*/*z* 90, and *m*/*z* 89 were interpreted to arise from (1) loss of CO and C_2H_2, (2) double loss of CO and C_2H_2, and (3) loss of CO, COH, and C_2H_2, respectively. The spectrum and gas chromatographic retention time, however, were different from authentic 2-methyl-1,4-naphthoquinone (menadione), only leaving the possibilities of positions 5 or 6 for the methyl group. The compound was tentatively identified as 6-methyl-1,4-naphthoquinone by its good correspondence to a literature mass spectrum (from the NIST mass spectral database).

Peak R exhibited the typical isotopic pattern of a monochlorinated compound, indicated by M^+ at *m*/*z* 192 (84%) and an isotopic M+2 peak at *m*/*z* 194 (27%), corresponding to a relative intensity of 32% of the molecular ion. Furthermore, the compound showed sequential loss of two CO fragments from *m*/*z* 192 and 194, leading to twin peaks at *m*/*z* 164 and 166 and to peaks at *m*/*z* 136 and 138, respectively. Also, ions due to loss of Cl (*m*/*z* 157), Cl and CO (*m*/*z* 129, base peak), Cl and double loss of CO (*m*/*z* 101) were observed. The compound was conclusively identified by matches with an authentic standard of 4-chloro-1,2-naphthoquinone.

Peak X also exhibited the isotopic pattern of a mono-chlorinated compound, showing a molecular ion at *m*/*z* 206 (72%) and M+2 at *m*/*z* 208 (22%; corresponding to 31% of M^+). The compound appeared to be a methylated homolog of 4-chloro-1,2-naphthoquinone, exhibiting the loss of a methyl group (twin peaks at *m*/*z* 191 and 193) and again showing repeated decarbonylation and loss of Cl (–CO: *m*/*z* 178 and 180; –CO–CO: *m*/*z* 150 and 152; –Cl: *m*/*z* 171; –Cl and –CO: *m*/*z* 143, base peak). Thus, if peak L is indeed 6-methyl-1,4-naphthoquinone, the compound might be 6-methyl-4-chloro-1,2-naphthoquinone on the basis of mass spectral data.

Secretion Patterns of S. duricorius and S. exilis. In all samples investigated, scent gland secretion profiles of *S. duricorius* and *S. exilis* each showed

[a] Compounds B (undecan-2-one), D (dodecan-2-one), E (1,4-naphthoquinone), J (tetradecan-2-one), and R (4-chloro-1,2-naphthoquinone) were identified by comparison of retention times to authentic samples; all other compounds were tentatively identified on the basis of their mass spectral data.

qualitatively and quantitatively consistent compositions (see Table 2). Qualitatively, profiles of the two species were nearly indistinguishable: *S. duricorius* exhibited a maximum of 24 components (some of the trace components were not detectable in certain individuals of two of the three collections), whereas *S. exilis* consistently showed 23 of these compounds, only lacking acetophenone (peak A). In contrast, profiles of *S. duricorius* and *S. exilis* differed significantly in the relative proportions of secretion components, based on the comparison of relative proportions of peak areas from profiles of 114 samples of *S. duricorius* and 35 samples of *S. exilis*. Major components of the *S. duricorius* secretion of adults were (in order of decreasing abundance) tridecan-2-one (about 20%), 7-tridecen-2-one (about 19%), 1,4-naphthoquinone (about 18%), the tentatively identified 6-methyl-1,4-naphthoquinone (about 12%), undecan-2-one (about 10%), 4-chloro-1,2-naphthoquinone (about 7%), and 6-tridecen-2-one (4%). Other components appeared in minor or trace amounts only (Table 2). Secretion patterns did not show large differences between samples of the three different collections, nor between samples of adults and juveniles. Thus, the secretion profile appeared to be consistent within this species. In juveniles, however, the relative quantitative composition of secretion showed higher variation, leading to higher standard deviations, even within samples of the same collection.

Scent gland profiles of *S. exilis* revealed eight major components (five were also major components in *S. duricorius*: see above) including tridecan-2-one (about 20%), 7-tridecen-2-one (about 15%), 1,4-naphthoquinone (about 14%), the tentatively identified 6-methyl-1,4-naphthoqinone (about 13%), 4-chloro-1,2-naphthoquinone (about 12%), pentadecan-2-one (about 5%), the tentatively identified 6-methyl-4-chloro-1,2-naphthoquinone (about 4%), and 6-tridecen-2-one (about 4%). The same components were also major components of juvenile extracts, although in slightly different proportions (Table 2).

DISCUSSION

Cyphophthalmid Scent Gland Chemistry. We present here results from the first chemical investigation into scent gland secretions of cyphophthalmid opilionids for a European and an American species of Sironidae. All components detected belong to the scent gland secretions of these species, as indicated by direct sampling of secretions from ozophores. Profiles appeared to be consistent within each species, only varying slightly between populations and among developmental stages, representing stable and possibly species-specific characters. However, a common ketone- and naphthoquinone-rich chemistry is obvious. Apart from acetophenone, profiles in *S. exilis* seem to be shifted to larger homologous components such as pentadecanone with regard to the ketone series, or the tentatively identified 6-methyl-4-chloro-1,2-naphthoquinone with

regard to the naphthoquinone series, both of which are only trace components in *S. duricorius*. Even though only two species have been studied here, this kind of scent gland chemistry may be representative for a whole group of Cyphophthalmi, at least for the genus *Siro*, considering that the two study species were from different continents.

All methyl ketones as well as the chloronaphthoquinones found in our investigation represent new compounds for scent gland secretions of Opiliones. However, similar ketones, mainly smaller methyl or dimethyl-branched ethyl ketones (Meinwald et al., 1971; Blum and Edgar, 1971; Jones et al., 1976, 1977) are widespread among phalangid Palpatores, and 1,4-naphthoquinone and 6-methyl-1,4-naphthoquinone also have been found in the scent gland secretion of one phalangid species (Wiemer et al., 1978). On the other hand, chlorinated naphthoquinones, to our knowledge, have never been reported previously from exocrine secretions of any arthropod species. Chlorinated exocrine components of arthropods seem to be rare, with the only well-known source for such compounds being the foveal glands of ticks, which produce chlorophenols for sexual communication (Berger, 1972; Yoder et al., 2002; Benoit et al., 2004).

With regard to current concepts of opilionid phylogeny (Martens, 1976; Martens et al., 1981; Shultz and Regier, 2001; Giribet et al., 2002) and the suggested near-basic position of Cyphophthalmi, the *Siro* secretions may represent examples for the ancestral composition of opilionid scent gland chemistry. Interestingly, as mentioned above, phalangid Palpatores, but not Laniatores display characters of the *Siro* secretions. Thus, the ketone-rich secretion profiles of *Leiobunum* and *Hadrobunus* may be derived from ketones analogous to those found in *Siro*. Also, the naphthoquinones detected in *Phalangium opilio* may originate from a cyphophthalmid-like chemistry. In contrast, the lack of ketones and naphthoquinones in scent gland secretions of Laniatores, at least with respect to hitherto known data, would either indicate the complete loss of these compounds and replacement by other compounds in the course of evolution or, alternatively, it might even suggest a distinct evolutionary root for Laniatores, not sharing a common ancestor with Cyphophthalmi. The former case may be supported by preliminary results suggesting the presence of ketones in the scent gland secretion of the laniatorid species, *Parampheres ronae* (Gonzalez et al., 2004), whereas the latter case would confirm the Cyphopalpatores concept of Martens (1976). In this concept, Cyphophthalmi are placed within the classic Palpatores (*sensu* Shear, 1982), and Laniatores represent a separate lineage. However, to begin a comprehensive chemosystematic analysis of Opiliones, chemical data from scent glands of groups hitherto not investigated such as Caddoidea, Ischyropsalidoidea, Troguloidea, and Oncopodoidea must be obtained.

Biology and Roles of Scent Glands of Sironidae. As generally assumed for scent glands of opilionids, also the small, short-legged and mitelike repre-

Main components (comprising more than 3% relative peak area) are printed in bold.

sentatives of Sironidae use their secretions for defense. When disturbed, *S. duricorius*, for example, expels a small yellowish to brownish droplet from ozophores and transfers this droplet to the aggressor by leg dabbing. This behavior is also known from other species of Sironidae (Juberthie, 1961). The defensive or toxic potential of the secretions to predatory microarthropods seems to be high: as reported for *S. rubens*, spiders and isopods died immediately when contaminated with the secretion, and when exposed to vapors of secretions, narcosis occurred (Juberthie, 1976). For *S. rubens*, no chemical data are available yet, but a ketone–naphthoquinone-dominated chemistry of scent gland secretions, comparable to our congeneric study species, is to be expected. Thus, similar defensive properties against predatory arthropods may be proposed for secretions of *S. duricorius* and *S. exilis* as well. However, bioassays with single secretion components have not yet been performed. Also, a possible alarm pheromonal role, as recently demonstrated for an opilionid scent gland secretion (Machado et al., 2002), should be investigated. In addition, compounds such as naphthoquinones are known to possess antimicrobial properties. For example, 6-methyl-1,4-naphthoquinone inhibits growth of *Staphylococcus aureus* (Bendz, 1951). Thus, the *Siro* secretion might also have a role in protecting against microorganisms, which would be of particular importance to inhabitants of a humid, fungi- and bacteria-rich environment in soil.

Acknowledgments—We thank Prof. Dr. Roy A. Norton, State University of New York, College of Environmental Science and Forestry, Syracuse, for providing soil samples containing *Siro exilis* from West Virginia, USA. We are grateful to Prof. Dr. Ferdinand Hofer, Technical University of Graz, Research Institute of Electron Microscopy, for access to the scanning electron microscope, and to Prof. Dr. Reinhart Schuster and Dr. Guenther Krisper, both at the Institute of Zoology, Karl-Franzens-University Graz, Austria, for critically reading the manuscript.

[2]*Natural Resources Institute, University of Greenwich, Chatham Maritime, Kent, ME4 4TB, UK*

(Received August 23, 2004; accepted October 18, 2004)

Abstract—Two major components have been detected in the headspace volatiles of adult male *Frankliniella occidentalis* (Pergande) (Thysanoptera: Thripidae) that are not present in the headspace volatiles of adult females. The compounds were identified as (*R*)-lavandulyl acetate and neryl (*S*)-2-methylbutanoate by comparison with synthetic standards using gas chromatography (GC), GC–mass spectrometry (MS), and chiral GC. Field trials were conducted with synthetic compounds in naturally infested crops of sweet pepper grown in large plastic greenhouses in Spain. The catch of adult females and males on blue sticky traps was increased by neryl (*S*)-2-methylbutanoate alone or by a 1:1 blend of (*R*)-lavandulyl acetate and neryl (*S*)-2-methylbutanoate, but (*R*)-lavandulyl acetate was not active alone. This is the first identification of an aggregation pheromone in the order Thysanoptera. The possible role of (*R*)-lavandulyl acetate is discussed.

Key Words—Western flower thrips, *Frankliniella occidentalis*, Thysanoptera, Thripidae, aggregation pheromone, (*R*)-lavandulyl acetate, neryl (*S*)-2-methylbutanoate.

INTRODUCTION

The adult males of many species of thrips (order Thysanoptera) possess sternal glands or *areae porosae* (Mound et al., 1980), which are structurally consistent with the production of a pheromone (Bode, 1978; Sudo and Tsutsumi, 2002).

* To whom correspondence should be addressed. E-mail: j.g.c.hamilton@keele.ac.uk

Until now, no sex or aggregation pheromones have been identified in the Thysanoptera, although many defensive anal secretions are known (Suzuki et al., 2004). Recent experiments have provided behavioral evidence for a male-produced sex pheromone in two species in the genus *Frankliniella*, both of which possess sternal glands. Live adult male *Frankliniella schultzei* (Trybom) increased the catch of adult females, but not of adult males, on gray sticky traps (Milne et al., 2002), and the odor of adult male *Frankliniella occidentalis* (Pergande), but not of adult females, attracted adult females in a Y-tube olfactometer (Hamilton and Kirk, 2003; de Kogel and van Deventer, 2003; Kirk and Hamilton, 2004). The male odor of *F. occidentalis* was found by Kirk and Hamilton (2004) to be attractive also to adult males, but this was not found by de Kogel and van Deventer (2003).

F. occidentalis has spread since the 1970s to become a major worldwide pest of horticulture and agriculture (Kirk and Terry, 2003), so an attractive pheromone could have considerable applied value. The males form mating aggregations, within which there are aggressive male–male interactions, and females arrive, mate, and leave immediately (Terry and Gardner, 1990; Terry and Dyreson, 1996). A male-produced pheromone could play several roles in these complex interactions. Kirk and Hamilton (2004) used gas chromatography (GC) analysis to demonstrate that two major odor components and five minor components were present in male odor and not in female odor of adult *F. occidentalis*.

The objectives of this study were to identify the major components of the male volatiles and to test these compounds for attractiveness in the field.

METHODS AND MATERIALS

Thrips Rearing. A colony of *F. occidentalis* from commercial glasshouses in the UK was maintained on potted chrysanthemums (*Dendranthema grandiflora* Tzvelev) at 25 ± 2°C and L8:D6. Lighting was provided by full-spectrum fluorescent tubes (58 W Sylvania Activa 172 Professional). Adult male thrips collected arbitrarily from this culture are described as "mixed age."

Collection of Male Volatiles. Mixed age thrips were knocked from the chrysanthemum flowers onto a white tray. Adult males were collected with a small aspirator, anesthetized with carbon dioxide, and transferred into a clean glass container (1.9 ml) that was then sealed with Teflon tape. The thrips were illuminated from above with a bright light (60 W tungsten filament lamp) to induce patrolling behavior (Kirk and Hamilton, 2004). Patrolling occurs when the males swarm, and this behavior may be necessary for pheromone production. Head space volatiles were collected on a divinylbenzene (DVB)/carboxen/polydimethylsiloxane (PDMS) solid phase microextraction (SPME)

fiber assembly (57348-U, Supelco, Poole, UK) at 27 ± 2°C for 4–5 hr (Kirk and Hamilton, 2004). The numbers of males entrained in this way varied from 30 to 70 per replicate.

Gas Chromatography–Mass Spectrometry (GC–MS). GC–MS analyses were carried out on HP 5890 II+ gas chromatographs coupled to HP 5972A (Keele) or HP 5973 Natural Resources Institute (NRI) mass spectrometers (Agilent Technologies, Ipswich, UK) operated in electron impact (EI) (70 eV, 180°C) or chemical ionization (CI) mode. CI analyses were carried out using isobutane or ammonia as the reagent gas.

SPME-collected headspace volatile samples and synthetic standards were analyzed at Keele with a DB5MS or a DBWax (30 m × 0.25 mm i.d., 0.25-μm film) analytical column (Agilent Technologies, Ipswich, UK). Samples were introduced into the GC via a Merlin Microseal (Thames-Restek, High-Wycombe, UK) septumless heated injector (180°C) fitted with a SPME glass injection sleeve (0.75-mm i.d.; Supelco, UK). SPME samples were desorbed for 8 min before the fiber assembly was withdrawn. The GC was programmed with 2 min at 40°C, then 10°C/min to 250°C (10 min).

Synthesis products were analyzed at NRI using SPB1 (30 m × 0.25 mm i.d., 0.2-μm film; Supelco, Belefonte, PA) or DBWax columns programmed from 60°C for 2 min then 6°C/min to 250°C. Kovats retention indices (KI) were calculated relative to the retention times of saturated hydrocarbons.

Chiral Chromatography. Analysis of enantiomeric composition was carried out by GC on either a Beta-Dex 325 column (30 m × 0.25 mm; 0.25-μm film: Supelco, UK) for lavandulyl acetate, or a CP-Chirasil-Dex CE column (25 m × 0.32 mm; 0.25-μm film: Varian, UK) for neryl 2-methylbutanoate. The injector temperature was set at 200°C, and the oven was run isothermally at 80°C for lavandulyl acetate and at 120°C for neryl 2-methylbutanoate.

Chemicals and Synthesis of Compounds. Racemic lavandulyl acetate (99% purity) was obtained from TCI-America (Portland, OR). The enantiomers of lavandulol were obtained previously (Cross et al., in press) from racemic lavandulol by kinetic resolution using conversion to the acetate by *Pseudomonas fluorescens* lipase (Amano AYS, Nagoya, Japan), isopropenyl acetate, and diisopropyl ether, essentially as described by Zada and Harel (2004). The enantiomerically enriched *R* acetate was hydrolyzed back to the alcohol with potassium carbonate in methanol and recycled twice. GC analysis on the cyclodextrin capillary column showed this material to have enantiomeric excess (ee) of 98.2%. The remaining alcohol was similarly recycled to give (*S*)-lavandulol with ee of 87.0%.

The stereochemistry was confirmed by comparison of the corresponding alcohol with (*R*)-(−)-lavandulol isolated from lavender oil (König et al., 1992). Lavender oils of different origins were screened by GC for lavandulol and the acetate, and the one with the highest levels (Goodebodies, Dublin, Ireland),

containing 4.7%, was selected. A sample (6 g) was hydrolyzed with potassium carbonate in methanol, and the lavandulol was isolated by column chromatography on silica gel eluted with 20% diethyl ether in hexane. Two fractionations gave material (0.18 g) containing 75% (*R*)-(−)-lavandulol, the major impurities being bomeol (13%) and linalool (4%). In GC analysis on the cyclodextrin column, the *S*-enantiomer was undetectable (<0.1%).

Geranyl and neryl acetate were synthesized by acetylation of the corresponding alcohols with acetic anhydride in pyridine. Other monoterpense esters were synthesized from the corresponding alcohol and acid in the presence of *N*,*N*′-dicyclohexylcarbodiimide (DCC) and 4-*N*,*N*′-dimethylaminopyridine (DMAP) (Neises and Steglich, 1978), as described below for neryl (*S*)-2-methyl-butanoate.

Neryl (S)-2-methylbutanoate. Nero1 (0.77 g, 5 mmol; Sigma-Aldrich, Gillingham, Dorset, UK), (*S*)-2-methylbutanoic acid (0.61 g, 6 mmol; Sigma-Aldrich), and DMAP (61 mg, 0.05 mmol; Sigma-Aldrich) were dissolved in dry dichloromethane (10 ml), and the solution was stirred in an ice bath. DCC (1.24 g, 6 mmol; Sigma-Aldrich) was added portionwise over 30 min, and stirring was continued for another 30 min with cooling and then for 3 hr at room temperature. The *N*,*N*′-dicyclohexylurea was filtered off, and the precipitate was washed with petroleum spirit (b.p. 40–60°C). The filtrate was washed with saturated aqueous sodium bicarbonate solution, dilute hydrochloric acid, and water, dried over magnesium sulfate, and filtered. After concentration, the residue was purified by flash chromatography on silica gel (40 g, 230–400 mesh) eluted with 1.5% diethyl ether in petroleum spirit. The resulting product was distilled in a Kugelrohr apparatus (90°C/0.02 mmHg, 1.05 g, 88%, e.e. 97.8%). ^{1}H NMR ($CDCl_3$, 270 MHz): δ 5.35 (br t, 1H, J = 7 Hz, =C*H*–CH_2O), 5.09 (m, 1H, =C*H*–CH_2), 4.56 (d m, 2H, J = 7 Hz, =CH–CH_2O), 2.36 (hextuplet, 1H, J = 7 Hz, C*H*–COOR), 2.1 (m, 4H, =C–CH_2–CH_2–C=), 1.77 (br s, 3H, CH_3–C=), 1.68 (br s, 3H, CH_3–C=), 1.67 (hextuplet, 1H, J = 6.5 Hz, CH_3–C*H*H–CH(CH_3), 1.61 (br s, 3H, CH_3–C=), 1.45 (hextuplet, 1H, J = 6.5 Hz, CH_3–CH*H*–CH(CH_3), 1.14 (d, 3H, J = 6.5 Hz, CH_3–CH), 0.90 (t, 3H, J = 7 Hz, CH_3–CH_2). ^{13}C NMR ($CDCl_3$, 67.8 MHz) δ 176.83, 142.32, 132.14, 123.63, 119.41, 60.86, 41.10, 32.19, 26.85, 26.69, 25.69, 23.52, 17.66, 16.62, 11.64.

Field Trials. The biological activity of the compounds was tested in May 2004 in commercial crops of sweet pepper (var. Habana) grown in greenhouses at Zamora (37°42.945′N, 0°57.720′W) near Torre Pacheco in the Murcia region of Spain. The crops were about 110 cm high, planted in rows 1 m apart, and were naturally infested with a low level of *F. occidentalis*. Three 2-d experiments were carried out, alternating between two nearby houses, each with an area of about 6500 m^2.

The compounds were released from rubber septa (6.3-mm diameter × 10.8 mm long) (100706; Aldrich, UK) that had been preextracted in hexane–dichloromethane and dried in an oven at 50°C. Septa were loaded with

solutions of the test compounds in hexane or with hexane alone (control). After evaporation of the solvent, the rubber septa were stored in aluminum foil bags. They were placed on traps in the field within 2 hr of preparation.

Blue plastic rectangular takitraps (10 × 25 cm) (Syngenta Bioline, UK), coated on both surfaces with insect glue, were suspended vertically with the base about 10 cm above crop height, by attaching them to crop support strings with a wooden clothes peg. One rubber septum was stuck to the center of the north-facing side of each trap.

Each experiment was laid out in a randomized complete block design with 20 blocks and one replicate per block. Traps were placed about 3.4 m apart down rows of sweet pepper plants with 16 m between each row of traps. The first experiment compared two doses, 30 ng and 30 μg, of neryl (*S*)-2-methylbutanoate with a control. The second experiment compared two doses, 30 ng in total and 30 μg in total, of a 1:1 blend of (*R*)-lavandulyl acetate and neryl (*S*)-2-methylbutanoate with a control. The third experiment compared two doses, 30 ng and 30 μg, of (*R*)-lavandulyl acetate with a control.

Trap Counts and Statistical Analysis. Thrips caught on the blue sticky traps were examined under a stereoscopic microscope to identify their sex and to distinguish *F. occidentalis* from about 2% of the thrips that were other species (*Thrips* spp., aeolothripids, and phlaeothripids). The data were $\log_{10}(x + 1)$ transformed and analyzed by two-way ANOVA for females, males, and both sexes combined. Multiple comparisons with the control used Dunnett's multiple comparison test. Statistical analysis was carried out with Minitab 14 (Minitab Inc., Pennsylvania, USA).

RESULTS

Pheromone Identification. We collected volatiles from the headspace around male thrips with a SPME fiber. Subsequent coupled GC–MS analysis showed the presence of two principal compounds (Kirk and Hamilton, 2004). The earlier eluting compound (peak *a*) gave an EI mass spectrum with no clearly identifiable molecular ion (Figure 1A). However, the presence of a trace ion at *m*/*z* 154 (0.4%) with stronger ions at *m*/*z* 136 (14%), 121 (23%), 93 (73%), 69 (100%), and 41 (47%) suggested a compound with a monoterpenoid substructure. The presence of the ion at *m*/*z* 43 (72%) suggested the presence of a $C_2H_3O^+$ ion derived from an acetate moiety. Comparison with published spectra (SDBS, 2004) revealed close matches with the spectra of lavaudulyl acetate, neryl acetate, and geranyl acetate. Isobutane CI analysis gave a strong ion at *m*/*z* 197 ($[M + H]^+$) and ammonia CI gave strong ions at *m*/*z* 197 and 214 ($[M + H]^+$ and $[M + NH_4]^+$), confirming the molecular weight as 196. The

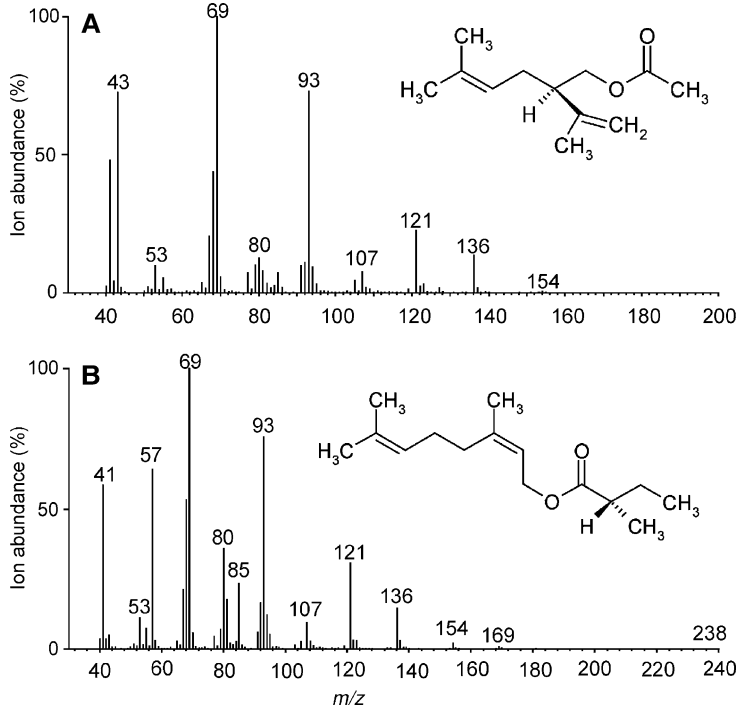

FIG. 1. EI mass spectra (70 eV) of the major components of the headspace volatiles of male western flower thrips *Frankliniella occidentalis*: (A) peak *a*; (B) peak *b*. Insets in (A) and (B) show the structures of the major components (*R*)-lavandulyl acetate and neryl (*S*)-2-methylbutanoate of the headspace volatiles of male western flower thrips *F. occidentalis*.

identity of the thrips-produced compound was confirmed by comparison of the EI and CI mass spectra and relative retention times of the unknown with (±)-lavandulyl acetate on polar and nonpolar GC columns (Table 1). Peak enhancement was achieved on coinjection of the entrained thrips volatiles and (±)-lavandulyl acetate.

The EI mass spectrum of peak *b* (Figure 1B) was similar to that of peak *a*, with ions at *m*/*z* 154 (1.9%), 136 (15%), 121 (31%), 93 (75%), 69 (100%), and 41 (60%), again suggesting a monoterpenoid substructure. An ion at *m*/*z* 238 (0.03%) suggested a molecular weight of 238 and an ion at *m*/*z* 85 (23%) suggested the loss of a $C_5H_9O^+$ fragment derived from a 5-carbon acid moiety. No database matches were found for this spectrum. Isobutane CI analysis gave a strong ion at *m*/*z* 239 ($[M + H]^+$) and *m*/*z* 256 ($[M + NH_4]^+$), confirming the molecular weight as 238.

TABLE 1. RETENTION INDICES (KI) OF NATURAL AND SYNTHETIC COMPOUNDS

	KI			
	DBSMS (Keele)	SPBI (NRI)	DBWax (Keele)	DBWax (NRI)
Natural component (peak *a*)	1292		1593	
Natural component (peak *b*)	1579		1850	
Lavandulyl acetate	1292	1274	1593	1608
Geranyl acetate		1363		1760
Neryl acetate		1346		1728
Lavandulyl pentanoate		1543		1839
Lavandulyl 3-methylbutanoate		1498		1772
Lavandulyl 2-methylbutanoate		1497		1761
Geranyl pentanoate		1636		1994
Geranyl 3-methylbutanoate		1590		1925
Geranyl 2-methylbutanoate		1584		1902
Neryl 3-methylbutanoate		1565		1884
Neryl 2-methylbutanoate	1581	1560	1851	1865

A series of isomeric esters of monoterpene alcohols and 5-carbon acids was synthesized for comparison of GC retention data (Table 1) and EI mass spectra with those of peak *b* in the thrips volatiles. The candidate compounds were selected on the basis of the changes in GC retention times and small changes in the EI mass spectrum that resulted from varying each part of the molecule. Neryl 2-methylbutanoate had identical retention times on nonpolar and polar GC columns to those of natural peak *b* (Table 1), and the mass spectra were superimposable. Coinjection of the thrips volatiles with neryl (*S*)-2-methylbutanoate gave peak enhancement of peak *b*.

Chiral Chromatography. Racemic lavandulyl acetate gave two peaks at 27.91 and 25.09 min, (*R*)-lavandulyl acetate eluted at 27.89 min, and peak *a* of the entrained thrips headspace volatiles eluted at 27.97 min. Coinjection of entrained thrips headspace volatiles (peak *a*) and (*R*)-lavandulyl acetate (1 ng) gave an enhanced single peak at 27.94 min proving the (*R*)-configuration of the thrips-produced compound.

Racemic neryl 2-methylbutanoate (5 ng) gave two peaks at 21.85 and 22.23 min on the chiral column, whereas neryl (*S*)-2-methylbutanoate (5 ng) gave a peak at 22.43 min, and entrained thrips headspace volatile peak *b* gave a peak at 22.51 min. Coinjection of entrained thrips headspace volatiles and neryl (*S*)-2-methylbutanoate (5 ng) gave a single peak at 22.54 min, confirming the (*S*)-configuration for peak *b*.

The ratio of the area of peak *a* to peak *b* varied considerably among entrainments, ranging from 1:0.8 to 1:5. A ratio within this range (1:1) was selected for field trials.

TABLE 2. MEAN CATCH OF ADULT *F. occidentalis* ON BLUE STICKY TRAPS WITH (*R*)-LAVANDULYL ACETATE [(*R*)-LA] OR NERYL (*S*)-2-METHYLBUTANOATE [N(*S*)2MB] SEPARATELY OR AS 1:1 BLEND

	Males	3.9 ± 1.0	5.5 ± 1.7 ns	5.8 ± 1.3*
	Both sexes	6.8 ± 1.6	10.0 ± 2.7 ns	11.1 ± 2.4**

[a]Of the compound, 30 ng is for low dose and 30 μg is for high dose.
[b]The 1:1 blend comprising 15 ng of each compound for low dose (total 30 ng) and 15 μg of each compound for high dose (total 30 μg).
[c]Dunnett's test comparing each dose with corresponding control using $\log_{10}(x + 1)$ transformed data: ns = not significant; $*P < 0.05$; $**P < 0.01$; $***P < 0.001$.

Field Trials. There was no significant effect of (*R*)-lavandulyl acetate on trap catches at a dose of 30 ng or 30 μg (Table 2). However, neryl (*S*)-2-methylbutanoate and the 1:1 blend of (*R*)-lavandulyl acetate and neryl (*S*)-2-methylbutanoate increased trap catches significantly at a dose of 30 μg (Table 2). Both sexes were attracted, and the effect was similar for both females and males. The percentage increases with neryl (*S*)-2-methylbutanoate (54% for females and 38% for males) were broadly similar to those with the 1:1 blend (84% for females and 50% for males). There were no significant effects at 30 ng for the test compounds.

DISCUSSION

This report presents the first identification of an aggregation pheromone in the Thysanoptera. Although our previous studies of this pheromone have referred to it as a sex pheromone (Kirk and Hamilton, 2004) it should have been referred to as an aggregation pheromone because it attracts both sexes. (*R*)-lavandulyl acetate and neryl (*S*)-2-methylbutanoate were identified as the two main male-specific compounds, but only the latter showed activity in field trials. The sternal glands are the most likely source of the two compounds in *F. occidentalis*, but this has not yet been proven. These two compounds do not

appear to have been identified previously as insect semiochemicals. However, lavandulyl acetate is a component of the essential oil of lavender (Lis-Balchin, 2002), occurring as the *R*-enantiomer (unpublished data). It may be relevant that the natural distribution of the lavender genus (*Lavandula*) in parts of Europe, Asia, and Africa (Upson, 2002) does not overlap the original distribution of *F. occidentalis* in western North America (Kirk and Terry, 2003). Other lavandulyl esters have been identified recently as sex pheromone components in mealybugs: (*S*)-lavandulyl senecioate and (*S*)-lavandulyl isovalerate in the vine mealybug *Planococcus ficus* (Millar et al., 2002; Zada et al., 2003) and (*R*)-lavandulyl (*S*)-2-methylbutanoate in the pink hibiscus mealybug *Maconellicoccus hirsutus* (Zhang et al., 2004).

Field trapping trials showed neryl (*S*)-2-methylbutanoate alone was attractive to both female and male *F. occidentalis*, whereas (*R*)-lavandulyl acetate was not attractive. The 1:1 blend gave similar results to neryl (*S*)-2-methylbutanoate alone; thus, there was no strong indication of synergism between the two compounds. The considerable natural variation in the ratio of the two compounds found in headspace volatiles also suggests that synergism is unlikely or at least does not depend on a critical ratio. Thus, the role of (*R*)-lavandulyl acetate remains unclear. It could have a role in the close-range behavioral interactions between males at a mating aggregation, or it could have a role during copulation. The situation may be analogous to that in the cockroach *Nauphoeta cinerea*, in which the three principal active components from the male sternal glands have overlapping roles in attracting females from a distance and in close-range interactions between females and males (Moore, 1997). Alternatively, although our high dose of (*R*)-lavandulyl acetate was 1000 times that of the low dose, the release rates from the rubber septa could still have been outside the active range. Furthermore, the relative release rates of the two compounds were not determined.

Both females and males responded to neryl (*S*)-2-methylbutanoate, which mirrors the walking response shown earlier by adult females and males to the odor of adult males in a Y-tube olfactometer (Kirk and Hamilton, 2004).

Blue traps are widely used for trapping *F. occidentalis* because one shade of blue gives the highest visual attraction (Brødsgaard, 1989; Vernon and Gillespie, 1990). We tested our compounds on these traps to see whether the catch could be increased on the most visually attractive traps available and also because mating aggregations usually occur on highly visible objects, particularly brighter blues (Kirk, 1985; Matteson and Terry, 1992). The trap catches for each sex were increased by 38–84% upon addition of the high doses of the test compounds. Larger percentage increases in trap catches of thrips have been found with other odors, but those experiments used traps of less attractive colors, such as green (Murai et al., 2000) or much higher doses of chemical (Teulon et al., 1993). Other factors that could have reduced the effect in our

experiments were that the traps were close together; thus, the odor could have reached adjacent control traps, and the air was relatively still in the greenhouse. Little is known about whether thrips fly upwind to odors and thus need a flow of air to respond effectively (Teulon et al., 1999). Also, the best release rate is not yet known, and it is possible that minor components in the male odor may play a role. Further experiments to test these possibilities are in progress.

Acknowledgments—The research was supported in part by Syngenta Bioline and Mercia Spinner. We are grateful to Gines and Pepe Zamora for access to their greenhouses to conduct our experiments. We thank Cedar Chittenden, Ian Dublon, Sophia Fuchs, Neil Holmes, Kenneth MacDonald, Tracy Nevatte, Ann O'Leary, Mark Whittaker, and Emma Wilkins for assistance with rearing and entrainments, Krishnakumari Bandi for preparing septa, and Ian Dublon for counting trap catches.

4,8-DIMETHYLDECANAL, THE AGGREGATION PHEROMONE OF *Tribolium castaneum*, IS BIOSYNTHESIZED THROUGH THE FATTY ACID PATHWAY

JUNHEON KIM, SHIGERU MATSUYAMA, and TAKAHISA SUZUKI*

Division of Life Sciences and Bioengineering, Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Ibaraki 305-8572, Japan

(Received October 31, 2004; accepted January 31, 2005)

Abstract—4,8-Dimethyldecanal (4,8-DMD) is the aggregation pheromone produced by male red flour beetles (RFB), *Tribolium castaneum*. To elucidate the biosynthetic origin of 4,8-DMD, the following studies were performed: (1) effects of juvenile hormone (JH) III, and pathway inhibitors mevastatin, an inhibitor of the mevalonate pathway, and 2-octynoic acid, an inhibitor of the fatty acid pathway, were tested to determine whether 4,8-DMD is derived from the fatty acid pathway or the mevalonate pathway; (2) incorporation of ^{13}C-labeled acetate, propionate, and mevalonolactone into 4,8-DMD was measured to directly determine the biosynthetic origin of 4,8-DMD; and (3) incorporation of deuterium-labeled precursors, including 2-methylbutanoate (C5D), 4-methylhexanoate (C7D), 2,6-dimethyloctanoate (C10D), and 4,8-dimethyldecanoate (C12D) was tested to determine whether 4,8-DMD is biosynthesized in the sequence Ac–Pr–Ac–Pr–Ac (Ac; acetate, Pr; propionate). JH III was topically applied to males at various doses. Inhibitors and isotopically labeled substrates were administered orally by feeding the beetles flour treated with the substrates of interest, after which volatiles were collected from both sexes of RFBs. The amount of 4,8-DMD produced was significantly reduced with increasing doses of JH III. Also, 2-octynoic acid inhibited the production of 4,8-DMD, but mevastatin did not. Exposure of RFBs to [1-^{13}C]acetate and [1-^{13}C]propionate, but not [2-^{13}C]mevalonolactone, resulted in incorporation of the labeled compounds into 4,8-DMD. RFBs fed flour treated with deuterium-labeled C5D, C10D, and C12D, but not C7D, incorporated these compounds into 4,8-DMD. The findings that the production of 4,8-DMD was inhibited by 2-octynoic acid but unaffected by mevastatin, combined with the high incorporation of [1-^{13}C]acetate and [1-^{13}C]propionate into 4,8-DMD and the incorporation of

deuterated precursors, unambiguously demonstrated that 4,8-DMD is of fatty acid rather than terpene biosynthetic origin, and that the biosynthesis of 4,8-DMD proceeds in the sequence Ac–Pr–Ac–Pr–Ac.

Key Words—*Tribolium castaneum*, red flour beetle, Tenebrionidae, aggregation pheromone, 4,8-dimethyldecanal, biosynthesis, JH III, mevastatin, 2-octynoic acid, fatty acid pathway.

INTRODUCTION

Males of the flour beetle *Tribolium castaneum*, *T. confusum*, and *T. freemani* (Coleoptera: Tenebrionidae) produce 4,8-dimethyldecanal (4,8-DMD) as a common aggregation pheromone (Suzuki, 1980; Suzuki et al., 1987). 4,8-DMD has since been thought to be biosynthesized through the mevalonate pathway because it has a partial terpene skeleton and is easily obtained by oxidative cleavage of the isopentenyl group of a sesquiterpene farnesol derivative (Vanderwel and Oehlschlager, 1987; Howse et al., 1998). However, it is also possible that 4,8-DMD is biosynthesized via the fatty acid pathway, as in the case of 4-methyl-1-nonanol, the sex pheromone of *Tenebrio molitor* (Coleoptera: Tenebrionidae) (Tanaka et al., 1986, 1989; Islam et al., 1999).

Enzyme activators and inhibitors have been used for investigation of the biosynthetic origins of pheromones in Coleoptera (Tillman et al., 1999; Seybold and Vanderwel, 2003). JH III reportedly activates 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-R) and synthase (HMG-S) (Tittiger, 2003). JH III and its analogs enhanced the production of pheromones derived from the mevalonate pathway in Scolytidae (Chen et al., 1988; Ivarsson and Birgersson, 1995). In contrast, mevastatin blocks the action of HMG-R in the biosynthesis of the terpene precursor mevalonate (Endo et al., 1976; Monger et al., 1982). Ivarsson et al. (1993) provided indirect evidence for *de novo* biosynthesis of ipsdienol in *Ips duplicatus* using mevastatin. 2-Alkynoic acids, such as 2-octynoic acid, have been reported to inhibit the action of fatty acid synthase (FAS) and general acyl-CoA dehydrogenase leading to blocking of chain elongation of fatty acids (Freund et al., 1985; Barkawi et al., 2003; Zhao et al., 2004). Therefore, we reasoned that if 4,8-DMD is derived from the mevalonate pathway, the production of 4,8-DMD would be enhanced by JH III and decreased by mevastatin. Alternatively, if 4,8-DMD is derived from the fatty acid pathway, the production of 4,8-DMD should be decreased by 2-octynoic acid.

Incorporation of isotopically labeled substrates, such as acetate, propionate, and mevalonate, into pheromones has provided direct evidence for the biosynthetic origins of pheromones (Seybold and Vanderwel, 2003). Acetate serves as the building block for both the fatty acid and mevalonate pathways (Lehninger et al., 1993). Propionate is known to be the source of the methyl

branch(es) in long-chained lipids and fatty acids with odd chain lengths (reviewed by Nelson, 1993), whereas mevalonate is the universal precursor of terpenes in the mevalonate pathway. Based on these facts, it was predicted that if 4,8-DMD is of terpene origin, isotopically labeled acetate and mevalonate would be incorporated into 4,8-DMD by RFBs, whereas if 4,8-DMD is of fatty acid origin, isotopically labeled acetate and propionate would be incorporated into 4,8-DMD by RFBs.

The biosyntheses of pheromones originating from fatty acids in insects have been studied and they are characterized as: (1) preparation of the precursor fatty acid by *de novo* synthesis or acquisition from the host; (2) functionalization and change in chain length; and (3) modification of the terminal carboxyl group (reviewed by Jurenka, 2003, 2004). In Tenebrionidae, 4-methyl-1-nonanol was formed by the sequence of Pr–Ac–Pr–Ac (Ac, Acetate; Pr, Propionate) (Islam et al., 1999). Therefore, we hypothesized that the biosynthesis of 4,8-DMD proceeds via the sequence of Ac–Pr–Ac–Pr–Ac (Figure 1).

In the current studies, the effects of JH III and the inhibitors were examined by topical application and oral administration, respectively, and followed by analysis of the amount of 4,8-DMD produced by the treated animals. In addition, the biosynthetic origin and the hypothesized biosynthetic pathway of 4,8-DMD were investigated by feeding RFBs flour treated with isotopically labeled substrates, followed by analysis of substrate incorporation into 4,8-DMD by gas chromatography-mass spectrometry (GC-MS).

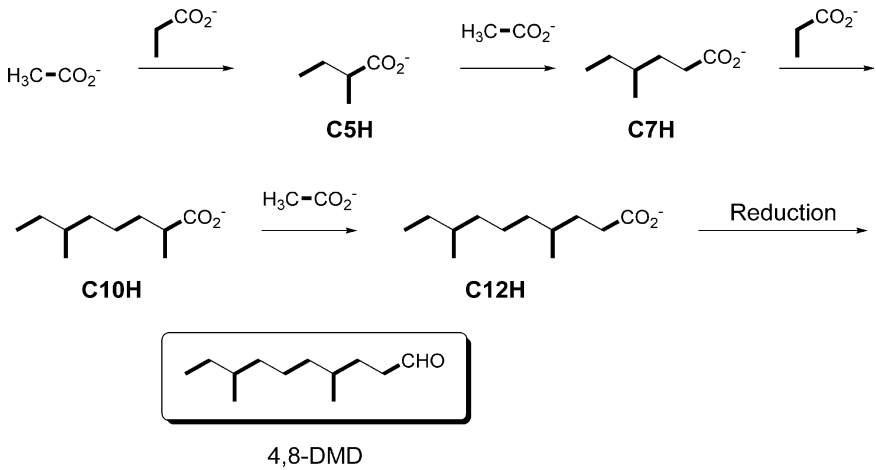

FIG. 1. The hypothesized biosynthetic pathway of 4,8-DMD in *T. castaneum via* a modified fatty acid pathway.

METHODS AND MATERIALS

Insect Cultures. A laboratory colony of *T. castaneum*, established over 20 yr, was used in all experiments. Beetles were reared on a mixture of whole wheat flour and 5% brewer's yeast (Ebios®; Asahi Food & Healthcare Ltd., Tokyo, Japan) at 27 ± 1°C, ca. 70% RH on a L:D 16:8 cycle. Pupae were sexed by the genitalia and after emergence, adults were reared separately for 4 d with flour. In preliminary experiments, aeration of both sexes produced significant levels of 4,8-DMD in males only. Therefore, adults (4 d old) of both sexes were used in all experiments.

Chemicals and Materials. The following chemicals were purchased: mevastatin (EMD Biosciences, Inc., San Diego, CA, USA); mevalonate (Aldrich Chemical Co., Milwaukee, WI, USA); [1-^{13}C]sodium acetate, [2-^{13}C]sodium acetate, and [1-^{13}C]sodium propionate (Cambridge Isotope Laboratories, Andover, MA, USA); methyl decanoate, sodium acetate, sodium propionate, diethyl ether, and Florisil® (Kanto Chemical Co. Inc., Tokyo, Japan); ethanol, hexane, and Wakogel® (C-200) (Wako Pure Chemical Industries Ltd. Osaka, Japan); Super Q, 80/100 mesh (Alltech Associates Inc., Deerfield, IL, USA); Porapak Q, 80/100 mesh (Waters Co., Milford, MA, USA). Hexane and diethyl ether were distilled prior to use.

Syntheses. JH III was prepared as follows: geranyl bromide, prepared from geraniol (Aldrich) following the method of Kim et al. (2004), was chain-extended by acetoacetate synthesis to afford geranylacetone (Nagano et al., 1997, 1999). Ethyl (2*E*/*Z*,6*E*)-farnesoate was obtained by the Wittig–Horner reaction of geranylacetone with triethyl phosphonoacetate (Kim et al. 2004). The resulting ethyl ester was transesterified to the corresponding methyl ester by refluxing in KOH-methanol solution for 4 hr. Epoxidation by the method of Hanzlik (1988) then yielded JH III (chemical purity: 94%, isomeric purity: 73%). 2-Octynoic acid was synthesized according to the procedure of Freund et al. (1985), and its chemical purity was >99.9% as the corresponding methyl ester. Mevalonolactone and [2-^{13}C]mevalonolactone were synthesized according to the synthetic scheme outlined in Figure 2. The final products were purified by Florisil® column chromatography. Spectra of mevalonolactone and [2-^{13}C]mevalonolactone corresponded with those of an authentic standard and the literature (Lawson et al., 1975), respectively (chemical purity of both compounds was >96.0%). The following deuterium-labeled and unlabeled putative precursors (sodium salts) were prepared as described by Kim et al. (2004), and their chemical purity was between 98% and 99.9% as the corresponding ethyl esters: 2-trideuteriomethylbutanoate (C5D), 4-methylhexanoate-*3*,*3*-d_2 (C7D), 2-trideuteriomethyl-6-methyloctanoate (C10D), and 4,8-dimethyldecanoate-*3*,*3*-d_2 (C12D). Deuterated and nonlabeled 4,8-DMDs were similarly prepared (Kim et al., 2004). The structures of the synthetic compounds

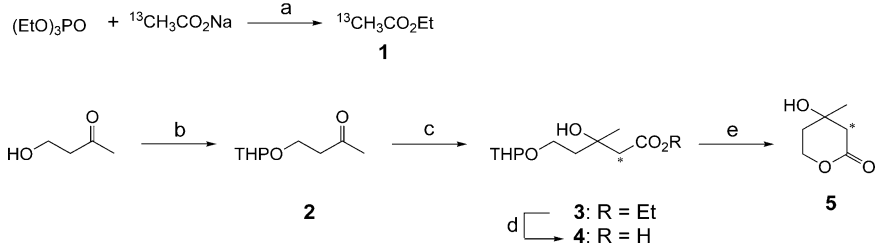

FIG. 2. Synthesis of [2-^{13}C]mevalonolactone. (a) Heating and distillation according to Ropp (1950); (b) dihydropyran, conc. HCl (four drops); (c) **1**, LDA (from *n*-BuLi and diisopropylamine)/THF, −78°C; (d) hydrolysis with NaOH in ethanol; (e) deprotection of THP group using Dowex (50W-X8, H form) in ethanol by modified procedure of Beier and Mundy (1979). were confirmed by GC-MS and ^{1}H and ^{13}C NMR (500 and 125 MHz, respectively) with a Bruker Avance 500 spectrometer using tetramethylsilane (TMS) in $CDCl_3$ as an internal standard.

Effect of JH III on the Production of 4,8-DMD. Male beetles were anesthetized with CO_2 and then attached to double-sided Scotch® tape on a glass slide cooled with ice. After the elytra were slightly lifted with an insect pin, the specified dose of JH III (0, 1, 10, or 100 μg) dissolved in 1 μl acetone was topically applied to the dorsal abdominal cuticle using a 10-μl syringe fitted with a 33-gauge needle (Hamilton Co., Reno, NV, USA). After JH III was applied, beetles were allowed to recover in a Petri dish for 30 min at room temperature. JH III-treated males and untreated females (50 of each) were introduced into a 200-ml Erlenmeyer flask (standard taper, 24/40) containing whole wheat flour (10 g). Each flask was plugged with a joint (standard taper, 24/40), in which two glass tubes (6 mm OD) were embedded. The distance from the surface of the flour to the lower end of the long or short tube was 1 or 8 cm, respectively. A Super Q column (ca. 90 mg, 2 cm in length, 6 mm OD) was connected to the upper end of the long tube for collecting the insects' volatiles, whereas a Porapak Q column (ca. 95 mg, 2 cm in length, 6 mm OD) was connected to the upper end of the short tube to introduce purified air into the chamber. Each Super Q column was connected to an air pump (Takatsuki, Tokyo, Japan) via a metal 10-way distributor (Takatsuki). Each flask was aerated at a rate of 250 ml/min. Volatiles were collected for 4 d. The captured volatiles were eluted with 1.1 ml of hexane and the eluate was concentrated to 100 μl under N_2. After addition of 1 μl of methyl decanoate solution (1000 ppm in hexane) as an internal standard, the solution was subjected to GC-MS analysis. The experiments were replicated three times.

Effects of Mevastatin and 2-Octynoic Acid. The effects of these inhibitors on the production of 4,8-DMD were tested by allowing the RFBs to feed on

flour treated with each inhibitor. Nontreated flour was made as follows: wheat flour (30 g) was added to a round-bottom flask (300 ml) containing ethanol (60 ml), and the ethanol was completely distilled off under reduced pressure at room temperature with a rotary evaporator. Similarly, inhibitor-treated flour was prepared using flour (10 g) and an ethanol solution (20 ml) of each inhibitor (50 mg; 0.5% by weight to media). A glass Petri dish (7 cm ID × 1.5 cm) containing the nontreated flour (10 g) and 50 males and 50 females was placed in a separable flask (500 ml volume; lower part, 12 cm ID × 5 cm) equipped with a Super Q column and a Porapak Q column. Three sets of this apparatus were prepared and each Super Q column was connected to an air pump via a metal 10-way distributor. Each flask was aerated at a rate of 250 ml/min. Volatiles were trapped for 10 d (Aeration I) before the beetles in each set were transferred separately to mevastatin-treated, 2-octynoic acid-treated or non-treated flour (10 g of each). Aeration was continued for an additional 10 d (Aeration II). In preliminary experiments using the same apparatus, when the beetles were fed inhibitor-treated flour during the first 10 d, the amount of 4,8-DMD varied substantially, even after feeding with nontreated flour. Therefore, in order to reduce this variability, beetles were fed nontreated flour for 10 d, and were then fed inhibitor-coated flour. Trapped volatiles were eluted with 1.1 ml hexane every 5 d and pooled in a 2-ml microreaction vessel (Supelco, Bellefonte, PA, USA). The pooled eluates (Eluate I contained volatiles from d 0–5 and 5–10 and Eluate II contained volatiles from d 10–15 and 15–20) were stored in a freezer at −15°C. Each pooled eluate was concentrated to 100 μl and analyzed by GC-MS after addition of methyl decanoate (1 μl of 1000 ppm hexane solution). The experiments were replicated four times.

Incorporation Experiments of ^{13}C-Labeled Substrates into 4,8-DMD. Each sodium salt (500 mg, 5% by weight to media) was dissolved with 1–2 ml of distilled water and diluted to 20 ml with ethanol, whereas ^{13}C-labeled or unlabeled mevalonate was dissolved in ethanol alone (20 ml). To the solution, 10 g of whole wheat flour were added, and the solvent was removed with a rotary evaporator. The resulting lump of flour was crushed with a mortar and pestle, and then sifted with a tea strainer. Nontreated flour was prepared in the same manner as described above without any substrate. Red flour beetles (50 males and 50 females) were fed flour (10 g in each set) coated with ^{13}C-labeled or unlabeled substrate (four sets each), or nontreated flour (two sets). Aeration was performed for 20 d with the same apparatus as that used for the JH III experiments. Volatiles were eluted, pooled, and analyzed as described in the inhibitor experiments (Eluate I and Eluate II).

Incorporation Experiments of Deuterated Putative Precursors into 4,8-DMD. The flour coated with deuterium-labeled or unlabeled putative precursors (500 mg; 5% by weight to media) was prepared as described for the experiments using ^{13}C-labeled substrates. Red flour beetles (50 males and 50 females) were

fed flour (10 g in each set) coated with deuterium-labeled or unlabeled putative precursors (four sets each), or nontreated flour (two sets). Aeration was performed for 20 d with the same apparatus used in the JH III experiments. Volatiles were eluted and pooled as described in the inhibitor experiments (Eluate I and Eluate II). Each pooled eluate was concentrated to ca. 100 μl, then chromatographed on a SiO_2 column (400 mg Wakogel®, Pasteur pipette) using step-wise elution with hexane (1 ml), 5% ether in hexane (2 ml), and ether (1 ml). 4,8-DMD was eluted with 5% ether in hexane solution. This fraction was concentrated to 100 μl and analyzed by GC-MS after addition of methyl decanoate internal standard (1 μl of 1000 ppm hexane solution).

GC-MS Analysis of 4,8-DMD. Mass spectra were obtained using a JEOL MS Router MS-600 (JEOL Ltd., Tokyo, Japan) coupled with an HP 6890N GC equipped with an HP-1MS column (30 m × 0.25 mm ID, 0.25 μm film; J&W Scientific, Folsom, CA, USA). The oven temperature was programmed at 50°C for 1 min, 6°C/min to 200°C, and then 8°C/min to 270°C. Chemical ionization (CI) analysis was carried out using isobutane as reagent gas. 4,8-DMD in the eluate was identified by comparing its retention time and mass spectrum to those of authentic standards. Quantification of 4,8-DMD was performed by comparison to a standard curve constructed for the GC-MS by plotting the ratio of total ion chromatogram (TIC) peak area for various amounts of 4,8-DMD to that of methyl decanoate. The amount of 4,8-DMD was expressed as ng/male-day-equivalents (MDE). Thus, the volatiles obtained in the JH III experiment and the other experiments contained 200 MDE/100 μl (50 males × 4 d) and 500 MDE/100 μl (50 males × 10 d), respectively. To quantify the amount of 4,8-DMD, the internal standard was added to the final concentrated eluate. This method was convenient for comparing the amount of 4,8-DMD in each treatment, but could lead to an underestimate of the absolute amount of 4,8-DMD.

Incorporation of each isotopically labeled substrate into the pheromone was assessed by single ion monitoring (SIM) of the fragments at m/z $(140 + n)$ on EI analysis and at $[M^+H\ (185) + n]$ on CI analysis in the TIC of 4,8-DMD. Incorporation rate of each isotopically labeled substrate was calculated by the following equation reported by Campbell (1974):

$$\text{Incorporation rate } (\%) = \frac{\text{Intensity of } (M^+H + n)}{\text{Sum of intensities of } M^+H \text{ and } (M^+H + n)} \times 100$$

where n represents the different mass unit value(s) between labeled and unlabeled 4,8-DMDs.

CI GC-MS yielded more effective information than EI GC-MS because 4,8-DMD gave the ion $M + H^+$ at m/z 185 as the base peak, whereas its M^+ was not observed in the EI GC-MS spectrum because of the McLafferty rearrangement.

Statistical Analyses. In the JH III experiment, the mean amount of 4,8-DMD was compared between each dose by one-way ANOVA followed by Fisher's LSD test ($P = 0.05$). In the inhibitor experiments, the mean amount of 4,8-DMD between Eluate I and Eluate II for each treatment was compared by *t*-test ($P = 0.05$). Using one-way ANOVA followed by Fisher's LSD test ($P = 0.05$), the mean amounts of 4,8-DMD obtained in Aeration I (Eluate I) among three noncoated treatments were compared, and those in Aeration II (Eluate II) were analyzed similarly. The mean amount of 4,8-DMD were transformed into $\log_{10}(x + 1)$ to assure normality (Sokal and Rohlf, 1995). The incorporation of ^{13}C-labeled acetate, propionate, or mevalonolactone into 4,8-DMD was confirmed by comparing the relative intensities of diagnostic fragments of 4,8-DMD derived from ^{13}C-labeled and nonlabeled substrates using *t*-tests ($P = 0.05$). Diagnostic fragments in the ^{13}C-labeled pheromone were *m*/*z* 112, 138, and 141 in EI mode and $(MH + 1)^+$ and $(MH + 2)^+$ in CI mode. The relative intensities (%) of diagnostic fragments were calculated as follows:

$$\text{Relative intensity of diagnostic fragment}(\%) = \frac{\text{Intensity of } m/z(X+1)}{\text{Intensity of } m/z\ X} \times 100$$

where *m*/*z X* represents 111, 137, and 140 in EI mode, and MH^+ (185) in CI mode. Computer calculations were carried out using S-Plus® 2000 (MathSoft, Seattle, WA, USA).

RESULTS

Effects of JH III and Inhibitors. The production of 4,8-DMD was reduced with increasing doses of JH III ($F_{3,8} = 8.15$; $P < 0.001$) (Table 1). In the in-

TABLE 1. EFFECT OF JH III ON THE PRODUCTION OF 4,8-DMD IN *T. castaneum*

Dose of JH III (μg)	Amount of 4,8-DMD (ng/MDE, mean ± SD)*
0	4.36 ± 0.89[a]
1	3.00 ± 0.39[b]
10	2.65 ± 0.40[b]
100	1.56 ± 0.27[c]

All experiments were replicated three times with 50 JH III-treated males and 50 nontreated females. MDE, male-day-equivalents.
*Values followed by the same letter are not significantly different (ANOVA, $P < 0.05$, means compared by Fisher's LSD).

hibitor experiments, 4,8-DMD was obtained in the range of 4.76–11.68 ng/MDE when RFBs were fed nontreated flour during the first 10 d (Aeration I), and there was no significant difference ($F_{2,9}$ = 1.03; P = 0.40) among the mean amounts of 4,8-DMD in each of the nontreated groups (Figure 3). The RFBs produced larger amounts of 4,8-DMD during d 10–20 (Eluate II) than during d 0–10 (Eluate I) (t-test, $P < 0.01$). However, there were differences among the mean amounts of 4,8-DMD obtained from inhibitor feeding experiments ($F_{2,9}$ = 13.33; P = 0.002) (Figure 3). The amount of 4,8-DMD from mevastatin treatment was 21.00 ± 3.27 ng/MDE (mean ± SD), equivalent to that of the control treatment (22.90 ± 3.27 ng/MDE). In contrast, the production of 4,8-DMD was significantly inhibited (13.13 ± 0.91 ng/MDE) by 2-octynoic acid (Figure 3). These results suggested that the 4,8-DMD produced by *T. castaneum* was derived from the fatty acid pathway rather than from the mevalonate pathway.

Incorporation of ^{13}C-Labeled Substrates into 4,8-DMD. Sufficient amounts of 4,8-DMD were obtained for analysis from both Eluates I (2.7–5.0 ng/MDE) and II (4.3–8.4 ng/MDE) in the incorporation experiments of ^{13}C-labeled substrates. In the mass spectra of 4,8-DMD obtained from RFBs exposed to ^{13}C-labeled acetate and propionate, the relative intensities of all diagnostic fragments were significantly increased compared to RFBs exposed to the unlabeled substrates (Table 2, Figure 4). This indicated that RFBs incorporated [1-^{13}C]acetate and [1-^{13}C]propionate into 4,8-DMDs. When the RFBs were treated with [1-^{13}C]acetate, approximately 9% of the 4,8-DMD was enriched in

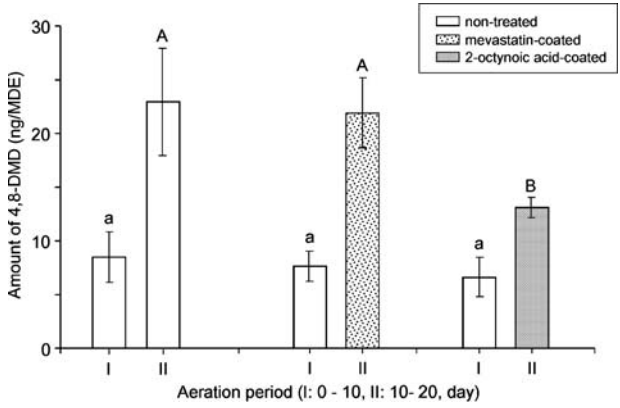

FIG. 3. Effect of inhibitors on the production of 4,8-dimethyldecanal by *T. castaneum.* Values (mean ± SD) followed by the same letter are not significantly different (ANOVA, $P < 0.05$, means compared by Fisher's LSD). All experiments were replicated four times with 50 males and 50 females. MDE, male-day-equivalents.

	[2-^{13}C]Mevalonolactone	100	14.58 ± 1.36***	1.56 ± 0.09
II	Control (Mevalonolactone)	100	12.63 ± 2.37	1.10 ± 0.27
	[2-^{13}C]Mevalonolactone	100	15.09 ± 1.46	1.74 ± 0.17

[a]Aeration periods I and II correspond to d 0 to 10 and 10 to 20, respectively.
*, **, and *** Significantly different values at $P < 0.05$, $P < 0.01$, and $P < 0.001$, respectively, compared to their corresponding unlabeled compounds (control) by *t*-test (one-tailed).

one ^{13}C atom, and approximately 1–2% was enriched in two ^{13}C atoms. When the insects were treated with [1-^{13}C] propionate, approximately 14–21% of the 4,8-DMD was enriched in one ^{13}C atom, and approximately 4.7–10% was enriched in two ^{13}C atoms (Table 3). When the RFBs were fed flour coated with [2-^{13}C]mevalonolactone, the relative intensities of some diagnostic fragments of 4,8-DMD appeared to be increased in both EI and CI modes (Table 2). However, the mean relative intensity of diagnostic fragment (*m/z* 112) in EI mode was not significantly increased, and the increase in the $[MH + 1]^+$ ion in CI mode was only statistically different when Eluate I of mevalonolactone-treated and [2-^{13}C]mevalonolactone-treated RFBs were compared with 4,8-DMD enriched in one ^{13}C atom at approximately 2.7% by [2-^{13}C]mevalonolactone (Table 3). Thus, at best, RFBs might incorporate small amounts of [2-^{13}C]mevalonolactone into 4,8-DMD only during Aeration I. The much higher and more consistent incorporation of the ^{13}C-labeled acetate and especially propionate provided strong evidence that 4,8-DMD is biosynthesized from these precursors.

Incorporation of Deuterium-Labeled Putative Precursors into 4,8-DMD. The amount of 4,8-DMD obtained from RFBs exposed to each precursor ranged between 0.5–1.4 ng/MDE (in Eluate I) and 1.2–3.5 ng/MDE (in Eluate II). The amount of 4,8-DMD in Eluate I was not sufficient for confirming the incorporation

of the labeled putative precursors into 4,8-DMD because of high background. Therefore, Eluate II was used to determine whether the deuterium-labeled substrates were incorporated into 4,8-DMD. The deuterium-labeled and unlabeled pheromones were separated by GC-MS. Deuterated 4,8-DMDs eluted faster than unlabeled ones (Figures 5 and 6). MS fragmentation patterns of each 4,8-DMD at the maximum peak of m/z (140 + n) were similar to those of the corresponding authentic deuterated standards. The n amu (atom mass unit)-shifted fragment ions were observed in the TIC of 4,8-DMDs obtained from RFBs treated with C5D, C10D, and C12D (Figures 5 and 6). This indicated that RFBs incorporated C5D, C10D, and C12D into 4,8-DMD, and that the deuterated substrates served as precursors. Unlike these deuterated substrates, 4,8-DMDs obtained from C7D treatment did not result in any n amu-shifted fragment ion in any of the treatments (Figure 5). The incorporation rates of these substrates are summarized in Table 4. Based on these experiments, we demonstrated that 4,8-DMD is biosynthesized in the sequence of Ac–Pr–Ac–Pr–Ac via the fatty acid pathway.

DISCUSSION

Our results show that the production of 4,8-DMD by *T. castaneum* is inhibited by 2-octynoic acid but not by mevastatin. These findings, combined with the high incorporation of [1-^{13}C]acetate and [1-^{13}C]propionate into 4,8-DMD and the incorporation of deuterium-labeled putative precursors, provide unambiguous evidence that 4,8-DMD is of fatty acid and not terpene

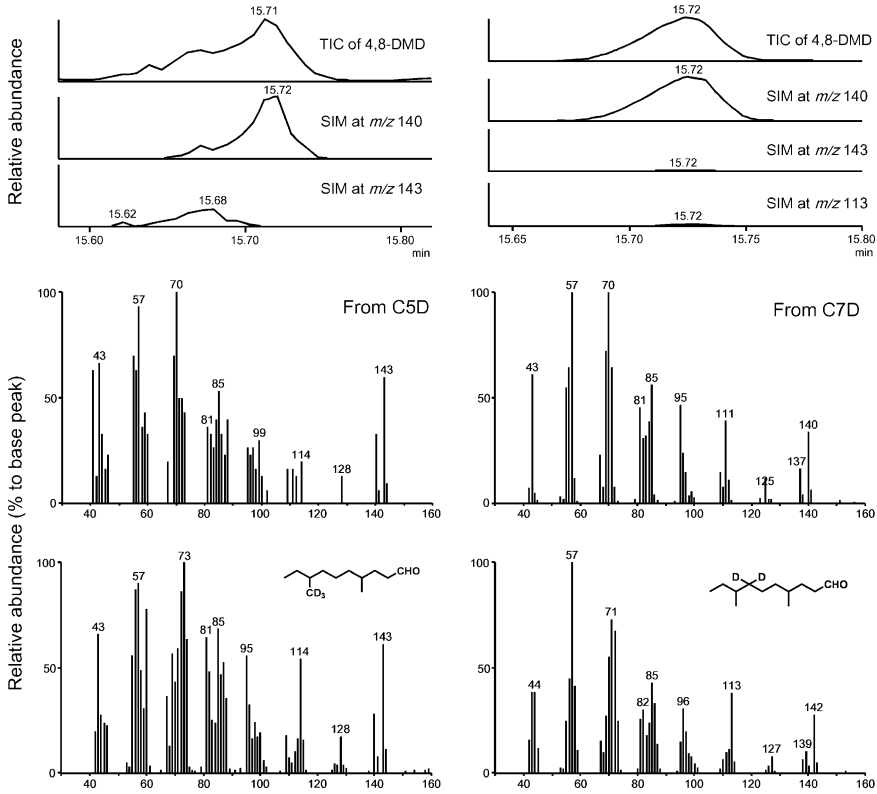

FIG. 5. Mass chromatograms (upper panels) and mass spectra (middle panels) of 4,8-DMD obtained from *T. castaneum* fed on flour coated with deuterium-labeled C5D (left; R_t = 15.68 min) or C7D (right; R_t = 15.72 min). Also shown are the mass chromatograms and spectra of authentic deuterated 4,8-DMD with the precursor incorporated as expected (lower panels). TIC, total ion chromatogram. SIM, single ion monitoring.

biosynthetic origin, and that the biosynthesis of 4,8-DMD proceeds in the sequence Ac–Pr–Ac–Pr–Ac.

Topical application of JH III caused a reduction in the level of 4,8-DMD. To our knowledge, an inhibitory effect of JH III on fatty acid biosynthesis has not been reported. Ivarsson and Birgersson (1995) reported that higher doses of methoprene suppressed the production of pheromones in *I. duplicatus*. A similar suppression mechanism seems to account for the effect of the higher doses of JH III observed here. However, it is surprising that even the lowest dose (1 μg/male) of JH III reduced the production of 4,8-DMD. One possible interpretation is that even 1 μg of JH III is too much for a young male RFB (4 d old). In

Also shown are the mass chromatograms and spectra of authentic deuterated 4,8-DMD with the precursor incorporated as expected (lower panels). TIC, total ion chromatogram. SIM, single ion monitoring.

contrast to our results, Pierce et al. (1986) reported that the production of both 4,8-DMD and nonmethyl branched cucujolides, which are aggregation pheromones of *Oryzaephilus mercator*, *O. surinamensis*, and *Cryptolestes ferrugineus* (Cucujidae), were enhanced when these species were fed methoprene-treated oats for 20 d. However, the nonmethyl branched cucujolides were later demonstrated to be of fatty acid origin (Vanderwel et al., 1990, 1992). Considering the results of Vanderwel et al. and our present results, the enhanced production of 4,8-DMD reported by Pierce et al. (1986) appears to be different from that of the terpene pheromones observed in *I. duplicatus* and *I. pini*, which

TABLE 4. INCORPORATION RATE OF DEUTERIUM-LABELED PRECURSORS INTO 4,8-DIMETHYLDECANAL BY *T. castaneum* DURING AERATION PERIOD DAYS 10 TO 20

Precursor	Incorporation rate (%, mean ± SD, $N = 4$)
2-Trideuteriomethylbutanoate (C5D)[a]	26.23 ± 2.76
4-Methylhexanoate-3,3-d_2 (C7D)	0.00
2-Trideuteriomethyl-6-methyloctanoate (C10D)[b]	13.03 ± 1.33
4,8-Dimethyldecanoate-3,3-d_2 (C12D)	22.05 ± 3.81

[a] $N = 3$ (4,8-DMD obtained from one of replicates was lost during fractionation).
[b] The value was determined by GC-MS EI analysis.

occurred by activation of the enzymes (HMG-R and HMG-S) involved in the mevalonate pathway (Tittiger, 2003).

