Abstract Feeding larvae of *Chrysomela lapponica* (Coleoptera: Chrysomelidae) acquire characteristic *O*-glucosides from the leaves of their food plants. The glucosides are selectively channeled from the gut to the defensive gland. Subsequent enzymatic transformations generate a blend of different defensive compounds, e.g., salicylaldehyde and two series of 2-methylbutyl and isobutyryl esters. By using systematically modified and hydrolysis-resistant thioglucosides as structural mimics of the plant-derived glucosides, e.g., salicin and its *o*-, *m*-, and *p*-isomers 1, 2, and 3; *o*-, *m*-, and *p*-cresols 5, 6, 7; along with thioglucosides of 2-phenylethanol 9 and (3*Z*)-hexenol 10, we demonstrated that the larvae of *C. lapponica* are able to sequester a broad range of structurally different thioglucosides with comparable efficiency. This sharply contrasts with the sequestration habitus previously observed in *Chrysomela populi* and *Phratora vitellinae*, which secrete almost pure salicylaldehyde and posses a highly specific transport mechanism for salicin (Kuhn et al., Proc. Natl. Acad. Sci. USA 101:13808–13813, 2004). Also, neither *C. lapponica* nor *C. populi*

sequester in their gland the thioglucoside of 8-hydroxygeraniol, the mimic of the glucoside specifically transported by larvae secreting iridoid monoterpenes (*Phaedon cochleariae*, *Gastrophysa viridula*). Accordingly, leaf beetle larvae possess selective membrane carriers in their gut and their defensive systems that match the orientation of the functional groups of glucosides from their food plants probably by embedding the substrate in a network of hydrogen bonds inside the membrane carriers. The synthesis and the spectroscopic properties of the test compounds along with a comparative evaluation of the transport capabilities of larvae of *C. populi* and *C. lapponica* are described.

Introduction

Sequestration of plant toxins or pretoxins is widespread among insects (pyrrolizidines: Hartmann and Witte, 1995; cardenolides: Malcolm and Brower, 1989; iridoid glycosides: Dyer and Bowers, 1996; cyanogenic glycosides: Nahrstedt, 1996; glucosinolates: Nishida, 2002), but only little is known on the functional molecular basis of the uptake process. Leaf beetles offer excellent opportunities to explore this process, as sequestered compounds are often stored and concentrated in easily accessible reservoirs, in which final transformations occur. Larvae of chrysomeline leaf beetles possess pairs of dorsal defensive glands in the mesothorax and metathorax and the abdominal segments one to seven. When the larvae are disturbed, the reservoirs are everted by blood pressure and small droplets of a defensive secretion appear on top. As soon as the danger is over, the reservoirs are pulled back within the body cavity by muscle fibers and the remaining secretion is sucked back into the reservoir. Although this basic structure is fairly constant across taxa (Hollande, 1911; Garb, 1915; Paterson, 1930; Berti, 1968), the secreted toxins vary both in structure and biosynthetic origin (Fig. 1).

Several species secrete iridoid monoterpenes, e.g., chrysomelidial (Meinwald et al., 1977; Blum et al., 1978; Pasteels et al., 1982; Lorenz et al., 1993; Veith et al., 1994), which are generally synthesized *de novo* by the insect (Oldham et al., 1996; Søe et al., 2004). Species that specialize on Salicaceae, i.e., *P. vitellinae* and *Chrysomela* spp., derive salicylaldehyde from plant phenolglucosides, such as salicin and salicortin (Pavan, 1953, Pasteels et al., 1983). Particularly diverse is the defensive chemistry of the larvae of *Chrysomela lapponica* feeding on willow and poplar. Prominent series of compounds are isobutyrates or 2-methylbutyrates of 2-phenylethanol, (3*Z*)-hexenol, or benzylalkohol, respectively (Hilker and Schulz, 1994; Schulz et al., 1997; Termonia and Pasteels, 1999). The advantage of using plant-derived, glycosidically bound precursors is obvious. The compounds are often abundant in the leaves of the food plant, they are mostly non toxic *per se*, but can be readily cleaved into toxic aglycons or compounds that can be converted into toxic principles by common enzymatic activities. The glycosides are polar precursors that cannot pass membranes without the involvement of functional transport systems, and leaf beetle larvae have evolved selective transport systems that allow a channeling of certain plant-derived glucosides through the gut membrane into the defensive gland via hemolymph transport. For example, larvae of *Chrysomela populi* and *Phratora vitellinae* specifically import salicin (Feld et al., 2001; Kuhn et al., 2004). Final transformations of the glucosides into the actual defensive compounds occur within the gland (Pasteels et al., 1990; Daloze and

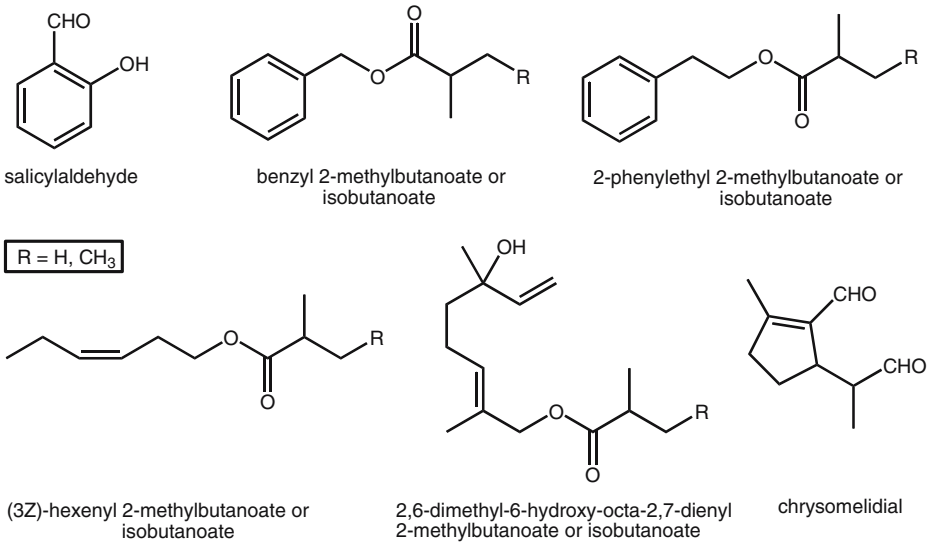

Fig. 1 Selected defense compounds from leaf beetles larvae

Pasteels, 1994; Oldham et al., 1996). As illustrated in Fig. 2, the glucosides are assumed to be selected from the food by selective carrier systems located in the gut membrane that load the glucosides into the epithelial cells, followed by export to the hemolymph. A second system shuttles the glucoside from the hemolymph to the reservoir, and here all subsequent steps of toxification can occur with strict separation from the body tissue. Besides import systems for plant-derived compounds, export systems should also exist that keep the hemolymph level of the imported molecules low to prevent an uncontrolled pretoxin accumulation in the insect body. Altogether, a network of selective and well-balanced import and export systems that facilitate the sequestration of glycosides could safely guide polar glucosides from the gut to the defensive gland.

C. lapponica is remarkable in that it is distributed into isolated populations adapted to different host plants. Larvae from Bavaria and Czech Republic feed on *Betula* and secrete complex mixtures of compounds, including series of isobutyrates and 2-methylbutyrates (Hilker and Schulz, 1994; Gross and Hilker, 1995), whereas larvae from Finland feeding on *Salix borealis*, a plant rich in phenolglucosides, have been reported to produce nearly pure salicylaldehyde (Gross and Hilker, 1995).

The current work addresses and compares the molecular basis and the selectivity of the sequestration processes in the two species *C. populi* and *C. lapponica*. Because the plant-derived *O*-glucosides are rather unstable compounds that are easily cleaved by glucosidases in the insect gut, we selected the hydrolysis-resistant *S*-glucosides instead of the natural *O*-glucosides to study the mode of their transport from the gut to the defensive gland. The glycomimics are stable against the glucosidases in the gut and the gland, and they accumulate in the reservoir where they can be easily quantified by high-performance liquid chromatography–mass spectrometry (HPLC–MS; Feld et al., 2001). We report on the synthesis of thioanalogues of salicin and several other analogues that were designed to provide information on the selectivity of the uptake of the plant-derived glucoside. Finally, we demonstrate that the larvae of *C. lapponica* possess transport systems with a higher

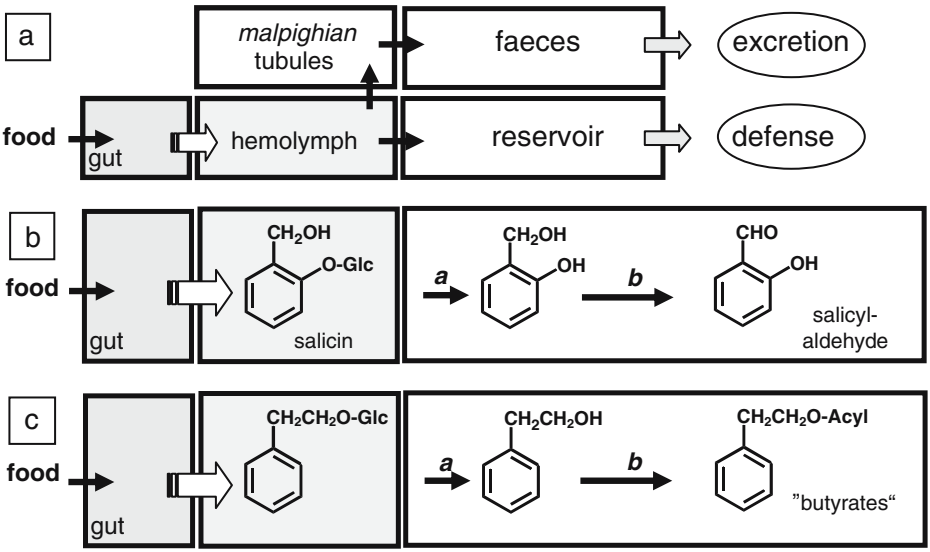

Fig. 2 (a) Transport pathways of plant-derived glucosides in the larvae of leaf beetles. Shown is the passage of glucosides from the gut into the defensive gland. At least two transport systems, from the gut to hemolymph (transport system I) and from hemolymph to the reservoir (transport system II), are necessary for sequestration. A third system may exist to excrete excess or wrong glucosides from the hemolymph to the feces. (b) Sequestration and transformation of salicin by larvae of *C. populi*. (c) Sequestration and transformation of, e.g., the glucoside of 2-phenylethanol by larvae of *C. lapponica*. After cleavage of the glucoside (a: glucosidase), the aglycon salicylalcohol (b: oxidase) is converted into salicylaldehyde (modified from Kuhn et al., 2004)

substrate tolerance, albeit with a lower overall import rate for individual compounds than those previously observed in other leaf beetle larvae.

Methods and Materials

General

Reactions were performed under Ar. Solvents were dried according to standard methods. IR: Bruker Equinox 55 FTIR Spectrophotometer. ^{1}H and ^{13}C nuclear magnetic resonance (NMR): Avance DRX 500 spectrometer; $CDCl_3$ as solvent, if not stated otherwise. Chemical shifts of ^{1}H and ^{13}C NMR are given in ppm (δ) downfield relative to TMS as internal standard. Gas chromatography (GC)–MS (70 eV): Finnigan Magnum, equipped with a fused silica capillary, coated with DB5 (30 m×0.25 mm); helium served as carrier gas. HR–MS: high-resolution GC–MS was performed on a Micromass MasSpec (Micromass, Manchester, UK) double-focusing magnetic sector mass spectrometer (geometry EBE) via solid probe. Mass spectra were measured in electron impact (EI) mode at 70 eV, with a source temperature of 200°C, an acceleration voltage of 8 kV, and a resolution of 5000. The mass range was scanned between *m*/*z* 35 and *m*/*z* 300 at 1 scan sec^{-1}. Perfluorokerosene (PFK, Aldrich, D-82041 Deisenhofen, Germany) served for calibration. Silica gel: Si 60 (0.200–0.063 mm, E. Merck, Darmstadt, Germany) was used for chromatography. Thin layer chromatography was performed with silica gel plates from Merck (60 F_{256}).

Collection and Rearing of Insects

Egg-laying *C. lapponica* were collected near Saint-Veran (Queyras, France) on *Salix breviserrata*. Neonate larvae were reared in Jena at 18°C with a photophase of 16 hr on *S. caprea* leaves until the third instar. *S. caprea* was selected because of its very low content in phenolglucoside in its leaves. As a consequence, larval secretion is not dominated by salicylaldehyde, allowing an easier detection of the other compounds.

Administration of Thioglucosides to Feeding Larvae

Leaves from *S. caprea* were painted on the upper side with 0.5 ml of MeOH/H_2O (1:1, v/v, 25 μmol ml^{-1}) containing the test compound at a concentration of 25 mM. After evaporation of the solvent, third instars (four larvae per ca. 35 cm^{-2} leaf segment) were allowed to feed on the treated leaves for 48 hr, followed by sampling of defensive secretion and hemolymph. The defensive secretion was withdrawn with a small capillary from the everted glands of four larvae. The entire operation was conducted under a binocular while the larvae were gently squeezed by tweezers to provoke extrusion of the dorsal reservoirs. To avoid contamination with material from the leaf surface adhering to the larval body, the secretion was collected only from the tip of the everted glands. Hemolymph was obtained most conveniently from larvae that were previously killed by cooling to −20°C for 30 min. The surface of the larvae was cleaned by brief dipping into water (three times), followed by clipping of a single leg. The emerging hemolymph was collected with a small capillary. The collected secretion or hemolymph was determined by weighing the capillaries before and after collection. Weighing was repeated three times to minimize errors. Defensive secretions or hemolymph were transferred into MeOH/H_2O (1:1, v/v, 40 μl). Following centrifugation, the supernatant was directly analyzed by liquid chromatography (LC)–MS.

Analysis of Thioglucosides by LC–MS

To monitor and quantify the polar thioglucosides in the defensive secretion or the hemolymph, a combination of reversed-phase HPLC and mass spectrometry was used. Analyses were carried out using a Thermoquest LCQ (Thermoquest, D-63329 Egelsbach, Germany) in the APCI mode (vaporizer temperature: 560°C) connected to an Agilent HP1100 HPLC system equipped with an RP18 column, GROM-SIL ODS-3 CP (125× 2 mm, 3 μm; Grom Chromatography GmbH, D-72108 Rottenburg-Hailfingen, Germany), and GROM-SIL ODS-7 ph (125×2 mm, 4 μm). Samples were analyzed by using gradient elution at 0.25 ml min^{-1} (solvent A: H_2O+0.5% CH_3COOH; solvent B: MeCN+0.5% CH_3COOH) according to the following protocol: starting with 2% B, then after 20 min to 100% B maintained for 8 min, and 2% B for 5 min before recycling. UV detection before the mass spectrometer allowed a convenient and reliable quantification of the thioglucosides (λ_{max}=224 nm, 254 nm). Standard curves were recorded for **1** to **11** and used for calibration (Figs. 4 and 5). Abundance was expressed as nanomoles of compound per milligram of sample (undiluted secretion or hemolymph). The threshold of detection was set to 1 nmol mg^{-1} thioglucoside in secretion. Quantification by UV was particularly valuable for the quantification of acylated thioglucosides in the defensive secretion of larvae of *C. lapponica.* Acylated thioglucosides displayed significant differences in their response based on mass spectrometry; calibration was achieved by using synthetic references (unpublished).

Statistics

Data are presented as mean values±standard deviation (Sachs, 1999). Outliers according to Grubbs test were eliminated. To obtain valid data, feeding experiments were repeated several times. *C. populi*: compounds **1** and **4** ($N=10$); **11** ($N=7$); **8** ($N=6$); **10**, **5**, and **2** ($N=5$); **9** and **3** ($N=4$); **7** and **6** ($N=3$). *C. lapponica*: compounds **10** and **9** ($N=10$); **5**, **2**, **1**, and **4** ($N=9$); **11** ($N=8$). In all experiments, *post hoc* multiple comparisons (Tamhane's T2 test, SPSS) were carried out to evaluate significant differences ($P<0.05$) between secretion samples. The hemolymph samples were not treated statistically owing to the low concentrations at the limit of the analytical approach.

Synthesis of Thioglucosides. Königs–Knorr Approach to Acetylated Aromatic Thioglucosides: General Procedure

A solution of 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (0.824 g, 2.0 mmol), triethylamine (560 µl, 4 mmol), and the respective aromatic thiol (2.0 mmol) in acetonitrile (4.0 ml) was stirred under argon for 2 hr at room temperature. Trichloromethane (50 ml) was added and the organic layer was thoroughly washed with water (3×10 ml). Removal of solvent ($CHCl_3$) afforded the per-acetylated thioglucoside as a light-brown oil. The product was dissolved in a small amount of warm ethanol and filtered, affording white crystals upon cooling. Spectroscopic data for the acetylated thioglucoside intermediates **12** to **21** are given in the Supplementary Material.

2-Methoxycarbonyl-phenyl-2',3',4',6'-tetra-O-acetyl-1'-thio-β-D-glucopyranoside (**12**)

Prepared from 2-mercapto-benzoic acid methyl ester (1.5 ml, 8.9 mmol), triethylamine (3.0 ml), and 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (4.08 g, 9.92 mmol) as described. Yield: 4.48 (8.99 mmol, 91%).

3-Methoxycarbonyl-phenyl-2',3',4',6'-tetra-O-acetyl-1'-thio-β-D-glucopyranoside (**13**)

Prepared from 3-mercapto-benzoic acid methyl ester (336 mg, 2.0 mmol), triethylamine (560 µl), and 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (824 mg, 2.0 mmol) as described. Yield: 917 mg (1.84 mmol, 93%).

4-Methoxycarbonyl-phenyl-2',3',4',6'-tetra-O-acetyl-1'-thio-β-D-glucopyranoside (**14**)

Prepared from 4-mercapto-benzoic acid methyl ester (0.336 g, 2.0 mmol), triethylamine (560 µl) and 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (0.824 g, 2.0 mmol) as described. Yield: 0.625 g (1.25 mmol, 63%).

Phenyl-2',3',4',6'-tetra-O-acetyl-1'-thio-β-D-glucopyranoside (**15**)

Prepared from thiophenol (615 µl, 6.0 mmol), triethylamine (1.68 ml), and 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (2.472 g, 6.0 mmol). Yield: 2.421 g (5.5 mmol, 92%).

2-Methyl-phenyl-2',3',4',6'-tetra-O-acetyl-1'-thio-β-D-glucopyranoside (**16**)

Prepared from 2-methyl-benzenethiol (0.242 g, 2.0 mmol), triethylamine (560 µl), and 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (0.824 g, 2.0 mmol). Yield: 0.772 g (1.7 mmol, 85%).

3-Methyl-phenyl -2',3',4',6'-tetra-O-acetyl-1'-thio-β-D-glucopyranoside (**17**)

Prepared from 3-methyl-benzenethiol (0.248 g, 2.0 mmol), triethylamine (560 µl), and 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (0.824 g, 2.0 mmol) as described. Yield: 0.757 g (1.67 mmol, 83%).

4-Methyl-phenyl -2',3',4',6'-tetra-O-acetyl-1'-thio-β-D-glucopyranoside (**18**)

Prepared from 4-methyl-benzenethiol (0.246 g, 2.0 mmol), triethylamine (560 µl), and 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide (0.824 g, 2.0 mmol) as described. Yield: 0.764 g (1.68 mmol, 84%).

2-Methoxycarbonyl-phenyl-2',3',4',6'-tetra-O-acetyl-1'-thio-β-D-galactopyranoside (**19**)

Prepared from 2-mercapto-benzoic acid methyl ester (300 µl, 2.0 mmol), triethylamine (560 µl), and 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide (824 mg, 2 mmol) as described. The crude product was purified instantly by flash-chromatography (flash silica 32–63 µm, 60 Å pore size), using a solvent mixture of petroleum ether (100–0%) and diethyl ether (0–100%). The product eluted at a solvent ratio of ca 1:4 and was monitored by TLC (silica gel 60, F254). Yield: 0.499 g (1.0 mmol, 50%).

Mitsunobu-Type Synthesis of Acetylated Thioglucosides **20** and **21**: General Procedure

To a solution of carefully dried ADDP (0.504 g, 2.0 mmol) in dry tetrahydrofurane (40 ml) was added with cooling (0°C) a solution of trimethylphosphane (2.0 ml, 1 M in tetrahydrofurane). The mixture was stirred at room temperature until the color turned from orange to light yellow. Then, 2,3,4,6-tetra-*O*-acetyl-thio-α-D-glucopyranose (0.472 g, 1.3 mmol) and a solution of the respective aglycon (1.0 mmol) in tetrahydrofurane (20 ml) were added with stirring at room temperature. A white precipitate occurred and after 2 hr the solvent was removed. The residue was dissolved in the minimum amount of ethyl acetate and the hydrazide was precipitated with petroleum ether. Solids were removed by filtration and the solvent was evaporated under reduced pressure. The crude product was dissolved in dichloromethane (50 ml) and washed with water (2×25 ml) and a saturated solution of $NaHCO_3$ (25 ml) solution. The product was purified by flash chromatography on silica gel using a binary solvent mixture (ethyl acetate/petroleum ether, 1:1) for elution.

2-Phenethyl-2',3',4',6'-tetra-O-acetyl-1'-thio-β-D-glucopyranoside (**20**)

Prepared from 2,3,4,6-tetra-*O*-acetyl-thio-α-D-glucopyranose (1.42 g, 3.9 mmol) and 2-phenylethanol (0.366 g, 3.0 mmol) as described. Yield: 0.37 g (1.65 mmol, 55%).

(3Z)-Hex-3-enyl-2',3',4',6'-tetra-O-acetyl-1'-thio-β-D-glucopyranoside (**21**)

Prepared from 2,3,4,6-tetra-*O*-acetyl-thio-α-D-glucopyranose (0.472 g, 1.29 mmol) and (3*Z*)-hex-3-en-1-ol (0.10 g, 1.0 mmol) as described. Yield: 0.366 g (0.82 mmol, 82%).