The fact that the production of 4,8-DMD was not inhibited by mevastatin but was inhibited by 2-octynoic acid provides further evidence that 4,8-DMD produced by RFB is derived from the fatty acid pathway rather than from the mevalonate pathway. These inhibitors have been used previously to provide indirect information on the biosyntheses of pheromones, and they have been administered by microinjection or topical application to the pheromone gland (Seybold and Vanderwel, 2003; Ivarsson et al., 1993; Barkawi et al., 2003; Zhao et al., 2004). However, oral administration was conducted in our study, because the pheromone gland for 4,8-DMD remains unknown. The femoral setiferous glands has been reported to be the major site of production of 4,8-DMD (Faustini et al., 1981), but it was also reported that they are not the sole source of 4,8-DMD (Hussain, 1993; Qazi et al., 1998). Oral administration was also used because of technical difficulties in microinjection; specifically, there was high mortality following injection of the RFBs with either glass capillaries or a microsyringe fitted with a 33-gauge needle.

The results of the ^{13}C-labeled substrate incorporation experiments provided direct evidence that 4,8-DMD is of fatty acid pathway origin. Both ^{13}C-labeled acetate and possibly lesser amounts of mevalonolactone were incorporated into 4,8-DMD; the incorporation rate of [1-^{13}C]acetate was much higher than that of [2-^{13}C]mevalonolactone. Based on this result, it is unlikely that 4,8-DMD is produced via the mevalonate pathway. If 4,8-DMD was produced by the mevalonate pathway, a higher rate of incorporation of [2-^{13}C]mevalonolactone than [1-^{13}C]acetate into 4,8-DMD would have been expected because acetate would be incorporated into mevalonate before it was incorporated into 4,8-DMD. In addition, loss of a ^{13}C atom in [1-^{13}C]acetate and dilution of [1-^{13}C] acetate by unlabeled acetate would occur during mevalonate formation

(Lehninger et al., 1993). Barkawi et al. (2003) reported that in *Dendroctonus jeffreyi* (Scolytidae), both ^{14}C-labeled acetate and mevalonolactone were incorporated into frontalin derived from the mevalonate pathway, and that the incorporation rate of mevalonolactone was two or three times higher than that of acetate. In addition, when RFBs were fed flours coated with other deuterated terpenoids (geraniol, farnesol, and 2,6,10-trimethyl-2-dodecene), they did not incorporate these substrates into 4,8-DMD (J. Kim, personal communication). The low incorporation of [2-^{13}C]mevalonolactone into 4,8-DMD may be a result of the degradation of [2-^{13}C]mevalonolactone during digestion by the beetles or preparation of the media.

The incorporation of [1-^{13}C]propionate into 4,8-DMD provided further evidence that 4,8-DMD was of fatty acid origin. Propionate is well known to be a source of methyl groups in methyl-branched insect lipids (Nelson, 1993). In tenebrionid pheromones, Islam et al. (1999) demonstrated that 4-methyl-1-nonanol, the sex pheromone of *T. molitor*, was biosynthesized through a modified fatty acid pathway and that [1-^{13}C]propionate was incorporated into the pheromone and responsible for the methyl branch. Propionate could be converted into acetyl-CoA from propionyl-CoA (Chase et al., 1992; Nelson, 1993), and be subsequently incorporated into 4,8-DMD. However, Dillwith et al. (1982) proposed that the ^{13}C atom in [1-^{13}C]propionate would be lost during conversion to acetyl-CoA. Therefore, the enrichment of 4,8-DMD in ^{13}C indicated that propionate was directly involved in the biosynthesis of 4,8-DMD. However, there is no previous evidence that propionate is involved in the mevalonate pathway.

The 4,8-DMD obtained from ^{13}C-labeled substrate incorporation experiments was analyzed by conventional GC-MS. This analysis provided information on the position of ^{13}C atoms in the pheromone and should allow determination of the biosynthetic route (Bartelt and Weisleder, 1996; Islam et al., 1999). Unfortunately, because of the complex MS fragmentation pattern of 4,8-DMD, incorporation studies using ^{13}C-labeled substrates could not identify the exact position of the ^{13}C atom, and, therefore, we were unable to use it to determine the biosynthetic route to 4,8-DMD. However, the results of the experiments using deuterium-labeled precursors provide evidence that 4,8-DMD was formed according to the sequence shown in Figure 1. The deuterated precursors C5D, C10D, and C12D were incorporated into 4,8-DMD, and their MS patterns were similar to those of the corresponding authentic deuterated standards. In contrast to our expectations, C7D, one of the hypothesized precursors, was not incorporated into 4,8-DMD in all replicates. Considering that C5D and C10D were incorporated into 4,8-DMD and that the chain elongation reaction involves reduction of double bonds, it is possible that there is a more complex biosynthetic pathway that is distinct from the pathway producing lepidopteran pheromones from fatty acids. For example, as shown in Figure 7, 2,6-dimethyloctanoate (C10H)

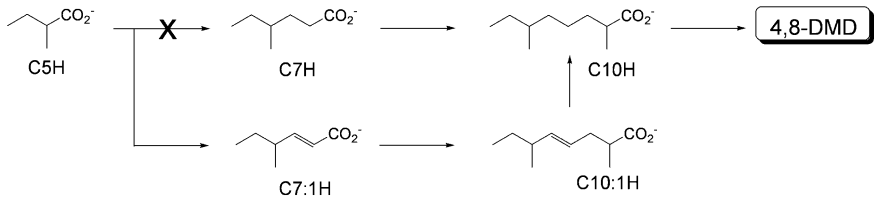

FIG. 7. A plausible alternate chain elongation reaction in biosynthesis of 4,8-DMD.

could originate from 2,6-dimethyl-4-octenoate (C10:1H) via 4-methyl-2-hexenoate (C7:1H), rather than from 4-methylhexanoate (C7H). This detoured pathway could be tested by examining the incorporation of deuterated C7:1H and C10:1H into the pheromone.

Figure 8 shows the structural and biosynthetic similarities between 4,8-DMD and 4-methyl-1-nonanol. The only difference in the biosynthetic sequence between them is whether or not it initiates with Ac (Ac–Pr–Ac–Pr–Ac for 4,8-DMD and Pr–Ac–Pr–Ac for 4-methyl-1-nonanol). Moreover, the absolute configuration at the C-4 position of the natural forms of both pheromones is (4*R*) (Suzuki and Mori, 1983; Tanaka et al., 1989). This information suggests that the pheromones of *T. castaneum* and *T. molitor* are derived from a common biosynthetic pathway.

On the other hand, the male-produced aggregation pheromones of *Gnatocerus cornutus*, a terebrionid beetle, are the sesquiterpenes, (+)-acoradiene and α-cedren-14-al (Tebayashi et al., 1998a,b; Tashiro et al., 2004). Although tenebrionid pheromones are known from only three genera, their pheromones are rather complex. Studies of other tenebrionid pheromones and their biosyntheses would provide useful information for understanding the evolution of chemical communication in this taxonomically complex group.

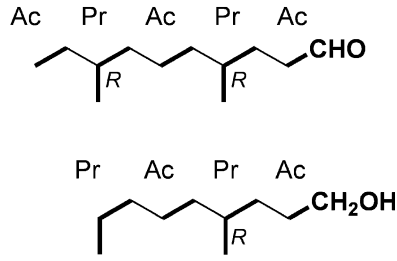

FIG. 8. Structural and biosynthetic analogy of pheromones of *Tribolium castaneum* (upper) and *Tenebrio molitor* (lower).

(Received September 1, 2004; revised November 11, 2004; accepted February 21, 2005)

Abstract—Previous work showed that females of the European tarnished plant bug, *Lygus rugulipennis* Poppius (Heteroptera: Miridae), produced three chemicals, hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal, and that these were suspected to be components of the female sex pheromone. In field experiments, traps baited with blends of these chemicals dispensed from polyethylene vials and sachets failed to catch significant numbers of males. Here, we report more recent field experiments in which the chemicals were released from glass microcapillary tubes. A blend of hexyl butyrate and (*E*)-4-oxo-2-hexenal was significantly attractive to male *L. rugulipennis*. In addition, whereas the mixture of all three components attracted fewer *L. rugulipennis* males, this tertiary blend captured significantly greater numbers of males of the congeneric species *Lygus pratensis* than the binary mixture. The possible reasons for the success of the microcapillaries compared with other dispensers are discussed.

Key Words—*Lygus rugulipennis*, *Lygus pratensis*, Heteroptera, Miridae, tarnished plant bug, sex pheromone, hexyl butyrate, (*E*)-2-hexenyl butyrate, (*E*)-4-oxo-2-hexenal.

INTRODUCTION

The use of pheromones for detecting, monitoring, and controlling lepidopteran and coleopteran pests has been well explored (Ridgway et al., 1990; Copping, 1998). In contrast, the identification and application of pheromones within the Heteroptera is in its infancy, especially in the Mirid family (Smith et al., 1991; Millar et al., 1997; Millar and Rice, 1998; Kakizaki and Sugie, 2001; Downham et al., 2002; Zhang and Aldrich, 2003a). The genus *Lygus* contains some of the most damaging of all bugs to a range of crops (McBrien and Millar, 1999), and consequently, they are the subject of intensive scientific research, and novel methods of control are constantly being sought. To date, numerous compounds have been reported as potential female sex pheromone components of *Lygus* sp., but synthetic blends do not attract males to traps in the field (e.g., Ho and Millar, 2002).

Our previous work on the European tarnished plant bug, *Lygus rugulipennis* (Heteroptera: Miridae) Poppius, showed that virgin females attracted males to traps (Innocenzi et al., 1998). The male antennae were stimulated by three components released by females, and these were identified as hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal (Innocenzi et al., 2004). All three chemicals were found in body extracts of both virgin males and females, but virgin males did not release detectable amounts of any of them under undisturbed conditions. Despite this circumstantial evidence indicating a possible pheromonal role for one or more of these chemicals, field trials with various mixtures dispensed from different combinations of polyethylene vial and polyethylene sachet dispensers failed to show any significant attraction of male *L. rugulipennis*. Significant repulsion of females by blends containing hexyl butyrate was observed (Innocenzi et al., 2004). Here, we report the results of more recent field trapping experiments in which the same chemicals were released from glass microcapillary tubes, as described by Kakizaki and Sugie (2001) for the pheromone components of another mirid species. Attraction of male *L. rugulipennis* to a two-component blend was demonstrated, and a blend of all three components was found to attract the congener, *Lygus pratensis* Linnaeus.

METHODS AND MATERIALS

Gas Chromatography. Gas chromatography (GC) analyses were performed using a Carlo Erba Mega 5300 instrument equipped with fused silica capillary columns (25 m $\times$ 0.32 mm i.d.) coated with polar CPWax52CB (Carbowax 20 M equivalent; Chrompak, London, UK) or nonpolar CPSil5CB (methyl silicone; Chrompak). The carrier gas was helium at 50 kPa, and the

oven temperature was held at 50°C for 2 min then programmed at 6°C/min to 240°C. Injector and detector temperatures were 200 and 240°C, respectively. Injection was splitless, and detection was by flame ionization detection (FID). Data were captured and processed using EzChrom 6.1 software (Aston Scientific, Stoke-Mandeville, Bucks, UK).

Chemicals. Butyrate esters were synthesized by reaction of butyryl chloride with the corresponding alcohol in dichloromethane in the presence of pyridine at 0°C followed by aqueous workup and distillation: hexyl butyrate (98% purity, b.p. 76°C/7 mm), (*E*)-2-hexenyl butyrate (99% purity, b.p. 120°C/10 mm). (*E*)-4-Oxo-2-hexenal (99% purity, b.p. 100°C/5 mm) was synthesized according to Ward and van Dorp (1969) or by a route similar to that subsequently described by Marques et al. (2000).

Dispensers. Dispensers were glass microcapillaries (vol. 5 μl, cat. no. TLC-940-040X, Fisher Scientific, UK) or polyethylene vials (22 × 8 × 1.5 mm thickness, Just Plastics Ltd., London). The microcapillaries were loaded with a solution (5 μl) of the chemicals in dichloromethane (10 mg/ml). Hexyl butyrate and (*E*)-2-hexenyl butyrate were combined in 3:2 ratio, respectively, in a single solution (total 10 mg/ml), matching that produced by a single female *L. rugulipennis* (Innocenzi et al., 2004). The (*E*)-4-oxo-2-hexenal was loaded into a separate microcapillary. The polyethylene vials were loaded with the 3:2 mixture of butyrates (10 mg total) dissolved in an involatile, chlorinated hydrocarbon, "Cereclor" (100 mg; Shell Chemicals Ltd.). Dilution of volatile materials in an involatile solvent reduces the release rate relative to that of the neat material (Torr et al., 1997). The (*E*)-4-oxo-2-hexenal (2 mg) in Cereclor (20 mg) was dispensed from a separate vial. The butyrates and (*E*)-4-oxo-2-hexenal were placed in separate dispensers because chemical interaction between (*E*)-2-hexenyl butyrate and (*E*)-4-oxo-2-hexenal had been observed previously (Innocenzi et al., 2004).

Release rates were measured from duplicate dispensers maintained in a laboratory wind tunnel (27°C, 8 km/hr wind speed). Volatiles were collected by placing each dispenser in a separate glass chamber (10 × 3 cm diam) and air drawn (2 l/min) into the chamber through an activated charcoal filter (20 × 2 cm, 6–18 mesh) and out through a collection filter containing Porapak Q (200 mg, 50–80 mesh, Waters Corp., MA, USA), held between plugs of silanized glass wool in a Pasteur pipette. The Porapak was purified by soxhlet extraction with chloroform for 8 hr, and filters were washed well with dichloromethane immediately before use. After 1 hr, adsorbed volatiles were removed from the filters with dichloromethane (pesticide grade; 1 × 0.5 ml, 1 × 1 ml), decyl acetate (5 μg) added as internal standard, and the solution analyzed by GC on the polar column. Volatiles from the microcapillaries were collected and analyzed immediately after evaporation of the solvent (2 hr after loading) and then after 24 and 48 hr. Volatiles from polyethylene vials were collected 1, 2, 3,

5, 7, and 9 d after loading. The release rates from microcapillaries were also measured using residual analysis of pheromones 1, 2, 3, 13, and 24 hr after loading. The microcapillaries were extracted with dichloromethane (1 ml) containing undecane (10 μg) as internal standard, and the resulting residue in solution was analyzed by GC on the nonpolar column.

Traps. Traps were constructed from a wooden stake (2 × 2 × 50 cm long) with a band of viscous polybutene sticker (10 cm wide, 2 cm from the top; Oecotac, Oecos, Kimpton, Herts, UK) and a small corrugated plastic board (5 × 5 cm; Correx) on top to act as a rain shield. Lures were suspended from the corner of the latter with sticky tape (microcapillaries) or a wire hook (polyethylene vials).

Field Trials. A field at East Malling Research Station (1.4 ha) was sown with a mixture of the host plants, fathen, *Matricaria recutita*, and scented mayweed, *Chenopodium album* (both at 1 kg/ha), in March 2002 and 2003 to ensure large resident populations of *L. rugulipennis*. Randomized complete block designs were used for all experiments with traps placed 5–10 m apart within a block and blocks separated by at least 10 m.

In 2002, two replicated field experiments were carried out from 29 July to 14 August and from 14 August to 3 September to evaluate the glass microcapillary lures containing all possible binary combinations of the three candidate pheromone components and the three-component blend, previously tested by Innocenzi et al. (2004). Thus, treatments were unbaited, hexyl butyrate + (*E*)-2-hexenyl butyrate, hexyl butyrate + (*E*)-4-oxo-2-hexenal, (*E*)-2-hexenyl butyrate + (*E*)-4-oxo-2-hexenal, and all three chemicals. Traps were examined, and the number of insects was recorded every 48–72 hr, after which the microcapillaries were replaced.

The same experiment was repeated in 0.8 ha of the field between 21 July and 3 August 2003. In a second experiment from 19 to 21 August 2003, treatments were unbaited, microcapillaries containing hexyl butyrate, (*E*)-4-oxo-2-hexenal or hexyl butyrate + (*E*)-4-oxo-2-hexenal, and polyethylene vials containing hexyl butyrate + (*E*)-4-oxo-2-hexenal in Cereclor. Trials began between 1100 and 1400 hr. Traps were checked every hour for the first 3 hr, and again after 24 hr, after which the microcapillaries were replaced.

Insect Identification. Because of the morphological similarity of *Lygus* spp., the diverse coloration of *L. rugulipennis* (Southwood and Leston, 1959), and the damaging effect of the polybutene adhesive on insect structure, *L. rugulipennis* and *L. pratensis* were not distinguished in 2002. Therefore statistical analysis was conducted on the combined *Lygus* spp. catch. However, the catches were saved in 70% ethanol, and retrospective examination of these insects was possible, although statistical testing could not be applied for the separate species as the individual trap catches for each treatment had been combined. In 2003, as trap counts were conducted hourly, it was possible to identify both *L. rugulipennis* and *L. pratensis*, the latter being longer with a

reddish wing coloration and possessing distinct markings on the pronotum and scutellum (Southwood and Leston, 1959). Species identifications were confirmed by the Natural History Museum, London.

Statistical Analysis. After square root transformation, data from the field experiments were analyzed using a general linear model (SPSS v.10, SPSS Inc., Chicago, IL 60606, USA). *Post hoc* pairwise comparisons were computed using Tukey highest significant differences (HSD). A significance level of 5% was used for all statistics.

RESULTS

Release Rate Studies. Estimates from the analysis of residual pheromone (Figure 1) indicate that hexyl butyrate and (*E*)-4-oxo-2-hexenal were released from microcapillaries at approximately 5 and 10 μg/hr, in the first 2 hr. Then, after the solvent had completely evaporated, the release rate decreased to approximately 1 and 2 μg/hr, respectively. Release rate for the 3:2 mixture of hexyl butyrate and (*E*)-2-hexenyl butyrate combined was 0.7 μg/hr and for (*E*)-4-oxo-2-hexenal approximately 2 μg/hr (Table 1), in reasonable agreement with the above figures. Collection of volatiles showed that release of the butyrates was complete within 48 hr and that of the (*E*)-4-oxo-2-hexenal within 24 hr at 27°C.

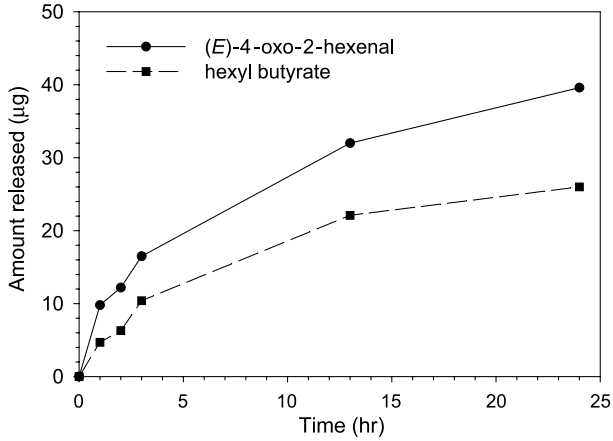

FIG. 1. Release of hexyl butyrate and (*E*)-4-oxo-2-hexenal from separate microcapillary tubes in laboratory wind tunnel determined by analysis of residual material at intervals (27°C, 8 km/hr wind speed; $N = 2$).

TABLE 1. RELEASE RATES OF HEXYL BUTYRATE, (*E*)-2-HEXENYL BUTYRATE, AND (*E*)-4-OXO-2-HEXENAL FROM MICROCAPILLARY TUBES AND POLYETHYLENE VIALS MEASURED BY COLLECTION OF VOLATILES AT 27°C

Dispenser/loading	Duration	Release rate ± SE (μg/hr)		
		Hexyl butyrate	(*E*)-2-Hexenyl butyrate	(*E*)-4-Oxo-2-hexenal
Microcapillary				
50 μg 3:2 hexyl butyrate + (*E*)-2-hexenyl butyrate	<48 hr (n = 8)	0.38 ± 0.016	0.25 ± 0.014	
50 μg (*E*)-4-oxo-2-hexenal	<24 hr (n = 4)			2.07 ± 0.20
Polyethylene vial				
10 mg 3:2 hexyl butyrate + (*E*)-2-hexenyl butyrate in 100 mg Cereclor	9 d (n = 10)	4.49 ± 0.34	3.12 ± 0.24	
2 mg (*E*)-4-oxo-2-hexenal in 20 mg Cereclor	9 d (n = 10)			7.04 ± 0.49

Release of the butyrates from a 10% solution in Cereclor in the polyethylene vial was at least an order of magnitude higher than that from the microcapillary tubes, and for (*E*)-4-oxo-2-hexenal, it was over three times greater. Release was relatively constant over at least 9 d (Table 1).

Field Trials. During the first experiment in 2002, significantly more *Lygus* spp. ($P < 0.05$) were caught in traps baited with all three components dispensed from microcapillary tubes, i.e., a 3:2 mixture of hexyl butyrate and (*E*)-2-hexenyl butyrate in one capillary and (*E*)-4-oxo-2-hexenal in a separate tube, than in traps baited with binary mixtures or unbaited (Figure 2A). Subsequent examination of the catches showed that 70% of the total male catch was *L. pratensis*, and 93% of the catch with the most attractive tertiary blend was of this species (Figure 2A). In the second experiment, significantly more *Lygus* spp. ($P < 0.05$) were caught in traps baited with hexyl butyrate and (*E*)-4-oxo-2-hexenal dispensed from separate microcapillaries (Figure 2B). In this case, 84% of the males captured were *L. rugulipennis* and constituted 97% of the catch with the most attractive blend of hexyl butyrate and (*E*)-4-oxo-2-hexenal (Figure 2B). Small numbers of female *Lygus* spp. were caught in all traps. Similar results were obtained in 2003. In the first 3 hr of trapping, catches of male *L. rugulipennis* were significantly ($P < 0.05$) greater in traps baited with the blend of hexyl butyrate and (*E*)-4-oxo-2-hexenal, whereas *L. pratensis* catches (although at lower densities) were significantly greater in traps baited with the tertiary blend (Figure 3A). Again, catches of female *Lygus* spp. were low. Catches of male *L. rugulipennis* during the period 3–24 hr after

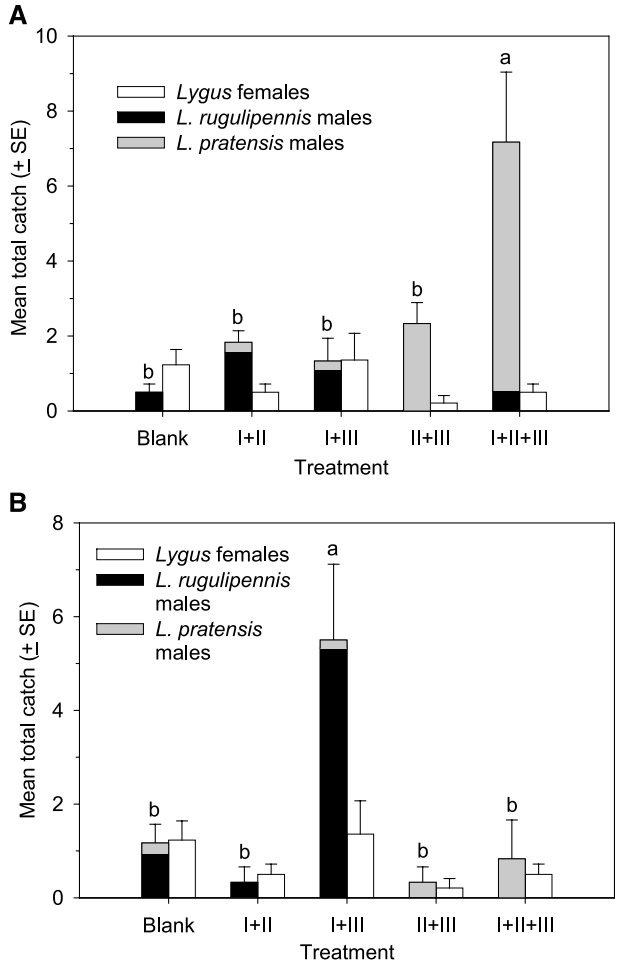

FIG. 2. Mean total catches ($N = 6$) of *L. rugulipennis* and *L. pratensis* males and *Lygus* spp. females in 2002 field experiments: (A) Experiment 1 from 29 July to 14 August; (B) experiment 2 from 15 August to 3 September [blends of hexyl butyrate **(I)**, (*E*)-2-hexenyl butyrate **(II)**, and (*E*)-4-oxo-2-hexenal **(III)** dispensed from microcapillaries; means for each species with different letters are significantly different ($P < 0.05$) by Tukey HSD]. Columns followed by the same letter are not significantly different.

deployment of lures were lower, and there were no significant differences between catches in unbaited or baited traps (0–3 hr, $P < 0.005$; 3–24 hr, $P > 0.05$) (Figure 3B).

In the second experiment, the combination of hexyl butyrate and (*E*)-4-oxo-2-hexenal in microcapillary dispensers attracted significantly more male *L. rugulipennis* than the individual components, although more males were caught in traps baited with (*E*)-4-oxo-2-hexenal alone than in the unbaited traps ($P < 0.001$) (Figure 4). Some male *L. rugulipennis* were caught in traps baited with the binary blend dispensed from a polyethylene vial, but numbers were not significantly different from those caught in unbaited traps or the single components alone in capillary tubes.

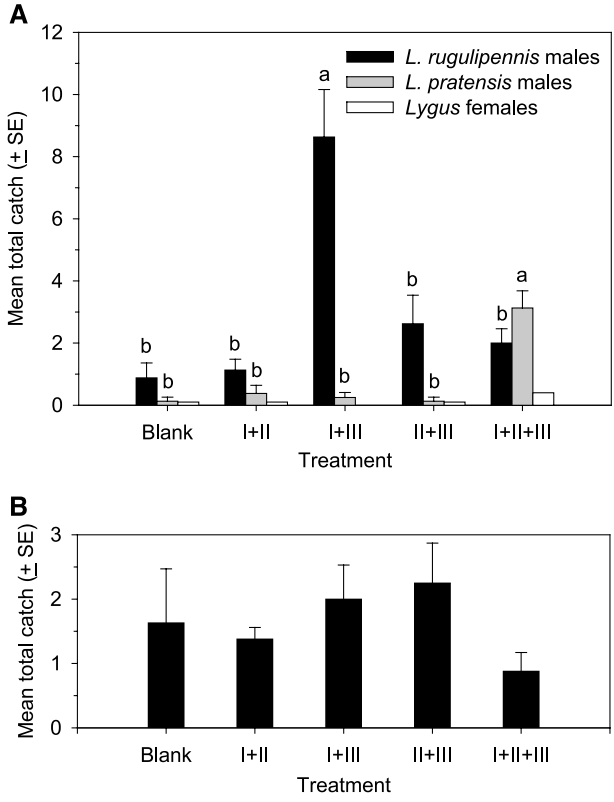

FIG. 3. Mean total catches (±SE; $N = 8$) of *L. rugulipennis* males, *L. pratensis* males, and *Lygus* spp. females in 2003 field experiments: (A) over the first 3 hr and (B) 3–24 hr from 21 July to 3 August [blends of hexyl butyrate **(I)**, (*E*)-2-hexenyl butyrate **(II)**, and (*E*)-4-oxo-2-hexenal **(III)** dispensed from microcapillaries; means for each species with different letters are significantly different ($P < 0.05$) by Tukey HSD]. Columns followed by the same letter are not significantly different.

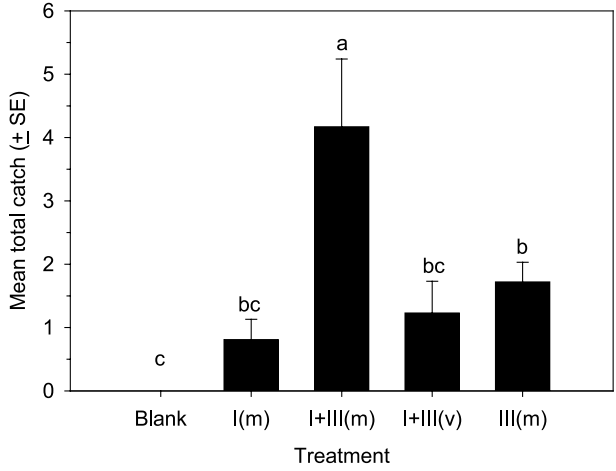

FIG. 4. Mean trap catches (±SE; $N = 6$) of *L. rugulipennis* males over first 3 hr from 19 to 21 August 2003 [blends of hexyl butyrate **(I)** and (*E*)-4-oxo-2-hexenal **(III)** dispensed from microcapillaries (m) or as 10% solution in Cereclor in polyethylene vial (v); means with different letters are significantly different ($P < 0.05$) by Tukey HSD]. Columns followed by the same letter are not significantly different.

DISCUSSION

In the present study, male *L. rugulipennis* were attracted to traps baited with (*E*)-4-oxo-2-hexenal alone, and the efficacy increased with the addition of hexyl butyrate when glass microcapillary tubes were used as the release system. These results differ significantly from those of our previous study (Innocenzi et al., 2004), when the same compounds released from either polythene vials or sachets were not attractive. Hexyl butyrate and (*E*)-4-oxo-2-hexenal are commonly found as defensive chemicals in Heteroptera (Staddon, 1979; Aldrich, 1988), although intraspecific communication functions of compounds traditionally regarded as defensive compounds are becoming increasingly evident, especially within the Miridae (e.g., Blum, 1996; Zhang and Aldrich, 2003b). Zhang and Aldrich (2004) also recently reported use of these types of compound as kairomones by predators of mirid species. The identification of an ester, hexyl butyrate, as a pheromone component is in keeping with other identified mirid pheromones (e.g., Smith et al., 1991; Millar et al., 1997). However, (*E*)-4-oxo-2-hexenal has, to our knowledge, never been previously reported as a sex pheromone component.

Attraction of male *L. rugulipennis* when the blends of these chemicals are dispensed from microcapillary tubes but not from polyethylene vials could be a result of one or more of several factors.

Pheromone Release Rate. Under laboratory conditions (27°C, 8 k/hr wind speed), release rates of the butyrate esters or (*E*)-4-oxo-2-hexenal from polyethylene sachet dispensers were approximately 1,500 and 140 μg/hr, respectively, whereas from polyethylene vials, the values were 158 and 7.5 μg/hr (Innocenzi et al., 2004). Dilution of these compounds as a 10% solution in the involatile, chlorinated hydrocarbon, Cereclor, reduced these release rates from vials by an order of magnitude (Table 1) compared with our previously published results (Innocenzi et al., 2004). Similarly, release rates for the butyrate esters from the microcapillary tubes were a further order of magnitude less and of the (*E*)-4-oxo-2-hexenal more than three times less under the same conditions (Table 1). Single female *L. rugulipennis* released hexyl butyrate at 0.04 μg/hr, whereas groups of four did so at 0.4 μg/hr/female under laboratory conditions (Innocenzi et al., 2004), the latter rate being similar to that of microcapillary tubes. This would suggest that the release rate is a critical factor in attraction of *L. rugulipennis* and that those in our previous experiments were too high. This suggestion is supported by the observation that significantly fewer *L. rugulipennis* females were caught in traps baited with blends containing hexyl butyrate than in unbaited traps (Innocenzi et al., 2004). Similarly, Wardle et al. (2003) found that *Lygus lineloaris* bugs were repelled by high doses of the same chemicals in a laboratory bioassay, although they could not demonstrate this effect in the field.

In 2003, *Lygus* males were no longer attracted to traps baited with the attractive blends after 3 hr. This was probably because of very rapid release of the chemicals, as temperatures in sunlight reached 37°C, and it had previously been shown that microcapillaries loaded with (*E*)-4-oxo-2-hexenal contained little material after 3 hr in the field (Aldrich et al., 1993).

Pheromone Plume Structure. The importance of pheromone plume structure in source location by Lepidoptera has been well established (e.g., Mafra-Neto and Carde, 1997). Thus, the greater success using microcapillary tubes (with an i.d. 0.6 of mm) may result from them producing more effective point source emissions than the relatively diffuse plumes created by sachets and vials. This may be particularly important where two or more dispensers are used for different components of the blend. Todd and Baker (1999) have shown that plumes from different dispensers can remain separate for distances of several meters downwind, so adjacent capillaries may provide a better approximation to a single plume than adjacent vials or sachets.

However, if this point-source emission is important, then it is necessary to reconsider release rate in terms of the concentration of material in the turbulent plume (Murlis and Jones, 1981) as this will influence the insect's behavioral responses (Mayer et al., 1987). The glass microcapillaries have an emission surface area of approximately 0.25 mm^2 at each end, compared with 650 mm^2 for the polyethylene vials and 1250 mm^2 for the polyethylene sachets used

previously (Innocenzi et al., 2004). Assuming pheromone is released uniformly over the dispenser surface, then using the data from Innocenzi et al. (2004), the surface release rates of butyrate esters and (*E*)-4-oxo-2-hexenal would have been 0.24 and 0.01 μg/hr/mm^2, respectively, from the polyethylene vials and 1.2 μg/hr/mm^2 each from the polyethylene sachet. Initial release rates of the butyrate esters and (*E*)-4-oxo-2-hexenal from the microcapillary tubes were up to 5 and 10 μg/hr, respectively, equating to 10 and 20 μg/hr/mm^2, respectively. Thus, attraction of *L. rugulipennis* males to the microcapillary dispensers may be the result of point source emission with a high concentration of the pheromone components, which more closely resembles the female insect.

Pheromone Blend. The blend of hexyl butyrate, (*E*)-2-hexenyl butyrate, and (*E*)-4-oxo-2-hexenal released by female *L. rugulipennis* was found to be 1.5:1:0.08 from a single insect and 35:1:2 from four insects (Innocenzi et al., 2004). Release of (*E*)-4-oxo-2-hexenal from the microcapillary tubes was faster than that of the butyrate esters (Figure 1 and Table 1), so the blends used in these experiments would have been different from that produced by the insects. Furthermore, various combinations of vial and sachet dispensers were used in the previous experiments (Innocenzi et al., 2004) so that blends rich in (*E*)-4-oxo-2-hexenal quite similar to those used here would have been tested. Thus, it is unlikely that blend composition accounts for the attractiveness of the microcapillary dispensing system to male *L. rugulipennis*, but clearly, there is considerable scope for optimization of the synthetic blend in relation to that produced by the female.

Microcapillary tubes were used as pheromone dispensers by Kakizaki and Sugie (2001) to attract another mirid species, the rice leaf bug, *Trigonotylus caelestialium*. Release rates were not reported, and dispensers were used for up to 2 wk in the field, although our results show they would have been exhausted within a few days. Rubber septa have also been used as dispensers for the pheromones of other mirid bugs (e.g., Millar et al., 1997; Millar and Rice, 1998; Zhang and Aldrich, 2003a). Interestingly, release of hexyl butyrate (5 mg) from these septa under laboratory conditions was shown to be extremely rapid at first, but dropped to less than 1 μg/hr within 3 d (Innocenzi et al., 2004), comparable to the release rate from the microcapillary tubes.

Whereas (*E*)-2-hexenyl butyrate is produced by *L. rugulipennis*, adding it to the blend of hexyl butyrate and (*E*)-4-oxo-2-hexenal suppressed the attraction of male *L. rugulipennis*. However, this three-component mixture was significantly more attractive to males of the congeneric species, *L. pratensis*. Catching such high numbers of *L. pratensis* was unexpected as this species had not been recorded at East Malling in several years prior to the trials (Easterbrook, 1997, personal communication). Nothing is known about pheromone components produced by female *L. pratensis*, but trapping results suggest an interspecific role for (*E*)-2-hexenyl butyrate between *L. pratensis*

and *L. rugulipennis* that merits further investigation, especially as Glinwood et al. (2003) reported that (*E*)-2-hexenyl butyrate alone attracted *L. rugulipennis* males in an olfactometer.

The above results indicate that hexyl butyrate and (*E*)-4-oxo-2-hexenal are components of the female sex pheromone of *L. rugulipennis*, and the synthetic compounds attract significant numbers of males when dispensed from glass microcapillary tubes. To the best of our knowledge, this is the first report of males of a *Lygus* species being attracted to synthetic components of the female sex pheromone in the field. However, female-baited traps were not used in these preliminary trials, and only a limited range of blends was tested. Thus, it is not possible to say whether these are the only components of the pheromone or what is the optimum blend. Future work will determine the optimal ratio of hexyl butyrate and (*E*)-4-oxo-2-hexenal for attraction of *L. rugulipennis* males, and the role of (*E*)-2-hexenyl butyrate produced by the females will be investigated. The criteria for attractive dispensing systems will also be defined and more practical dispensers will be developed which have a longer field life than the microcapillary tubes. In addition, the trap design must be improved as we often observed that males alighting were able to escape from the sticky surface.

(Received September 22, 2004; revised December 16, 2004; accepted February 17, 2005)

Abstract—Olfactometer bioassays showed that odors from mature *Thyanta perditor* males attracted females but not males. Furthermore, odors from females did not attract either sex, indicating that like other phytophagous pentatomid bugs, the males produce a sex pheromone. Attraction appeared to peak in late afternoon to evening. The headspace volatiles collected from male and female *T. perditor* were analyzed by GC-MS and HPLC. A male-specific compound, methyl (2*E*,4*Z*,6*Z*)-decatrienoate (2*E*,4*Z*,6*Z*-10:COOMe), was identified along with a number of other compounds found in extracts from both sexes. Bioassays carried out with 2*E*,4*Z*,6*Z*-10:COOMe showed it was as attractive to females as the crude extract of male volatiles, suggesting that the male-produced sex pheromone consists of 2*E*,4*Z*,6*Z*-10:COOMe as a single component. Consecutive volatiles collections from males showed that 2*E*,4*Z*,6*Z*-10:COOMe began appearing in extracts from males about 9 d after the final molt, as the males became sexually mature.

Key Words—Sex pheromone, methyl (2*E*,4*Z*,6*Z*)-decatrienoate, defensive compounds.

INTRODUCTION

Soybean, *Glycine max* (L.) Merrill, an important food and forage crop, is susceptible to attack by a variety of phytophagous Hemiptera (Turnipseed and Kogan, 1976; Kogan and Turnipseed, 1987; Jackai et al., 1990; Sediyama et al.,

* To whom correspondence should be addressed. E-mail: mborges@cenargen.embrapa.br

1993). Soybean is a relatively new crop in the tropics, but the endemic insect fauna have adapted rapidly to feeding on this plant (Panizzi and Corrêa-Ferreira, 1997). In Brazil, more than 30 species of hemipterans are associated with the soybean crop, with several reaching significant pest status (Panizzi and Corrêa-Ferreira, 1997). The most damaging include *Nezara viridula* (L.), *Euschistus heros* (F.), and *Piezodorus guildinii* (Westwood) (Panizzi and Slansky, 1985; Panizzi and Rossi, 1991), whereas others such as *Acrosternum aseadum* (Rolston) and *Thyanta perditor* (F.) are of lesser importance (Panizzi and Slansky, 1985). More than 4×10^6 l of insecticides are used annually to control stink bugs on soybean in Brazil (Corrêa-Ferreira and Moscardi, 1996). Alternatives, such as the exploitation of semiochemicals in the monitoring and control of these pests, might contribute to a more ecologically benign approach to their management.

Male-produced sex or aggregation pheromones have been identified for several species in the soybean stink bug complex in the last two decades (Aldrich et al., 1987, 1991, 1993, 1994; Baker et al., 1987; Borges et al., 1987, 1998a,b; Borges and Aldrich, 1994; Borges, 1995; Zhang et al., 2003). Two nearctic *Thyanta* species, *T. pallidovirens* and *T. custator accerra* (Millar, 1997; McBrien et al., 2002), use methyl (2*E*, 4*Z*, 6*Z*)-decatrienoate (2*E*,4*Z*,6*Z*-10:COOMe) and the three sesquiterpenes (+)-α-curcumene, (−)-zingiberene, and (−)-β-sesquiphellandrene as a male-produced sex pheromone blend. The congeneric neotropical species, *T. perditor*, is part of the stink bug complex attacking soybeans in Brazil, as well as other crops such as wheat and sorghum (Gomez, 1980; Grazia et al., 1982; Busoli et al., 1984; Panizzi and Corrêa-Ferreira, 1997). As part of our ongoing studies of semiochemicals of economically important stink bugs in Brazil, we initiated an investigation of the pheromone of this species. Our specific objectives were (1) to determine whether the stink bug *T. perditor* produces a sex pheromone, similar to those of its two nearctic congeners, *T. custator accerra* and *T. pallidovirens*, and if so, (2) to identify the chemical structure(s) of the biologically active compound(s). During these investigations, we also identified several defensive compounds from adult bugs of both sexes.

METHODS AND MATERIALS

Insects. T. perditor individuals were obtained from a laboratory colony started from adults collected from soybean fields during 2002/2003 near Embrapa Genetic Resources and Biotechnology Laboratory in Brasilia, DF, Brazil (15°47′S, 47°55′W). They were reared in 5-l containers on raw peanuts (*Arachis hypogaea*) and soybean (*Glycine max*) seeds, fresh green beans (*Phaseolus vulgaris*), boldo (*Plectranthus barbatus*) stalks, and water, at 26 ±

1.0°C and 65% ± 10% relative humidity under a 14:10 light/dark photoperiod (from 0600 to 2000 hr). The food supply was renewed three times per week. A square of plastic mesh (~40 mesh, 15-cm^2) was placed against an inner wall of each container as an oviposition substrate and shelter for the bugs. Egg masses were collected daily and incubated in 9-cm ID plastic Petri dishes until they hatched. When the resulting nymphs molted into second instars, they were transferred to plastic containers and reared as above.

To prevent interactions between the sexes, males were separated from females after cuticular hardening, ca. 24 hr after their imaginal molt. For all experimental bioassays, sexually mature adults, 9 d after the final molt, were used.

Collection of Volatiles. Volatiles were collected from groups of 20 male or female *T. perditor* (N = 13) in 1-l glass containers (Zhang et al., 1994) by drawing air through 6-14-mesh activated charcoal (Fisher Scientific, Pittsburgh, PA, USA), and out through two traps (15 cm × 1.5-cm OD) containing Super Q (200 mg each; Alltech Associates Inc., Deerfield, IL, USA) by vacuum (~1 l/min). Two traps in series were used to check for breakthrough of the volatiles being collected. Collection of volatiles from male and female bugs was started when they were 5 d old and bugs were aerated continuously for 15 d, changing adsorbent traps daily. This provided a continuous series of extracts reflecting the volatiles produced by adult bugs both before and after sexual maturation. Bugs in aeration chambers were fed with fresh green beans (replaced weekly). The adsorbent traps were eluted with hexane (4 × 0.5 ml), and the four resulting aliquots were combined and stored at −30°C until needed for analysis or bioassays.

Additional material for bioassays and analysis were obtained from aerations of groups of approximately 80 sexually mature, virgin individuals of each sex (N = 20) for periods of 15 consecutive d. The resulting daily extracts were concentrated under N_2 to yield a concentration of approximately 0.1 bug day equivalent (B.E.)/μl of solution for bioassays. For quantitative analysis, the volume of the extract was reduced to ~200 μl and an internal standard [40 ng (*E*)-2-decenyl acetate in 40 μl of hexane] was added to the solution.

Analysis and Fractionation of Extracts. The total and fractionated extracts were analyzed by gas chromatography (Perkin-Elmer GC; DB-1 column, 30 m × 0.25 mm ID, 0.25 μm film; J&W Scientific, Folsom, CA, USA), using a temperature program of 50°C/2 min, 15°C/min to 250°C. Data were collected with Autosystem Software in ASCII format and processed using Origin 5.0 (Microcal Software). Mass spectra were obtained with a Varian Saturn 2000 mass spectrometer interfaced to a Varian 3800 GC (DB-5 column, 30 m × 0.25 mm ID, 0.25 μm film; J&W Scientific). Crude extracts were also analyzed using a DB-5 column (30 m × 0.25 mm ID, 0.25 μm film thickness) at the University of California, Riverside, on a Hewlett-Packard 6890 GC interfaced to an H-P

5973 mass selective detector, using electron impact ionization (70 eV). The temperature program was 40°C/1 min, 10°/min to 250°C, injector temperature 250°C, and transfer line 280°C.

An extract of 80 mature virgin males in 1 ml of hexane was fractionated as described by McBrien et al. (2002). A column (0.5 cm ID × 6.0 cm long) with 500 mg of silica gel (80/100 mesh, Merck, Germany) was conditioned by eluting with 6 ml 25% ether in hexane followed by 6 ml hexane. The extract was loaded onto the column, which was then eluted sequentially with 3 × 2 ml hexane, and 3 × 2 ml ether, collecting each aliquot as a separate fraction. Hydrocarbons eluted in the first hexane fraction, whereas more polar esters, alcohols, and other compounds eluted in the first ether fraction.

A thermally unstable compound was previously found in the pheromone blend of the nearctic species *T. pallidovirens* (Millar, 1997), and so a crude extract from aeration of male *T. perditor* was analyzed by high-pressure liquid chromatography (HPLC) (Shimadzu) using a reverse-phase column (Lichrosorb RP-18, 250 × 4.6 mm, 5 μm particle size) eluted with 1:1:1 CH_3CN:CH_3OH:H_2O. The eluent was monitored at 300 nm with a diode array detector.

To determine the number of double bonds in the thermally unstable male-specific compound, a 20-μl aliquot of the crude extract in hexane was reduced in an H_2 atmosphere with 10% Pd on activated charcoal catalyst in a conical vial, stirring for 1 hr. The resulting mixture was filtered through a 1-cm plug of cellite, rinsing with pentane. The filtrate was analyzed by GC-MS.

Some of the insect-produced components from both sexes of *T. perditor* were tentatively identified by comparison of their GC retention times and mass spectral data with library data (NIST-Wiley database, 2000) with those of authentic standards. The only exception was α-ocimene, for which a standard was not available. All standards were obtained from Aldrich Chemical Co., with the exception of undecane (Matheson, Coleman, and Bell, Cincinatti, OH, USA), and tridecane and pentadecane (K&K Laboratories, Cleveland, OH, USA). The identification of the *T. perditor* male-specific ester was confirmed by comparison with authentic standards of 2*E*,4*Z*,6*Z*-10:COOMe and its isomers, available from previous studies on *T. pallidovirens* (Millar, 1997; McBrien et al., 2002).

Olfactometer Bioassays. Bioassays were carried out using a Y-shaped olfactometer, modified from Collaza et al. (1999) and consisting of an acrylic block (27.5 × 21.2 × 1.5 cm) in which a 2.0-cm-wide Y-shaped slot had been milled. The two arms of the Y were 10.3 cm long with a 45° angle between them. A 4.0-cm-diameter circle was cut out at the end of the 11.5-cm-long third leg of the olfactometer as a release chamber for the bug to be tested. A hole (0.5 cm ID) was drilled through the end of the slab into each arm to allow attachment of air lines. The end of the release chamber was perforated with two

holes, one of 0.5-cm diameter as an air outlet, and another in a rectangular shape (1.7 × 1.2 cm) to introduce test insects into the release chamber. The olfactometer block was placed on top of a translucent glass plate, and the upper surface was covered with transparent glass, with the glass plates held in place with large paper clips. Charcoal-filtered, humidified air was drawn through the system at a flow rate of 800 ml/min (regulated by flow meters, Accura Flow Products Div., Advanced Controls Engineering Corp., Hatboro, PA, USA). The olfactometer was surrounded with a black curtain to exclude external light and was illuminated from below by infrared lamps (homogenous emission of light at 950 nm provided by a panel of 108 light-emitting diodes) and from above with four 40-W fluorescent lamps. The temperature in the bioassay room was maintained at 26.0 ± 1.0°C. The insect behavior was monitored from above using a monochrome CCD video camera (Sony SPT M324CE) fitted with a 12.5–75 mm/F1.8 zoom lens interfaced to a personal computer. A video frame grabber digitized analog video signals from the camera, and "Xbug" software (Colazza et al., 1999) was used to process the data.

A single *T. perditor* was gently introduced into the release chamber of the Y tube with the aid of a artist's paint brush (Camel Hair, number 1) and allowed to acclimatize for a short period (ca. 3 min). Then it's pattern of movement (response) was recorded for 15 min/replicate. The first choice of the insect was recorded, i.e., the arm of the olfactometer into which a bug walked up at least 5 cm past the Y junction and remained there for at least 100 sec. The positions of control and treatment arms were alternated every five replicates. The chambers with the treatments consisted of two 10-ml syringes, one each for treatment and control, and were connected to the upwind side of the treatment and control arms, respectively. The apparatus was cleaned with fragrance-free liquid soap, rinsed thoroughly with water, and dried after each five replicates.

Determination of the Pheromone-Producing Sex. The attraction of mature adults of both sexes to odors emitted by five live males or females was tested against a clean air control. The live insects used as an odor source were changed each 10 replicates.

Determination of Period of Maximum Activity. Bioassays were carried out to determine the period of maximum pheromone-mediated activity, using five live male bugs as a pheromone source, with individual, sexually mature, female bugs as the test subjects. The males were replaced every 10 replicates. For this experiment, the following periods were designated: morning (M, 0800–1100 hr), early afternoon (EA, 1200–1500 hr), late afternoon (LA, 1600–1800 hr), and evening (E, 1900–2100 hr). A minimum of 74 individuals were tested during each time period and the number attracted to the pheromone source was recorded.

Bioassays with Insect Extracts and Synthetic Compounds. The Y-tube bioassay was used to compare the biological activity of crude male extracts,

fractions of extracts, and synthesized standards, with the solution of test stimulus [one bug day equivalent (BE) of extract or fraction] being spotted on a strip of filter paper (1.5 × 0.5 cm). Controls consisted of filter papers treated with hexane. Only sexually mature virgin females (>9 d old) were tested in these bioassays, which were carried out during the late afternoon and evening period.

Thirty bioassays were carried out with a crude extract obtained from a 24-hr aeration of 20 male bugs. The extract contained approximately 4 μg of 2*E*,4*Z*,6*Z*-10:COOMe. Hexane and ether fractions of an extract from males were tested vs. a hexane control ($N = 16$), and 20 and 14 replicates of the ether and hexane fractions, respectively, were assayed vs. the crude male extract. The ether fraction was also compared to the hexane fraction ($N = 34$). Finally, bioassays tested the responses of *T. perditor* females to synthetic 2*E*,4*Z*,6*Z*-10:COOMe vs. a hexane control ($N = 45$).

Statistical Analyses. Data from experiments comparing females' responses during different times of the day were analyzed using Kruskal–Wallis ANOVA and Dunn's test. Data on the number of responses of males and females to different treatments (live insects, aeration extracts and fractions thereof, and synthetic compounds, vs. controls) were analyzed using chi-square tests. Statistical analyses were carried out using MathCAD 2001.

RESULTS

Bioassays with Live Insects. Female bugs were attracted to odors from live mature males ($\chi^2 = 18$, $N = 32$, $P < 0.001$) but not to those of mature females ($\chi^2 = 0.25$, $N = 20$, $P = 0.62$) (Figure 1). Males were not attracted to odors of either sex (male: $\chi^2 = 0.29$, $N = 20$, $P = 0.58$; female $\chi^2 = 1.32$, $N = 20$, $P = 0.25$) (Figure 1). The attraction of females to males was highest in the afternoon/evening ($H = 8.60$, $df = 3$, $P = 0.035$; Dunn's test, $P < 0.05$) (Figure 2), indicating that females were most responsive and/or that production of pheromone by males was highest during this period.

Chemical Analyses of Insect Extracts. Comparisons of extracts from both sexes by GC and GC-MS analyses showed one large male-specific compound that was only seen in sexually mature individuals and was produced at a rate of about 200 ng/d, in addition to several compounds that were common to both sexes (Figure 3). Most of the components in the extracts were identified as α-pinene (**1**), β-pinene (**2**), α-ocimene (**3**), (*E*)-2-octenal (**4**), (*E*)-2-octen-1-ol (**5**), undecane (**6**), nonanal (**7**), dodecane (**8**), (*E*)-2-decenal (**9**), tridecane (**10**), and pentadecane (**12**). Most of these compounds are typical components of stink bug defensive secretions (e.g., Borges and Aldrich, 1992).

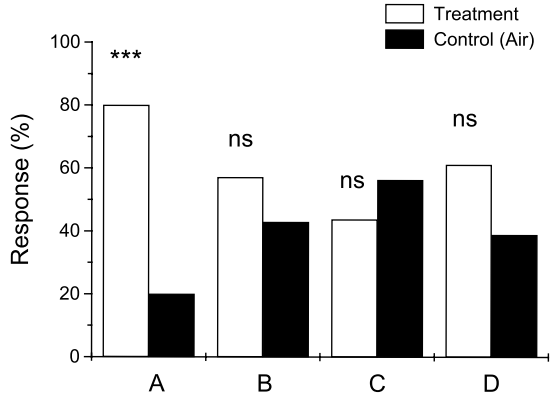

FIG. 1. Proportion of mature *T. perditor* males and females responding in a Y-olfactometer to different treatments vs. solvent controls: (A) Females' response to odors of live males. (B) Females' response to odors of live females. (C) Males' response to odors of live males. (D) Males' response to odors of live females. ***$P < 0.001$; ns, not significantly different (chi-square test).

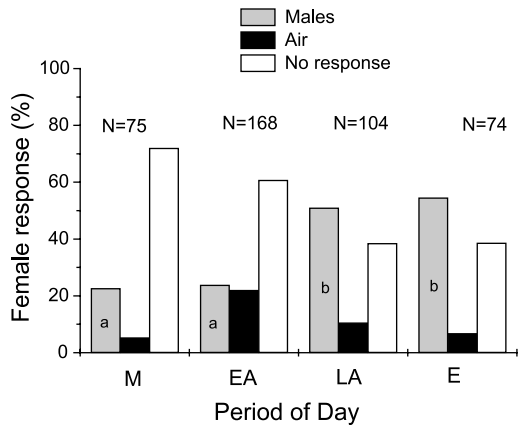

FIG. 2. Response of mature *T. perditor* females to odors of live males during different periods of the day in laboratory bioassays. The photophase in the laboratory was divided into four periods: "morning" (M), from 0800 to 1100 hr; "early afternoon" (EA), from 1200 to 1500 hr; "late afternoon" (LA), from 1600 to 1800 hr; and "evening" (E), from 1900 to 2100 hr. Response bars followed by the same letters are not statistically different (Kruskal–Wallis ANOVA and Dunn's test, $P < 0.05$).

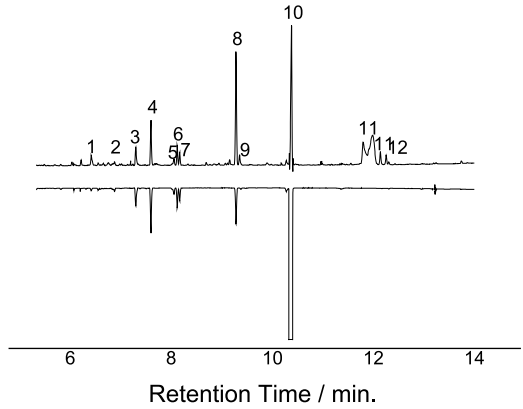

FIG. 3. Gas chromatograms of volatiles collected from live male (top) and female (bottom, inverted) *T. perditor*: **1**, α-pinene; **2**, β-pinene; **3**, α-ocimene; **4**, (*E*)-2-octenal; **5**, (*E*)-2-octen-1-ol; **6**, undecane; **7**, nonanal; **8**, dodecane; **9**, (*E*)-2-decenal; **10**, tridecane; **11**, distorted peak from thermal decomposition of methyl (2*E*,4*Z*,6*Z*)-decatrienoate; **12**, pentadecane.

The male-specific compound (**11**) gave a broad, irregularly shaped peak, suggestive of a thermally unstable compound (Figure 3). The mass spectrum of the unknown showed a distinct molecular ion of *m*/*z* 180 (M^+) and fragments at [*m*/*z* (abundance)] 149 (12), 133 (5), 120 (20), 105 (70), 91 (100), 79 (60), 74 (16), 65 (16), 39 (28) (Figure 4). The presence of fragments at *m*/*z* 105 and 74 suggested McLafferty rearrangement of a methyl ester and the fragments at *m*/*z* 148 and 149 (M^+-32, loss of CH_3OH, and M^+-31, loss of CH_3O, respectively) also indicated a methyl ester (Figure 4). The relatively low intensity of the *m*/*z* 74 ion suggested that the compound might be unsaturated at C_α and C_β or C_γ and C_δ. The molecular weight of 180 amu and the presence of a methyl ester resulted in a possible molecular formula of $C_{11}H_{16}O_2$, corresponding to three double bond equivalents once the ester carbonyl was accounted for. Experiments were carried out to determine the number, position, and stereochemistry of the double bonds. First, an aliquot of the crude extract was hydrogenated, resulting in the disappearance of the irregularly shaped, male-specific peak, and the appearance of a new peak, readily identified as methyl decanoate (*m*/*z* 186 amu) by comparison with an authentic standard, confirming that the insect-produced compound consisted of an unbranched chain with three carbon–carbon double bonds. HPLC analysis of the crude extract using a diode array detector showed that the unknown peak with *m*/*z* 180 amu comprised a single component with a UV absorption maximum at 300 nm, with the position of the absorbance proving that all three double bonds had to be conjugated with the ester carbonyl

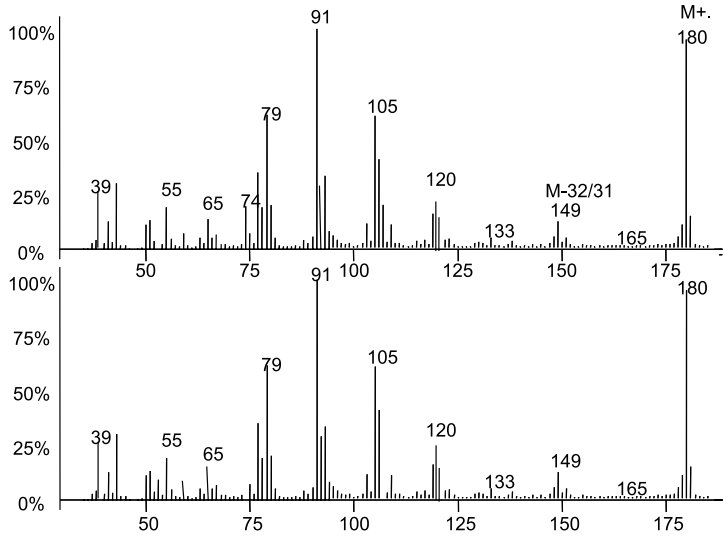

FIG. 4. Mass spectra of the naturally occurring ester in the male volatiles (top) and a synthetic standard of methyl (2*E*,4*Z*,6*Z*)-decatrienoate (bottom).

(Millar, 1997), that is, a methyl 2,4,6-decatrienoate isomer. Comparison of the GC retention time and peak shape, and the mass spectrum (Figure 4) of the unknown peak with those of the (2*E*,4*E*,6*E*)-, (2*E*,4*Z*,6*E*)-, (2*E*,4*E*,6*Z*)-, and (2*E*,4*Z*,6*Z*)-isomers of methyl (2,4,6)-decatrienoate resulted in matches only with the last compound. Furthermore, 2*E*,4*Z*,6*Z*-10:COOMe was the only isomer that was thermally unstable, apparently rearranging upon heating via a 1,7 sigmatropic hydrogen shift (Millar, 1997). Thus, the male-produced compound was identified as 2*E*,4*Z*,6*Z*-10:COOMe, identical to the compound produced by the congeneric *T. pallidovirens* (Millar, 1997; McBrien et al., 2002).

Bioassays with Insect Extracts. T. perditor females chose the treatment arm with the crude extract of males significantly more often than the hexane control arm ($\chi^2 = 6.13$, $N = 30$, $P = 0.013$) (Figure 5A). Whereas the hexane fraction was no more attractive than the hexane control ($\chi^2 = 0.11$, $N = 16$, $P = 0.74$) (Figure 5B), the ether fraction containing 2*E*,4*Z*,6*Z*-10:COOMe was ($\chi^2 = 3.84$, $N = 16$, $P = 0.045$) (Figure 5C). The ether fraction was more attractive than the hexane one ($\chi^2 = 5.76$, $N = 34$, $P = 0.016$) (Figure 5D) and equivalent to the crude extract ($\chi^2 = 0.053$, $N = 20$, $P = 0.82$) (Figure 5E), whereas the crude extract was more attractive than the hexane fraction ($\chi^2 = 0.807$, $N = 14$, $P = 0.005$) (Figure 5F). In a final bioassay, synthetic 2*E*,4*Z*,6*Z*-10:COOMe proved to be highly attractive, with 90% of the females choosing the arm with this stimulus ($\chi^2 = 15.51$, $N = 45$, $P < 0.001$) (Figure 5G).

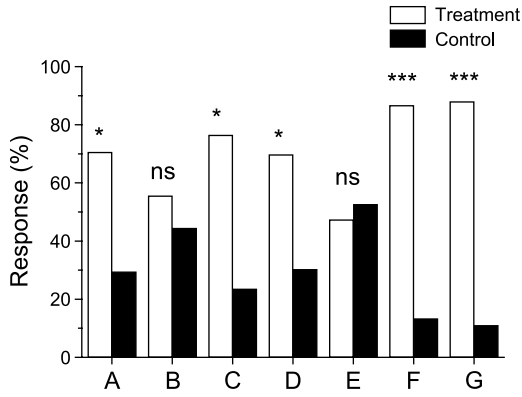

FIG. 5. Response of mature *T. perditor* females in the Y-tube olfactometer to different treatments and controls. In all cases, the first treatment mentioned is the open bar, and the second treatment (control) is the solid bar. (A) Crude aeration extract of male-produced volatiles vs. hexane. (B) Hexane fraction of a crude extract vs. hexane. (C) Ether fraction of a crude extract vs. ether. (D) Ether fraction of a crude extract vs. hexane fraction of the extract. (E) Crude aeration extract of male-produced volatiles vs. the ether fraction of the extract. (F) Crude aeration extract of male-produced volatiles vs. the hexane fraction of the extract. (G) 4 μg of synthetic methyl (2*E*,4*Z*,6*Z*)-decatrienoate in hexane vs. hexane (*$P < 0.05$, ***$P < 0.001$); ns, not significantly different.

DISCUSSION

Bioassays using all combinations of live insects as odor sources and responders showed that females were attracted to odors of male bugs, but that no other combination of odor and test subject produced significant attraction. These results indicated that male *T. perditor* produce a sex pheromone, analogous to the congeneric *T. pallidovirens* and *T. custator accerra* (McBrien et al., 2002).

Maximum attraction of males to females occurred during the afternoon/evening, similar to the peak response period of the stink bug *E. heros* (Borges et al., 1998b). In contrast, other pentatomids such as *N. viridula* (Borges et al., 1987) and *E. obscurus* (Borges and Aldrich, 1994) appear to exhibit no periodicity of response throughout the photophase. The reason for the differences in activity patterns between these species is unclear, but because they often share hosts and habitats temporal separation may play a role in maintaining interspecific reproductive isolation.

Our results suggest that the sex pheromone of *T. perditor* consists of only 2*E*,4*Z*,6*Z*-10:COOMe, one component of the sex pheromones of the nearctic congeners *T. pallidovirens* and *T. custator accerra,* (McBrien et al., 2002).

2*E*,4*Z*,6*Z*-10:COOMe alone attracted neither of these species and required at least one of the three sesquiterpenes, (+)-α-curcumene, (−)-zingiberene, and (−)-β-sesquiphellandrene, produced by the males (McBrien et al., 2002), but none of these sesquiterpenes were present in aeration extracts from *T. perditor.* The phenomenon of shared pheromone components appears to be common in the family Pentatomidae. For example, Aldrich et al. (1991) reported that methyl (2*E*,4*Z*)-decadienoate was a major male-specific component of volatiles produced by several *Euschistus* species. Pheromonal parsimony has also been seen with *N. viridula* and several *Acrosternum* species, all of which produce bisabolene epoxide pheromone components (Aldrich et al., 1993). *P. guildinii* and *E. heros* (Borges et al., 1999) also have methyl-2,6,10-trimethyltridecanoate as a shared component in their pheromones.

The reasons for the comparative simplicity of the pheromone of *T. perditor* relative to its congeners are not immediately apparent and merit further attention. Although they share many host plants, such as soybeans, this may be a relatively recent and, thus, a misleading "ecological" artefact resulting from man's introduction of exotic crop plants into new habitats rather than the evolution of species-specific communication systems. Furthermore, although *T. perditor* is now sympatric with *T. pallidovirens* and *T. curstator accerra* in Florida (Panizzi et al., 2000), it is of tropical origin (Panizzi et al., 2000), whereas the two neartic congeners are restricted to the western and southern United States (Schotzko and O'Keefe, 1990).

The defensive compounds identified in the headspace volatiles from adults of both sexes of *T. perditor*, such as (*E*)-2-octenal, (*E*)-2-decenal, nonanal, tridecane, and undecane, have been reported previously from other stink bug species (Borges and Aldrich, 1992), although (*E*)-2-decenal and nonanal were only observed in the male volatiles. In addition, both genders released some compounds that have been less commonly reported from stink bug airborne collections, such as α-pinene and β-pinene. These compounds are clearly insect-produced and not from the diet, because extracts of exuvia and metathoracic glands of both sexes contain these compounds. The specific functions of these compounds remain to be determined.

In summary, our results have shown that female *T. perditor* are attracted to 2*E*,4*Z*,6*Z*-10:COOMe, a pheromone released by sexually mature males of this species Because female bugs were strongly attracted to synthetic 2*E*,4*Z*,6*Z*-10:COOMe in laboratory bioassays, future efforts will focus on determining whether this compound can be exploited as an effective and selective trap bait for monitoring this stink bug species.

Acknowledgments—We thank Hélio Santos, Diva Tiburcio, and Josiane de Souza Rodrigues for helping with field collection and laboratory rearing of the insects. This work received financial support from CNPQ and EMBRAPA. We also thank Peter W. Inglis (visiting scientist at Embrapa Genetic Resources and Biotechnology) for reviewing the manuscript.

(Received June 30, 2004; accepted February 17, 2004)

Abstract—The sex pheromones of four Plusiinae species in the family Noctuidae, *Ctenoplusia albostriata* (CA), *Macdunnoughia purissima* (MP), *Syngrapha ain* (SA), and *Diachrysia stenochrysis* (DS) were identified by GC-EAD and GC-MS analyses. These were subsequently evaluated by a series of field trials in different ecological habitats. CA females produced (*Z*)-5-decenyl acetate (**I**), (*Z*)-7-dodecenyl acetate (**II**), and (*Z*)-7-dodecen-1-ol (**III**) in a ratio of 2:100:13. While the antennae of CA males responded to all three components, neither **I** nor **III** was essential to capture males. The MP females produced **II**, **III**, and (*Z*)-5-dodecenyl acetate (**IV**) in a ratio of 100:80:20, and this blend captured the most MP males. Compounds **II** and **III** were also identified from SA females, and mixtures ranging from 4:1 to 2:3 were equally attractive to males. DS females only produced one active compound, (*Z*)-7-decenyl acetate (**V**), and DS is the first Plusiinae species identified as using only the ω3-compound and none of ω5-compounds, such as **II** and **III**, which are common components of Plusiinae pheromones. Using previously published chemical and biosynthetic data, together with the finding from this study, we propose a classification of the Plusiinae sex pheromones.

Key Words—Sex pheromones, Lepidoptera, Noctuidae, Plusiinae, male attractants, monoenyl acetate, GC-EAD, GC-MS.

INTRODUCTION

The Plusiinae is a major subfamily in Noctuidae, comprising more than 400 species worldwide (Nomura, 1998). They are found from the tropics to the arctic, with many occurring in grasslands. The first sex pheromone reported in the Plusiinae was (*Z*)-7-dodecenyl acetate (Z7-12:OAc) from *Trichoplusia ni* females (Berger, 1966). Subsequently, 18 other species have been investigated (Ando, 2005; El-Sayed, 2005; Witzgall et al., 2004), and Z7-12:OAc is a pheromone component in 60% of species in Plusiinae subfamily studied to date (Ando et al., 2004).

There are 59 species from this subfamily found in Japan, one third of which are considered as pests of crops (Ichinose, 1962). Our research group has examined the pheromones of several important grassland species, i.e., *Plusia festucae* (Ando et al., 1995), *Thysanoplusia intermixta* and *Thysanoplusia orichalcea* (Ando et al., 1998), *Anadevidia peponis* (AP) and *Macdunnoughia confuse* (Inomata et al., 2000), and while they produce species-specific blends, Z7-12:OAc is a pheromone component in the latter four species. However, a pheromone blend of AP also attracted males of two other species, *Ctenoplusia albostriata* (CA) and *Macdunnoughia purissima* (MP) that occur in the same habitat (Inomata et al., 2000). In the present study, we examined the sex pheromones of CA and MP, as well as those produced by *Syngrapha ain* (SA) and *Diachrysia stenochrysis* (DS), two Plusiinae that occur in mountainous habitats, as little attention has been given to the pheromones of non-pestiferous species. Using the results of this study, together with previously published information, we discuss the diversity of Plusiinae pheromone chemistry and classify the Japanese species according to the biosynthetic pathways used to produce their key pheromone components.

METHODS AND MATERIALS

Insects and Pheromone Extracts. Laboratory colonies of CA and MP were established using adults on flowers of *Abelia grandiflora* near the vegetable fields of the Tokyo University of Agriculture and Technology (Fuchu, Tokyo). Larvae of CA were reared on fresh leaves of *Erigeron annuus*, and those of MP on an artificial diet [Insecta LF(S), Nippon Nosan Kogyo Co., Yokohama, Japan] mixed with dry powder of *Artemisia princeps* (5% w/w). Colonies of DS were set up, using adults captured in a black light trap run in a highland forest (Yunomaru-kogen, Nagano Prefecture) and larvae maintained on the same diet for MP. Colonies were reared at 25°C under a 16L:8D photoperiodic regime, and an extract for each species was obtained by soaking >100 pheromone glands, excised from 2- to 3-d-old female moths in the middle of the scotophase,

in hexane for 15 min. In the case of SA, a laboratory colony was not established and the extracts were obtained from 15 females captured with a black light trap at the same highland forest site as DS. Their glands were excised at the same time in the scotophase as the other species.

Chemicals. Monoenyl compounds with purity levels greater than 98%, supplied by Shin-Etsu Chemical Co. (Tokyo, Japan), were used as authentic standards for the analyses of natural pheromones and as lures for the field attraction of male moths. The chemical structures of pheromone components and related compounds are abbreviated in the same manner as in databases published on internet web sites (Ando, 2005; El-Sayed, 2005; Witzgall et al., 2004).

GC-EAD Analyses. Responses of male antennae to conspecific pheromone gland extracts were measured by GC-EAD (Struble and Arn, 1984) using an HP-6890 gas chromatograph (Hewlett-Packard, Wilmington, DE, USA) with a DB-23 capillary column (0.25 mm × 30 m, 0.25 μm; J & W Scientific, Folsom, CA, USA). The carrier gas was helium. The oven temperature was maintained at 80°C for 1 min, then heated at rate of 8°C/min up to 210°C, where it was maintained for 10 min. The effluent from the column was split equally into two lines, one leading to a flame ionization detector (FID) and the other to the EAD. An antenna was excised at the base from the corresponding male, and a few distal segments were cut off. *Bombyx mori* saline was used for the electrodes, and airflow (7.8 cm/min) carried eluted compounds to the antenna. Each extract was analyzed with at least four antennae cut from different 2- to 3-d-old males from the laboratory colonies. In the case of SA, antennae were obtained from wild males of unknown age, captured in a black light trap.

GC-MS Analyses. Electron impact GC-MS was carried out on a Hewlett-Packard HP5973 mass spectrometer system equipped with a DB-23 capillary column operating with a mass range of *m*/*z* 50–500. The ionization voltage was 70 eV. The ion source temperature was 230°C, and the column temperature program was the same as the GC-EAD analysis of crude pheromone extracts. A crude extract of 30 female equivalents (FE) from each species except for SA was derivatized at 40°C overnight in a mixture of dimethyl disulfide (DMDS) (50 μl) and diethyl ether solution of iodine (60 mg/ml, 5 μl) (Buser et al., 1983; Inomata et al., 2000). DMDS adducts were then analyzed using the following program: 50°C for 2 min, heated at a rate of 10°C/min to 160°C and 4°C/min to 220°C, where it was maintained for an additional 10 min.

Field Tests. Lures were prepared by applying 100 μl of single or multicomponent hexane solution to individual rubber septa (8 mm OD, white rubber; Aldrich), and tested by using sticky traps (Takeda Chemical Ind., Osaka, Japan) set at 1.5 m above ground. The evaluation of CA and MP lures was carried out on a University farm cultivating vegetables in a suburb of Tokyo,

while those for SA and DS were tested at the Nagano Prefecture forest site where adults had originally been collected. The traps were emptied every 2 wk, while the duration of trials and the number of replicates (two or three) varied depending on the species.

RESULTS

Pheromone Components Produced by CA Females. There were three EAG-active components in the CA female gland extract (1 FE, **I**, **II**, and **III** in Figure 1a): 60 μV at retention time (R_t) 9.7 min [Kováts relative index (RI) 1710], 300 μV at R_t = 12.0 min (RI 1920), and 10 μV at R_t = 12.2 min (RI

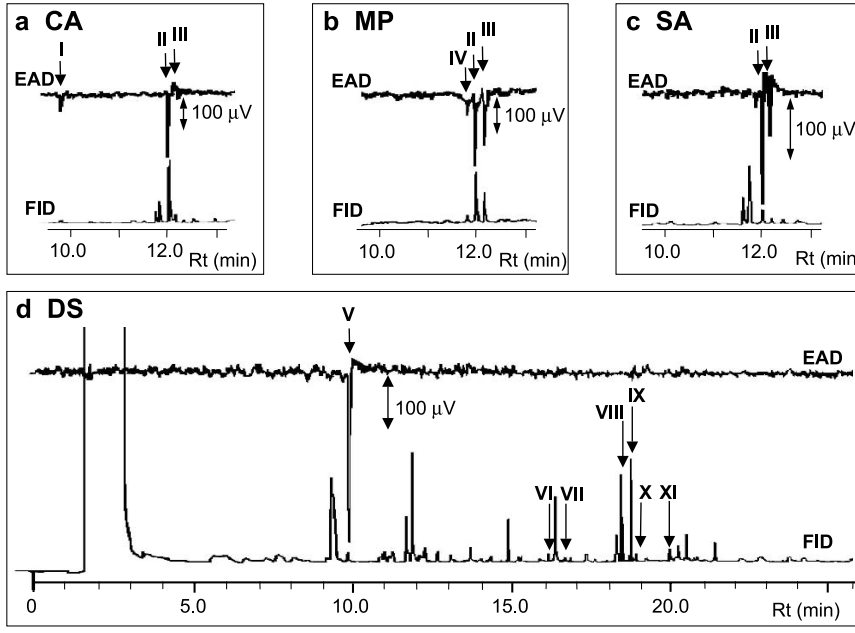

FIG. 1. GC-EAD analysis of the pheromone extract (1 FE) prepared from sex pheromone glands of (a) *Ctenoplusia albostriata* (CA), (b) *Macdunnoughia purissima* (MP), (c) *Syngrapha ain* (SA), and (d) *Diachrysia stenochrysis* (DS). Component **I** = Z5-10:OAc, **II** = Z7-12:OAc, **III** = Z7-12:OH, **IV** = Z5-12:OAc, and **V** = Z7-10:OAc. While the extract of DS females included a C_{10} acetate (**V**) and C_{16}–C_{20} acetates (component **VI** = 16:OAc, **VII** = Z11-16:OAc, **VIII** = 18:OAc, **IX** = Z11-18:OAc, **X** = Z13-18:OAc, and **XI** = 20:OAc), antennae of DS males responded to only **V**.

1930). These values coincided with the R_ts of synthetic Z5-10:OAc, Z7-12:OAc, and Z7-12:OH on the same column and not with the geometrical isomers E5-10:OAc at R_t = 9.5 min (RI 1690), E7-12:OAc at R_t = 11.8 min (RI 1900), and E7-12:OH at R_t = 12.0 min (RI 1920). The identifications were confirmed by comparing the mass spectra values of the components in the crude pheromone gland extract with synthetic standards. The mass spectrum of **I** at R_t = 8.70 min (RI 1706), which shows the largest ion at *m*/*z* 138 indicating $[M\text{-}60]^+$ of decenyl acetate, was almost the same as that of synthetic Z5-10:OAc. The spectrum of **II** at R_t = 11.16 min (RI 1917) with the largest ion at *m*/*z* 166, $[M\text{-}60]^+$ of dodecenyl acetate, and that of **III** at R_t = 11.30 min (RI 1928) with the largest ion at *m*/*z* 166, $[M\text{-}18]^+$ of dodecen-1-ol, coincided with the spectra of synthetic Z7-12:OAc and Z7-12:OH, respectively. A total ion chromatogram (TIC) gave an estimated ratio of 2:100:13 for the three components in the pheromone gland extract (Figure 2a). In addition, the double-bond position of

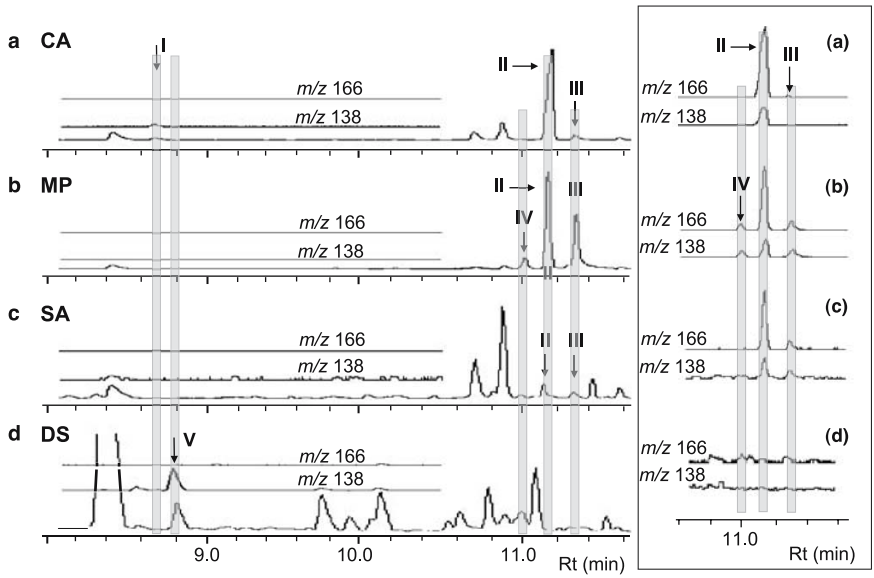

FIG. 2. TIC and mass chromatograms from GC-MS analyses of extracts (1 FE) prepared from sex pheromone glands of (a) *Ctenoplusia albostriata* (CA), (b) *Macdunnoughia purissima* (MP), (c) *Syngrapha ain* (SA), and (d) *Diachrysia stenochrysis* (DS). Component **I** = Z5-10:OAc, **II** = Z7-12:OAc, **III** = Z7-12:OH, **IV** = Z5-12:OAc, and **V** = Z7-10:OAc. Diagnostic fragment ions of the acetates ($[M\text{-}60]^+$) and alcohol ($[M\text{-}18]^+$) were monitored at *m*/*z* 166 for the C_{12} monoenyl compounds and *m*/*z* 138 for the C_{10} monoenyl compound. The mass chromatograms from R_t = 10.6 to 11.6 min are shown separately in the box to the right.

each component was confirmed by a GC-MS analysis of the DMDS derivatized crude pheromone with adducts derived from **I**–**III** showing their diagnostic ions.

Pheromone Components Produced by MP Females. The MP female gland extract (1 FE) showed three EAG-active components (**II**, **III**, and **IV** in Figure 1b) 200 μV at R_t = 12.0 min, 140 μV at R_t = 12.2 min, and 45 μV at R_t = 11.8 min (RI 1900). The first two proved to be Z7-12:OAc and Z7-12:OH, the same as in CA females. However, the third component (**IV**) was a C_{12} straight chain compound with identical chromatographic behavior as Z5-12:OAc but not the geometrical isomer, E5-12:OAc at R_t=11.6 min (RI 1890). GC-MS analysis of the MP extract supported the identification of the three components, which occurred in an estimated ratio of 100:80:20 for Z7-12:OAc, Z7-12:OH, and Z5-12:OAc, respectively (Figure 2b). Figure 3 shows TIC and mass spectra of DMDS adducts of the three C_{12} chain compounds. This measurement revealed the existence of the adducts derived from Z7-12:OAc showing ions at *m*/*z* 117, 203, and 320 [M^+] (Figure 3b), from Z7-12:OH showing ions at *m*/*z* 117, 161, and 278 [M^+] (Figure 3c), and from Z5-12:OAc showing ions at *m*/*z* 145, 175, and 320 [M^+] (Figure 3d).

Pheromone Components Produced by SA Females. GC-EAD analysis of the SA pheromone extract (1 FE) revealed two active components (**II** and **III** in

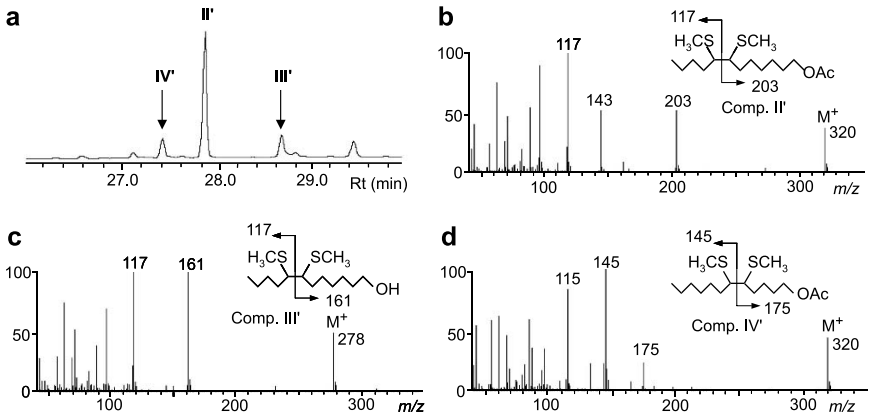

FIG. 3. GC-MS analysis of the pheromone extract of *Macdunnoughia purissima* (MP, 30 FE) treated with DMDS; TIC (a) and mass spectra (b–d) of DMDS adducts; (b) **II′** derived from Z7-12:OAc (R_t = 27.83 min), (c) **III′** derived from Z7-12:OH (R_t = 28.64 min), and (d) **IV′** derived from Z5-12:OAc (R_t = 27.41 min). Each spectrum shows M^+ and some diagnostic fragment ions produced by cleavage of the bond between the sulfur-substituted carbons, indicating the original position of the double bond.

Figure 1c): 160 μV at R_t=12.0 min and 80 μV at R_t=12.2 min. Their R_t and RI values were the same as authentic Z7-12:OAc and Z7-12:OH, and a GC-MS analysis confirmed this identification. The TIC analysis gave an estimated ca. 3:2 ratio of the two components (Figure 2c) but as the gland extract was prepared with a limited number of females of unknown age or mating status, this ratio may have little biological significance.

Pheromone Components Produced by DS Females. Only one compound in the pheromone gland of DS stimulated male antennae (**V** in Figure 1d): 400 μV at an R_t of 9.9 min (RI 1720). The R_t was the same as that of synthetic Z7-10:OAc but different from E7-10:OAc at R_t = 9.7 min (RI 1700). GC-MS analysis of the crude extract gave a mass spectrum at 8.81 min (RI 1720) with the largest ion at *m*/*z* 138, $[M\text{-}60]^+$ of decenyl acetate, that was the same as the synthetic standard (Figure 2d). The DMDS adduct showed the ions at *m*/*z* 89, 203, and 292 $[M^+]$, indicating the double bond at 7-position, which confirmed the identification of the compound as Z7-10:OAc. In addition to this component, GC-MS measurements also indicated the occurrences of six other longer chain (C_{16}–C_{20}) saturated or monoenyl acetates: 16:OAc, Z11-16:OAc, 18:OAc, Z11-18:OAc, Z13-18:OAc, and 20:OAc, with 18:OAc and Z11-18:OAc at very high levels. The ratio of Z7-10:OAc and the six acetates detected in the extract was

MP = *Macdunnoughia purissima*, AP = *Anadevidia peponis*.

[a] Trials, with three traps for each type of lure, were run from October 20 to November 13, 2003 in a field where several vegetable crops were cultivated.

[b] Values within each column followed by a different letter are significantly different at $P < 0.05$ using a Tukey–Kramer test.

2:2:1:15:25:2:3 (Figure 2d). The antennae of DS males, however, scarcely responded to the longer-chain acetates (Figure 1d).

Field Tests in a Vegetable Field. When the three EAG active components isolated from CA females were tested in the field, lures with the major component Z7-12:OAc alone were as attractive to CA males as either the binary (Z7-12:OAc and Z7-12:OH) or tertiary (Z5-10:OAc, Z7-12:OAc, and Z7-12:OH) blends with relative proportions similar to those found in the pheromone gland extracts. Thus, there is no evidence of synergy by the minor components. However, when the concentration of Z5-10:OAc was increased in either the binary or tertiary blend, the numbers of CA males significantly decreased while those of *A. peponis* (AP) increased. In addition, some MP males were attracted to the tertiary blend with the highest concentration of Z5-10:OAc (Table 1), which was not detected in the MP pheromone extract.

CA = *Ctenoplusia albostriata*, AP = *Anadevidia peponis*.

[a] Trials, with three traps for each type of lure, were run from (A) October 6 to November 9,1999, or (B) November 13 to December 18, 2003 in a field where several vegetable crops were cultivated.

[b] Values within each column followed by a different letter are significantly different at $P < 0.05$ using a Tukey–Kramer test.

[c] Lure for AP, which is additionally baited with fourth and fifth components (0.25 mg of Z5-10:OAc and 0.15 mg of Z5-10:OH).

In the 1999 field trial with the three EAG active components (Z7-12:OAc, Z7-12:OH, and Z5-12:OAc) isolated from MP females, MP males were only captured by the lure including the components at the same 100:80:20 ratio found in the pheromone gland extract (Table 2A). This suggests that all components are essential to attract the males. However, while the highest catches were also seen with the tertiary blend in the 2003 field trail, some MP males were caught in traps baited with the binary blend of Z7-12:OAc and Z5-12:OAc (Table 2B). It is of interest to note that the number of MP males captured in traps baited with a five-component lure for AP (Z7-12:OAc, Z7-12:OH, Z5-12:OAc, Z5-10:OAc, and Z5-10:OH) did not differ from those baited with the MP tertiary blend. Thus, Z5-10:OAc and Z5-10:OH are not inhibitory for MP males. These field trials also indicate that significant greater numbers of CA males were captured by lures containing Z7-12:OAc alone or with Z7-12:OH than any of the other lures, with Z5-12:OAc clearly being an inhibitor (Table 2).

Field Tests in a Highland Forest. Significantly more SA males were captured in traps baited with either Z7-12:OAc or Z7-12:OH than in blank traps, but the binary blend was significantly better than either of the single components alone. However, the ratio of the two components in the lure did not significantly influence trap catches (Table 3). None of the lures tested for SA captured DS males. Z7-10:OAc, the only compound isolated from the DS pheromone gland that gave an EAG response, was significantly more effective at catching DS males than other acetates present in the gland extract (Table 4A). The inclusion of Z5-10:OAc, a pheromone component of two other species in the genus *Diachrysia* (Löfstedt et al., 1994), significantly reduced the number

of DS males captured (Table 4B). None of the lures tested for DS captured SA males.

DISCUSSION

Analyses of the pheromone gland extracts (Figures 1–3) and field evaluations. of the components (Tables 1–4) identified the sex pheromones of four more Plusiinae species, *C. albostriata* (CA), *M. purissima* (MP), *S. ain* (SA), and *D. stenochrysis* (DS). Previous trials in a vegetable field had shown male attraction of CA and MP by the synthetic pheromone of *A. peponis* (AP) composed of Z5-10:OAc, Z7-12:OAc, and Z7-12:OH (50:100:10) (Inomata et al., 2000), but this study revealed that their actual pheromones differed from the AP pheromone. The CA pheromone is composed of the same three compounds but is produced at a quite different ratio (2:100:13), while MP females produced another tertiary blend with Z5-12:OAc instead of Z5-10:OAc. SA females from a highland forest produced a binary mixture composed of Z7-12:OAc and Z7-12:OH (3:2). This species is a defoliator of larch (*Larex* spp.), and this identification is the first pheromone from a nonpest Plusiinae species in Japan feeding on woody plants. The pheromone of DS, another species inhabiting the same mountainous habitats, consisted of one component, Z7-

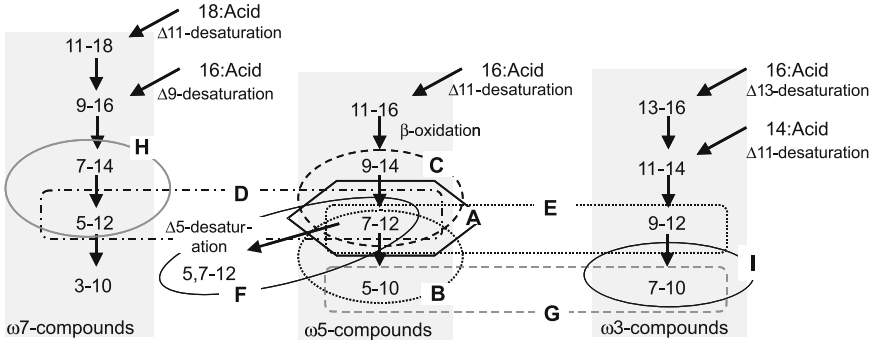

FIG. 4. A proposed classification of Plusiinae pheromones based on their biosynthetic pathways. The species of each group inhabiting Japan are as follows: (A) *Trichoplusia ni* (Berger, 1966), *Autographa gamma* (Dunkelblum and Gothilf, 1983), *Ctenoplusia albostriata* and *Syngrapha ain* (this work), (B) *Anadevidia peponis* (Inomata et al., 2000), (C) *Macdunnoughia confusa* (Inomata et al., 2000), (D) *Autographa nigrisigna* (Sugie et al., 1991) and *Macdunnoughia purissima* (this work), (E) *Chrysodeixis eriosoma* (Benn et al., 1982) and *Ctenoplusia agnata* (Sugie et al., 1990), (F) *Thysanopluia intermixta* and *Thysanopluia orichalcea* (Ando et al., 1998), (G) *Diachrysia chrysitis* (Löfstedt et al., 1994), (H) *Plusia festucae* (Ando et al., 1995), and (I) *Diachrysia stenochrysis* (this work).

10:OAc. Although six other saturated or monoenyl acetates were detected in the pheromone glands, they do not appear to be components of the sex pheromone.

Z7-12:OAc and Z7-12:OH, typical components of Plusiinae pheromones, were found in the pheromone blends of three of the four species, and there is evidence of redundancy for certain components, as reported for other Plusiinae species (Benn et al., 1982; Linn et al., 1984). However, species-specific aspects of the blends would still ensure reproductive isolation between sympatric species, such as CA, MP, and AP that all occur in cultivated fields near Tokyo. CA males respond equally well to lures made up of Z7-12:OAc alone as they do to those with Z7-12:OAc and Z7-12:OH, or the three-component blend Z5-10:OAc, Z7-12:OAc, and Z7-12:OH found in the female gland extract. However, while CA and MP share Z7-12:OAc and Z7-12:OH, the presence of Z5-12:OAc, an essential component for the attraction of MP males, inhibits attraction of CA males (Table 2). It has been shown that Z5-10:OAc may be substituted for Z5-12:OAc in MP lures and still attract males (Inomata et al., 2000). However, Z5-10:OAc must be present at much higher concentrations and at different ratios from those found in CA pheromone glands, so MP males would not respond to the real CA blend (Table 1). Similarly, while males of another sympatric species, AP, are attracted to a blend of the three components produced by the CA females, they respond to a different ratio (Table 1). In

addition, the AP males would not be attracted to MP females, as their pheromone blend lacks Z5-10:OAc.

The two-component Z7-12:OAc and Z7-12:OH blend found in the pheromone gland extract of SA might also attract CA males, although the ratios of compounds in the pheromone glands of the two species are quite different (Tables 1 and 3). There is, however, little likelihood of interbreeding, even if CA males responded to an off ratio, as the two species are not sympatric. DS and SA are sympatric in the forested area in the Nagano Prefecture, but as they share no common pheromone components (Figures 1 and 2), there would be no interspecific attraction (Tables 3 and 4).

The biosynthetic pathways of pheromone production in the Plusiinae have been studied using labeled precursors (Bjostad and Roelofs, 1983; Komoda et al., 2000) and at the molecular level (Knipple et al., 1998; Jurenka, 2004). The major component of many Plusiinae pheromones (Z7-12:OAc), as well as other acetates (Z9-14:OAc and Z5-10:OAc) with a double bond at the ω5-position, are biosynthesized *via* a (*Z*)-11-hexadecenoic intermediate, which is produced by Δ11-desaturation of palmitic acid (16:Acid). This C_{16} monoenyl compound is shortened to C_{14}–C_{10} acyl intermediates by β-oxidation and then converted into pheromone components by acetylation after the reduction of the acyl group into a hydroxyl group. In light of these findings, one could postulate that: (1) 7-tetradecyl (7-14) and 5-dodecyl (5-12) compounds (acetates and alcohols) unsaturated at the ω7-position result from Δ11-desaturation of 18:Acid or Δ9-desaturation of 16:Acid, and (2) other monoenyl components unsaturated at the ω3-double bond, 9-dodecyl (9-12), and 7-decyl (7-10) compounds arise *via* Δ13-desaturation of 16:Acid or Δ11-desaturation of 14:Acid. In fact, biosynthesis of E5,Z7-12:OAc *via* Δ5-desaturation of the 7–12 acyl intermediate has been documented (Ono et al., 2002).

Based on these proposed biosynthetic pathways and the known chemical components, we have classified the Plusiinae pheromones into the following eight groups (Figure 4): (A) 7-12 compounds only, (B) 7-12 and 5-10 compounds, (C) 7-12 and 9-14 compounds, (D) 7-12 and 5-12 compounds, (E) 7-12 and 9-12 compounds, (F) 7-12 and 5, 7-12 compounds, (G) 5-10 and 7-10 compounds, and (H) 5-12 and 7-14 compounds. Species with pheromone components in groups A–C would be biosynthesized *via* Δ11-desaturation of 16:Acid, whereas additional pathways would be required for the biosynthesis of certain compounds found in the pheromones of groups D–H. If one assumes that primitive species of Plusiinae utilized Z7-12:OAc for sexual communication, then one could postulate that the changes in the β-oxidation enzyme and the acquisition of new desaturases enabled the more recently evolved species to biosynthesize new pheromone components.

Z7-10:OAc has been reported as a component in five lepidopteran species: a gelechiid (Arn et al., 1997), a tortricid (McNair et al., 1999), and a Noctuiinae

(Wakamura, 1978), as well as two other species in the genus *Diachrysia*, *D. chrysitis*, and *D. tutti* (Löfstedt et al., 1994). However, DS, a species taxonomically remote from the primitive Plusiinae is the first to have a 7-10 compound as its sole pheromone component. This represents a ninth class of Plusiinae pheromones (group I in Figure 4), while the pheromones of the above two species in the *Diachrysia* genus fall in the group G. We are currently interested in studying the pheromones of several other *Diachrysia* species that inhabit the mountainous regions of Japan as this information could provide additional insight into the taxonomy and evolution of the subfamily Plusiinae.

(Received September 30, 2004; revised December 29, 2004; accepted March 15, 2005)

Abstract—Quantitative experimental results on the antiherbivorous effect of cyanogenesis are rare. In our analyses, we distinguished between the total amount of cyanide-containing compounds stored in a given tissue [cyanogenic potential (HCNp)] and the capacity for release of HCN per unit time (HCNc) from these cyanogenic precursors as a reaction to herbivory. We analyzed the impact of these cyanogenic features on herbivorous insects using different accessions of lima beans (*Phaseolus lunatus* L.) with different cyanogenic characteristics in their leaves and fourth instars of the generalist herbivore *Schistocerca gregaria* Forskål (Orthoptera, Acrididae). Young leaves exhibit a higher HCNp and HCNc than mature leaves. This ontogenetic variability of cyanogenesis was valid for all accessions studied. In no-choice bioassays, feeding of *S. gregaria* was reduced on high cyanogenic lima beans compared with low cyanogenic beans. A HCNp of about 15 μmol cyanide/g leaf (fresh weight) with a corresponding HCNc of about 1 μmol HCN released from leaf material within the first 10 min after complete tissue disintegration appears to be a threshold at which the first repellent effects on *S. gregaria* were observed. The repellent effect of cyanogenesis increased above these thresholds of HCNp and HCNc. No repellent action of cyanogenesis was observed on plants with lower HCNp and HCNc. These low cyanogenic accessions of *P. lunatus* were consumed extensively—with dramatic consequences for the herbivore. After consumption, locusts showed severe symptoms of intoxication. Choice assays confirmed the feeding preference of locusts for low over high cyanogenic leaf material of *P. lunatus*. The bioassays revealed total

losses of HCN between 90 and 99% related to the estimated amount of ingested cyanide-containing compounds by the locusts. This general finding was independent of the cyanogenic status (high or low) of the leaf material.

Key Words—Cyanogenesis, chemical defense, *Phaseolus lunatus*, *Schistocerca gregaria*, herbivory, cyanogenic potential, cyanogenic capacity, plant–herbivore interactions.

INTRODUCTION

Cyanogenesis is widespread in the plant kingdom (Møller and Seigler, 1999). Over 2500 plant species are known to be cyanogenic and have the capacity to release gaseous HCN from endogenous cyanide-containing compounds, generally cyanogenic glycosides (Jones, 1988; Poulton, 1990; Seigler, 1998; Gleadow and Woodrow, 2002). Cyanogenic glycosides are β-glucosides of α-hydroxynitriles derived from protein and nonprotein amino acids (Zagrobelny et al., 2004). Hydrogen cyanide is toxic to the plant itself. Thus, cyanogenic plants must be able to synthesize and accumulate this toxin as inactive precursors to prevent autotoxicity (Vetter, 2000). Cyanogenic glycosides are separated in the intact plant from one or more specific β-glucosidases that are localized in the apoplast. In addition to separation on the cellular level, the cyanogenic component and the enzyme can be located in different tissues (Thayer and Conn, 1981; Frehner and Conn, 1987; Poulton, 1988; Swain et al., 1992). In case of injury, the β-glucosidase is brought into contact with its substrate. By hydrolysis of the cyanogenic glycosides, α-hydroxynitriles are formed that are relatively unstable and dissociate either spontaneously or are enzymatically accelerated by an α-hydroxynitrile lyase into HCN and an aldehyde or a ketone (Conn, 1980; Hösel and Conn, 1982; Poulton, 1990; Poulton and Li, 1994; Swain et al., 1992).

Hydrogen cyanide is toxic because of its affinity to the terminal cytochrome oxidase in the mitochondrial respiratory pathway and a number of other reactions (Solomonson, 1981; Brattsten et al., 1983). Despite the obvious toxicity of the products of plant cyanogenesis, its role in the scope of plant–herbivore interaction is very complex (Lieberei, 1988, 1989). A range of aspects determines its effectiveness as a mechanism of plant defense. The potential of cyanogenic glycosides as feeding deterrents depends on their concentration in the host plant. The concentration is often highly variable in natural populations. In addition, its phenotypic appearance depends on environmental conditions, the organ and tissue, and its ontogenetic status (Hughes, 1991; Bokanga et al., 1994; Schappert and Shore, 1999a,b; Gleadow and Woodrow, 2000b). If the concentration of cyanogenic precursors is below threshold toxicity, herbivores might not be affected (Feeny, 1976; Gleadow and Woodrow,

2000a). Herbivores can also avoid threshold toxicity by feeding on cyanogenic plants only as part of a mixed diet (Provenza et al., 1992). Furthermore, different herbivores are influenced in different ways by the presence of cyanogenic precursors because of their mode of feeding. Insect herbivores with sucking mouthparts such as phloem feeders (e.g., aphids) cause minimal tissue disruption during the feeding process and, therefore, avoid the release of toxic HCN or even reach tissues with low concentration of cyanogenic precursors depending on the length of their stylus (McMahon et al., 1995). A further important aspect is the degree of adaptation of the particular herbivore to its cyanogenic host. Specialist herbivores have evolved mechanisms to face cyanogenic glycosides (Provenza et al., 1992). Some use the cyanide as source of nitrogen or for their own defense against predators (Schappert and Shore, 1999b; Engler et al., 2000). For such herbivores, cyanogenic glycosides sometimes act as phagostimulants instead of feeding inhibitors (Calatayud and Le Rü, 1996; Mowat and Clawson, 1996). Thus, cyanogenesis may act as plant defense against generalist herbivores, but the effectiveness depends on many factors on both sides of the plant–animal interaction (reviewed by Gleadow and Woodrow, 2002).

Numerous authors have reported observations for defense functions of plant cyanogenesis against herbivores (e.g., Nahrstedt, 1985, 1988; Hruska, 1988; Jones, 1962, 1988, 1998; Crush and Caradus, 1995; Caradus and Forde, 1996; Schappert and Shore, 1999b,c; Tattersal et al., 2001). However, clear experimental results considering quantitative aspects of the action of HCN as causal factor of plant defense are rare (Feeny, 1976; Patton et al., 1997; Gleadow and Woodrow, 2000a,b). Analyses are complicated by the fact that the concentrations of cyanogenic precursors vary within a single plant and in relation to the ontogenetic status of the organs. For example, the concentration of cyanogenic precursors in leaves of different age differed by up to 90%. Furthermore, quantitative and kinetic analysis of the capacity for release of hydrogen cyanide as reaction to tissue disrupture—the basic measure of plant cyanogenesis—is often neglected. Qualitative statements concerning the release of HCN such as “yes” or “no” or semiquantitative test paper methods are insufficient to describe the complexity of cyanogenesis in interaction with a herbivore.

In view of these gaps, the goal of our study was to investigate quantitatively whether or not and how plant cyanogenesis interacts with the feeding behavior and feeding damage invoked by a generalist herbivorous insect. Furthermore, it has to be considered that deterrent properties of cyanogenic plants could depend on the total amount of bitter-tasting, cyanide-containing compounds stored in a given tissue [cyanogenic potential (HCNp)] or the amount of toxic hydrogen cyanide which can be released per unit time [cyanogenic capacity (HCNc)] or both.

For this, we designed a series of no-choice feeding experiments and additional binary-choice bioassays using lima beans (*Phaseolus lunatus*) as cyanogenic plants and the fourth instars of the African locust *Schistocerca gregaria* as generalist herbivores. Using this model system, we measured the HCNp of every leaf used in the bioassays and, in addition, the release of plant hydrogen cyanide per unit time during the course of feeding as response to damage of the leaf material. In this way, we obtained precise quantitative information on the action of plant hydrogen cyanide.

METHODS AND MATERIALS

Plants. P. lunatus seems to be an obligate cyanogenic plant. Extensive screenings of wild and weedy forms and cultivated genotypes revealed no acyanogenic forms (Baudoin et al., 1991). We tested seven defined *P. lunatus* accessions for resistance: L 2357 [origin: Spain; seed color: white/brown/violet, speckled; 100 grain weight (gw): 149.99 g], L 2233, wild type (origin: Cuba; seed color: gray/brown/black; 100 gw: 8.91 g), L 1315 (origin: Peru; seed color: white; 100 gw: 267.73 g), L 1259 (origin: unknown; seed color: brown/red/black, speckled; 100 gw: 82.39 g), L 2441 (origin: Bulgaria; seed color: white; 100 gw: 134.21 g), L 8079 (origin: unknown; seed color: white; 100 gw: 42.65 g), and L 8071 (origin: unknown; seed color: auburn; 100 gw: 45.23 g). In the following, only the numbers are used for specification of the accessions (2357, 2233, 1315, 1259, 2441, 8079, and 8071). Seed material was provided by the Institut für Pflanzengenetik und Kulturpflanzenforschung (IPK) in Gatersleben, Germany.

In addition to these plants, the almost noncyanogenic *Phaseolus vulgaris* L. cultivar "Saxa" was used as control. This cultivar with the stock number 40.176 was purchased from Carl Sperling & Co., Lüneburg, Germany.

Growing and Treatment of Plants. To work with homogenous, biochemically well-defined plant material, single plants of the respective accessions were cultivated and vegetatively propagated as clones. The clones were cut as one node cutting from the mother plant, rooted in water, and, after a 2 wk rooting phase, transferred into standard substrate (TKS®-1-Instant, Floragard®), which was mixed with one third sand of a grain size of 0.3–0.7 mm and one third sand with a grain size of 1–2 mm. Plant containers with a diameter of 18 cm were used.

Between July and August, clonal collections of at least 30 plants were prepared per accession. Plant material was cultivated under greenhouse conditions at a light regime of 16:8-hr light/dark by a photon flux density of 400 μmol s^{-1} m^{-2} at the plant container and 900 μmol s^{-1} m^{-2} on the top of the plants, respectively. Accessional light was provided by 400-W high-pressure

sodium lamps with plant-grow broad-spectrum fluorescent bulbs (Son-Targo 400, Philips®). Temperature in the chamber was 30/20°C in a 16:8-hr light/dark period and ambient relative air humidity (range, 60–70%). Climatic conditions and irrigation of the plants were computer-based and controlled by INTEGRO® software. Plants were fertilized with a nitrogen-phosphate fertilizer (Blaukorn®-Nitrophoska®-Perfekt, Compo GmbH) twice a week.

Leaf material was classified by morphological parameters of development into the three classes "young," "intermediate," and "mature." In addition, the insertion position of the leaves at the stem was documented. Leaves at the apex or a side stem that were unfolded for at least 3 days were classified as "young." These leaves did not exceed one third to one half of the final leaf size. Leaves that were located one to two leaf insertion positions below the category of "young" leaves were defined as "medium" leaves. Leaves assigned to this category were not completely expanded and still showed thin and delicate leaf tissue. "Mature" leaves were located at the stem at least two insertion positions below the leaves that were classified as "medium." These leaves were characterized by a dark green color and a hardened midrib, and were always completely expanded.

The occurrence of pests and diseases was controlled, and the harvest of leaf material of a particular plant was followed by at least 4 wk until the next harvest of leaves to minimize possible effects of various induced defense mechanisms known from the Fabaceae (Fischer et al., 1990; Liu et al., 1992; Underwood, 1999; Underwood et al., 2000; Heil, 2004).

Insects. S. gregaria is a polyphagous insect and an economic pest throughout many regions of Africa (Mainguet et al., 2000). Locusts were provided by the Biocenter Grindel and Zoological Museum (University of Hamburg) and were held under the same conditions as the plants. They were offered a diet consisting of leaf material of different Poaceae (*Poa annua* and *Agropyron repens*) together with fruits (apple and banana). The fourth instars were used as herbivores.

Cyanogenic Features of Plants. Plant cyanogenesis requires at least two basic physiological properties: the ability to synthesize and accumulate cyanide-containing compounds [the cyanogenic potential (HCNp)] and the capacity to release hydrogen cyanide from these endogenous compounds [the cyanogenic capacity (HCNc)]. Therefore, release of HCN is described by two cyanogenic features. The HCNp is defined as the total amount of HCN that can be released from a specific tissue (Loyd and Gray, 1970). HCNc describes the release of HCN per unit time (Lieberei, 1988).

Analysis of Cyanogenic Potential. HCNp was measured by extraction of the cyanogenic precursors from leaf material. To avoid a premature release of HCN by degradation, the complete procedure from harvest of the leaves to extraction of the cyanogenic precursors was conducted with cooled solutions and devices (4°C). In addition, all steps of processing were conducted on ice.

Any injury of leaf material during harvest and transport was avoided, and the harvested leaves were immediately put into water-filled Eppendorf® tubes to minimize effects of wilting. Only the laminae of the leaves were used for analysis. Leaf material was ground with a mortar and pestle for extraction by adding 0.067 mol/l disodium hydrogen phosphate (2 ml/g fresh leaf material). The homogenized sample was filtered and centrifuged for 20 min at $13000 \times g$ and 4°C. The supernatant was used for further analysis.

For enzymatic degradation of the cyanogenic precursors, exogenous β-glucosidase was added to the respective sample to cleave the precursor glycosides and to detect all HCN that can be released. Different cyanogenic substrates require different β-glucosidases. Therefore, the cyanogenic substrate must be matched with appropriate and possibly specific β-glucosidases. The rubber tree *Hevea brasiliensis* (Willd.) Muell. Arg. (1865) contains the cyanogenic glycosides linamarin and lotaustralin, as does *P. lunatus* (Lieberei et al., 1986). Thus, the β-glucosidase of *H. brasiliensis* was assumed to show specific activity for hydrolysis of the cyanogenic precursors found in the lima bean. Fresh leaf material of *H. brasiliensis* was frozen in liquid nitrogen, ground with mortar and pestle by adding cooled phosphate buffer (4°C), and adjusted to pH 6.8 [1 g leaf fw/4 ml buffer (fw = fresh weight)]. The homogenized sample was filtered and centrifuged for 20 min at $13000 \times g$ and 4°C. The supernatant was filtered through membrane caps with a pore size <10,000 kD (Schleicher & Schuell Bioscience GmbH, Dassel, Germany) and frozen at −20°C for further analysis. Generally, β-glucosidase activity was determined by using *p*-nitrophenyl-β-D-glucopyranoside (Merck) as artificial chromogenic substrate. The amount of β-glucosidase added per sample corresponded to 20 nkat. Thunberg vessels were used as reaction flasks for the determination of the HCNp. These were stoppered by a glass stopper with a side bulb of about 1-ml volume. Thus, the Thunberg vessel contained a closed headspace, and the released HCN could not leak from the preparation. The mixture for incubation consisted of 0.05 ml supernatant of the centrifuged sample, 0.45 ml 0.067 mol/l aqueous sodium dihydrogen phosphate solution, 0.10 ml β-glucosidase solution in McIlvaine buffer, pH 5.6 (20 nkat), and 0.60 ml 0.2 mol/l NaOH in the side bulb of the stopper. This mixture was incubated in a water bath for 20 min at a temperature of 30°C. The enzymatic reaction was stopped by the NaOH solution, which was added from the side bulb of the stopper to the incubation mixture. Sodium salt of HCN was formed, and the concentration of cyanide was measured spectrophotometrically by use of the Spectroquant® cyanide test (Merck). This test is based on the formation of cyanogen chloride. This compound reacts with pyridine forming glutacone dialdehyde, which condenses with 1,3-dimethyl barbituric acid to a violet polymethine dye with a maximum absorbance at a wavelength of 585 nm. One mol of polymethine dye corresponds to 1 mol cyanide.

The standard preparation for spectrophotometric measurement of cyanide consisted of one aliquot (0.1 ml sample) that was taken from the stopped incubation mixture. The sample was neutralized by adding an aliquot of 0.1 mol/l HCl (0.1 ml) and made up to 5 ml with 4.8 ml aqua dest. HCl was added for the neutralization of the alkaline sample because pH 7 had to be adjusted to guarantee optimal reaction of Spectroquant® reagents by Merck. The concentration of the chromogenic product was measured spectrophotometrically after 5 min of incubation.

Analysis of Cyanogenic Capacity. We tested the clonal plant material of different accessions for the total quantities of HCN release and the pattern of HCN release, respectively. In these experiments, we also differentiated for the ontogenetic leaf developmental stages "young," "medium," and "mature" of each accession. For this analysis, single trifoliate leaves were treated with 400 μl chloroform. Chloroform disintegrates cell membranes and leads to a breakdown of cellular compartmentation. HCN is released by this chemical tissue rupture from cyanogenic precursors if any active endogenous β-glucosidases with affinity for the cyanogenic precursors are present. Pattern of hydrogen cyanide, which was released to the atmosphere after addition of chloroform, was followed over a time period of 1 hr. The leaf was treated with chloroform a second time later to test for further release of hydrogen cyanide.

HCN Detection System. Both the release of HCN from cyanogenic leaf material as reaction to chloroform treatment and the release from injured leaf tissue in the course of the feeding trials were detected by using the same airflow system (Figure 1). This system was passed by an adjustable airflow provided by a pump with upstream potentiometer for capacity control. The pump was connected with an air humidifier (Figure 1B) consisting of a triple neck flask with a total volume of 2 l filled with 1 l aqua dest. to ensure a sufficient ambient air humidity in the experimental system and to guarantee optimal ambient conditions for locust activity and avoid wilting of the leaf during the bioassays (air humidity was >90%). From the humidifier, air was passed through a 200-ml Erlenmeyer flask (Figure 1C) containing leaf material used for the analysis of the HCNc or for feeding trials with single locust nymphs, respectively. The flask was immersed into a water bath adjusted at 30°C to ensure high activity of the insects in the course of feeding trials, whereas light with an intensity of 200 μmol s^{-1} m^{-2} was provided by a 150-W spot (Philips®). The discharge opening of the flask was connected to a glass capillary inserted into a test tube filled with 0.1 mol/l aqueous NaOH solution (Figure 1D). The capillary released bubbles of a defined volume of 0.83 ml at an immersion depth of 10 cm. The airflow in the equipment was adjusted precisely to 70 bubbles per minute (≈3.5 l/hr). Inflowing air was kept at this relatively low speed because higher speed had a negative impact on locusts. The test tube containing the NaOH solution served as collector of the released HCN and was exchanged at intervals

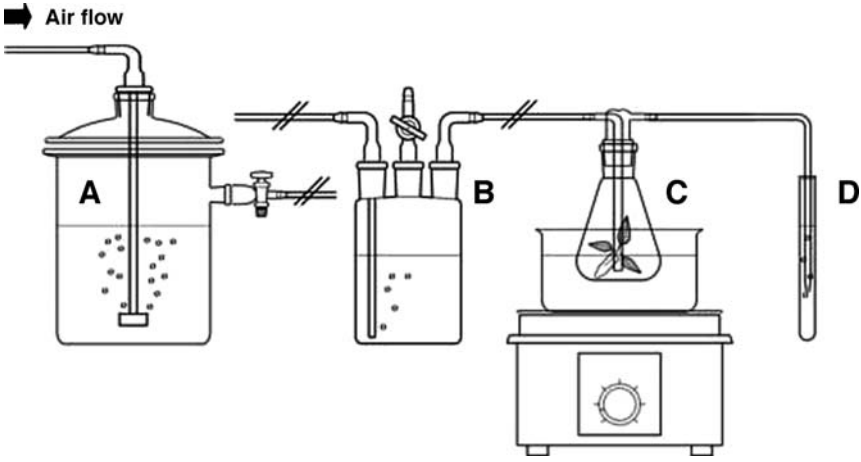

FIG. 1. Equipment for detection of gaseous HCN. The airflow in the vessel system was provided by a diaphragm pump with adjustable capacity. The air passes an air humidifier filled with aqua dest. (**B**) or a HCN generator (**A**) depending on the experiment. The HCN generator was filled with KCN solution (0.025–2.0 mmol/l) to provide a continuous HCN atmosphere within the airflow system for observation of behavior patterns depending on concentration of gaseous hydrogen cyanide. For detection of the cyanogenic capacity (HCNc), single trifoliate leaves were put into an Erlenmeyer flask (**C**) and treated with chloroform. In the course of bioassays, single locust nymphs were put into the flask (**C**) together with a trifoliate leaf. The flask was immersed into a water bath with a temperature of 30°C. Gaseous HCN—provided by the HCN generator, released from leaves as reaction to chemical cell disintegration or released from leaves as a result of tissue damage due to insect feeding—was detected quantitatively at the output of the equipment (**D**).

of 10 min. The pattern of the HCN release from leaf material per unit time was revealed by quantitative measurement of cyanide in the detection solutions by use of the Spectroquant® cyanide test (Merck). A pH of 7 was adjusted by adding 0.1 mol/l HCl to satisfy conditions required for this reagent kit. For analysis of the HCNc by chloroform treatment of particular leaves, the same speed of airflow was chosen, and the air humidifier was kept connected to the vessel system to achieve a similar experimental situation as in the feeding trials.

Bioassays. For no-choice feeding trials, single locust nymphs were placed into the 200-ml Erlenmeyer flask for HCN detection (Figure 1C) containing a trifoliate leaf of a defined accession and developmental stage. *P. lunatus* leaf material was characterized by specific cyanogenic features and was offered to the animals for 1 hr in no-choice feeding trials. In addition to the lima beans, *P. vulgaris* var. Saxa with extremely low cyanogenic concentrations was used

as control. Only locust nymphs of similar size and body weight were chosen for the experiments (mean ± SD, 0.987 ± 0.054 g; $N = 245$). Locust nymphs that molted about 48 hr previously were kept for 24 hr with *ad libitum* access to *Poa annua* leaf material which was part of their normal diet under the conditions mentioned above. They were food deprived for 1 hr prior to the bioassay.

The leaves used in the bioassays were harvested 1 hr after irrigation by the computer-based greenhouse control system. Leaves were put into water-filled Eppendorf® tubes with the petiole immediately after harvest and used in this form in the bioassays to guarantee a constant water supply. The amount of consumed leaf material was determined by weighing the particular leaf before and after the bioassay (MC 1 Analytic AC 210 S, Sartorius®) during constant water supply. This method for estimation of consumed leaf material was favored over leaf area measurements because even slight pressure during scanning in addition to interrupted water supply may lead to premature release of HCN. During the bioassay, release of HCN as a reaction to leaf material consumption by the locusts was consequently detected per unit time, and the duration of feeding on the particular leaf was documented. Detection of released hydrogen cyanide started with the first feeding incidence of the particular locust. Additional binary-choice feeding trials were conducted under the same experimental conditions. In these trials, selected single trifoliate leaves of high and low cyanogenic accessions were presented pairwise to the locusts, and the amount of leaf consumption was determined, respectively.

Behavior of Insects. A general statement as to whether feeding occurred or not did not seem to be sufficient to characterize the herbivore response. In preliminary studies, behavior of locust was observed by offering leaves of *P. vulgaris* and *Poa annua* as standard fodder. The animals were observed for 1 hr under the experimental setup for HCN detection. The HCNp of *P. vulgaris* var. Saxa was close to zero, and *Poa annua* did not contain any detectable cyanogenic components. In these preliminary experiments, very low and acyanogenic leaf material was used to ensure that insects were not affected by cyanogenic precursors or released HCN. These observed characteristics of behavior were interpreted as "normal." The following feeding trials were carried out under the same experimental conditions, but with leaf material of different cyanogenic accessions of *P. lunatus*. Leaf material of *P. vulgaris* var. Saxa was used as a control. Apart from feeding time, the following behavioral patterns were considered to reflect responses of the locusts to leaf consumption: general agility of the insects including the change of location after feeding, cleaning of the mouthparts, antennae, and legs, presence of flight reaction, and posture of the antennae and of the legs.

Behavioral patterns were defined as follows: 0, "normal" behavior (similar to behavior after consumption of leaf material of *Poa annua* and *P. vulgaris*); 1, no change of location, legs are angled and pressed onto the abdomen; 2, like 1,

but loss of any flight reaction and no cleaning of the mouthparts, antennae, and legs; 3, like 2, but, in addition, the antennae are sloped downwards by 45°.

During and after feeding on leaf material, changes of behavior occurred that were classified as defined above. Normal behavior on leaf material of *P. vulgaris* and *Poa annua* was characterized by high agility of the insects and by complete excitability to visual stimuli or vibrations. The feeding interval of the insects was followed by change of the location on the leaf and cleaning of the antennae, the compound eyes, wings, mouth parts, and legs. After intake of cyanogenic leaf material, the legs were pressed on the abdomen, and the locusts were less agile. This behavior was defined as the first level of negative effects (class 1). At this level, the insect still showed complete excitability with respect to visual stimuli or vibrations. The loss of this ability and the loss of comfort behavior together with the posture described above were interpreted as a more severe level of intoxication (class 2). In some cases, the locusts lowered their antennae downwards by about 45° in addition (class 3). In 1.7% (4 of 230 bioassays), the locust nymph died 1–2 hr after the experiment. These most severe signs of intoxication were included in class 3.

Exogenous Application of HCN. To test if application of exogenous hydrogen cyanide leads to similar effects with regard to locust behavior, we added quantified doses of gaseous HCN into the experimental vessel system by replacing the air humidifier (Figure 1B) by a gas generator (Figure 1A). This generator was made of a glass vessel with a total volume of 5 l that was filled with 3 l HCN-containing buffered solutions (phosphate buffer 6.7 mmol/l, adjusted to pH 5.5) and bubbled by a constant stream of air (≈3.5 l/hr). By use of defined cyanide solutions in the gas generator from 0.025 to 2 mmol/l, defined concentrations of gaseous HCN were constantly applied to *S. gregaria* individuals that had *ad libitum* access to almost noncyanogenic leaves of *P. vulgaris*. Gaseous HCN was added over a time period of 60 min. The speed of the airflow was controlled by detection of bubbles with defined volume that were released into a 0.1 mol/l aqueous NaOH solution by passing a capillary at the output of the equipment. The constancy of the HCN atmosphere within the equipment could be proven by spectrophotometric measurement of the amount of cyanide that was fixed in the NaOH solution per unit time using the Spectroquant® cyanide test (Merck). Experiments were conducted at a room temperature of 25°C, whereas the 200-ml Erlenmeyer flask containing the locust and leaf material was immersed into a water bath with a temperature of 30°C to ensure optimal conditions for locust activity. Light intensity was 200 μmol s^{-1} m^{-2} provided by a 150-W spot (Philips®).

HCN Balance. We calculated a HCN balance to investigate in which way the feeding insect gets in contact with HCN. Contact with released HCN could occur mainly during the feeding process, or large amounts of cyanide in bound form could be ingested and HCN might be released within the gastrointestinal

tract of the locust. Five aspects were considered to evaluate the fate of cyanogenic substances during the experiments: (1) amount of cyanide in bound form present in the particular leaf; (2) amount of cyanide consumed by the insect; (3) released HCN from leaf material during the feeding process of the insect; (4) released HCN from the locust bodies after consumption of leaf material; and (5) amount of cyanide in the feces.

The HCNp of every single leaf used in experiments was estimated. Leaf material that was left behind in the particular bioassay was used for analysis of the HCNp, and from these data, the amount of cyanogenic precursors within the consumed part of the leaf was calculated. The total amount of consumed leaf material was determined by weighing the particular leaf before and after the bioassay during constant water supply (MC 1 Analytic AC 210 S, Sartorius®).

The release of HCN from leaf material during the feeding of *S. gregaria* was measured per unit time with the equipment for HCN detection. For detection of hydrogen cyanide released from locust bodies into the atmosphere after leaf consumption, the insect was taken out of the experimental vessel and put in the center of a Conway's microdiffusional apparatus (semimicro type, Shibata Scientific Technology) with the outer ring filled with 10 ml 0.1 mol/l NaOH. The locust was left in there for 30 min. After that, the cyanide concentration of the surrounding NaOH solution was measured spectrophotometrically. The HCN content of the excrements that were obtained for up to 1 hr after the bioassay was analyzed by the method described for the HCNp determination of leaf material.

Statistics. Statistical analyses were run with Statistica 6.0 (Statistica System Reference, 2001).

RESULTS

Cyanogenic Features of P. lunatus. The clonal plants of all accessions studied were cyanogenic. All plants synthesized and accumulated cyanide-containing compounds in their leaves and were capable of releasing hydrogen cyanide from these compounds as reaction to chemical or mechanical damage.

Cyanogenic Potential. The variation of the HCNp was high and ranged from a HCNp of 0.7 μmol HCN/g leaf fw in mature leaves of accession 8071 to 82.0 μmol HCN/g leaf fw in young leaves of accession 2233. In general, the HCNp of young leaves was higher than in leaves of the intermediate or mature developmental stage. This ontogenetic pattern of variation was apparent in all clonal plants of all accessions studied (Table 1; Figure 2). Leaves of the cultivar "Saxa" (*P. vulgaris*) that served as control were characterized by very low concentrations of HCNp. This genotype was almost noncyanogenic.

Notes: Cyanide ingestion by locust is calculated from the weight of consumed fresh leaf material and the cyanogenic potential (HCNp) of the particular leaf. The HCNp of every trifoliate leaf that was used in the bioassays was measured ($N = 230$). Data in percentage are related to the calculated amount of ingested cyanide that was considered as 100%.

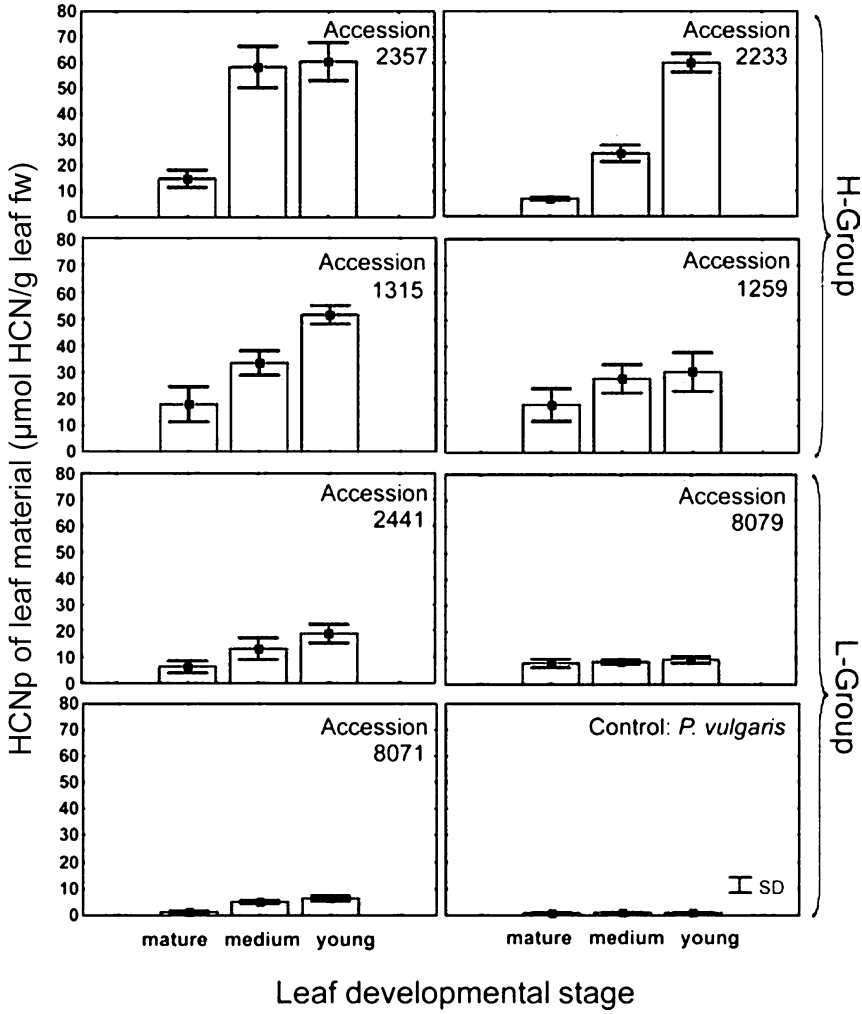

FIG. 2. Cyanogenic potential (HCNp) of *P. lunatus* accessions. Leaves of defined ontogenetic developmental stages of clonal plant material were analyzed. The clearly varying HCNp of the clonal lines allowed to distinguish between a high (H-group) and a low cyanogenic group (L-group) of plants. The control plants (*P. vulgaris* var. Saxa) revealed no substantial HCNp. Values are means ± SD. For number of observations, see Table 1.

Cyanogenic Capacity. The HCNc was estimated by measuring the kinetics of HCN release from leaves as reaction to chemically induced tissue disintegration. The pattern and the total amount of HCN released varied considerably between the accessions and the leaf developmental stages used for analysis (Figure 3).

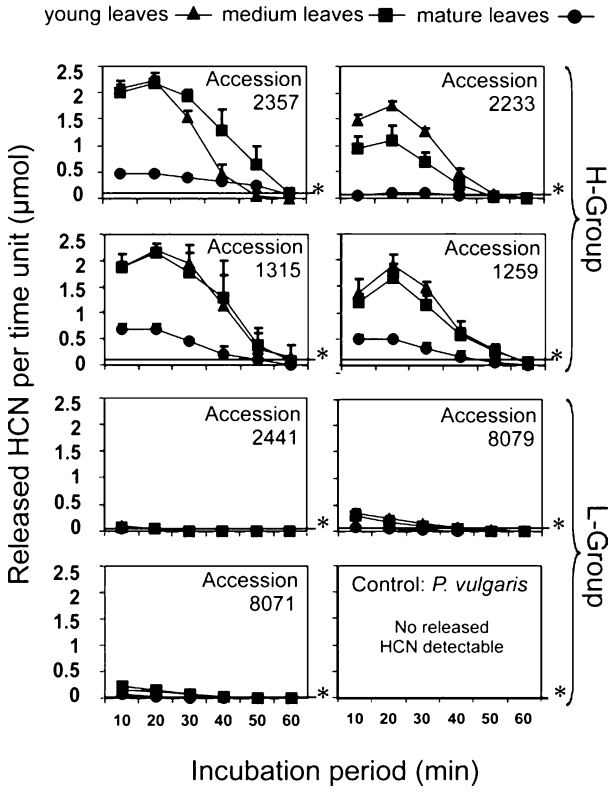

FIG. 3. Cyanogenic capacity (HCNc) of *P. lunatus* accessions. Leaves of defined developmental stages were analyzed for their capacity to release HCN from endogenous cyanide-containing precursors as reaction to chemical tissue disintegration due to chloroform application ($N = 5$ per accession and leaf developmental stage). Values given in the figure are means + SD. The release of HCN was quantitatively estimated per time periods (10 min) between the measurements. The experiments were carried out using the airflow system for detection of gaseous HCN and span a total time period of 1 hr. Application of chloroform to the same leaf a second time later in the experiment revealed no substantial release of hydrogen cyanide. Mean values of released HCN as reaction to this further treatment were below the level marked with an asterisk. The almost noncyanogenic *P. vulgaris* var. Saxa served as control.

Young and intermediate leaf developmental stages of the high cyanogenic accessions 2357, 2233, 1315, and 1259 revealed a rapid release of HCN and also a fast decrease of measurable hydrogen cyanide within 50 min when treated with chloroform. Mature leaves of these accessions were characterized by a lower and more continuous release of HCN that lasted as long as 60 min. No distinct maximum of hydrogen cyanide release was observed for these leaves. HCN was also released from leaves of all developmental stages of the low cyanogenic accessions of *P. lunatus* (2441, 8079, and 8071), but the release of HCN especially from mature leaves was close to zero. Control plants (*P. vulgaris*) had no capacity to release HCN from leaves. Thus, the pattern of HCN release from leaf material of *P. lunatus* depends on the cyanogenic status of the accessions as well as on the developmental stages of the leaves. No additional HCN loss was observed when chloroform was added to the leaves a second time later in the experiments. In addition, grinding the remaining leaf tissue under application of exogenous β-glucosidase isolated from *H. brasiliensis* revealed no substantial release of HCN (Figure 3).

Grouping of Plants for Analysis. Considering the results for the HCNp (Figure 2) and the corresponding HCNc (Figure 3), the accessions were assigned into a high (H-group) and a low cyanogenic category (L-group). Plants of the H-group were characterized by a HCNp of 34.4 ± 18.4 μmol HCN/g leaf fw (mean ± SD; $N = 108$). These plants (accessions 2357, 2233, 1315, and 1259) release more than 1 μmol HCN per trifoliate leaf within the first 10 min after treatment with chloroform. The plants of the L-group (accessions 2441, 8079, and 8071) showed a HCNp of 8.5 ± 5.7 μmol hydrogen cyanide/g leaf fw ($N = 89$). The H- and L-groups differed significantly (ANOVA, $F = 154.97$, $df = 1$, $P < 0.001$). The control *P. vulgaris* var. Saxa was almost noncyanogenic.

No-Choice Bioassays. Different effects of cyanogenesis on the susceptibility of leaf material to *S. gregaria* were observed in the feeding trials in relation to differences of HCNp and HCNc between the accessions of *P. lunatus* and their leaf developmental stages. Below a HCNp of 15 μmol HCN/g leaf fw that corresponds to a release of about 5 nmol HCN/10 min from the beginning of feeding under experimental conditions, there was no deterrent effect of cyanogenic leaf material observed (Figure 4). When feeding on plants of the H-group, locusts consumed less leaf material than when feeding on the L-group ($F = 197.02$, $df = 1$, $P < 0.001$). The intake of plants assigned to the H-group was 22.3 ± 19.6 mg fresh leaf material ($N = 108$). Within the H-group, substantial leaf consumption occurs exclusively on mature leaves with an HCNp near the threshold range of 15 μmol HCN/g leaf fw and a low capacity for HCN release. Leaves of accession 2233 were barely consumed despite the wide range of HCNp from 5.9 μmol HCN/g leaf fw in mature leaves up to more than 81 μmol HCN/g leaf fw in leaves of the young developmental stage. It is assumed that feeding deterrence of these plants is partly because of factors not

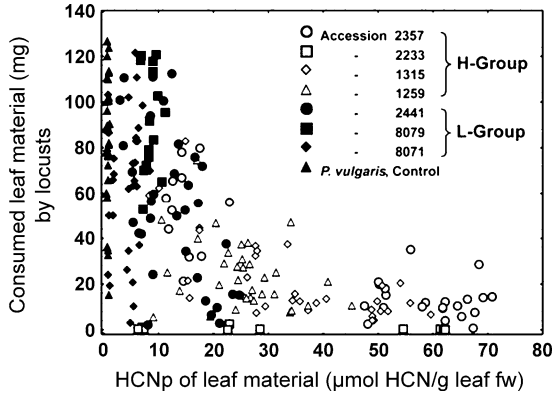

FIG. 4. Cyanogenic potential (HCNp) vs. leaf consumption. Leaves of high (H-group) and low (L-group) cyanogenic accessions of *P. lunatus* were presented to locusts over a time period of 1 hr within the airflow equipment for detection of gaseous HCN. Leaf consumption decreased with increasing HCNp of the presented leaf material. In this figure, there is no discrimination among ontogenetic leaf developmental stages. Results of statistical analyses are given in the text. For number of observations, see Table 1. The almost noncyanogenic *P. vulgaris* var. Saxa served as control.

considered in the present study, but may be a consequence of their outstanding high capacity for HCN release as reaction to feeding (Table 1). The intake of L-group plants of *P. lunatus* was 65.7 ± 32.9 mg fresh leaf material ($N = 89$). A tendency of reduced feeding was observed on the L-group accession 2441 where young leaves revealed the highest HCNp within this group and reached the threshold level of 15 µmol HCN/g leaf fw (Table 1). There was no measurable effect of the HCNp observed within the L-group of *P. lunatus* accessions with regard to leaf consumption. The leaf consumption by locusts on the *P. vulgaris* control plants (83.9 ± 26.6 mg fresh leaf material; $N = 33$) was significantly higher than the leaf intake on plants of the L-group of *P. lunatus* ($F = 7.99$, $df = 1$, $P = 0.006$). The HCNp and the corresponding HCNc affected the feeding behavior of locusts depending on threshold levels.

Binary-Choice Bioassays. Young leaves of the highest and the lowest cyanogenic accession (2357 vs. 8071) and leaves of the second highest and second lowest cyanogenic accession (1315 vs. 8079) were presented pairwise to the locusts (Figure 5). The choice tests between these leaves yielded a significant preference for the lower cyanogenic leaf material ($F = 88.62$, $df = 1$, $P < 0.001$).

Release of HCN as Reaction to Insect Feeding. Similar to the chemically induced release of HCN, the pattern of hydrogen cyanide released from leaf

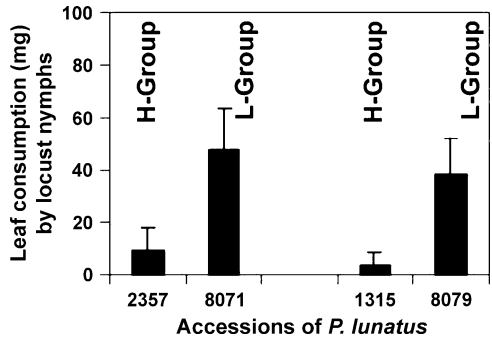

FIG. 5. Binary-choice bioassay. Leaves of H- and L-group plants were offered pairwise to single locust nymphs. Values are means and standard deviations ($N = 9$). Results of statistical analyses are given in the text.

material as reaction to insect feeding revealed differences depending on the general status of the HCNp, the accession, and the ontogenetic leaf developmental stage (Figure 6). Furthermore, the liberation pattern and amount of released HCN depended on the duration of feeding on selected leaf material. The time of feeding on H-group leaf material was 5 ± 4 min ($N = 108$) over the total observed period of 1 hr. On leaves of L-group plants, the locusts fed 18 ± 9 min ($N = 89$). The duration of feeding on H- and L-group plant materials was significantly different (ANOVA, $F = 164.87$, $df = 1$, $P < 0.001$). On high cyanogenic leaf material, further feeding incidences of a few locusts were observed over the time period of 1 hr. These further feeding incidences started 30–60 min after the beginning of the experiment; they were very short, and were not considered as time of feeding, but resulted in visible additional peaks of HCN release (Figure 6).