Reductive Deprotection of the Thioglucosides **12**, **13**, and **14**: General Procedure

A solution of the acetylated thioglucosides **12**, **13**, or **14** (1.0 mmol) in dry tetrahydrofurane (15 ml) was added slowly to a cooled and well stirred suspension of $LiAlH_4$ [0.12 g, 3.2 mmol in the same solvent (15 ml) kept under argon]. The reaction mixture was heated to reflux for 2 hr. After cooling (0°C), excess $LiAlH_4$ was hydrolyzed by sequential addition of water (0.15 ml), 15% $NaOH_{(aq)}$ (0.15 ml), and water (0.45 ml). The resulting solid was removed by filtration. After removal of the solvent, the crude thioglucoside was purified by medium pressure liquid chromatography (MPLC) on reversed phase (RP 18 LiChroprep 40–63 μm; column 3.2 cm ID×23 cm length) using a solvent gradient for elution. For elution, a binary mixture of water (60%) and methanol (40%) was ramped within 20 min to pure methanol. Flow rate: 35 ml min^{-1} at 20 bar. The elution of products was monitored by UV at 254 nm.

2-Hydroxymethyl-phenyl-1'-thio-β-D-glucopyranoside (**1**)

Prepared from **12** (0.50 g, 1.0 mmol) by reduction with $LiAlH_4$ (0.120 g, 3.16 mmol) as described. Yield: 0.147 g (0.49 mmol, 50%). M.p.: 199.1°C. UV λ_{max} [nm]: 205 ^{1}H NMR (CD_3OD) δ [ppm]: 7.74 (dd, *J*=7.6, 1.3, 1H), 7.46 (dd, *J*=7.6, 1H), 7.32 (td, *J*=7.5, 1.4, 1H), 7.27 (td, *J*=7.5, 1.5, 1H), 4.88 (d, *J*=12.8, 1H), 4.74 (d, *J*=12.8, 1H), 4.49 (d, *J*=9.8, 1H), 3.85 (dd, *J*=11.9, 2.1, 1H), 3.65 (dd, *J*=12.2, 5.5, 1H), 3.36 (dd, *J*=8.7, 1H), 3.30–3.22 (m, 2H), 3.16 (dd, *J*=9.6, 8.7). ^{13}C NMR (CD_3OD) δ [ppm]: 144.9, 135.8, 132.8, 129.8, 129.5, 129.2, 89.8, 82.2, 79.7, 73.8, 71.5, 63.8, 63.0. IR (KBr) ν [cm^{-1}]: >3200, 3100, 3063, 3052, 2943, 2887, 1587, 1473, 1459, 1445, 1429, 1365, 1332, 1246, 1213, 1180, 1103, 1086, 1070, 1037, 1000, 751. MS (70 eV) *m/z* (%): 302(6); 145(25); 140(82); 123(40); 122 (100); 121(51); 87(28); 85(42); 77(33); 73(41); 57(29). HR–MS *m/z* [M^+]: calcd. for $C_{13}H_{18}O_6S$ 303.082410; found 303.082832.

3-Hydroxymethyl-phenyl-1'-thio-β-D-glucopyranoside (**2**)

Prepared from **13** (0.50 g, 1.0 mmol) by reduction with $LiAlH_4$ (0.120 g, 3.16 mmol) as described. Yield: 0.119 g (0.40 mmol, 40%). UV λ_{max} [nm]: 201, 251. ^{1}H NMR (D_2O) δ [ppm]: 7.60 (s, 1H), 7.55 (d, *J*=7.8, 1H), 7.30 (dd, *J*=7.9, 7.7, 1H), 7.24 (d, *J*=7.8, 1H), 4.69 (d, *J*=9.8, 1H), 4.52 (s, 2H), 3.78 (dd, *J*=12.5, 2.1, 1H), 3.60 (dd, *J*=12.5, 5.8, 1H), 3.42 (t, *J*=9.2, 1H), 3.38 (ddd, *J*=9.8, 6.0, 2.1, 1H), 3.30 (t, *J*=9.4, 1H), 3.24 (t, *J*=9.4, 1H). ^{13}C NMR (D_2O) δ [ppm]: 142.7, 133.6, 131.9, 131.4, 130.7, 128.2, 88.4, 81.2, 78.5, 73.0, 70.6, 64.7, 62.1. IR (KBr) ν [cm^{-1}]: >3100, 2925, 2853, 1269, 1120, 1016. MS (70 eV) *m/z* (%): 302(2), 162 (6), 145(14), 141(8), 140(100), 139(5), 127(9), 123(7), 109 (5), 107(7), 97(5), 91(9), 87(14), 85(20), 79(7), 77(11), 73(17). HR–MS *m/z* [M^+]: calcd. for $C_{13}H_{18}O_6S$ 302.082410; found 302.082123.

4-Hydroxymethyl-phenyl-1'-thio-β-D-glucopyranoside (**3**)

Prepared from **14** (0.475 g, 0.95 mmol) by reduction with $LiAlH_4$ (0.120 g, 3.16 mmol) as described. Yield: 0.165 g (0.55 mmol, 57%). M.p.: 77°C. UV λ_{max} [nm]: 201, 252. ^{1}H NMR (D_2O) δ [ppm]: 7.46 (d, J=8.2, 2H), 7.27 (d, J=8.2, 2H), 4.67 (d, J=10.1, 1H), 4.52 (s, 2H), 3.78 (dd, J=12.4, 1.7, 1H), 3.60 (dd, J=12.4, 5.6, 1H), 3.41 (t, J=9.0, 1H), 3.37 (ddd, J=10.0, 5.9, 1.0, 1H), 3.29 (t, J=9.6, 1H), 3.23 (dd, J=9.5, 9.6, 1H). ^{13}C NMR (D_2O) δ [ppm]: 142.9, 134.5, 133.9, 130.8, 89.9, 82.6, 79.9, 74.4, 72.0, 66.0, 63.5. IR (KBr) ν [cm^{-1}]: >3100, 2893, 2449, 2363, 1489, 1405, 1275, 1035, 860, 800. MS (70 eV) *m/z* (%): 302(3), 145(14), 142(5), 141(8), 140(100), 139(5), 127(10), 123(9), 122(7), 111(8), 109(4), 107(13), 97(6), 91(8), 87(12), 85(21), 79(8), 78(4), 77(12), 73(17), 71(3), 69(9), 61(10), 60 (9), 57(6). HR–MS *m/z* [M^+]: calcd. for $C_{13}H_{18}O_6S$ 302.082410; found 302.082756.

2-Hydroxymethyl-phenyl-1'-thio-β-D-galactopyranoside (**4**)

Prepared from **19** (0.556 g, 1.0 mmol) by reduction with $LiAlH_4$ (0.120 g, 3.16 mmol) as described. The product was separated from the solid by 12-hr continuous extraction with diethyl ether. After removal (rotavapor) of the solvent (tetrahydrofuran), the crude thiogalactoside was purified by MPLC on reversed phase (RP 18, LiChroprep 40–63 μm; column 3.2 cm ID×23 cm length) using a mixture of water (60–0% in 20 min) and methanol (40–100% in 20 min) for elution. Flow rate: ca. 35 ml/min (ca. 20 bar). The eluting product was monitored by UV at 254 nm. Yield: 0.165 g (0.55 mmol, 55%). M.p.: 158°C. UV λ_{max} [nm]: 201, 250. ^{1}H NMR (CD_3OD) δ [ppm]: 7.78 (dd, J=7.7, 1.3, 1H), 7.49 (dd, J=7.5, 1.3, 1H), 7.35 (td, J=7.5, 1.3, 1H), 7.30 (td, J=7.5, 1.5, 1H), 4.89 (d, J= 13.1, 1H), 4.79 (d, J=12.9, 1H), 4.51 (d, J=9.8, 1H), 3.91 (dd, J=3.6, 0.8, 1H), 3.79 (dd, J=11.5, 6.8, 1H), 3.73 (dd, J=11.3, 5.2, 1H), 3.60 (t, J=9.4, 1H), 3.56 (dd, J=5.4, 1.0, 1H), 3.55 (dd, J=5.8, 0.6, 1H), 3.51 (dd, J=9.2, 3.2, 1H). ^{13}C NMR (CD_3OD) δ [ppm]: 144.8, 135.2, 133.6, 129.6, 129.2, 90.8, 80.7, 76.3, 71.1, 70.5, 63.8, 62.7. IR (KBr) ν [cm^{-1}]: >3100, 2940, 2917, 2886, 1417, 1130, 1085, 1045, 1009, 950, 860, 820, 802, 758. MS (EI) *m/z* (%): 302(15), 140(71), 123(33), 122(100), 121(41), 91(46), 85(28), 77(22),73 (55), 69(16), 61(21), 57(24). HR–MS *m/z* [M^+]: calcd. for $C_{13}H_{18}O_6S$ 303.082410; found 303.082154.

Base-Catalyzed Deacetylation of Thioglucosides **15**, **16**, **17**, and **18**: General Procedure

A solution of the acetylated thioglucosides **15**, **16**, **17**, or **18** (0.73 mmol) in methanol (10 ml) is treated with sodium methoxide (0.01 ml of a 30% soln., 3.0 mmol) and stirred for 12 hr at room temperature. After neutralization with amberlite IRC50, the product is purified by MPLC on reversed phase (RP-18, Büchi column no. 17982) using a binary solvent of MeOH/H_2O (3:2) for isocratic elution or high-speed countercurrent chromatography (Triple Coil, P.C., Inc., $CHCl_3$/MeOH/H_2O (7:13:8), S_f = 0.8).

Phenyl-1'-thio-β-D-glucopyranoside (**8**)

Prepared from **15** (2.42 g, 5.50 mmol) as described. Yield: 0.94 g (3.45 mmol, 63%). Mp: 113°C. UV λ_{max} [nm]: 204, 3. ^{1}H NMR (CD_3OD) δ [ppm]: 7.58 (dd, J=8.2, 1.2, 2H), 7.32 (dd, J=8.5, 7.0, 2H), 7.27 (tt, J=7.2, 1.1, 1H), 4.50 (d, J=9.8, 1H), 3.89 (dd, J=12.2, 2.1,

1H), 3.57 (dd, *J*=12.2, 5.3, 1H), 3.41 (t, *J*=8.7, 1H), 3.35 (ddd, *J*=9.6, 5.5, 2.1, 1H), 3.32 (t, *J*=9.3, 1H), 3.25 (dd, *J*=9.6, 8.7, 1H). ^{13}C NMR (CD_3OD) δ [ppm]: 135.5, 132.9, 130.1, 128.6, 89.6, 82.3, 79.9, 74.0, 71.6, 63.1. IR (KBr) ν [cm^{-1}]: >3100, 2972, 2931, 2900, 2528, 1582, 1482, 1438, 1384, 1271, 1123, 1045, 876, 819, 738, 687. MS (70 eV) *m/z* (%): 272(3), 145(18), 127(11), 111(10), 110(100), 109(12), 97(6), 91(7), 87(14), 85(23), 77(7), 73(18), 69(10), 66(5), 65(5), 61(11), 60(5), 61(11), 60(5),57(11). HR–MS *m/z* [M^+]: calcd. for $C_{12}H_{16}O_5S$ 272.071846; found 272.071877.

2-Methyl-phenyl-1'-thio-β-D-glucopyranoside (**5**)

Prepared from **16** (0.450 g, 0.99 mmol) as described. Yield: 0.278 g (0.97 mmol, 98). UV λ_{max} [nm]: 210,3. ^{1}H NMR (CD_3OD) δ [ppm]: 7.52 (dd, *J*=7.2, 1.7, 1H), 7.21 (dd, *J*=7.8, 1.4, 1H), 7.18 (td, *J*=7.2, 1.9, 1H), 7.15 (td, *J*=7.4, 1.8, 1H), 4.69 (d, *J*=10.1, 1H), 3.78 (dd, *J*=12.5, 2.1, 1H), 3.60 (dd, *J*=12.5, 5.5, 1H), 3.35 (t, *J*=8.7, 1H), 3.48 (ddd, *J*=9.6, 5.5, 2.1, 1H), 3.45 (d, *J*=6.1, 1H), 3.43 (dd, *J*=8.5, 7.6, 1H), 2.42 (s, 3H). ^{13}C NMR (CD_3OD) δ [ppm]: 140.0, 135.2, 132.7, 131.1, 128.2, 127.7, 89.3, 82.0, 79.7, 74.2, 71.4, 62.9, 21.1. IR (KBr) ν [cm^{-1}]: >3100, 2925, 1589, 1466, 1363, 1272, 1228, 1108, 1045, 921, 884, 825, 737, 680. MS (70 eV) *m/z* (%): 286(3), 145(12), 124(100), 97(6), 91(21), 87 (13), 85(22), 73(15), 69(9), 61(10), 57(12). HR–MS *m/z* [M^+]: calcd. for $C_{13}H_{18}O_5S$ 286.087496; found 286.087761.

3-Methyl-phenyl-1'-thio-β-D-glucopyranoside (**6**)

Prepared from **17** (0.476 g, 0.99 mmol) as described. Yield: 0.297 g (1.04 mmol, 99%). M.p.: 91°C. UV λ_{max} [nm]: 203, 250. ^{1}H NMR (CD_3OD) δ [ppm]: 7.36 (s, 1H), 7.30 (d, *J*=7.6, 1H), 7.13 (t, *J*=7.6, 1H), 7.02 (d, *J*=7.6, 1H), 4.54 (d, *J*=10.1, 1H), 3.82 (dd, *J*=12.2, 1.8, 1H), 3.62 (dd, *J*=12.2, 5.5, 1H), 3.35 (t, *J*=8.7, 1H), 3.28 (ddd, *J*=9.2, 5.9, 1.9, 1H), 3.25 (dd, *J*=9.3, 8.7, 1H), 3.18 (dd, *J*=9.8, 8.9, 1H), 2.22 (s, 3H). ^{13}C NMR (CD_3OD) δ [ppm]: 140.1, 135.3, 133.4, 130.0, 129.3, 89.7, 82.3, 79.9, 74.1, 71.7, 63.2, 21.6. IR (KBr) ν [cm^{-1}]: >3100, 2908, 1586, 1473, 1419, 1375, 1280, 1214, 1123, 1067, 890, 828, 772, 688. MS (70 eV) *m/z* (%): 286(4), 145(10), 127(8), 126(5), 125(10), 124 (100), 123(6), 97(5), 91(21), 87(10), 85(18), 73(13), 69(7), 61(9), 57(9). HR–MS *m/z* [M^+]: calcd. for $C_{13}H_{18}O_5S$ 286.087496; found 286.087410.

4-Methyl-phenyl-1'-thio-β-D-glucopyranoside (**7**)

Prepared from **18** (0.459 g, 1.01 mmol) as described. Yield: 0.274 g (0.96 mmol, 96%). M.p.: 148°C. UV λ_{max} [nm]: 201, 250. ^{1}H NMR (CD_3OD) δ [ppm]: 7.37 (d, *J*=8.2, 2H), 7.14 (d, *J*=8.2, 2H), 4.59 (d, *J*=9.8, 1H), 3.77 (dd, *J*=12.5, 2.1, 1H), 3.59 (dd, *J*=12.4, 5.6, 1H), 3.40 (t, *J*=8.9, 1H), 3.33 (ddd, *J*=9.8, 5.5, 2.1 1H), 3.27 (t, *J*=9.6, 1H), 3.21 (q, *J*= 9.0, 1H), 2.22 (s, 3H). ^{13}C NMR (CD_3OD) δ [ppm]: 139.0, 133.8, 131.4, 130.8, 89.9, 82.2, 79.9, 73.9, 71.6, 63.1, 21.4. IR (KBr) ν [cm^{-1}]: >3200, 3021, 2912, 2878, 2641, 1488, 1438, 1388, 1322, 1239, 1211, 1178, 1079, 1045, 868, 807. MS (70 eV) *m/z* (%): 286(6), 145(8), 127(6), 124(100), 123(10), 97(5), 91(22), 87(10), 85(15), 73(13), 69(7), 61(8), 57 (9). HR–MS *m/z* [M^+]: calcd. for $C_{13}H_{18}O_5S$ 286.087496; found 287.087404.

2-Phenyl-ethyl-1'-thio-β-D-glucopyranoside (**9**)

Prepared from **20** (0.773 g, 1.65 mmol) as described. Yield: 0.476 g (1.58 mmol, 96%). UV λ_{max} [nm]: 201, 259. ^{1}H NMR (CD_3OD) δ [ppm]: 7.24–7.17 (m, 4H), 7.17 (tt, J=6.8, 1.8, 1H), 4.37 (d, J=9.5, 1H), 3.87 (dd, J=11.9, 2.1 1H), 3.62 (dd, J=11.9, 5.5, 1H), 3.37–3.37 (m, 1H), 3.31 (t, J=8.7, 1H), 3.27 (ddd, J=9.5, 6.0, 2.4, 1H), 3.21 (dd, J=9.8, 8.5, 1H), 2.99–2.84 (m, 4H). ^{13}C NMR (D_2O) δ [ppm]: 141.2, 129.3, 129.2, 127.1, 85.6, 80.4, 77.8, 73.0, 70.1, 61.5, 36.2, 31.6. HR–MS m/z [M^+]: calcd. for $C_{12}H_{22}O_5S$ 278.118796; found 278.118609.

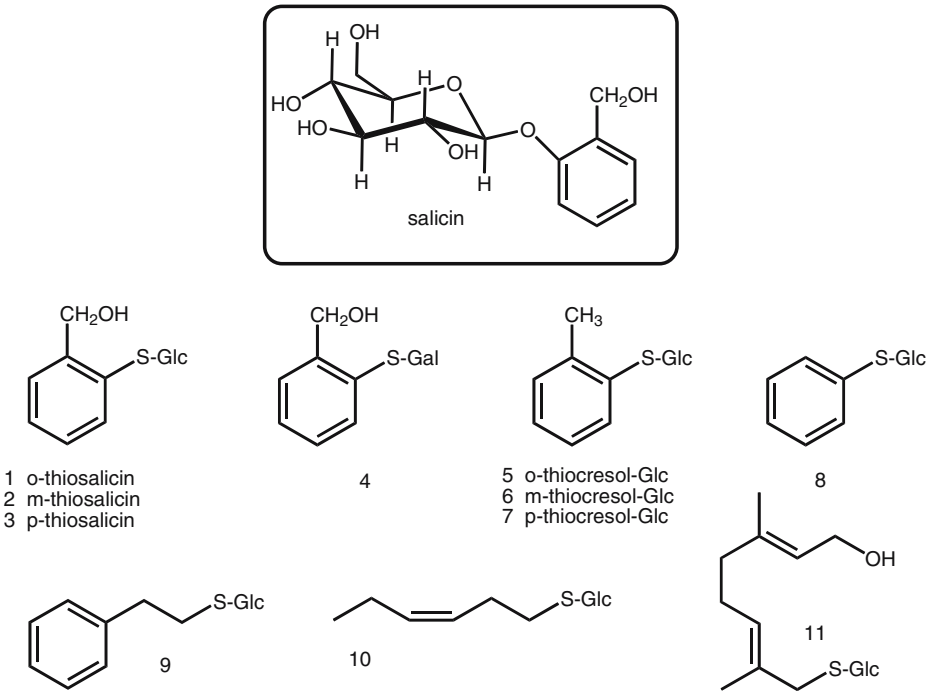
Results



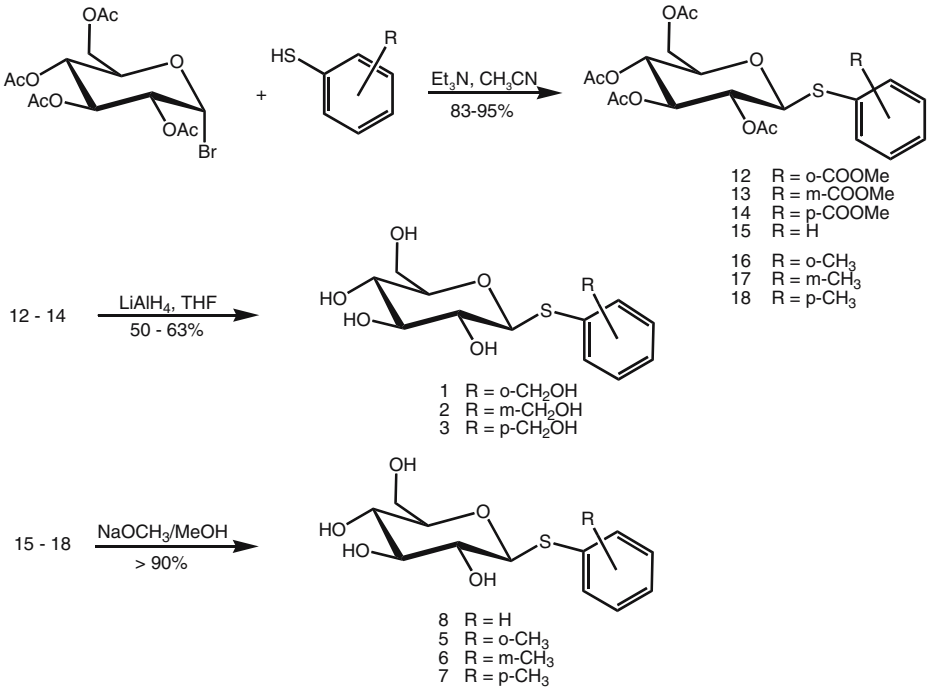
Analysis of the Defensive Secretion of *C. lapponica* Larvae Fed on *S. caprea* (Queyras, France)

Chrysomela lapponica were collected near Saint-Veran, Queyras, France, and their larvae were fed on *S. caprea*. The total ion chromatogram of their exocrine secretion is shown in Fig. 3. For comparison, the secretion of *C. populi* is shown as an insert. Although both species feed on *Salix* spp., generally rich in different phenolglucosides, only the secretion of *C. lapponica* shows a large number of compounds ultimately derived from glucosides of the host plant. A list of the identified compounds of *C. lapponica* comprising salicylaldehyde and of two series of isobutyrates and 2-methylbutyrates of 2-phenylethanol, benzylalcohol, hydroxylinalool, and (3*Z*)-hexenol is given in the legend of Fig. 3. A more detailed analysis will be reported elsewhere.