An interesting fact is that young and intermediate leaves of the L-group accession 2441 showed a substantial capacity for release of HCN as a reaction to feeding (Figure 6). This finding is in contrast to the very low HCNc detected as reaction to chemical tissue disintegration by chloroform treatment (Figure 3) and may indicate the existence of endogenous β-glucosidases in the locusts' saliva.

Effects of Leaf Development. Young leaves of the high cyanogenic accessions that were characterized by the highest HCNp and HCNc were consumed in small amounts. To clarify whether these cyanogenic features were acting as the effective components of plant defense, or if any other chemical or physical factors could be correlated with leaf maturation and might have influenced the feeding behavior of locusts quantitatively, we applied a post hoc test after ANOVA to the data set (Tukey's HSD for unequal N, $P < 0.05$;

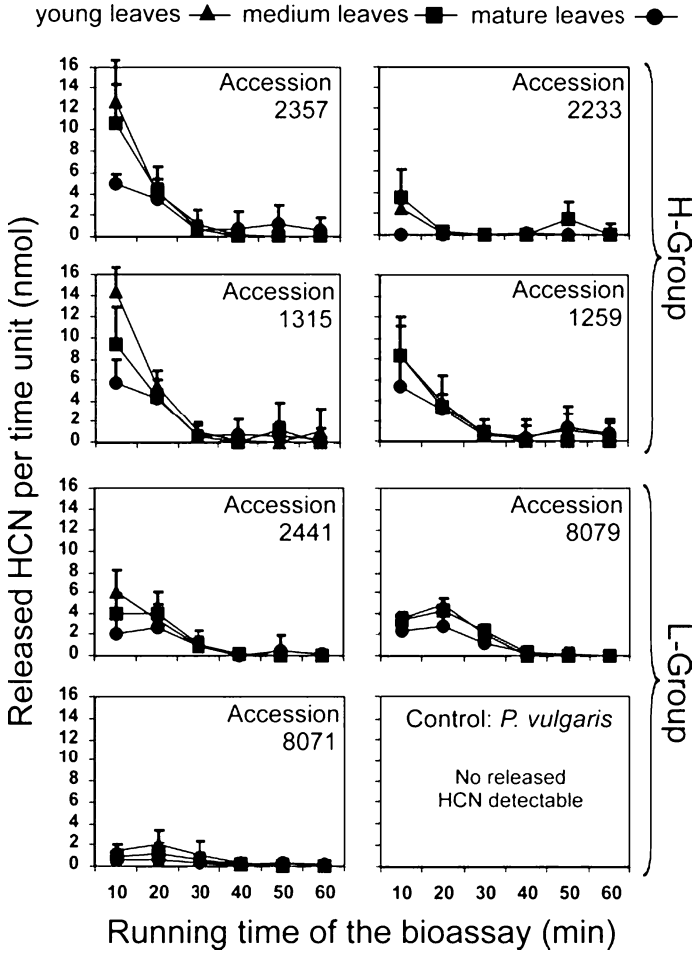

FIG. 6. Release of HCN from leaves as reaction to herbivory. Illustrated is the quantitative release of HCN as reaction to leaf consumption. This experiment was run with the airflow system for detection of gaseous HCN. The total period of detection of HCN release was 1 hr. The experiments started with the first feeding incidence of the locusts where duration is significantly different between the H- and the L-groups of plants. Peaks of HCN release, 30–60 min after start of the feeding trial, were results of further feeding incidents of single locusts. Values given in the figure are means + SD. The duration of the first feeding incidence and results of statistical analyses are given in the text; for number of observations, see Table 1. The almost noncyanogenic *P. vulgaris* var. Saxa served as control.

H-group, $N = 108$; L-group, $N = 89$). Within the H-group, no significant differences in consumption of young and intermediate leaves were found, but there was a significant difference between these leaves and the mature developmental stage characterized by lower HCNp and HCNc. Within the L-group, there was no significant difference in leaf consumption between the developmental stages. Thus, among the H-group plants, leaf consumption decreased with the increase of the cyanogenic features in younger leaves. Young and intermediate leaves of the high cyanogenic plants were not consumed less than mature leaves just because of the leaf developmental stage itself. Deterrent effects on locusts appeared to depend on the high HCNp and HCNc that occurred at this ontogenetic leaf developmental stages.

Effects of Cyanogenesis on Locust Behavior. The state of cyanogenic features affected locust behavior and led to different symptoms of intoxication. The reactions of the locusts feeding on *P. vulgaris* var. Saxa were defined as normal (behavioral pattern 0). This behavior contrasted with reactions of the insects after feeding on cyanogenic plant material of *P. lunatus*. These deviating patterns were interpreted as symptoms of intoxication (behavioral patterns 1–3). Strong symptoms of intoxication occurred after extensive consumption of leaf material of accessions 2441, 8071, and 8079 with a low HCNp and a corresponding low HCNc, whereas feeding on high cyanogenic leaf material (accessions 2357, 2233, 1315, and 1259) resulted in fewer or no symptoms of intoxication (Figure 7). The severity of intoxication strongly interacted with the

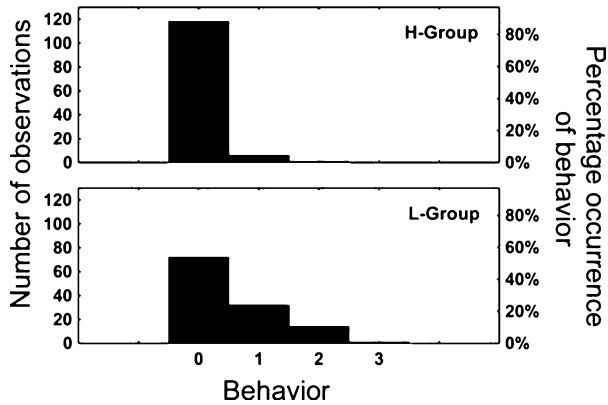

FIG. 7. Behavior of locusts. The behavioral patterns as reaction to consumption of high (H-group) and low (L-group) cyanogenic leaf material were documented and assigned to defined categories. These categories represent different levels of intoxication that range from normal behavior (0) to massive impairment of the herbivore (3). Presented are the total number of observations and the percentage occurrence of defined behavioral patterns among the H-group and L-group of plants.

amount of consumed leaf material ($F = 27.96$, $df = 3$, $P < 0.001$). Furthermore, the release of HCN from leaf material as a reaction to locust feeding was significantly higher for bioassays in which low symptoms of intoxication occurred ($F = 62.94$, $df = 3$, $P < 0.001$). Thus, the results indicate detrimental effects because of extensive ingestion of cyanogenic leaf material and a strong repellent action of high HCNc.

Exogenous Application of HCN. Locusts kept under a HCN atmosphere of 0.260–0.876 μmol/l revealed normal behavior (0). Agility, feeding behavior, and flight reactions were unaffected throughout the 1 hr of incubation under these conditions (Table 2). At a HCN concentration of 1.805 μmol/l in the gas phase, which corresponds to a cyanide concentration in the liquid phase of the generator of 0.5 mmol/l, the locusts showed reduced movements and angled legs that were pressed on the abdomen, whereas other aspects of behavior remained unchanged. This behavior corresponded to pattern 1 that was observed in the bioassays with cyanogenic *P. lunatus* leaf material. At the level of 3.612 μmol/l, the locusts showed reduced movements and, in addition, less feeding on the leaf material and loss of flight reaction. Therefore, this behavior was similar to pattern 2. At the highest HCN concentration of 7.518 μmol/l, the insects stopped feeding on leaf material and the antennae were sloped downwards as was characteristic for behavioral pattern 3 in the feeding experiments. The symptoms of intoxication caused by application of exogenous HCN at higher levels were the same as observed during or after feeding on cyanogenic leaf material. However, an additional characteristic of behavior was the frequent cleaning of the antennae at HCN concentrations above 3.612 μmol/l. All symptoms were completely reversible and disappeared about half an hour after taking the locusts out of the equipment and putting them on fresh leaf material.

In this experiment, we chose relatively low concentrations of cyanide compared to the conditions in cyanogenic leaf material. Even the highest concentrations of hydrogen cyanide in the HCN generator were in the lowest

TABLE 2. LOCUST BEHAVIOR UNDER EXPERIMENTAL HCN APPLICATION

KCN solution (mmol/l)	HCN atmosphere (μmol/l)	Locust Behavior	*N*
0.025	0.260	0	5
0.100	0.312	0	5
0.250	0.876	0	5
0.500	1.805	1	5
1.000	3.612	2	5
2.000	7.518	3	5

Notes: The HCN generator of the airflow system (A, Figure 1) was filled with adjusted KCN solutions to provide defined concentrations of atmospheric HCN. Behavioral patterns of locust on leaf material of control plants (*P. vulgaris* var. Saxa) were documented under these experimental conditions. The meaning of the codes for assignment of locust behavior is given in the text.

range of cyanogenic precursor variation present in *P. lunatus* leaf material. However, the concentration of gaseous HCN in the atmosphere at which first intoxication effects could be observed was 60 times higher than the highest concentrations of released HCN that was measured in the course of the feeding trials as reaction to leaf injury by the locusts.

HCN Balance. The amount of cyanide-containing compounds that were consumed together with the leaf tissue was calculated for every bioassay (N = 230). In addition, the amount of cyanide in the feces of the particular locust and the HCN released to the atmosphere from the locusts' bodies after the bioassay was included into the HCN balance (Table 1). The total calculated intake of cyanide-containing compounds present in the consumed parts of the leaves was not significantly different among all *P. lunatus* accessions ($F = 2.44$, $df = 1$, $P = 0.120$). But, when feeding on leaves on the mature developmental stage of the L-group accession 8071, the intake of hydrogen cyanide was low because of the extreme low HCNp of these leaves. HCN intake was even lower when locusts were feeding on the H-group accession 2233 with a high HCNp because of the small amounts of leaf material that were consumed from this accession. Within the H-group of plants, the intake of leaf material and, therefore, the intake of HCN tended to be lower by locusts feeding on young leaves with high cyanogenic features than by feeding on intermediate and mature leaves with lower cyanogenic properties. Considering the L-group of plants, in contrast, the intake of HCN by feeding on young leaves tended to be higher than when feeding on intermediate and mature leaf developmental stages because of the similar intake of leaf material but the higher HCNp of the young leaves compared with intermediate and mature leaves. The percentage release of HCN to the atmosphere during the feeding process was higher in the H-group than in the L-group of plants ($F = 475.16$, $df = 1$, $P < 0.001$). The young and medium leaf developmental stages especially revealed a high percentage of HCN release compared to the intake of hydrogen cyanide. A special situation was observed in bioassays with the H-group accession 2233. Here, the percentage of HCN released was 6.5 and 15.9% for the young and medium leaf developmental stages, respectively, higher than for any other accession.

Within the L-group, only young and intermediate leaves of accession 2441 and the mature leaves of accession 8071 revealed a considerable percentage release of HCN as reaction to feeding by the locusts. The relatively high percentage release of the latter was because of the fact that the intake of cyanogenic precursors by locust feeding on these leaves was extremely low corresponding to the very low HCNp that was not much higher than in the case of the control plants (*P. vulgaris*). Therefore, even low amounts of released HCN represent a relatively high percentage release. The release of HCN to the atmosphere from the locusts bodies for a time period of 1 hr after the bioassay was low for all accessions with the exception of locust that fed on young and

intermediate leaves of the H-group accession 2233. Here, the mean release of HCN was clearly higher than for the other bioassays.

Considerable amounts of hydrogen cyanide in locust excrement was detected after feeding on leaves of accession 2441 (Table 1). This might depend on the obviously low activity of the endogenous β-glucosidase that resulted in extraordinary low release of HCN as reaction to chemical tissue disintegration (Figure 3).

Among all bioassays, the total loss of HCN in this balance was high. Only for young and intermediate leaves of the H-group accession 2233 and the L-group accession 2441 was the loss lower. In bioassays using this leaf material, a high percentage release of HCN to the atmosphere occurred as a reaction to insect feeding, and high contents of HCN were found in the excrement, respectively.

DISCUSSION

There is substantial evidence that plant cyanogenesis acts as an effective herbivore deterrent against generalist herbivores (Jones, 1962; Hughes, 1991; Schappert and Shore, 1999c, 2000). The potential of cyanogenic glycosides in plants to act as a chemical defense was recently demonstrated by transferring the entire pathway for the synthesis of the aromatic tyrosine-derived cyanogenic glycoside dhurrin from *Sorghum bicolor* to *Arabidopsis thaliana*. The accumulation of dhurrin resulted in resistance of the transformed host plant to the flea beetle *Phyllotreta nemorum*, a Chrysomelid beetle, which is a natural pest on members of the cruciferous plants (Tattersal et al., 2001).

Furthermore, cyanogenesis seems to be beneficial for plants under specific environmental conditions (Kakes, 1989). The distribution of cyanogenesis in populations of *Lotus corniculatus* L. and *Trifolium repens* L. depends on abiotic factors that are also determining the occurrence and activity of snails, the important herbivores of clover (Jones, 1966, 1972, 1988). Hayden and Parker (2002) regarded this plasticity in *T. repens* as an important mechanism to reduce fitness-related defense costs.

According to Bernays et al. (1977), leaves of the cyanogenic tuber crop Cassava (*Manihot esculenta* Crantz) are consumed more frequently by nymphs of *Zonocerus variegatus* (Acrididae) in a senescent or wilted state than young and fresh leaf tissue. These wilted leaves showed a reduced release of HCN from their leaf tissues, but it should be kept in mind that it is not known to what extent other factors also change in a wilted leaf of *M. esculenta*.

In obligate cyanogenic plants such as *M. esculenta* and the lima bean *P. lunatus*, the precursors and the cleaving enzymes are present in the plant without any induction by abiotic stress or attack by pathogens and herbivores.

However, for these obligate cyanogenic plants, the release of HCN during the feeding process of a herbivore has never been quantified. There are several studies which analyze the amount of cyanide-liberating compounds in plants, its spatial distribution, and its dependence on environmental conditions (Jones, 1966; Cooper-Driver and Swain, 1976; Abbott, 1977; Cooper-Driver et al., 1977; Ellis et al., 1977a; Till, 1987; Caradus et al., 1990; Blaise et al., 1991; Hughes, 1991; Shore and Obrist, 1992; Calatayud et al., 1994; Caradus and Forde, 1996; Schappert and Shore, 1999a; Gleadow and Woodrow, 2000a). However, the central aspect of cyanogenesis, the capacity to release hydrogen cyanide from these endogenous compounds to the atmosphere, was just roughly classified by "yes" or "no" or semiquantitative estimation by Feigl–Anger test paper methods (Hayden and Parker, 2002). In addition, the additional measurement of β-glucosidase activity together with analysis of the content of cyanogenic precursors in plant material is not a conclusive measure for cyanogenesis occurring under natural conditions because there may be variation in tissue distribution of both factors (Gleadow and Woodrow, 2000b). Apart from the general ability for release of hydrogen cyanide and its total amount, the kinetics of HCN release may be an important aspect of plant cyanogenesis as protection against herbivores. It has to be assumed that the velocity of HCN release will affect the rate of herbivore deterrence. The fast movement of gaseous HCN in leaf tissue has been pointed out by Lieberei et al. (1996).

P. lunatus is an obligate cyanogenic species with quantitative variation of its cyanogenic properties. The status of HCNp and HCNc of leaves varied considerably depending on genotype, physiological state, and ontogenetic leaf development. Quantitative variation was evident in leaves of defined developmental stages of clonal plant material under controlled greenhouse conditions. Young leaves are generally characterized by a higher HCNp and HCNc than leaves of intermediate and mature developmental stages. Young tissues and organs of reproduction are mostly, but not in general, characterized by high contents of cyanogenic precursors. It may be assumed that these tissues need special protection because of their essential functions (Poulton, 1983, 1988; Gleadow and Woodrow, 2002). Alternatively, there might be investment decisions based on the expected life span of leaves (e.g., Coley, 1980, 1988; Coley et al., 1985). An attractive hypothesis would be that these cyanogenic substances are first used as feeding deterrents by young leaves before nitrogen is being metabolized (Selmar, 1986). Previous studies on the effects of cyanogenic glycosides on *Schistocerca americana* (grasshopper, Neoptera) and *Hypera brunneipennis* (alfalfa weevil, Coleoptera) revealed that these compounds deterred insects from feeding, but were not detrimental if ingested. Grasshoppers and weevils seemed to be more sensitive in detecting cyanogenic glycosides within food plants (Bernays, 1991).

The present study indicates a more complex action of cyanide-containing compounds and plant cyanogenesis. We were able to analyze the effect of

cyanogenesis concerning the herbivore–plant interaction between nymphs of the generalist locust *S. gregaria* and the cyanogenic plant *P. lunatus*. This was accomplished by the precise measurement of the HCNp of the particular leaf presented to the locusts and by quantitative detection of the HCN released during the feeding process of the insects. However, in consideration of these data and by additional observation of the locusts behavior during and after leaf consumption, the results suggest that plant cyanogenesis in this experimental system is involved in at least two levels of plant defense. On the one hand, high HCNp and HCNc result in a clear repellent effect. On the other hand, consumption of leaves with low HCNp and HCNc leads to severe intoxication. So, this complex action is based both on the presence of cyanide-containing compounds and the kinetics of their bioavailability.

The identification of a certain threshold level at which the HCNp and the HCNc become effective is of special interest. Certain thresholds of cyanogenic precursors and released HCN must be reached to achieve repellent action against *S. gregaria*. Severe intoxication of locusts occurred after extensive consumption of low cyanogenic leaf material. Obviously, the insects did not react to the small amounts of HCN released during the feeding process, and, thus, the total intake of cyanogenic leaf material was above a critical threshold for intoxication. It cannot be excluded that factors other than the HCN releasing compounds may be toxic to the locusts and may have caused the detrimental effects. But, the time sequence and symptoms of intoxication were the same regardless of whether we applied exogenous HCN to locusts feeding on almost noncyanogenic leaf material or whether they were feeding on the cyanogenic varieties. During feeding on high cyanogenic leaf material—especially on young leaves—considerably more HCN was released per unit time than during feeding on low cyanogenic leaves. This physiological feature of immediate HCN release in high amounts obviously represents a potent repellent effect. Thus, high and low cyanogenic leaves revealed different modes of action on the herbivore. Calculation of a HCN balance based on the consumed cyanogenic leaf material revealed that the amount of cyanide in the excrements and the amount of HCN released from the locust bodies after feeding were always low. Accordingly, the total loss of hydrogen cyanide within this balance was always high, indicating a metabolization of cyanide by the locust or an interaction of this highly reactive substance with the insect tissues. The HCN balance prepared from feeding trials with leaves of the H-group accession 2233 (wild type) indicated the impact of the HCNc as a feature with high repellent potential. Concerning this accession, bioassays with leaves of all developmental stages revealed extraordinary high percentage rates of HCN release as reaction to locust feeding compared to the other high and low cyanogenic accessions. However, leaves of all developmental stages of this accession were consumed in very low amounts independent of the widely varying HCNp.

This study demonstrates for the first time a quantified protective effect of the HCNp and of the corresponding HCNc against herbivorous insect attack depending on threshold levels. The different modes of action of high and low cyanogenic accessions of *P. lunatus* deserve further discussion, and experiments with respect to the biological function and with special regard to the ecological costs of these systems. *P. lunatus* is an agricultural crop of increasing importance as source for human food and green fodder for livestock (Debouck, 1991). It is important to evaluate possible agroecological advantages or disadvantages of cyanogenesis. HCN release is not only acting on plant–herbivore interaction, but it is also influencing plant–microbe balances (Lieberei et al., 1983) and may also give an allelochemical input to plant–soil relations. The insights gained from this experimental system could easily be transferred to other cyanogenic plants of global economic importance such as cassava (*M. esculenta* Crantz).

Acknowledgments—We thank Prof. Dr. David S. Seigler for fruitful discussions. We also thank the "Institut für Pflanzengenetik und Kulturpflanzenforschung" in Gatersleben for providing the seed material of our experimental plants.

BIOLOGICAL ACTIVITY OF ACYL GLUCOSE ESTERS FROM *Datura wrightii* GLANDULAR TRICHOMES AGAINST THREE NATIVE INSECT HERBIVORES

J. DANIEL HARE*

Department of Entomology, University of California, Riverside, California 92521, USA

(Received August 11, 2004; revised November 18, 2004; accepted March 12, 2005)

Abstract—*Datura wrightii* is dimorphic for leaf trichome type in southern California. "Sticky" plants produce glandular trichomes that secrete acylsugars, whereas velvety plants produce nonglandular trichomes. Glandular trichomes confer resistance to some potential insect herbivores and are associated with reduced feeding in the field by two native coleopteran herbivores: the tobacco flea beetle, *Epitrix hirtipennis*, and a weevil, *Trichobaris compacta*. In contrast, another native beetle, *Lema daturaphila*, damages sticky and velvety plants similarly in the field. A series of choice and no-choice "ester removal" and "ester addition" feeding experiments were performed in the laboratory to evaluate the role of acylsugars in feeding by all three insect species. Consumption of sticky leaves after their esters were removed by washing was compared to consumption of unwashed sticky leaves and velvety leaves in ester removal experiments. Consumption of velvety leaves was measured after acylsugars were applied to those leaves in controlled amounts in the ester addition experiments. Consumption by *E. hirtipennis* was reduced by acylsugars in all experiments. Consumption by *T. compacta* was reduced by acylsugars in the ester removal experiments, but not in the ester addition experiments. The location of the acylsugars at the tip of a long trichome, rather than simply on the leaf surface, may be an important component of the biological activity of acylsugars against *T. compacta* in nature. Consumption by *L. daturaphila* was not significantly reduced by acylsugars in any experiment. The acylsugars caused no significant mortality of any of the three insect species.

Key Words—Acylsugars, bioassays, chemical defense, coleoptera, genetic variation.

INTRODUCTION

Glandular trichomes may serve many functions in plants, but one of the more important is protecting them from herbivorous insects (Werker, 2000). The glandular trichomes of solanaceous plants contain or secrete a number of phytochemicals that are either toxic or deterrent to a wide variety of herbivorous insects (Dimock and Kennedy, 1983; Duffey, 1986; Goffreda et al., 1989; Neal et al., 1990; Buta et al., 1993; Severson et al., 1994; Yencho et al., 1994; Liedl et al., 1995; Eigenbrode et al., 1996; Wilkens et al., 1996; Liu et al., 1996). One class of compounds produced by glandular trichomes is acylsugars, or esters of simple sugars and one or more fatty acids. These compounds increase the mortality of whiteflies, aphids, mites, and psyllids, and inhibit the growth and survival of phytophagous Lepidoptera (Buta et al., 1993; Juvik et al., 1994; Neal et al., 1994; Puterka and Severson, 1995; van Dam and Hare, 1998a, b). However, the effects of acylsugars vary widely among insect species. They caused no mortality or inhibition of feeding of larvae of the Colorado potato beetle, *Leptinotarsa decemlineata* (Neal et al., 1994), and at least one insect species utilizes these compounds as feeding and oviposition stimulants (van Dam and Hare, 1998a). Despite their potential role in insect pest management (e.g., Puterka et al., 2003), relatively little is known of the role of acylsugar production in plant defense against native insect herbivores.

Datura wrightii Regel, a native perennial plant, is dimorphic for leaf trichome morphology. Within populations, leaves of some plants are covered with relatively long, multicellular trichomes with a secretory gland at their tip and feel sticky when touched. Other plants are covered with a higher density of shorter, nonglandular trichomes, and feel velvety when touched. Trichome morphology is governed by a single gene, and the sticky allele is dominant (van Dam et al., 1999). Glandular trichomes of sticky plants produce several esters of glucose and straight-chain organic acids (van Dam and Hare, 1998b). In laboratory studies, these esters conferred resistance to whiteflies (van Dam and Hare, 1998a) and reduced the growth rate of *Manduca sexta* larvae (van Dam and Hare, 1998b). In the same laboratory studies, however, van Dam and Hare (1998a) showed that addition of acylsugars to velvety *D. wrightii* leaves stimulated feeding and oviposition by *Tupiocoris notatus* (Distant), a mirid bug with specific morphological adaptations to cope with glandular trichomes (Southwood, 1986).

The concentration of acylsugars on sticky *D. wrightii* leaves is strongly influenced by environmental conditions (Forkner and Hare, 2000). Acylsugar concentration per unit leaf area was approximately one-third less for plants that received twice-weekly irrigations than for plants that remained unirrigated for the whole growing season, despite the fact that irrigation did not affect the density of glandular trichomes (Forkner and Hare, 2000). Acylsugar concentra-

tion also differed between years, although this variation could have been the result of sampling plants at different times during the growing season in each of 2 yr (Forkner and Hare, 2000). Environmental variation in acylsugar concentration suggests that the level of herbivore resistance that glandular trichomes confer may vary both among populations growing under different environmental conditions and seasonally within populations.

To better understand the role of natural concentrations of acylsugars as a plant defense mechanism in *D. wrightii*, the following two objectives were addressed. First, the acylsugars produced by sticky plants were quantified monthly from field-grown plants in two irrigation treatments to determine the range of variation in concentration over one growing season. Second, the role of acylsugars as a defense against three common Coleopteran herbivores of *D. wrightii* was evaluated through a series of experiments in which insects were offered sticky and velvety leaves or leaf disks in a series of "choice" and "no choice" experiments. Treatments included unaltered disks from sticky and velvety plants, disks from sticky plants where the acylsugars were removed, and disks or leaves from velvety plants to which esters were added in measured amounts.

The three herbivores were adults of *Lema daturaphila* Kogan and Goeden (formerly *Lema trilineata daturaphila*, see Riley et al., 2003), adults of the tobacco flea beetle, *Epitrix hirtipennis* (Melsheimer), and adults of a weevil, *Trichobaris compacta* (Casey). All are common native insect herbivores of wild and cultivated solanaceous plants. The first species damages sticky and velvety *D. wrightii* similarly in the field, whereas feeding damage by the latter two species is largely confined to velvety *D. wrightii* (Elle and Hare, 2000; Hare and Elle, 2002). Based upon the field observations, I predicted that *E. hirtipennis* and *T. compacta* would be inhibited more than *L. daturaphila* by the acylsugars of sticky *D. wrightii*.

METHODS AND MATERIALS

Variation in Acylsugar Concentration in the Field. Because trichome morphology is a Mendelian trait with the sticky condition being dominant (van Dam et al., 1999), the distribution of phenotypes of backcrossing a heterozygous F1 individual to its homozygous recessive parent is expected to be a 1:1 mixture of velvety (homozygous recessive) and sticky (heterozygous) progeny. This experiment utilized progeny from backcross families # 1, 2, and 4, described in van Dam et al. (1999), and grown in the field in 2000. Although there were initially a total of 216 plants arranged in four blocks for other experiments, data on acylsugar concentration were taken from 48 plants that

were sprayed weekly with acephate to protect them from insect attack. Plants in alternate blocks were assigned to two irrigation treatments. The two "irrigated" blocks were furrow-irrigated for 8 hr once a week from April through November, while the two remaining "unirrigated" blocks were left dry.

The youngest, fully expanded leaf was collected from all surviving plants on July 28, 2000 to determine trichome densities under a microscope using standard procedures (van Dam et al., 1999). Plants were flowering and producing seed capsules at this time.

Acylsugar concentration was determined for protected sticky plants every 4 wk starting on June 21 and ending October 11, 2000 using methods described by Forkner and Hare (2000) and briefly outlined here. The youngest, fully expanded leaf on each plant was collected, placed into a plastic bag, and brought back to the laboratory. The use of plastic bags to transport the leaves may have introduced an error into the experimental design because some exudate might have been transferred from the leaves to the bags. This error is likely conservative, because such potential losses would actually decrease the probability of finding statistical differences in acylsugar concentration between treatments or among sampling dates.

Acylsugars were extracted three times with $CHCl_3$, and leaf areas were measured with a leaf area meter (Li-Cor Model 3000, Li-Cor, Inc., Lincoln, NE, USA). $CHCl_3$ was filtered and removed by evaporation, then the acylsugars were redissolved in MeOH and saponified with 0.04 N NaOH in water. The liberated glucose was quantified spectrophotometrically using a hexokinase-based glucose assay reagent [Sigma Glucose (HK) reagent; Sigma Diagnostics, St. Louis, MO, USA] prepared according to the manufacturer's instructions. The molar concentration of glucose was calculated per leaf from the absorbance, then expressed as μmol of glucose esters per cm^2 of leaf area.

Concentrations were analyzed statistically with a repeated-measures multi-way analysis of variance. The repeated factor was the different sampling dates and the fixed treatment effect was the irrigation treatment. Potential random sources of variation included blocks within irrigation treatments, families, and the interactions of families with irrigation treatment and sampling date.

The data were analyzed using the PROC MIXED procedure of SAS because the design contained both fixed and random factors. PROC MIXED calculates significance tests using a restricted maximum likelihood (REML) method and is more robust for the analysis of mixed models with uneven sample sizes than PROC GLM (SAS Institute, 2000). The logarithmic transformation was applied to ensure normality of residuals.

Ester Removal Experiments. As in other solanaceous species (e.g., Neal et al., 1990), the acylsugars of *D. wrightii* can be removed from sticky foliage simply by washing the leaf for 15 sec in 95% ethanol, followed by a 15-sec rinse in deionized water, without damaging the leaves. In the following bio-

assays, the feeding activity of *L. daturaphila*, *T. compacta*, and *E. hirtipennis* was compared on: (1) sticky vs. velvety leaves, (2) sticky leaves vs. sticky leaves with their esters removed (hereafter "washed sticky leaves"), and (3) washed sticky leaves vs. velvety leaves. Both choice and no-choice experiments were performed. Adult insects of undetermined age and sex were collected from the field on the morning of the trial. For the no-choice experiment, there were 10 trials of 10 replicates, with each replicate comprising a pair of 1.5-cm leaf disks of one of the three leaf treatments above, and a single field-collected adult of *L. daturaphila* or *T. compacta*, or 10 adults of *E. hirtipennis*. Different numbers of adults of each species were used because of the differences in size and feeding mode of each species. Only five trials could be set up for *E. hirtipennis* because of a shortage of insects. After 48 hr, the quantity of foliage consumed by each *L. daturaphila* adult was determined by placing an acetate overlay marked with a grid (1-mm spacing) over the leaf and counting the number of 1×1 mm squares of leaf area removed. For both *T. compacta* and *E. hirtipennis*, the feeding pits per leaf were counted and recorded.

For the choice tests, there were five trials of 15 replicates, where each replicate comprised a pair of leaf disks from each of two treatments and individual adults of *L. daturaphila* or *T. compacta*, or 10 adults of *E. hirtipennis*. Feeding was scored after 48 hr as described above. In some cases, the leaf disks shriveled and the replicate was discarded. Additionally, a few *T. compacta* refused to feed on any leaf disks, and these replicates were also discarded. Both factors led to unequal sample sizes within trials. All bioassays were performed during the months of July and August to try to maximize the difference between sticky and velvety types (see Results), contingent upon the availability of insects in the field.

The "sticky vs. velvety" comparison provides a baseline difference between the leaf types, whereas the "washed sticky vs. sticky" comparison tests the effect of acylsugars on insect feeding on a background of long trichomes, and the "washed sticky vs. velvety" comparison tests the effect of variation in trichome morphology in the absence of acylsugars. In the comparison of sticky vs. washed sticky leaves, the appropriate control was sticky leaves washed for 15 sec in deionized water; in the comparison of washed sticky leaves vs. velvety leaves, the appropriate control was velvety leaves washed identically to sticky leaves, i.e., in both 95% ethanol and deionized water for 15 sec each.

Ester Addition Experiments. Acylsugars were extracted in bulk from various wild-grown sticky *D. wrightii* plants as described elsewhere (van Dam and Hare, 1998b). Numerous extractions were performed in order to obtain the large quantities of acylsugars required for study. Branches were clipped from plants and brought to the laboratory. All leaves were removed from their branches and soaked for 1 hr in 3 l of $CHCl_3$. The extract was filtered through Whatman # 1 filter paper under vacuum to remove solid debris, then the volume of $CHCl_3$ was

reduced by rotary evaporation. The $CHCl_3$ extract was filtered over anhydrous Na_2SO_4 to remove water then further concentrated, transferred to a preweighed vial, and evaporated to dryness under an air stream. The mass of the residue was determined and dissolved in CH_3CN at a rate of 100 ml/g. The material was placed into a sonicating bath (10 min) to ensure that all material was dissolved or suspended in CH_3CN. This material was partitioned three times against equal volumes of hexane to remove leaf waxes and other nonpolar compounds. Then CH_3CN was taken to dryness by rotary evaporation. The residue was dissolved in 50 ml/g of CH_2Cl_2 and partitioned two times against 1 N tartaric acid and three times against water to remove alkaloids and other water-soluble compounds. The CH_2Cl_2 fraction was concentrated by rotary evaporation and transferred into a preweighed vial. Remaining traces of solvent were removed *in vacuo*. The mass of the residue, the "alkaloid-free acylsugars," was determined, and yields ranged from 0.1% to 0.2% of the fresh mass of the leaves.

Acylsugars were applied to velvety leaves using methods derived from Puterka and Severson (1995). On the day that a feeding trial was to be established, a group of 12 young but fully expanded leaves from field-grown velvety *D. wrightii* were collected and brought to the laboratory. Leaves were surface-sterilized by soaking them for 3 min in a solution of 1% commercial bleach (equivalent to 0.0525% $NaHClO_3$). Leaves were rinsed thrice in deionized water and kept turgid by placing their petioles in water reservoirs.

A suspension of acylsugars in water (10 mg/ml) was prepared, and a sonicating bath was used to keep the acylsugars in suspension. This was the highest concentration of acylsugars in water that would remain in suspension during the application process. Acylsugars were applied to velvety leaves by using an ultra-low volume spray device modified from that described in Puterka and Severson (1995). A Nalgene aerosol spray bottle (# 2430-200, Nalgene, Rochester, NY, USA) was modified by affixing a commercial 3/8-in. pipe-to-hose adapter to the side of the spray bottle so that a hose from a cylinder of nitrogen or compressed air could be attached. For each application, 800 μl of the acylsugar suspension were transferred into a 12 × 75 mm test tube. This tube was placed into the spray bottle, and the pick-up tube of the sprayer was placed into the test tube.

To ensure uniform applications, a spraying stand was constructed from ring stands and clamps that consistently held the sprayer at the appropriate distance and angle from the leaf to be sprayed. The concept of the fixed spray platform was taken from Puterka and Severson (1995), but the design was modified in order to accommodate the larger leaves used in this study. The sprayer was clamped into a fixed position, and a 15-cm-diam plastic Petri dish was clamped 50 cm away from the nozzle of the sprayer in which the test leaf was placed. After the leaf and sprayer were set in proper position, the bottle was pressurized to 103 kPa, and all of the acylsugar suspension was sprayed onto the leaf and Petri dish.

In each trial, two of the 12 leaves were treated with 10 mg/ml of acylsugars per leaf surface (top and bottom) to serve as a check on the uniformity of application. Prior to treatment, the areas of these two leaves were determined with a leaf area meter. After treatment, the acylsugars were extracted from the leaves and quantified using methods described above. From this, the quantities of acylsugars actually applied to leaves per unit of leaf area were calculated.

Each trial consisted of five treatments. Control leaves were sprayed top and bottom with 800 μl of water. Leaves were treated with 20, 40, 80, or 120 mg/ml of acylsugars (1, 2, 4, or 6 applications per leaf surface of 800 μl of a 10 mg/ml mixture of acylsugars). These rates were chosen to span the range of acylsugars that occur on field-grown, sticky plants (see Results). Leaves sprayed top and bottom with 800 μl of a 10 mg/ml mixture of acylsugars received an average concentration of 0.097 (±0.003 *SE*, $N = 40$) μmol acylsugars/cm^2 of leaf. Thus, the quantities of acylsugars applied to leaves were approximately equivalent to 0.097, 0.194, 0.388, and 0.582 μmol/cm^2 of leaf. Leaves were returned to their water reservoirs to maintain leaf turgor while the leaf surfaces dried between applications.

For the no-choice bioassays, a piece of filter paper (Whatman #2, 12.5 cm) was placed into the bottom of a 15-cm-diam Petri dish and moistened with deionized water, then a whole treated leaf (above) was placed into the dish. One adult *L. daturaphila* was placed onto each treated leaf, whereas two *T. compacta* adults were used per leaf, and 10 adult *E. hirtipennis* were used per leaf. The dish was sealed with Parafilm® (American National Can, Menuasa, WI, USA) and the dish was placed into a growth room (constant 28°C, 16L:8D photoperiod). Insect feeding was scored after 48 hr as above.

For choice bioassays, only leaves from the control (water only) and 120 mg/ml treatments were utilized. Leaves were treated as described above and allowed to dry, then a cork borer was used to punch out 1.5-cm-diam disks from each leaf, avoiding the midrib. Pairs of disks were placed equidistant from the center of a 9.0-cm Petri dish on a disk of moistened filter paper (Whatman # 2, 7.0 cm) and insects added as above. For these tests, the number of *T. compacta* was reduced from two per dish to one. These experiments were repeated five times for *L. daturaphila* and *T. compacta*, but only three times for *E. hirtipennis* due to a shortage of insects. Additional procedures and data collection were as in the no-choice experiments above.

Data Analysis. Data from both the ester removal and ester addition experiments were analyzed by two-way mixed-model ANOVA using the PROC MIXED procedure of SAS with doses (no-choice) or treatments (choice) being fixed effects, and trials and the interaction between trials and treatments or doses being random sources of variation. For the choice trials, the potential variation among replicates within trials was also included in the model as a random source of variation to control for systematic differences in consumption

rates among individual replicate insects (*L. daturaphila* and *T. compacta*) or groups of insects (*E. hirtipennis*) across treatments. The interaction between treatment and trials was pooled with the error term when not significant at $P \leq 0.25$ prior to testing for significance of the fixed effects, following rules for pooling (Sokal and Rohlf, 1995). The square root ($X + 0.5$) transformation was applied to the feeding data for *L. daturaphila* and *T. compacta*, to ensure that the residuals were normally distributed, but the data for *E. hirtipennis* required no transformation.

RESULTS

Variation in Acylsugar Concentration in the Field. Overall, acylsugar concentration varied from 0.03 to 0.84 μmol/cm^2 of leaf. Acylsugar concentration differed significantly due to irrigation treatment, but not between blocks within treatments (irrigation $F_{1,86} = 4.41$, $P = 0.039$, pooled over blocks). Acylsugar concentration was 27% higher in unirrigated plants (Figure 1). The magnitude of variation over time was statistically significant ($F_{4,86} = 34.26$, $P < 0.001$), and mean concentrations in August were 2.6 times the concentrations in October (Figure 1). The interaction between irrigation treatment and month was not statistically significant ($F_{4,86} = 1.41$, $P = 0.24$). Families did not differ in their response either to irrigation or to season, as there was no significant effect of family or interactions of family with either months or irrigation (all $P \geq 0.15$).

The densities of glandular trichomes on sticky plants averaged 94.6 (±3.0 SE, $N = 82$) per mm^2 and did not differ among families, irrigation treatments, or their interaction (all $P \geq 0.24$, data not shown). Similarly, the density of non-glandular trichomes on velvety plants averaged 242.0 (±4.9 SE, $N = 119$) per mm^2, and also did not differ among families, irrigation treatments or their interaction (all $P \geq 0.23$, data not shown).

Ester Removal Experiments. When given a choice between sticky and velvety disks, both *T. compacta* and *E. hirtipennis* consumed more velvety foliage ($F_{1,63} = 28.12$, $P < 0.001$ for *T. compacta* and $F_{1,59} = 9.26$, $P = 0.0035$ for *E. hirtipennis*, Figure 2). There were more than 2.5 times the number of *T. compacta* feeding pits on velvety as sticky foliage (back transformed means) and 25% more *E. hirtipennis* feeding pits on velvety than sticky foliage (Figure 2). When given a choice between sticky foliage and washed sticky foliage, both species preferred washed sticky foliage ($F_{1,44} = 8.78$, $P = 0.005$ for *T. compacta* and $F_{1,66} = 19.26$, $P < 0.001$ for *E. hirtipennis*). There were more than 2.3 times the number of *T. compacta* feeding pits, and 46% more *E. hirtipennis* feeding pits on washed sticky foliage than on sticky foliage with

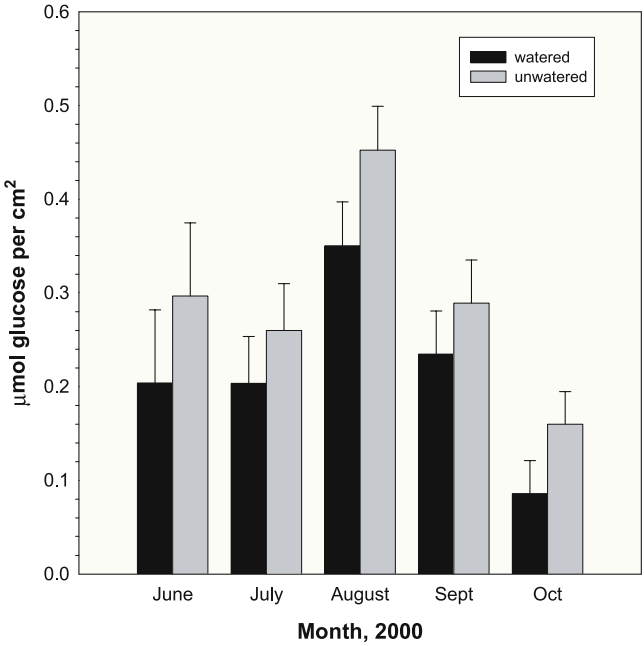

FIG. 1. Least squares means (±SE) quantity of glucose ester produced per cm^2 of leaf surface for watered and unwatered sticky plants sampled monthly. Data are pooled over blocks and families.

acylsugars (Figure 2). When given a choice between washed sticky foliage and velvety foliage, the number of feeding pits from either species did not differ significantly ($F_{1,36} = 2.63$, $P = 0.11$ for *T. compacta* and $F_{1,8} = 0.46$, $P = 0.52$ for *E. hirtipennis*, Figure 2).

L. daturaphila consumed 1.6 times more sticky foliage (back transformed means) when given a choice between sticky and velvety foliage, ($F_{1,8} = 7.65$, $P = 0.025$), but exhibited no significant choice for washed sticky foliage vs. sticky foliage with acylsugars ($F_{1,8} = 1.56$, $P = 0.25$), or washed sticky foliage vs. velvety foliage ($F_{1,8} = 0.03$, $P = 0.87$). In contrast to the bioassays with *T. compacta* and *E. hirtipennis*, the trial × type interactions were sufficiently large in the *L. daturaphila* bioassays that pooling of this potential source of variation with the error was not justified.

In no choice experiments, consumption of the three foliage types by *T. compacta* and *E. hirtipennis* differed significantly ($F_{2,280} = 13.05$, $P < 0.001$ for the former and $F_{2,128} = 3.76$, $P = 0.026$ for the latter.) Both species consumed more sticky foliage with the acylsugars removed than velvety foliage,

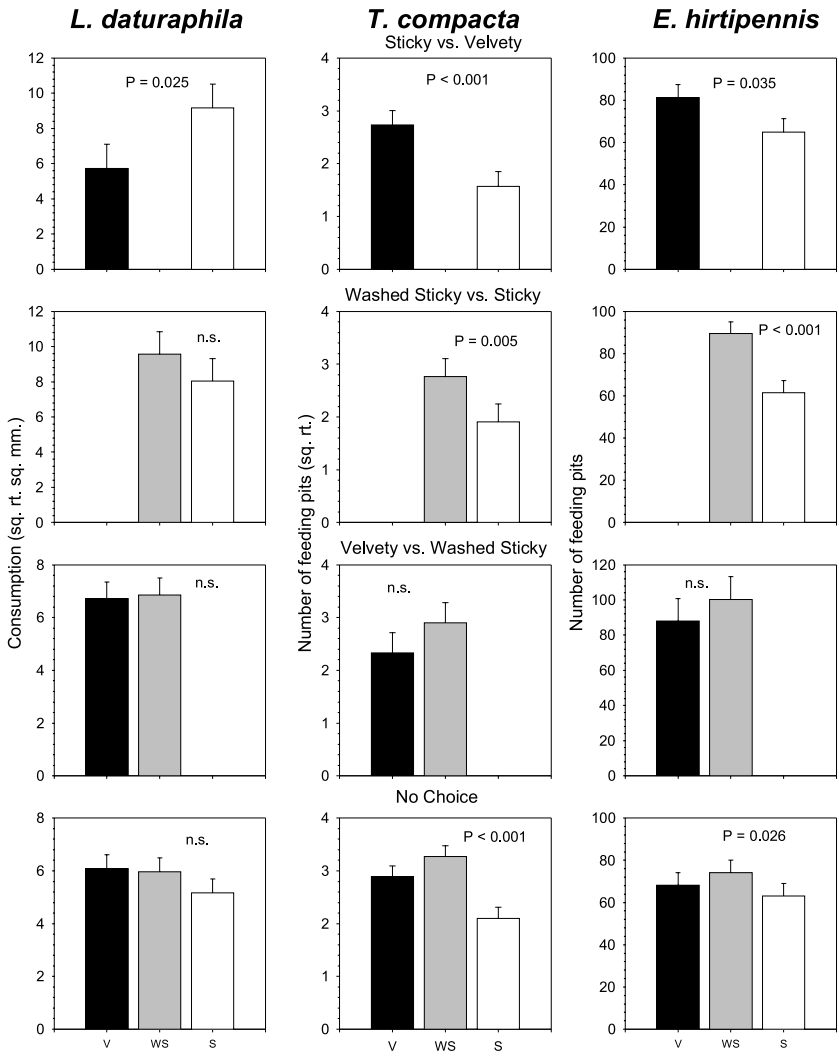

FIG. 2. Least squares means (±SE) feeding by *L. daturaphila, T. compacta*, and *E. hirtipennis* adults on disks of sticky leaves with their acylsugars (S), disks of sticky leaves with the acylsugars removed by washing (WS), and disks of velvety leaves (V) in choice and no-choice bioassays. Top row: sticky vs. velvety choice; second row: washed sticky vs. sticky choice; third row: velvety vs. washed sticky choice; fourth row: no choice. The probability of a statistically significant difference in means is shown. n.s.: Not statistically significant.

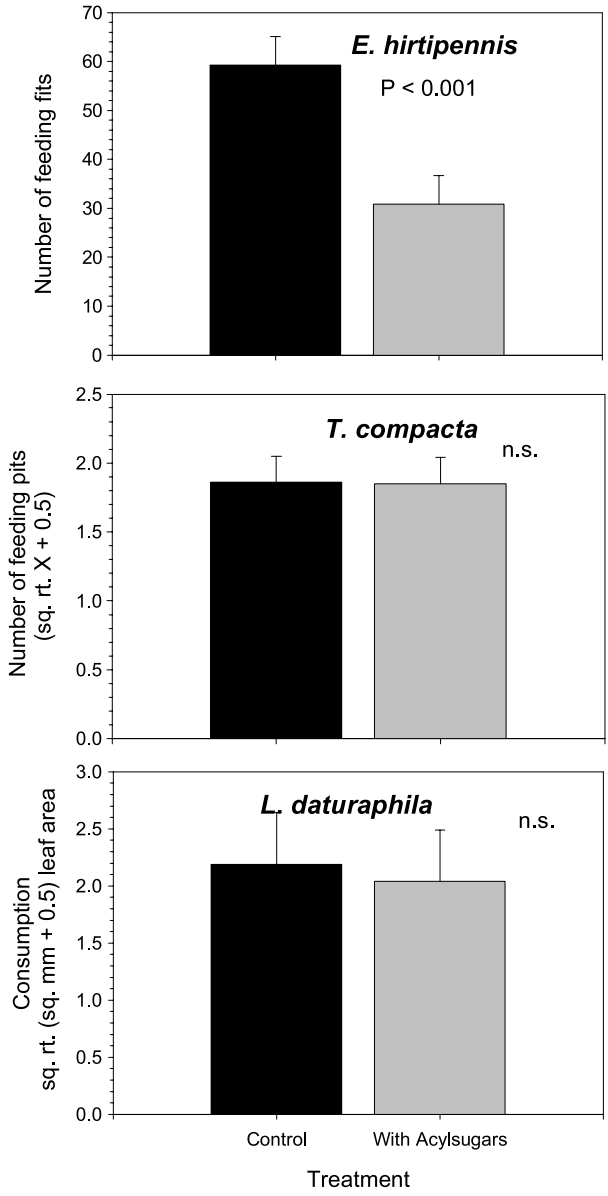

FIG. 3. Least squares means (±SE) feeding by *E. hirtipennis, T. compacta*, and *L. daturaphila* adults on disks of velvety leaves either sprayed with water (Control) or with 0.582 μmol/cm^2 of acylsugars in choice experiments. The probability of a statistically significant difference in means is shown. n.s.: Not statistically significant.

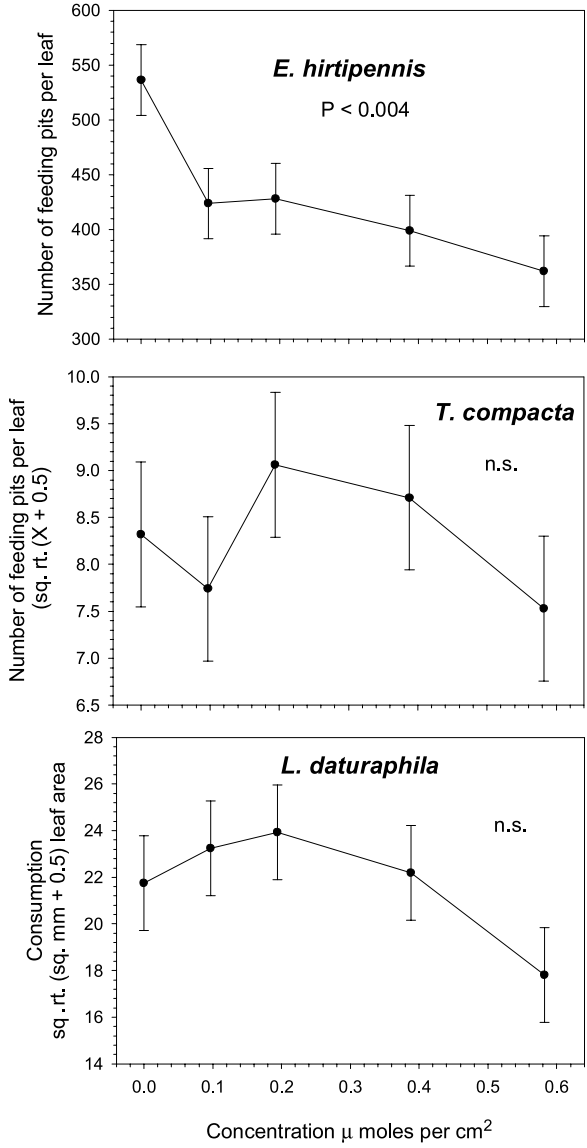

FIG. 4. Least squares means (±SE) feeding by *E. hirtipennis, T. compacta*, and *L. daturaphila* adults on velvety leaves either sprayed with water or with different concentrations of acylsugars in no-choice experiments. The probability of a statistically significant difference among means is shown. n.s.: Not statistically significant.

followed by sticky foliage. Consumption of washed sticky foliage was 30% and 8% greater than velvety foliage, and 161% and 17% greater than sticky foliage for *T. compacta* and *E. hirtipennis*, respectively (Figure 2). *L. daturaphila* consumed similar quantities of all three types of foliage in no-choice experiments ($F_{2,27} = 1.56$, $P = 0.23$, Figure 2). Mortality of all three insect species was negligible in these experiments and was not recorded.

Ester Addition Experiments. In the choice experiments, only feeding by *E. hirtipennis* was significantly reduced by adding 0.582 μmol acylsugars/cm^2 leaf ($F_{1,61} = 43.81$, $P < 0.001$), and the number of feeding pits was nearly cut in half by adding acylsugars to velvety foliage (Figure 3). Similarly, in the no-choice experiments, only feeding by *E. hirtipennis* was reduced by adding acylsugars to velvety leaves ($F_{4,41} = 4.54$, $P = 0.004$), and the highest quantity was no more effective in inhibiting feeding than the lowest (Figure 4). Neither *T. compacta* nor *L. daturaphila* showed any preference for treated or untreated velvety leaves in choice tests ($F_{1,4} = 0.001$, $P = 0.97$ for *T. compacta* and $F_{1,4} = 0.06$, $P = 0.82$ for *L. daturaphila*, Figure 3) nor feeding inhibition by acylsugars in no-choice tests ($F_{4,41} = 0.92$, $P = 0.46$ and $F_{4,40} = 1.65$, $P = 0.18$, respectively, Figure 4).

Survival of *L. daturaphila* adults in the no-choice experiments averaged 98.0 ± 2.0%, whereas survival of *T. compacta* adults averaged 95.0 ± 2.0%, and survival of *E. hirtipennis* adults averaged 85.4 ± 2.4%. In no case was the variation in survival associated with acylsugar dose (all $P \geq 0.32$, data not shown). Insect mortality in the choice experiments was similarly trivial and not analyzed.

DISCUSSION

All three beetle species tolerate the acylsugars of *D. wrightii*, but the acylsugars moderately deter feeding by *E. hirtipennis* and *T. compacta*. The acylsugars were not toxic to any species. This is not surprising because all beetles commonly feed on *D. wrightii* in nature and might be expected to be less affected by the acylsugars of *D. wrightii* than herbivores that encounter *D. wrightii* less frequently, if at all, under natural conditions. The absence of any effect of acylsugars on feeding by *L. daturaphila* was not unexpected because feeding damage by this insect was shown to be independent of trichome type in detailed field studies (Elle and Hare, 2000; Hare and Elle, 2002). Observations of feeding behavior under the microscope show that both adults and larvae of *L. daturaphila* cope with glandular trichomes simply by feeding upon them and ingesting both the gland and the stalk until the trichome layer is short enough for the insects to begin feeding on leaf lamellar tissue. Such

behavior implies that *L. daturaphila* has an effective physiological adaptation to acylsugars, although the mechanism of such an adaptation is not yet known.

T. compacta was more sensitive to acylsugars in the ester removal experiment than in the ester addition experiments. Feeding on sticky foliage was significantly reduced in all comparisons in the ester removal experiments (Figure 2), but not in the ester addition experiments (Figures 3 and 4). The application of acylsugars to velvety leaves does not completely mimic the presence of acylsugars on sticky leaves. Nonglandular trichomes of velvety leaves are less than 30% the length of glandular trichomes of sticky leaves (48 vs. 168 μm, van Dam et al., 1999), but occur at nearly 2.6 times the density. Application of acylsugars to velvety leaves replicates only the overall concentration per unit of leaf area, but not the location of the acylsugars at the tip of a long trichome. For weevils, the present results suggest that the location of the acylsugars on the tips of relatively long trichomes may be more important for deterrence than simply being present on the surface of leaves in a uniform layer. Future experiments to better understand the role of acylsugars on *T. compacta*, and perhaps other insect herbivores, might best be carried out by manipulating and exploiting natural variation in acylsugar production by glandular trichomes rather than by experimentally applying acylsugars to nonglandular foliage.

It is difficult to relate the relatively low biological activity of the acylsugars of *D. wrightii* reported here with the higher levels of other acylsugars against different insect species. High levels of mortality at relatively low doses (e.g., 1 mg/l or 1000 ppm or lower) are commonly reported against aphids, whiteflies, mites, and psyllids (Neal et al., 1994; Puterka and Severson, 1995; Liu et al., 1996), whereas only moderate feeding deterrence and negligible mortality occurred even after multiple applications of acylsugars totaling 120 mg/ml in the current study. It is unclear at this point to what extent the low mortality is the result of specific adaptations of all three coleopterans to *D. wrightii*'s acylsugars, or low overall toxicity of *D. wrightii*'s acylsugars in general. Different insect species may vary widely in their sensitivity to acylsugars (e.g., Neal et al., 1994; Puterka et al., 2003), and changes in either the sugars or the acid components of acylsugars often lead to unpredictable changes in biological activity (Puterka et al., 2003).

The range of acylsugar concentrations found in *D. wrightii* are similar to those found in other solanaceous species. For example, the concentration of total acylsugars in *Lycopersicon pennellii* lines ranged from 0.015 to 0.416 μmol/cm^2 in one study (Goffreda et al., 1990) and from 0.035 to 1.265 μmol/cm^2 in another (Mutschler et al., 1996). In *L. pennellii*, nearly a sevenfold range in concentration also occurred in different populations of the species when grown in a common garden (Shapiro et al., 1994). Although these acylsugars are responsible for resistance of *L. pennellii* to many pests of cultivated

tomato, little is known about the biological significance of variation in the total quantities or composition of acylsugars in natural *L. pennellii* populations (Shapiro et al., 1994).

The prediction that *E. hirtipennis* and *T. compacta* would be more sensitive to the acylsugars of *D. wrightii* than *L. daturaphila* was supported by the ester removal experiments. Additional support for the hypothesis was provided by the ester addition experiments for *E. hirtipennis*, but the ester addition experiments provide more equivocal support of the hypothesis for *T. compacta*. In both the ester removal and ester addition experiments, biological activity appeared to be via inhibition of feeding rather than toxicity. In addition to providing absolute protection against whiteflies (van Dam and Hare, 1998a) and reducing feeding by *Manduca sexta* larvae (van Dam and Hare, 1998b), the acylsugars of *D. wrightii* also reduce feeding by *E. hirtipennis* and *T. compacta*. The more specialized *L. daturaphila* (Kogan and Goeden, 1970) was completely unaffected by *D. wrightii*'s acylsugars.

(Received October 15, 2004; revised February 4, 2005; accepted March 23, 2005)

Abstract—The evolution of the diversity in plant secondary compounds is often thought to be driven by insect herbivores, although there is little empirical evidence for this assumption. To investigate whether generalist insect herbivores could play a role in the evolution of the diversity of related compounds, we examined if (1) related compounds differ in their effects on generalists, (2) there is a synergistic effect among compounds, and (3) effects of related compounds differed among insect species. The effects of pyrrolizidine alkaloids (PAs) were tested on five generalist insect herbivore species of several genera using artificial diets or neutral substrates to which PAs were added. We found evidence that structurally related PAs differed in their effects to the thrips *Frankliniella occidentalis*, the aphid *Myzus persicae*, and the locust *Locusta migratoria*. The individual PAs had no effect on *Spodoptera exigua* and *Mamestra brassicae* caterpillars. For *S. exigua*, we found indications for synergistic deterrent effects of PAs in PA mixtures. The relative effects of PAs differed between insect species. The PA senkirkine had the strongest effect on the thrips, but had no effect at all on the aphids. Our

INTRODUCTION

Plants often synthesize a diversity of structurally related secondary metabolites, such as the 34 glucosinolates in *Arabidopsis thaliana* (Kliebenstein et al., 2001) and the 200 alkaloids in *Catharanthus roseus* (Mersey and Cutler, 1986). The evolution and maintenance of this diversity in related compounds are poorly understood. Many secondary metabolites act as defense against herbivores, and it is often postulated that insect herbivores play an important role in the evolution of these compounds (Ehrlich and Raven, 1964; Rhoades and Cates, 1976). It has been shown that plant chemistry can indeed be under selection by insect herbivores (Mauricio and Rausher, 1997; Shonle and Bergelson, 2000). One explanation for the diversity of structurally related secondary metabolites is that new compounds evolve in a continuous evolutionary arms race between a plant and its insect herbivores, in which a plant that synthesizes new compounds is able to escape herbivory and insect herbivores, in turn, adapt to these compounds. This coevolutionary model implies that structurally related compounds differ in their effects on herbivores, and that more recently developed compounds in a biosynthetic pathway are more effective against present-day insects (Berenbaum and Feeny, 1981; Miller and Feeny, 1983). If the production of less effective compounds is costly, there would be selection against such compounds, although compounds that are earlier in the biosynthetic pathway can remain in the plant in small quantities as necessary precursors. Additionally, related compounds can act synergistically on herbivores (Adams and Bernays, 1978; Lindroth et al., 1988; Berenbaum et al., 1991). Furthermore, the diversity can be maintained through selection by several different herbivores and/or pathogens (Simms, 1990; Mithen et al., 1995; Juenger and Bergelson, 1998).

Although there are a few examples of differential toxic effects of structurally related compounds on specialist insect herbivores (Berenbaum et al., 1986, 1989; Bowers and Puttick, 1988), other studies have shown that related compounds do not differ in their effects on specialist insects (Lindroth et al., 1988; Johnson et al., 1996, Macel et al., 2002). Agrawal (2000) found that induction of a diversity of glucosinolates in *Lepidium virginium* had no effect on a specialist but decreased feeding by a generalist herbivore. Less adapted generalist herbivores could be more susceptible to differences in structure among related compounds and, hence, play an important role in the evolu-

tion and maintenance of the diversity of structurally related secondary plant compounds.

As a model system to study the evolution of the diversity of secondary metabolites, we used the pyrrolizidine alkaloids (PAs) in *Senecio* species. Senecionine-type PAs, comprising over 100 structures, are abundant in the genus *Senecio* (Asteraceae) (Hartmann and Witte, 1995), and senecionine is the primary product in the biosynthesis of these structures (Hartmann and Dierich, 1998). *Senecio jacobaea* L. can contain more than 10 different senecionine-type alkaloids (Witte et al., 1992), and variation in PA patterns has a genetic basis (Vrieling et al., 1993; Macel et al., 2004). PAs are toxic to some mammals (Bull et al., 1968; Mattocks, 1968), have antifungal activity (Hol and van Veen, 2002), and are mutagenic to *Drosophila melanogaster* (Frei et al., 1992). PAs are known to deter generalist insect herbivores (Bentley et al., 1984; Dreyer et al., 1985; van Dam et al., 1995; Hägele and Rowell-Rahier, 2000). Specialist herbivores can detoxify (Hartmann, 1999; Naumann et al., 2002) and sequester PAs (Rothschild et al., 1979; Dobler, 2001; Pasteels et al., 2003). Larval performance of the specialist moth *Tyria jacobaeae* L. was not affected by different PA profiles in its host plant *S. jacobaea* (Macel et al., 2002). Furthermore, larval performance and oviposition preference of this specialist among different *Senecio* species were not correlated with PA patterns (Macel et al. 2002; Macel and Vrieling, 2003). Host plant choice of PA-sequestering specialist flea beetles of the genus *Longitarsus* was also not correlated with PA patterns of *Senecio* species (Kirk et al., unpublished data). These results indicate that it is unlikely that these specialist herbivores play a role in the evolution and maintenance of the diversity of PAs in *Senecio* species. In this study, we focus on the effects of structurally related PAs on feeding and survival of five generalist insect herbivore species.

We addressed the following questions: (1) do related PAs differ in effects on generalists? (2) Do PAs act synergistically? (3) Do the relative effects of individual PAs (most effective PA) differ between insect species? Survival experiments were performed with the western flower thrips (*Frankliniella occidentalis* Pergande) and the green pea aphid (*Myzus persicae* Sulzer) using artificial diets with PAs. The deterrent effects of PAs on insect feeding were tested with the polyphagous Lepidopteran species *Spodoptera exigua* Hübner and *Mamestra brassicae* L. and with the gramnivorous migratory locust (*Locusta migratoria* L.).

METHODS AND MATERIALS

Pyrrolizidine Alkaloids. Most of the pyrrolizidine alkaloids we used in our experiments belong to the structural group of senecionine-type PAs. To specify

structural related activity of PAs, we also selected two PAs from other structural groups: heliotrine (lycopsamine-type PA) and monocrotaline (monocrotaline-type PA) (Hartmann and Witte, 1995). Senecionine-type PAs are mostly 12-membered macrocyclic diesters with a retronecine or otonecine base. Lycopsamine-type PAs are monoesters or diesters containing as a necic acid a hydroxylated 2-isopropylbutyric acid, and monocrotaline-type PAs are 11-membered macrocyclic diesters with retronecine base (Hartmann and Witte, 1995). The structures of the pyrrolizidine alkaloids we used are shown in Figure 1. Senecionine, seneciphylline, retrorsine, jacobine, and senkirkine are all present in *Senecio* species. Senecionine and seneciphylline are commonly found in most *Senecio* species (Hartmann and Zimmer, 1986; Macel et al., 2002). Jacobine is found in *S. jacobaea* together with senecionine and seneciphylline, and senkirkine is found in *S. vernalis* together with senecionine and seneciphylline. Retrorsine occurs in several *Senecio* species but is present in large quantities in *S. inaequidens*. Monocrotaline is found in *Crotalaria* species and heliotrine in *Heliotropum* species. Jacobine was isolated by centrifugal partition chromatography (CPC) from a PA extract of flowering plants of *S. jacobaea* extracted as described by Hartmann and Zimmer (1986). Monocrotaline, retrorsine, and retrorsine N-oxide were obtained from Sigma Chemical Co. Senecionine, seneciphylline, and senkirkine were obtained from Roth Chemical Co., and heliotrine was obtained from LATOXAN, France. We tested the effects of

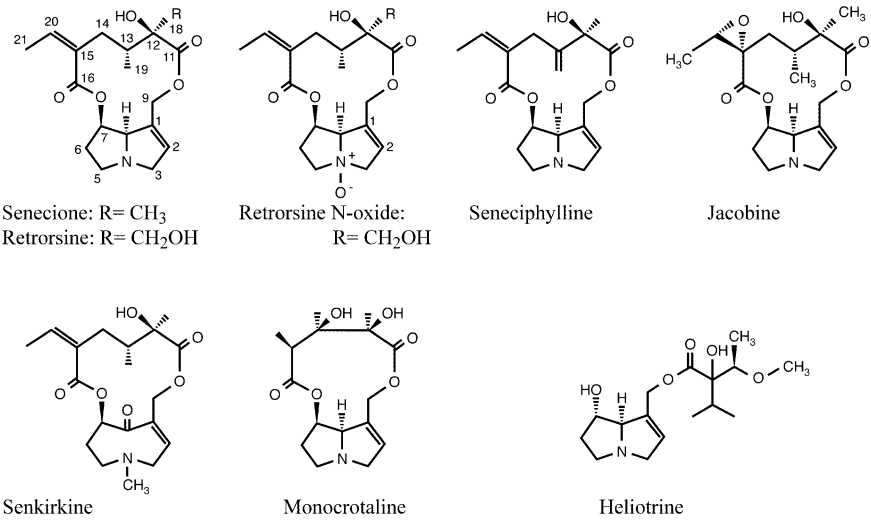

FIG. 1. Structures of pyrrolizidine alkaloids used in this study. Senecionine, R = CH_3, retrorsine: R = CH_2OH; retrorsine N-oxide, R = CH_2OH; seneciphylline; jacobine; senkirkine; monocrotaline; heliotrine.

senecionine, seneciphylline, senkirkine, and monocrotaline on each herbivore. We also tested the other PAs when available. A mixture of senecionine and seneciphylline (commonly found together in *Senecio* species) was tested for all herbivores but *Ma. brassicae*. For *S. exigua* and *L. migratoria*, other PA mixtures were tested as well. The average concentration of PAs found in *S. jacobaea* plants is 5 mg g^{-1} dry weight (Vrieling et al., 1993). This concentration was tested for all herbivores. For some herbivores, a range of concentrations of PAs was tested. PA concentrations differ between plant organs. In *Senecio vulgaris*, PA concentrations range from 0.5 mg g^{-1} dw in the leaves to 60 mg g^{-1} dw in achenes. In *S. vernalis*, PA concentrations in inflorescences can be 30 mg g^{-1} dry weight, more than 10 times the concentration found in the leaves (Hartmann and Zimmer, 1986). The effects of tertiary PAs were tested. In plants, PAs mainly occur as N-oxides (Hartmann and Toppel, 1987). After ingestion, the N-oxides are reduced to tertiary PAs in the gut of insects and then passively absorbed (Hartmann, 1999). For retrorsine, we also tested the effects of retrorsine N-oxide.

Frankliniella occidentalis (Thysanoptera; Thripidae). First instars of *F. occidentalis* were obtained from a lab culture reared on chrysanthemum cut flowers in a growth chamber at 20°C, 12-hr light/dark photoperiod, 60% RH. For the experiments, we used an artificial diet modified after Singh (1983) by de Jager et al. (1996). PAs were added to the diet by dissolving them in dichloromethane, adding the solution to the diet, and heating the diet (40°C) to let the dichloromethane evaporate. As a control treatment, we added dichloromethane without PAs to the diet and heated accordingly. For the experiments, we used "observation plates" as described by de Jager et al. (1996). Each plate contained six separate cells, and each cell contained one thrips. On every plate, six larvae could be observed independently. Experiments were done in the same growth chamber in which the thrips were reared. Senecionine, senkirkine, retrorsine, senkirkine, monocrotaline, and heliotrine were used in three different concentrations per PA: 0.5, 5, and 50 mg g^{-1} dw, equivalent to 0.1×, 1×, and 10× the plant concentration of *S. jacobaea*. Survival of the larvae was measured on 3, 6, 9, and 11 d after the start of the experiment. Per diet, four observation plates ($N = 24$) were used. In a separate experiment, we used control, retrorsine, and retrorsine N-oxide diets at 10× plant concentration and measured survival on each diet on d 3 and d 6 of the experiment. Per diet, five observation plates ($N = 30$) were used. In another experiment, we made diets with a 1:1:1 mixture of senecionine, seneciphylline, and retrorsine, 1:1 mixture of senecionine and seneciphylline, only senecionine, and a control diet. Two concentrations of total alkaloids were used, 2.5× and 5× plant concentration. Survival of the thrips larvae was measured on d 3 and d 6 of the experiment. Per diet, five observation plates ($N = 30$) were used. Thrips survival was analyzed with a Cox regression (Fox, 1993).

Myzus persicae (Homoptera; Aphididae). M. persicae were first reared on chilli pepper plants (*Capsicum frutescens*). Two months before the experiments, they were transferred to an artificial diet as described by Dadd and Mittler (1966). The aphids were reared in petri dishes (200 aphids per dish) (5-cm diam), and 350 μl of diet were applied between two layers of Parafilm®. Once every 3 d, the diet was refreshed. Rearing conditions were 20°C, 12-hr light/dark photoperiod, 50% RH. Senecionine, seneciphylline, senkirkine, monocrotaline, and a 1:1 mixture senecionine and seneciphylline were added to artificial diets. To dissolve the PAs in the diets, the pH was adjusted to pH 5. For each PA, we made four diets of different concentrations: 1.5, 3, 4.5, and 6 mM, equivalent to 0.5×, 1×, 1.5×, and 2× the average plant concentration for *S. jacobaea*. Per experiment, we put 10 adult, apterous aphids on the petri dish. Experiments were repeated 11 times. The experiments lasted 120 hr and were done in a growth chamber at 20°C, 12-hr light/dark photoperiod, 50% RH. Not all PAs could be tested simultaneously. We started experiments with three randomly chosen PA diets and a control per day. The mortality on the control diets did not differ significantly among days. Therefore, we grouped the mortality on the control diets on different days together. The percentage mortality of *M. persicae* on the different PA diets was tested against the percentage mortality on control diet with a Mann–Whitney *U*-test with the sequential Bonferroni correction for the number of PA diets we tested.

Spodoptera exigua (Lepidoptera; Noctuidae). Third instar caterpillars from *S. exigua* were obtained from a lab culture reared on an artificial diet (Singh, 1983) in a growth chamber at 25°C, 16:8-hr light/dark photoperiod, 70% RH. The experiments were performed in the same growth chamber. Senecionine, seneciphylline, retrorsine, retrorsine N-oxide, jacobine, senkirkine, monocrotaline, and heliotrine were dissolved in methanol and applied on lettuce disks (*Latuca sativa*) of 4-cm diam using a pipette to distribute droplets on the upper side of the lettuce disks. For each PA, three solutions of different concentrations were used: 0.15, 0.5, and 1.5 mg g^{-1} fw, equivalent to 0.3×, 1×, and 3× the natural PA concentration found in *S. jacobaea*. As a control, lettuce disks were treated with only methanol. A lettuce disk with a PA was placed on moist filter paper (4.25-cm diam) in a petri dish (10-cm diam) and offered to a caterpillar. After 24 hr, the amount of lettuce eaten was determined by measuring the leaf area (mm^2) eaten. The no-choice experiments were repeated 25 times. Differences in amount eaten among the PAs were analyzed with a Kruskal–Wallis test. In a separate experiment, mixtures of two PAs (1:1 senecionine/seneciphylline, 1:1 senecionine/senkirkine), mixtures of three PAs (1:1:1 senecionine/seneciphylline/jacobine, 1:1:1 senecionine, seneciphylline, senkirkine), and the single senecionine were applied to the lettuce disks (total PA concentration 0.5 mg g^{-1} fw in all cases). The amount eaten of the disk was normally distributed and analyzed with an ANOVA with *post hoc* Bonferroni tests.

Mamestra brassicae (Lepidoptera; Noctuidae). Third and fourth instars from *Ma. brassicae* were obtained from a lab culture where they were first reared on white cabbage (*Brassica oleracea* var. *alba*). One generation prior to the experiments, they were transferred onto an artificial diet (Singh, 1983) in a growth chamber at 20/15°C 16:8-hr light/dark photoperiod, 70% RH. Experiments were performed under the same conditions. Senecionine, seneciphylline, retrorsine, retrorsine N-oxide, jacobine, senkirkine, monocrotaline, and heliotrine were dissolved in methanol and applied on lettuce disks of 4.2-cm diam at a concentration of 0.5 mg g^{-1} fw. The dissolved PAs were applied in the same way as in the *Spodoptera* experiments. As control, lettuce disks were treated with only methanol. Two lettuce disks, one with a PA and one control, were placed on a moist filter paper (4.25-cm diam) in a petri dish (14-cm diam) and were offered to a caterpillar in a two-choice experiment. After 24 hr, the amount eaten from each lettuce disk was determined by measuring the leaf area (mm^2) eaten. The choice experiments were repeated 30 times. For each experiment, the preference was tested with the Wilcoxon signed-ranks matched-pairs test. To be able to compare deterrent effects among PAs, a preference index was generated: preference index = 100 × (amount eaten of PA − amount eaten of control)/(amount eaten PA + amount eaten control).

Differences in preference indices among the PAs were tested with a Kruskal–Wallis test. *Post hoc* Mann–Whitney *U*-tests were done with a sequential Bonferroni correction for significance levels.

Locusta migratoria (Orthoptera; Acrididae). The fifth instar hoppers of *L. migratoria* (gregarious form) that were used for experiments had been reared on dried grass. The experiments were performed in a growth chamber at 20/15°C, 16:8-hr light/dark photoperiod, 70% RH. Senecionine, seneciphylline, retrorsine, retrorsine N-oxide, jacobine, senkirkine, monocrotaline, and heliotrine were dissolved in methanol and applied on glass microfiber filters (Whatman® GF/A, 4.7-cm diam). To each filter, 0.5 ml of distilled water was added. The PA concentration was 0.5 mg g^{-1} fw (fw of filter with water), and to the control, only methanol was added. Two disks, one with PA and one control, were offered in a choice situation to the nymphs. The filters were placed in a white plastic box (17 × 12.5 × 6 cm) covered with a transparent lid. After 16 hr, the amount eaten from each filter was determined by measuring the number of mm^2 eaten. In the same way, the preference between a single PA and a 1:1(:1) PA mixtures was tested by offering the nymphs a disk with one PA and a disk with a mixture of two or three PAs in a two-choice test. Experiments were repeated 19–26 times. For each experiment, the preference was tested with the Wilcoxon signed-ranks tests. For comparison between PAs, preference indices were calculated and compared in an identical way as for *Ma. brassicae*.

RESULTS

F. occidentalis. The survival of the thrips larvae differed among the PA diets. Heliotrine did not affect survival of the larvae, whereas the other PAs significantly reduced larval survival at 10× plant concentration (Figure 2). At 1× plant concentration, only senkirkine decreased survival, although this was only marginally significant. Because senecionine is the precursor for senecionine-type PAs, we tested if survival on the senecionine diets differed from the other PAs. Over all concentrations tested, survival on senecionine diets was lower than on the heliotrine diets but higher than on the senkirkine diets (Table 1). We found no indications for a synergistic effect of PAs in PA mixtures. At both 2.5× and 5× plant concentration, survival on the PA diets did not differ among diets with only senecionine and diets with PA mixtures (Cox regression, senecionine–mixtures: $P > 0.05$). Both the retrorsine N-oxide and

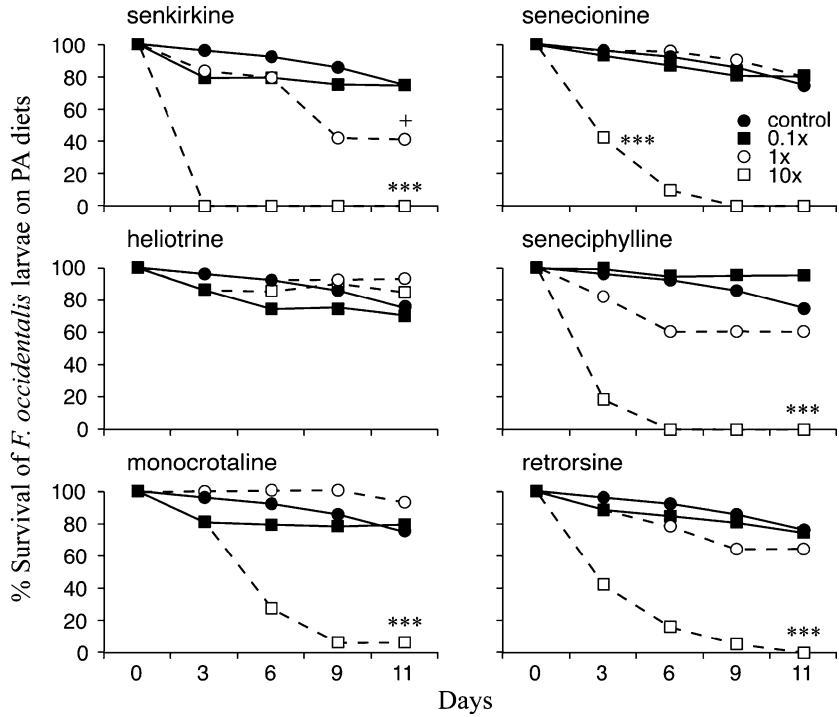

FIG. 2. Percentage survival of larvae of the thrips *F. occidentalis* on diets with pyrrolizidine alkaloids. Three different pyrrolizidine alkaloid concentrations were used, 0.1×, 1×, and 10× the plant concentration ($N = 24$ thrips per diet). ***($P < 0.001$) $^{+}$($P < 0.07$) (Cox regression, alkaloid diet compared to control).

TABLE 1. SURVIVAL ANALYSIS (COX REGRESSION) OF LARVAE OF THE THRIPS *F. occidentalis* ON PYRROLIZIDINE ALKALOID (PA) DIETS

	B	SE	Wald	df	P	R
Senecionine–PAs			32.70	5	<0.001	0.129
Retrorsine	0.192	0.265	0.525	1	0.469	0
Seneciphylline	0.199	0.280	0.504	1	0.478	0
Monocrotaline	−0.355	0.289	1.508	1	0.220	0
Heliotrine	−1.479	0.378	15.28	1	<0.001	−0.099
Senkirkine	0.568	0.265	4.576	1	0.032	0.043

All alkaloids are tested against senecionine with concentrations as strata in the model. See also Figure 2.

the free-base retrorsine significantly decreased survival compared with the control, but the N-oxide was less toxic than the free base (Figure 3).

M. persicae. The survival of *M. persicae* differed among the PA diets (Figure 4). Senecionine and seneciphylline reduced survival at plant concentration levels. Monocrotaline reduced survival only at the highest PA concentration (2× plant concentration). Senkirkine did not affect the survival of the aphids at all. There was no synergistic effect of PAs in the PA mixture (Figure 4).

S. exigua. We found no deterrent effects of any individual PA on the feeding of *S. exigua* caterpillars. At all three PA concentrations (0.3×, 1×, and 3× plant concentration), the amount consumed by the caterpillars from the lettuce disks with PAs did not differ from the control disks or among the PAs (Kruskal–Wallis, all $P > 0.30$). We did find indications for synergistic effects of PAs in the PA mixtures (Figure 5). The amount eaten tended to differ among the

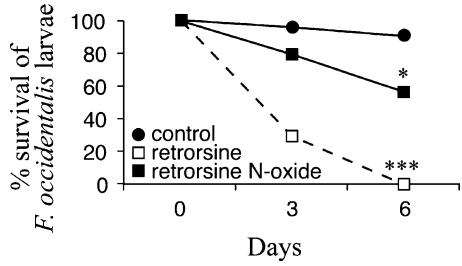

FIG. 3. Percentage survival of larvae of the thrips *F. occidentalis* on diets with retrorsine and retrorsine *N*-oxide and a control diet. PA concentration was 10× plant concentration ($N = 30$ thrips per diet). ***($P < 0.001$), *($P < 0.05$) (Cox regression, alkaloid diet compared to control).

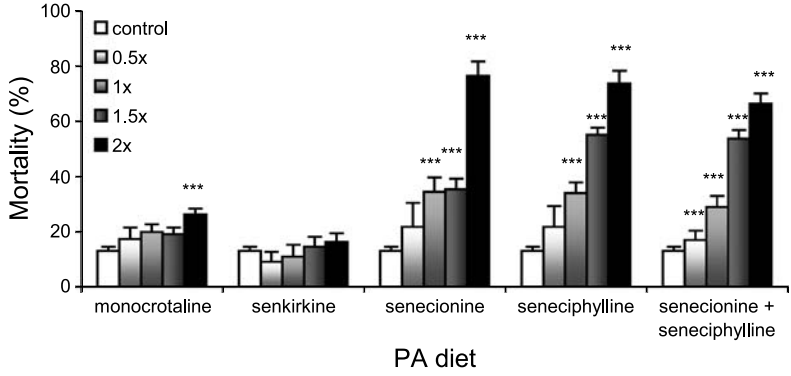

FIG. 4. Survival (±SE) of the aphid *M. persicae* on diets with pyrrolizidine alkaloids (N = 11 replicates per diet, 10 aphids per replicate). Concentrations of 0.5×, 1×, 1.5×, and 2× the plant concentration of *S. jacobaea* were used. Significance levels of Mann–Whitney *U*-test for independent samples, alkaloid compared to control, corrected with sequential Bonferroni test: *($P < 0.05$), ***($P < 0.001$).

PA mixtures (ANOVA, $F = 2.13$, $df = 4$, $P = 0.081$). *Post hoc* tests showed that the caterpillars consumed less from the PA mixture of senecionine/seneciphylline/senkirkine than from senecionine. The feeding from the other mixes did not differ significantly from senecionine.

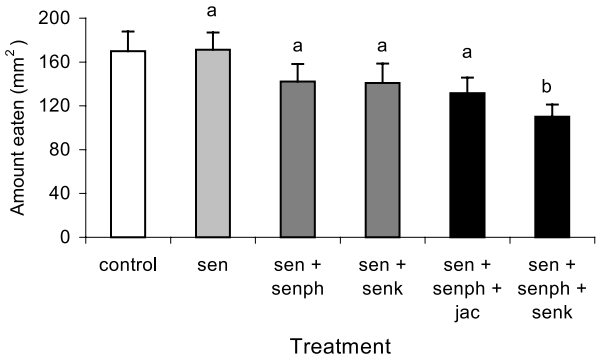

FIG. 5. Amount eaten (±SE) by caterpillars of *S. exigua* of lettuce disks with single pyrrolizidine alkaloids, alkaloid mixtures, or control (methanol). Total pyrrolizidine alkaloid concentration was 1× plant concentration. Different letters indicate significant differences [one-way ANOVA among alkaloids (P = 0.081) followed by *post hoc* Bonferroni tests ($P < 0.05$)] N = 25 replicates per test. Pyrrolizidine alkaloid codes: sen = senecionine; senph = seneciphylline; senk = senkirkine; jac = jacobine.

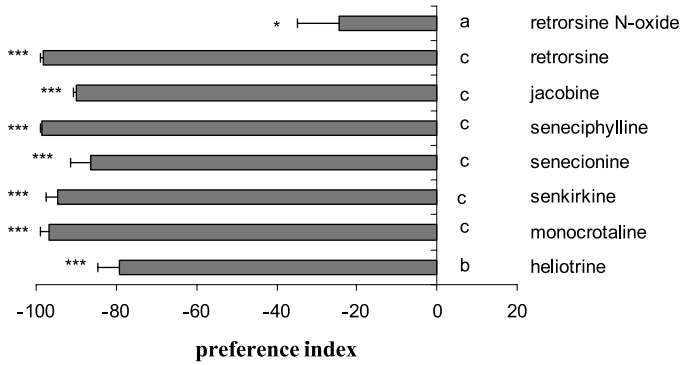

FIG. 6. Preference indices (±SE) for *L. migratoria* feeding on glass fiber filters with pyrrolizidine alkaloids. $N = 21–25$ replicates per test. Comparison per alkaloid for testing for preference for control: *($P < 0.05$), ***($P < 0.001$) (Wilcoxon signed-ranks matched-pairs test). Comparison of preference indices: different letters indicate significant differences between preference indices [Mann–Whitney *U*-test with sequential Bonferroni correction ($P < 0.05$)].

Ma. brassicae. No deterrent effects of PAs on the feeding of *Ma. brassicae* caterpillars were found in any of the two-choice experiments (Wilcoxon signed-ranks match-pairs tests, all $P > 0.05$). There were no differences in preference indices between the PAs (Kruskal–Wallis, $\chi^2 = 8.04$, $df = 6$, $P = 0.24$).

L. migratoria. All PAs deterred feeding of *L. migratoria*, but not all PAs were equally deterrent (Figure 6). Heliotrine was the least deterrent of the free-base PAs. All other PAs were equally deterrent when tested against the control (Figure 6). However, when senecionine and seneciphylline were tested against

TABLE 2. FEEDING OF *L. migratoria* FROM GLASS FIBER DISKS WITH PYRROLIZIDINE ALKALOIDS IN TWO-CHOICE EXPERIMENTS

Choice	mm^2 eaten (±SE)	*N*	P^a
Senecionine	157.9 (15.4)	19	0.082
Seneciphylline	10.6 (1.2)		
Senecionine	186.0 (14.9)	19	0.006
Senecionine + Seneciphylline	4.3 (0.3)		
Seneciphylline	14.9 (11.1)	20	0.149
Senecionine + Seneciphylline	39.9 (6.5)		
Senecionine + Seneciphylline	17.3 (2.0)	24	0.016
Senecionine + Seneciphylline + Jacobine	2.8 (0.3)		

[a] *P* values of Wilcoxon signed-ranks matched-pairs test.

each other, the locusts tended to prefer senecionine to seneciphylline (Table 2). Senecionine alone was less deterrent than a mixture of senecionine + seneciphylline, but seneciphylline alone was equally deterrent as the senecionine + seneciphylline mixture (Table 2). These results show that seneciphylline is more deterrent than senecionine. The senecionine + seneciphylline mixture was less deterrent than the mixture of senecionine + seneciphylline + jacobine (Table 2), indicating possible synergistic effects. Although the retrorsine N-oxide deterred the locusts, it was less deterrent than the free-base PAs (Figure 6).

DISCUSSION

Our results showed that the effects of PAs differed among the insect species. All PAs significantly deterred feeding of the locust. Individual PAs did not deter feeding by the caterpillars of the two polyphagous moth species. The two moth species are truly polyphagous and are possibly less sensitive to various secondary metabolites in their diet than the migratory locust that is a specialist on grasses. We performed no-choice tests for *S. exigua*, and choice tests for *Ma. brassicae* and *L. migratoria*. Perhaps if we had used choice tests for *S. exigua*, our results would have been different. van Dam et al. (1995) found that the single PAs from *Cynoglossum officinale* deterred feeding of *S. exigua* in choice tests. These PAs are of a different structural type than the PAs we tested, which could also explain the contrasting results. The PA N-oxide had less effect on the locust and the thrips than the free-base form of the same PA. Other studies have also shown that PA N-oxides are less deterrent to insects than the free-base PAs (Dreyer et al., 1985; van Dam et al., 1995). Nevertheless, the PA N-oxide still significantly deterred feeding or decreased survival in our experiments. In *Senecio* species, young leaves and flowers have a relatively high concentration of PAs compared with old leaves (Hartmann and Zimmer, 1986; De Boer, 1999). The concentration-dependent effect of PAs on the aphids and thrips showed that in *Senecio* species, the more valuable plant parts, flowers, and young leaves are better defended against these generalists than less important organs, as is predicted by the optimal defense theory (Zangerl and Bazzaz, 1992; van Dam et al., 1996).

The coevolutionary arms race hypothesis between plants and insect herbivores (Ehrlich and Raven, 1964) implies that related compounds have different effects on herbivores. Our results showed that structurally related PAs differed in their effects on the locust *L. migratoria*, the aphid *M. persicae*, and the thrips *F. occidentalis*, indicating a potential for selection on individual PAs by insects. Differences in (deterrent) effects among structurally related PAs were also found on spruce budworm larvae (Bentley et al., 1984) and the pea aphid *Acyrthosiphon pisum* (Dreyer et al., 1985). The arms race hypothesis

further implies that evolutionary older compounds are less effective than more recently developed ones (Feeny, 1976; Berenbaum and Feeny, 1981). It is generally assumed that successive steps in biosynthesis of compounds represent successive evolutionary stages (Rodman, 1981). We found that some, but not all, senecionine-derived PAs were more effective than the precursor senecionine, and this depended on the herbivore species that was tested.

Another explanation for the diversity of plant secondary metabolites could be that related compounds act synergistically (Adams and Bernays, 1978; Lindroth et al., 1988; Berenbaum et al., 1991). However, we did not find any evidence for synergistic effects of PAs on survival of the thrips or aphids. We did find indications that a mixture of PAs is more deterrent than single PAs for the locust and *S. exigua* caterpillars. Therefore, we cannot exclude that plants with a more diverse PA composition will be more successful in deterring generalist insect herbivores than plants with a simpler PA pattern.

The diversity in related secondary metabolites may also be maintained by selection pressure from different herbivores (Simms, 1990; Mithen et al., 1995; Juenger and Bergelson, 1998). The experiments with the thrips and the aphid show that generalist insect species can respond differently to the same PA. While senkirkine was the most effective PA against the thrips at plant concentration level, it had no effect on the aphid. Senecionine and seneciphylline were the most effective against the aphid. Herbivore populations will change over time and, thus, selection pressure on plant defense chemistry will change accordingly. Many authors have linked variation in plant secondary metabolites with contrasting selection pressures from generalist and specialist herbivores (e.g., Linhart, 1991; van der Meijden, 1996). Our results show that it is likely that contrasting selection pressures from different generalist herbivores will also maintain variation in plant secondary compounds. In conclusion, we found that there is a potential for selection of generalist insect herbivores on plant PA profiles and PA diversity.

Acknowledgments—This research was supported by a grant from the Gratama foundation. We thank Helene de Vos for the isolation of jacobine, Lily Muñoz, Henk Nell, and Kees Koops for their technical assistance, Leo Koopman for providing the *Mamestra*, and Klaas Vrieling, Nicole van Dam, and Ed van der Meijden for their valuable comments on earlier drafts of the manuscript.

Abstract—The identification and quantification of flavonoids (rutin and genistin) present in extracts of soybean genotypes, and their effects on the biology and physiology of *Anticarsia gemmatalis* Hübner (Lep.: Noctuidae) were studied. Analysis of covariance and bicoordinate utilization plots were used to remove the effect of feeding time from pupal weight and consumption as well as to separate pre- and postingestive effects of treatment on *A. gemmatalis* growth. Genotypes PI 274454, PI 227687, and "IAC-100" extracts in general, caused higher mortality, negatively influenced initial larval and pupal weight, and elongated larval cycle. Larvae fed on the "IAC-100" extract diet ingested larger amounts of food per unit of time, but were less efficient in its conversion to biomass. Leaf extracts of PI 227687 had the largest concentration of rutin (quercitin 3-*O*-rhamnosylglucoside), followed by PI 274454, and "IAC-100"; PI 74454 also had the highest genistin (genistein 7-*O*-glucoside) content. The susceptible cultivar "BR-16" showed only a kaempferol-based flavonoid in its chemical profile, indicating that after successive crosses, secondary compounds responsible for plant defenses were eliminated. Genotypes PI 274454, PI 227687, and "IAC-100" showed accentuated resistance characteristics and were considered inadequate sources for the development of *A. gemmatalis*. Considering rutin and genistin concentration in these genotypes, it is suggested that flavonoids are important factors conferring resistance to *A. gemmatalis*.

Key Words—Resistance, velvet bean caterpillar, rutin, genistin.

INTRODUCTION

The velvet bean caterpillar (*Anticarsia gemmatalis* Hübner) (Lep.: Noctuidae) is considered the main defoliator pest of soybean [*Glycine max* (L.) Merrill] in Brazil. Utilization of insect-resistant cultivars have advantage of being less harmful to the environment and, at the same time, do not require adoption of complex technologies by growers. Resistance to insect attack is due largely to chemicals present in the host plant (Kubo and Hanke, 1986). These compounds, which generally are secondary metabolites, can have behavioral (preingestive) and physiological (postingestive) effects on insects (Berenbaum, 1986).

Efforts have been made with many crops to obtain lines and cultivars with moderate levels of resistance to insects. Wild soybean introductions PI 171451, PI 227658, and PI 229358 have been used since the early 1970s as sources of resistance to defoliator insects such as *Epilachna varivestis* (Van Duyn et al., 1971, 1972), *Trichoplusia ni* (Luedders and Dickerson, 1977), *Diabrotica speciosa*, and *Colaspis* sp. (Rezende and de Miranda, 1980), *Pseudoplusia includens* (Killen et al., 1977; Beach and Todd, 1988), *Spodoptera* spp. (Beach and Todd, 1987), and *A. gemmatalis* (Beach and Todd, 1988; Lambert and Killen, 1984; Oliveira et al., 1993). In addition, these PIs were considered moderately resistant to some seed-sucking insects (Jones and Sullivan, 1979; Piubelli et al., 2003a,b). In field trials, breeding lines with PI 274454 in their genealogy were less defoliated than cultivars used as susceptible controls (Rezende et al., 1980). Cultivar IAC-100, which in addition to other sources of resistance, has PI 274454 and PI 229358 in its genealogy, was released by the breeding program of the Instituto Agronômico (Campinas, São Paulo State, Brazil) because of its resistance to leaf feeders and stink bugs (Rossetto et al., 1995; Veiga et al., 1999).

Few attempts have been made to investigate the chemical basis for insect resistance in soybean. Consumption by *P. includens* larvae of an artificial diet, in which crude CH_2Cl_2 (methylene dichloride) leaf extracts of PI 227687 had been incorporated, caused strong allelochemical effects, such as weight reduction and increased mortality (Smith and Fischer, 1983). Sharma and Norris (1991) reported the extraction, separation, and identification of isoflavonoids of PI 227687 foliage as well as their antifeedant and/or antibiotic properties against *T. ni*.

In general, soybean and other leguminous species lack some potent secondary metabolites that are present in other plant families, such as Cruciferae and Solanaceae (Kogan, 1986). Nevertheless, some constitutive (Hoffmann-Campo, 1995) or induced flavonoids (Kogan and Fisher, 1991) were identified in diverse soybean organs. Those phenolic compounds also play important functions in defense against microorganisms and insects (Dixon and

Steele, 1999). Some of them may be antifeedant and/or antibiotic to soybean pests (Neupane and Norris, 1991; Sharma and Norris, 1991, 1994; Hoffmann-Campo et al., 2001).

Extracts from leaves of the insect-resistant genotype PI 227687 negatively affected the physiology and behavior of *Heliothis virescens* larvae (Hoffmann-Campo, 1995) and *T. ni* (Hoffmann-Campo, 1995; Hoffmann-Campo et al., 2001). The effects persisted when the most polar fraction, named fraction A, was added to the artificial diet. This fraction was composed mainly of rutin (quercitin 3-*O*-rhamnosylglucoside), quercitin 3-*O*-glucosylgalactoside, and genistin (genistein 7-*O*-glucoside). In further studies, rutin negatively affected the development of *H. virescens* (Hoffmann-Campo, 1995) and *T. ni* (Hoffmann-Campo et al., 2001). These insects are occasional and none of them are main pests of soybean (Kogan and Turnipseed, 1987) and, thus, likely not exposed to compounds of this plant. The aglycone quercitin and its glycoside rutin increased mortality and elongated larval period of *A. gemmatalis* (Gazzoni et al., 1997), although the physiological effect of flavonol was not investigated.

This study was conducted to evaluate the effects of different soybean genotype extracts with respect to the biology and physiology of *A. gemmatalis*, and also to quantify the flavonoids rutin and genistin present in these genotypes that are used as sources of resistance to insect pests in the breeding programs of Embrapa Soybean. Furthermore, we tested the hypothesis that, as a leguminous specialist and major defoliator, *A. gemmatalis* could cope with the mixture of allelochemicals present in soybean leaves by postingestive mechanisms.

METHODS AND MATERIALS

Plant Material. Soybean leaves of the genotypes "BR-16," PI 229358, PI 227687, PI 274454, and "IAC-100," produced under greenhouse conditions ($T = 23 \pm 2°C$, RH = 78%), were harvested at growth stage V6 (Fehr and Caviness, 1977) to carry out bioassays and chromatographic analyses. The bulk leaves were collected to perform bioassays, and samples of the fourth trifoliolate were taken to the Phytochemistry Laboratory to be analyzed by high-performance liquid chromatography.

Plant Extract for Diet Incorporation. To carry out the feeding experiments, 50g of dried leaves of each genotype were ground, mixed with 40% aqueous ethanol (EtOH), and left overnight (approximately 18 hr) in a shaker at 100 rpm. The extract was filtered through Framex paper and reduced by rotary evaporator. The aqueous extract was passed into a glass-wool plugged column (3×38 cm), with a nonionic Amberlite XAD-4 resin as adsorbent. Ultrapure water (pH 2.0 and 7.0) was passed through the column to eliminate the bulk of

non-flavonoid compounds. Methanol (MeOH; 80%) was used for flavonoid elution. The resulting extract was concentrated on a rotary evaporator, maintained frozen (−17°C) until addition to the artificial diet of *A. gemmatalis* (Greene et al., 1976, modified by Hoffmann-Campo et al., 1985), and offered to the larvae. A diet without addition of extract was used as control.

Feeding Experiments. A. gemmatalis larvae were obtained from the Embrapa Soybean Laboratory of Insect Mass Rearing, located in Londrina, PR, Brazil. Since eclosion, the larvae were reared on the diet containing each soybean extract. From late second and early third instars, larvae were weighed and housed individually in 30-ml acrylic cups (Fill-rite Corp., Newark, NJ, USA). Insects were maintained in controlled environmental chambers (25 ± 2°C; RH: 70 ± 10%; 14 L:10 D photoperiod) and observed daily to evaluate the average duration of each larval stage, until reaching the prepupal stage; numbers of dead insects were recorded to calculate percent mortality. Pupae were frozen (−50°C), oven-dried (60°C, 72 hr), and weighed to obtain dry pupal mass. Remaining food and frass were placed into tubes, oven-dried (60°C, 72 hr), and weighed. To estimate the initial dry weight of the larvae, five (second/third instar) were taken from each treatment, weighed, frozen (−50°C), oven-dried (60°C, 72 hr), and reweighed. The correction factor for initial fresh to dry weight was calculated. Values obtained were multiplied by the fresh weight of each set of experimental larvae. The same procedure was used to calculate the dry weight of the food.

Plant Extract Chemical Analysis. The fourth trifoliolate leaves of each genotype were excised and cut into small pieces. Aliquots of each sample (500 mg) were placed into glass tubes, macerated, and homogenized with 5.0 ml of 80% MeOH. After heating (50°C), extracts were maintained with constant shaking (150 rpm) for approximately 18 hr, and the supernatants were transferred into 50-ml beakers, and kept in fume cupboards until dryness (±96 hr). Samples were redissolved in 1.0 ml of 80% MeOH, and 20-µl aliquots were injected into an HPLC (Shimadzu, model SPD-M10A VP) and developed on a reverse-phase column (CLS-ODS-C18-M, 4.6-mm internal diam × 250 mm in length). Flavonoids were eluted with a linear gradient system (Hoffmann-Campo, 1995) composed of two solvents: (A) 2% acetic acid (HOAc, Vetec, UV/spectrometry grade) and (B) a solution composed of MeOH (J.T. Baker, HPLC grade), HOAc, and water (18:1:1). The initial gradient consisted of 75% solvent A and 25% B, which changed to 35% A and 65% B in 23 min, and returned to the initial condition at 25 min. This condition was maintained for 5 min for column cleaning. Solvent flow rate was 1.0 ml/min, and absorption was measured at 260 nm.

Flavonoid concentrations in the genotypes were estimated by comparing the concentration of rutin ($C_{27}H_{30}O_{16}$, quercitin 3-*O*-rhamnosylglucoside) and genistin ($C_{21}H_{20}O_{10}$, genistein 7-*O*-glucoside) in the genotype samples with

those obtained from HPLC-injected standards (Sigma). Standard concentrations of rutin (0.01, 0.02, 0.04, 0.08, 0.16, 0.32, and 0.64 mg/ml) and of genistin (0.01, 0.02, 0.04, and 0.08 mg/ml) were injected onto the HPLC to construct the compound equations. After the injection of samples, scanning by photodiode array was performed to compare HPLC trace spectra and retention times with those of the standards. The area corresponding to each compound trace was calculated and applied to the equation (standards) to estimate the concentrations of rutin and genistin in each genotype.

Statistical Procedures, Feeding Experiments. Bioassays were developed in a completely randomized design, with six treatments and 30 replicates. Mortality in each treatment was compared by using a χ^2 test of homogeneity, according to Banzatto and Kronka (1992), at a 5% probability. All other data were analyzed using the SAS statistical package for PC (SAS Institute, 1996). The effects of treatments on larval initial weight, pupal weight, food consumption, frass production, and feeding time (days) were analyzed through ANOVA, performed by the general linear model (GLM) procedure. If a significant effect of treatments at minimal 5% of probability was observed, the means were compared by least significant difference (LSD). Analysis of covariance (ANCOVA), proposed by Raubenheimer and Simpson (1992), followed by bicoordinate utilization plots (Raubenheimer and Simpson, 1994), was used to remove the effect of covariate feeding time from consumption and pupal weight. This statistical procedure was also used to separate pre- and postingestive effects of treatment on *A. gemmatalis* growth. Thus, differences in pupal weight were adjusted for covariates consumption and digested food (consumption − frass produced). When the interaction among covariate and treatments was not significant, the parallel line model was used, and the main effect of treatment and/or covariate was considered. If the effect of treatment was significant at a minimal 5% probability, means were compared by ANCOVA means (least square means).

Statistical Procedures, HPLC Analyses. A completely randomized design was used in the HPLC data analyses, with four genotypes and five replicates, injected in duplicate. Data were analyzed by ANOVA, and the means of each genotype were compared by Tukey's test at a 5% probability, by using the SAS statistical package (SAS Institute, 1996).

RESULTS

Differences in larval mortality rates were dependent on the treatment as indicated by a significant χ^2 test. Mortality rates were higher when larvae were fed on PI 274454, "IAC-100," or PI 227687 extract diets compared with the control, PI 229358, and "BR-16" extract diets (Table 1).

There was a significant effect of diet, by ANOVA, on larval and pupal weight, consumption, frass produced, and feeding time (Table 1). Larval weight was negatively affected by extracts of any soybean genotype, including "BR-16" (our control cultivar) as compared with plain diet. The lowest pupal weight was observed for larvae fed on diet containing extracts of PI 227687 (64.4 ± 4.41 mg) and PI 274454 (68.3 ± 5.98 mg). When larvae fed on PI 229687 extract diets, pupal weight was 96.6 ± 5.73 mg. Larvae fed on "IAC-100," "BR-16" extract diets, and control diet consumed larger amounts of food than those fed on PI 274454 extract; larvae feeding on the latter diet also produced the lowest amount of frass, whereas larvae fed on "BR-16" produced the largest amount of frass. The feeding time of *A. gemmatalis* larvae was negatively affected by all diets containing soybean extracts. The larval cycle was more elongated

when extracts of PI 274454, PI 227687, and "IAC-100" were added to the diet in comparison with the plain diet, "BR-16," and PI 229358 extract diets.

Feeding time (covariate) and diets containing soybean extracts (treatments) affected pupal weight (Table 2a), indicating that *A. gemmatalis* growth depended on an interactive effect of covariate and treatments. Positive slopes were observed in the adjusted lines for the control and PI 227687 extract diets (Figure 1). All other treatments yielded negative slopes, indicating that increases in feeding time did not contribute to increased insect growth.

The interaction of covariates feeding time (Table 2a) and consumption (Table 2c) with diets was not significant for their relationships with the amount of ingested food or weight of pupae. Thus, a parallel line model was fitted. The

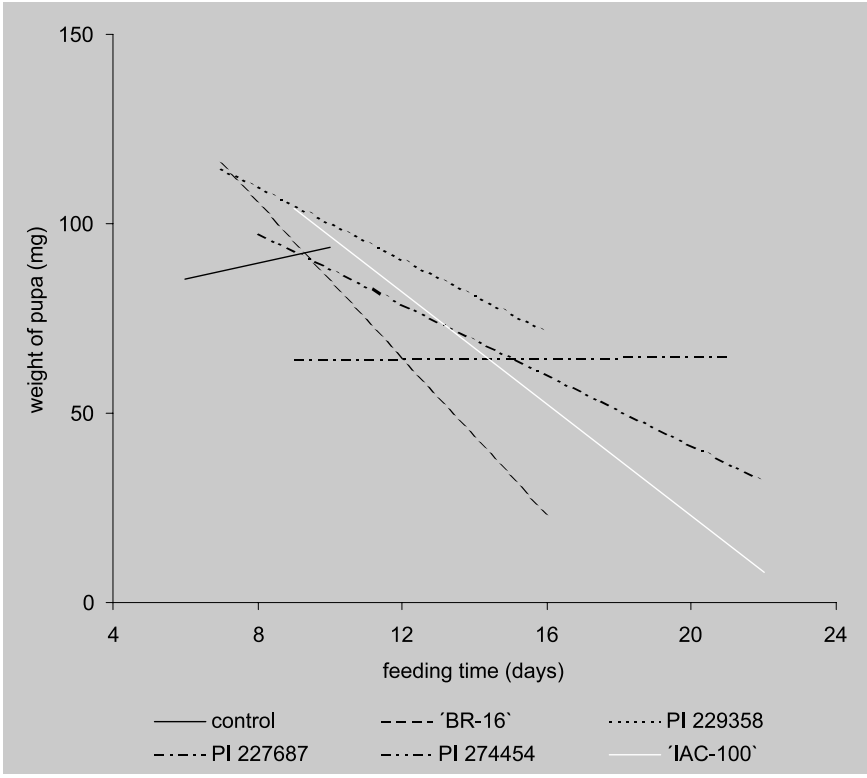

FIG. 1. Relationship between pupal weight and feeding time of *Anticarsia gemmatalis* fed on artificial diets containing extracts of different soybean genotypes or control diet. For statistical analysis, see Table 2a.

main effect of the diet and feeding time (Table 2b) or consumption (Table 2d) as covariate was significant, showing that the amount of ingested food depended on both factors, but not of the interaction between them. ANCOVA means of consumption adjusted by time (Figure 2) shows that larvae fed on "IAC-100" extract diet ingested a larger amount of food per unit of time, in comparison with the other treatments. Insects that fed on the PI 229358 extract diet converted more ingested food to biomass, as indicated by ANCOVA means of weight of pupae adjusted by consumption (Figure 3). Differently, lower conversion was observed when larvae were fed on extracts of "IAC-100" and PI 227687 compared with control diet, "BR-16," and PI 229358 extract diets.

The covariate digested food and diets significantly influenced pupal weight (Table 2e, Figure 4). Therefore, insect growth was dependent of the interactive effect between digested food and treatment. A positive relationship among the

factors is observed in Figure 4 for most of treatments, suggesting that those larvae that had higher amount of digested food (ingestion–excretion) became heavier. An exception was observed in larvae fed on the "IAC-100" extract diet, which presented a shallow negative slope, indicating that even with increased digested food, pupal weight remained at the same level.

The highest concentration of rutin (3.682 mg/g dried leaves) was observed in the extracts of PI 227687 (Table 3). PI 274454 and "IAC-100" presented intermediate, whereas PI 229358 had the lowest rutin content. The concentration of genistin in PI 227454 was higher than in the other tested genotypes. The susceptible cultivar BR-16 showed a smaller number of HPLC traces in comparison with the genotypes considered resistant. Rutin or genistin were not detected in its leaf extract, and, in fact, only a kaempferol-based compound was observed.

DISCUSSION

For this study, we selected PI 227687, PI 229358, and PI 274454. The first two are those most used globally as sources of resistance to defoliating insects, and the latter is used similarly in Brazil. We also tested the cultivar IAC-100, which is regarded as possessing multiple insect-resistance characteristics (Rossetto et al., 1995), and "BR-16" as a nonresistant cultivar. Host-plant resistance can negatively affect insect physiology (antibiosis) or behavior (antixenosis). As morphological factors (trichomes, etc.) were ruled out, resistance was probably due to chemical factors (Soo Hoo and Fraenkel, 1966). These authors also stated that insects achieve appropriate growth when they have shorter development time (here we evaluated feeding time), heavier larva and/or pupa, and low mortality rate. Larvae fed on diet containing genotypes PI 227687, PI 274454, and "IAC-100" had protracted growth rates, higher mortality, and longer feeding times. The weights of pupae after adjustment by consumption were lower for insects fed on PI 227687 and "IAC-100" compared with other treatments, including the control and "BR-16," and PI 229358 extract diets, indicating that those insects were not able to efficiently transform food eaten in body mass.

In contrast, larvae fed on PI 229358 extract diet had lower mortality (5.1%), were heavier, and took the same time in the feeding period as those on "BR-16." When studying the biology of *H. virescens* in diets containing extracts of soybean genotypes, Hoffmann-Campo (1995) observed 45 and 10% mortalities when larvae were fed on PI 227687 and PI 229358 extracts, respectively. In field experiments, Hatchett et al. (1979) observed 87% (PI 227687) and 100% (PI 229358) larval mortalities. It should be pointed out that Hoffmann-Campo (1995) studied the effects of soybean crude extracts added to artificial diet, whereas Hatchett et al. (1979) evaluated the direct effects of insect feeding on resistant-genotype leaves. Thus, resistance of PI 229358 probably resulted from some morphologic factor than in this experiment, as in Hoffmann-Campo (1995), was removed by extraction, or else the whole plant has more resistant factors than could be detected with the extract provided in the present study.

An apparent contradiction was observed regarding the behavior of *A. gemmatalis* fed on the "IAC-100" extract diet. Larvae showed high mortality but consumed larger amounts of food, and pupal weight was similar to larvae fed on plain diet and on "BR-16" extract diet. In fact, this is not a completely atypical behavior for insects; they sometimes eat more to compensate for low nutrient levels (Slansky and Wheeler, 1989) and for intermediate level of allelochemicals in the diet (Paradise and Stamp, 1990). Consequently, mortality of larvae fed on the "IAC-100" extract did not result from preingestive, but likely postingestive effects. By ANOVA, larvae fed on such diet produced heavier pupae compared with those fed on PI 227687 extract diet, but after

adjustment by consumption, they showed lower ANCOVA means of pupal weight (similar to PI 227687). Additionally, despite retaining (digesting) large amounts of food, "IAC-100" extract diet was not able to transform this into heavier pupae, as indicated by the shallower slope, showed in Figure 4.

Higher consumption rates result in ingestion of greater doses of active compounds (Wheeler and Slansky, 1991), and *A. gemmatalis* probably failed to detect detrimental compounds present on "IAC-100" extract and, in the sequence, had to deal with their toxic effect in the diet. The same effect was also observed with *Helicoverpa* (*Heliothis*) *zea* (Duffey and Isman, 1981; Isman and Duffey, 1982a,b), *Manduca sexta* (Stamp and Scrobola, 1993), and *T. ni* (Hoffmann-Campo, 1995) when fed on rutin-enriched diet.

The highest concentration of rutin was found in PI 227687 compared with the other genotypes. Rutin concentration in "IAC-100" foliage was similar to PI 274454 and PI 229358, which are part of its genealogy (Veiga et al., 1999). Genistin was observed in all resistant genotypes, and its concentration in PI 274454 was nearly two times higher than in the other resistant genotypes. Before analysis, our crude leaf extracts were passed into a nonionic XAD-4 column to eliminate the bulk of nonflavonoid compounds, without any further fractionation. The identification of genistin and daidzin were performed by comparison of their ultraviolet spectra (from photodiode array), and retention time with authentic genistin and daidzin, and by coelution from HPLC. Neither daidzin nor daidzein (aglycone) were observed in our crude, unfractionated extracts of soybean leaf. Differently, Sharma and Norris (1991) reported the aglycone daidzein in methanolic extracts of PI 227687 after TLC fractionation in ethyl acetate. These authors did not refer to genistein (and its glycoside genistin) and rutin in PI 227687 leaf extracts. Also, there was no remark regarding how they identified daidzein.

The flavonoid aglycones, according to Markham (1982), are more reactive than the glycosides because the glycosylation makes possible their storage in the cell vacuoles. Flavonoid aglycones are rarely found as internal constituents, but regularly encountered on the external surface of leaves and fronds (Markham, 1989). In many years of analysis, we have not found isoflavone aglycones in healthy plants in our lab, even in pods/seeds. However, it is known that daidzein and genistein conjugates (7-*O*-glucosyl and 6″-*O*-malonyl-7-glucosyl) are constitutively present in large quantity in soybean seedlings after fungal infection (Graham et al., 1990) and in immature seeds after stinkbug damage (unpublished data). Graham et al. (1990) observed that daidzin conjugates can be rapidly hydrolyzed into free daidzein, which is the precursor of glyceollins, phytoalexins produced *de novo* in all soybean seedling organs.

Leaf extracts of genotype PI 227687 contain the isoflavone genistin and seven flavonol glycosides, i.e., three kaempferol-, two isorhamnetin-, and two quercitin-based compounds, one of them rutin (Hoffmann-Campo, 1995). This

compound was not observed in "BR-16," used as the susceptible control in the present study; kaempferol was the only flavonoid observed in other susceptible cultivars, such as Embrapa-1, Embrapa-4, IAS-5, and Davis (Hoffmann-Campo, 1995). Chan et al. (1978) observed that kaempferol was less toxic to *H. virescens*, *H.* (*Heliothis*) *zea*, and *Pectinophora gossypiella*, compared to quercitin-based compounds that possess a catechol group. According to Chan et al. (1978) and Elliger et al. (1980), there is a relationship between the presence of a catechol B-ring in a flavonoid and the inhibition of insect growth. This fact suggests that soybean-breeding programs usually do not allot priority to resistance to insects and, in practice, have eliminated secondary compounds otherwise responsible for plant defense.

Hoffmann-Campo (1995) qualitatively examined the flavonoid profile of 16 soybean genotypes. Rutin was found in one resistant cultivar (IAC-100), one breeding line (BR82-12547), and two wild soybean genotypes (PI 227687 and PI 229358). The present study reports that rutin concentration in PI 229358 was very low, which may explain the good performance of *A. gemmatalis* fed on diet containing this extract. Flavonoids are frequently used by monophagous and oligophagous insects to recognize their host plants (Harborne and Grayer, 1993), and, as *A. gemmatalis* is a leguminous specialist insect, it would be expected to be less affected by flavonoids from soybean leaves. However, this important growth inhibitor of lepidopterans is being removed after successive breeding crosses, and likely, *A. gemmatalis* has lost the ability to cope with this toxic compound.

The information obtained in the present work provides elements for future studies on the genetics of chemical compounds conferring resistance to defoliators. Consequently, the knowledge that PI 227687 and PI 274454 possess high rutin and genistin concentrations, respectively, and caused deleterious effects on *A. gemmatalis* physiology has various potential applications in IPM and in breeding programs, contributing to the sustainability of soybean-based agricultural systems. The identification of chemicals responsible for plant defense and their role in the interactions with insects can help breeders in the development of cultivars resistant to pests. Recent progress in biotechnology, especially in molecular biology, has opened new opportunities in developing host-plant resistance (Panda and Khush, 1995), and, according to Dixon and Steele (1999), flavonoids possess strong potential for metabolic engineering. In addition, with continual exposure to *Bacillus thuringiensis* (Bt) toxins, mainly in transgenic crops, resistance may develop in several insect pests (Tabashnik, 1994). Combining traditional chemically based breeding programs and genetically engineered *B*t toxin-based resistance has a potential to be much more sustainable and easily adopted than the usual higher dose/refuge strategies (Cooper et al., 2004). Thus, considering the concentrations of rutin and genistin in these genotypes, it is reasonable to suggest that flavonoids are important

factors in terms of resistance to *A. gemmatalis*. Effort is needed to maintain or increase flavonoid concentration in soybean cultivars. Finally, further studies regarding the effect of rutin, genistin alone, and interactively are necessary for a complete understanding of the role of flavonoids in the defense of soybean to *A. gemmatalis*.

(Received November 4, 2004; revised March 1, 2005; accepted March 23, 2005)

Abstract—Ethanolic extract of aerial parts of *Artemisia annua* L. and artemisinin were evaluated as anti-insect products. In a feeding deterrence assay on *Epilachna paenulata* Germ (Coleoptera: Coccinellidae) larvae, complete feeding rejection was observed at an extract concentration of 1.5 mg/cm^2 on pumpkin leaf tissue. The same concentration produced a feeding inhibition of 87% in *Spodoptera eridania* (Cramer) (Lepidoptera: Noctuidae). In a no-choice assay, both species ate less and gained less weight when fed on leaves treated with the extract. Complete mortality in *E. paenulata* and 50% mortality in *S. eridania* were observed with extract at 1.5 mg/cm^2. Artemisinin exhibited a moderate antifeedant effect on *E. paenulata* and *S. eridania* at 0.03–0.375 mg/cm^2. However, a strong effect on survival and body weight was observed when *E. paenulata* larvae were forced to feed on leaves treated at 0.03 and 0.075 mg/cm^2. *Artemisia annua* ethanolic extract of aerial parts at 1.5 mg/cm^2 showed no phytotoxic effect on pumpkin seedlings.

Key Words—*Artemisia annua*, *Epilachna paenulata*, *Spodoptera eridania*, insecticide, artemisinin.

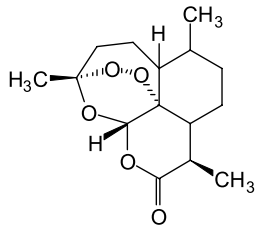
INTRODUCTION

Many wild plants are capable of synthesizing secondary metabolites with biological properties that are important in the fight against insect pests (Matthews, 1993; Enriz et al., 2000; Calderón et al., 2001; Céspedes et al., 2001; Gonzalez-Coloma et al., 2002). For these to be practical and economical, the selected species must meet some requirements, such as being cultivatable, and having a potent active principle, high stability, and a good yield. In our search for naturally occurring insecticide products, we previously studied the anti-insect activity of extracts of *Melia azadarach* L. (Meliaceae) (Valladares et al., 1997, 1999; Carpinella et al., 2002, 2003), and now we have focused on *Artemisia annua*.

The genus *Artemisia* is a rich source of biologically active natural products. Approximately 200 *Artemisia* sp. grow in China, where more than 50 of them have been used in traditional Chinese medicine (Tan et al., 1998). *Artemisia annua* L., known as "sweet Annie" or "annual wormwood," is an annual herb native to Asia (China) where it is known as "quinghao." The plant has become naturalized in many countries including Argentina, Bulgaria, France, Hungary, Italy, Spain, and the United States (Klayman, 1989, 1993), and it is well known for its antimalarial activity, attributed to the presence of artemisinin (**1**) (Klayman et al., 1984). This compound is also phytotoxic (Duke et al., 1987) in laboratory assays (Chen et al., 1991), but has performed poorly in the field (Duke et al., 2000). The essential oil from aerial parts of the plant has been used in cosmetics and pharmaceuticals, and it has been recently reported as protecting stored products and plants against insect attack (Rao et al., 1999; Tripathi et al., 2000, 2001).



Artemisinin **(1)**

As far as we know, neither organic extracts from aerial parts of this plant nor artemisinin has been assayed on insects of agronomical interest,

although some authors have apparently noted that artemisinin has anti-insect activity (Jia, 1997; Wang and Wang, 2002), but have not published in a peer-reviewed journal. In the present paper, we study the effects of an ethanolic extract of *A. annua* aerial parts on the feeding behavior, development, and survival of the leaf-feeding coccinelid, *Epilachna paenulata* Germ. (Coleoptera: Coccinellidae), and also on the polyphagous pest, southern armyworm, *Spodoptera eridania* (Cramer) (Lepidoptera: Noctuidae). The anti-insect activity exhibited by **1** is also reported here.

METHODS AND MATERIALS

Plant Material. Aerial parts of the *A. annua* plant were collected in the hill area of Córdoba, Argentina, after the plants bloomed in March 2000, and were identified by Prof. Luis Ariza Espinar from the Botanic Museum of Córdoba National University, Argentina. The vegetable material was air-dried at 20°C, crushed and Soxhlet extracted with ethanol (133.68 g). After exhaustive solvent removal, a viscous residue was obtained (22.21 g, 16.6% yield), and then a weighed amount of extract was dissolved in enough 95% ethanol to make concentrations of 1% and 10%. The presence of artemisinin in the extract was confirmed and quantified by high-performance liquid chromatography (HPLC) (Na-Bangchang et al., 1998), yielding 0.53 g (2.41%). Pure artemisinin was dissolved in 95% ethanol at concentrations of 2, 5, and 25 mg/ml for testing for anti-insect activity.

Insects. Larvae for the experiments were obtained from continuous colonies, reared on a natural diet of pumpkin, *Cucurbita maxima*, maintained in a growth chamber at 24 ± 1°C, 70–75% relative humidity, with a photoperiod of 16:8 light–dark cycle, and periodically renewed with field specimens (Aranda et al., 1996).

Chemicals. Artemisinin was purchased from Sigma (St. Louis, MO, USA). All organic solvents were of HPLC-grade and purchased from Merck (Darmstadt, Germany). Acetonitrile and acetic acid were obtained from Fisher Scientific (New Jersey, NJ, USA).

Equipment. HPLC was performed on a Shimadzu liquid chromatography system equipped with an LC-10AS pump and an L-ECD-6A electrochemical detector. A Phenomenex Luna C18 5 μm particle size (250 × 4.6 mm i.d.) reversed-phase column was used. The compound was eluted with 45% (v/v) MeCN in water containing 0.1 M acetic acid (pH 4.8), as previously reported (Na-Bangchang et al., 1998). The electrochemical detector was operated in the reductive mode at an applied potential of 1.0 V.

Phytotoxicity Assay. Pumpkin, *Cucurbita maxima*, seedlings were used for a phytotoxicity assay. Pumpkin seeds were germinated, and seedlings grown in a growth chamber for 5 d, in pots (250 ml) containing a sterile soil mix (2:2:1 sand/loam/peat, by volume). For every 2 d, the 5 d-old seedlings (N = 15) were sprayed with a 10% solution of *A. annua* ethanolic extract (approximately 2.4 mg/ml of **1**) dissolved in water (~500 µl per plant), during 20 d. This dosage was equivalent to 1.5 mg/cm^2 of extract and 0.03 mg/cm^2 of **1**. A control, sprayed with water, was run in parallel. The number of new leaves and symptoms of chlorosis were determined. Data were analyzed with analysis of variance (ANOVA) and Tukey's honestly significant difference test.

Feeding Deterrence Assay. To survey the antifeedant properties of the extract and of artemisinin, a modified leaf-disk choice test (Carpinella et al., 2003) was used. Two cotyledon leaves from a *C. maxima* seedling (both the same size, age, and from the same plant) were placed in a 9-cm-diam. Petri dish, and a glass disk with two 1.3-cm-diam. holes was placed on top. A third-instar *E. paenulata* or *S. eridania* larva was placed equidistant from a leaf disk treated with 20 µl of the test solution, and a control leaf disk treated with 20 µl ethanol. The larvae were allowed to feed for 24 hr. Ten replicates were used for each treatment. The relative amounts of the treated and untreated leaf areas eaten (recorded in percentages from 0 to 100) were visually estimated by dividing the leaf area into imaginary quarters. Measurements were always made by the same operator. Data were then compared by using the Wilcoxon paired-sample test (α = 0.05). The Antifeedant Index (AI%) was calculated as $(1 - T/C) \times 100$, where T and C represent the consumption on treated and untreated disks, respectively (Gonzalez-Coloma et al., 1998). After calculation of the AI% for compound **1**, the relative potency (ED_{50} values, the effective dosage for 50% feeding reduction) for **1** was determined by linear regression of AI% on log dose. These, and all the following experiments, were carried out at 24 ± 1°C and with a 16:8 (L/D) photoperiod.

No-Choice Assay. This test was carried out to analyze the effects of the extract and of artemisinin on the development and survival of larvae of both insect species. A first-instar *E. paenulata* and a third-instar *S. eridania* were each placed into a Petri dish and fed with fresh pumpkin leaves (renewed every 48 hr), treated either with 20 µl of the ethanolic extract solution, artemisinin solution, or with ethanol (control). Ten replicates were used for each treatment. A similar set of larvae of both insects were not fed at all, and acted as starved controls. Leaf consumption, development, and survival were recorded regularly. Data were analyzed with analysis of variance (ANOVA), Tukey's honestly significant difference test (Zar, 1996) and the Kaplan–Meier method (Hollander and Wolfe, 1999).

RESULTS AND DISCUSSION

In order to assess the insect control effects of *A. annua* extract, and the possibility of developing it as a natural insecticide for use in pest management programs, two phytophagous species belonging to two different orders, *E. paenulata* and *S. eridania*, were used.

Before starting with the insecticide assays, an evaluation of phytotoxicity was made on 5-d-old pumpkin seedlings, and no differences were observed in the development of new leaves or in phytotoxicity symptoms, such as chlorosis and death, between treatment and control (data not shown) during 20 d. These results suggest that phytotoxicity did not occur at the highest concentration (1.5 mg/cm^2 of extract, *vide infra*) evaluated in our feeding deterrence and no-choice assays.

Both species, *E. paenulata* and *S. eridania*, were deterred from feeding on pumpkin leaves treated with 1.5 mg/cm^2 *A. annua* extract (approximately equivalent to 1% w/w), consuming significantly less food (Wilcoxon, $P < 0.05$) than the control (Table 1). Feeding inhibition of *E. paenulata* larvae was almost complete at this concentration, and a significant difference was still observed at 0.15 mg/cm^2 (approximately equivalent to 0.1% w/w), where an AI of 78.8% was observed. These values indicate the potent antifeedant activity of *A. annua* extract, at the same level of activity as that previously shown by *M. azedarach* extract against *E. paenulata* (Carpinella et al., 2003).

After 3 d, larvae of *E. paenulata* confronted with leaves treated with 0.15 mg/cm^2 of ethanolic extract had consumed approximately half the leaf area of those receiving untreated leaves, and this trend was maintained throughout the experiment (Table 2). When larvae were fed on leaves treated with 1.5

TABLE 2. MEAN LEAF AREA CONSUMED BY *Epilachna paenulata* AND *Spodoptera eridania* LARVAE ON LEAVES TREATED WITH *Artemisia annua* AERIAL PARTS ETHANOLIC EXTRACT IN NO-CHOICE ASSAY (% PER INDIVIDUAL/DAY)

Days	Area consumed (%)[a]		
	Control	0.15 mg/cm^2	1.5 mg/cm^2
Epilachna paenulata			
3	21.2a	11.3b	2.4c
5	22.5a	24.6a	5.3b
7	40.1a	23.3b	5.0c
13	33.3a	17.6b	0.0
Spodoptera eridania			
2	16.1a	14.5a	18.6a
6	20.2a	13.7b	13.2b
9	48.6a	38.4b	22.1c
13	72.5a	53.3b	9.6c

[a] Means within rows followed by the same letter are not significantly different in ANOVA test with repeated measures (Tukey's test, $P < 0.05$).

mg/cm^2, an abrupt decrease in the area consumed was observed during the experiment, amounting to at least four times less than that consumed by the control larvae ($F = 52.9$; $df = 27$; $P < 0.001$).

From d 3 onwards, there were significant differences in the mean weight of *E. paenulata* larvae between treatments and control (data not shown). Whereas control larvae steadily increased their body weight, larvae treated with 1.5 mg/cm^2 lost weight. At d 5, significant differences were observed between both dosages ($F = 8.14$; $df = 27$; $P < 0.001$).

The distribution of survival for *E. paenulata* was significantly different between the treatments at 5, 7, and 13 d (data not shown). On the fifth day, 30% survival was observed at the 1.5 mg/cm^2 dosage, while 90% of the starved larvae had survived. These data suggest the presence of one or more toxic compounds, whose toxicity was evident at the highest concentration. The small amount of leaf ingested was enough to incorporate these compounds in toxic doses. At d 7, complete mortality was observed for these two treatments showing significant differences with both control and 0.15 mg/cm^2 dosages. At this time, the mortality could be attributed either to toxic metabolites present in the extract, or to the highest concentration provoking a strong antifeedant effect on larvae, causing 100% mortality through starvation.

In the no-choice assay, *S. eridania* larvae consumed less of leaves treated with 0.15 mg/cm^2 than controls (Table 2). When larvae were fed on 1.5 mg/cm^2 treated leaves, there were significant differences in the consumed area compared with controls from d 6 to the end of the study ($F = 3.86$, $df = 54$, $P = 0.04$).

These findings show that the inhibitory effect of the *A. annua* extract was more effective on *E. paenulata* larvae than on *S. eridania*, and probably acted in the latter as a secondary antifeedant, where reduction of food intake follows some initial consumption (Ascher, 1993).

There was a great difference in mean body weight of *S. eridania*, which began to be significant on d 2 and continued until the end of the assay for both treatments (data not shown). Moreover, from d 9 the body weight of larvae eating 1.5 mg/cm^2 was half or less than that of those fed with the lower dose ($F = 5.18$, $df = 54$, $P = 0.021$). The distribution of survival for *S. eridania* was significantly different between treatments at d 9 and 13 (data not shown). The survival rate by d 2 of larvae fed on 1.5 mg/cm^2 was 70%. However, survival declined to 50% at the end of the study, while, with starved larvae, 0% survived at d 9.

The dose of 1.5 mg/cm^2 artemisinin contained approximately 0.03 mg/cm^2 of **1**. We, therefore, checked the antifeedant effect of **1** at concentrations around this value. Artemesinin exhibited a moderate antifeedant effect on *E. paenulata* and *S. eridania* at 0.375 mg/cm^2 with an AI% of 87.9 and 81.0, respectively (Table 3). Lower doses (0.075 and 0.03 mg/cm^2) showed an AI% of approximately 60% to 75%. This did not account for the strong feeding inhibition of the extract, suggesting that the activity is only partially attributable to the presence of **1**, and that an additive or synergistic effect between **1** and other active principles could be present. From the data from both species (Table 3), the effective dosage for 50% feeding reduction (ED_{50}) calculated for compound **1** was 0.0136 mg/cm^2. Comparing the antifeedant activity of

TABLE 4. MEAN LEAF AREA CONSUMED BY *Epilachna paenulata* LARVAE ON LEAVES TREATED WITH ARTEMISININ IN NO-CHOICE ASSAY (% PER INDIVIDUAL/DAY)

Days	Area consumed (%)[a]		
	Control	0.03 mg/cm^2	0.075 mg/cm^2
3	15.5a	3.6b	6.8b
5	46.7a	24.5b	26.2b
7	39.5a	1.4b	–
9	47.8	–	–
11	32.5	–	–

[a] Means within rows followed by the same letter are not significantly different in ANOVA test with repeated measures (Tukey's test $P < 0.05$).

1 with that reported (Carpinella et al., 2002) for meliartenin (ED_{50} = 0.0008 mg/cm^2), azadirachtin (ED_{50} = 0.00072 mg/cm^2), and toosendanin (ED_{50} = 0.0037 mg/cm^2), **1** is approximately 17, 19, and 4 times less active than meliartenin, azadirachtin, and toosendanin, respectively.

Larvae of *E. paenulata*, forced to feed on pumpkin leaves treated with 0.03 and 0.075 mg/cm^2 of **1**, consumed less than the control ($F = 16.15$; $df = 2$; $P < 0.001$) (Table 4). At d 7, the 0.03 mg/cm^2-leaf area consumed by larvae was 28 times lower than that ingested of the control. At the same time, larvae exposed to 1.5 mg/cm^2 of extract ate eight times less than the larvae fed with untreated leaves (Table 2). Although **1** showed a moderate antifeedant effect, it provoked a strong inhibition of feeding once a significant quantity of treated food was ingested in no-choice assays.

Body weight of control larvae increased throughout the experiment (data not shown), while the two treatments showed almost no change in body weight ($F = 53.47$, $df = 2$, $P < 0.001$), and at d 5 weighed at least four times less than the controls.

Larvae were observed to tremor, move without coordination, and collapse when they were forced to feed on **1**-treated leaves. This behavior was similar to symptoms of insects under the effects of neurotoxins (Wang et al., 2000).

The distribution of survival for *E. paenulata* (data not shown) was significantly different $P < 0.001$ between the treatments at d 7, 9, and 11. Complete mortality was reached at d 7 and 9 for 0.075 and 0.03 mg/cm^2, respectively, while all starved larvae died at d 7. These data would suggest that death was attributable to the inhibition of feeding by **1**, although the possible neurotoxic effect observed suggests that other mechanisms may be involved.

In summary, *A. annua* ethanolic extract inhibited feeding and produced negative effects on the survival and development of the leaf-feeding coccinelid, *E. paenulata*, and the polyphagous pest, southern armyworm, *S. eridania*.

High mortality was observed in both *E. paenulata* and *S. eridania* with the extract at a dose of 0.15 mg/cm^2. Its activity at concentrations of 0.15 and 1.5 mg/cm^2 opens up the possibility of using *A. annua* ethanolic extract for the control of these pests. Artemisinin affected the development and survival of *E. paenulata* at a dose of 0.03 mg/cm^2, equivalent to 1.5 mg/cm^2 of *A. annua* extract, indicating that **1** is its main active principle. The strange behavior of larvae of this species fed on **1**, as if under a neurotoxic effect, warrants further investigation.

(Received January 3, 2005; accepted March 4, 2005)

Abstract—As a response to attack by herbivores, plants can emit a variety of volatile substances that attract natural enemies of these insect pests. Predators of the banana weevil, *Cosmopolites sordidus* (Germar) (Coleoptera: Curculionidae) such as *Dactylosternum abdominale* (Coleoptera: Hydrophilidae) and *Pheidole megacephala* (Hymenoptera: Formicidae), are normally found in association with weevil-infested rotten pseudostems and harvested stumps. We investigated whether these predators are attracted to such environments in response to volatiles produced by the host plant, by the weevil, or by the weevil–plant complex. We evaluated predator responses towards volatiles from banana pseudostem tissue (synomones) and the synthetic banana weevil aggregation pheromone Cosmolure+ in a two-choice olfactometer. The beetle *D. abdominale* was attracted to fermenting banana pseudostem tissue and Cosmolure+, whereas the ant *P. megacephala* was attracted only to fermented pseudostem tissue. Both predators were attracted to banana pseudostem tissue that had been damaged by weevil larvae irrespective of weevil presence. Adding pheromone did not enhance predator response to volatiles from pseudostem tissue fed on by weevils. The numbers of both predators recovered with pseudostem traps in the field from banana mats with a pheromone trap were similar to those in pseudostem traps at different distance ranges from the pheromone. Our study shows that the generalist predators *D.*

* To whom correspondence should be addressed. E-mail: w.tinzaara@kari.go.ug

abdominale and *P. megacephala* use volatiles from fermented banana pseudostem tissue as the major chemical cue when searching for prey.

Key Words—Aggregation pheromone, *Cosmopolites sordidus*, Curculionidae, infochemicals, prey searching, synomone, olfactometer, natural enemies, plant volatiles.

INTRODUCTION

During host searching, natural enemies of herbivorous insects (predators and parasitoids) are known to utilize volatile chemicals emitted by plants or herbivorous insects (Vinson, 1976; Vet and Dicke, 1992; Turlings et al., 1995; Dicke and Vet, 1999). Predators and parasitoids that forage for herbivorous prey by using infochemicals may have a problem concerning reliability and detectability of these stimuli (Vet and Dicke, 1992; Wiskerke et al., 1993). Stimuli from the prey's food are detectable but are not reliable in indicating prey presence. In contrast, prey-derived stimuli are generally the most reliable sources of information but usually not easily detectable at long distances (Vet and Dicke, 1992). Natural enemies have evolved different mechanisms to cope with this reliability–detectability problem (Vet and Dicke, 1992). One of these mechanisms is that natural enemies can exploit pheromones from their victim as kairomones in long distance herbivore location (Lewis et al., 1982; Noldus et al., 1991; Wiskerke et al., 1993; Hedlund et al., 1996; Hendrichs and Hendrichs, 1998; Hoffmeister and Gienapp, 1999; Wertheim et al., 2003; Francis et al., 2004; Fatouros et al., 2005). The use of chemical information that is both reliable and easy to detect enhances natural enemy searching efficiency (Vet and Dicke, 1992).