Synthesis of Thioglucosides

To understand the selection criteria for the selective sequestration of salicin by larvae of *C. populi*, and the broad range import of plant-derived glucosides by *C. lapponica* (see Fig. 3), we chose isomeric thioglucosides of salicin, and other aliphatic or aromatic

thioglucosides, which occur in different host plants, as test compounds. Thioglucosides offer a unique structural similarity to the natural substrates retaining the ability to adopt the same bioactive conformations as natural carbohydrates and conjugates (Nicotra, 1998). At the same time, they exhibit exceptional chemical and biological stability, making them to ideal tools to study transport phenomena of glucosides (Scheme 1).

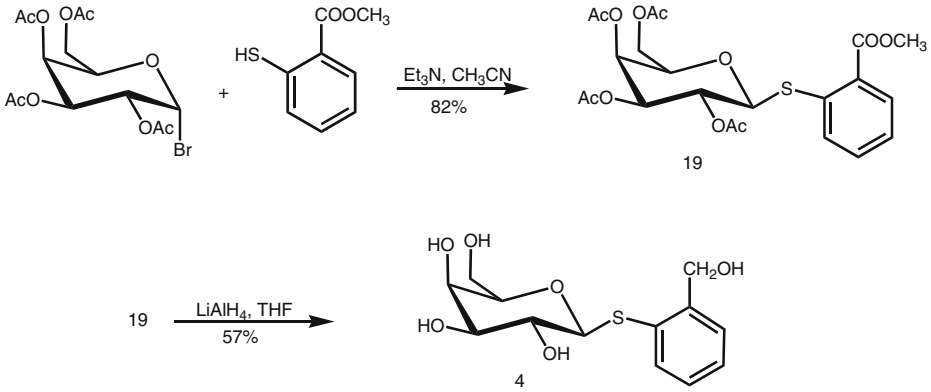


Scheme 1 Survey on thioglucosides **1** to **10** designed as structural analogues of the natural *O*-glucoside salicin from poplar leaves

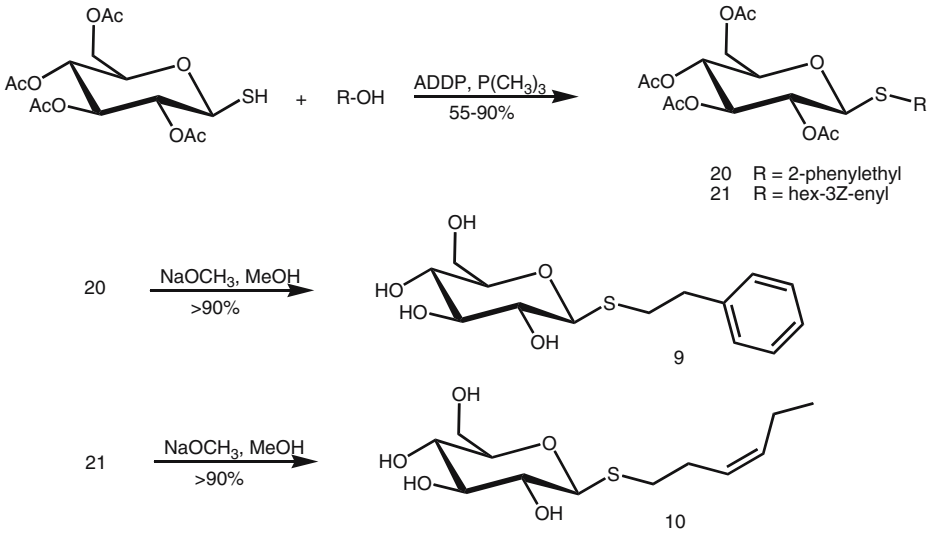
The test compounds **1** to **9** cover thioglucosides of the *o*-, *m*-, and *p*-isomers of salicin, as well as those of thiocresols, which lack the hydroxyl group of the C_1 substituent of salicin. Compound **4** maintains all features of **1**, except that the glucose moiety is replaced by galactose, epimeric to glucose at C-4. The thioglucoside **8** lacks the hydroxymethyl group of salicin. Compounds **9**, **10**, and **11** represent stable *S*-analogues of natural *O*-glucosides found in *Salix* or birch leaves that are sequestered by larvae of *C. lapponica* (Table 1 in Schulz et al., 1997). Compound **11** was demonstrated to be specifically transported by larvae secreting iridoid monoterpenes (Feld et al., 2001; Kuhn et al., 2004). Compounds **1** to **11** were previously tested on *C. populi* (Kuhn et al., 2004; see Fig. 4) and the thioglucosides **1**, **2**, **4**, **6**, **9**, **10**, and **11** were used in the present study to evaluate the selectivity of the transports system(s) of *C. lapponica*.

The synthesis of most of the aromatic thioglucosides **12** to **18** followed a uniform protocol based on alkylation of acetobromoglucose with *o*-, *m*-, *p*-mercaptobenzoates or *o*-,

m-, *p*-mercaptocresols as nucleophiles (Scheme 2). The isomeric thiosalicins **1**, **2**, **3**, and **8** were obtained after reductive removal of the acetate moieties with $LiAlH_4$. The hydride reagent simultaneously reduced the benzoate ester to the required -CH_2OH substituent. The thioglucosides of the isomeric cresols **6**, **7**, and **8** were liberated from the acetylated precursors by treatment with methoxide in methanol. The basic cleavage was the method of choice, if only the acetates had to be removed, because the work-up proved to be more efficient than after reduction with $LiAlH_4$.



Scheme 2 Synthesis of aromatic thioglucosides via Königs-Knorr protocol



The galactoside **4** was also obtained via the Königs–Knorr protocol by using peracetylated α-bromogalactose and *o*-mercaptobenzoate as the nucleophile.

After reductive removal of the acetates with simultaneous reduction of the benzoate, the galactoside **4** was obtained in 57% yield (Scheme 3). The synthesis of the thioglucosides **9** and **10** required a different approach, because the thionucleophile corresponding to (*Z*)-hex-3-enol or phenylethanol was not readily available. In this case, the alcohols were condensed with 2,3,4,6-tetra-*O*-acetyl-β-D-thioglucopyranose according to a modified Mitsunobu protocol (Falconer et al., 1999). The acetates were saponified in high yield with sodium methoxide in methanol (Scheme 4).

Purification of all glucosides was best achieved by MPLC on reversed phase (RP 18) by using methanol/water for elution or by high-speed counter-current chromatography as described in Methods and Materials.

Scheme 3 Synthesis of aromatic thioglucosides via Mitsunobu protocol

Scheme 4 Synthesis of thioglucosides derived from (*Z*)-3-hexenol and 2-phenylethanol

Analysis of the Transport Characteristics of the Thioglucosides by Larvae of *C. lapponica* and *C. populi*

Third instars of *C. populi* were allowed to feed on leaves of *Populus canadensis* pretreated with aqueous solutions of the different thioglucoside **1** to **11**. After 48 hr, their defensive secretions and their hemolymph were collected and analyzed by LC–MS in the atmospheric pressure chemical ionization mode after minimal sample preparation (see Methods and Materials). Although the results of the feeding experiments with *C. populi* were already published (Kuhn et al., 2004), the data are repeated in Fig. 4 to allow a comparative analysis of the transport modalities of the two systems of *C. populi* and *C. lapponica*. Because all compounds were applied at the same concentration and because the leaves were consumed to a comparable extent, the accumulation of the thioglucosides in the defensive secretion can be taken as a measure for the efficiency of the transport process.

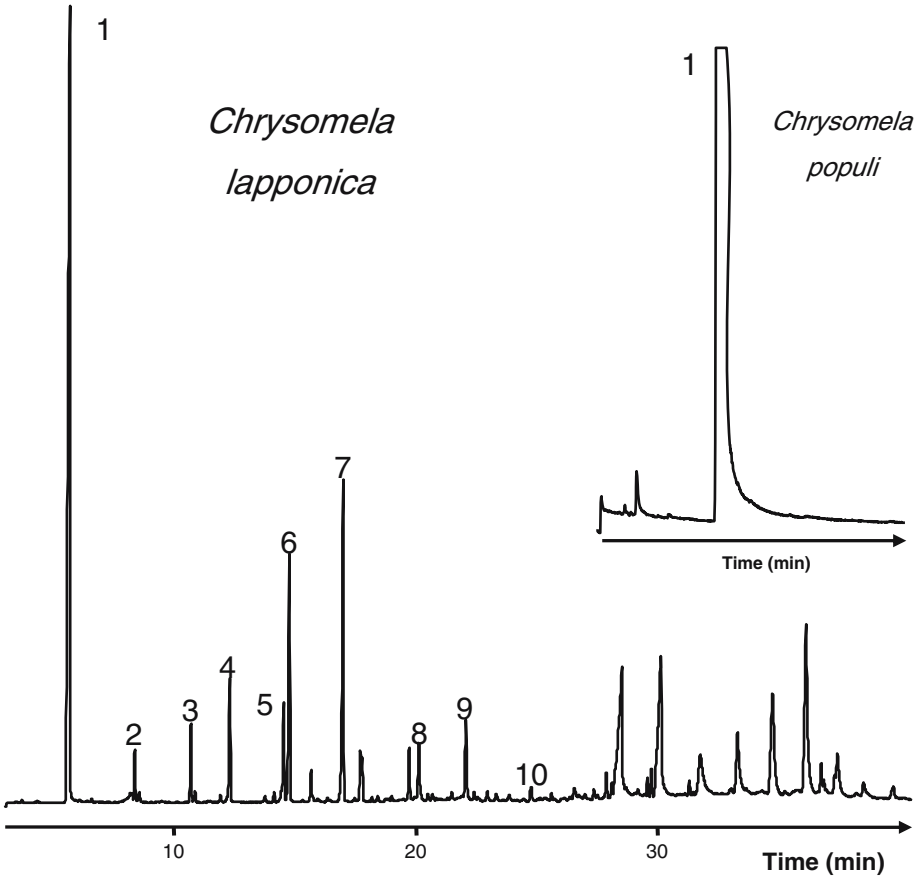


Fig. 3 Total ion chromatogram of the low boiling fraction of the exocrine defensive secretions of larvae of *C. lapponica* (Queyras, France) feeding on *S. caprea*; inset: *C. populi* feeding on *P. canadensis*. Identification of compounds: **1**, salicylaldehyde; **2**, (3*Z*)-hexenyl isobutyrate; **3**, (3*Z*)-hexenyl 2-methylbutryrate; **4**, benzyl isobutyrate; **5**, benzyl 2-methylbutyrate; **6**, 2-phenylethyl isobutyrate; **7**, 2-phenylethyl 2-methylbutyrate; **8**, 8-(isobutyryloxy)-linalool; **9**, 8-(2-methylbutyryloxy)-linalool; **10**, 2-phenylethyl benzoate

Larvae of *C. populi* sequestered only the thiosalicin **1** with high efficiency, and the compound accumulated to a final level of 1100 nmol mg^{-1} in the defensive secretion. The concentration in the hemolymph did not exceed ca. 1 to 2 nmol mg^{-1}. Unlike thiosalicin **1**, the *m*- and the *p*-isomers **2** and **3** were not notably transported and did not accumulate in the secretion (final level 10–20 nmol mg^{-1}). Surprisingly, the thioglucoside of the cresol **5**, lacking only the hydroxyl group of the salicin side chain, was also not significantly enriched in the gland reservoir. Within the limits of error, the transport efficiency was roughly the same for all three regioisomeric cresol thioglucosides **5**, **6**, and **7**, and was comparable with the transport rate of the nonnatural regioisomers of thiosalicin (**1**). The thioglucoside of 8-hydroxygeraniol **11**, the precursor for iridoid biosynthesis, was not significantly imported by larvae of *C. populi*.

When larvae of *C. lapponica* were allowed to feed on leaves of *S. caprea* pretreated with the thioglucosides **1**, **2**, **4**, **6**, **9**, **10**, or **11**, sequestration into the glandular reservoir was observed for all compounds except for the thiogalactoside **4** (Fig. 5). The latter compound

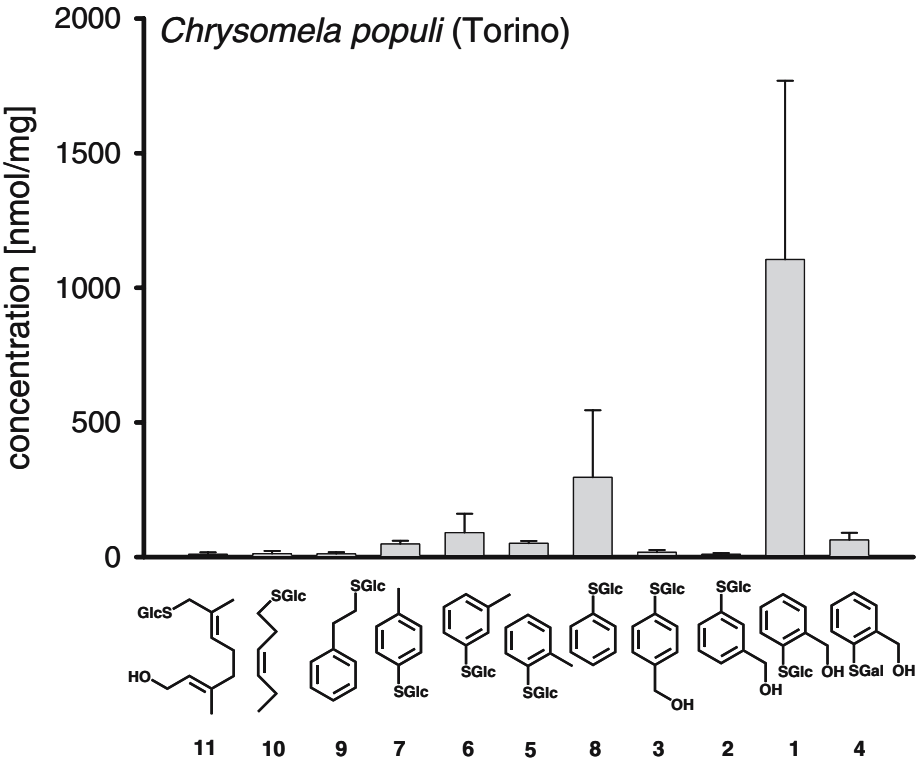

Fig. 4 Survey on the accumulation of the thioglucosides **1** to **10** in the defensive secretion of feeding larvae of *C. populi*; modified from Kuhn et al., 2004

was not imported by the feeding larvae of *C. lapponica* and only to a very low extent by other previously studied chrysomeline larvae (Kuhn et al., 2004). Consistent with the low concentration of the thioglucosides in the hemolymph of *C. populi*, in the larvae of *C. lapponica*, only a very low titer of the sequestered thioglucosides was also observed and hampered a reliable quantification. The major difference observed in *C. populi* was in the final concentrations of the imported thioglucosides in the reservoir. Although larvae of *C. populi* accumulated thiosalicin **1** to about 1100 nmol mg^{-1} in their defensive secretion, **1** and other test compounds did not exceed 200–450 nmol mg^{-1} in the secretion of *C. lapponica*. Moreover, the import pattern did not show a clear preference for a single compound. Another remarkable difference in *C. populi* was the observation that a fraction of the imported thioglucosides was acylated at the conjugating sugar or even at the alcohol moiety if additional hydroxy groups were present in the aglycon, e.g., in **1**, **2**, and **11**. The total concentration of the imported thioglucosides was, therefore, corrected for the acylated fraction by using synthetic references for calibration (unpublished data).

In larvae of *C. lapponica*, the missing hydroxyl group in the thioglucoside **6** does not affect the import of the compound; the import of **1** and **6** is achieved with similar efficiency. Moreover, the structurally unrelated thioglucosides of 2-phenylethanol **9** and (3*Z*)-hexenol **10** are also readily sequestered and accumulate to the same level as thiosalicin **1**. On the other hand, the import of the terpenoid-type thioglucoside **11** was low in larvae of *C. lapponica* from Queyras, but not from other locations (unpublished results).

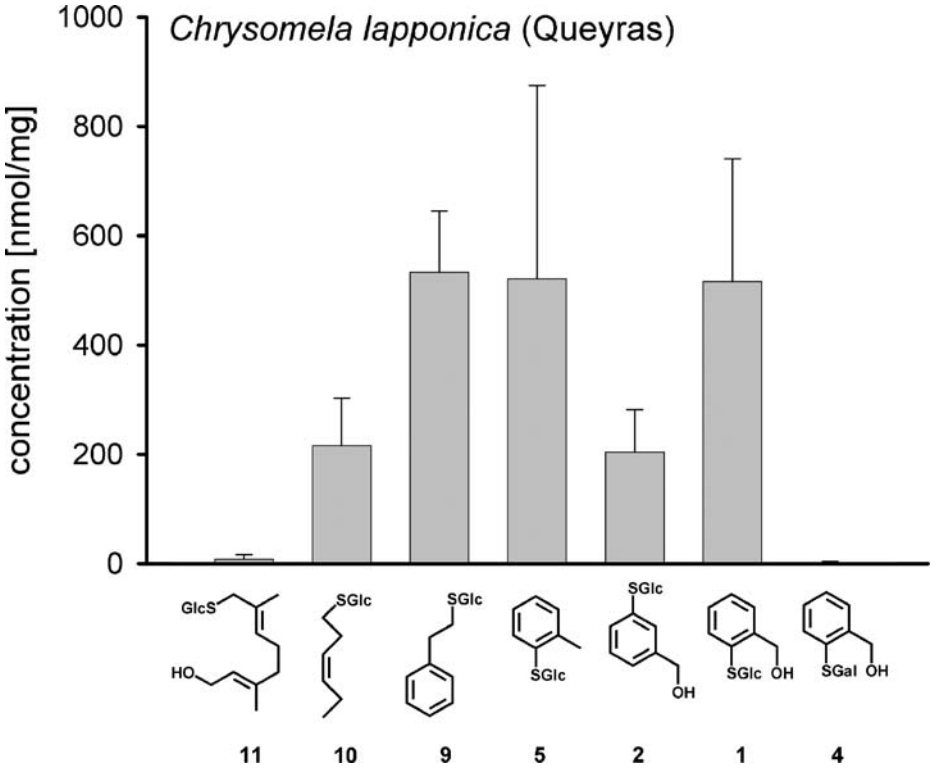

Fig. 5 Survey on the accumulation of the test compounds **1**, **2**, **4**, **5**, **9**, **10**, and **11** in the defensive secretion of feeding larvae of *C. populi*

Discussion

Selective transport systems that facilitate the sequestration of secondary metabolites from plants have been postulated or demonstrated several times (Rothschild, 1973; Blum, 1981; Hartmann, 1999). For example, transport systems are required for the uptake of pyrrolizidine-*N*-oxides from Asteraceae by *Oreina cacaliae* (Hartmann et al., 1999) or for the sequestration of the highly polar cardenolide glycosides (Duffey and Scudder, 1972). Irrespective of the enormous importance of the phenomenon of sequestration of plant-derived metabolites, none of the involved transport systems has, as yet, been identified and characterized at the molecular level. The current work, together with similar experiments with other leaf beetle larvae (Feld et al., 2001; Kuhn et al., 2004), provides the first information on the different molecular and stereochemical features that govern the uptake processes of salicin from *Populus* leaves by larvae of *C. populi*, and also other plant-derived glucosides by larvae of *C. lapponica* from Queyras (France). In both cases, thioglucosides could be successfully used as substitutes of the naturally occurring *O*-glucosides. Owing to their stability against glucosidases, which are omnipresent in the defensive secretions of leaf beetle larvae (Pasteels et al., 1990), the compounds are not cleaved during the gut passage and accumulate unchanged in the defensive gland. As illustrated in Fig. 1, a first transport system has to be located in the membrane of the gut, facilitating the uptake of the precursors into the hemolymph. A second transport system has

to be associated with the membranes of the defensive system. The latter selectively imports the glycosides from the circulating hemolymph. The concentration of the most efficiently transported glycoside **1** in the hemolymph of *C. populi* never exceeded 1–2 nmol mg^{-1}, whereas in the reservoir up to 1100 nmol mg^{-1} were measured. Comparable observations were made for *C. lapponica*, but the maximum concentrations of the thioglucosides in the reservoir were much lower (up to 450 nmol mg^{-1} secretion).

The sequestration strategy of the larvae of *C. populi* and *C. lapponica* is remarkably different. Although the import system of *C. populi* is specialized for salicin, finally converted to salicylaldehyde, larvae of *C. lapponica* import a broad range of glucosides that are converted into a blend of defensive compounds (see Fig. 5). In addition to salicylaldehyde, the secretion of *C. lapponica* contains significant amounts of isobutyl and 2-methylbutyl esters, of e.g., (3*Z*)-hexenol and 2-phenylethanol. This coincides with the observation that the thioglucosides of both alcohols are readily sequestered from food (Fig. 3). Apparently, the import of a broader range of glucosides is facilitated in these larvae by a reduced selectivity of the transport systems. This becomes particularly obvious by the comparable import rate of the thioglucosides **1**, **5**, **9**, and **10**. The lack of the hydroxyl group in the thiocresol **5** does not affect the import rate, and this may suggest that this functional group is not involved in interactions with the transport system of *C. lapponica*. This is very different in larvae of *C. populi*. Their transport system responds to this structural modification by ca. 90% reduction of the import of **5** when compared to **1** (Fig. 3). Apparently, the transport system of *C. populi* interacts with all hydroxyl groups of the substrate salicin by formation of hydrogen bridges. In the case of *C. lapponica*, the recognition of the aglycon is less strict and shows a larger tolerance to structural changes. In particular, the presence or absence of hydroxy groups within the aglycon is not critical in the case of *C. lapponica*.

A mechanistic model postulating hydrogen bridges between the functional groups of the glucoside and the transport system would also explain why the galactoside fails to be sequestered (Figs. 3 and 4). In this case, the hydroxyl group at C(4) of the sugar moiety has the wrong orientation and is not able to interact with the transport system. Because both insect species rely on the import of glucosides, this structural element is of equal importance to both. A selective interaction with the hydroxyl group of the salicin aglycon by larvae of *C. populi* also accounts for the differences between the *m*-, and *p*-isomers **2** and **3**. Because these compounds are less efficiently accumulated than the *o*-, *m*-, and *p*-cresols **5**, **6**, and **7** (Fig. 4), a hydroxyl group out of place may even prevent the correct positioning of the substrate in the transport system.