Infochemicals, both those used within and between species, can be utilized in pest management by either exploiting the way the natural enemy responds, or by manipulating the source of the infochemical (Dicke et al., 1990; Vite and Baader, 1990; Foster and Harris, 1997; Degenhardt et al., 2003; Powell and Pickett, 2003). For example, infochemicals can be used to enhance the searching efficiency, host utilization, and reproductive capacity of natural enemies (Renwick, 1992; Turlings et al., 1995; Scutareanu et al., 1997; Steidle and van Loon, 2003; McGregor and Gillespie, 2004). There are a few studies on the application of infochemicals to manipulate the behavior of predators or parasitoids in the field (e.g., Drukker et al., 1995; Shimoda et al., 1997; Bernasconi et al., 2001; James, 2003; James and Price, 2004). However, data on the role of infochemicals in predator foraging have become available for several groups such as predatory mites (Sabelis and Dicke, 1985), pentatomids (van Loon et al., 2000), anthocorids (Dwumfour, 1992; Drukker et al., 1995; James and Price, 2004), chrysopids (Reddy et al., 2002; James and Price, 2004), and

coccinellids (Le Ru and Makosso, 2001; Ninkovic et al., 2001; Steidle and van Loon, 2002; James and Price, 2004). The predator *Rhizophagus grandis* (Gyll.) (Coleoptera: Rhizophagidae) is attracted to traps baited with a kairomone produced by the bark beetle *Dendroctonus micans* Kug (Coleoptera: Scolytidae) (Aukema et al., 2000), and this can be exploited to monitor the predator's distribution in the field.

The banana weevil *Cosmopolites sordidus* (Germar) (Coleoptera: Curculionidae) is a major pest of bananas in East Africa. Yield losses of up to 100% have been reported (Sengooba, 1986, unpublished). The weevil oviposits in the leaf sheaths and corm at the base of the banana mat (a banana mat consists of plants arising from a common corm/rhizome) (Abera et al., 2000). The larvae tunnel in the corm and pseudostem (the plant part between the corm and leaves), damaging the vascular system and weakening the stability of the plant. In Uganda, distribution studies showed that over 60% of the adult weevils in the banana field were associated with crop residues such as rotting pseudostem (Gold et al., 2004). The weevil has predators that have been mostly found in environments harboring weevils such as banana pseudostem traps and fermenting banana pseudostem tissue, often in larval weevil tunnels (Koppenhofer et al., 1992; Koppenhofer, 1993; Tinzaara et al., 1999; Abera, 2004). Some ant species that have the potential to control *C. sordidus* include *Pheidole megacephala* and *Tetramorium guineese* (Mayr) (Hymenoptera: Formicidae) (Gold et al., 2001; Abera, 2004). Nonant predators known to prey on weevil eggs and larvae include *Dactylosternum abdominale* (Fabricius) (Coleoptera: Hydrophilidae), *Euborellia annulipes* (Lucas) (Dermaptera: Carcinophoridae), and *Thyreocephalus interocularis* (Eppelscheim) (Coleoptera: Staphylinidae) (Koppenhofer et al., 1992). Of these five predator species, *D. abdominale* and *P. megacephala* are the most abundant predators in environments preferred by weevils in Uganda (Tinzaara et al., 1999; Gold et al., 2001; Abera, 2004).

D. abdominale and *P. megacephala* are generalist predators that feed on microfauna and -flora of decomposing plant tissues, eggs, and small larvae of insects. Decomposing tissue is more attractive to these predators than fresh tissue (Koppenhoefer, 1993). Generalist predators are known to use infochemicals during prey location (Dwumfour, 1992; Scutareanu et al., 1997; Haberkern and Raffa, 2003; Steidle and van Loon, 2003; McGregor and Gillespie, 2004). Information on how volatiles from decomposing banana pseudostem tissue influence prey location by generalist predators is not available. Therefore, we have investigated the behavior of *D. abdominale* and *P. megacephala* predators under laboratory and field conditions to assess whether they use volatile infochemicals associated with banana weevils and/or their food.

An aggregation pheromone has been identified for *C. sordidus*, which is specific to the weevil (Jayaraman et al., 1997). A synthetic pheromone source containing a mixture of the four sordidin isomers is sold under the trade name

Cosmolure+. The pheromone has been studied in the laboratory and in the field for the management of *C. sordidus* (Tinzaara et al., 2000, 2003) and attracts both male and female weevils (Alpizar et al., 1999; Tinzaara et al., 2000). The pheromone-baited trap captures up to 18 times more weevils than a conventional split pseudostem trap (Tinzaara et al., 2000). Information on the effect of this aggregation pheromone on the behavior of the weevil's predators has not been investigated. Several species of predators have been reported to use the aggregation pheromones of their hosts during host searching and location (Dwumfour, 1992; Vet and Papaj, 1992; Hedlund et al., 1996; Scutareanu et al., 1997; Haberkern and Raffa, 2003; Steidle and van Loon, 2003).

The objectives of this study were to determine whether: (1) volatiles from banana pseudostem tissue and *C. sordidus* pheromone attract the predators *D. abdominale* and *P. megacephala*; (2) the predators respond to host plant volatiles and whether this response is dependent on dose or weevil feeding; (3) the pheromone enhances the predators' response to weevil-damaged pseudostem tissue; and (4) the pheromone affects the predators' distribution around pheromone-baited traps in the field.

METHODS AND MATERIALS

Site Description

Laboratory and field studies were conducted at Kawanda Agricultural Research Institute (KARI) (0°25′N, 32°51′E, 1190 m), 13 km north of Kampala, Uganda. The site has two rainy seasons (March–May and September–November) with an average precipitation of 1180 mm per year. Average daily temperatures range between 16 and 29°C. Relative humidity in the laboratory ranged from 60 to 80%.

A field experiment was conducted in banana plots at KARI planted with cultivar Nabusa (*Musa* spp., AAA-EA group). The plot size was 12 × 10 mats at a spacing of 2.5 × 3 m (Figure 1). The plots were weeded after every 2 mo and were not mulched.

Odor Sources

Pieces of fresh pseudostem (less than a week after harvest) from the banana cv Nabusa collected from banana fields at KARI were placed in plastic containers for 7 d at room temperature to get fermented pseudostem tissue. Fresh pseudostem tissue was collected at the time of the bioassays. Fifty grams of either fresh or fermented pseudostem tissue was used for bioassays. This same dose was previously successfully used for studies of the weevil's response to infochemicals (Tinzaara et al., 2003).

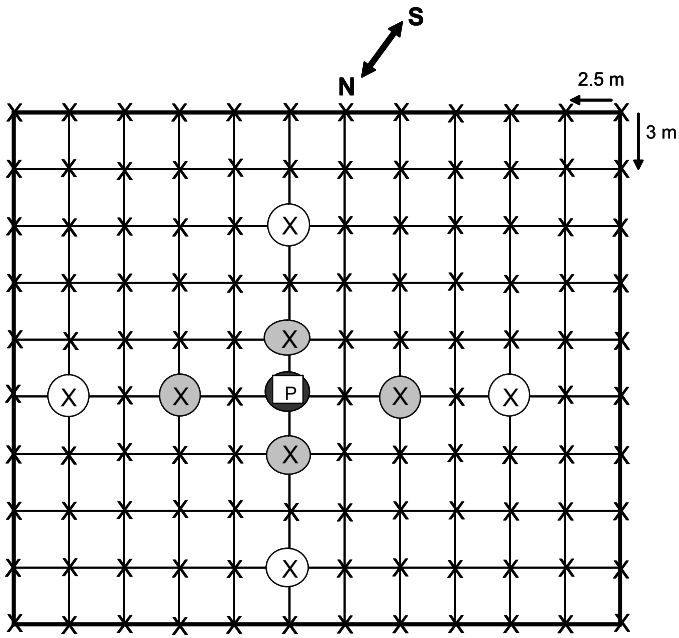

FIG. 1. A schematic diagram of the plot used in the field experiment to determine the effect of the aggregation pheromone on the distribution of predators. Pseudostem trap pieces were placed on banana mats (X) at different distance ranges indicated by circles (black = 0 m, grey = 0.1–5 m, white = 5.1–10 m) from the pheromone trap (P).

Pheromone lures for use in laboratory bioassays and field experiments were obtained from ChemTica International in San Jose, Costa Rica. They were sealed in plastic sent by a courier (transit time <1 wk) and subsequently stored in a freezer at −5°C upon arrival until use. Each pheromone pack contained 90 mg of Cosmolure+ with a release rate of 3 mg/day (Oehlschlager, personal communication). The pheromone packs were individually used as odor sources in their original plastic package material.

Predators

Adults of the beetle *D. abdominale* and the ant *P. megacephala* were selected for use in laboratory bioassays to assay their response to infochemicals. Predators were collected by hand searching in rotten banana pseudostems and corms from the field and kept on a nonsubstrate tissue (wetted tissue paper) in the laboratory for 24–48 hr before use in bioassays. Neither age nor sex of the

collected *D. abdominale* beetles was known. Worker ants of *P. megacephala* of unknown age were used.

Olfactometer

An olfactometer similar to that employed by Lofgren et al. (1983) and Cordova-Yamauchi et al. (1998) to study laboratory response of ants to banana weevil aggregation pheromone was used in all experiments. The apparatus consists of a petri dish with 19-cm diam and 4 cm in height, without a lid. Two holes were made through the sides of the dish close to the base, and two delivery tubes were inserted into them. A filter paper was placed at the floor of the petri dish and wetted with about 50 ml of water before each test. One of the (arms) tubes of the olfactometer was connected to a jar (125 ml) containing a test odor source and the other to a jar containing clean air as control. Volatiles entered the arena by diffusion.

A single predator was placed at the center of the olfactometer arena. Each predator was observed for a maximum of 10 min and was considered to have responded when it entered one arm of the olfactometer or when at the end of the 10 min, the predator was within less than 1 cm from the entry port of the arms. After testing five individuals for each odor set, the odor sources were replaced with fresh ones. For all experiments, five individuals of each predator species were tested for all odor sets per day. The first experiment was repeated during 6 d (N = 30, total number of individuals per predator species per odor set), whereas the rest of the laboratory experiments were repeated on 10 d (50 individuals per predator species per odor set, unless mentioned otherwise). Each predator individual was tested only once and then discarded. Treatment and control arms were exchanged after testing each predator by connecting the tubes at the opposite side to avoid trail formation. This had been observed to occur especially in the case of *P. megacephala* in preliminary tests. This procedure also precluded the effects of unforeseen asymmetry in the setup. The apparatus was washed with ethanol and air-dried before using a new predator species (i.e., after testing five individuals).

Experiments

We conducted five experiments with *D. abdominale* and *P. megacephala*. The first four were done in the laboratory using the olfactometer, and the fifth was done in the field.

Testing of the Olfactometer. This experiment was conducted to test whether any directional bias interfered with the responses of the two predator species in the olfactometer. The following odor sets were compared in this

experiment: (1) clean air vs. clean air and (2) fermented pseudostem tissue vs. fermented pseudostem tissue.

Predator Response to Pseudostem Tissue and Weevil Pheromone. The response of the predators to banana pseudostem tissue and the weevil's aggregation pheromone was evaluated in this experiment. Odor sets that were tested in the olfactometer were (1) fresh pseudostem tissue vs. clean air, (2) fermented pseudostem tissue vs. clean air, (3) fermented vs. fresh pseudostem tissue, and (4) pheromone vs. clean air.

Predator Response to Different Doses of Fermented Pseudostem Tissue. This experiment was conducted to determine whether predator response to infochemicals was dose-dependent. Odor sources were 1, 5, 25, and 125 g of fermented pseudostem tissue. Predator response to volatiles emanating from these amounts of tissue was compared to clean air in the olfactometer.

Predator Response to Weevil-Damaged Pseudostem Tissue in the Absence and Presence of Pheromone. This experiment was conducted to determine whether feeding by weevil larvae influences predator response to the banana pseudostem tissue and to evaluate whether the presence of pheromone enhances the predators' responses to volatiles from banana pseudostem tissue without weevil larvae feeding. Treatments were as follows: (1) fresh pseudostem, fed on by weevil larvae for 48 hr and larvae removed (F-LR); (2) fresh pseudostem, fed on by weevil larvae for 48 hr and larvae present (F-LP); and (3) weevil larvae alone. The following odor sets were compared: (1) F-LR vs. clean air, (2) F-LP vs. clean air, (3) larvae vs. clean air, (4) F-LP vs. larvae, (5) F-LR vs. F-LP, and (6) F-LR plus pheromone vs. F-LR.

Pseudostems of the cultivar Nabusa were collected from the fields at KARI. Weevil larvae (third to fifth instar) collected from the field were allowed to feed on fresh pseudostem tissue for 48 hr. Five larvae were placed on a pseudostem piece measuring 30 × 10 cm. After 48 hr at 22–28°C, the tissue had been tunneled, and tissue had turned dark brown and was used in bioassays with or without the larvae present. The larvae that were tested without food were collected from the field 24 hr before bioassays. They were placed in petri dishes (9-cm diam) with a nonsubstrate food material (moist tissue paper).

Field Distribution of Predators Around the Pheromone-Baited Traps. A field experiment was conducted at KARI to determine the distribution of banana weevil predators around pheromone-baited traps. We evaluated the hypothesis that predators aggregate around the trap mat as a result of a response to the pheromone and/or weevil-related volatiles. A pitfall pheromone-baited trap (Tinzaara et al., 2000) was placed at the center of each plot (Figure 1). Soapy water was placed in the trap to retain the predators that had entered. The soapy water was renewed at every sampling occasion. Pheromone traps were checked every 37 d, and predators captured in the traps were recorded and taken to the laboratory in vials for sorting and identification.

Ten fresh split pseudostem pieces (each 30 cm long) were placed in the plots at the time of installing the pheromone traps. In each plot, pseudostem pieces were placed on the trap mat and on four mats in each of the distance range of 0.1–5 and 5.1–10 m from the trap. Selection of the distance ranges was based on previous data on response by the weevil to the aggregation pheromone (Tinzaara et al., 2000). Six replicate plots were used. To determine distribution of predators around the pheromone-baited traps, predators were searched for in banana pseudostem pieces after 30 d at different distances from the trap.

Statistical Analysis

The χ^2-test for goodness of fit was used to determine the preference for one of the stimuli tested during the olfactometer bioassays (distribution of expected values 50:50). Field data on the number of predators and the weevils distributed around the pheromone-baited traps relative to distance were subjected to analysis of variance (ANOVA) using the GLM procedures of SAS software (SAS, 1990). The means were compared using the Student–Newman–Keuls (SNK) test. A regression analysis was used to determine the relationship between weevil and predator catches in pheromone-baited traps.

RESULTS

Both predator species, *D. abdominale* and *P. megacephala*, showed equal distributions when offered clean air vs. clean air and when offered fermented pseudostem tissue vs. fermented pseudostem tissue ($P > 0.05$) (Table 1). There were fewer nonresponders for *P. megacephala* (22%) than *D. abdominale* (40%) in the olfactometer apparatus used. The data indicate that the apparatus has no symmetrical bias and can be used for evaluating responses of these predators to banana pseudostem tissue and the pheromone.

TABLE 1. NUMBER OF PREDATORS RESPONDING TO CLEAN AIR AND FERMENTED BANANA PSEUDOSTEM ODORS IN A TWO-CHOICE OLFACTOMETER ASSAY IN THE LABORATORY

	Dactylosternum abdominale			*Pheidole megacephala*		
Comparison odor sources (A/B)	A	B	No response	A	B	No response
Clean air/clean air	10	9	11	12	11	7
Fermented/fermented tissue	9	8	13	11	13	6

A total number of 30 individual predators were tested per comparison set. The responses of the predators to the two odor sources did not differ significantly in either experiment ($P > 0.05$, χ^2 test).

Both *D. abdominale* and *P. megacephala* preferred fermented pseudostem tissue over clean air ($P < 0.001$ and $P < 0.05$, respectively). Neither predator species discriminated between fresh pseudostem tissue and clean air (Figure 2). In a direct comparison, more beetles and ants chose the fermented rather than the fresh pseudostem tissue, but this was only statistically significant for the ant *P. megacephala* ($P < 0.05$). Significantly more beetles moved to the side of the olfactometer with the pheromone ($P < 0.01$) than to the one with clean air, whereas the ants were not attracted to the weevil's pheromone.

The response of both *D. abdominale* and *P. megacephala* to fermented pseudostem tissue was dose-dependent. At all doses, the number of *D. abdominale* and *P. megacephala* choosing the side of the olfactometer with

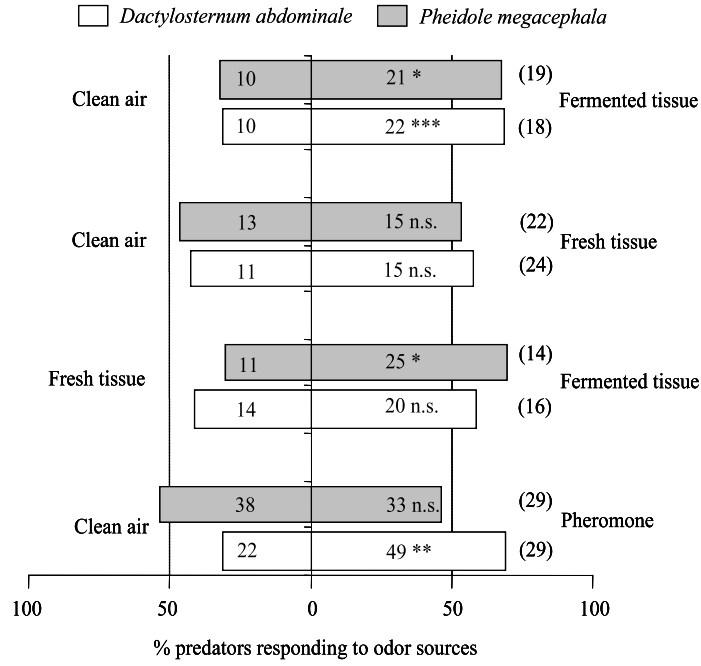

FIG. 2. Response of the banana weevil predators *Dactylosternum abdominale* and *Pheidole megacephala* to volatiles from banana pseudostem tissue and the pheromone in an olfactometer: percentage of responding individuals of each predator per comparison set, choosing one odor source or the other. Significantly different values are indicated with $*P < 0.05$, $**P < 0.01$, and $***P < 0.001$; n.s. = nonsignificant at $P > 0.05$, χ^2 test. The total number of individuals tested per odor set was 50, except for pheromone vs. clean air when 100 individuals were tested for response. The nonresponding predators are indicated in brackets at the right of bars.

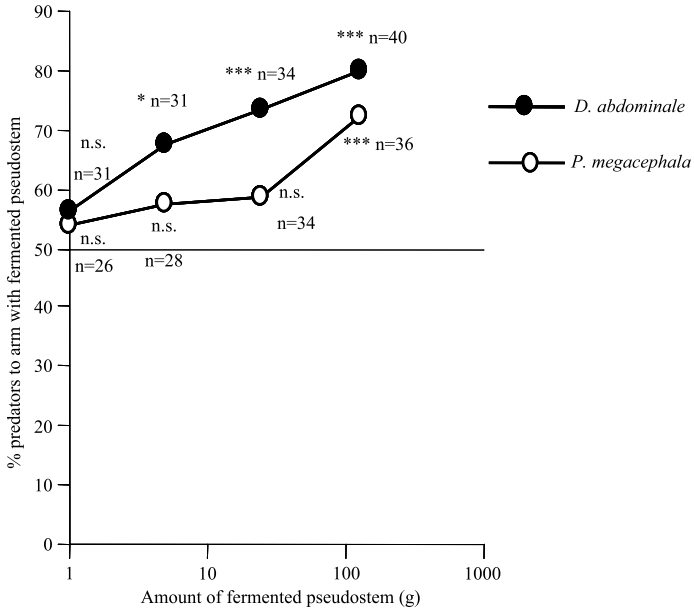

FIG. 3. Dose response of the predators *D. abdominale* and *P. megacephala* to volatiles from fermented banana pseudostem tissue in an olfactometer when the alternative was clean air. *$P < 0.05$, ***$P < 0.001$, n.s. = nonsignificant ($P > 0.05$) (χ^2 test, N indicates total number of responding predators out of 50 individuals tested per dose).

the fermented banana tissue was higher than the number choosing the side with clean air (Figure 3), even when small amounts were used (down to 1 g). However, only the following responses were significant: more *D. abdominale* chose for fermented pseudostem tissue when 5, 25, and 125 g were used than for clean air, and more *P. megacephala* chose for the pseudostem tissue when 125 g was used compared to clean air. Both *D. abdominale* and *P. megacephala* also significantly preferred 50 g of fermented tissue over clean air (Figure 2).

The presence of weevil larvae did not influence the predators' responses to pseudostem tissue. More *D. abdominale* chose fermented pseudostem tissue with or without feeding larvae present than clean air ($P < 0.05$) (Figure 4). There was no significant ($P > 0.05$) difference between the numbers of beetles choosing larvae vs. clean air, fermented pseudostem with larvae vs. larvae only, and fermented pseudostem tissue with larvae either present or absent. The effect of the pheromone when tested in the presence of fermented pseudostem tissue (without larvae) vs. the fermented tissue alone was not significant ($P > 0.05$).

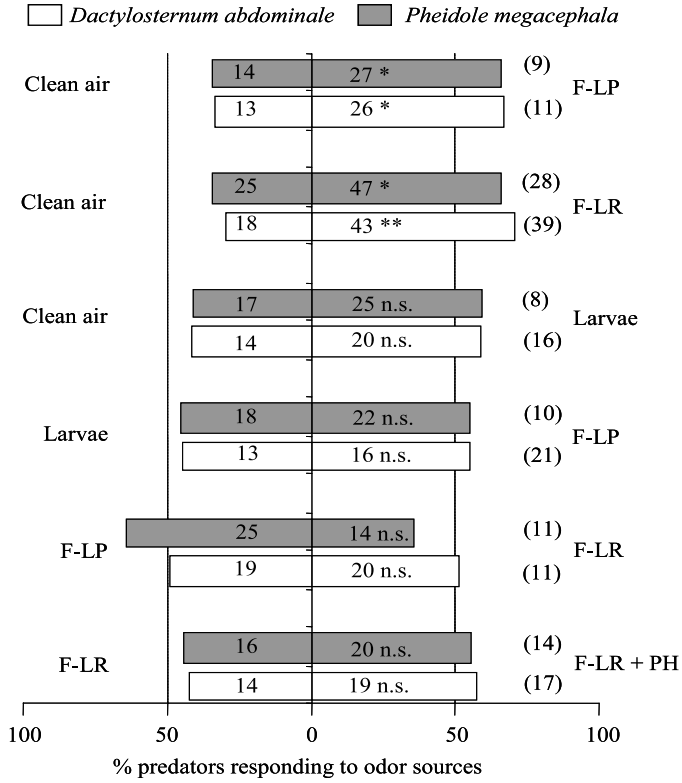

FIG. 4. Response of predators in an olfactometer to fermented tissue with (F-LP) or without (F-LR) feeding weevil larvae and in combination with the pheromone (PH): percentage of responding individuals of each predator per comparison set, choosing one odor source or the other. Significantly different values are indicated with $*P < 0.05$ and $**P < 0.01$; n.s. = nonsignificant at $P > 0.05$, χ^2 test. The total number of individuals tested per odor set was 50, except for F-LR vs. clean air when 100 individuals were tested for response. Nonresponding predators are indicated in brackets at the right of bars.

More *P. megacephala* ants chose the side of the olfactometer with fermented pseudostem with larvae present or absent than the side with clean air ($P < 0.05$). There was no significant difference in the responses between the other odor sources tested.

The presence of pheromone traps had no effect on predator distributions in the field. The numbers of *D. abdominale* and *P. megacephala* that were recovered on the mats where pheromone traps were present compared to those that

TABLE 2. MEAN NUMBER (±S.E.) OF PREDATORS AND *C. sordidus* RECOVERED FROM PSEUDOSTEM PIECES PLACED AT DIFFERENT DISTANCES FROM THE PHEROMONE-BAITED TRAP IN BANANA PLOTS AT KARI, UGANDA

Predators and *C. sordidus*	Number of insects recovered from different distances (m)		
	0	0.1–5	5.1–10
Labia spp. (Dermaptera: Labiidae)	2.0 ± 0.9a	0.8 ± 0.3a	1.3 ± 0.6a
D. abdominale (Coleoptera: Hydrophilidae)	4.8 ± 1.0a	3.2 ± 0.9a	3.3 ± 1.0a
P. megacephala (Hymenoptera: Formicidae)	2.0 ± 1.2a	0.3 ± 0.3a	0.6 ± 0.3a
Banana weevil larvae, *C. sordidus*	3.8 ± 2.0a	1.1 ± 0.4a	1.1 ± 0.7a
Adult banana weevils, *C. sordidus*	21.5 ± 6.3a	7.1 ± 2.3b	6.5 ± 1.2b

In each of the six plots, there were 10 pseudostem traps at each of the points per distance range. Means for each predator and *C. sordidus* followed by similar letter in a row are not significantly different ($P < 0.05$, SNK).

were recovered from mats less or more than 5 m from the trap were similar (Table 2). Numbers of adult weevils were significantly higher at the pheromone trap mat than on mats less than 5 m and in the range of 5.1–10 m from the trap. The numbers of weevil larvae recovered at all distances from the pheromone trap were similar.

The ants *P. megacephala* were the only predators that were captured in the pheromone-baited traps in the field. The mean number of weevils and *P. megacephala* captured in pheromone traps was 2.4 (±0.4 S.E.) and 4.2 (±1.2 S.E.) per plot per 3 d, respectively. There was no significant relationship between the numbers of *P. megacephala* and the number of weevils caught in pheromone-baited traps ($r^2 = 0.04$, $P = 0.61$).

DISCUSSION

Predators of the banana weevil are often observed in decomposing banana tissue such as harvested stumps, and often in tunnels where banana weevil eggs, larvae, and pupae are normally found (Koppenhofer, 1993). The results of our olfactometer experiments demonstrate that the predators *D. abdominale* and *P. megacephala* respond to volatiles from fermented banana pseudostem tissue. Attraction to the food of its host was similarly reported for several natural enemy species, such as *Leptopilina* parasitoids (Hymenoptera: Eucoilidae) (Vet, 1985; Vet and Van Opzeeland, 1985), *Anthocoris nemorum* (Heteroptera: Anthocoridae) (Dwumfour, 1992), *Orius tristicolor* (Hemiptera: Anthocoridae)

(Van Laerhoven et al., 2000), and *Chrysoperla carnea* (Neuroptera: Chrysopidae) (Reddy et al., 2002).

Many predator species are known to discriminate between volatiles from herbivore-damaged and undamaged plants (Geervliet et al., 1994; Dicke, 1999). Damaged plants become more attractive soon after the herbivores start feeding on them (Dicke et al., 1990, Turlings et al., 1990; Vet and Dicke, 1992; Geervliet et al., 1994). In our study, the predators did not discriminate between volatiles from larva-damaged pseudostem tissue with or without the larvae present. In addition, neither predator species discriminated between volatiles from weevil larvae and clean air. Similar data have been reported for other tritrophic systems as well (e.g., Turlings et al., 1990; Vet and Dicke, 1992; Geervliet et al., 1994), including a system consisting of fermenting substrates, a fungivore, and its parasitoid (Dicke et al., 1984). Fermented pseudostems that had not been damaged by weevil larvae were also attractive to the predators, which has also been recorded for parasitoids of fungivores (Dicke et al., 1984; Vet, 1985). Stimuli originating from the host habitat may influence host habitat location, although volatile stimuli originating from the host are more reliable (Vet and Dicke, 1992). Our results indicate that the predators *D. abdominale* and *P. megacephala* exploit volatiles from fermented pseudostem tissue, and that prey-related odors do not play a role in prey location.

Several species of natural enemies have been reported to use the aggregation pheromones of their hosts during host searching and location (Aldrich et al., 1984; Wiskerke et al., 1993; Hedlund et al., 1996; Bruni et al., 2000; Reddy et al., 2002; Wertheim et al., 2003, 2005). In our study, the predatory beetle *D. abdominale* was observed to respond significantly to the pheromone compared to clean air in the laboratory. Contrary to what was expected, the pheromone did not enhance the response of *D. abdominale* to volatiles from weevil-damaged pseudostem tissue in the laboratory. The ant *P. megacephala* was not attracted to the banana weevil's aggregation pheromone in the laboratory.

Our field data indicate that banana weevil aggregation pheromone has no effect on the predator distribution around the trap. Although volatiles from the herbivore itself would provide reliable information to the predator (Vet and Dicke, 1992; Wiskerke et al., 1993), the distribution of both predator species in the field was not related to the number of adult weevils captured in pheromone traps indicating that the aggregation pheromone released by male *C. sordidus* is not used by the predators in the field. In addition to the lack of response to the aggregation pheromone, generalist predators such as formicine ants have not been reported to use prey-derived chemicals as kairomones during foraging (Cosens and Toussaint, 1985). In contrast, several other predator species have been reported to use pheromones of their prey during prey searching and location (Dwumfour, 1992; Hedlund et al., 1996; Haberkern and Raffa, 2003; Steidle and van Loon, 2003).

Acknowledgments—The research was funded by the Rockefeller Foundation through a grant to International Institute of Tropical Agriculture and the Wageningen University fellowship Program. We are grateful to Dr. A.C. Oehlschlager of Chemtica International, Costa Rica, for providing the pheromone lures used in the study. We thank Dr. J.J.A. van Loon for comments on earlier versions of this manuscript. Dr. W. Tushemereirwe is acknowledged for his support. F. Sebulime, A. Namirimu, and H. Nakaro assisted in collecting weevil larvae and predators from the field.

(Received March 19, 2004; revised March 11, 2005; accepted March 21, 2005)

Abstract—Defensive secretions of adult and larval *Suocerathrips linguis* (Phlaeothripidae, Thysanoptera) were found to contain a long-chained acetate, (11*Z*)-11,19-eicosadienyl acetate, that was not previously known to occur naturally. This substance occurred together with octadecyl acetate and other long-chained acetates. The eicosadienyl acetate repels ants and spreads on the surface of such potential predators. The mixture can provide a long-lasting surface coating.

Key Words—*Suocerathrips linguis*, Thysanoptera, Phlaeothripidae, defensive secretion, repellent, octadecyl acetate, (11*Z*)-11,19-eicosadienyl acetate, GC-MS.

INTRODUCTION

Defensive secretions with low volatility produced by *Suocerathrips linguis* Mound and Marullo (Thysanoptera, Phlaeothripidae) were investigated in this study. The production of volatile substances by a species of Thysanoptera was noticed long ago by Hodson (1935) as "a pungent and distinctive but not unpleasant odour." During the last three decades, there have been more than 30 papers dealing with secretions of thrips. Several thrips species, when they are attacked by an enemy, raise and lower their abdomen with a drop of a fluid on the abdominal tip (Lewis, 1973). The secretory reservoir seems to be the hindgut

* To whom correspondence should be addressed. E-mail: tschuch@zoologie.uni-halle.de

(Howard et al., 1983). Some of the complete secretions, as well as single components, e.g., lactones such as mellein, have been found to be ant repellents (Howard et al., 1983; Blum, 1991; Blum et al., 1992). They may also function as contact irritants, alarm pheromones, or in some cases fumigants.

S. linguis was described from specimens occurring in the Royal Botanical Garden Kew, London, UK, where it was living on cultivated *Sansevieria* plants (Mound and Marullo, 1994). Despite being restricted to members of this genus, *S. linguis* feeds on fungi growing on the surface of these plants (Moritz, 2002). *Sansevieria* is an endemic Afrotropical genus, and presumably *S. linguis* is also African in origin. Like many other Phlaeothripidae, *S. linguis* shows aggregation and subsocial behavior (Moritz, 2002; Moritz et al., 2003).

METHODS AND MATERIALS

Rearing and Sample Collection. S. linguis was reared on *Sansevieria trifasciata* under a constant light regime of 16:8-hr light/dark (light on at 6:00 am), a temperature of around 23°C, and a relative humidity of 80%. Thrips were stimulated mechanically to produce droplets, and these were collected on the inner wall of a fine capillary glass tube (Minicaps 5 µl, Hirschmann Laborgeräte). The tube was then rinsed with the following solvents: distilled methanol (Aldrich, 49,429-1), hexane (Fluka, 52767), and, for preparation of derivatives, carbon disulfide (Aldrich, 18,017-3). For GC-MS, droplets were collected from 10 to 20 thrips and investigated within 2 hr. For derivative reactions, droplets from 50 thrips were used. For comparison and to examine differences between males and females, whole-body extracts were obtained by soaking 10–20 adults in methanol or hexane for 2 hr. From second instars, 20 droplets were collected and dissolved in methanol.

Chemical Analysis. For GC-MS analyses, samples were dissolved in a small amount (50–100 µl) of methanol or hexane, and then 5 µl were injected into an HP 5890 GC equipped with 5972 MSD and an HP5-MS column (30 m $\times$ 0.25 mm ID; stationary phase: 0.25 µm cross-linked 5% phenyl methyl silicone) that used electron impact ionization. The carrier gas was helium at a flow rate of 1 ml/min, the injector temperature was set to 300°C, and the detector temperature to 280°C. Column temperature was maintained at 100°C following the injection and then linearly increased to 300°C at a rate of 7K/min. The NIST database, literature data, and the software AMDIS (NIST, version 2.1) and NIST MS Search (version 1.7) were used to analyze mass spectra and to compare retention times.

To determine position of double-bonds, samples were treated with dimethyl disulfide (DMDS, Aldrich, 52,801-3) as follows. They were dissolved in 50 µl carbon disulfide for 10 min, then 10 µl of a 5% iodine solution (in CS_2)

and 60 µl DMDS were added and mixed together with the help of a microliter syringe. After 10 hr at 40°C, the reaction was quenched by the addition of 50-µl 5% solution of sodium thiosulfate (Aldrich, 21,726-3) in H_2O. The organic phase was evaporated on a slide, and the solid residue was dissolved in methanol and investigated as described above. Pure solvent without thrips secretion was treated and checked for impurities. The resulting mass spectra of the derivatives were evaluated by self-written software ACE_FIND, based on the findings of Buser et al. (1983) and Vincenti et al. (1987). The software calculates the diagnostic mass peaks of DMDS derivatives of aliphatic acetates in a selected chain length range with all possible positions of two double-bonds. It considers aliphatic derivatives, cyclic derivatives, and special properties in conjugated double-bonds as well and compares the resulting mass peaks with up to 16 input values. The output is a list of substances sorted by the number of mass peaks that fit the input data.

Bioassay. For the first preliminary bioassay tests, two colonies of *Myrmica rubra* (Linnaeus, 1758) (about 25 individuals each, obtained from Antstore, Berlin) were reared separately in glass tanks $0.2 \times 0.3 \times 0.2$ m^3, filled to a depth of 50 mm with garden soil. In the test, ants had to choose between two pieces of food (ca. 75 mg of turkey meat). The pieces were placed on a sheet of filter paper at a distance of 50 mm, and a circle (radius 20 mm) was drawn in pencil around each. The edge of one circle was soaked with 0.5 µl of test substance dissolved in 50 µl methanol, and the second was treated only with 50 µl methanol as a control. The sheet of filter paper was placed on a glass slide in the tank to prevent contamination from the soil. The number of ants inside the circles was recorded every 10 min until the food was consumed. Test and control were not replaced during each test.

RESULTS

The main components of the droplets were long-chained acetic acid esters (acetates) of one saturated (C18) (Figure 1, peak at 17.53 min retention time) and several unsaturated alcohols (C16, . . . , C20) (other peaks from 17.11 to 19.82 min retention time). These constituents have a low volatility. In all cases, it was possible to find the peak for the molecular (M^+) ion, as well as a fragment at m/z 61 (CH_3CHOOH) and a fragment M^+-60 because of McLafferty rearrangement in acetates.

No differences were detected between males, females, and second instar larvae. The secretion does not contain any compound from the fungi on which the thrips feed, nor from the host plant (*Sansevieria*). Sex-specific concentrations of substances with high volatility were found only if the whole thrips were extracted (Tschuch et al., 2002). Thus, the thrips must have additional

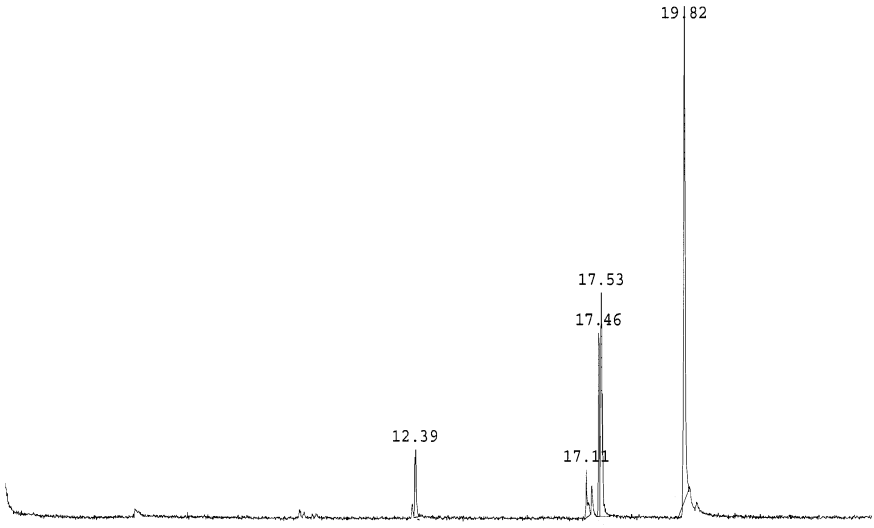

FIG. 1. Total ion gas chromatogram of 20 secretion droplets (numbers are retention times in minutes).

secretory glands to produce volatile semiochemicals, although these are not the topic of this paper.

The molecular (M^+) ion of the main component is 336. A fragment at *m*/*z* 61 ($CH_3COOH+H$) and a small fragment at *m*/*z* 276 suggested that this compound was an eicosadienyl acetate (C20:2-OAc). The other mass peaks were similar to some octadecadienyl acetates (C18:2-OAc, library data). In the DMDS derivatives of the secretion, one substance had a characteristic mass spectrum with *m*/*z* 61 as the highest peak (spectrum measured from *m*/*z* 50). There are only four peaks >5% above *m*/*z* 120: 121, 169, 217, and 259. With software, all derivatives of acetates between C18:2 and C22:2 were investigated. The only DMDS derivatives fitting all four peaks according to Vincenti et al. (1987) were C20:2-OAc with one double-bond at position 11 and the other double-bond at position 17, 18, or 19. The 11,17-isomer must have a prominent peak at *m*/*z* 89, the 11,18-isomer at 75, and the 11,19-isomer at 61. *m*/*z* 89 and 75 could not be found as high peaks, so the result must be 11, 19-C20:2-OAc. The mass peaks are as follows: 61 $[c]^+$ together with the 61 from CH_3CHOOH (therefore, this *m*/*z* has the highest abundance), 121 $[bc\text{-}3*CH_3SH]^+$, 169 $[bc\text{-}2*CH_3SH]^+$, 217 $[bc\text{-}CH_3SH]^+$, and 259 $[a]^+$ (where a = 259 is the part from the acetic acid to former double-bond at position 11, b = 204 is the part between the former two double-bonds, and c = 61 is the remaining part). Small peaks are also visible at 403 and 429 corresponding to

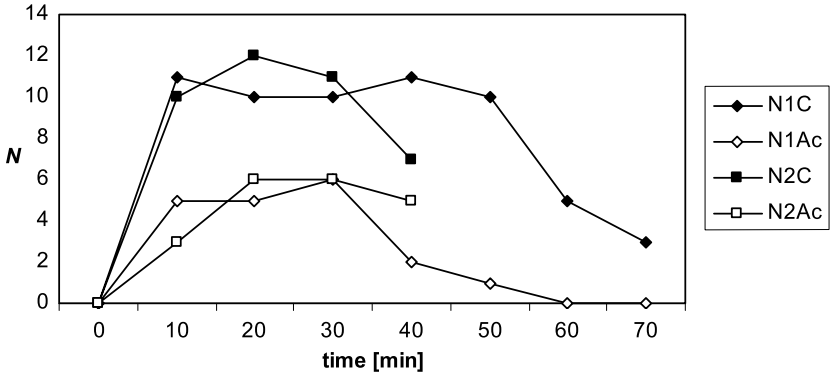

FIG. 2. Number of *Myrmica rubra* ants choosing between two pieces of food, each surrounded by a ring. One ring was treated with (11*Z*)-11,19-eicosadienyl acetate solved in methanol (Ac), and the second only with methanol (C). N1 and N2 are the nests 1 and 2; *N* is the number of ants inside the ring.

$[ab\text{-}CH_3CHOOH]^+$ and $[M\text{-}2*CH_3SH]^+$. Thus, the main component is an 11,19-C20-OAc.

The identified constituents were compared with authentic substances: octadecyl acetate was bought (Sigma, S-5003 stearyl acetate), and (11*Z*)-11,19-eicosadienyl acetate was synthesized as described in Csuk et al. (2004) because (*E*) isomers are seldom found in insect allomones or pheromones (with the exception of Lepidoptera sex pheromones). Mixtures of authentic substances with *S. linguis* secretion were analyzed by GC-MS and yielded only a single peak. Furthermore, the mass spectra of the constituents and authentic compounds matched closely.

Preliminary bioassay tests showed that the (11*Z*)-C11,19-OAc alone is an effective repellent against *M. rubra* (Figure 2). For 1 hr, the number of ants inside the acetate ring was at all times lower than inside the control ring. The food in the control ring was removed by the ants in small portions, whereas the food in the acetate ring was left more or less untouched. The test with nest 2 (N2) ended after 40 min because the food in the control (C) was consumed. Only two tests could take place because of the limited amount of substance synthesized.

DISCUSSION

The main constituent of the anal secretion of *S. linguis* adults and larvae, (11*Z*)-11,19-eicosadienyl acetate (C20:2-OAc), is a new natural product not

previously reported in animals or plants. Secretions of Thysanoptera species consist of different chemical constituents, such as aliphatic hydrocarbons, carboxylic acids, aliphatic esters, cyclic esters of hydroxyl carboxylic acids (lactones), pyranones, naphthoquinones, and terpenes (Terry, 1997). In this discussion, only aliphatic esters of acetic acid, found in 30% of the investigated species, are the focus of attention. The aliphatic ester with the longest chain known previously from Thysanoptera is octadecyl acetate (C18:0-OAc) from *Gynaikothrips uzeli* (Suzuki et al., 1989: only 2.2% of secretion). Hexadecyl acetate (C16:0-OAc) is reported from *Gynaikothrips ficorum* (Howard et al., 1987: in 1:1 mixture with pentadecane one of the main constituents), from *G. uzeli* (Suzuki et al., 1989: in 1:2 mixture with pentadecane one of the main constituents), from *Leeuwenia* (=*Varshneyia*) *pasaniae*, and from *Liothrips kuwanai* (Suzuki et al., 1988: only 3.0 and 4.7%). A small part of the *Li. kuwanai* secretion is probably hexadecenyl acetate (C16:1-OAc, double-bond position unknown) (Suzuki et al., 1988: 1.2%). The secretion of *L. pasaniae* contains mainly tetradecyl acetate (C14:0-OAc: 15.4%), tridecane (51.3%), and pentadecane (12.4%). In contrast to these species of Tubulifera, the only species of Terebrantia from which chemicals have been identified so far, *Frankliniella occidentalis*, produce a mixture of dodecyl (C12:0-OAc) and decyl acetate (C10:0-OAc) in the anal droplets of second instars, although only in traces in secretions by adults (Teerling et al., 1993a,b; Teerling, 1995; MacDonald et al., 2003). Tubulifera with gregarious and commonly social or gall-dwelling lifestyles may be more prolific producers of defensive secretions than solitary Tubulifera or Terebrantia. To maintain safety within a colony, a strong repellent allomone or alarm pheromone would be effective (Terry, 1997). In solitary Thysanoptera, defensive secretion is more important in larvae because adults are able to fly away if predators are near.

Most species of Tubulifera discharge the fluid from the apex of their tube. This allows them to apply the droplet to a predator, but to resorb the droplet if the application fails (Howard et al., 1987). For this reason, the secretion must be liquid down to the lowest temperature at which predators are active. If the secretion is to disable or irritate potential predators by coating them with the liquid, then a secretion with a low vapor pressure at all possible ambient temperatures would be best. This is necessary to avoid fast evaporation. To fulfill both requirements, the mixture should have a melting point (mp) near 0°C and a boiling point as high as possible. If one of the main constituents is an aliphatic acetate (discussed below), then there are several possible solutions: saturated acetates C12:0-OAc (mp 1°C) or C10:0-OAc (mp −15°C) singly or mixed; longer-chained saturated acetates (e.g., C16:0-OAc, mp 24°C) dissolved in a liquid hydrocarbon or other solvent; and unsaturated acetates with melting points near 0°C.

The first of these is used by larvae of *F. occidentalis*, and the second by the two species of *Gynaikothrips* mentioned above. Pentadecane has a melting point

of 10°C. The mixture has a melting point below 10°C because the acetate acts as an impurity of the pentadecane.

The third of these methods is used by *S. linguis*. Because of the lack of experimental data, estimations of melting points are necessary. Unfortunately, software such as MPBPWIN (version 1.41, part of EPI Suite from United States Environmental Protection Agency) is not suitable. For example, it estimates a melting point between 76 and 102°C for eicosyl acetate, whereas the measured melting point is approximately 41°C. Furthermore, this and other software that use the Joback algorithm, the Gold & Ogle algorithm, or similar methods do not consider the position of double-bonds or the stereochemistry. Kobayashi et al. (1978) found the following data for the 11-eicosenyl acetates (C20:1-OAc) and alcohols: (*Z*)-11-eicosenol (mp 26°C), (*E*)-11-eicosenol (mp 44°C), (*Z*)-11-eicosenyl acetate (liquid), and (*E*)-11-eicosenyl acetate (mp 20°C). The saturated eicosyl acetate has a melting point of 41°C. From data in Beilstein database (BS0402AE, Beilstein GmbH and MDL Information Systems GmbH 2004), it appears that acetates melt 26K (±3K) below the corresponding alcohol (data from nine pairs between C12:0 and C22:1). So the melting point of the (*Z*)-11-eicosenyl acetate can be estimated as below 0K. The change from single bond to ally group at the end of the alcohol lowers the melting point of fatty alcohols by 0–6K only (Duhamel, 1963; Stubbs and Smith, 1984). Thus, with an error of ±10K, it is possible to estimate the melting point of (11*Z*)-11,19-C20:2-OAc to be below −3°C and the melting point of (*E*)-11,19-C20:2-OAc to be around 17°C. The estimation for the *Z* isomer seems to be good because the synthesized reference substance remains liquid at 0°C in a refrigerator. As a single substance, the *Z* isomers of 11-C20:1-OAc and 11,19-C20:2-OAc acetate possess an appropriate melting point (around or below 0°C), but the *E* isomers do not.

The vapor pressure of 11,19-C20:2-OAc is lower than the vapor pressure of C10:0-OAc or C12:0-OAc because the boiling point rises with increasing chain length. In addition, saturated acetates possess lower boiling points than unsaturated acetates. In the secretion of *S. linguis*, the solid C18:0-OAc (mp 32°C) is dissolved in the main constituent, which leads to an additional vapor pressure lowering according to Raoult's law. If a potential predator is coated by such a mixture, the C18:0-OAc will remain on the surface after the unsaturated acetate has evaporated. However, it is also conceivable that modifications occur in the unsaturated acetate under the influence of oxygen and ultraviolet light [Panades et al., 1998: (7*E*,9*Z*)-7,9-C12:2-OAc] or ozone [Arndt et al., 1996: (*Z*)-11-C18:1-OAc and (*Z*)-9-C14:1-OAc]. The reaction products, e.g., epoxides and oligomers, are solid and would also stay for a longer time on the predator.

Acetates with 18, 20, and more C-atoms are well-known sex pheromones in Lepidoptera. In *Drosophila* species, (*Z*)-11-C18:1-OAc and (*Z*)-11-C20:

1-OAc act as aggregation pheromones. Acetates with defensive functions can be found in secretions of Coleoptera and Hymenoptera (Wheeler and Duffield, 1988). In Hymenoptera, larvae of a tenthridinid sawfly (Jonsson et al., 1988) and adults of social parasitic bumblebees (Zimma et al., 2003) use acetates such as C18:0-OAc in their defensive secretions. In the parasitic bumblebees, the main component C12:0-OAc is an effective repellent against host bumblebees. (*Z*)-11-C20:1-OAc can be found in the secretion of some chrysomelid beetles: in larvae of *Linaeidea aenea* [mixed with (*Z*)-9-C18:1-OAc and C16:0-OAc] (Sugawara et al., 1979), in adults of *Gastrophysa viridula* [mixed with (*Z*)-13-C22:1-OAc] (Eggenberger et al., 1994), and in *Gastrophysa atroceanea* [mixed with C18:0-OAc] (Sugawara et al., 1978). The last secretion was effective against *Lasius niger* ants and is similar to the secretion of *S. linguis* except that it has no allyl group at the end of the alcohol. There is thus strong evidence for long-chained acetates acting as repellents against predators, especially predatory ants.

Some other findings are also relevant. In a primitive Australian ant of the genus *Myrmecia*, (*Z*)-11-C20:1-OAc serves, together with (*Z*)-9-C18:1-OAc and some minor constituents, as an alarm pheromone produced by their Dufour gland (Jackson et al., 1989). C16:0-, C18:0-, C18:1 (9*Z*), and C20:0-OAc were found in the ovarioles of the weevil *Hylobius abietis* (Kalo, 1985; Kalo and Nederstrom, 1986), and the acetates may be useful in protecting the eggs against predators. An eicosadienal (double-bond positions unknown) has been described by Attygalle et al. (1998) as a trace component in the trail pheromone of the ant *Dolichoderus thoracicus*.

In Thysanoptera, Howard et al. (1987) tested the major constituents of *G. ficorum* secretions, C16:0-OAc and pentadecane, individually and in combination, and found that they were defensive allomones for predatory ants. C16:0-OAc individually is a better repellent than pentadecane, but a 1:1 mixture is more effective. They pointed out that the range of repellency is apparently short but effective. *G. ficorum* can disable potential predators by coating them with the irritating anal exudates.

Thus, many long-chained acetates serve as repellents, but why did they evolve to be repellents? Ester cocktails similar to the *S. linguis* defensive secretion are probably optimized to coat predators, especially jamming the chemosensory receptors. Acetates from C14:0 to C18:0 alcohols are known as water-insoluble surfactants able to spread quickly on surfaces (Karkare et al., 1993). In predators such as ants and mites that use mainly the olfactory sense, coating the sensory organs would make the animals "blind." They would not be able to find the prey again, and ants would have difficulty evaluating their own pheromones, such as trail pheromones to return to the nest and inform nest mates about potential prey. Further studies are needed to prove this and to find out why, in contrast to other insects, the allyl group is necessary in the main constituent of *S. linguis* secretions.

Acknowledgments—We gratefully acknowledge Laurence Mound, CSIRO Canberra, and William Kirk, Keele University, Staffordshire, for valuable discussion. We are also grateful to Phil Griffiths and Alison Scott-Brown, Royal Botanic Garden, Kew, London, for sending us the founders for a stock culture of *S. linguis*. We thank a diploma student, Gitte Kiessling, for her help in sample collection.

(Received December 6, 2004; accepted March 13, 2005)

Abstract—The seeds of two *Apiaceae* species, *Ligusticum hultenii* and *Lomatium californicum*, were investigated. Preliminary bioassays indicated that methylene chloride extracts of seeds of both species contained selective phytotoxic activity against monocots and antifungal activity against *Colletotrichum fragariae*. Active constituents were isolated by bioassay-guided fractionation, and the structures were elucidated by NMR and GC-MS as apiol and Z-ligustilide, isolated from *L. hultenii* and *L. californicum*, respectively. Apiol and Z-ligustilide had I_{50} values of about 80 and 600 μM, respectively, for inhibition of the growth of *Lemna paucicostata*. The methylene chloride (CH_2Cl_2) extracts of the seeds and the isolated and purified compounds were tested against the 2-methylisoborneol-producing cyanobacterium (blue-green alga) *Oscillatoria perornata*, and the green alga *Selenastrum capricornutum*. The CH_2Cl_2 extracts of both *Apiaceae* species and apiol were weakly toxic to both species of phytoplankton, while Z-ligustilide was toxic to both with a lowest complete inhibitory concentration (LCIC) of 53 μM. Seeds of *L. californicum* and *L. hultenii* were found to be rich sources of Z-ligustilide (97 mg/g of dry seed) and apiol (40 mg/g of dry seed), respectively.

Key Words—*Ligusticum hultenii*, *Lomatium californicum*, *Apiaceae*, Z-ligustilide, apiol, phytotoxic activity, antifungal activity, *Colletotrichum fragariae.*

INTRODUCTION

The seeds of two *Apiaceae* species, *Lomatium californicum* (Torrey & A. Gray) Mathias & Constance, and *Ligusticum Hultenii* (Fernald) (Calder & Taylor), were investigated for their phytotoxic and antifungal activities. *Lomatium californicum*, also known as *California lomatium* or celery weed, is a perennial herb native to California and can be found in the southern part of Oregon on bushy slopes. *Ligusticum hultenii* is a perennial, common in the northwestern United States, particularly in Alaska. Seeds of both species have a distinct, strong aromatic odor similar to dill seeds. These two species have been previously categorized in the Umbelliferae family (renamed *Apiaceae*), but were recently reclassified in the subfamily Apioideae of the *Apiaceae* family (Watson, 2000). *Apiaceae* species possess compounds with many types of biological activities, such as apoptosis inducers, antibacterial, hepatoprotective, vasorelaxant, cyclooxygenase inhibitory, and antitumor compounds (Okuyama et al., 1991; Gonzalez et al., 1995; Liu et al., 1998; Matsuda et al., 2000; Ye et al., 2001; Pae et al., 2002). We reasoned that these species might have compounds with potential as pest management chemicals.

METHODS AND MATERIALS

Materials. Dried seeds of *L. hultenii*, and *L. californicum* were supplied by Aromagen (Albany, OR, USA). The plants were grown in Albany, OR, and the seeds were harvested in July 2002. All solvents were reagent grade and used without further purification. Extracts of the seeds were analyzed on silica gel thin-layer chromatography (TLC) plates (250 μm thickness, with fluorescent indicator; GF Uniplate Analtech, Newark, DE, USA) using 10% ethylacetate in hexane as the solvent system. Anisaldehyde spray reagent, iodine vapor, and UV light were used for the detection of compounds on the TLC plates. Column chromatography was carried out with kieselgel 60 (particle size 0.063–0.2 mm; Merck, Germany). Seeds of chewing fescue (*Festuca rubra* L., subsp. *commutata* Gaud.), lettuce (*Lactuca sativa* L., cv. Iceberg), and creeping bent grass (*Agrostis stolonifera* L., cv. Pencross) were purchased from Turf Management, Inc., Burpee Seeds, and Tee-2-Green Corp (USA), respectively.

Instrumentation. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker Avance DPX 300 spectrometer operating at 300 MHz for ^{1}H NMR and at 75 MHz for ^{13}C NMR. GC-MS analysis was carried out on an HP5790 MSD spectrometer (Hewlett Packard, USA) equipped with a GC 5890 using a 20 m × 0.2 mm i.d., 0.18 μm DB-1 column (J&W Scientific Inc., California, USA). The oven was temperature programmed from 60°C (5 min) to 280°C (20 min) at 5°C/min with helium as the carrier gas.

Extraction and Isolation of Bioactive Constituents. Dried seeds of *L. hultenii* (100 g) and *L. californicum* (100 g) were ground separately into a powder by macerating in a blender and then stirring the powdered seeds in CH_2Cl_2 (3 × 1 l each) for 1 hr at ambient temperature. The extracts were filtered through filter paper (Whatman #1), and the solvent was evaporated at 40°C to afford viscous oils (11.78 and 7.2 g, respectively).

*Isolation of Z-ligustilide (**1**).* The CH_2Cl_2 extract of *L. californicum* (5 g) was column chromatographed on silica gel (40 mm i.d., 200 mm length) using hexane and increasing amounts of CH_2Cl_2 (0–100%). Fractions of 125 ml were collected and concentrated at 40°C, and similar fractions according to TLC profiles were combined to yield eight fractions. Each fraction was tested with TLC bioautography and phytotoxicity bioassays (see below) to identify the bioactive fractions. Fractions that possessed antifungal activity and phytotoxicity, with similar TLC profiles, were pooled and further purified by silica gel column chromatography. The identity of the active compound eluted with 50% CH_2Cl_2 in hexane was confirmed by GC-MS and comparison of and ^1H and ^{13}C NMR data with those reported in the literature (Fischer and Gijbels, 1987; Miyazawa et al., 2004) as Z-ligustilide (**1**) (2.9 g).

*Isolation of Apiol (**2**).* The CH_2Cl_2 extract of *L. hultenii* (5 g) was column chromatographed on silica gel in a similar manner as that for the isolation of Z-ligustilide to afford 10 fractions from *L. hultenii*. Each fraction was tested on TLC bioautography and phytotoxicity bioassays to identify the bioactive fractions. Fractions that possessed antifungal activity and phytotoxicity with similar TLC profiles were pooled separately and further purified by silica gel column chromatography using ethyl acetate in hexane. The active compound was eluted with 20% ethyl acetate in hexane and was identified as apiol (**2**) (1.7 g) by GC-MS and comparison of ^1H and ^{13}C NMR data with those reported in the literature (Tyagi et al., 1993).

Phytotoxicity Assays. Phytotoxicity bioassays were carried out according to Dayan et al. (2000), using chewing fescue (*Festuca rubra* L., subsp. commutata Gaud.), bentgrass (*A. stolonifera*), and lettuce (*Lactuca sativa* cv L., Iceberg), in 24-well plates. The crude extracts and fractions were tested at 1 mg/ml in 10% acetone in water.

Phytotoxicity to *Lemna paucicostata* was determined according to the method of Michel et al. (2004). Plants were grown in non-pyrogenic polystyrene sterile 6-well plates (Costar 3506, Corning Incorporated) with a lid. Each well contained 4950 µl of the Hoagland's media plus 50 µl of apiol and Z-lugustilide in acetone, with the final concentration of acetone 1%. Each well was inoculated with two, three-frond colonies of approximately the same size. Total frond area per well was recorded by the image analysis system Scanalyser (LemnaTec, Würselen, Germany) once per day from d 0 to d 7. To test the potential influence of the acetone, an acetone control was included in each experiment.

Fungicidal Assays

Pathogen Production. Isolates of *Colletotrichum acutatum* Simmonds, *C. fragariae* Brooks, and *C. gloeosporioides* (Penz.) Penz. & Sacc. in Penz. were obtained from B.J. Smith (USDA, ARS, Small Fruit Research Station, Poplarville, MS, USA). *Colletotrichum fragariae*, *C. acutatum*, and *C. gloeosporioides* were used for all pathogen and bioautography studies. The three *Colletotrichum* species were isolated from strawberry (*Fragaria* × *ananassa* Duchesne). *Botrytis cinerea* Pers.:Fr, was isolated from commercial grape (*Vitis vinifera* L.), and *Fusarium oxysporum* Schlechtend:Fr from orchid (*Cynoches* sp.) were used additionally in the microtiter assays of apiol and Z-ligustilide.

Bioautography. Bioautography on silica gel TLC plates with *Colletotrichum fragariae* was used as the preliminary bioassay to identify the antifungal activity according to a previously published method (Wedge and Nagle, 2000).

Microtiter Assay. A standardized 96-well microtiter plate assay developed for discovery of natural product fungicidal agents (Wedge and Kuhajek, 1998) was used to evaluate purified apiol and Z-ligustilide.

Algicidal Assays. Algicidal bioassays were carried out for CH_2Cl_2 extracts of *L. californicum* and *L. hultenii*, and the isolated, purified Z-ligustilide and apiol against the 2-methylisoborneol (MIB)-producing cyanobacterium *Oscillatoria perornata* and the green alga *Selenastrum capricornutum* according to previously published methods (Schrader et al., 1997) in order to determine the lowest observed effect concentration (LOEC) and the lowest complete inhibitiory concentration (LCIC).

Quantification of Active Components

Sample Preparation. For quantification, 5 g of dried seeds from each species were exhaustively extracted with CH_2Cl_2 (45 ml × 5) using a Dionex ASE 200 accelerated solvent extractor at 40°C and 68.9 bar pressure. Solvent in each sample was evaporated at 40°C under reduced pressure.

GC-MS Analysis. The concentrations of apiol and Z-ligustilide in the crude CH_2Cl_2 extracts were determined by GC-MS analysis. Standard curves were generated by linear regression, using pure apiol ($R^2 = 0.98$) and Z-ligustilide ($R^2 = 0.99$), which were isolated.

RESULTS AND DISCUSSION

The CH_2Cl_2 extracts of *L. hultenii* and *L. californicum* on lettuce (dicot) and bentgrass (monocot) were selectively phytotoxic toward bentgrass at 1.0 mg/ml with a ranking of 5 in the scale of 0–5, where 0 indicated no effect and 5

indicated no germination. The *L. hultenii* extract gave a ranking of 1 on lettuce, whereas the *L. californicum* extract gave a ranking of 2. Through bioassay-guided fractionation, the active compounds were isolated and characterized by NMR and GC-MS as Z-ligustilide (**1**) from *L. californicum* and apiol (**2**) from *L. hultenii* (Figure 1). These two compounds, (**1**) and (**2**), were further tested in a dose-response manner, in the phytotoxicity bioassays (Table 1). Both compounds were much more toxic to the two monocots, bentgrass and fescue, than to lettuce.

Phytotoxicity was further evaluated in a *L. paucicostata* bioassay (Figure 2). Apiol caused about 75% reduction of growth of *L. paucicostata* at 80 μM, whereas Z-ligustilide caused similar effects at 1000 μM. At concentrations of 166 μM and above, apiol completely inhibited the growth of *L. paucicostata*. Apiol and Z-ligustilide had I_{50} values of about 80 and 600 μM, respectively, for inhibition of the growth of *Lemna paucicostata*. At doses of apiol between 25 and 50 μM, slight stimulation of the growth of *L. paucicostata* was observed. This type of stimulation by lower doses of phytotoxins (hormesis) occurs with some other phytotoxins (Schabenberger et al., 1999). The complete inhibition of *L. paucicostata* by Z-ligustilide was observed only at 1000 μM and above. These results suggest that apiol is a more potent growth inhibitor than Z-ligustilide. Aromatic compounds having allyl or isoallyl and methylenedioxy

groups are plant growth inhibitors (Harada et al., 1985). Myristicin, apiol, and dillapiol inhibit growth of rice, affecting mostly the foliar part of the plants without inhibiting the growth of the roots (Harada et al., 1985).

Antifungal activity was observed using bioautography with *C. fragariae* (Figure 3). In order to obtain a quantitative evaluation of antifungal activity, a microtiter plate-based bioassay was carried out according to Wedge and Kuhajek (1998). Results indicated that both apiol and Z-ligustilide had antifungal activity at the concentrations that we tested (1, 10, and 100 μM). Z-Ligustilide and apiol showed the highest activity against *B. cinerea* (Figure 4) among all the pathogens tested. Benomyl at 1 μM was more active than at 100-μM concentrations of apiol and Z-ligustilide. Low antifungal activity was observed for apiol and Z-lingustilide against *C. acutatum*, *C. fragariae*, *C. gloeosporioides*, and *F. oxysporium* in the microtiter assay (data not shown).

The cyanobacterium *O. perornata* is a pest in commercial catfish production ponds in the southeastern region of the USA. MIB is produced by *O. perornata* and accumulates in the flesh of pond-raised channel catfish (*Ictalurus punctatus*) causing a musty "off-flavor" that results in an unpalatable and unmarketable product. Green algae (Division Chlorophyta) such as *S. capricornutum* do not produce the off-flavor compounds commonly encountered in channel catfish aquaculture and are the preferred type of phytoplankton in catfish aquaculture ponds. Algicidal bioassay results indicated that CH_2Cl_2 extracts of both seeds had LOEC and LCIC values of 100 ppm and

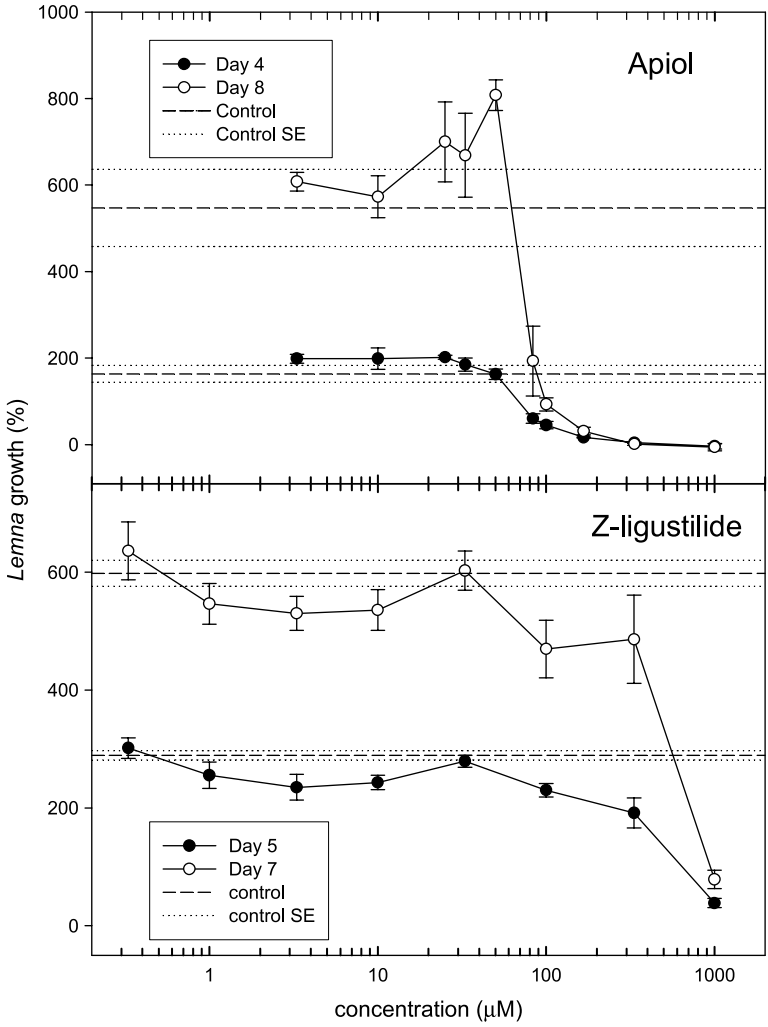

FIG. 2. Growth response of *L. paucicostata* at various concentrations of apiol and Z-ligustilide. Growth was monitored at d 4 and 8 after treatment for apiol and at d 5 and d 7 for Z-ligustilide.

higher (Table 2). Z-Ligustilide showed nonselective activity against *O. perornata* and the green alga *S. capricornutum* with LOEC and LCIC values of 53 μM (Table 2). Apiol showed no activity against either species of phytoplankton at the concentrations tested.

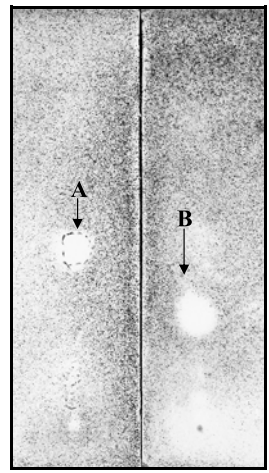

FIG. 3. Bioautography of apiol (A) and Z-ligustilide (B). The plate was sprayed with spores of *Colletotrichum fragariae*. Apiol and Z-ligustilide were chromatographed on silica gel TLC plate using 10% ethyl acetate in hexane.

Z-Ligustilide has been found previously in *Lomatium californicum* (Beauchamp et al., 1993), and is widely occurring with its *trans*-isomer in *Ligusticum* and *Lomatium* spp. (Kobayashi and Mitsuhashi, 1987; Bedrossian et al., 1998; Lu et al., 2004). Apiol can be found with ligustilides in other *Ligusticum* spp. (Brandt and Schultze, 1995).

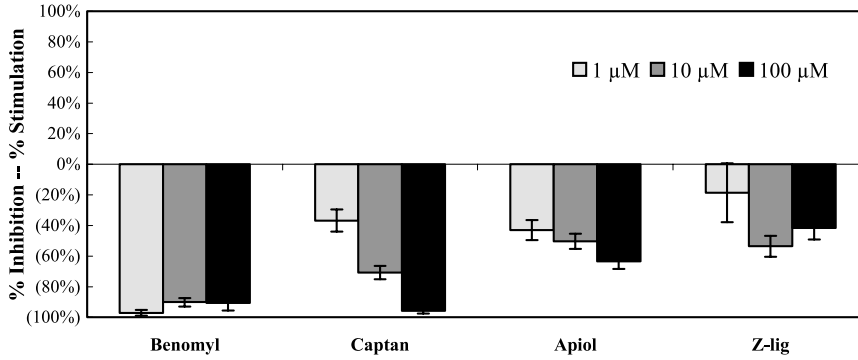

FIG. 4. Mean percent growth inhibition of *Botrytis cinerea* in response to 1, 10, and 100 μM concentrations of Z-ligustilide and apiol after 72 hr. Fungal growth showed that Z-ligustilide and apiol demonstrated less inhibition than the commercial fungicide standards benomyl and captan against *B. cinerea*.

TABLE 2. EFFECT OF CH_2CL_2 EXTRACTS OF *L. californicum* AND *L. hultenii* AND THE ISOLATED, PURIFIED Z-LIGUSTILIDE AND APIOL ON THE CYANOBACTERIUM *Oscillatoria perornata* AND *Selenastrum capricornutum*

	Test organism			
	Oscillatoria perornata		*Selenastrum capricornutum*	
Extract/compound	LOEC	LCIC	LOEC	LCIC
L. californicum	100 ppm	100 ppm	100 ppm	>100 ppm
Z-ligustilide	53 μM	53 μM	53 μM	53 μM
L. hultenii	100 ppm	>100 ppm	>100 ppm	>100 ppm
Apiol	>100 μM	>100 μM	>100 μM	>100 μM

LCIC: lowest complete inhibitory concentration.
LOEC: lowest observed effective concentration.

According to GC-MS analysis, the concentration of Z-ligustilide was 85% and that of apiol was 65% of the CH_2Cl_2 extracts of the seeds of *L. californicum* and *L. hultenii*, respectively (Figure 5). *L. californicum* and *L. hultenii* seeds were found to contain 97 mg of Z-ligustilide per g of dry seed and 40 mg of apiol per g of dry seed, respectively. These results indicated that both Z-ligustilide and apiol occur in high concentrations in these two seeds. The reason for the occurrence of these compounds in such high concentration is unclear. Insect antifeedant assays are ongoing for apiol and Z-ligustilide.

Z-Ligustilide is present in many other plants, and it is the active compound in the Chinese herbal drug *Angelica sinensis,* which is also known as Danggui or Female Gingseng (Zhao et al., 2003). This compound is chemically unstable at ambient temperature and will produce polymerized products when exposed to light and heat (Rios et al., 1998). The chemical instability is attributed by the presence of double bonds in the molecule that can undergo [2 + 2] Diels–Alder type cycloaddition, whereby one molecule serves as a diene and the other as a dienophile and resulting in insoluble complex molecules (Rios et al., 1998).

Our results show that apiol and Z-ligustilide are phytotoxic to the monocots tested in this study and are weakly antifungal. Apiol was not toxic to the MIB-producing cyanobacterium *O. perornata* and the green alga *S. capricornutum*, while Z-ligustilide was toxic, but not selective, to *O. perornata*. Z-Ligustilide is considered the active compound in the herbal drug *Angelica sinensis*, but there are no reports of the use of *L. californicum* as an herbal remedy. The possible uses of this plant or its seeds as herbal drugs as sources of Z-ligustilide are yet to be explored. Although the antimicrobial and phytotoxic activities are not sufficient for commercial use, these natural compounds could be used as templates to produce more active compounds. Furthermore, we have found Z-ligustilide to be a major compound in *L. californicum* seeds.

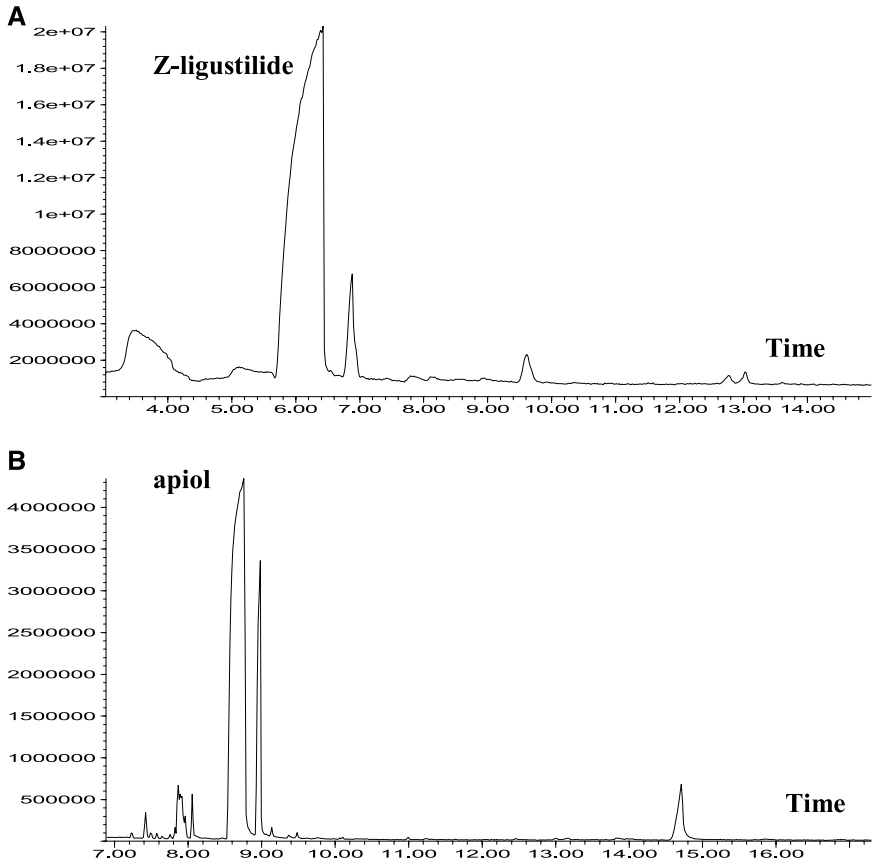

FIG. 5. Sample total ion chromatogram for the CH_2Cl_2 extracts of *L. californicum* (A) and *L. hultenii* (B).

The biological and/or ecological functions of these compounds in such high concentrations in the seeds of these species are topics worthy of further studies. Seeds of wild plants must have some resistance to herbivores and microbes in order to survive until dormancy is broken. The biological activities of the compounds that we report here suggest that they may play a role as antimicrobial compounds to prevent seed decay. Ligustilide has been reported to have activity against insects (Miyazawa et al., 2004). Whether the ecological function(s) of these two compounds also includes antifeedant or other properties should be investigated. Lastly, these compounds could have a role in the regulation of seed dormancy, a more challenging biological function to explore.

Abstract—The influence of autoclaved fungal materials such as culture filtrate, freeze-dried mycelium (FDM), mycelium suspension, and spore suspension (SS) on the growth, morphogenesis, and carvone production of spearmint (*Mentha spicata* L.) plants was studied. Fungal materials were either applied as a drench or spray on the plants. Spearmint plants (cv. "294099") drenched with SS (1×10^8 spores/ml) of *Trichoderma reesei* showed no significant differences in leaf numbers, root numbers, or shoot numbers compared with nontreated controls. However, significantly higher fresh weights and carvone levels were observed in plants drenched with *T. reesei* SS compared with the untreated controls. Fungal materials derived from *Aspergillus* sp., *Fusarium graminearum*, *F. sporotrichoides*, *Penicillium* sp., *P. acculeatum*, *Rhizopus oryzae*, and *T. reesei* were sprayed on spearmint foliage. *F. graminearum*, *F. sporotrichoides*, or *R. oryzae* elicited no enhanced growth, morphogenesis, or secondary metabolism responses. The best growth and morphogenesis responses were obtained employing *Aspergillus* sp., *Penicillium* sp., or *T. reesei* foliar sprays. For example, spearmint cv. "557807" plants sprayed with 100 mg/l FDM *T. reesei* isolate NRRL

[4] Names are necessary to report factually on available data; however, the USDA neither guarantees nor warrants the standard of the product, and the use of the name by USDA implies no approval of the product to the exclusion of others that may also be suitable.

11460 C30 stimulated higher fresh weights (75%), shoot numbers (39%), leaf numbers (57%), and root numbers (108%) compared with untreated plants. This effect was not dose-dependent because similar growth and morphogenesis responses were obtained by testing 10, 100, or 1000 mg/l FDM concentrations. Carvone levels in fungal-treated foliar-sprayed plants were comparable to nontreated controls. However, total carvone levels per plant were higher in fungal-treated plants because of their increased fresh weight.

Key Words—*Aspergillus*, carvone, freeze-dried mycelium, *Fusarium*, mycelium, *Penicillium*, secondary metabolites, *Rhizopus*, spearmint, spores, *Trichoderma.*

INTRODUCTION

Some biocontrol microorganisms aside from combating pathogens may also cause plants to exhibit enhanced growth (Chang et al., 1986; Ryu et al., 1999, unpublished data; Raj et al., 2003). Microorganism preparations enhancing plant growth may be rhizobacteria (Ryu et al., 1999; Zehnder et al., 2000; Raj et al., 2003) or fungus (Elad, 2000). In these reports, biological preparations were composed of living microorganisms. In contrast, little research has been conducted studying the effects of dead microorganism fractions on growth (i.e., dry or fresh weights) and morphogenesis (i.e., leaf, root, and shoot numbers and sizes) responses in plants. Elad (2000) reported the effective biocontrol of powdery mildew on cucumber (*Cucumis sativus* L.) by application of foliar sprays containing either live or dead *Trichoderma harzianum* T39 cells. In addition, a slight increase in the leaf number occurred in sprayed plants employing either living or dead cells of T39 compared with untreated controls. This study suggested that dead fungal material may elicit both defense and growth and morphogenesis enhancement responses. Effective application of nonliving microorganism fractions to stimulate growth and/or combat pathogens would be of great benefit to the nursery and field grower. The drawbacks of using living microorganisms include their opportunistic human pathogenic nature (e.g., aspergillosis) and the permanent introduction of undesirable foreign fungal populations into soil (Anderson et al., 2002; Barkhage and Bernhard, 2002). These problems would be avoided by employing inert dead fungal materials.

In this study, we sought to determine the influence of applying dead fungal fractions on the growth, morphogenesis, and secondary metabolism responses in spearmint (*Mentha spicata* L.) plants. Secondary metabolites are constitutive chemicals that may represent a first-line defense to pathogen attack (Kuc, 1997). Treatments that stimulate secondary metabolite production could be useful to combat pathogens. The objectives of this study were to evaluate: (1) the effect of drenching the rhizosphere with spore suspensions (rhizosphere stimulation);

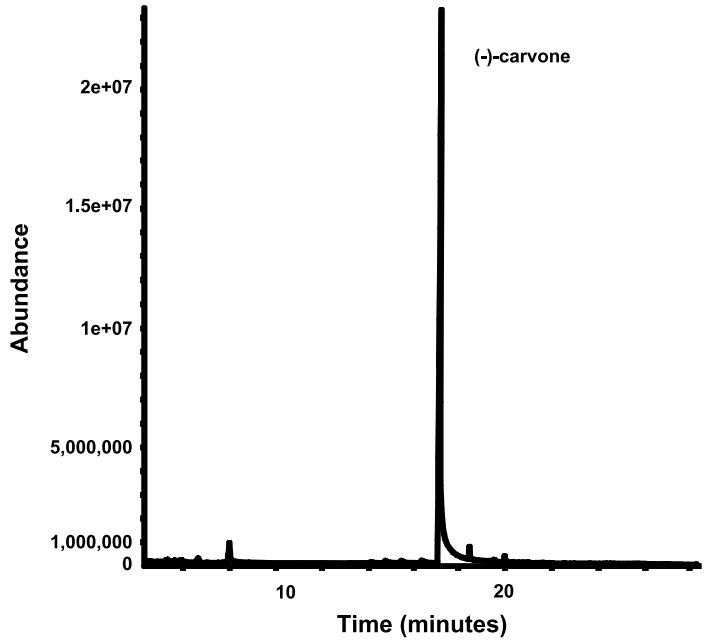

FIG. 1. Typical GC-MS profile of a spearmint plant showing the dominant monoterpene (–)-carvone in relationship to other monoterpenes present.

(2) the effect of applying suspensions of autoclaved mycelium suspension (MS), freeze-dried mycelium (FDM), spore suspensions (SS), or culture filtrate (CF) as foliar sprays (phylosphere stimulation); and (3) the effect of the concentration of FDM foliar sprays (dosage–response stimulation).

Spearmint was employed because it can be easily grown in the greenhouse as uniform-sized rooted shoots that readily manifest growth, morphogenesis, and secondary metabolism responses to various chemical and environmental treatments. The dominant essential oil component in spearmint oil is (−)-carvone, which constitutes >90% of the essential oil composition (Figure 1). Spearmint is commercially grown for its oils, which are employed as fragrance components in toothpastes, mouthwashes, soaps, detergents, lotions, insecticides, and perfumes (Leung, 1980).

METHODS AND MATERIALS

Fungal Cultures and Medium. For the production of SS, fungi isolates (*Aspergillus* sp. NRRL 32534 and *Trichoderma reesei* NRRL 11460 C30) were

grown on potato dextrose agar (PDA) medium at room temperature under fluorescent lighting (12 hr light/12 hr dark) for 7 d. For production of mycelium, fungi isolates (*Aspergillus* sp. NRRL 32534 and NRRL 363, *Fusarium graminearum* NRRL 23639, *F. sporotrichoides* NRRL 3299, *Penicillium* sp. NRRL 32532 and *P. acculeatum* NRRL 2129, *Rhizopus oryzae* NRRL 395, and *T. reesei* NRRL 11460 C30 and NRRL 3652) were grown in liquid potato dextrose broth (PDB) in Fernbach flasks inoculated with fungal cultures maintained on PDA and then placed on a shaker at 250 rpm and incubated at 25°C in the dark. MS were harvested after 72 hr by pouring the mycelium and medium through four layers of sterile cheesecloth followed by squeezing the cheesecloth to extract excess medium and then frozen at −20°C. FDM was prepared by freeze drying MS and then grinding first with mortar and pestle and then with a coffee grinder to produce a fine powder. CFs were collected from liquid PDB and kept in a sterile glass bottle at 0°C until use. All fungal sprays contained 0.025% Tween-80 as a surfactant and were autoclaved at 20 psi at 120°C for 15 min and allowed to cool to room temperature prior to application.

Plant Material. Spearmint stock plants cvs. "294099" and "557808" were maintained via shoot cuttings in soil under greenhouse conditions prior to testing with fungal treatments. For experiments, 4-cm tall plants established in Cone-tainers™ (RLC-4 Pine Cell, Stuewe and Sons Inc., Corvallis, OR, USA) containing 10 g of soil were employed. The soil mixture consisted of 1 peat moss/1 vermiculite (v/v) amended with 10.9 g/kg Micromax (Scotts Co., Marysville, OH, USA) and 62.3 g/kg Osmocote 14–14–14 (Scotts Co. USA). Plants were grown in a greenhouse at 20 ± 2°C under natural daylight.

Rhizosphere Stimulation. Spearmint (cv. "294099") plants were given the following drenching treatments (2 ml/cone): water only, 0.1% Tween-80, *Aspergillus* sp. NRRL 32534 SS (1×10^8 spores/ml), *T. reesei* NRRL 11460 C30 SS (1×10^8 spores/ml), 0.5% DMSO, or 1% DMSO. Treatments were administered once a week for two consecutive weeks. Following treatments, plants were grown on greenhouse benches for an additional 4 wk.

Phylosphere Stimulation. The following fungal species and isolates were employed in foliar spray testing: *Aspergillus* sp. NRRL 32534, *F. graminearum* NRRL Z3639, *F. sporotrichoides* NRRL 3299, *Penicillium* sp. NRRL 32532 and NRRL 32533 and *P. acculeatum* NRRL 2129, *R. oryzae* NRRL 395, or *T. reesei* NRRL 11460 C30. Spearmint (cvs. "294099" or "557808") plants were given the following fungal foliar sprays: water only, 0.025% Tween-80, 10% PDB, 10% CF, 100 mg/l FDM, 100 mg/l MS, or SS (1×10^8 spores/ml). Plants were sprayed until runoff twice with a 1-wk interval between sprays and then grown on the greenhouse benches for an additional 4 wk.

Dose Response Effect of FDM. FDM suspension from *Aspergillus* sp. NRRL 32534 or NRRL 363, *T. reesei* NRRL 11460 C30 or NRRL 3652, or

Penicillium sp. NRRL 32532 or NRRL 32533 or *P. acculeatum* NRRL 2129 were sprayed on spearmint plants at 10-, 100-, or 1000-mg/l concentrations. Plants were sprayed once a week for 2 consecutive wk and then grown on greenhouse benches for additional 4 wk prior to taking data.

Statistical Analysis. Whole seedlings fresh weight, leaf number per plant, root number per plant, and shoot number per plant were recorded from 5 to 10 plants with the remaining plants employed in essential oil analysis. Experiments were repeated at least twice. Data were analyzed by PC SAS using GLM or ANOVA procedures, and means were separated by Fisher's protected LSD at a 0.05 rejection level.

Essential Oil Analysis. Spearmint plants were randomly selected from each treatment. The top (4 cm from the apical tip) of each individual plant was excised to represent a replicate, and three to five replicates were mixed together per treatment. One gram of fresh plant tissue per treatment was incubated with 15 ml CH_2Cl_2 for 72 hr, allowing carvone levels to come to equilibrium in the solvent. Investigative studies have shown that this method is superior to multiple solvent extractions and subsequent roto-evaporation that result in losses of the volatile carvone (unpublished data). After filtering, samples were analyzed on an HP 5890 gas chromatograph (GC) equipped with a flame ionization detector (FID). GC–mass spectrometry was performed using an HP 6890 Series II gas chromatograph attached to an HP 5972A mass select detector. Columns used were fused silica HP-5MS capillaries (0.25-μm film thickness, 30 ml $\times$ 0.25 mm ID). The major compound found in the extracts, (−)-carvone, hereafter referred to simply as carvone, was identified by comparison with mass spectra of a library database, and concentration was calculated from a standard carvone curve. Carvone was measured at mg/g fresh weight.

RESULTS

Rhizosphere Stimulation. Spearmint cv. "294099" drenched with Tween-80, 0.5% DMSO, or 1.0% DMSO treatments did not show any significant differences for fresh weights, leaf numbers, root numbers, shoot numbers, or carvone levels compared with water-drenched controls. However, spearmint plants drenched with *T. reesei* spores showed higher fresh weights and carvone levels compared with controls, whereas the leaves, shoots, and roots were unchanged compared with controls (Figure 2). Spearmint plants drenched with *Aspergillus* sp. spores showed higher root numbers than control plants, although the other growth and morphogenesis responses were unchanged (Figure 2).

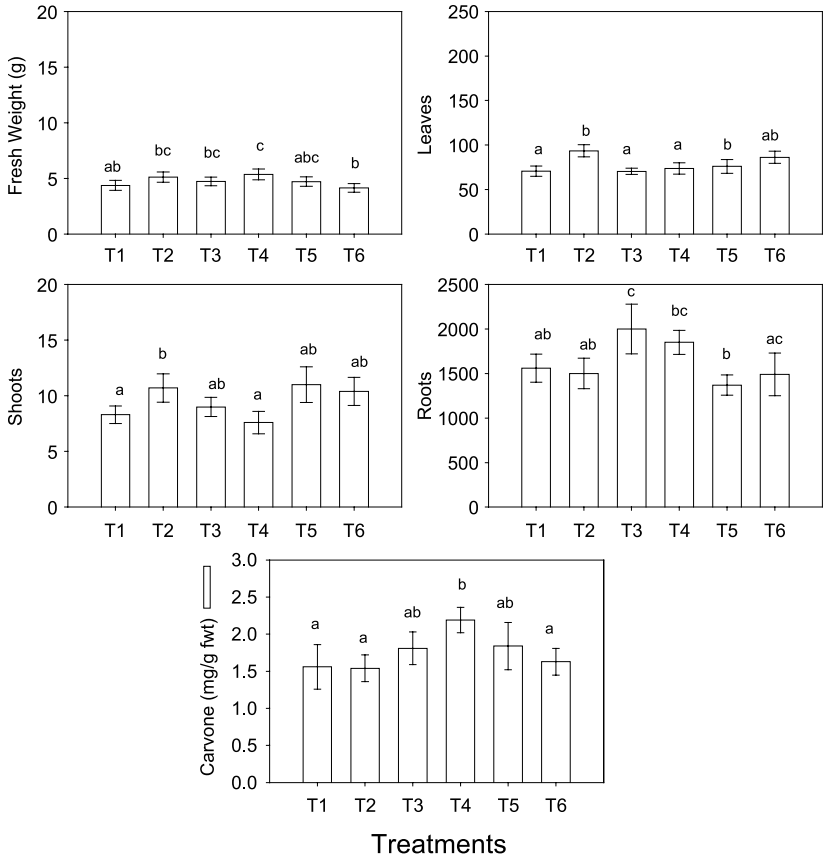

FIG. 2. Influence of various drench treatments on spearmint cv. "294099" carvone levels. T1 = Control; T2 = Tween-80; T3 = *Aspergillus* sp. NRRL 32534; T4 = *T. reesei* NRRL 11460 C30; T5 = 0.5% DMSO; and T6 = 1.0% DMSO. Columns having the same letters do not differ significantly ($P > 0.05$) in LSD test.

Phylosphere Stimulation. Plants sprayed with Tween-80, PDB, or DMSO did not exhibit any difference in growth or morphogenesis responses compared with untreated controls (Figures 3–6). Both spearmint cvs. sprayed with either *Aspergillus* sp. or *T. reesei* fungal materials had increased fresh weights, leaf numbers, root numbers, and shoot numbers compared with nontreated controls (Figures 3–6). For example, spearmint cv. "557808" plants sprayed with *T. reesei* NRRL 11460 C30 FDM or MS increased fresh weights (75 and 121%, respectively), shoot numbers (39 and 70%, respectively), leaf numbers (57 and 103%, respectively), and root numbers (108 and 108%, respectively) compared

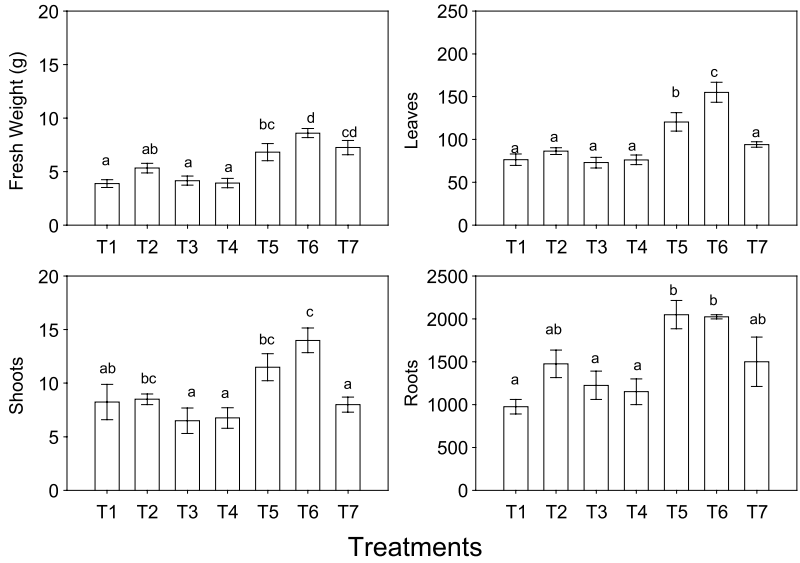

FIG. 3. Influence of *T. reesei* NRRL 11460 C30 foliar sprays on the growth and morphogenesis of spearmint cv. "557807." T1 = Control; T2 = Tween-80; T3 = potato dextrose broth; T4 = culture filtrate; T5 = freeze-dried mycelium; T6 = mycelium suspension; and T7 = spore suspension. Columns having the same letters do not differ significantly ($P > 0.05$) in LSD test.

with nontreated controls (Figure 2). In addition, fresh weights were also higher in plants sprayed with SS (87%) compared with controls (Figure 3). Nevertheless, regardless of the fungal material employed, no significant differences were observed among treatments for carvone levels compared with untreated controls ($P > 0.05$, data not shown).

Spearmint cv. "294099" plants sprayed with *T. reesei* NRRL 32534 CF, FDM, MS, or SS increased fresh weights (36, 53, 47, and 69%, respectively), leaf numbers (84, 91, 56, and 117%, respectively), root numbers (29, 69, 100, and 147%, respectively), and shoots (95, 129, 33, and 67%, respectively) compared with nontreated controls (Figure 4).

Spraying spearmint cv. "557807" plants with *Aspergillus* sp. NRRL 32534 CF, FDM, MS, or SS increased in fresh weights (88, 81, 108, and 85%, respectively) over nontreated controls (Figure 5). Significant increases in leaf numbers were observed in plants sprayed with FDM, MS, and SS (59, 129, and 69%, respectively) over those of nontreated controls. Significant increases in root numbers in plants sprayed with MS or SS were observed (69 and 69%, respectively) over those of nontreated controls. Plants sprayed with *Aspergillus*

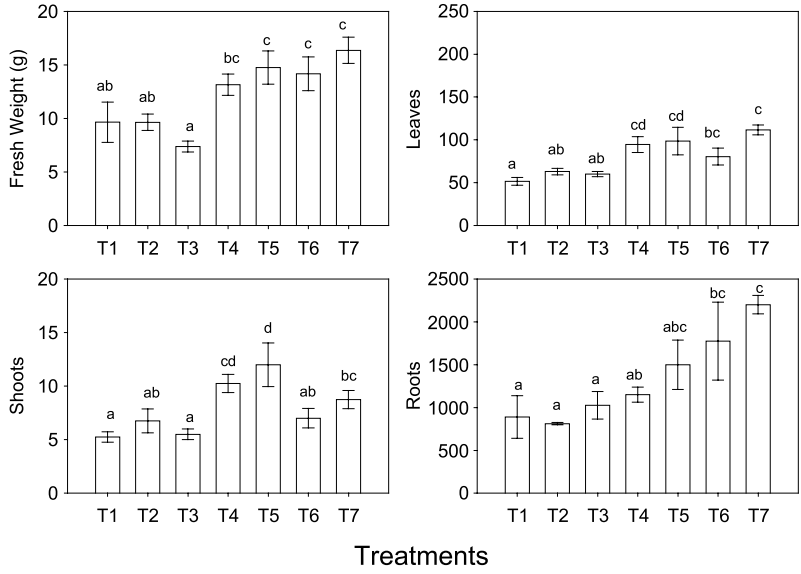

FIG. 4. Influence of *T. reesei* NRRL 11460 C30 foliar sprays on the growth and morphogenesis of spearmint cv. "294099." T1 = Control; T2 = Tween-80; T3 = potato dextrose broth; T4 = culture filtrate; T5 = freeze-dried mycelium; T6 = mycelium suspension; and T7 = spore suspension. Columns having the same letters do not differ significantly ($P > 0.05$) in LSD test.

sp. MS also showed significant increases in shoot number (73%) over controls (Figure 5). Spearmint cv. 294099 plants sprayed with *Aspergillus* sp. CF, FDM, MS, or SS caused higher fresh weights (68, 86, 78, and 56%, respectively), leaves (100, 90, 145, and 131%, respectively), roots (139, 55, 98, and 145%, respectively), and shoots (71, 71, 124, and 90%, respectively) compared with those of nontreated controls (Figure 6).

Dosage Response Effect of FDM. Plants sprayed with 10, 100, or 1000 mg/l FDM from isolates of *T. reesei* NRRL 11460 C30 or NRRL 3652 exhibited significant increases in all fresh weights (>41%) and shoot numbers (>54%) (Table 1). Similarly, for all concentrations tested, higher but not always significant increases occurred for root numbers and leaf numbers compared with untreated control plants. No change in carvone levels were observed in any plants treated with any isolate concentration tested (Table 1). Both isolates of *Aspergillus* sp. NRRL 32534 or NRRL 363 administered at 10, 100, and 1000 mg/l caused spearmint plants to exhibit higher (but not always significantly higher) fresh weights, root numbers, shoot numbers, and leaf numbers compared with untreated controls (Table 2). Only spearmint plants treated with *Asper-*

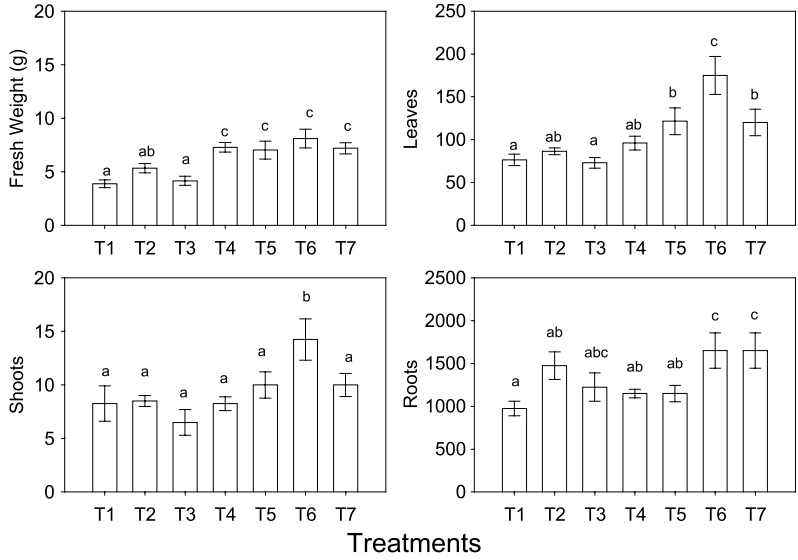

FIG. 5. Influence of *Aspergillus* sp. NRRL 32534 foliar sprays on the growth and morphogenesis of spearmint cv. "557807." T1 = Control; T2 = Tween-80; T3 = potato dextrose broth; T4 = culture filtrate; T5 = freeze-dried mycelium; T6 = mycelium suspension; and T7 = spore suspension. Columns having the same letters do not differ significantly ($P > 0.05$) in LSD test.

gillus sp. NRRL 32534 at 100 and 1000 mg/l gave significantly higher fresh weights, leaf numbers, shoot numbers, and root numbers compared with untreated plants. Carvone levels were similar for all plants treated with *Aspergillus* sp. isolates compared with untreated controls. All *Penicillium* sp. isolates NRRL 32532, NRRL 32533, and *P. acculeatum* NRRL 2129 increased fresh weights, shoot numbers, leaf numbers (except 10 mg/l NRRL 32532), and root numbers compared with untreated controls (Table 3). Overall, *Penicillium* sp. isolates were less effective for the induction of significant increases in growth and morphogenesis responses compared with other fungal species isolates tested. Nevertheless, higher and sometimes significant increases in growth and morphogenesis occurred in plants sprayed with the 100-mg/l concentrations (except for fresh weights and root numbers with isolate NRRL 32532) compared with that occurring in plants sprayed with the 10-mg/l concentration regardless of the *Penicillium* sp. isolates tested. Generally, carvone levels were similar for all isolates, and concentrations tested, except 100 mg/l NRRL 32533, caused a significant increase in carvone production to occur from treated spearmint plants.

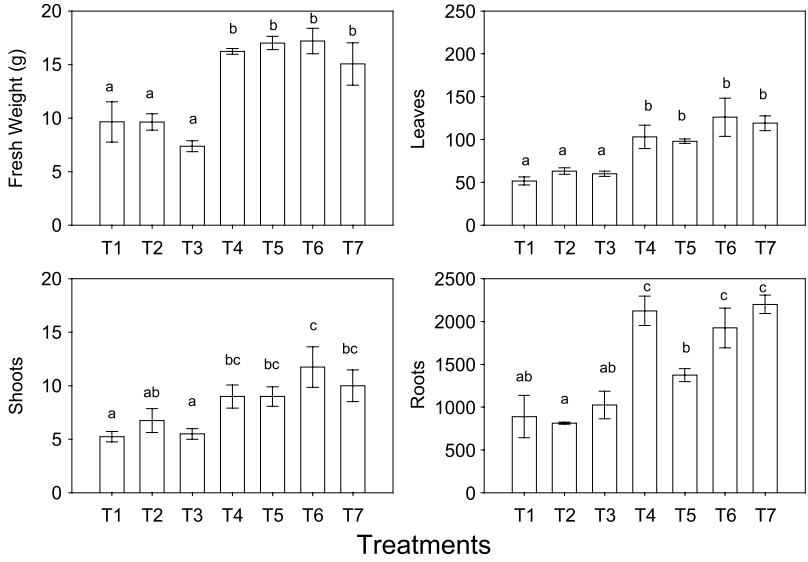

FIG. 6. Influence of *Aspergillus* sp. NRRL 32534 foliar sprays on the growth and morphogenesis of spearmint cv. "294099." T1 = Control; T2 = Tween-80; T3 = potato dextrose broth; T4 = culture filtrate; T5 = freeze-dried mycelium; T6 = mycelium suspension; and T7 = spore suspension. Columns having the same letters do not differ significantly ($P > 0.05$) in LSD test.

DISCUSSION

In this study, we have identified isolates of dead fungi that enhance spearmint growth, morphogenesis, and secondary metabolism. Aside from the enhanced leaf production noted by Elad (2000), the application of dead fungal cells to plants to enhance growth has not been reported in the literature. Drenching soil with fungal spores was found to be a less effective method of promoting growth and morphogenesis responses on spearmint plants than foliar sprays. For some fungal species (i.e., *F. graminearum*, *F. sporotrichoides*, and *R. oryzae*), foliar sprays failed to elicit any response whatsoever in terms of growth, morphogenesis, or secondary metabolism in spearmint, whereas other fungal species foliar sprays such as from *Aspergillus* sp. and *T. reesei* elicited strong growth and morphogenesis responses. Clearly, the species and isolate type appear important in obtaining growth and morphogenesis responses. The method of application (foliar spray vs. drench) and type of fungal material (CF, FDM, MS, or SS) employed are critical to obtaining increased growth and morphogenesis responses. We also found that growth and morphogenesis were

enhanced more by FDM, MS, or SS than by using CF. We usually did not observe any differences between employing FDM, MS, or SS on the growth and morphogenesis responses obtained (Figures 3–6). CF activity was inconsistent and may or may not enhance growth and morphogenesis in spearmint depending on the isolate employed. Both clones of spearmint reacted similarly in the presence of fungal isolates, types, and concentrations. Our results confirm those by Elad (2000) in which leaf number in cucumber was enhanced by the application of dead *T. harzianum* T39 cells. In addition, we noted strong positive correlations between fresh weight, shoot number, leaf number, and root number responses when growth or morphogenesis is stimulated in the presence of dead fungal materials.

We did not promote any significant increases in absolute mint carvone levels by using any of the fungal foliar spray studies. Apparently, enhanced growth and morphogenesis is not associated with enhanced secondary metabolism. However, inert dead fungal material applications did not reduce

carvone levels compared with untreated control plants. Secondary metabolites have been found to increase in plants in response to microorganism infection and stress (Bell, 1981; Cheniclet et al., 1988; Dalkin et al., 1990; Dixon and Lamb, 1990). For example, terpene content increased when maritime pine (*Pinus pinaster*) was attacked by *Tomicus piniperda* beetle (Cheniclet et al., 1988). Inclusion of dead microorganisms into nutrient medium is commonly employed to enhance secondary metabolite production in plant cell suspension cultures (Heinstein, 1985; Eilert and Contabel, 1986; Eilert et al., 1986; Dalkin et al., 1990; Mahady and Beecher, 1994). For example, Mahady and Beecher (1994) reported that addition of *Penicillium expansum* to a culture of *Sanguinaria canadensis* induced the production of benzophenanthridine alkaloids such as sanguinarine and chelerythrine in a dose-dependent manner. Similarly, the addition of fungal elicitors to cultures of *Papaver somniferum* stimulated sanguinarine production (Eilert et al., 1986). It is interesting that these fungal additions were administered typically at the end of the cell

suspension growth cycle. It is not reported if the fungal additives stimulated or depressed cell suspension growth.

Under favorable environmental conditions, plants prioritize their resources towards growth and differentiation over secondary metabolism (Bazzaz et al., 1987; Chapin et al., 1990; Dickson and Isebrands, 1991). Plant growth processes require high amounts of primary carbon resources that may come at the cost of secondary metabolite production (Gulmon and Mooney, 1986; Williams et al., 1987; Margna et al., 1989; Lambers and Rychter, 1990; Chapin, 1991). Generally, in our study, there was no significant change in carvone levels in spearmint plants that showed significant increases in growth and morphogenesis over untreated controls. However, because of the increases in growth, the total carvone levels per plant were significantly higher in fungal-treated plants than untreated spearmint plants.

Dead fungal cell stimulation of plant growth and differentiation may be either chemical or physical or both. If the phenomenon is physical, the plants

may perceive themselves under attack by fungal cells and in response initiate rapid growth. If chemical, we speculate that dead fungal cells may emit a stimulatory chemical substance that then encourages plant growth.

Currently, we are extending our studies into this phenomenon by examining various fungal species and isolates with different plant species. Thus far, the results confirm those presented in this paper. These studies may lead to industrial products that can be used as growth stimulators for a variety of nursery and greenhouse plants. For two of the fungi (*T. reesei* and *Aspergillus* sp.) examined in this study, both are employed in the paper pulp processing (Toyama et al., 2002) and enzyme production (Chen and Reese, 2002) industries. Perhaps mycelium suspension, which is currently obtained as a waste product, may have potential as a plant growth promoter.

Abstract—Blooms of *Lyngbya majuscula* have been reported with increasing frequency and severity in the last decade in Moreton Bay, Australia. A number of grazers have been observed feeding upon this toxic cyanobacterium. Differences in sequestration of toxic compounds from *L. majuscula* were investigated in two anaspideans, *Stylocheilus striatus*, *Bursatella leachii*, and the cephalaspidean *Diniatys dentifer*. Species fed a monospecific diet of *L. majuscula* had different toxin distribution in their tissues and excretions. A high concentration of lyngbyatoxin-a was observed in the body of *S. striatus* (3.94 mg/kg^{-1}) compared to bodily secretions (ink 0.12 mg/kg^{-1}; fecal matter 0.56 mg/kg^{-1}; eggs 0.05 mg/kg^{-1}). In contrast, *B. leachii* secreted greater concentrations of lyngbyatoxin-a (ink 5.41 mg/kg^{-1}; fecal matter 6.71 mg/kg^{-1}) than that stored in the body (2.24 mg/kg^{-1}). The major internal repository of lyngbyatoxin-a and debromoaplysiatoxin was the digestive gland for both *S. striatus* (6.31 ± 0.31 mg/kg^{-1}) and *B. leachii* (156.39 ± 46.92 mg/kg^{-1}). *D. dentifer* showed high variability in the distribution of sequestered compounds. Lyngbyatoxin-a was detected in the digestive gland (3.56 ± 3.56 mg/kg^{-1}) but not in the head and foot, while debromoaplysiatoxin was detected in the head and foot (133.73 ± 129.82 mg/kg^{-1}) but not in the digestive gland. The concentrations of sequestered secondary metabolites in these animals did not correspond to the concentrations found in *L. majuscula* used as food for these experiments, suggesting it may have been from previous dietary exposure. Trophic transfer of debromoaplysiatoxin from *L. majuscula* into *S. striatus* is well established; however, a lack of knowledge

* To whom correspondence should be addressed. E-mail: capper@sms.si.edu

exists for other grazers. The high levels of secondary metabolites observed in both the anaspidean and the cephalapsidean species suggest that these toxins may bioaccumulate through marine food chains.

Key Words—*Stylocheilus striatus*, *Bursatella leachii*, *Diniatys dentifer*, lyngbyatoxin-a, debromoaplysiatoxin, bioaccumulation, Opisthobranchia, secondary metabolites.

INTRODUCTION

Opisthobranch mollusks are renowned for their ability to sequester a range of dietary-derived compounds (Avila, 1995; Johnson and Willows, 1999). Pennings and Paul (1993a) suggest that sea hares have a generic mechanism for sequestering algal metabolites rather than mechanisms that are tightly linked to different compounds. If this is the case, then the physiology of sequestration would not be different among species. Study of the storage, secretion, and egestion of these compounds by marine mollusks helps us to understand defensive strategies and transfer of toxins within food webs.

Stylocheilus striatus Quoy and Gaimard 1832 (formerly *longicauda*; Rudman, 1999) is an anaspidean species that can sequester, store, and transform marine plant secondary metabolites (Faulkner, 1984; Avila, 1995), including those found in the toxic cyanobacterium *Lyngbya majuscula* (Watson and Rayner, 1973; Kato and Scheuer, 1975; Pennings and Paul, 1993a,b; Pennings et al., 1996). *S. striatus* adults preferentially feed and grow well upon a monospecific diet of *L. majuscula* (Paul and Pennings, 1991). Some *L. majuscula* compounds (malyngamides and majusculamides) stimulate feeding by *S. striatus* at low concentrations (Nagle et al., 1998; Nagle and Paul, 1999). *S. striatus* sequester secondary metabolites in the digestive gland where transformation to less harmful acetates could reduce negative postingestive consequences (Pennings et al., 1996). This hypothesis is supported by the isolation of lyngbyatoxin-a and debromoaplysiatoxin acetates from *S. striatus* (Kato and Scheuer, 1976). Both compounds are less toxic than their precursors in mice bioassays (Kato and Scheuer, 1975; Gallimore et al., 2000).

The fate of *L. majuscula* secondary metabolites is known for *S. striatus*, but other grazers of *L. majuscula* have received little attention. Cruz-Rivera and Paul (2002) identified 43 invertebrate species in *L. majuscula* mats in Guam including 14 species of opisthobranchs. The cephalaspidean *Diniatys dentifer* (Adams, 1850) is one of the most abundant organisms observed in *L. majuscula* blooms in Guam (Cruz-Rivera and Paul, unpublished data). *D. dentifer* was observed feeding on *L. majuscula*, but this has not yet been quantified (Cruz-Rivera, personal communication), nor its dietary repertoire established. *Bursatella leachii* de Blainville, 1817, is a "generalist" grazer of cyanobacteria

(Ramos et al., 1995) and is a common component of shallow water subtropical fauna (Lowe and Turner, 1976; Paige, 1988). Like *S. striatus*, this anaspidean species appears to use chemical cues from *L. majuscula* to induce settlement and development of larvae (Switzer-Dunlap and Hadfield, 1977; Paige, 1988). To date, there are no comprehensive studies to determine the fate of *L. majuscula* compounds in *D. dentifer* and *B. leachii*.

In this study, we examined intraspecific differences in internal partitioning of lyngbyatoxin-a and debromoaplysiatoxin between two populations of *S. striatus*: (1) those previously feeding on *L. majuscula*; and (2) those naïve to *L. majuscula*. Interspecific differences in internal compartmentalization, secretion, and egestion of lyngbyatoxin-a were investigated between *S. striatus*, *B. leachii*, and *D. dentifer* over a 10-d-feeding experiment. The strategies for storage and excretion of *Lyngbya* compounds by these species have important implications for understanding the transfer of toxins through marine food chains.

METHODS AND MATERIALS

Study Sites. Two areas were chosen because they had persistent blooms of *L. majuscula*: Deception Bay (DB), on the Western shore of Moreton Bay (27°05′S, 153°09′E); and Adams Beach (AB), a sheltered area on the Eastern side of Moreton Bay (27°51′S, 153°41′E). Both sites have extensive sea grass beds with macroalgae locally dominating in places (Abal et al., 2001). *L. majuscula* was collected from these sites and maintained in aquaria at Moreton Bay Research Station (MBRS).

Study Organisms. S. striatus (*Lyngbya* exposed) were collected from *L. majuscula* blooms at the sites described above in 2002. A second group of *S. striatus* was obtained from a prawn pond at Bribie Island Aquaculture Research Centre (BIARC). Sea hares had been recruited in the pond as larvae and as there was no apparent *L. majuscula* growth, they were considered "naïve" to *L. majuscula* (*Lyngbya* naïve). In the laboratory, the *Lyngbya*-naïve group of *S. striatus* was fed a diet of blanched lettuce before our feeding experiments. *B. leachii* and *D. dentifer* were collected from a *L. majuscula* bloom at Adams Beach. All opisthobranchs were maintained in separate 50-l tanks in a closed aquarium system at MBRS. Salinities were kept between 34 and 36 ppt and temperature consistent with ambient (24°C) with 12-hr light and dark cycles.

Sample Preparation and Chemical Analyses. To quantify *L. majuscula* secondary metabolites in mesograzers, animals were starved for 24 hr to allow evacuation of gut contents before being euthanized in iced salt water. Shells

were removed from *D. dentifer* and discarded. Organisms were dissected into head and foot (HF) to represent external body parts, and digestive gland (DG) to represent total viscera (Avila, 1995). These samples were exhaustively extracted (five times) using 1:1 dichloromethane:methanol. Extracts were rotary evaporated and dried under pure nitrogen before being resolubilized in 1:1 methanol:distilled water and then analyzed by high-performance liquid chromatography–tandem mass spectrometry (HPLC–MS/MS).

To determine if *L. majuscula* secondary metabolites were secreted or egested by *S. striatus* and *B. leachii*, samples of ink, feces, and eggs (where available) were analyzed. Ink was collected on absorbent filter paper after gently squeezing an emersed animal between the fingers. Ink was extracted three times in 1:1 dichloromethane:methanol (Pennings and Paul, 1993a). Replicates were pooled and dried by rotary evaporation. Fecal samples were collected, frozen, freeze-dried, and then extracted in acetone three times. Acetone was used, as it extracts organics from plant-derived matrices due to its hydrophilic properties. Replicates were pooled and dried by rotary evaporation. The extract was resolubilized in 1:1 methanol:distilled water and analyzed by HPLC–MS/MS.

To quantify secondary metabolites in *L. majuscula*, voucher samples from all assays were frozen at −20°C and then freeze-dried. Plant material was extracted three times in acetone. Three replicate extracts were dried by rotary evaporation. Concentrations of secondary metabolites (in milligrams per kilogram) were determined by HPLC–MS/MS using a PE/Sciex API 300 mass spectrometer equipped with a high-flow electrospray interface (TurboIonspray) coupled to a Perkin Elmer series 200 HPLC system. Separation was achieved using a 150 × 4.6-mm Altima C_{18} column (Alltech) run at 35°C, with a mobile phase consisting of 80/20 acetonitrile/hi-pure water containing 0.1% formic acid and 2 mM ammonium formate at a flow rate of 0.8 ml min^{-1}. The flow was split post column such that the flow to the mass spectrometer interface was 250 µl min^{-1}. Under these conditions, the retention times were 11.7 and 9.3 min for lyngbyatoxin-a and debromoaplysiatoxin, respectively. The mass spectrometer was operated in the positive ion, multiple-ion monitoring mode. Ions monitored with dwell times of 300 msec were 438.3 $(M+H)^+$ and 410.3 for lyngbyatoxin-a and 543.3 for debromoaplysiatoxin. Quantification was achieved by comparison to standards of DAT (kindly provided by Dr. R.E. Moore, Department of Chemistry, University of Hawaii at Manoa) and LTA (Calbiochem) run under the same conditions. Using a 20-µl injection, the detection limit for both toxins was typically 0.01 mg kg^{-1} in the extracted solution.

Partitioning of Secondary Metabolites. Lyngbya-exposed *S. striatus* (1.31 g_{wwt} ± 0.10 SE, $N = 9$) were housed individually in 1-l glass jars filled with unfiltered aerated seawater and allowed to acclimate for 48 hr. Seawater was changed every 2 d. Each sea hare was offered *L. majuscula* from the Deception Bay bloom and left to feed for a 10-d-period (Table 1). Voucher samples of

			10	3.493 (±0.26)	n/d

[a] Letters in parentheses refer to location of *L. majuscula* collected for use in feeding assays: AB, Adams Beach; DB, Deception Bay.
[b] Numbers in parentheses refer to standard error values.
[c] n/d = not detected by HPLC–MS/MS.

L. majuscula were retained on d 1 and d 10 to quantify secondary metabolite concentrations (Table 1). The second group of *S. striatus* (0.79 g_{wwt} ± 0.06 SE, $N = 9$), *Lyngbya* naïve, was only fed blanched lettuce (Table 1).

B. leachii (0.26 g_{wwt} ± 0.03 SE, $N = 9$) and *D. dentifer* (0.23 g_{wwt} ± 0.03 SE, $N = 9$) were maintained as described above. *B. leachii* were fed with fresh *L. majuscula* collected from blooms at Adams Beach every 2 d (Table 1), while *D. dentifer* received fresh *L. majuscula* only on d 1 since they only consumed a small amount during our study. Voucher samples of *L. majuscula* from each food change were retained for secondary metabolite quantification (Table 1).

S. striatus (0.11 g_{wwt} ± 0.01 SE, $N = 9$) and *B. leachii* (1.05 g_{wwt} ± 0.09 SE, $N = 9$) were collected from the Adams Beach bloom of *L. majuscula*. *S. striatus* were maintained as described above and fed with fresh *L. majuscula* collected from Adams Beach every 2 d since they rapidly consumed their food. *B. leachii* individuals consumed less *L. majuscula* and so they were only fed on d 1 (Table 1). Body secretions including ink, eggs (where available), and fecal matter were collected from each animal at the end of our experiment. Nine whole animals were pooled to form three replicates for HPLC–MS/MS analysis. Secretions were processed in the same manner.

The mean concentration of secondary metabolites in whole animal, secretions, and egested material were analyzed using single-factor analysis of variance (ANOVA), followed by Fisher's least significant difference (LSD) pairwise comparison tests. Data sets were subjected to Cochran and Levene's homogeneity of variance tests. Data that deviated from a normal distribution were transformed using √mean concentration.

RESULTS

Internal Partitioning of Secondary Metabolites. Significant differences were observed between the sequestration of secondary metabolites in the digestive gland (DG), and head and foot (HF) of *S. striatus* fed *L. majuscula* from Deception Bay (Figure 1A, ANOVA, df_1, $F_{318.36}$, $P < 0.001$). Both secondary metabolites (lyngbyatoxin-a and debromoaplysiatoxin) were sequestered at equivalent rates (ANOVA, df_1, $F_{1.95}$, $P = 0.20$). No secondary metabolites were detected in *S. striatus* fed blanched lettuce. Significant differences were also observed in the concentrations of lyngbyatoxin-a sequestered between the DG and HF of *B. leachii* (Figure 1B, ANOVA, df_1, $F_{10.77}$, $P = 0.030$). *Diniatys denifer* exhibited high individual variability in concentrations of secondary metabolites sequestered in both DG and HF (Figure 1C) with lyngbyatoxin-a detected in the DG but not the HF, and debromoaplysiatoxin in the HF and not in the DG.

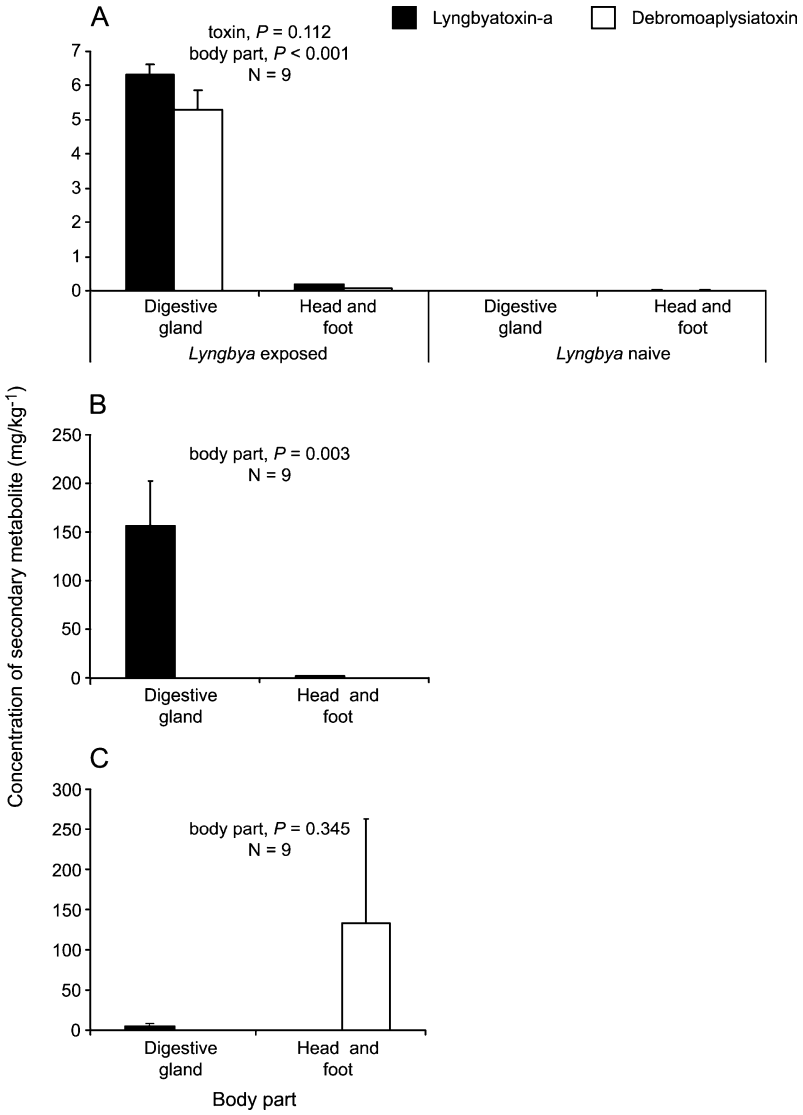

FIG. 1. Concentrations of lyngyatoxin-a and debromoaplysiatoxin in digestive gland and body tissue of (A) *S. striatus* previously exposed to *L. majuscula* fed *L. majuscula* from Deception Bay and *S. striatus* not knowingly exposed to *L. majuscula* fed blanched lettuce. (B) *B. leachii* fed *L. majuscula* from Adams Beach; (C) *D. dentifer* fed *L. majuscula* from Adams Beach. Bars are mean concentration of secondary metabolite (+SE). Body parts are significantly different from each other in (A) and (B) (single-factor ANOVA), but not (C). Scales differ between vertical axes.

Partitioning of Secondary Metabolites between Whole Animal and Secretions. Significant differences were observed between whole animal, secretions, and egested material for both *S. striatus* and *B. leachii* (ANOVA, df_1, $F_{441.89}$, $P < 0.001$) (Figure 2A,B). Lyngbyatoxin-a concentrations in *S. striatus* whole animal (3.94 mg/kg^{-1}) was much greater than secretions or egested material (ink 0.12 mg/kg^{-1}, fecal matter 0.56 mg/kg^{-1}, and eggs 0.05 mg/kg^{-1}) (ANOVA, df_3, $F_{188.93}$, $P < 0.001$, Figure 2A). *B. leachii*

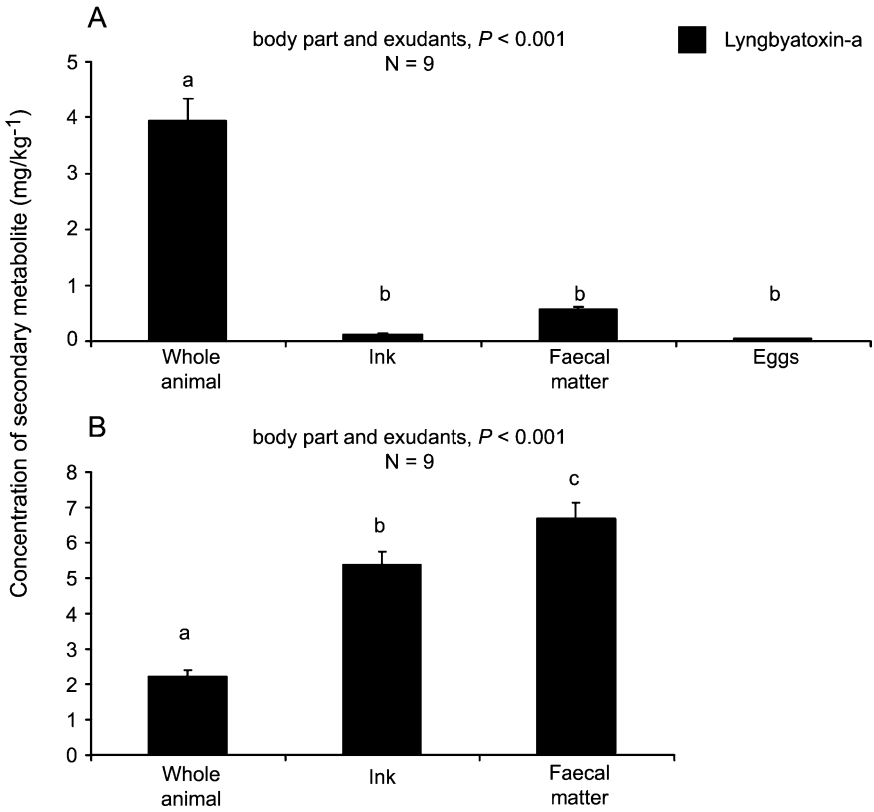

FIG. 2. Concentrations of lyngyatoxin-a (LTA) in whole animal, secretions, and egested material of (A) *S. striatus* and (B) *B. leachii* fed *L. majuscula* from Adams Beach. Bars are mean concentrations of LTA (+SE). Significant differences between whole animal and their bodily secretions are shown (single factor ANOVA). Different letters above the bars indicate significant differences between tissues, secretions and egested material ($P < 0.05$) using Fisher's LSD pairwise comparison tests. Bars with the same letter are not significantly different. (Eggs were not available from *B. leachii* during the trial period). Scales differ between vertical axes.

had lower concentrations of lyngbyatoxin-a (ANOVA, df_2, $F_{57.62}$, $P < 0.001$, Figure 2B) in whole animal (2.24 mg/kg^{-1}) compared to that of its ink (5.41 mg/kg^{-1}) and fecal matter (6.71 mg/kg^{-1}) (Figure 2B).

DISCUSSION

Our results show that *S. striatus* can sequester and compartmentalize both lyngbyatoxin-a and debromoaplysiatoxin. The different concentrations of lyngbyatoxin-a and debromoaplysiatoxin in the digestive gland were lower than those detected in whole *L. majuscula*, which may indicate bioaccumulation from feeding before our experiments. This highlights the importance of diet history when examining secondary metabolite dynamics in sea hares. Pennings and Paul (1993a) found that over a 3 wk period the concentration of malyngamides in *S. longicauda* did not change.

B. leachii has a different strategy for sequestering *L. majuscula* secondary metabolites. The digestive gland, ink, and the fecal matter had high concentrations of lyngbyatoxin-a. Transfer of lyngbyatoxin-a from body tissue to body secretions is one potential mechanism for toxin excretion. *S. striatus* seems to transform lyngbyatoxin-a and debromoaplysiatoxin into less harmful acetates (Pennings et al., 1996), but *B. leachii* may lack the digestive and physiological ability for transformation and, therefore, excretes these compounds. Lyngbyatoxin-a in the ink could also provide *B. leachii* with a defense mechanism against predation (Johnson and Willows, 1999).

The question of whether opisthobranch mollusks use sequestered secondary metabolites for defensive purposes has sparked some debate (Paul and Pennings, 1991; Pennings et al., 1999, 2001; Rogers et al., 2000). Compartmentalization of compounds in the digestive gland offers little protection if the sea hare must be eaten before the predator encounters the deterrent (Pennings et al., 2001). Pennings et al. (1999) argue that accumulation of extremely high concentrations of dietary-derived metabolites in the digestive gland are more likely to assist detoxification of a chemically rich diet than deter predators, whereas deployment of secondary metabolites to the skin or ink may afford some defensive protection (Pennings and Paul, 1993a; Rogers et al., 2000).

Ink containing high concentrations of lyngbyatoxin-a excreted by *B. leachii* might provide a defensive role; however, we suggest that this transfer might be an excretory mechanism employed by *B. leachii* to avoid toxicity. *B. leachii* demonstrated increasing growth rates over a 10-d period in the laboratory when fed a monospecific diet of *L. majuscula*. This reached a plateau between 10 and 20 d (Capper et al., unpublished data) with the death of the animal following soon after (personal observation). While morbidity may be related to the

toxicity of *L. majuscula*, it could also be related to incomplete nutritional requirements. Dense aggregations of *B. leachii* are found in local *L. majuscula* blooms. This may reflect exploitation of an abundant food source rather than dietary specialization. It is more likely that *B. leachii* consumes a mixed diet in the field (Paige, 1988), possibly getting more nutrients and preventing harmful additive accumulation of secondary metabolites in the digestive gland. The consequences of debromoaplysiatoxin consumption in *B. leachii* are unknown, as none was detected in *L. majuscula* used in these feeding trials.

Lyngbyatoxin-a and debromoaplysiatoxin found in *D. dentifer* after it ate *L. majuscula* for 10 d showed high individual variability. This may be related to the palatability of *L. majuscula* used in our feeding trials. However, a lack of uniformity in the distribution of secondary metabolites among test animals may suggest *D. dentifer* are not preferential consumers of *L. majuscula*. *D. dentifer* may use *L. majuscula* as a source of refuge from predation rather than a food source (Cruz-Rivera and Paul, 2002). Little is known of the dietary repertoire in this species and fate of *L. majuscula* secondary metabolites.

Debromoaplysiatoxin was the predominant toxin in *L. majuscula* blooms at Deception Bay during our experiments, but lyngbyatoxin-a was also detected. Lyngbyatoxin-a and debromoaplysiatoxin had previously been detected at Adams Beach, however, only lyngbyatoxin-a was detected during these experiments. This variation in *L. majuscula* secondary metabolites highlights their temporal and spatial variability.

Our results show distinct differences in sequestration mechanisms utilized by three species of opisthobranchs fed *L. majuscula*. This suggests that the generic sequestration hypothesis may not be applicable to all opisthobranch mollusks. Implications for bioaccumulation or biomagnification of lyngbyatoxin-a and debromoaplysiatoxin through the marine food web warrant further investigation in both *B. leachii* and *S. striatus*, particularly following mass mortalities after the disappearance of *L. majuscula* blooms. High quantities of lyngbyatoxin-a egested via fecal matter in *B. leachii* may also result in the introduction of *L. majuscula* secondary metabolites to phagotrophic or detrital food webs.

COMPARISON OF THE VOLATILE ORGANIC COMPOUNDS PRESENT IN HUMAN ODOR USING SPME-GC/MS

ALLISON M. CURRAN, SCOTT I. RABIN, PAOLA A. PRADA, and KENNETH G. FURTON*

Department of Chemistry and Biochemistry, International Forensic Research Institute, Florida International University, University Park, CP 345, Miami, FL 33199, USA

(Received January 4, 2005; accepted March 12, 2005)

Abstract—We evaluated the volatile organic compounds (VOCs) present in human odor by using headspace solid phase microextraction gas chromatography–mass spectrometry for the extraction, separation, and analysis of the collected samples. Volatile organic compounds present in the headspace above axillary sweat samples collected from different individuals showed the presence of various types of compounds including organic fatty acids, ketones, aldehydes, esters, and alcohols. Qualitative differences and similarities noted between the males and females studied along with differences in chemical ratio patterns among the common compounds demonstrated the ability to differentiate between individuals through the examination of VOCs.

Key Words—Human scent, odor, uniqueness of odor profiles, axillary sweat, absorbent material, cotton absorbers, VOCs, SFE, headspace SPME, SPME-GC/MS.

INTRODUCTION

The idea that people can be distinguished based on their odors is not a new concept; tracking, trailing, and scent identification lineup canines have been used successfully for over 100 yr. Until recently, technological limitations have restricted the ability of researchers to identify the chemical components that comprise human odor or to use the information to chemically distinguish individuals.

Individual body odors of humans are determined by several factors that are either stable over time (genetic factors) or vary with environmental or internal conditions. We have developed distinguishing terminology for these factors: the

* To whom correspondence should be addressed. E-mail: furtonk@fiu.edu

"primary odor" of an individual contains constituents that are stable over time regardless of diet or environmental factors; the "secondary odor" contains constituents that are present because of diet and environmental factors; and the "tertiary odor" contains constituents that are present because of the influence of outside sources (i.e., lotions, soaps, perfumes, etc.) (Curran et al., 2005).

There is a limited understanding of how the body produces the volatile organic compounds present in human odor. Most of the relevant scientific research pertaining to human scent has evaluated the contents of axillary (armpit) and plantar (foot) sweat. Compounds present in both male (Zeng et al., 1991) and female (Zeng et al., 1996) pH-adjusted axillary secretion extracts have been isolated and identified through preparative gas chromatography, analysis by gas chromatography/mass spectrometry (GC/MS) and by gas chromatography/Fourier transform infrared spectroscopy (GC/FTIR). The analysis showed the presence of several C_6–C_{10} straight chains, branched, and unsaturated acids. Important odor contributors were terminally unsaturated acids, 2-methyl C_6–C_{10} acids, and 4-ethyl C_5–C_{11} acids, along with (*E*)-3-methyl-2-hexenoic acid, which was said to be the major odor-causing compound. Male and female extracts were qualitatively similar with minor quantitative differences. Short-chain fatty acids have also been extracted from sweat samples obtained from feet (Kanda et al., 1990). Extracts from socks were obtained through a 6-hr Soxhlet extraction with diethyl ether and analyzed by GC/MS. Short-chain fatty acids were found in all of the samples, but in greater amounts in subjects that claimed to have strong foot odor. Isovaleric acid was found only in the subjects who claimed to have strong foot odor.

Investigations into compounds emitted by humans that attract the yellow-fever mosquito have also provided insight into compounds present in human secretions (Bernier et al., 1999, 2000, 2002). Samples were collected using glass beads rolled between the fingers. The beads were loaded into a GC and cryofocused by liquid nitrogen at the head of the column before analysis by GC/MS. A total of 277 compounds were identified as components of human skin emanations. The results showed qualitative similarities in compounds among the individuals studied; however, quantitative differences were also noted.

Studies pertaining to residual axillary odor in clothing have shown the absence of organic acids and the presence of other odiferous compound classes. Laundry soiled with human sweat and then washed with a color laundry detergent has been analyzed for the residual presence of human odor (Munk et al., 2000). Esters, ketones, and aldehydes were identified as primary odorants in the swatches postwashing. However, organic acids, which are considered to be the dominant characteristic odorants in human axillary sweat, were not present in the extracts of residual odor.

Although the components of human sweat have been studied extensively, comparatively little work has been carried out to determine the volatile organic

compounds (VOCs) present in human odor. Knowing the contents of human sweat may not accurately represent the nature of what volatile compounds are present in the headspace above such samples that would comprise the odor.

Human odor components have been studied through headspace GC-MS for compounds specific to age (Haze et al., 2001). Compound classes such as hydrocarbons, alcohols, acids, ketones, and aldehydes were present in human odor. This study also presented 2-nonenal as a compound that is only present in the odor of individuals over 40 yr of age. 2-Nonenal, as well as other aldehydes, was produced through oxidative degradation of monosaturated fatty acids, such as palmitoleic acid and vaccenic acid.

Solid phase microextraction in conjunction with GC/MS has been used to identify volatile components from the skin of females (Ostrovskaya et al., 2002). Several different classes of compounds, including short- and long-chain hydrocarbons, short-chain aldehydes, and a branched ketone, were identified in human skin headspace analysis. The abundances of these compounds varied among individuals, and some subjects exhibited specific volatiles, such as 6-methyl-5-hepten-2-one, and hydrocarbons of shorter-chain lengths including decane.

We have previously shown human scent to be a combination of various compounds differing in ratio from person to person along with some compounds that differ among individuals (Curran et al., 2005). The chromatographic distinction among the headspace analysis of axillary sweat samples from males is possible based on a combination of the relative ratios of the common compounds among individuals. With the presence of some differing compounds, this combination of relative ratios supports the individual odor theory that has been anecdotally demonstrated by the ability of canines to discriminate among individuals based on their odor. Although there is some variation present within the same individual when sampled on multiple occasions, the ratio pattern of common compounds has been shown to be distinguishable among individuals. There were significantly greater variations in the ratio of components observed among individuals tested than for one individual.

We have defined human scent to be the most abundant VOCs identified in the headspace above scent samples. Other substances, however, may make contributions to human odor. Here, we discuss the use of headspace solid phase microextraction gas chromatography/mass spectrometry (SPME-GC/MS) as a method for the extraction, separation, and identification of the volatile components of human odor and how to use the information to differentiate among individuals.

METHODS AND MATERIALS

Materials. In previous studies by the authors, the absorbent material used to collect the odor samples was biologically sterile (meaning that it had been

sterilized utilizing an autoclave); however, it was determined that biologically sterile does not equate to "analytically clean," resulting in the exclusion of several key odor compounds including decanal and nonanal because of their initial presence in the headspace of the absorbent material. In this study, supercritical fluid extraction (SFE) using methanol modified carbon dioxide has been introduced as a pretreatment for the absorbent material that allows for an "analytically clean" collection medium. Gauze pads were Dukal brand, sterile, 2×2, 8-ply, gauze sponges (Dukal Corporation, Syosset, NY, USA). The vials used to hold the gauze were 10-ml glass, clear, screw top vials with PTFE/silicone septa (Supelco, Bellefonte, PA, USA). The extraction solvent for the pretreatment of the gauze pads by SFE was supercritical grade carbon dioxide (Air Products, Allentown, PA, USA). The methanol used as the modifier for the pretreatment of the gauze pads was HPLC grade (Fisher Scientific, Pittsburgh, PA, USA).