The high accumulation in the reservoir is only possible if the membrane carrier in the glandular system is coupled to an active energy source (Hartmann et al., 1999). With respect to a low hemolymph titer of **1**, the transport system in the gut must not operate against a steep gradient. Here, the concentration in the gut should be generally higher due to a constant supply of the compound from the ingested food.

An interesting aspect concerns the identity of the two required transport systems, the first in the gut and the second in the membrane of the defensive gland (see Fig. 1). The current feeding experiments give only an overall view on the selectivity of the passage of compounds through both systems. Individual analyses of the gut-associated and gland-based transport systems are needed.

Another important aspect of this work is the finding that the transport systems, once evolutionary adapted to plant-derived glucosides, apparently remain quite stable within related groups of insects. For example, larvae of the iridoid-producing *Phaedon cochleariae*, *Gastrophysa viridula*, and *Hydrothassa marginella* are able to import the

(thio)glucoside of 8-hydroxygeraniol from pretreated leaves, but fail to enrich any aromatic glucoside (Kuhn et al., 2004). Inversely, larvae of *C. populi* and *Phratora laticollis* sequester salicin, but not the glucoside of 8-hydroxygeraniol. In all cases, the high preference for a single plant-derived glucoside coincides with the composition of the defensive secretion that is based on a single or a few compounds. The more evolved *C. lapponica* apparently use transport systems of moderate selectivity that allow the import of a broader range of plant-derived glucosides. After removal of the sugar moiety, the aglycons may be oxidized (e.g., to salicylaldehyde) or acylated to give the isobutyl or 2-methylbutyl esters. Whether the import of a broad range of phytogenic glucosides is achieved by a single system with low selectivity or by a number of highly selective transport systems remains to be clarified. This and related questions on the existence of a network of interacting import and export systems within the insect have to await the isolation of the corresponding transport proteins and their genes allowing a thorough phylogenetic analysis.

Acknowledgments We thank Angelika Berg for rearing of the insects, and Dr. A. Burse for proofreading of the manuscript. Financial support by the Fonds der Chemischen Industrie, Frankfurt a.M. and from the Belgian Fund for Join Basic Research is gratefully acknowledged.

De novo Synthesis vs. Sequestration: Negatively Correlated Metabolic Traits and the Evolution of Host Plant Specialization in Cyanogenic Butterflies

Abstract Larvae of *Heliconius* butterflies (Nymphalidae: Heliconiinae) feed exclusively on cyanogenic leaves of *Passiflora* (passion vine). Most *Heliconius* manufacture cyanogenic glycosides (cyanogens) and some species sequester cyanogens from host plants. We compare ability to sequester simple monoglycoside cyclopentenyl (SMC) cyanogens and manufacture aliphatic cyanogens in 12 *Heliconius* species, including larvae that are specialized (single host species) and generalized (many host species). All butterflies tested higher for cyanide concentrations when reared on plants that larvae can sequester from (SMC plants) than when reared on plants that larvae do not sequester from (non-SMC plants). Specialists in the *sara–sapho* clade sequestered SMC cyanogens from specific host plants at seven times that of *Passiflora* generalists fed the same hosts. In contrast, *sara–sapho* clade species reared on non-SMC plants had significantly lower cyanide concentrations from *de novo* synthesis than generalists fed the same plants. Furthermore, cyanogen analyses indicated that *Heliconius sara* butterflies reared on an SMC host had a greater proportion of sequestered SMC cyanogens (95.0%) than *de novo*-synthesized aliphatic cyanogens (5.0%). Thus, sequestration and *de novo* synthesis are negatively correlated traits. Results suggest that losing the ability to synthesize cyanogens has restricted *sara–sapho* clade species to specific hosts containing SMC cyanogens and explains dietary restriction in this clade.

Introduction

Almost 80% of all herbivorous insects are specialized on plants of a single family, genus, or even a single species (Bernays and Graham, 1988; Bernays and Chapman, 1994). Insects may specialize on host plants because of ecological factors such as "enemy-free space" (Gilbert and Singer, 1975; Price et al., 1980; Strong et al., 1984; Bernays, 1989; Gratton and Welter, 1999; Lill et al., 2002; Zangerl et al., 2002; Singer et al., 2004), interspecific competition (Gilbert and Singer, 1975; Strong et al., 1984; Denno et al., 1995), and local host plant abundance (Gilbert and Singer, 1975; Futuyma, 1983; Beccaloni and Symons, 2000; Ballabeni et al., 2003). An alternative explanation is that plant secondary chemistry is the primary driving force for a narrowing of host range in herbivorous insects (Ehrlich and Raven, 1964; Feeny, 1975; Cates, 1980; Cornell and Hawkins, 2003).

Clearly, both chemical and non-chemical factors are important to consider when interpreting patterns of diet breadth in phytophagous insects (Schultz, 1988; Gotthard et al., 2005). Herbivores must deal with plant secondary chemistry, particularly compounds that are potentially harmful to their cellular processes (Karban and Agrawal, 2002). And, although it may be difficult to determine whether plant chemistry is the ultimate basis for host plant specialization, plant chemistry must exert some selection pressure on insect host range (Thompson, 1988).

There are few insect systems for which we have a detailed understanding of the patterns and mechanisms of sequestration and *de novo* synthesis of secondary compounds (Nishida, 2002) and the possible role of these mechanisms in dietary restriction. The *Heliconius–Passiflora* system is of particular value for addressing issues of chemical ecology because of its comparative potential (Gilbert, 1991). Approximately 65 heliconiine species (40 of which are *Heliconius*) and 600 species of *Passiflora* are available for study. Furthermore, a phylogeny is available for both *Passiflora* (Hansen, 2004; MacDougal and Feuillet, 2004) and *Heliconius* (Brower and Egan, 1997; Penz, 1999) (Fig. 1).

Larvae of *Heliconius* butterflies feed exclusively on cyanogenic leaves of *Passiflora* (passion vine). *Passiflora* is a diverse Neotropical genus in which coevolution with *Heliconius* in local populations apparently accounts for morphological innovations in some passion vines (Gilbert, 1971; Benson et al., 1976; Gilbert, 1979; Williams and Gilbert, 1981; Gilbert, 1982; Futuyma, 1983). Cyanogen diversity, particularly the cyclopentenyl cyanogen class (Olafsdottir et al., 1989; Seigler, 1975; Spencer and Seigler, 1984c) (Fig. 2) in passion vines, may be another product of the evolutionary arms race between *Passiflora* and their primary herbivores, species of *Heliconius* butterflies (Spencer, 1988).

Similar to their hosts, species of *Heliconius* are cyanogenic. *De novo* synthesis of aliphatic cyanogenic glycosides (Fig. 2) from amino acid precursors characterizes *Heliconius* species (Nahrstedt and Davis, 1981, 1983). Subsequently, we have shown that sequestration of simple monoglycoside cyclopentenyl (SMC) cyanogens (Fig. 2) characterizes *Heliconius* species that were fed *Passiflora* containing these compounds (SMC plants) (Engler et al., 2000). However, until the present study, no investigation has been made of the relationship between *de novo* synthesis and sequestration of cyanogens in *Heliconius* and the impact of this relationship on patterns of host plant specialization.

In this study, we examine whether larval sequestration of plant allelochemicals has influenced diet breadth in certain species of *Heliconius* butterflies. Specifically, we address the following questions: (1) Given that *Heliconius* sequester cyanogens from SMC plants, does cyanide concentration of plants influence cyanide concentration of *Heliconius* herbivores? (2) As the same *Passiflora* species may be used by specialist and generalist *Heliconius*, do

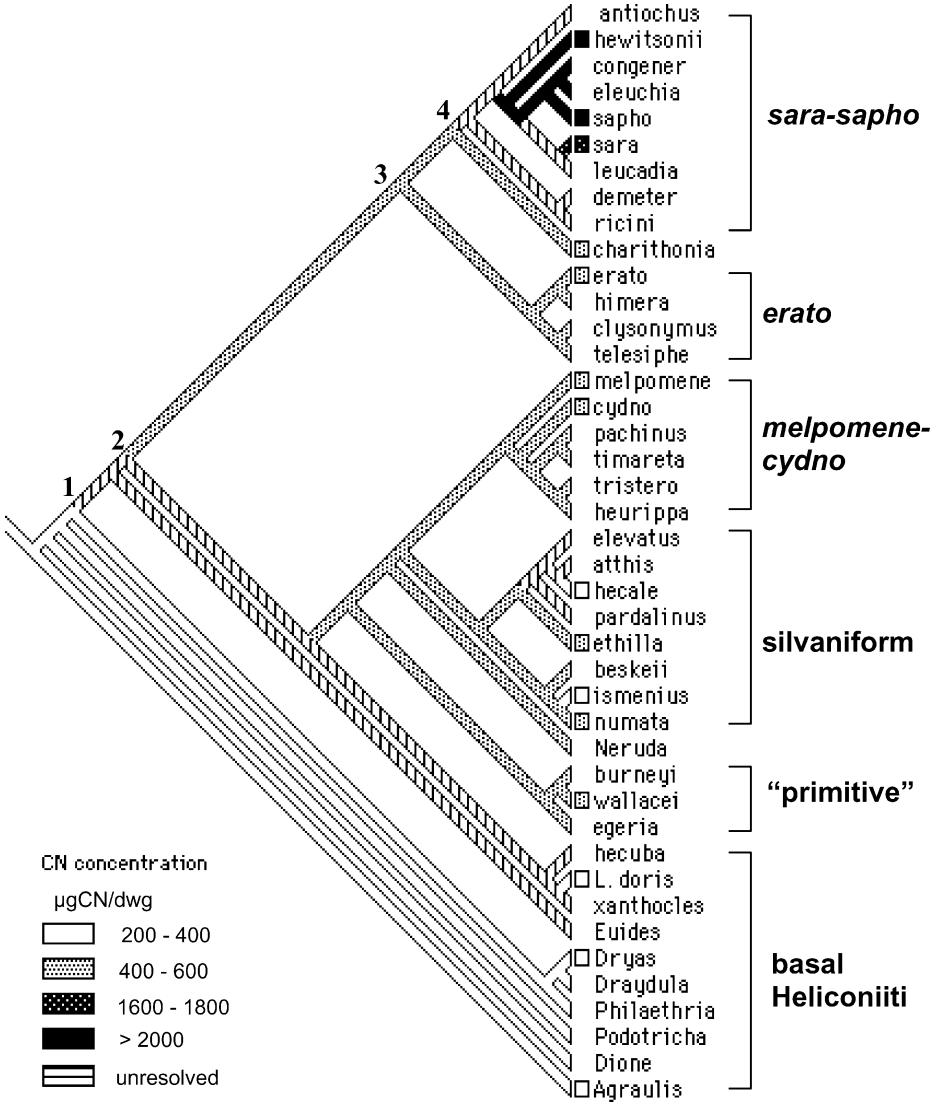

Fig. 1 Annotated phylogeny of the sub-tribe Heliconiiti (Brower and Egan, 1997; Penz, 1999) showing cyanide concentrations of species compared in the study

host specialist *Heliconius* species sequester higher cyanide concentrations from their particular SMC host plants than species with broader host range do? (3) As we know that many, if not most, *Heliconius* and relatives manufacture cyanogens, do those species that sequester lose the ability to carry out *de novo* synthesis?

Methods and Materials

Plants and Insects Our study was conducted at the University of Texas in Austin. Most of the greenhouse populations of heliconiines and Passifloraceae used originated from lowland

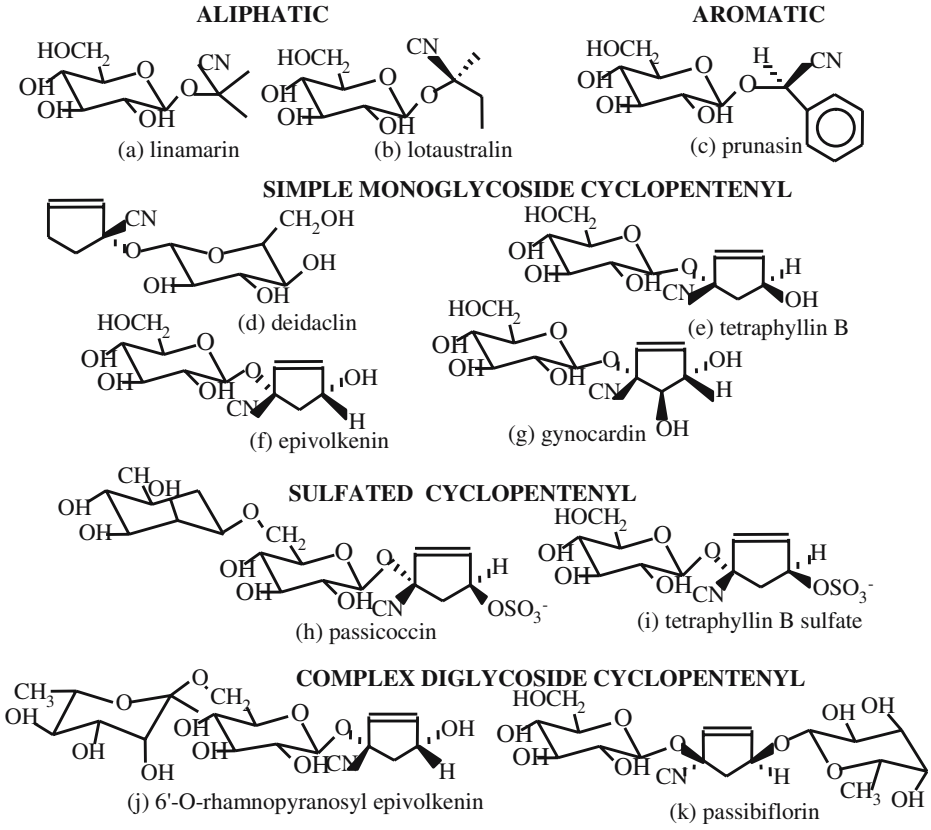

Fig. 2 Structural formulae of the major cyanogenic glycoside (cyanogen) classes found in Passifloraceae (Spencer, 1988; Seigler and Brinker, 1993)

tropical rainforest at the Sirena Field Station in Corcovado National Park, Costa Rica. However, a few species originated from other localities in the neotropics. Most live cultures were established several years before the beginning of our study, but occasional collections of new stocks were made during the study to ensure genetic diversity.

We selected 12 plant species from five subgenera within the Passifloraceae (Killip, 1938). The distribution of cyanogens or cyanogen profile found in the 12 species of Passifloraceae is shown in Table 1 (data derived from Engler, 1998). Host plants from one community (Sirena station in Corcovado Park, Costa Rica) received special focus. In this study, we refer to host plants with simple monoglycoside cyclopentenyl cyanogens that can be sequestered by any *Heliconius* as SMC plants. Host plant taxa without these cyanogens are designated as non-SMC plants. *Passiflora biflora* and *P. vitifolia* were the principal non-SMC host plants utilized in our feeding experiments.

Butterfly Rearing and Feeding Experiments Our study included nine *Heliconius* species from the Pacific slopes and lowlands of Costa Rica. Three *Heliconius* species originated from South America, including *H. ethilla* (South Brazil), *H. numata* (Amazonian Ecuador), and *H. wallacei* (Amazonian Ecuador). We included some close relatives to *Heliconius*, including *Agraulis vanillae* (Austin, TX, USA), *Dryas julia* (Costa Rica), and *Laparus*

doris (Costa Rica), to expand our representation of the subtribe *Heliconiiti* (Brower and Egan, 1997; Penz, 1999).

Heliconius species generally utilize a small subset of *Passiflora* available in microhabitats and preferred by each species for reproductive activity (Gilbert, 1991). To appropriately describe the patterns of diet in larval *Heliconius*, we use the terms specialist (single host species), oligophagous (few host species), and generalist (many host species) to indicate the relative degree of restriction of various species of *Heliconius* to species of *Passiflora* available in a local site. Patterns of larval host plant use and diet breadth among *Heliconius* species (Benson et al. 1976; Brown, 1981; Smiley 1978, 1985) used in the study are shown in Table 2.

Butterfly cultures were maintained as free flying, continuously breeding populations under controlled, semi-natural environmental conditions in (5×8 m) glass greenhouses on the roof of Patterson Laboratories (Austin, TX, USA). Host plants have been grown in these facilities continuously, allowing long-term persistence of stock populations. Healthy cultures depend upon the availability of suitable *Passiflora* larval host plants, and appropriate adult nectar and pollen resources (*Psiguria*, *Gurania*, *Psychotria*, and *Lantana* species) (Gilbert, 1972; O'Brien et al., 2003). Adults were also provided two supplements to floral resources. First, a synthetic diet based on the amino acid content of *Psiguria* pollen, plus

[a] *H. melpomene*, although not a larval specialist, is an oviposition specialist on *P. oerstedii*.

25% sucrose solution, was sprayed onto yellow and orange "Tuffy" plastic scrubbing pads and allowed to dry. Second, 25% sucrose solution was continuously presented in styrofoam cups that contained Tuffy pads for an attractive signal and landing platform. All of these solutions were changed once per week.

For each experimental assay, larvae were reared from egg to adult on plants within an environmental chamber at 25°C and 80% RH. The average life cycle of *Heliconius*, from egg to adult, is approximately 25 d. Newly hatched larvae were fed young leaves and tendrils in individual two-ounce (50 ml) condiment cups. Third instar larvae were moved to ventilated, 1-gallon plastic aquaria or 0.3×0.3×0.3 m screen cages. Older larvae were fed fresh leaves on stem cuttings whose cut ends were kept submerged in distilled water in 25-ml bottles. Pupae were hung in sealed, humidified 1-gallon plastic aquaria. Larval rearing containers were cleaned on a daily basis. After butterflies emerged, teneral butterflies were stored in double-bagged plastic containers and prepared for cyanogen analyses.

It is important to note that it was virtually impossible to rear *Heliconius* species of the *sara–sapho* clade on more than a couple of non-SMC plants because of their high level of larval host specificity. To successfully rear specialized larvae on non-host plants, we moved second instar larvae from their normal host to the new host. This sufficed for our cyanogen analyses, but larvae had lower viability.

Quantification of Cyanogens in Plants and Butterflies Using Colorimetric Analysis We quantified cyanogen levels in SMC and non-SMC plants and in butterflies reared on SMC and non-SMC plants using the colorimetric method of Lambert et al. (1975), as modified by Brinker and Seigler (1989) and Schappert and Shore (1995). By this method, we estimate cyanogen levels in plants and insects by the amount of hydrogen cyanide (HCN) released from crushed samples.

For *Passiflora* assays, six 0.6-cm leaf disks were sampled from living plants of each species. Three age categories of leaves, as indicated by length of midvein (cm), were sampled from each plant to control for developmental variation in cyanide concentration. In the cyanophoric *P. oerstedii*, it was necessary to add exogenous β-glucosidase enzyme, prepared from *Gynocardia odorata*, to drive cyanide out of the plant tissue for quantification. This is because *P. oerstedii*

contains an SMC cyanogen but lacks β-glucosidase enzymes (Engler-Chaouat, unpublished data). For *Heliconius* assays, teneral adult butterflies were quantified individually. It was not necessary to add exogenous β-glucosidase enzyme to any butterfly samples as determined from a previous pilot experiment.

Each plant or butterfly sample was ground with a plastic tissue homogenizer in a 1.5-ml microcentrifuge tube. Immediately after homogenization of samples, the tubes were placed uncapped in individual 20-ml glass scintillation vials, with 0.5 ml 1.0 M NaOH covering the bottom surface of each vial. Vials were sealed tightly and incubated at 37°C for 24 h. Under these conditions, β-glucosidase enzymes hydrolyze cyanogens and release HCN. In solution, CN^- ions are trapped in the NaOH as NaCN. Previous analyses have shown that all detectable HCN is driven out of samples in 24 h (Brinker and Seigler, 1989; Schappert and Shore, 1995), and we confirmed this finding.

After the incubation period, a 0.1-ml aliquot of each 1.0 M NaOH/NaCN sample was placed in a 20-ml test tube and diluted with 0.9-ml of double distilled water. The following reagents were added to each tube: 0.5 ml 1.0 M acetic acid, 5.0 ml succinimide/N-chloro-succinimide reagent, and 1.0 ml barbituric acid/pyridine (Lambert et al., 1975; Brinker and Seigler, 1989). The tubes were vortexed at room temperature and, after a 10-min color reaction period, a 1.0-ml aliquot of each sample was measured at 580 nm in a Shimadzu™ spectrophotometer.

Optical density (OD) values were used to estimate cyanide concentrations based upon a calibration curve performed with known NaCN concentrations. A strong linear relationship exists between OD and μg HCN liberated using this method (R^2=0.99, P<0.001). Crushed samples were dried to constant mass for 4 to 6 d in a drying oven at 67°C. Dry mass of samples was used, in conjunction with the calibration curve, to calculate micrograms of HCN liberated per gram dry weight of tissue (μg CN/dwg) (Tables 3, and 4).

Quantification of Cyanogens in Butterflies Using Chromatographic Analysis We quantified the proportion of aliphatic and SMC cyanogens in specialist, *Heliconius sara*, using paper chromatography (PC) and high performance liquid chromatography (HPLC) following published methods (Jaroszewski et al., 1987; Seigler and Brinker, 1993; Spencer, 1988). First, cyanogens were extracted from 14 teneral female (total dry mass=0.55 g), and 21 teneral male (total dry mass=0.50 g) *H. sara* that were reared on their specific SMC host *P. auriculata*. To extract cyanogens, butterflies were ground in cold 80% methanol, filtered,

Number of butterflies is indicated in parentheses. Host plants with simple monoglycoside cyclopentenyl cyanogens (SMC plants) are shaded.

[a] Cyanide concentration of samples was measured as micrograms of HCN liberated per gram dry weight of tissue (μgCN/dwg).

[b] *L. doris* samples were the only butterflies reared in the field.

dried, and partitioned exhaustively between $CHCl_3$ and H_2O several times. After cyanogen extraction, the aqueous layer was run on Whatmann 3-mm chromatography paper with 6:3:1 (Isoprop: *n*-but: H_2O) as an eluent. The aliphatic (R_f=0.50) and SMC (R_f=0.37) cyanogen bands were cut out and desorbed separately in H_2O from a total of 30 PCs. Finally, cyanogen products were concentrated under vacuum and prepared for further purification.

After paper chromatography, the partially purified aliphatic and SMC cyanogen isolations were separated using a SSI HPLC [C-18 Beckman column (5 μm, 2 mm×25 cm], 5.0% methanol in water, flow rate 0.18 ml/min, refractive index detector). Under these conditions,

all cyanogens, except enantiomers, elute as separate peaks. Relative retention times of eluted cyanogens were calibrated with reference standards including aliphatic cyanogen linamarin (8.9 min), and SMC cyanogens, epivolkenin (7.4 min), and gynocardin (5.3 min). The proportion of aliphatic and SMC cyanogen compounds in *H. sara* was calculated based on the percent area of chromatogram peaks.

Chemical Correlates of Host Plant Use All statistical analyses were carried out using Statview. Quantitative differences in *Passiflora* host plants and in butterfly species using these hosts were analyzed using regression analysis and analysis of variance (ANOVA) (Sokal and Rohlf, 1981).

Our first analysis addressed question 1: Do cyanide concentrations of SMC and non-SMC plants differ in influencing cyanide concentrations of *Heliconius* herbivores? We performed two regression analyses to test whether cyanide concentration in host plants is related to cyanide concentrations in *Heliconius* butterflies. Host plants utilized at the source locality of each *Heliconius* species were used in each analysis. The first regression related the mean cyanide concentrations (μgCN/dwg) of butterflies that were fed SMC host plants to the mean cyanide concentration (μg CN/dwg) of the SMC host plants. The second regressed mean cyanide concentrations of butterflies that were fed non-SMC host plants (*P. biflora* and *P. vitifolia*) against mean cyanide concentration of these non-SMC host plants.

Our second analysis addressed question 2: Do host specialist *Heliconius* species sequester higher cyanide concentrations from their particular SMC host plants than species with broader host range do? Using ANOVA, we compared mean cyanide concentrations of butterflies reared on SMC host plants (*P. auriculata*, *P. pittieri*, and *P. oerstedii*) with mean cyanide concentrations of the same butterflies reared on a non-SMC plant (*P. biflora*). Two-way ANOVAs were performed with butterfly and host plant species as independent factors and mean cyanide concentration of butterflies as the dependent variable. These comparisons also allowed us to address question 3: Do those *Heliconius* species that sequester lose the ability to carry out *de novo* synthesis?

Phylogenetic Associations of Host Specialization, Sequestration, and Cyanogenesis Given that species can share traits due to common ancestry, species data points may not be independent in comparative studies. Therefore, to account for phylogeny, we reanalyzed our data using an independent contrasts program [comparative analysis by independent contrasts (CAIC); Felsenstein, 1985; Harvey and Pagel, 1991; Garland et al., 1993; Purvis and Rambaut, 1995] to control for the independence of species (Irschick et al., 2005). We compared mean cyanide concentrations of 12 *Heliconius* species and two close relatives reared on SMC and non-SMC plants using CAIC and regression analysis.

Three CAIC analyses were employed to control for host plant differences. In the first analysis, we computed contrasts for mean cyanide concentrations of butterflies reared on a SMC plant. The SMC plant was either *P. auriculata* or *P. pittieri*, in most cases. In the second analysis, we computed contrasts for mean cyanide concentrations of butterflies reared on a natural host plant at the source locality. In the third analysis, we computed contrasts for mean cyanide concentrations of butterflies reared on a non-SMC plant, either *P. biflora or P. vitifolia*.

CAIC reduced our data to four sequential nodes of the *Heliconiiti* tree, beginning at the base (basal *Heliconiiti*) and moving out to the tips (*sara–sapho*) of the tree (see Fig. 1). Topological data for the *Heliconiiti* phylogeny, obtained from Brower and Egan (1997) and Penz (1999), were coded for independent contrasts analysis. Relative branch lengths in the phylogeny were coded assuming that the ages of taxa are proportional to the number of

species (Grafen, 1989; Purvis and Rambaut, 1995) We repeated each analysis assuming equal branch lengths as a control.

Standardized linear contrasts were computed at each node of the tree using a "Crunch" algorithm for continuous characters. Contrasts began at the tips of the tree and worked back to the root of the tree. "Brunch" is preferred for dichotomous data, but it produced too few contrasts for statistical analysis. Purvis and Rambaut (1995) report that Crunch is acceptable for most analyses.

After each CAIC analysis, the three sets of contrasts were analyzed using three regression analyses. In all regression analyses, sequestration from the primary host plant was the categorical, independent variable. In other words, species were considered "sequesterers" if an SMC plant was a primary host plant at source localities. Cyanide concentration was the dependent variable. (Purvis and Rambaut, 1995; Sokal and Rohlf, 1981). Only nonzero contrasts of the independent variable and dependent variable were plotted, as contrasts of zero indicated no difference between the taxa compared. Positive contrasts in the dependent variable indicate variation between taxa driven in the same direction as the independent variable. Negative contrasts indicate variation between taxa driven in the opposite direction to the independent variable. All regressions were forced through the origin as required by CAIC.

Results

Chemical Correlates of Host Plant Use

1. Does cyanide concentration of plants influence cyanide concentration of *Heliconius* herbivores? We found no relationship between the mean cyanide concentration of *Passiflora* host and the mean cyanide concentration of butterfly herbivores. The cyanide concentration of butterflies reared on non-SMC plants (*P. biflora* and *P. vitifolia*) was not correlated with the cyanide concentration found in these host plants (r^2=0.09; P=0.1758). Similarly, the cyanide concentration of butterflies reared on SMC plants (*P. auriculata*, *P. pittieri*, and *P. oerstedii*) was not significantly related to the cyanide concentration of these SMC plants (r^2=0.071; P=0.2689). However, butterflies reared on SMC plants (*P. auriculata*, *P. pittieri*, and *P. oerstedii*) generally had significantly higher cyanide concentrations than the same butterflies reared on non-SMC plant, *P. biflora* (Fig. 3), indicating that sequestration of SMC cyanogens increases the mean cyanide concentration in the butterfly herbivore.
2. Do host specialist *Heliconius* species sequester higher cyanide concentrations from their particular SMC host plants than species with broader host range do? Oviposition and larval specialist species from the *sara–sapho* clade, *H. hewitsoni*, *H. sapho*, and *H. sara*, had significantly higher cyanide concentrations, as high as seven times that of generalist species reared on their specific SMC host plants, *P. pittieri*, *P. pittieri*, and *P. auriculata*, respectively (Table 4, Fig. 3). In contrast to the situation observed in the *sara–sapho* clade, oviposition specialist *H. melpomene* did not have higher cyanide concentrations than other butterflies reared on its SMC host, *P. oerstedii*. These data also show that although *P. pittieri* is a SMC plant, *H. sara* does not contain significantly higher cyanide concentrations than generalist *Heliconius* when reared on this plant. This indicates a significant degree of specialization by *H. sara* within the set of different SMC host species.

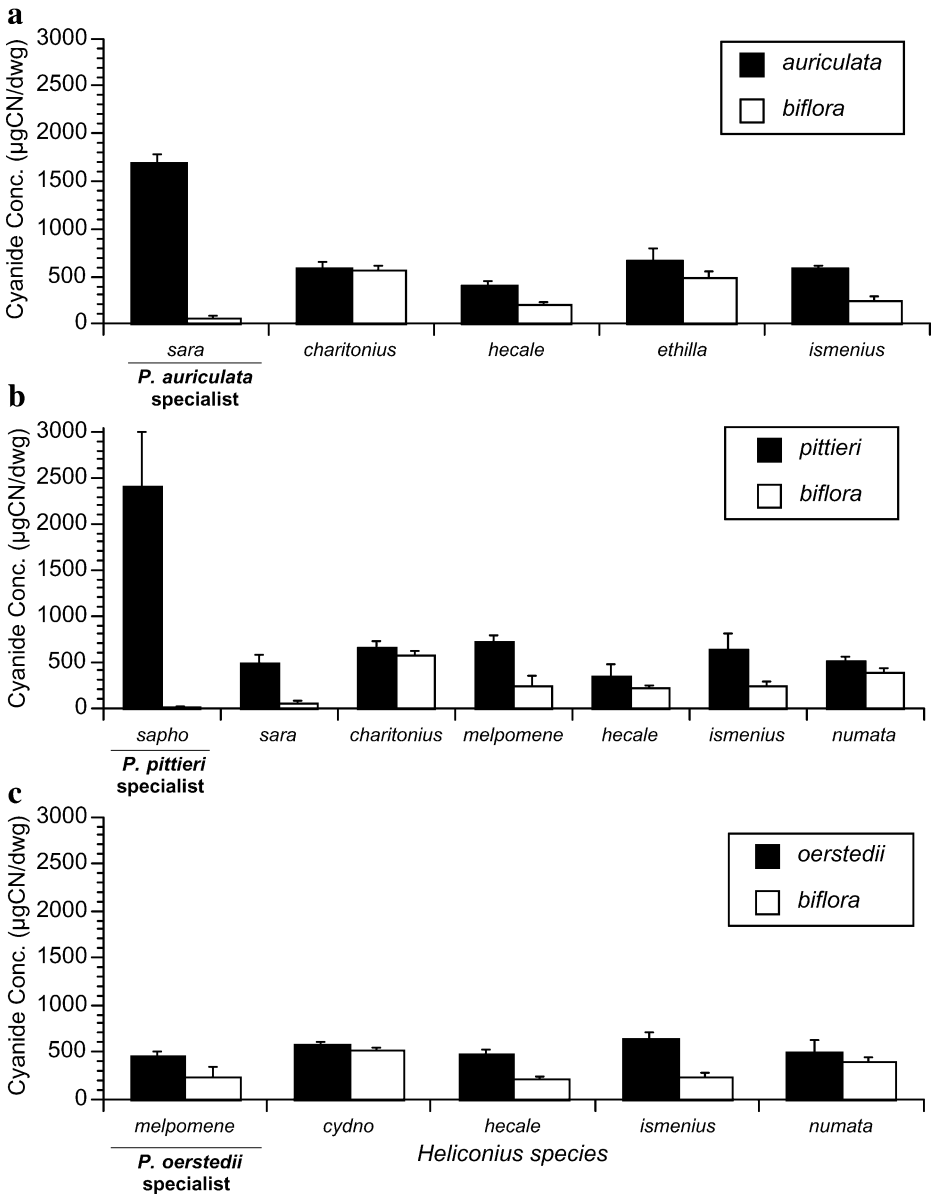

Fig. 3 Mean cyanide concentrations of specialist and generalist species of *Heliconius* reared on SMC host plants, *P. auriculata*, *P. pittieri*, *P. oerstedii*, and the non-SMC host *P. biflora*. (A) Butterflies: $F_{4,\ 222}$= 26.948, P<0.001; plants: $F_{1,\ 222}$=81.689, P<0.001; butterflies × plants: $F_{4,\ 222}$=63.406, P<0.001; (B) butterflies: $F_{6,\ 203}$=5.421, P<0.001; plants: $F_{1,\ 203}$=46.767, P<0.001; butterflies × plants: $F_{6,\ 203}$=8.702, P<0.001; (C) butterflies: $F_{4,\ 176}$=3.998, P=0.0040; plants: $F_{1,\ 176}$=22.221, P<0.001; butterflies × plants: $F_{4,\ 176}$=1.807, P=0.1295

3. Do those *Heliconius* species that sequester lose the ability to carry out *de novo* synthesis? Species in the *sara–sapho* clade, *H. sapho* and *H. sara*, had significantly lower cyanide concentrations, by a mean factor of 10 times that of generalist species, when they were reared on a non-SMC host (Table 4, Fig. 3). Chromatographic analyses also showed that *H. sara* butterflies fed their specific SMC host, *P. auriculata*, had a greater proportion of sequestered SMC cyanogens (95.0%) than *de novo* synthesized aliphatic cyanogens (5.0%). This demonstrates a negative relationship between the ability of butterflies to sequester SMC cyanogens and to *de novo* synthesize aliphatic cyanogens.

Phylogenetic Associations of Host Specialization, Sequestration, and Cyanogenesis The relationship between host specialization, sequestration, and cyanogenesis depends heavily on whether or not host plants produce simple monoglycoside cyclopentenyl (SMC) cyanogenic compounds. Cyanogenesis in the butterfly can be attributed to *de novo* synthesis and sequestration when host plants produce SMC cyanogens, whereas cyanogenesis in the butterfly can be attributed to only *de novo* synthesis when host plants contain non-SMC cyanogens.

We found a highly significant, positive relationship between sequestration from the primary host plant and the cyanide concentration of the butterfly among butterflies reared on SMC plants (Fig. 4) (r^2=0.987, P<0.001). Similarly, we found a highly significant, positive relationship between sequestration from the primary host plant and the cyanide concentration of the butterfly in comparing butterflies reared on natural host plants from their source locality (Fig. 4) (r^2=0.988, P<0.001). The statistical significance of this result is driven by the fact that the primary host plants of *sara–sapho* clade species are SMC plants. By contrast, in comparing species reared on a non-SMC plant, there was a highly significant, negative relationship between sequestration from the primary host plant and the cyanide concentration of the butterfly (Fig. 4) (r^2=0.916, P=0.0016). Thus, sequestration of SMC cyanogens and *de novo* synthesis of aliphatic cyanogens are negatively correlated metabolic traits in passion vine butterflies.

Discussion

This research adds significantly to the knowledge of sequestration and *de novo* synthesis of cyanogenic glycosides in heliconiine butterflies. More importantly, our results have broad implications for understanding the evolution of host plant specialization in phytophagous insects and factors, such as sequestration, contributing to such specialization. Although it has been suggested that monophagy is associated with effective sequestration of secondary chemicals in the Lepidoptera (Duffey, 1980; Bowers, 1992; Dyer, 1995; Nishida, 2002, ours is the first interspecific comparative study to demonstrate a correlation between host plant specialization and sequestration.

Ecological factors may drive the evolution of host specificity in herbivorous insects (Zangerl et al., 2002; Ballabeni et al., 2003), including species of *Heliconius* (Smiley, 1985; Gilbert, 1991). In the present study, however, we highlight an instance in which the secondary chemistry of host plants drives the evolution of specificity among some, but not all, of the insect herbivores that use them as larval hosts. Specifically, our study suggests that physiological mechanisms involved in sequestration of SMC cyanogens and consequent loss of *de novo* synthesis of cyanogens might be a factor promoting and enforcing dietary restriction to SMC host plants in a derived clade of *Heliconius* butterflies.

Studies of chemical factors influencing diet breadth have led to the "trade-off" or "metabolic load" hypothesis (Whittaker and Feeny, 1971; Rausher, 1988; Jaenike, 1990). Under this hypothesis, as specialist insects adapt their physiology (i.e., metabolic enzymes) to sequester or counter specific host plant allelochemicals (Duffey, 1980; Bowers, 1990), they lose their ability to deal with non-host plant toxins (Cohen, 1985; Bowers and Collinge, 1992; Rowell-Rahuer and Pasteels, 1992; Adler et al., 1994; Joshi and Thompson, 1995; Camara, 1997). However, few studies have provided support for this hypothesis (Hare and Kennedy, 1986; Futuyma and Phillipi, 1987; Bernays, 1988; Bowers, 1988; Kearsley and Whitham, 1992;

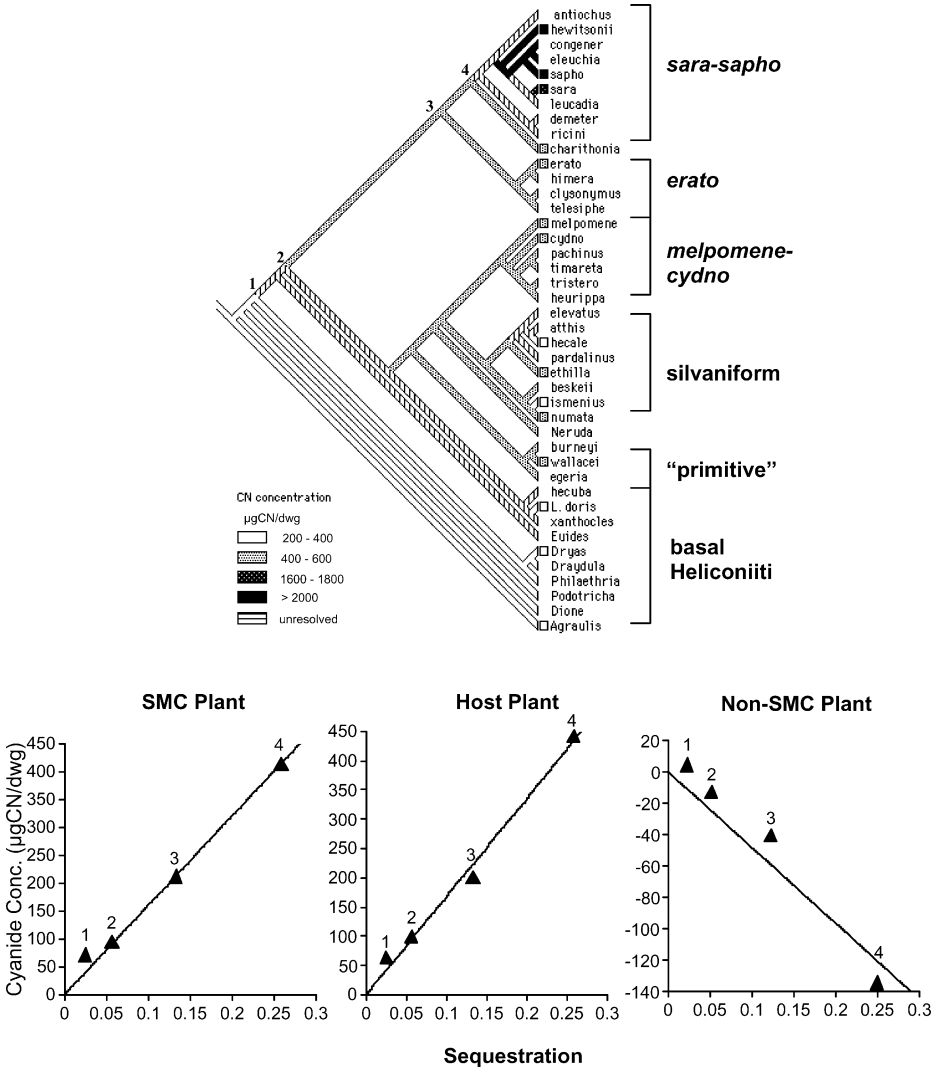

Fig. 4 Regressions of phylogenetic contrasts of sequestration and cyanide concentration of *Heliconius* reared on either an SMC plant (r^2=0.987, P<0.001), natural host plant (r^2=0.988, P<0.001), or non-SMC plant (r^2=0.916; P=0.0016). The numbers 1–4 represent CAIC analysis contrasts at four nodes of the *Heliconiiti* tree

Fry, 1996; Camara, 1997; but see Cornell and Hawkins, 2003) and tradeoffs may be difficult to detect (Fry, 2003).

We show in our study of *Heliconius* that several species of a derived clade (*sara–sapho*), characterized by the highest degree of host restriction as adults and larvae, sequester SMC cyanogens from specific host plants at significantly higher concentrations than that of generalists fed the same hosts. In contrast, these same species reared on non-SMC plants manufactured significantly lower cyanide concentrations than generalists fed the same plants. Thus, we demonstrate that the ability of butterflies to sequester SMC cyanogens and to *de novo*-synthesize aliphatic cyanogens are negatively correlated traits in passion vine butterflies. This result constitutes evidence for an evolutionary "tradeoff" between sequestering plant-derived cyanogenic compounds *versus* manufacturing cyanogenic compounds *de novo*.

One possibility to consider is that *de novo* synthesis is resumed in adult *Heliconius*, even when it is absent in the larval stage. If adult *Heliconius* synthesize cyanogens from amino acid precursors obtained from pollen feeding as has been suggested (Gilbert, 1991), it would follow that any lack of cyanogen synthesis capability by larvae could be compensated by adults of the *sara–sapho* clade. However, in a preliminary screen, we found no evidence of aliphatic cyanogen synthesis in older adults of *H. sapho* (Engler, unpublished data). Therefore, we suggest that the virtual loss of *de novo* synthesis of cyanogens in the *sara–sapho* clade, and a subsequent "chemical dependency" (Brown et al., 1991) on host plants for acquiring and maintaining high cyanide levels, might explain why the *sara–sapho* species are restricted to SMC host plants.

Several lines of evidence suggest that the physiological mechanism(s) involved in such "high level" sequestration, as shown by *sara–sapho* clade, is not simply because of the presence of SMC cyanogens in host plants nor of their being a specialist. First, although all tested butterflies reared on SMC plants had higher cyanide concentrations than the same butterflies reared on non-SMC plants, only members of the *sara–sapho* clade had extremely high cyanide levels when reared on their SMC hosts. Second, Central American *H. sara* used in the study does not store significantly higher cyanide levels from SMC plant *P. pittieri* than other *Heliconius* species, although many South American populations of *H. sara* specialize on *pittieri*-like species of Astrophea. Third, H. *melpomene*, an oviposition specialist, does not store higher levels of cyanide than other *Heliconius* species reared on its specific SMC host plant in the Atlantic forests of Costa Rica, *P. oerstedii*.

Furthermore, adult and larval specialist *H. wallacei* does not have significantly higher concentrations than generalists reared on its non-SMC host plant, *P. vitifolia*. Thus, the extent of physiological specialization by both adults and larvae sets the *sara–sapho* clade apart from all other species of the genus *Heliconius* studied so far, including those that are strict specialists on non-SMC plants, and those, on the other hand, that are able to incorporate SMC plants into a broader diet.

Our work raises a puzzling question regarding why a group of insects that can synthesize cyanogens *de novo* would evolve cyanogen sequestration in the first place. It has been suggested that the ability of *Heliconius* and related genera to manufacture and store aliphatic cyanogens (Nahrstedt and Davis, 1981, 1983) provided protoheliconiines with a ready-made physiological mechanism for colonizing cyanogenic *Passiflora*. (Rothschild, 1971; Nahrstedt and Davis, 1985; Raubenheimer, 1989). However, physiological mechanisms involved in cyanogen biosynthesis may be very different from those mechanisms used for cyanogen resistance. As SMC cyanogens are common in ancestral *Passiflora* plants (Spencer, 1988), we suggest that sequestration of SMC cyanogens may have also enabled protoheliconiines to colonize basal Passifloracea such as the woody vines and trees of

subgenus, *Astrophea*. Raubenheimer (1989) also suggests that related *Acraea* may have diversified on cyanogenic plants because of its capability to sequester a SMC cyanogen, gynocardin. With the appearance of the derived *sara–sapho* group, *Heliconius* apparently reinvaded and radiated across ancestral woody passion vines (Benson et al., 1976), and sequestration of host cyanogens might be considered the innovation fueling this adaptive radiation (Gilbert, 2003).

The *sara–sapho* clade represents a recent adaptive zone within the genus *Heliconius*. But, what is the advantage of this specialization over more generalized species that can eat the same SMC plants? Are the larvae more toxic and thus able to group up and deal with the tough leaves of Astrophea? Are the eggs better protected from predators, especially as egg clusters laid by *sara–sapho* females? Are young adults more toxic without having to collect pollen first for cyanogens synthesis?

Ithomiine butterflies as a group do not sequester, and they are very edible until they start collecting pyrrolizidine alkaloids. But like our case, some are now known to sequester from larval hosts (Freitas et al., 1996).

We show that new adults of some members of the *sara–sapho* clade are more cyanogenic than the others and they sequester a more toxic class of cyanogens (Spencer, 1988), thus increasing distastefulness quantitatively as well as qualitatively. That could provide an important degree of protection and predicts these will be the models in intra-generic mimicry. In fact, one race of *H. cydno* has become polymorphic, mimicking two members of the *sara–sapho* clade in Ecuador, *H. sapho* and *H. eluchia*, and generally the polymorphic mimic is the more edible one (Kapan, 2001).

The genus *Heliconius* is already known for species that are apparently specialized on *Passiflora* for ecological reasons (Gilbert, 1991). This study reveals that some *Heliconius* species are monophagous because of physiological mechanisms involved in sequestration. Thus, we have added an important new twist to our knowledge of ecological and evolutionary interaction of *Heliconius* and *Passiflora*, increasing the applicability of this diverse system to the comparative analysis of plant–herbivore chemical interaction and coevolution.

Acknowledgments We thank K. Spencer for the training, equipment, and chemicals that made the work possible, and P. Schappert for the technical advice. K. Spencer, M. Cardoso, P. Schappert, C. Penz, E. Deinert, P. Chai, and R. Dudley contributed useful discussion and criticisms. We thank S. Bramblett for computer graphics, and undergraduates A. Gruetzmacher, R. Saberi, and G. Parikih for assistance in lab and insectary. We thank C. Penz and D. Kapan for providing Ecuadorian material via permits from INEFA and W. W. Benson for Brazilian material via permit with IBAMA. We thank the officials of MINENEM for permits to collect and export butterflies from Costa Rica, and to the staff of Corcovado National Park. Importation of butterflies was enabled by permits from USDA-APHIS. Greenhouse facilities were developed through NSF grants DEB-79060332 and BRS-8315399 with the support of U.T. Austin. Funding for this project was provided by the School for Biological Sciences and the Office of the VP for Research, U.T. Austin.

Changes in Volatile Production During the Course of Fungal Mycelial Interactions Between *Hypholoma fasciculare* and *Resinicium bicolor*

Abstract The mycelia of two wood decay basidiomycete fungi were grown opposing each other across a 1-μm pore membrane supported on the surface of malt broth, contained within a sealable reaction vessel. Production of volatiles during the time course of interaction was followed by collecting head space samples by solid phase microextraction (100 μm polydimethylsiloxane fiber) on five occasions over 25 d following coinoculation of the fungi: 1, 3 (i.e., immediately prior to mycelial contact), 9 (1–2 d after initiation of pigment production by *Resinicium bicolor*), 17, and 25 d. Ten volatiles were produced during interactions that were not detected in single species controls. In general, most (18) fungal volatiles were sesquiterpenes eluted between 12.5 and 21 min, with a further two eluted at 29.1 and 33.9 min; a benzoic acid methyl ester, a benzyl alcohol, and a quinolinium type compound with a distinctive fragmentation pattern at *m/z* 203, 204, 206, and 207 were also identified; three volatiles with *m/z* maxima of 163, 159, and 206–208, respectively, remained unidentified. The results are discussed in relation to possible ecological roles of volatiles.

Keywords Sesquiterpene hydrocarbons · Benzoic acid methyl ester · Benzyl alcohol · Insect attraction · Fungal volatiles · GC/MS

Introduction

During growth through organic resources and soil, basidiomycete mycelia frequently encounter mycelia of other fungi, both of the same and of different species (Rayner and Boddy, 1988; Boddy, 2000). When basidiomycete mycelia meet, recognition as "non-self" (both inter- and intraspecifically) results in antagonistic responses (unless the mycelia are mating compatible) accompanied by changes in morphology in the interaction zone (and often elsewhere) and in production of extracellular enzymes, volatile and diffusible secondary metabolites, often visually manifested as bright pigments in mycelium and

culture substratum (Rayner and Boddy, 1988; White and Boddy, 1992; Griffith et al., 1994a,b,c; Score et al., 1997). Mycelial growth is often stopped, reduced, or stimulated, and such responses are often induced prior to contact (Schoeman et al., 1996; Wheatley et al., 1997; Savoie, 2001; Humphris et al., 2002; Wald et al., 2004a,b), but also following contact, and in the case of intraspecific interactions, following hyphal fusion (Rayner and Boddy, 1988; Boddy, 2000). Responses occurring prior to contact are likely to be induced by diffusible and/or volatile organic compounds (VOCs) depending on the combination of interacting species (Rayner et al., 1994; Heilmann-Clausen and Boddy, 2005). In this paper, we concentrate on VOCs.

VOCs have been detected from fungal fruit bodies (Fäldt et al., 1999), fungal-spoiled food (de Lacy Costello et al., 2001; Demyttenaere et al., 2004), and fungi within buildings (Korpi et al., 1999; Ewen et al., 2004). VOCs produced by basidiomycetes and ascomycetes include alcohols, terpenes, aldehydes, ketones, sesquiterpenes, and aromatic compounds (Sunesson et al., 1995; Wheatley et al., 1997; Korpi et al., 1999; Rösecke and König, 2000; Rösecke et al., 2000; Abraham, 2001; Wheatley, 2002). Many sesquiterpenes from plants (e.g., Cakir et al., 2005; Cheng et al., 2005; Wang et al., 2005) and fungi (e.g., Florianowicz, 2000; Abraham, 2001; Roy et al., 2003) appear to have antifungal properties, and VOCs produced by some fungi have been considered as potential biocontrol agents in timber preservation (Schoeman et al., 1996; Wheatley et al., 1997). Some sesquiterpenes may be involved in defense responses against fungivores (Wiens et al., 1991; Stadler and Sterner, 1998).

Most studies have investigated the identities of VOCs produced as a snapshot at a single time point; however, the VOC profile can change over time (Sunesson et al., 1995; Nilsson et al., 1996; Korpi et al., 1999). For example, volatile production by *Penicillium* growing in pure culture reached a peak after 4–5 d (after normalization for colony size; (Nilsson et al., 1996). When mycelia are interacting, production of VOCs is likely to change considerably during different stages of the interaction. The current study follows VOC production over the time course of mycelial interaction between two wood decay basidiomycetes, *Hypholoma fasciculare* and *Resinicium bicolor*. Although the latter is most common in coniferous woodlands, they are both found in angiosperm woodland, where their mycelia could potentially interact while growing across soil or within wood (Kirby et al., 1990; Boddy, 2001).

Sampling was timed to coincide with different morphological manifestations of interaction: on agar, growth usually slows following hyphal contact, red/brown pigment is produced by *R. bicolor* in the interaction zone, while *H. fasciculare* forms cords following mycelial contact that produce a yellow pigmentation approximately 10 d later, ultimately with slow mutual replacement (Fig. 1). The following hypotheses were tested: (1) VOCs are produced prior to mycelial contact, initiating an early defense response; (2) VOC production is linked to the production of pigments during interspecific interaction; (3) VOC production increases over the course of the interaction independently of colony size; and (4) interspecific interactions produce additional VOCs, which are otherwise not produced during self interactions.

One means of sampling headspace VOCs is to use solid phase microextraction (SPME) fibers. The fiber coatings have different properties for adsorption of different polarity compounds (Nilsson et al., 1996; Jeleń, 2003), and both polydimethylsiloxane (PDMS) and polyacrylate fibers have been used successfully to sample fungal VOCs (Nilsson et al., 1996; Fäldt et al., 1999; Jeleń, 2003; Demyttenaere et al., 2004; Ewen et al., 2004). SPME PDMS sampling, combined with separation and identification by GC/MS, was used to monitor the production of VOCs emitted from interactions of *H. fasciculare* and *R. bicolor* grown over 0.5% malt extract broth.

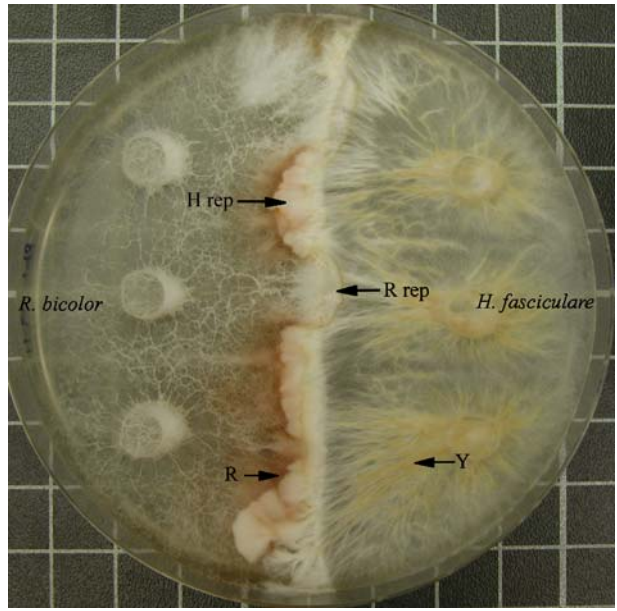

Fig. 1 *Resinicium bicolor* interacting with *Hypholoma fasciculare* on 2% malt agar in a 9-cm Petri dish, 18 d after mycelial contact at 20°C. *Resinicium bicolor* is partially replacing *H. fasciculare* (*R rep*) and *vice versa* (*H rep*). Note that there is dark red/brown pigment production by *R. bicolor* (*R*), and yellow pigment production around cords of *H. fasciculare* (*Y*). Photograph courtesy of Tim Rotheray

Methods and Materials

Fungi

Cultures of *H. fasciculare* (HF-DD2) and *R. bicolor* (RB1), from the Cardiff University Fungal Ecology Group culture collection, were initially grown separately on 2% malt extract agar (Lab M MC23 malt extract, Lab M agar no. 2) in 9-cm nonvented Petri dishes at 20°C to provide fungal inoculum. Inocula comprised plugs of mycelium plus agar (10 mm diameter) cut from the margin of growing cultures with a no. 5 cork borer. Growth rates of the two species were similar; thus, in interaction systems (see below), both plugs were added at the same time.

Interaction Systems

Interactions took place in Reacsyn™ fermentation vessels (BioDiversity, Enfield, UK)—polypropylene bottles containing a porous polyester/polypropylene support at the base of an inner chamber (Fig. 2). The support sat in contact with the surface of the broth medium [30 ml of sterile malt extract broth (0.5%, Lab M MC23 malt extract)] contained in the outer chamber. A Fluropore™ membrane (1 μm pore size; Millipore, Watford, UK) was placed onto the vessel support, and fungal inocula were placed on or near the center (see below). The membrane, although not completely preventing growth into the culture medium, encouraged horizontal growth of the mycelium ensuring a physical interaction (similar to that observed on solid agar plates) and provided a stark white background against which any hyphal pigmentation could clearly be seen. The neck of the inner chamber was stoppered with a gas permeable polyurethane foam bung. The inner/outer chamber design allowed simple sampling of both the headspace (40 ml) and broth (30 ml) within an aseptic system.

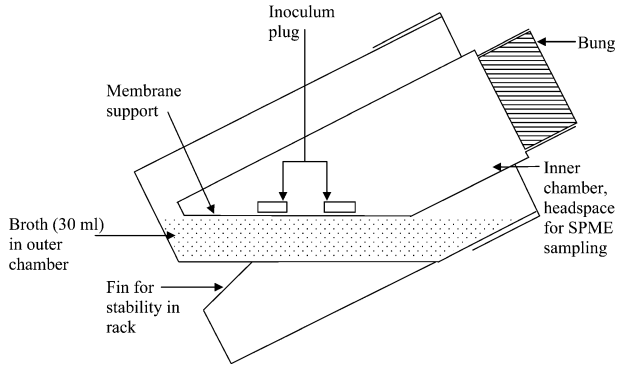

Fig. 2 Diagram of the Reacsyn™ fermentation vessels used to assess production of volatiles and diffusibles when mycelia were interacting and when growing alone

Treatments

Five treatments were prepared in triplicate, two single plugs of each isolate, two self pairings, and one interspecific interaction: (1) a single *H. fasciculare* plug inoculated centrally (HF), (2) two *H. fasciculare* plugs placed 10 mm apart (HFHF), (3) a single *R. bicolor* plug inoculated centrally (RB), (4) two *R. bicolor* plugs placed 10 mm apart (RBRB), and (5) one *H. fasciculare* plug placed 10 mm away from a single *R. bicolor* plug (HFRB). The vessels were placed in their commercial racking system and incubated in the dark at 20±0.5°C.

Sampling of Volatiles

Volatiles were collected by SPME (100 μm PDMS fiber, Supelco, Poole, Dorset, UK). Guided by a small preliminary experiment, sampling took place 1, 3, 9, 17, and 25 d after inoculation. The first sample of the volatiles, the baseline, was taken the day after inoculation, allowing the dispersal of any compounds produced or released as a result of mycelial severance. The 3-d sample was prior to mycelial contact with about 1.5–2-mm distance between the colonies. *Resinicium bicolor* started to produce pigment at 7–8 d; thus, pigment production was initiated 1–2 d prior to sampling at 9 d. The last two time samplings represented later stages of the interactions. The SPME sampling process was as follows: the SPME fiber (preconditioned according to the manufacturers' instructions) was briefly conditioned at the start of sampling each day (250°C, 15 min) and a fiber blank was then run. The inoculated Reacsyn vessels were flushed to clear any build up of fungal volatiles and plasticizer by placing in a sterile laminar flow system with the foam bung/cap system removed for 10 min (deemed suitable following preliminary trials). The cap was then replaced and the vessel was removed from the flow. The SPME fiber was pushed through the bung and exposed to the headspace of the inner chamber for 1 h. The SPME fiber was withdrawn and immediately injected into the GC/MS system.

GC/MS Analysis

Volatiles were analyzed by GC (GC8000, Thermofinnigan, Hemel Hempstead, UK) and MS (MD 800, Thermofinnigan). Samples were desorbed at 220°C in a split/splitless injection port in splitless mode for 2 min and resolved over 30 m VF23ms (Varian, Palo Alto, CA, USA) polar column (0.25 mm ID, 0.25 μm film thickness), with helium carrier

gas (55 KPa). The temperature program was as follows: start 45°C, increasing at 3°C/min to 200°C, then held at 200°C for 5 min. Mass spectra were recorded in electron ionization mode from m/z=35 to 400, with a source temperature of 200°C and interface at 280°C.

Fiber blanks were used to check for any signs of contamination. Control Reacsyn vessels containing malt broth but no fungus were tested by SPME for any exchange of volatiles between the vessels being incubated together. Putative identifications were made by comparing mass spectra with library entries (National Institute of Standards and Technology v2.1 mass spectral database). An absolute identification would have required preparation and/or provision of individual reference compounds and was beyond the scope of this project. Peaks of interest were integrated by using Masslab v1.4 (Thermofinnigan). Prior to statistical analysis, peak areas for each time point were normalized against dibutylbenzene (plasticizer signal, RT 11.9), which remained constant across all samples throughout the time course of the experiment. Peaks found in only one replicate of a treatment were reported but considered artifacts and were not included in further analysis. The evolution of each volatile (as peak area, in standard equivalent units, over time) was compared by using one-way analysis of variance or two-sample *t*-test (Minitab v13) by comparison of area under the curve determined by KaleidaGraph software (Synergy Software, Reading, PA, USA).

Results

Visible Changes

Mycelial morphology changed after mycelial contact. Red/brown pigment was produced beneath mycelium of *R. bicolor* between 3 and 9 d, and yellow pigment developed in *H. fasciculare* cords between 9 and 17 d.

Between Treatment Differences in Volatiles

Replicates within each treatment were generally consistent (and consistent with the preliminary experiment), although one replicate from the interspecific interaction produced the same volatile peaks as the other two replicates but at lower concentrations. In total, 25 fungal metabolites were detectable in the five treatments (Fig. 3). The interspecific interaction produced 12 volatiles that were not found in the single species samples (peaks 1–4, 6, 7, 9, 14, and 21–23), and additionally three (peaks 8, 12, and 17) were considered to be produced only during interspecific interaction because they were present only in a trace amount in a single replicate of the single-species samples. Four peaks were common to the interspecific interaction and *R. bicolor* samples (peaks 5, 11, 16, and 19), three to the interspecific interaction and *H. fasciculare* (peaks 10, 24, and 25), one peak was unique for *R. bicolor* (peak 13), and three peaks (peaks 15, 18, and 20) were identified in all treatments. Peak 20 was produced in significantly higher concentration by *R. bicolor* than *H. fasciculare* ($P<0.05$). An additional peak (peak 23), although only present in a single replicate of the interspecific interaction (suggesting it was not a consistently produced volatile), was included in the total peak count, as it was putatively identified as a sesquiterpene. The majority of the metabolites produced were determined to be sesquiterpenes eluting between 12.5 and 21 min (peaks 1–17). Two further sesquiterpenes eluted at 29.1 and 33.9 min (peaks 19 and 23). Two sets of diastereoisomers were putatively

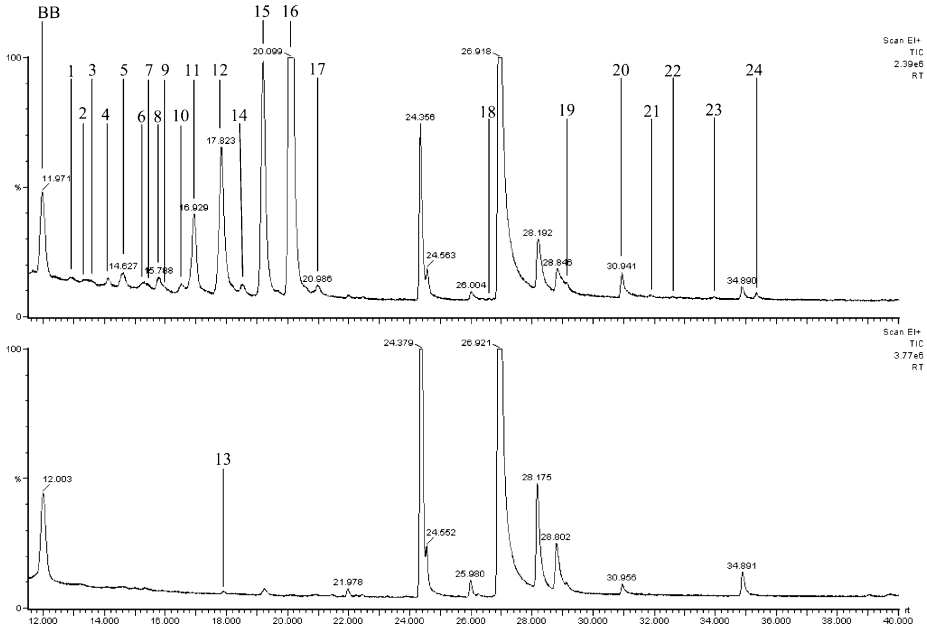

Fig. 3 Representative GC/MS traces indicating fungal metabolites: **(a)** *Hypholoma fasciculare* v *Resinicium bicolor* (HFRB) interaction at 17 d; **(b)** *R. bicolor* (RBRB) alone at 17 d indicating position of the peak found in *R. bicolor* only. Peaks are numbered individually. An additional small peak (25) was found in both treatments at 49.1 min (not shown), *BB* is dibutylbenzene

identified from mass spectral data, peaks 3, 5, 14, and 16 being γ-muurolene, γ-cadinene, γ-amorphene, and γ-bulgarene, and peaks 4, 11, 15, and 17 being α-muurolene, α-cadinene, α-amorphene, and α-bulgarene, although the order of elution of the isomers could not definitely be assigned due to the similarity of the mass spectra within each set. Peak 12, although a major peak, did not produce any matches in the database, so it was not identified. Of the remaining peaks, peak 18 appeared to be a benzoic acid methyl ester, peak 20 a benzyl alcohol, and peak 24 a quinolinium-type compound with a distinctive fragmentation pattern at *m/z* 203, 204, 206, and 207. The remaining peaks, peaks 21, 22, and 25, had *m/z* maxima of 163, 159, and 206–208, respectively, but could not be identified.

In most cases, the production of specific volatiles was not affected by colony size (no significant differences found between single- and double-plug single-species treatments, $P > 0.05$). Peaks 11 and 16, however, were detected in the double- but not in the single-plug *R. bicolor* treatment, and peak 19 also indicates some effect of colony size—HFRB being significantly different ($P \leq 0.05$) from RB but not RBRB (Fig. 4). Where volatiles were

Fig. 4 Evidence of up-regulation of VOCs during interspecific interaction in those volatiles that were also present in single species inoculations: *HF*, *Hypholoma fasciculare* inoculated singly; *HFHF*, *H. fasciculare* inoculated as two plugs; *HFRB*, *H. fasciculare* v *Resinicium bicolor*; *RB*, *R. bicolor* inoculated singly; *RBRB*, *R. bicolor* inoculated as two plugs. Values are means (with standard errors) of three replicates of total area under the curve produced over 25 d. For each peak, the same letter indicates no significant difference ($P \leq 0.05$). Log_{10} transformation of data were required for peaks 10, 11, 15, 16, and 20. One-way ANOVA with Tukey–Kramer *a posteriori* test performed on 5, 10, 15, 18–20, and 24. Two-sample *t*-test was carried out on peaks 11 and 16

present in both the interspecific interaction and other treatments, up-regulation tended to occur, the area under the volatile evolution curve from the interspecific interaction being greater ($P \leq 0.05$) than both single- and double-plug isolate samples for peaks 5 and 11 RBRB (Fig. 4). In the case of peaks 10, 15, and 16, the large amount of variability within the interspecific interaction, which was caused by the outlying response of replicate 1, resulted in a lack of significant difference between some samples (Fig. 4). No up-regulation occurred in the production of the metabolites corresponding to peaks 18, 20, 24, and 25.

Production of Volatiles Over Time

All VOCs detected increased over the time course of the experiment and then declined. Of the 25 metabolites, only four were detected at 1 d (Fig. 4, Table 1): peaks 18, 19, 20, and 24 from 4, 1, 4, and 9 samples, respectively; peak 24 being the only metabolite consistently present at 1 d. Production of other metabolites began between 3 and 17 d, but most commonly from 9 d following mycelial contact (Table 1), and increased over time, most reaching a maximum at 17 d and declining by 25 d (Table 1, Fig. 5).

Discussion

There was no evidence of long-distance antagonism (Boddy 2000) in the interaction between *H. fasciculare* and *R. bicolor*; morphological responses were not manifest until after mycelial contact, and there was no physiological response (as evidenced by lack of change in VOC profiles) until 8 d after inoculation. By this time, mycelial contact had been made, and *R. bicolor* had begun to produce red/brown pigments (3–9 d). Those \VOCs emitted before 9 d (peaks 4–6, 8–10, 13–15, 17–20, 22–24, and 25) may relate to *R. bicolor* pigment production, while those which did not occur until after 9 d (peaks 1–3, 7, 11, 12, 16, and 21) may be associated with the yellow pigment production seen in the mycelium of *H. fasciculare* at this time. Shifts in metabolism corresponding with pigment production have also been detected in *Phlebia radiata* (Griffith et al., 1994a; Rayner et al., 1994).

The decline in VOCs concentration towards the end of the experiment may have several causes. First, because there was no overall replacement of one fungus by the other, there was no new mycelial contact to induce fresh VOC production. Continued production of VOCs might be envisaged where one fungus replaces another with the production of

successive bands of pigment by either or both the invading and invaded fungus. In other fungal combinations, where pigment production is less, there may be less VOCs produced even during the height of the interaction. Second, the nutrient limitations of the media may have prevented further metabolite production as the number (Sunesson et al., 1995; Korpi et al., 1999) and concentration (Demyttenaere et al., 2004) of VOCs produced can vary depending upon the growth medium.

The outcome of an interaction may depend to some extent on the ability of a fungus to detoxify its opponent's metabolites. Catabolism or detoxification of VOCs may have occurred during the current study; at least one compound produced by *R. bicolor* grown on its own was not detected during the interspecific interaction. This may indicate the inhibition or switching off of some metabolites during interaction. Also, there was some evidence that plasticizer (at midretention times) from the Reacsyn vessels decreased with time, perhaps due to fungal metabolism. Evidence that *H. fasciculare* does breakdown diffusible compounds produced by other fungi was provided by Griffith et al. (1994b): *H. fasciculare* had a reduced radial extent when inoculated onto a cellulose film overlaid onto agar on which an opposing species had initially been grown; when this cellulose film plus fungus was removed and replaced by a fresh inoculum of *H. fasciculare* on a fresh cellulose film, the latter grew much more extensively, indicating that some degradation of

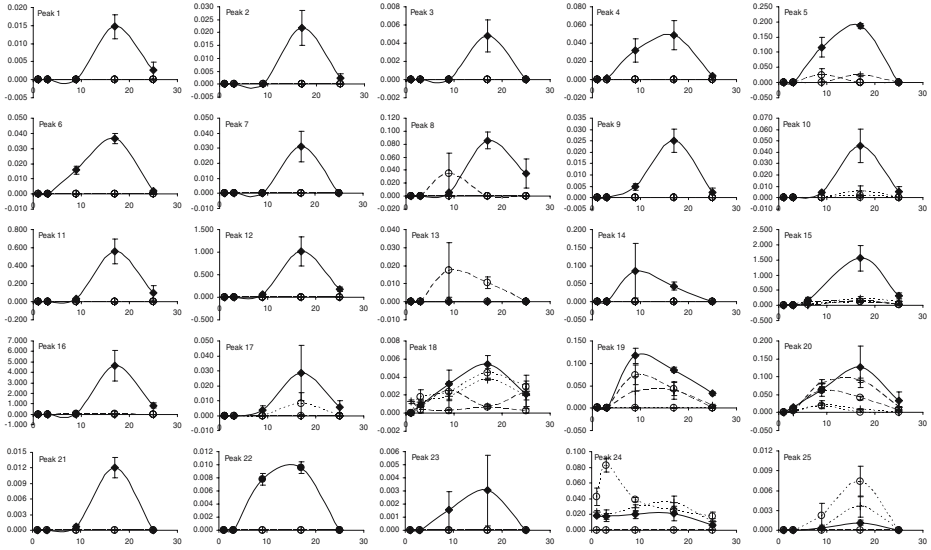

Fig. 5 Production of each volatile (Peaks 1 to 25) in all five treatments over time, values are means (with standard errors) of three replicates. *Dotted lines* HF, *open circles on dotted lines* HFHF, *dashed lines* RB, *circles on dashed lines* RBRB, *solid diamonds* HFRB

the inhibitory compounds had occurred during the growth of the initial *H. fasciculare* inoculum.

Some VOCs were produced as part of the normal metabolism of each fungal isolate, but may still have a role in the defense of territory against invasion by other fungi. Wood previously colonized by decay fungi is inhibitory (and occasionally stimulatory) to other fungi even when the original occupants are dead (Heilmann-Clausen and Boddy, 2005). VOCs may be up-regulated during interaction, and in the current study, two VOCs (peaks 5 and 11) were up-regulated to a statistically significant extent ($P \leq 0.05$) during the interaction compared with the fungi growing alone. There was also some indication that peaks 10, 15, 16, and 19, may be up-regulated during interaction. These four peaks, which were not specific to the mixed species interactions, were some of the nonsesquiterpene compounds detected.

Of the 25 VOCs detected when the fungi were growing alone and during interaction, 19 were sesquiterpenes. Sesquiterpenes are widely used for communication among invertebrates, used by invertebrates to locate plant or animal hosts and by plants and fungi to attract insects for propagule dispersal. Many plants (Cakir et al., 2005; Cheng et al., 2005; Wang et al., 2005) and fungi (Florianowicz, 2000; Roy et al., 2003) produce sesquiterpenes with antifungal activity. An increase in sesquiterpene concentration including that of γ-muurolene has been found in response to wounding and fungal inoculation of spruce, suggesting that sesquiterpenes are part of an antifungal response (Viiri et al., 2001). Other sesquiterpene extracts show antifeedant activity or are ultimately toxic to invertebrates (Wiens et al., 1991; Kahlos et al., 1994; Stadler and Sterner, 1998). α- and γ-muurolene and γ-cadinene have been detected in red and white cabbage and nasturtium infested with *Pieris brassicae* or *Pieris rapae* larvae, but not in uninfested plants, potentially forming part of an antifeedant plant defense response (Geervliet et al., 1997).

On the other hand, cadinenes, muurolenes, and amorphenes, putatively identified in our samples, are also used in insect communication systems (El-Sayed, 2005); for example, α-

and γ-muurolene contribute to the attraction of females of the moth, *Helicoverpa armigera*, to pigeon-pea plants (Hartlieb and Rembold, 1996). Germacrene D, an important precursor to the cadinenes, muurolenes, and amorphenes (Bulow and König, 2000), also strongly affects insect behavior (Prosser et al., 2004), activating an antennal response (Røstelien et al., 2000; Mozuraitis et al., 2002), and increases attraction to the substrate and oviposition by the tobacco budworm moth *Heliothis virescens* (Mozuraitis et al., 2002). The precise effect of the volatiles, produced during interspecific fungal interactions, on invertebrate behavior is, however, not yet known.

The two sets of putatively identified diastereoisomers (α- and γ-muurolene, cadinene, amorphene, and bulgarene, peaks 3, 4, 5, 11, 14, 15, 16, and 17) were generally associated with the interspecific interaction, although peaks 5, 11, and 16 were also found in RB treatments. The fact that peaks 11 and 16 occurred in the RBRB interaction but not RB only suggests some interaction response even with self isolates. General inducement or upregulation of compounds during the HFRB interaction suggests that they are part of non-self recognition and/or defense process, which is also visually manifest in the development of pigments from both species and the reduction of growth towards each other. Initial experiments with collembola also indicate attraction to certain regions of fungal growth, and toxicity of the pigmented cords of *H. fasciculare* (T.D. Rotheray, personal communication).

The preponderance of sesquiterpenes in the VOC profile should, however, be viewed with some caution as SPME fibers are particularly good at absorbing sesquiterpene hydrocarbons (often reported as fungal VOCs), and the PDMS-coated fiber absorbed the highest proportion of sesquiterpenes when compared against three other fiber coatings (Jeleń, 2003). Not all compounds can be picked up by SPME sampling. Sesquiterpene oxygenated compounds were completely missed by SPME sampling, while they were detected by simultaneous distillation extraction. However, other compounds that were detected by SPME were missing from the simultaneous distillation extraction (Jeleń, 2003). Other extraction techniques such as absorption on tenax followed by thermal desorption and solid sample injection (SSI) may offer a more comprehensive extraction. Other extraction techniques also have their disadvantages with respect to, for example, time for preparation and losses by degradation during the introduction of the analyte to the GC column in the case of SSI, and the decomposition of certain compounds on tenax (Ewen et al., 2004). In summary, although SPME sampling by PDMS fiber may provide an incomplete selection of the VOCs released by the fungi, it allows for rapid simple nondestructive sampling, and has provided a sufficient selection of compounds to elucidate the changes in metabolism associated with fungal interactions.

Of the four hypotheses tested, hypothesis 1, that VOCs are produced prior to mycelial contact initiating an early defense response, was not supported. Findings, however, supported the other three hypotheses: VOC production was linked to the timing of pigment production and may even provide a way of separating the metabolites produced by each species where the pigments are produced at distinctly different times (hypothesis 2). Some VOCs produced by the fungi when growing alone and during the interspecific interaction were significantly up-regulated during the interaction (hypothesis 3), while, compared with the individual fungi, a new set of VOCs was produced during the interspecific interaction (hypothesis 4).

Future priorities are further identification of volatiles and diffusibles exuded during fungal interactions. This will also involve determining whether or not the VOCs are attractive and/or toxic to insects and inhibitory to other fungi. We need to link volatiles/

diffusibles back to genes and to determine if genes are being up-regulated. The function of the pigmentation and the relationship between pigmentation and VOC production must be determined. The work also needs to be extended to combinations of fungal species beyond those used here. Different species of fungi are likely to produce different sets of metabolites when growing alone and during interaction, although there is some crossover in the metabolites produced.

Abstract Host location and acceptance by egg parasitoids can be mediated by close-range host stimuli. In this study, we tested the response of *Trichogramma japonicum* Ashmead to cuticular extracts of adult and larval rice yellow stem borer (YSB), *Scripophaga incertulas* Walker. We also studied the wasps' response to extracts from YSB larval frass. Laboratory bioassays revealed that hexane extracts of the adult host body stimulate ovipositor probing of *T. japonicum*. Extracts of larval frass also stimulated parasitization. In contrast, host larval cuticular extracts had no effect on parasitization rates. Fractionation of the crude extracts of adult YSB cuticular extracts was performed using silica gel chromatography, followed by bioassays of the individual fractions to test their effects on wasp behavior. Analyses of the most active fractions by gas chromatography–mass spectrometry revealed that the extract contained saturated long chain alkanes and alkenes, with carbon numbers ranging from C_{20} to C_{32}. Hydrocarbons were applied onto host eggs to test their effects on parasitization rates. Treatments of eggs with docosane, tetracosane, pentacosane, and eicosane enhanced host egg parasitization, while pentadecane, hexadecane, and nonadecane deterred oviposition.

Introduction

Parasitoids of phytophagous insects are known to orient to plants on which their hosts are found. They often use plant- and host-derived chemicals that indicate or confirm the

presence of the host (Vinson, 1976). Chemicals emanating from the host insect or the plant itself may arrest parasitoids in the vicinity of their hosts, thus mediating successful host location and parasitization (Gross et al., 1984). During host finding, two types of stimuli may operate: "attractant" stimuli that elicit orientation to areas with hosts and "arrestant" stimuli that elicit a reduction in the distance or area covered per unit time by parasitoids moving within this area (sensu Dethier et al., 1960). The stimuli influencing searching, parasitization, or retention of the parasitoids originate from various sources, such as host food source, the host itself, or host body emissions (Turlings et al., 1995; Rutledge, 1996; Dorn et al., 1999). In parasitoid–host relationships where kairomones are involved in host location, the duration of parasitoid patch visits is often mediated by, e.g., a host kairomone, host contact cues that may affect the handling time, host density, and rate of oviposition (Strand and Vinson, 1982). Waage (1978) and Weseloh (1980) found that an increasing concentration of kairomone is an indication of increased host density that prolongs the parasitoid's patch arrestment.

Among host-related materials, scales from adult hosts display kairomonal activity towards several parasitoid species. For example, Lewis and Jones (1971) demonstrated that parasitization by *Trichogramma evanescens* was higher for eggs placed in areas contaminated with moth odor. Scales left by the moths were suspected as the source eliciting parasitization (Lewis et al., 1972). In addition to volatile semiochemicals, nonvolatile kairomones also mediate searching behavior of *Trichogramma* spp. Plants on which adult moths have been present may provide cues for host location. Furthermore, egg deposition by herbivorous insects can induce changes of the plant that attract or arrest parasitoids (Hilker et al., 2000; Hilker and Meiners, 2006).

Larvae of the yellow stem borer (YSB) *Scripophaga incertulas* are a major agricultural pest on rice in India and several other countries in Asia. A single female lays about 2–3 egg masses on the tip of the upper surface of tender leaf blades and covers them with hairs and scales from its anal tuft. The larvae enter the leaf sheaths, feed for 2–3 d, and bore into the stem near the nodal region (Pathak and Khan, 1994). They infest plants during their entire larval development. Rice plants, from seedlings to maximum tillering stages that have been attacked at the base of the stem, have dead hearts on the dried up central shoots of tillers. The rice YSB is monophagous on rice, and larvae may feed within the stem without causing severe damage to growing plant parts at the base. However, larval feeding can result in reduction of plant vigor (van Vreden and Ahmadzabidi, 1986). Before pupation, a larva covers the exit hole with thin webbing. Often, larval frass is visible at this exit hole. The larvae and pupae that cause the most damage are concealed inside the stem. Hence, these pests are difficult to control. Traditionally, YSB has been controlled primarily by repeated application of pesticides. In recent years, as the awareness of the economic costs of pesticides and their ecological impact on the environment has increased, biological control by means of parasitoids and predators has been used with varying degrees of success in many different areas (Perez and Cadapan, 1986).

Trichogramma japonicum is an important egg parasitoid of YSB in southern India. It parasitizes the egg masses of YSB that are laid on rice leaves. The mechanisms by which *T. japonicum* locates YSB on rice have not been investigated. In this paper, we demonstrate that chemicals originating from adult hosts mediate close range orientation and oviposition by *T. japonicum* females in host eggs, thereby enhancing the level of parasitization. An attempt was also made to isolate the active chemicals by fractionation and to identify them. Comparisons of the oviposition stimulatory activity, as well as the nature of the chemicals present in the host adult cuticular extracts and frass, were made with that of the larval body

extracts. Extracts of the YSB larval body material were used only for comparison. As internal feeders, larvae might not emit any attractive volatiles.

Methods and Materials

Insects

Plants infested with the YSB *S. incertulas* were collected from Rice Research Station, ANGR Agricultural University, Rajendranagar area of Hyderabad, India, and maintained in the laboratory glass house. Rice YSBs were reared on potted rice plants, Samba masoori variety. Rearing conditions were 30±2°C under natural day light conditions. Pure cultures of *T. japonicum* were obtained from the Project Directorate of Biological Control, Bangalore, India, where they were reared on eggs of a factitious host, *Corcyra cephalonica* Stainton (rice moth) (Lepidoptera: Pyralidae). *Corcyra cephalonica* was reared on sorghum grain. Female parasitoids used for the experiments were 1–2 d old, mated, naïve with respect to the host-related volatiles, and fed with 1:1 water-diluted honey.

Adult YSB were collected from the rearing cages before each experiment and were killed or immobilized by placing them for a few minutes into the refrigerator. Stems of rice plants were cut open to collect frass and 5th instar larvae separately, followed by immobilization of the larvae in the refrigerator.

Extraction

YSB adults and larval body washings were obtained by placing immobilized moths and larvae of known weight in small conical flasks (50 ml) containing analytical grade hexane (2 g per 10 ml that is 18 AE/ml) and shaking them vigorously at a room temperature of 24± 12°C for 2 min. Adults were 2–4 d old. Larval extracts were taken from 5th instars. The washings were filtered through a Whatman no. 1 filter paper. The extract was subsequently concentrated by vacuum evaporation and stored at −20°C. Extracts of frass of 5th instars were obtained in a similar manner.

Isolation and Identification

Concentrated crude extracts were separated using SiO_2 as adsorbent in a 25-mm-diameter column. The extract (0.5 ml) was loaded onto a column (1.5×50 cm) containing 20.0 g silica gel (200 mesh) and was eluted consecutively with 300 to 500 ml of solvent of increasing polarity. Elution was carried out gradually with hexane–ethyl acetate in the following combinations: 100, 98:2, 96:4, 94:6, 92:8, 90:10, 88:12, and 80:20. Analytical-grade solvents were used. Several fractions were collected, and their homogeneity was monitored by using thin layer chromatography. Resulting fractions were reduced to 1.0 ml by passing N_2 gas to avoid loss of volatile monoterpenes, which were significant components of these fractions as indicated by gas chromatography–mass spectrometry (GC–MS) analyses.

All fractions were subjected to bioassays with *T. japonicum*. Bioactive compounds were selected for further chemical studies. Semipurified fractions of each extract were separately bioassayed, and the active fraction was subjected to GC and GC–MS identification.

Certain hydrocarbon compounds were found in the extracts of YSB-related materials by GC and GC–MS (see below). To study their kairomonal activity to the parasitoids, hexadecane, eicosane, docosane, pentacosane, tetracosane, tricosane, pentadecane, nonadecane, heneicosane, and hexacosane (99% pure) were purchased from Sigma Chemicals, St. Louis, MO, USA, and tested.

Gas Chromatography

Each fraction (1 μl) was injected into a GC (Agilent 6890 series) with a HP-1 capillary column (30.0 m long×320 μm i.d.×0.25 μm film thick). The GC was temperature programmed from 100°C to 300°C at 10°C/min. Nitrogen was the carrier gas, and the flow was fixed at 2 ml/min. Injection temperature was 150°C.

Gas Chromatography–Mass Spectrometry

The concentrates of the hexane–ethyl acetate eluate of the extracts were injected into an Agilent 6890 GC equipped with a 5973N model mass selective detector (MS). A HP 5 MS (Hewlett Packard, Palo Alto, CA, USA) capillary column (30 m long×250 μm i.d.× 0.25 μm film thick) was used. The column oven was programmed after an initial delay of 2 min from 50°C to 300°C at 10°C/min. Helium was used as carrier gas with a flow rate of 1.2 ml/min. The sample (1 μl) was introduced in split ratio of 10:1 at an injection temperature of 150°C.

The chemical structure of each compound was elucidated by comparison of the mass spectra with those of authentic chemical samples or by comparison with data in the mass spectral library of the Analytical Division, Indian Institute of Chemical Technology. Relative amounts were calculated from the chromatogram peak area.

Testing Effects on Parasitization Rates

To study the effect of different samples on parasitization rates, the surfaces of host eggs were treated with either a test solution or solvent. Laboratory assays were conducted as tests following the methods used by Jones et al. (1973) and Ananthakrishnan et al. (1991). Responses of *T. japonicum* to the stimuli offered were measured in terms of the number of eggs parasitized. A circle of Whatman no. 1 filter paper (150 mm diameter) was divided into eight sections by lining with a pencil and then fitted to the bottom of a plastic petri dish (150 mm diameter). About 50 eggs of *C. cephalonica* were glued to white card squares (1× 1 cm). Such a card was placed in the center of each section and stuck to the filter paper lining with a tiny drop of light, odorless adhesive (Camlin India, Mumbai, India). Eight groups (cards) of eggs were placed in a single dish.

Dual choice tests were conducted. Parasitoids were exposed to host eggs treated with chemical and solvent-treated control simultaneously in a single petri dish. The test compound (i.e., 20 μl of the extract, chromatographic fraction, or synthetic hydrocarbon) was applied to each of the four pieces of egg cards and placed in four opposite sections. Solvent-treated controls were placed in the remaining four sections, so that each treated egg card was placed between two control cards.

In a second series of multiple choice tests, eight egg cards, each containing 50 eggs, were placed diagonally opposite to one another, and the surfaces of two opposite egg cards

were treated with a fraction. The preference of parasitoids was measured by giving them a choice of four test samples.

For both dual and multiple choice tests, glass tubes (3.7 cm diameter×20 cm long) containing 1–2-d-old *T. japonicum* were placed in the refrigerator for a few minutes to make the parasitoids inactive. Inactive wasps were sexed under a stereomicroscope. Sexes of *Trichogramma* can be easily distinguished by their differences in antennal structure (Knutson, 1998, and personal observation). They were allowed to recover fully before being released into test arenas. Five mated adult females *T. japonicum* (1–2 d old) were released into the petri dish before covering with a lid. After 1 hr, the parasitoids were removed and the petri dishes were kept for observation. After 5–6 d, the treated eggs that appeared black in color (an indication of parasitization) on each egg card were recorded and counted by using a stereomicroscope. Control egg cards were also checked for parasitization.

Hydrocarbon compounds occur in almost all YSB-related material extracts. They are the most abundant compounds. Therefore, experiments were conducted to test whether these compounds actually account for the activity of the extraction/fraction in which they were found. The effect of about 10 synthetic hydrocarbon compounds on the parasitization rate was studied by using the above-described method of dual and multiple choice tests. For each treatment, 12 observations were made per day, and all treatments were conducted simultaneously on the same day. Experiments were repeated on three different days to avoid day-to-day variation. The mean percentage parasitization was calculated from 36 replicates.

Differences in the parasitization rate of treatments and control host eggs in multiple choice tests were statistically analyzed by one-way ANOVA (Origin version 7.5 software) followed by Scheffe's tests. In dual choice tests, the differences between two treatments were analyzed by paired *t*-test (Origin version 7.5).

Egg Samples

Trichogramma females oviposit readily in uncovered egg clusters of *Chilo* species. Eggs of *Scripophaga* species covered with hairs are obviously less accessible for a tiny parasitoid (van Vreden and Ahmadzabidi, 1986). The parasitoids' responses to treated YSB eggs and eggs of the artificial host, *C. cephalonioca*, were compared. As the results obtained with both host species were similar (±2% variation), eggs of *C. cephalonica* were used throughout the experiments because they were available abundantly at all times of the year in contrast to YSB eggs.

Behavioral Bioassays

Studies on the response of parasitoids to the chemicals present in crude extracts and also to the synthetic hydrocarbon compounds were conducted in the laboratory as follows: Behavioral observations were conducted in small flat-bottomed culture tubes (9 cm long; 2.5 cm diameter). Sample material (20 µl) was applied with a micropipette to a localized spot on a piece of absorbent paper (4×0.7 cm). After evaporation of solvent for about 2 min, paper strips were placed onto the inner side of the lid of the tube. For each treatment, controls were maintained in a separate tube with the same amount of hexane. One single adult-mated female was released into the glass tube before closing the lid. Observations on landing behavior, time spent on each treated and control patch, probing, and antennation were recorded visually. Landing and antennation of the treated spot by the parasitoid was denoted a positive response and assigned a highest activity. The observations took 20 min.

Behaviors were classified 0–4, with 0 as no reaction, no movement; 1 as moved upwards towards the paper strip; 2 as made circular movements around the paper strip; 3 as entered/landed on the paper strip; and 4 as antennated and probed on the chemical spot.

Parasitoids almost always responded quickly, either positively or negatively, to a treatment. Twenty females were tested for each treatment, and controls were tested at the same time. All treatments were repeated on three different days, and the total number of insects (replicates) for each treatment was 60. Almost all parasitoids showed a response to a treatment, so hardly any nonresponders were observed.

All experiments and observations were conducted in the laboratory at room temperature (28±2°C) and 65±5% RH, under a light bank with fluorescent lighting.

Results

Testing Effects on Parasitization Rate

Cuticular extracts of adult YSB bodies applied onto host eggs significantly affected parasitization by *T. japonicum*. More treated eggs were parasitized than controls (~91.5±0.5% vs. 8.25±0.33%, N=36) both in dual and multiple choice tests. Extracts of YSB larval frass also had positive effects on the parasitization rate in dual choice tests. More eggs treated with extracts of YSB larval frass were parasitized than controls. However, the effect was not as pronounced as with the adult cuticular extract. Host eggs treated with cuticular

extracts of YSB larval bodies had the lowest effect on parasitization rates in dual choice tests, whereas no effect was detectable in multiple choice tests. The parasitoids response towards the adult cuticular extracts was significantly greater than to frass (~72.08±0.43%) or the larval extract (31.44±0.38%) (Fig. 1).

Among the chromatographic fractions, the eluate of the 12% ethyl acetate in hexane fraction of the adult extract was the most active one, followed by 8% ethyl acetate in hexane (Table 1). All other fractions were inactive. In the case of larval extracts, only the fractions eluted with 4 and 6% ethyl acetate in hexane stimulated a low percentage of oviposition. The remaining fractions were ineffective in causing any parasitization, and in these cases parasitization was significantly greater in solvent treated control eggs, suggesting an oviposition deterring activity of these fractions.

Treatment of the surface of host eggs with 20 μl of pentadecane, hexadecane, nonadecane, heneicosane, docosane, or pentacosane deterred oviposition. The percentage of eggs parasitized in these treatments was low compared to the other hydrocarbon compounds. Either these chemicals lack oviposition stimulatory activity or they possess deterrent activity (Fig. 2).

As was shown by the multiple choice tests, eicosane, docosane, tricosane, tetracosane, pentacosane, and hexacosane treatment of eggs enhanced the rate of parasitization (Fig. 2). Although host egg parasitization in heneicosane-, docosane-, and pentacosane-treated host eggs was less than the control in dual choice tests, no enhancement was found for heneicosane in the multiple choice test, and an enhanced parasitization was recorded for docosane and pentacosane during multiple choice bioassays. Similarly, triacontane was effective in stimulating the oviposition at a considerably higher rate in dual choice tests, but it was somewhat reduced in multiple-choice tests. The different results of dual- and multiple-choice tests might be due to the context (chemical background) in which a parasitoid (insect) experiences a chemical stimulus. Because this background was different in multiple- and dual-choice tests, the varying chemical context might explain these results (Vet and Groenewold, 1990; Mumm and Hilker, 2005; Faucher et al., 2006).

Table 2 Orientation responses of *T. japonicum* female to extracts of YSB adult, larval frass, and larval extracts

Samples	Score/Type of Response	Initial Time of Response (in min)
Crude extracts		
YSB AE	4	3
YSB FE	3	10
YSB LE	1	15
Hydrocarbons		
Pentadecane	1	0
Hexadecane	4	1
Nonadecane	4	3
Eicosane	0	0
Heneicosane	0	0
Docosane	4	0
Tricosane	4	15
Tetracosane	2	1
Pentacosane	4	1
Hexacosane	4	5
Triacontane	4	1

The type of response shown by 60 individual parasitoids is presented. 0=No response, 1=moved upwards, 2=landed on the paper strip, 3=moving around the patch, and 4=probing on the patch

Behavioral Bioassays

The bioassays on landing behavior in the small glass tube experiments revealed the wasps' responses towards the crude extracts, the chromatographic fractions, and the hydrocarbon compounds (Table 2). Parasitoids showed great preference for adult host cuticular extracts. In these treatments, wasps moved upwards and landed on the treated strip followed by ovipositor probing, which is an indication of the highest positive response. Extracts of larval frass also stimulated to a certain extent, although the parasitoids could only land on

The total number of chemicals found was 31, but the chemicals present in less than 1% of the area were not included

the paper strip containing the treatment spot. Larval extracts also evoked slight positive movements in the parasitoids; they made upward movements in the glass tube but did not reach the treated area. However, when testing control solvent strips, all wasps remained at the bottom of the glass tube without attempting to move upwards. These responses of *Trichogramma* were clear, always showing the same response to each chemical or extract.

The parasitoids' responses towards the various chromatographic fractions of adult extract eluted with different percents of ethyl acetate in hexane were as follows: 4%, 6%, 8%, and 12% ethyl acetate fractions stimulated quick directional movements, and almost within 1 min after introducing the insects, they moved towards the treated spot, landed, and started probing the patch (type 4 response). They remained there until the end of the experimental period. Only 2% and 10% ethyl acetate fractions elicited a type 2 response, i.e., only landing on the paper strip. Similar responses were shown by the parasitoids to the 2% fraction of the larval cuticular extracts.

Among the synthetic hydrocarbons tested for orientation behavior, hexadecane, docosane, tetracosane, pentacosane, and triacontane elicited maximum attraction reaching the target patch within or less than 1 min. This was followed by nonadecane, hexacosane, and tricosane. Interestingly, hexadecane and nonadecane, which failed to enhance parasitization, triggered an excellent orientation in this bioassay. Parasitoids were seen staying on these treatments even after the observation period (Table 2).

Chemical analysis of the active fractions by GC indicated the presence of different groups of chemicals. Among those found in chromatographic fractions of different crude extracts, hydrocarbons are the most abundant and prominent. The adult cuticular extracts of YSB contained most components compared to those present in larval frass (Tables 3 and 4) and (Figs. 3a–c). There were 52 hydrocarbons, 6 acids, 1 alcohol, 1 ester, and 1 terpene in

the cuticular extracts of the adult moths, whereas larval frass had 28 hydrocarbons, 2 acids, and 1 ester. However, a lower number of hydrocarbons were found in larval surface washings, i.e., 27 hydrocarbons, 1 acid. The active fraction (12% ethyl acetate) from the adult extract contained mainly saturated long chain alkanes and alkenes with carbon numbers ranging from C_{20} to C_{32}. The GC analysis of the extracts from YSB larval body

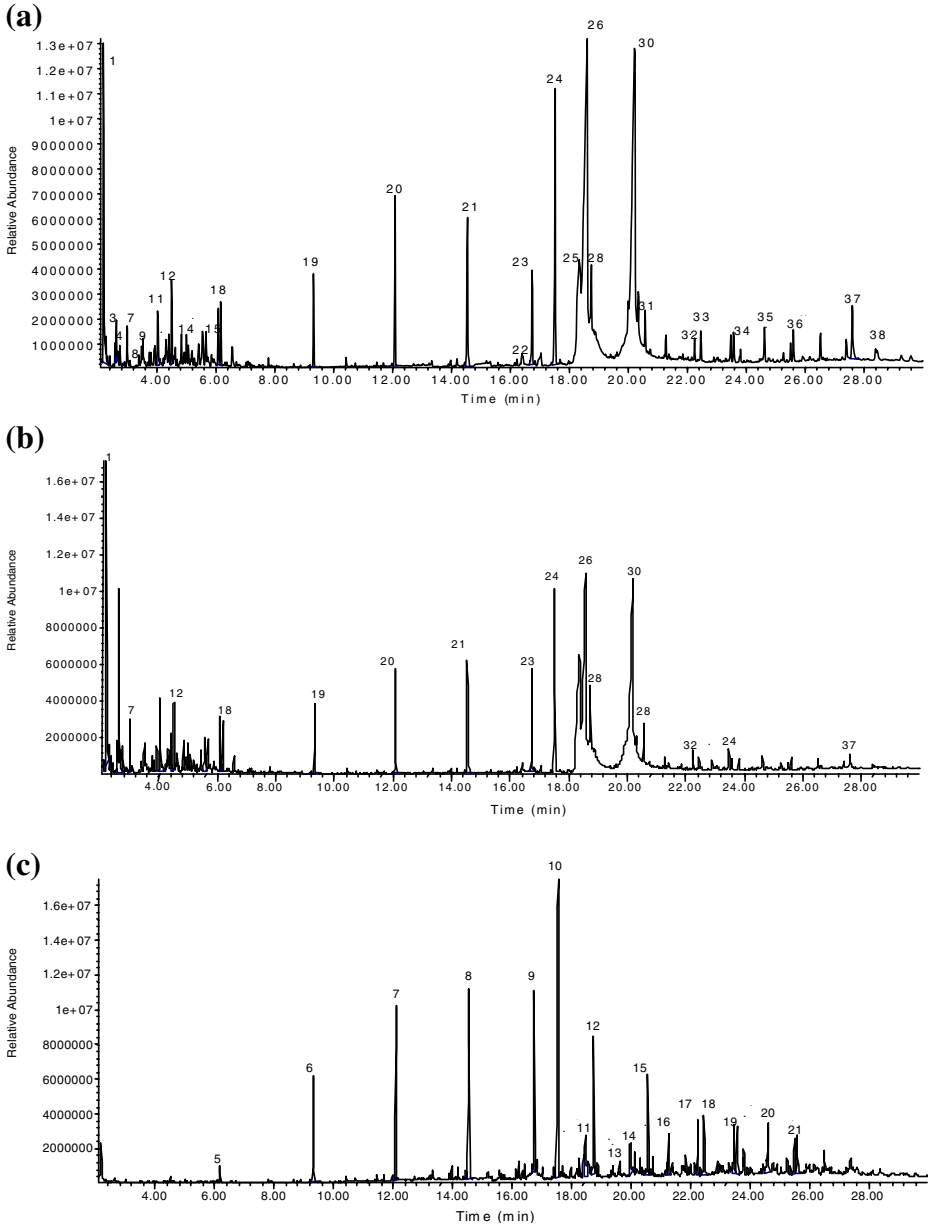

Fig. 3 Representative total ion current chromatograms of GC–MS analysis of adult cuticular extracts, the fraction eluted with 8:92 ethyl acetate in hexane (a), 12: 88 ethyl acetate in hexane (b), and larval frass (c) of YSB, *S. incertulas*. Compare numbers of (a) and (b) to Table 3 and numbers of (c) to Table 4

surface showed a different blend of chemicals, mostly those absent in the other two extracts (larval frass and adult). Toluene and 1,3-dimethyl benzene were present in larger quantities in larval YSB cuticular extracts than in the extracts of frass or the adult. All the fatty acids found in adult cuticular or frass extracts, such as palmitic, myristic, and oleic acids, as well as certain hydrocarbons, namely, tricosane and tetracosane, were totally absent from the larval body extracts. Squalene (2,6,10,14,18,22 tetracosahexaen) was present in all three extracts.

Discussion

The results demonstrate that cuticular extracts of adult host moths increase parasitization efficiency of *T. japonicum*. The active materials are hexane soluble. They indicate that the chemicals extracted from the surface of adult YSB cause arrestment of parasitoids in host vicinity and stimulate oviposition by *T. japonicum*. The parasitoid's stronger response to adult host cuticular extracts in comparison to larval frass or larval body extracts indicates that this response is specific to the adult host and not a general response to insect cuticular chemicals. Our findings support those of several previous studies that have shown that moth body extracts affect parasitoid behavior (Lewis et al., 1975a, b; Elzen et al., 1984; Gross et al., 1984; Nordlund et al., 1984; Boo and Yang, 2000).

Extracts of adult host moths are mainly extracts of wing scales. Previous studies have shown that scales left by ovipositing host females aid in actual location of host eggs by parasitoids. Kairomones in moth scales probably act as sign stimuli, eliciting intensified searching behavior, rather than as a guiding cue attracting and directing the parasitoid to the host (Boo and Yang, 2000). Scale shedding by ovipositing moths is either incidental or can have an adaptive value. Moth scales present at oviposition sites signal the presence of host eggs on a larger area than the eggs alone. The major compounds identified as attractant and oviposition stimulants for egg parasitoids are hydrocarbons, which generally serve many functions in insects. They comprise a significant portion of the cuticular lipids that prevent desiccation, and are important in chemical communication (Nelson and Blomquist, 1995). Parasites have evolved the ability to utilize hydrocarbon cues produced by their hosts as primary cues in locating their hosts. Contact chemicals that are often secreted by a host and are present in the host frass or webbing have been found to be important for a number of parasitoids (Dicke et al., 1990). These compounds seem to elicit a fixed behavioral pattern exhibited by antennal searching of a contaminated area, followed by ovipositor probing in some parasitoids. Tricosane, pentacosane, and hexacosane were the hydrocarbons present exclusively in the adult body washings. They may be important cues for host location and ovipositional stimulation in *T. japonicum*. Wäckers and Lewis (1994) suggest that egg parasitoids recognize host eggs in close range by sight, while chemical signals play a secondary role in host searching. Although several parasitoid species rely on visual cues in the close vicinity of host eggs, it is intriguing from our results that parasitoids, when confined with host eggs in small areas such as petri dishes in lab bioassays, could discriminate between host eggs treated with different chemicals.

Certain chemicals, such as docosane, tricosane, tetracosane, and pentacosane were isolated and identified by Jones et al. (1973) from scales of adult *Heliothis zea* and were shown to increase parasitism by the parasitoid *Trichogramma* when applied to host eggs. All these hydrocarbons were also found in YSB adult extracts. Additionally, GC and GC–MS analyses indicated the presence of several organic acids in YSB adult cuticular extracts.

Hexadecanoic acid (palmitic acid) and octadecanoic acid (oleic acid) are the two compounds commonly occurring in both active fractions, i.e., 8% and 12% ethyl acetate in hexane. They are assumed to contribute to an increase of parasitism by *T. japonicum*. Because these two compounds have a high number of carbon atoms, they might act as contact stimulants, whereas the chemicals with less than 10 carbon atoms are more volatile and might attract parasitoids to the near vicinity of the host eggs.

The triterpene squalene and a diterpene kaur 16-en were present in all three extracts studied. Behavioral effects of squalene in interactions among other organisms and on third trophic levels have been reported by Dutton et al. (2002), who observed the triggering of ovipositional probing behavior of the parasitic wasp *Pholetesor bicolor*. We assume a similar function of this chemical in *T. japonicum*. A small percentage of parasitoids preferred the eggs treated with the fractions of larval cuticular extracts eluted with 4% and 6% ethyl acetate in hexane, and perhaps the presence of squalene might be responsible for this.

It has been argued that stem boring behavior of several herbivore species avoids the release of feeding damage cues and reduces their accessibility to natural enemies (Strong et al., 1984). The extracts of body washings of the larva or the solvent were found to have little effect on parasitization by *T. japonicum*. Larvae of YSB live inside the feeding tunnels of the rice stem and are not exposed to the parasitoids. Hence, it is unlikely that parasitoids use chemical cues emanating from the larval body surface as cues in locating the egg masses of YSB. The intense antennation and the enhanced parasitization of host eggs treated with YSB larval frass are interesting as larval frass also occurs in the tunnels made by feeding host larvae. However, the entrance hole of the tunnel was usually filled with frass pushed out of the tunnel by the feeding stem borer larvae. Hence, larval frass may serve as host locating cue to the wandering parasitoid.

This study showed that adult YSB moths have contact kairomonal activity associated with their bodies. Hexane extracts of moth scales, wings, and abdominal tips were a source of kairomones eliciting positive responses in *T. japonicum*. Presence of chemicals on crop plants could enhance host finding chances and, thus, the percent parasitism and reproduction by parasitoids. Compounds that attract or arrest parasitoids could be used in treating crops with kairomones to enhance the success of parasitism, thus reducing the need for harmful pesticides. This would meet the increasing need to use biological control of pest insects that damage plants grown in monocultures.

Alkaloid Profiles, Concentration, and Pools in Velvet Lupine (*Lupinus leucophyllus*) Over the Growing Season

Stephen T. Lee · Michael H. Ralphs · Kip E. Panter · Daniel Cook · Dale R. Gardner

Received: 14 July 2006 / Revised: 18 September 2006 / Accepted: 21 September 2006 /
Published online: 5 December 2006
© Springer Science + Business Media, Inc. 2006

Abstract *Lupinus leucophyllus* is one of many lupine species known to contain toxic and/or teratogenic alkaloids that can cause congenital birth defects. The concentrations of total alkaloids and the individual major alkaloids were measured in three different years from different plant parts over the phenological development of the plant. All of the alkaloids were found in the different plant tissues throughout the growing season, although their levels varied in different tissues. Concentrations of total alkaloids and the individual alkaloids varied on an annual basis and in their distribution in the different tissues. Anagyrine levels were highest in the floral tissue, lupanine and unknown F accumulated to the greatest level in the vegetative tissue, and 5,6-dehydrolupanine accumulated to the highest level in the stem. These alkaloids appear to be in a metabolically active state with the teratogenic alkaloid anagyrine accumulating to its highest level in the developing seed. The latter is, thus, the phenological stage posing the greatest danger to grazing livestock.

Keywords Lupine · Anagyrine · Crooked calf

Introduction

Lupines (*Lupinus* spp.) are a common plant species on western U.S. rangelands. Several species contain alkaloids that can be toxic and/or teratogenic to livestock. Historically, lupines have been a major cause of sheep deaths from respiratory failure on foothill and mountain rangelands in the western US (Kingsbury, 1964). Ingestion of lupine by the dam was reported to cause congenital birth defects in calves (crooked calf disease) in the early 1960s (Binns et al., 1962; Shupe et al., 1967a). Additional research demonstrated that the principal time of insult was during the 40–70th day of gestation (Shupe et al., 1967b). The quinolizidine alkaloid, anagyrine (Keeler, 1976), and some piperidine alkaloids (Keeler and Panter, 1989; Panter et al., 1998) were shown to reduce fetal movement during this critical

e-mail: stlee@cc.usu.edu

period of gestation (Panter et al., 1990), causing the spine and limbs to develop in contracted or misaligned positions. Reports of calf losses due to crooked calf disease in several western states continue to be reported (Bagley and Panter, 1996; Panter et al., 1997; Warnock, 1997).

The objective of this study was to evaluate the toxicity of velvet lupine (*Lupinus leucophyllus*) over the growing season. Concentration of the teratogenic alkaloid anagyrine and total alkaloid concentration was measured in plant parts over the growing season, and profiles of the major alkaloids were determined.

Methods and Materials

Site Description

The study was conducted in conjunction with a grazing study (Ralphs et al., 2006) in the channel scabland region of eastern Washington state, USA about 25 km southeast of Ritzville (N 46°15.347′, W 118°13.031′), where losses of crooked calves have been catastrophic. In the spring of 1997, over 650 calves on 13 ranches were born deformed and had to be destroyed; occurrence on some individual ranches was as high as 100%. Additional calves that were deformed but functional were sold at minimal prices (Clive Gay, unpublished data).

The study site was characterized by basalt plateaus with depressions and valleys carved by geologic floods from the ancient lake Missoula. The original plant community of the bottomland site was dominated by basin wildrye (*Leymus cinereus*), and on the slopes by Palouse prairie species, such as bluebunch wheatgrass (*Pseudoroegneria spicata*), and Idaho fescue (*Festuca idahoensis*). The site has been degraded by fire and overgrazing to the point that it is dominated by annual species such as cheatgrass (*Bromus tectorum*), fiddleneck (*