The neutrality of the soap chosen for this study was not a determining factor for use; rather the presence of commonly reported compounds in humans in the headspace of soaps provided the criteria for exclusion. Headspace analysis of different soap types revealed that soaps made from animal fat show the presence of some compounds previously reported in humans. The soap used by the subjects to wash all areas of the body was Natural, Clear Olive Oil Soap from Life of the Party (North Brunswick, NJ, USA). The headspace analysis of this brand of olive oil soap did not reveal the presence of these types of compounds and, thus, was chosen for use in this study.

Pretreatment of Gauze Pads by SFE. The equipment used was an ISCO Model 260D Syringe Pump with an SFX 2-10 Supercritical Fluid Extractor. Each round of SFE began by filling the plastic extraction vessel with two pieces of sterile gauze pads (~0.6 g). The optimum SFE conditions developed to extract organic volatile compounds from sterile absorbers included a 30-min static extraction time followed by a 10-min dynamic extraction time at an extraction temperature of 130°C, a pressure of 4500 psi, and the direct spiking of 500 μl HPLC grade methanol into the 10-ml extraction vessel. These samples were analyzed by a similar SPME-GC/MS procedure for compound identification, and quantification was employed to analyze scent samples described later in the text.

Method for Armpit Sampling. Eight subjects were evaluated: four males (M1, M2, M3, and M4) and four females (F1, F2, F3, and F4). Male 2 was 17 yr of age and male 4 was 22 yr. Female 1 was 21, and female 3 was 23 yr. Male 1, male 3, female 2, and female 4 were 24 yr. It is relevant to note that F3 and F4 are sisters who live in the same household. Subjects were required to use the olive oil soap and directed to shower at least twice by using the provided soap during the 48-hr period prior to sampling. Subjects were also instructed to discontinue the use of deodorants, lotions, and perfumes for at least 48 hr before

sampling to minimize the potential influence of "tertiary odors." No attempt was made to control the diet of the subjects. Each subject exercised outdoors for a period of 30 min while wearing a tank top to minimize the influence of compounds present because of the influence of clothing. Subjects sampled themselves with a pretreated 2×2 sterile gauze pad. They were instructed to wipe the armpit area to collect their sweat and then reseal the sample back into the 10-ml glass vial. All samples were stored in the vials at room temperature and allowed to sit for approximately 24 hr prior to extraction. These storage conditions were chosen to simulate the conditions under which odor is collected for canine evaluation purposes, and no attempt was made to control microbial interactions with the substrate as it may make contributions to the overall odor profile. The climatic conditions present during the samplings included an average temperature of 22.8°C and an average humidity of 77%.

Extraction and Analysis of Armpit Samples (SPME-GC/MS). Divinylbenzene/carboxen on polydimethylsiloxane (DVB/CAR on PDMS) 50-/30-μm fibers (Supelco) were used to extract the volatile organic compounds from the headspace of the vials containing the gauze. Exposure was conducted at room temperature for 15 hr, which was previously determined to be the optimal extraction time based on a combination of the number and abundance of compounds recorded (Curran and Furton, 2004). An Agilent 6970 gas chromatograph (GC) was used with a 5973 mass selective detector (MSD), and the column was an HP5-MS, 30 m, 0.25 μm, 0.25 mm with helium as the carrier gas (flow rate: 1.0 ml/min). The analytes were desorbed in the injection port of the GC with an inlet temperature of 250°C. The GC method was initiated with an initial oven temperature of 40°C for 5 min. The temperature was then ramped at 10°C/min until it reached 300°C, and then was held at 300°C for 2 min (total run time: 33 min). The mass spectrometer used was an HP 5973 MSD with a quadrupole analyzer in full scan mode (range: 50–550).

RESULTS

Pretreatment of Gauze by SFE. Headspace evaluation of initially sterile gauze revealed the presence of many different compounds including those listed

TABLE 1. COMPOUNDS PRESENT IN DUKAL GAUZE PRIOR TO SFE

Examples of compounds extracted from DUKAL Gauze		
Nonanal	Tetradecane	Undecanal
Decanal	Heptadecane	Cyclotetradecane
Hexadecane	Phenol	Nonadecane
2-Ethyl-hexanoic acid	Benzyl alcohol	2-Butoxy-ethanol

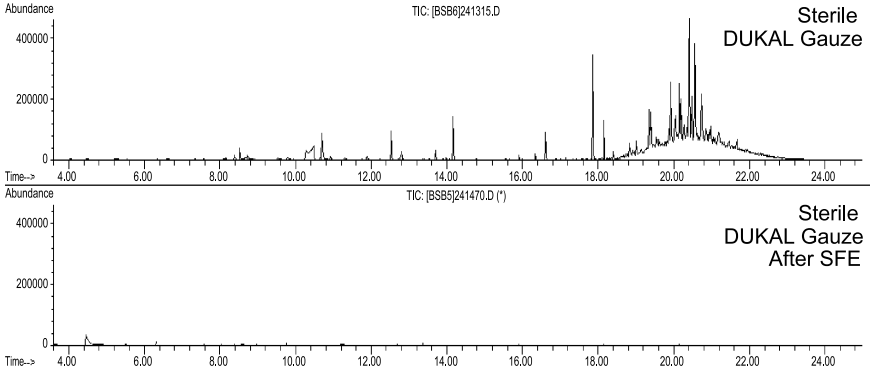

FIG. 1. Chromatographic comparison of sterile gauze before and after SFE treatment.

in Table 1. It is important to remove these compounds prior to sampling because some have been reported as components of human emanations, such as nonanal, decanal, and tridecane. Figure 1 shows the chromatographic difference between the gauze as purchased and after SFE extraction. It is shown with the siloxane peaks attributed to the SPME fiber coating and the column removed. The resulting headspace of the gauze is "chromatographically clean" meaning that all compounds have been removed.

Comparison of Chromatograms Produced from Different Individuals. Figure 2 shows two chromatograms produced from samplings of male 2 collected 7 d apart. It is shown with the siloxane peaks removed; these peaks are attributed to the SPME fiber coating and the column. Differences in abundance between the chromatograms are noted and may be due to concentration

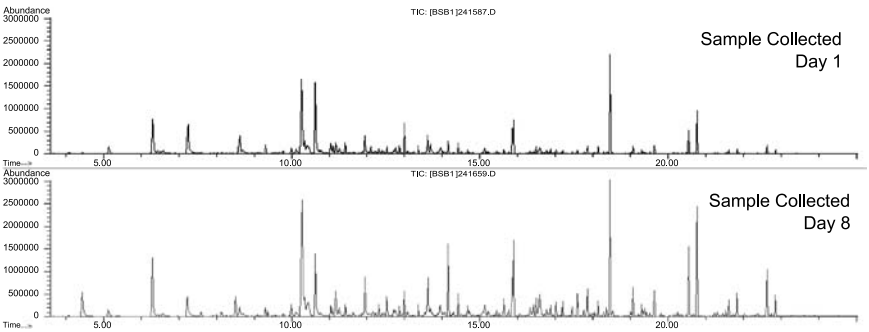

FIG. 2. Chromatograms from 3.5 to 25 min, comparison of male 2 odor profiles produced from samples collected 7 d apart.

differences among the samples; however, similarities in the ratio patterns of the peaks are evident between the two chromatograms. There are 23 common compounds extracted within the two samplings of male 2. We have previously shown the ratio patterns for an individual to be reproducible over time (Curran et al., 2005).

Figure 3 shows the chromatograms produced from the four different male subjects, and Figure 4 demonstrates the chromatograms produced from the different females. Figure 3 shows the chromatograms expanded to highlight the profiles produced among the male subjects, which results in off-scale decanal, dodecanoic acid-methyl ester, and dodecanoic acid peaks in the chromatogram for male 3. Figure 4 shows the chromatograms expanded to highlight the profiles produced among the female subjects, which results in off-scale nonanal and decanal peaks in the chromatogram for female 3. As can be seen from Figures 3 and 4, there are some common compounds present among the subjects and also some compounds present that differ. Table 2 lists the compounds found in the odor profiles of the eight individuals, with superscripts noting where they have been previously reported. The types of compounds determined to be in the odor

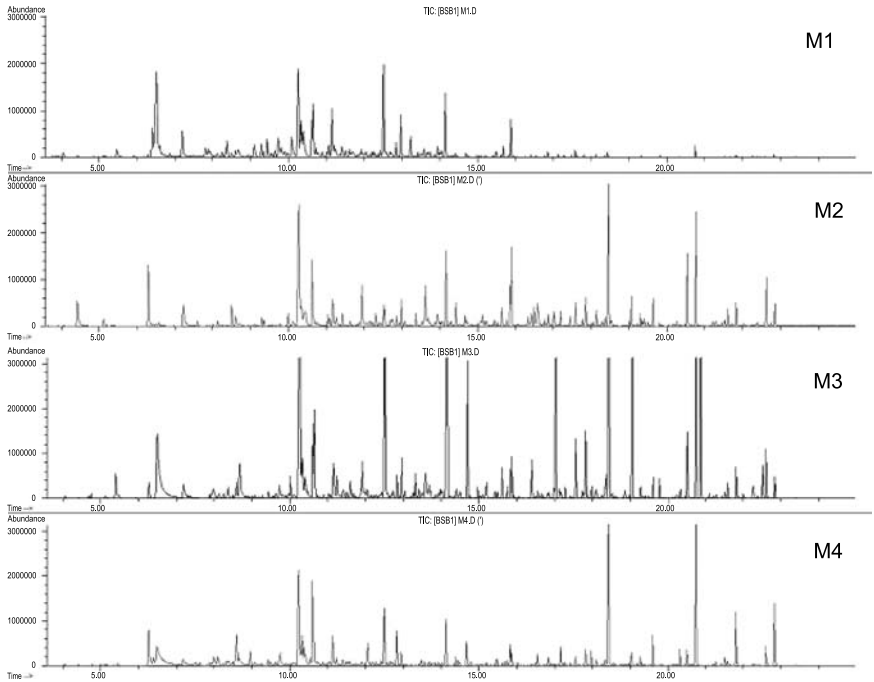

FIG. 3. Chromatograms from 3.5 to 24 min, comparison of odor profiles from male 1, male 2, male 3, and male 4 after 30 min of exercise.

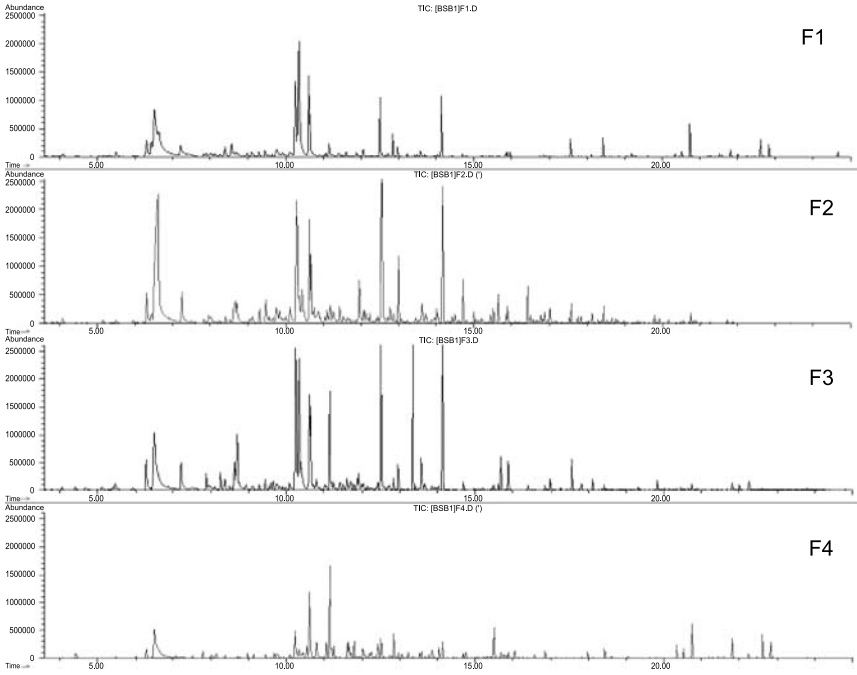

FIG. 4. Chromatograms from 3.5 to 24 min, comparison of odor profiles from female 1, female 2, female 3, and female 4 after 30 min of exercise.

profile include alcohols, aldehydes, alkanes, carboxylic acids, esters, and ketones. The compounds were identified by spectral library comparisons or by standard comparison. Seven of the compounds were present in all of the subjects studied: decanal, dodecanoic acid-methyl ester, nonanal, octanoic acid-methyl ester, phenol, tetradecane, and tetradecanoic acid-methyl ester. Hexanal and 1-chloro-nonane were extracted in only one of the subjects. Dodecanoic acid, propanedioic acid-methyl ester, octanal, and tetradecanoic acid were extracted in some of the males studied, yet were not present in any of the female profiles.

Table 3 shows the ratios of the 23 common compounds extracted from the samplings of male 2 across the eight subjects relative to decanal, which was chosen because it has been extracted in the profiles of every individual studied through this method. The resulting ratio patterns of the common compounds differ among the eight individuals studied. The differences in profiles determined for female 3 and female 4 who live in the same household suggest that the odor profiles produced from individuals with similar genetic makeup and residing in the same environmental conditions can produce distinguishable odor profiles.

DISCUSSION

The SPME-GC/MS headspace analysis method proved to be an effective route for obtaining odor profiles from both males and females. The use of SFE as a pretreatment for the absorber material used as the collection medium allows for the inclusion of compounds that were previously excluded because of their background presence, such as decanal and nonanal. Both qualitative and quantitative differences were observed among the males and females studied. Various types of compounds were extracted from males and females, including a variety of aldehydes, organic fatty acids, ketones, and alkanes, which agrees with Haze et al. (2001); Ostrovskaya et al. (2002); Curran et al. (2005) and our previous findings. Compounds including 2-furancarboxaldehyde, tetradecanal, tridecane, along with various esters are reported here for the first time as components of human odor. A majority of the compounds in the odor profiles of both males and females were esters and aldehydes, and this is in agreement with research previously conducted on the compounds responsible for the residual presence of human odor in washed clothing by Munk et al. (2000). The common

compounds determined among the individuals studied included aldehydes, an alcohol, alkanes, and esters. The common compounds were present in differing ratio patterns between the males and females, indicating qualitative similarities among individuals with quantitative differences.

It is worth noting that (*E*)-3-methyl-2-hexenoic acid was not detected in the headspace of the axillary samples studied, which was reported to be the major odor-causing compound by Zeng et al. (1991, 1996). Ostrovskaya et al. (2002) suggested that 6-methyl-5-hepten-2-one was a volatile compound specific to some individuals, and it was detected in male 1, male 4, female 1, and female 3. The compound 2-nonenal was also present in the odor profiles of three of the females and one of the males studied, and we have previously reported it in the odor profile of males (Curran et al., 2005). The presence of 2-nonenal in human odor has been reported by Haze et al. (2001) to be an age-specific compound that is only seen in individuals ≥40 yr of age. The presence of 2-nonenal in the odor profiles of individuals under 25 yr of age in the current and previous study does not support the conclusions reached by Haze et al. (2001). Further study into the effect of race, age, and sex on odor profiles is necessary to determine whether there are compounds present that are group specific.

Overall, the SPME-GC/MS headspace method developed for the analysis of human odor profiles allows for identification of the volatile organic compounds present in human scent samples. Through this method, a combination of the relative ratios of common compounds and the presence of differing compounds allows for the chromatographic distinction among individuals. The authors have defined human scent to be the most abundant VOCs present in the headspace above scent samples; however, other substances that have a relatively low volatility or are present in low concentrations may also make contributions to human odor. Ongoing studies include large scale sampling of population groups in an attempt to determine the compounds that lead to the uniqueness of human scent.

(Received June 17, 2004; revised September 9, 2004; accepted March 2, 2005)

Abstract—The mandibular gland secretion of *Melipona beecheii* contains a rich mixture of terpenoid and oxygenated compounds and unsaturated and saturated hydrocarbons. However, it differs markedly from the 11 other Brazilian species examined in previous studies, both by the absence of 2-heptanol and the presence of rose oxides. The most abundant compound was geranyl hexanoate, whereas the most volatile compounds were *cis*- and *trans*-rose oxide and geraniol. The complete blend and five individual components found in the gland secretion were tested by electroantennography (EAG) and behavioral assays. The complete mandibular gland extract and geraniol elicited the strongest EAG responses, whereas these and farnesyl acetate induced the strongest attack response from workers. The role of the rose oxides remains to be elucidated, as they do not appear to play a major role as an alarm pheromone of this species.

Key Words—Stingless bees, mandibular glands, *cis*-rose oxide, *trans*-rose oxide, geraniol, alarm response, electroantennography.

INTRODUCTION

Stingless bees employ a diversity of recruitment strategies ranging from odor communication to auditory signals produced inside the nest (Lindauer and Kerr,

* To whom correspondence should be addressed. E-mail: lcruz@tap-ecosur.edu.mx

1958; Esch et al., 1965; Biesmeijer et al., 1998; Nieh and Roubik, 1998; Aguilar and Briceño, 2002). Mandibular gland volatiles serve as alarm pheromones in honeybees and many species of stingless bees (Cruz-Landim, 1967; Collins et al., 1989). In others, such as *Trigona hyalinata*, the mandibular gland secretion is used as an odor trail to guide nest mates (Nieh et al., 2003). The mandibular gland secretion of *Melipona* species appears to be used for alarm recruitment and defense, as seen in *M. fasciata* and *M. interrupta triplaridis* (Smith and Roubik, 1983). Both species have 2-heptanol as the major component with a small amount of undecane, whereas *M. interrupta triplaridis* also contains skatole and nerol. Francke et al. (1987) found that the cephalic secretions of both *M. marginata* and *M. quadrifasciata* contained 2-heptanol as the major component. Gracioli-Vitti et al. (2004) recently studied the mandibular glands of different *M. bicolor* castes and sexes and found a blend of hydrocarbons, alcohols, esters, and carboxylic acids, with 2-heptanol present in both workers and virgin queens. However, in neither study was 2-heptanol tested in behavioral assays. In contrast, Nieh (1998) reported that workers of *M. panamica* exhibited typical alarm behavior towards conspecific mandibular gland extracts, but no chemical information was provided.

Melipona beecheii, a species distributed throughout much of South and Central America (Roubik, 1990) is of potential economic and ecological importance in Mexico (Quezada-Euán and González-Acereto, 1994; Ayala, 1999; Moo-Valle et al., 2000), both for honey production and as a pollinator of crops. Some evidence suggest that *Melipona* species do not use odor trails, but returned foragers produce a series of bursts of sounds to indicate the distance of the food source (Wille, 1983). Greater knowledge of the organization and communication of *M. beecheii* is required, so the aim of this work was to chemically identify the mandibular gland secretions and to learn something of their function.

METHODS AND MATERIALS

Extracts. Preliminary experiments were made using a colony from Costa Rica through the kind cooperation of M. J. Sommeijer, University of Utrecht, The Netherlands. For the main experiments, workers of *M. beecheii* were obtained from an established colony in the El Colegio de la Frontera Sur (ECOSUR) meliponary, located in Tapachula, Chiapas, Mexico. Foraging workers were collected outside of the nest, cooled, and then the mandibles, together with the mandibular glands, were dissected out under distilled water. Six glands were cleanly detached from the mandibles and sealed in individual small soft glass capillaries for analysis. Another series was extracted

in a small tissue grinder with HPLC-grade hexane (200 μl) for testing in bioassays.

Chemical Analysis. Glands were introduced directly into the gas chromatograph (GC), without solvent, as described by Morgan (1990). Gas chromatographic separation was performed on a Varian Star model 3400 CX GC (Palo Alto, CA, USA). A DB-5 column (30 m × 0.25 mm ID) was temperature programmed from 50°C (held for 2 min) to 250°C at 15°C min^{-1}. The injection port temperature was held at 200°C. The sample was heated in the injector to 200°C for 5 min before crushing the glass capillary. The GC was coupled to a Varian Saturn 4D mass spectrometer and integrated data system (Palo Alto, CA, USA). Ionization was by electron impact at 70 eV, 230°C. The amount of each compound was calculated from the peak area, whereas the relative percentage of the components was calculated from the sum of areas of all recorded peaks. Mass spectral identifications were confirmed, wherever possible, by comparison of retention times and mass spectra with those of synthetic standards. Where pure standards were not available, tentative identification was based on comparison with spectra from the computer library NIST 2001.

Chemicals. Synthetic geraniol, farnesyl acetate, (−)-*cis*-rose oxide, (−)-rose oxide, and (+)-rose oxide were obtained from Fluka Sigma-Aldrich (Toluca, Mexico). Both (−)-rose oxide, and (+)-rose oxide contained more of the *cis*-isomer, with a *cis*/*trans* ratio of 2:1. The purity of these compounds was >95% by GC. Geranyl hexanoate and geranyl octanoate were synthesized in our laboratory with a purity >95% using the method of Attygalle and Morgan (1986).

Bioassays. Tests were carried out using protocols similar to those of Smith and Roubik (1983). One established colony of *M. beecheii* in the ECOSUR meliponary was used. In a first experiment, the response of *M. beecheii* workers to different concentrations of mandibular gland extract was evaluated. In a second experiment, the effect of selected synthetic compounds found in the mandibular gland was tested at different doses. Test materials were applied to a 7-mm diam Whatman No. 2 filter paper disk, on an entomological pin, 2.5 cm above the control stimulus, a dark-blue nylon-cloth ball of approximately 8-cm diam. The number of bees biting the ball was recorded for 1 min when it was held 5 cm below the nest entrance. Ten microliters of extract (0.1, 0.5, or 1 gland equivalent) or 10 μl of an HPLC-grade hexane solution of individual synthetic compounds (1 μg, 100 ng, 10 ng) were applied to the filter paper disk. Controls consisted of 10 μl of HPLC-grade hexane, and in all cases, the solvent was allowed to evaporate for at least 20 sec before each test. After presenting the control stimulus alone, extracts, synthetics, and controls were tested in random order between 0700 and 0900 hr local time, with 20-min intervals between stimuli to allow the nest to calm down. The complete assay was repeated on eight dry days with a similar temperature (ca. 30°C).

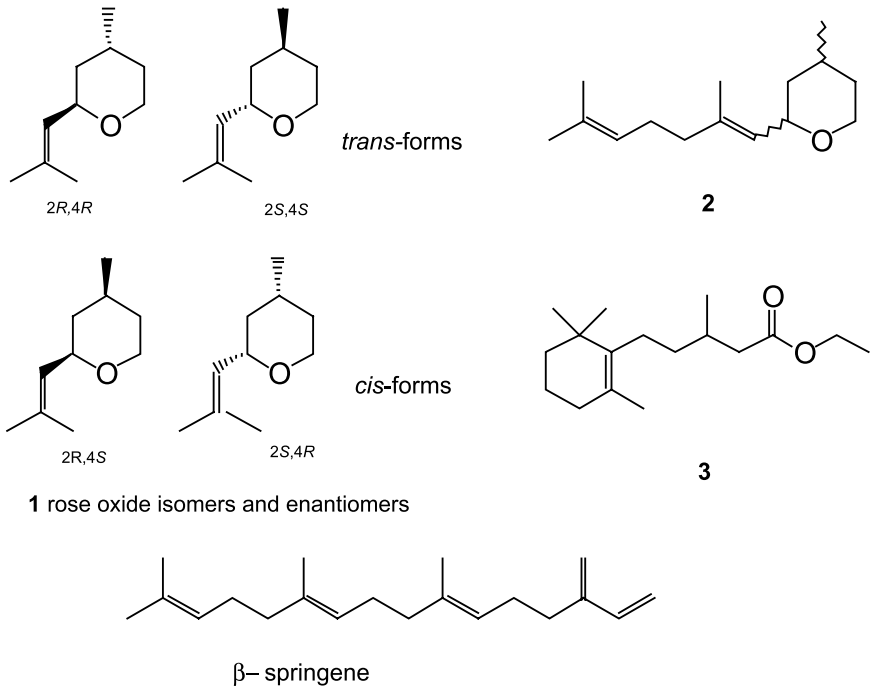

FIG. 1. Structures, and proposed structures, of compounds found in the mandibular gland of *Melipona beecheii* workers. **1**, The rose oxide enantiomers; **2**, the proposed structure of compounds 5–7 in Table 1, homologues of rose oxide; **3**, the suggested structure of compound 12 in Table 1, and the structure of β-springene.

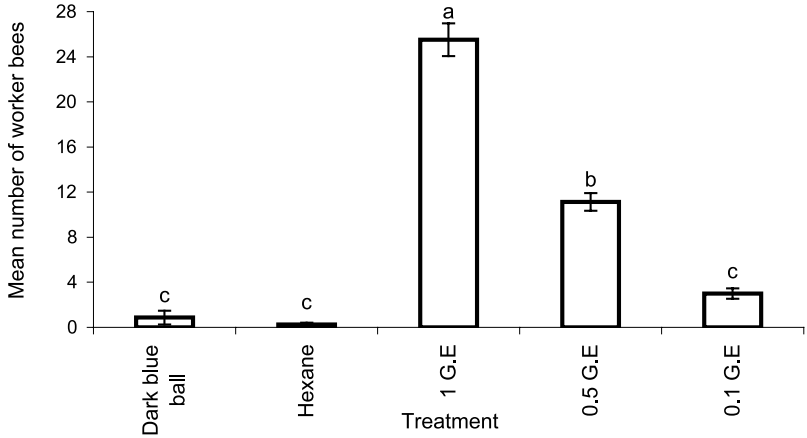

FIG. 2. Response of *M. beecheii* workers to different concentrations of mandibular gland extracts.

Electroantennography. Antennal receptivity of the *M. beecheii* workers to the selected chemical compounds was determined by electroantennography (EAG). The head of a worker was cut off carefully, and the reference glass capillary electrode was inserted into its base. The distal end of the antenna was inserted into the tip of the recording glass capillary electrode. The capillaries

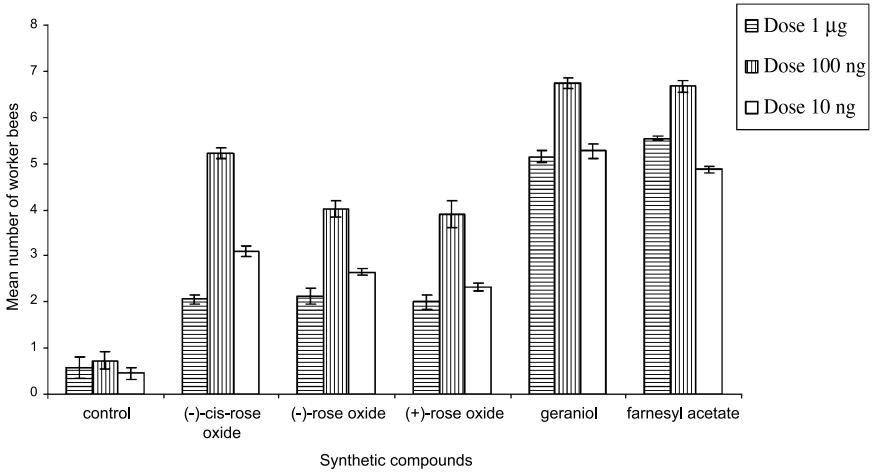

FIG. 3. Response of *M. beecheii* workers at different concentrations of synthetic compounds known to occur in the mandibular gland secretions.

were filled with saline solution (Malo et al., 2002). The signals generated by the antenna were passed through a high-impedance amplifier (Syntech NL 1200, Hilversum, The Netherlands) and displayed on a monitor using Syntech software for processing EAG signals.

Dilutions of the synthetic compounds and extracted mandibular glands were prepared in HPLC-grade hexane to make 1-μg/μl solutions. For each solution, 1 μl was applied to a filter paper (0.5 × 3.0 cm, Whatman no. 1), left 20 sec to allow the solvent to evaporate, and then inserted into a glass Pasteur pipette or sample cartridge 40 sec before testing. New cartridges were prepared for every insect tested. A stimulus controller (CS-05, Syntech) was used to generate stimuli at 1-min intervals. A current of humidified pure air (0.7 l/min) was constantly directed onto the antenna through a glass tube of 10-mm diam to ensure that odors were removed immediately from the vicinity. To present a stimulus, the pipette tip containing the test compounds or the extracts was inserted through a side hole located at the midpoint of the glass tube (10-mm diam) through which humidified pure air flowed at 0.5 l/min. The duration of the stimulus was 1 sec. Control stimulus (hexane) was presented at the beginning, followed by stimuli of the chemical products and gland extracts in

random order. At the end, a second control stimulus was applied. For analysis of the EAG recorded, we used only the amplitude value in mV. We used one antenna of the bee for each series of the chemical products and the extracts tested, and at least 10 bees were used.

Data Analysis. The workers dose response to the gland extracts and EAG data were analyzed by one-way analysis of variance (ANOVA) (program GLM, SAS Institute, 2001). In some cases, before ANOVA, data were $\sqrt{x}$ transformed to stabilize variances. Significant differences were separated by a Tukey test. Dose response to synthetic compounds was analyzed by a two-way ANOVA (Statistica, Statsoft, Inc., 2004). Data were $(\sqrt{x} + 0.1)^{0.6}$ transformed to stabilize variances. Means were separated by a Tukey test. In all cases, $P = 0.05$.

RESULTS

Chemical Analysis. The mandibular gland secretion of *M. beecheii* contains a rich mixture of terpenoids, fatty acid esters, and unsaturated and saturated hydrocarbons (Table 1). The major component geranyl hexanoate, as well as geranyl octanoate, farnesyl acetate, and *cis*- and *trans*-rose oxide (Figure 1),

TABLE 3. THE RESPONSE OF *M. beecheii* TO COMPOUNDS FOUND IN THE MANDIBULAR GLAND SECRETIONS AS A FUNCTION OF CONCENTRATION

was identified by using spectra and retention times of synthetic compounds. Other rose oxide homologues (peaks 5–7 in Table 1) have higher masses but all the spectral characteristics of rose oxides, with base peaks at *m*/*z* 139. We suggest they share structure **2** shown in Figure 1. Methyl 2,3-dihydrofarnesoate, as were the methyl and ethyl esters of common fatty acids, was tentatively identified based on good matches with the spectra in the NIST spectral library. β-Springene, identified by its mass spectrum, has already been identified in other stingless bees. The structure of an abundant ethyl ester, related to but not a homologue of methyl 2,3-dihydrofarnesoate, was tentatively deduced from its spectrum (*m*/*z* 109 as base peak) to be similar to structure **3** in Figure 1. There were also smaller amounts of hydrocarbons and higher unidentified terpenes. Some of the hydrocarbons were most likely of cuticular origin as they were found in an analysis of a small fragment of cuticle.

Bioassays. M. beecheii workers exhibited a significant dose-dependent response to mandibular extracts ($F = 168.87$, $df = 4, 35$; $P < 0.001$) (Figure 2). In the case of the individual synthetic compounds, *M. beecheii* workers exhibited a significant interaction between dose and synthetic compounds (two-way ANOVA, $F = 12.89$, $df = 10, 126$, $P < 0.001$) (Figure 3). At each concentration tested, all synthetic compounds resulted in significantly higher responses than controls, with geraniol and farnesyl acetate eliciting the highest

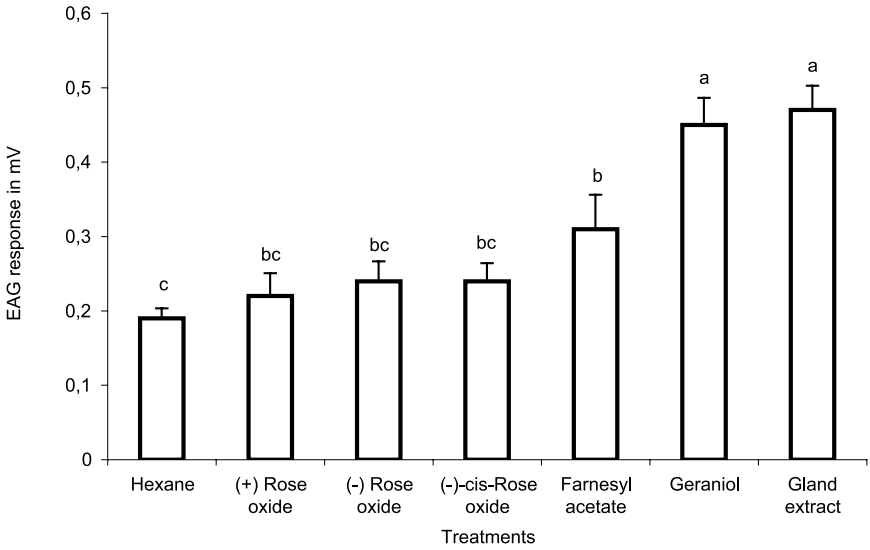

FIG. 4. Antennal response of *M. beecheii* to a 1 gland equivalent extract of mandibular gland secretions and to 1 μg of different synthetic compounds.

and similar responses (Table 2). Furthermore, for all compounds tested, the workers showed a significantly higher response to 100-ng dose than 1 μg and 10 ng (Table 3).

Electroantennography. There were significant differences in the antennal response to the different compounds tested ($F = 15.7$, $df = 6, 72$; $P < 0.001$). The mandibular gland extract, geraniol, and farnesyl acetate elicited significantly higher antennal responses than the control, whereas (+)-rose oxide, (−)-rose oxide, and (−)-*cis*-rose oxide did not (Figure 4).

DISCUSSION

A number of compounds found in the mandibular gland secretion of *M. beecheii* are common to other stingless bees, including geraniol, farnesyl acetate, and β-springene (Francke et al., 2000; Cruz-Lopez et al., 2001). Furthermore, geranyl hexanoate has been identified from the mandibular gland secretions of *Geotrigona mombuca* (Francke et al., 2000). In contrast, 2-heptanol, a common substance in previously studied *Melipona* species (Smith and Roubik, 1983; Francke et al., 1987), was not found. Our finding of two rose oxide isomers in *M. beecheii* is noteworthy, as these compounds were not found in 11 species from four different genera of Brazilian stingless bees (Francke et al., 2000). While these compounds are quite common in plant odors (de Maris and Moreira, 2003), in insects, they have only been previously reported from the secretions of two coleopteran species, and are thought to function as defensive substances (Vidari et al., 1973).

While rose oxide isomers do not give significantly greater EAG responses than hexane (Figure 4), they do elicit higher levels of defense behavior (Figure 3). There are two enantiomeric forms, the rose oxide *cis* and *trans* isomers (Figure 1), but we do not know which ones are present in the secretions, as we did not have a chiral column to separate the enantiomers. The names of the commercially available products tested are confusing. The (2*S*,4*R*)-enantiomer is available as (−)-*cis*-rose oxide, whereas (−)-rose oxide and (+)-rose oxide are 2:1 mixtures of (2*S*,4*R*):(2*R*,4*R*)-isomers and (2*R*,4*S*):(2*S*,4*S*)-isomers. The results of both EAGs and bioassays suggest that (2*S*,4*R*)-rose oxide [or (−)-*cis*-rose oxide] is responsible for all or most of the activity in (−)-rose oxide. However, geraniol and farnesyl acetate, at levels similar to a mandibular extract, elicit the most pronounced defense reactions from workers, which suggests that rose oxide isomers are of minor importance as an alarm pheromone. Clearly, more work is needed to determine what role, if any, these rose oxides play. The presence of the rose oxides, together with the lack of 2-alcohols, in the mandibular secretion of *M. beecheii* workers demarcates this

species from the other four *Melipona* species previously analyzed. These findings suggest that there may be different assemblages within the genus *Melipona*, but the mandibular secretions of more species need to be studied to clarify the situation.

Acknowledgments—We thank Yolanda Brindis and Alejandro del Mazo for assistance in the chemical and bioassays work, Javier Valle-Mora for statistical advice (all at ECOSUR), Eric Schoeters (University of Leuven, Belgium) for dissection of the first group of mandibular glands, and Prof. Sommeijer (Utrecht University, The Netherlands) for providing samples of bees. For EDM, this work was partly supported through the European Research Training Network "Insects" (FW5).

SEX PHEROMONE OF THE CITRUS FLOWER MOTH *Prays nephelomima*: PHEROMONE IDENTIFICATION, FIELD TRAPPING TRIALS, AND PHENOLOGY

(Received July 6, 2004; revised October 22, 2004; accepted March 23, 2005)

Abstract—Analysis of sex pheromone gland extract of the citrus flower moth, *Prays nephelomima* (Lepidoptera: Yponomeutidae) by coupled gas chromatography–electroantennogram detection, revealed one electrophysiologically active compound. Structural analysis using gas chromatography, gas chromatography–mass spectrometry, and dimethyldisulfide derivatization identified this as the monounsaturated aldehyde (*Z*)-7-tetradecenal. Field trials in commercial citrus orchards on the North Island of New Zealand showed that (*Z*)-7-tetradecenal was highly attractive to male *P. nephelomima*. Phenology data, collected over 19 months in three commercial orchards, from traps baited with the sex pheromone at a lure loading of 300 μg on a red rubber septum, indicated that male moths may be present throughout the year, with numbers peaking in late summer and autumn.

Key Words—Citrus flower moth, *Prays nephelomima*, Yponomeutidae, Lepidoptera, (*Z*)-7-tetradecenal, GC-EAD, GC-MS, DMDS derivatization, trapping trials, phenology.

INTRODUCTION

The citrus flower moth, *Prays nephelomima* (Meyrick), is a major pest of citrus in New Zealand (Sale, 2003). The larvae feed within a shelter formed by webbing flower or leaf parts together with a little silk and then pupate in a

* To whom correspondence should be addressed. E-mail: agibb@hortresearch.co.nz

flimsy open network cocoon. This feeding severely damages the flower buds, flowers, and young leaves of many citrus species. While citrus flower moths are regarded as thinning agents for flowers, and fruitlets in citrus, heavy infestations can result in excessive fruit loss and low yields.

We, therefore, aimed to identify the sex pheromone of *P. nephelomima*. Development of an effective attractant was considered to be the first step towards successful management of this pest, and may also allow alternative control techniques to insecticide use, such as mating disruption, lure and kill, and/or mass trapping (Sternlicht et al., 1990; Suckling and Karg, 2000) to be adopted by the industry, as part of an IPM strategy. Furthermore, the identification of the sex pheromone will help in understanding the biology, ecology, and behavior of this pest. For example, the yearly adult flight phenology of *P. nephelomima* in New Zealand citrus orchards is not known.

METHODS AND MATERIALS

Insects. Approximately 200 *P. nephelomima* larvae were collected from a citrus orchard (c.v. Yen Ben lemons) in Kerikeri, Northland, New Zealand (lat. 35.22°S, 173.95°E), by harvesting citrus flowers with visible feeding damage. The flowers were kept in tissue-lined plastic containers in the laboratory at room temperature. As the mature larvae exited the flowers, they were transferred to individual 50-cm petri dishes to pupate.

Pheromone Gland Extracts. Four batches (10, 19, 14, and 22) of pheromone glands from 24- to 48-hr-old female *P. nephelomima* were excised into liquid nitrogen-cooled 0.5-ml V-vials (Wheaton, Millville, NJ, USA) containing 20–30 μl of *n*-hexane. After all glands had been excised, each vial and its contents were brought to room temperature, and the glands were extracted for 5 min. The gland extract was then transferred to a 1.1-ml tapered-bottom clear glass vial (Alltech, IL, USA) and reduced to ca. 10 μl using a stream of argon before being stored at −18°C.

Chemicals. (*Z*)-7-Tetradecenal (>97% isomerically pure) was purchased from Pherobank, Wageningen, The Netherlands. Dimethyldisulfide (DMDS) was obtained from Merck, Darmstadt, Germany, and *n*-hexane (99%), iodine, sodium sulfate, and sodium thiosulfate were from BDH Laboratory Supplies, Poole, England.

Dimethyldisulfide Derivatizations. Dimethyldisulfide derivatizations of (*Z*)-7-tetradecenal (10 ng in 20 μl of *n*-hexane) and a pooled pheromone gland extract (the remnants of the 10 and 19 female gland extracts used initially for gas chromatography–mass spectrometry (GC-MS) and gas chromatography and electroantennographic detection (GC-EAD) analysis combined with those of 14 and 22 other females) were carried out based on the methods of Buser et al.

(1983) and Leonhardt and DeVilbiss (1985). In each case, approximately 50 μl of DMDS and 5 μl of iodine solution (60 mg of I_2 in 1 ml of diethyl ether) were added to the solution in a 1.8-ml glass vial, sealed with a Teflon-lined cap, and reacted at 40°C for 15 hr. The reaction was stopped with 50 μl of a 5% aqueous solution of sodium thiosulfate, and the aqueous layer was dried with anhydrous sodium sulfate. The remaining organic layer was then carefully removed to a clean 1.5-ml tapered-bottom vial (Alltech, Glenfield, New Zealand), blown down with a stream of argon to less then 5 μl, and a 1-μl aliquot immediately was analyzed by GC-MS.

Gas Chromatography and Electroantennographic Detection. A pheromone gland extract of 19 *P. nephelomima* females was analyzed by GC-EAD using a Varian 3800 gas chromatograph equipped with both polar and nonpolar columns, coupled to an EAD Recording Unit (Syntech Research and Equipment, Hilversum, Netherlands). A 1-μl aliquot of the extract [1.9 FE (female equivalent)] was first run on a DB-5 (Agilent Technologies, CA, USA) capillary column (30 m × 0.25 mm ID × 0.5-μm film thickness) and then a polar BPX-70 capillary column (SGE, Melbourne, Australia) (30 m × 0.25 mm ID × 0.25-μm film thickness). Both capillary columns had 1:1 split outlets. Helium was used as the carrier gas at a flow rate of 1 ml/min, and injections were in splitless mode. The injector temperature was set at 250°C, the detector at 300°C, and the GC oven temperature programmed from 80°C (1-min hold) to 240°C at 10°C/min and held for 15 min.

A male *P. nephelomima* antenna was excised and positioned between two glass electrodes, containing BE Ringer's solution with 10% polyvinylpyrrolidone (molecular weight 360,000) (Sigma Chemical Co., New South Wales, Australia). Each glass electrode held a length of 1-mm silver wire that electrically connected the preparation to the recording unit's preamplifier. The EAD exit port temperature was maintained at 200°C, and the antennal preparation was placed in a charcoal-filtered and humidified air stream (400 ml/min). Kováts retention indexes (KIs) (Kováts, 1965; Marques et al., 2000) were calculated for the antennally active compound and the (*Z*)-7-tetradecenal standard on both the polar and nonpolar columns.

Gas Chromatography–Mass Spectrometry. A 1-μl aliquot (1 FE) of a 10 female gland extract of *P. nephelomima*, (*Z*)-7-tetradecenal, and DMDS derivatizations of the pooled gland extract and (*Z*)-7-tetradecenal, were analyzed by GC-MS on a VF-5ms capillary column (30 m × 0.25 mm ID × 0.25-μm film thickness) (Varian Inc., CA, USA) using a Varian 3800 gas chromatograph in splitless injection mode coupled to a Varian 2200 MS. The injector temperature was set at 250°C, and the GC oven temperature was programmed from 80 to 240°C at 10°C/min and held for 15 min. Preliminary gas chromatography indicated that the (*Z*)-7-tetradecenal standard contained ca. 2% of (*E*)- 7-tetradecenal, but that separation was incomplete on the VF-5ms capillary

column. However, after derivatization with DMDS, the resulting isomeric adducts had identical spectra but were easily separated. KIs for these adducts were calculated and comparisons were made to an adduct formed in the derivatized gland extract of *P. nephelomima*.

Trapping Trials—Trial 1. A preliminary trapping trial was undertaken in a c.v. Yen Ben lemon orchard (Clevedon, Auckland, New Zealand) from 31st October 2002 until 31st January 2003 to ascertain if *P. nephelomima* males were attracted to (*Z*)-7-tetradecenal and to determine whether any dose response was evident. Red rubber septa (Thomas Scientific Inc., Philadelphia, PA, USA) pheromone lures were prepared with three replicates of six loadings (0, 10, 30, 100, 300, and 1000 μg) of (*Z*)-7-tetradecenal and tested using green delta pheromone traps (Clare et al., 2000). A randomized complete block design was used. Traps were placed at a height of 1–2 m in the crop canopy, with 15-m spacing between treatments and 50-m spacing between replicates. At fortnightly intervals, trap positions were rotated within each replicate and sticky bases changed and sent to HortResearch, Auckland, for identification and collation of *P. nephelomima* numbers.

Trial 2. A fully replicated dose response trapping trial was set up on three commercial citrus orchards in the Auckland and Northland areas to determine the optimum loading of (*Z*)-7-tetradecenal for use in monitoring traps. Properties were situated in Clevedon, Auckland (c.v. Yen Ben lemons), Kerikeri, Northland (c.v. Yen Ben lemons), and Houhora, Northland, New Zealand (c.v. Satsuma mandarins). The trial at the Clevedon orchard ran from 31st of January 2003 to 4th of April 2003. At the Kerikeri and Houhora orchards, the trials ran from 4th of February 2003 until 15th April 2003. Trap layout, replication, loading, and data handling were as in trial 1.

Phenology. After establishing the optimal pheromone loading for trapping *P. nephelomima* (see Results), three traps baited with septa loaded with 300 μg of (*Z*)-7-tetradecenal were maintained at each of the three trial orchards to monitor weekly catch of *P. nephelomima* moths from mid-April 2003 to late September 2004. Sticky bases were collected weekly if any moths were observed, coded, stored in a fridge/freezer, and sent to HortResearch, Auckland, for identification and collation of *P. nephelomima* numbers. Data were presented as males caught per trap per day. Pheromone lures were replaced every 6 wk.

Statistical Analyses. For all trapping experiments, a mixed model was fitted to the data using GenStat Release 7.2 (VSN International Ltd., United Kingdom) with sampling interval, loading, and its interaction as fixed effects, and replicates as random effects. The experimental model could be expressed as follows: $y_{ijkl} = \mu + \tau_i + \gamma_j + \tau\gamma_{ij} + \beta_k + \varepsilon_{ijkl}$ where y_{ijkl} is the response variable, τ_i is the effect of the ith sampling interval, γ_j is the effect of the jth loading, β_k is the effect of the kth replicate; and ε_{ijkl} is the error term

associated with the treatments. The model assumed that the error terms were normally and independently distributed with zero mean and constant variances. Moth counts were transformed to their respective $\log_{10}(x + 1)$ values prior to statistical analyses to ensure that the model assumptions were met.

To determine the amount of variability in the data that could be attributed to each of the model terms, an ANOVA was performed on the transformed data. Mean separation tests were carried out for different levels of the treatment factors using Fisher's protected LSD at the 5% significance level, and model adequacy checks were performed by examining various plots (histograms, normal probability plots, scatter plots) of the residuals. These showed no evidence of violation of the independence or constant variance assumptions of the model.

RESULTS

Gas chromatography and electroantennographic detection analyses of *P. nephelomima* pheromone extract identified one small peak that repeatedly elicited a response from male antennae (Figure 1). The elution time of this active

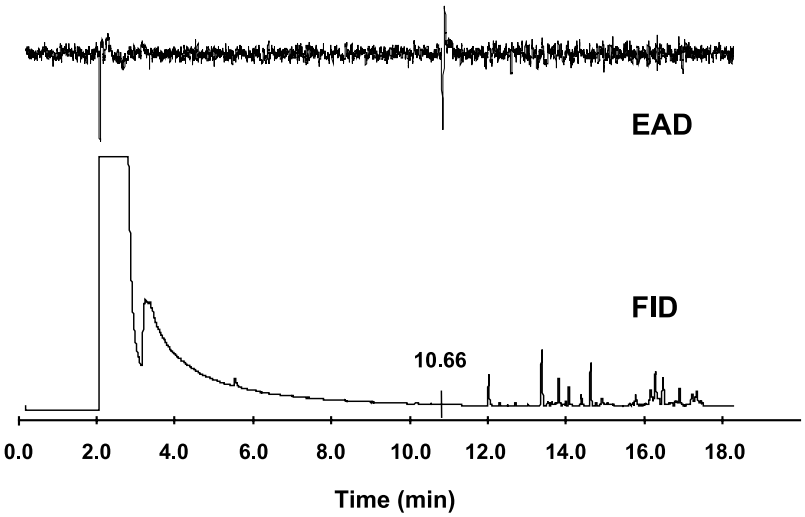

FIG. 1. GC-EAD of the response of a male *Prays nephelomima* antenna (EAD) to the active compound (*Z*)-7-tetradecenal (retention time of 10.66 min) in female moth pheromone extract eluting from a BPX-70 gas chromatography column (FID).

compound was identical with that of the (*Z*)-7-tetradecenal standard, on both the DB-5 (nonpolar) and the BPX-70 (polar) columns [KIs of 1602 and 2139, respectively, for the active compound and the (*Z*)-7-tetradecenal].

Analysis of *P. nephelomima* gland extract by GC-MS revealed a small peak with a spectrum suggestive of a monounsaturated aldehyde. The base peak was at *m*/*z* 67, and significant fragments were evident at *m*/*z* (relative intensity) 39 (63), 55 (93), 81 (81), 93 (50), 121 (41), and 149 (29). A peak at *m*/*z* 192 (7) suggested loss of water (M-18) from a molecule having a molecular weight of *m*/*z* 210. Furthermore, the fragmentation pattern and the compound's retention time were identical to that of a (*Z*)-7-tetradecenal standard. In addition, GC-MS analysis of the DMDS adduct formed in the derivatized *P. nephelomima* gland extract revealed a small peak with an identical spectrum to that of the (*Z*)-7-tetradecenal standard DMDS adduct. The molecular weight at *m*/*z* 304 (22.5) was the result of addition of *m*/*z* 94 from inclusion of two SCH_3 in one double bond of the parent compound, whereas the location of diagnostic peaks at *m*/*z* 145 (72) and *m*/*z* 159 (16) was indicative of a double bond at position 7. A KI of 2245 for this adduct confirmed the active compound as (*Z*)-7-tetradecenal rather than (*E*)-7-tetradecenal, as the (*E*)-7-tetradecenal DMDS adduct had a KI of 2256.

(*Z*)-7-Tetradecenal was highly attractive to male *P. nephelomima* capturing a total of 1579 moths, whereas control traps only captured seven (Table 1 and Figure 2). There were effects of both pheromone concentration ($P < 0.001$) and sampling interval ($P < 0.001$), as well as their resulting interaction ($P < 0.001$).

Similar results were obtained in full-scale trials in three different orchards (Tables 2–4), with 30,403 moths trapped in pheromone-baited traps compared

monitoring of male *P. nephelomima*. Many more male *P. nephelomima* were captured at the Kerikeri lemon and Houhora mandarin orchards than at the Clevedon lemon orchard. While the reasons for this observed difference in moth density are unknown, differing management practices (e.g., insecticide applications) and citrus type were likely to be factors.

The major activity period at all three sites extended from November through June, with lower activity but intersite variability in other months (Figure 3). Higher numbers of moths were trapped at the Kerikeri and Clevedon lemon orchards (18,295 and 13,005 moths, respectively) than at the Houhora mandarin orchard (4,545 moths) during the 19-mo period. This difference re-

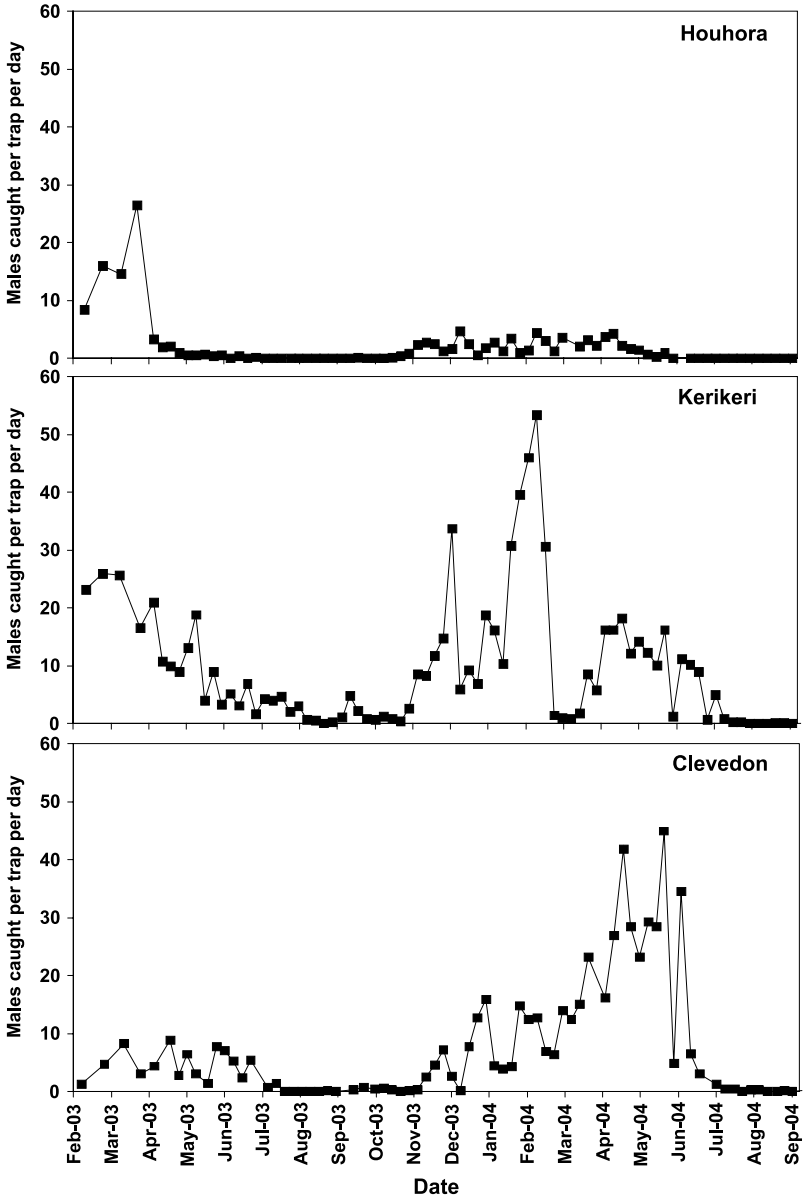

FIG. 3. Phenology of male *P. nephelomima* (using a 300-μg loading of (*Z*)-7-tetradecenal in sticky traps) from February 2003 to September 2004, in three commercial citrus orchards in the North Island of New Zealand.

flects the approximately threefold greater number of *P. nephelomima* larvae and pupae on lemons than mandarins in North Island citrus orchards during 2003–2004 (Jamieson et al., 2004).

DISCUSSION

We identified the sex pheromone of *P. nephelomima* as the monounsaturated aldehyde, (*Z*)-7-tetradecenal, which has proven to be highly attractive to male *P. nephelomima* moths in replicated field trials. The identification of a pheromone attractant for *P. nephelomima* has provided New Zealand citrus growers with a tool to monitor levels of this moth. While upwards of 300 moths per week were captured on the sticky base of a trap baited with a 300-μg lure during the summer months, given the small size of the adult male moth (ca. 5 mm in length), trap saturation is unlikely to be a major problem at this catch level. In addition, the pheromone may be useful as part of an IPM program to control or at least suppress levels of infestation in commercial citrus crops using mating disruption or lure and kill technologies. Trials are underway to investigate the potential of the pheromone for use in male annihilation of *P. nephelomima*.

(*Z*)-7-Tetradecenal has been identified as a pheromone component or sex attractant in a number of moths (Steck et al., 1982; El-Sayed, 2005) and the pheromone of three *Prays* species: *P. nephelomima* (this study), *P. citri* (Nesbitt et al., 1977), and *P. oleae* (Bernard) (Campion et al., 1979; Renou et al., 1979). Both *P. nephelomima* and *P. citri* share (like their common hosts in the *Citrus* genus) an Oriental/Indo-Malayan origin (Dugdale, personal communication). Although *P. nephelomima* superficially resembles the type (and topotypic) specimens of *P. citri*, there are differences in genitalia (Dugdale, 1988), which could play a role in reproductive isolation if the species are sympatric. However, it is unclear as to whether *P. nephelomima* and *P. citri* are allopatric or sympatric. In contrast, *P. citri* and *P. oleae* are sympatric (Campion et al., 1979; Renou et al., 1979), but *P. oleae* attacks olives rather than citrus, so, even if both species use (*Z*)-7-tetradecenal as their sex pheromone, then temporal/spatial differences in activity could insure reproductive isolation. However, one cannot rule out additional and as yet unidentified pheromone components in one or all of the *Prays* species. For example, Campion et al. (1979) and Renou et al. (1979) found that the addition of (*Z*)-9-tetradecenal to a synthetic lure containing (*Z*)-7-tetradecenal markedly reduced the attractancy for *P. oleae*, but not for *P. citri* males. Additional research is required to resolve this question, and an in-depth comparison of the seven *Prays* species attacking the Rutaceae in Australia (Nielsen and Common, 1991) would provide an excellent point of departure.

Acknowledgments—We thank the MAF Sustainable Farming Fund and New Zealand Citrus Growers Incorporated for funding this work. Additional funding was provided by the New Zealand Foundation for Research, Science and Technology. We also thank Diana Edwards (Clevedon), Amanda Little, Kira Anderson, Kathryn Wilson, Kerry Gibbs, and Andrew Harty (Kerifresh Group, Kerikeri), and Lynda Maskell, John Chapman, and Ryan Duffy (Houhora) for trial sites, maintaining pheromone traps, and collecting sticky bases. Dr. Robert Hoare from Landcare Research confirmed the initial moth identifications, and David Seldon assisted with counting moths and data collation.

(Received August 9, 2004; revised February 28, 2005; accepted March 8, 2005)

Abstract—We evaluated the sublethal effects of malathion treatment on the behavioral responses of male Asian corn borers, *Ostrinia furnacalis* (Guenée), to their sex pheromones. Doses of malathion causing 1–50% mortality were topically applied to Asian corn borer male moths. The survivors were tested for behavioral and electroantennogram (EAG) responses to their sex pheromones. Sublethal doses of malathion affected males' ability to locate a pheromone source. In wind tunnel tests, male moths treated with sublethal doses of malathion took 2.5 to 12 times as long to take flight as control moths. Malathion-treated male moths were 60–96% less likely to locate a sex pheromone source than control moths. Multiple linear regression analysis revealed that the proportions of males performing each key stage were significantly correlated with the doses of malathion, but not with the time since treatment. Sensitivity and specificity of perception to pheromones in male moths were also disrupted by sublethal doses of malathion. The EAG responses of males treated with malathion decreased 0.13 mV on average compared with control moths. In addition, the ratios of pheromone components that elicited the largest responses shifted from approximately 5:5 to 1:9 (*E*/*Z*) and 9:1. We conclude that treatment with sublethal doses of malathion significantly reduced the likelihood that male Asian corn borers could successfully locate a normal female releasing sex pheromones.

Key Words—*Ostrinia furnacalis*, malathion, sublethal effects, sex pheromone response.

INTRODUCTION

In recent years, much attention has been paid to the sublethal effects of insecticides and herbicides (Pinckney et al., 2002; Shofer and Tjeerdema, 2002; Yang and Du, 2003; Bain et al., 2004). These chemicals have been shown to affect not only target pests (Yang and Du, 2003), but also nontarget organisms such as estuarine phytoplankton (Pinckney et al., 2002), salamanders (Rohr et al., 2003), and fish (Shofer and Tjeerdema, 2002; Dutta and Meijer, 2003). Sublethal effects of pesticides are many and varied. For example, mosquitofish, *Gambusia affinis*, exposed to sublethal concentrations of malathion for several days showed a variety of histopathological effects under light microscopy (Cengiz and Unlu, 2003). Wang et al. (2003) found that the eggs of Asian ladybird beetles (*Harmonia axyridis*) treated with sublethal concentrations of imidacloprid, rotenone, fenvalerate, and abamectin were less likely to hatch than controls, and time to hatching was significantly prolonged.

The Asian corn borer, *Ostrinia furnacalis* (Guenée), is an important pest of corn and other crops in China and Southeast Asia. Its pheromone blend is a mixture of (*Z*)-12-tetradecenyl acetate and (*E*)-12-tetradecenyl acetate (Klun et al., 1980; Cheng et al., 1981). Because the insect lives inside its host plants throughout most of its life cycle, control of Asian corn borer has proven difficult. Pesticides are widely used against the corn borer, and it is not surprising that it has developed resistance to most insecticides applied. Management of resistance has thus become an important issue in pest control (Onstad et al., 2002).

Because female Asian corn borers exposed to sublethal doses of insecticide produced less sex pheromone (Yang and Du, 2003), sublethal treatment with specific doses of insecticide may also modify male behavioral responses. Previously, our laboratory demonstrated that female moths and larvae treated with doses of neurotoxicants reduced pheromone emissions (Yang and Du, 2003) or produced altered ratios of sex pheromone components (Wei et al., 2004). However, data on male responses were lacking. We report here the effects of sublethal doses of malathion on responses of Asian corn borer male moths to sex pheromones, and on the sensitivity and specificity of responses to different doses and ratios of sex pheromones.

METHODS AND MATERIALS

Insects. Mature larvae of *O. furnacalis* were collected from a corn field in Meng county, Henan Province, China, and maintained in our laboratory for 2 yr prior to our study. Larvae were fed on artificial diet as described by Zhou et al. (1980). Pupae were separated by sex. Male pupae were kept in $40 \times 20 \times 15$ cm^3

wooden boxes with screen covers at 23–25°C, 60–70% relative humidity and 14L:10D photoperiod until emergence. Adults were separated daily and fed with 5% sugar water.

Chemicals. The synthetic pheromone components, *E*12-14:OAc and *Z*12-14:OAc, were purchased from the Research Institute for Plant Protection (Wageningen, Netherlands), and the isomeric purity of these compounds was greater than 99% as determined by GC. Stock solutions of the single components were made up in redistilled hexane (10 μg/μl). Blends of components to be tested were prepared by diluting various amounts of the stock solutions with redistilled hexane to the desired concentrations. All blends were checked on a Hewlett-Packard (HP) 5890 GC fitted with a splitless injector and an HP-5 capillary column (25 m × 0.2 mm ID). The oven temperature was maintained at 100°C for 2 min, programmed at 10°C/min to 250°C. The carrier gas was nitrogen. Malathion (99% active ingredient, Ningbo Factory of Agricultural Chemicals) was dissolved in redistilled acetone, and a dose series of 30–150 ng/μl was prepared. Fresh solutions of all chemicals were prepared weekly.

Procedure for Treating Insects. Two-d-old Asian corn borer male moths were cold-anesthetized 2 hr before the onset of scotophase, and were dosed topically on the back of the thorax with 1 μl of insecticide solution (range of concentrations 30–150 ng/μl), using a Burkard microapplicator (Shanghai Institute of Entomology). Control moths were treated with 1 μl acetone. After treatment, moths were held as described above.

Determination of Sublethal Doses. A method based on Floyd and Crowder (1981) was used to determine the sublethal doses. Two-d-old male moths were treated with 1 μ1 of solution containing 10–500 ng of malathion ($N = 90$ moths/dosage). Mortality was recorded at 24-hr intervals for at least 96 hr until no additional mortality was observed. Doses resulting in mortality less than 50% were calculated with a probit line for lethal effects at 96 hr after treatment (the formula of the probit line: $y = 2.3988\ x - 0.2084$, $r = 0.8304$, $LD_{50} = 148.3$ ng/male). As a result, we used 30, 60, 90, 120, and 150 ng/male as sublethal doses in our experiments. Mortality ranging from 1% to 50% was observed within 96 hr after treatment. Only those survivors that did not show any abnormal behaviors were used for bioassays.

Procedure for Testing Insect Behavior. The behavioral responses of male moths to sex pheromones were observed in a wind tunnel by using the method of Zhou and Du (1999). For all tests, the wind tunnel conditions were 0.3 lux, 25 ± 2°C, 60–80% RH, and 0.3 m/sec wind speed. Males for testing were placed into individual screen cages [5 cm (diam.) × 10 cm (height)] with screen lids. Caged males were transferred 1 hr before the assay from their rearing room to the darkened room housing the wind tunnel. Assays were run 6–8 hr after the onset of scotophase, and each male was used once. Individual males were

released from a steel screen platform 28 cm above the floor of the wind tunnel and 2 m directly downwind from the pheromone source. Males were allowed 2 min to respond and were scored for the following behaviors: taking flight (TF), stationary orientation (OR), upwind flight (UF), and source contact (SC). Responses of at least 20 males were recorded for each test. The experiment was repeated three times. The pheromone source was a rubber septum impregnated with 100 μg of a 1:1 (*E*/*Z*) blend of the pheromone components, which was the most effective blend in previous tests (Zhou and Du, 1999).

Electroantennogram (EAG) Responses. EAGs were recorded using the methods of Du (1988), except that a block of hollow metal was used to hold the electrodes. All male moths tested were 2-d-old and were 6–7 hr into scotophase. The antennal flagellum was cut off with microscissors. The distal one to two segments of the antenna were removed and the antenna was rapidly mounted on the electrodes. Air (2 l/min) was delivered from a stream blown constantly over the antenna during the test period. The distance from air stream to antenna was 2 cm. Compounds tested were placed on 6-mm-diam circles of filter paper. After the solvent evaporated, the filter paper was held for 2 min, and then placed into the air stream 1 cm above the air stream outlet. A paper treated with solvent only was used as control. Each treatment was tested on nine antennae.

Data Analysis. Microsoft Excel 97 and Statistica for Windows™ 4.2 were used for ANOVA and regression analysis. Levels of statistical significance were estimated by arcsine square root permutation of the percent data to normalize the distribution.

RESULTS

Doses of 30 and 60, 90 and 120, and 150 ng/moth corresponded to 96 hr mortality of 1–20%, 20–40%, and 40–50%, respectively. The time required for *O. furnacalis* males to take flight was significantly increased by all doses of malathion tested, and the increase was positively related to malathion dose (Figure 1). At the LD_{50} of 150 ng/moth, it took 12 times longer for treated males to take flight than controls.

Sublethal doses of malathion adversely affected several other stages in the responses of Asian corn borer males to sex pheromones (Table 1). The TF, OR, and UF behaviors of males treated with lower dosages (30 and 60 ng/moth) were slightly affected, whereas males treated with the higher dosages (90 ng/moth or above) showed significantly lower response rates in these three stages than those in the control. Given that the TF rate was 100% in the control, males treated with 150 ng/moth were 84% less likely to take flight, 89% less likely to orient to the pheromone source, 90% less likely to fly upwind, and 96%

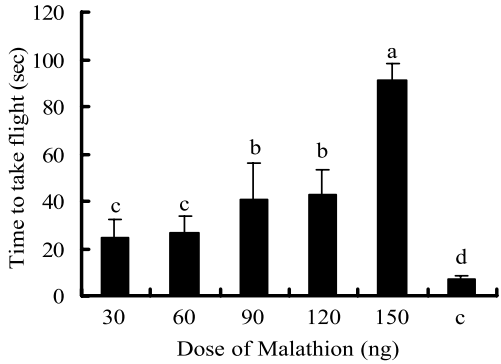

FIG. 1. Mean time required for male Asian corn borers to take flight towards a pheromone source after treatment with different doses of malathion. Males treated with 1 μl of acetone were used as control (C). Bars labeled with different letters differ significantly (LSD test, $P < 0.05$). Error bars represent 95% confidence intervals.

less likely to contact the pheromone source. In the tested dosage series, even at the dose of 30 ng/moth, SC behavior was 60% less likely than in the control. No significant differences in male responses to sex pheromone were found in males at different times after treatment with sublethal doses of malathion (Table 2).

A multiple linear regression was used to test the coeffect of the doses and time since treatment with sublethal malathion on male response to pheromone (Table 3). The results showed that the linear correlation was significant in

TABLE 1. EFFECT OF SUBLETHAL DOSAGES OF MALATHION ON THE BEHAVIORAL RESPONSES OF MALE ASIAN CORN BORER TO SEX PHEROMONE IN A WIND TUNNEL

	Percentage of behavioral response (%)[a]			
Dosage (ng/male)	TF	OR	UF	SC
30	95 ± 2ab	62 ± 3a	45 ± 4ab	13 ± 3bc
60	97 ± 2a	60 ± 5a	47 ± 2ab	20 ± 1b

[b] The 3-d-old males treated with 1 μl of acetone were used as control.

taking flight, orientation, and upwind flight ($P < 0.01$), and in source contact ($P < 0.05$). There was no significant correlation between response rates and the time since treatment (absolute value of r_y lower than $r_{1,23,\ 0.05\ =\ 0.396}$) although the response rates were significantly correlated with the doses ($P < 0.01$ each absolute value of r_x was more than $r_{1,23,0.01\ =\ 0.505}$; see Table 3). The standard regression coefficients (B_x, B_y) further suggested that the decrease in the response to pheromone was mainly caused by the dosages of malathion applied. The regression coefficients for the doses tested, at the stages of taking flight, orientation, upwind flight, and source contact, declined gradually in absolute value. This suggested that the later the stage in the flight sequence, the smaller the response rate with increasing sublethal dose of malathion.

TABLE 3. COEFFICIENTS FOR THE REGRESSION EQUATIONS

Behavior	R	r_x	r_y	b	B_x	B_y
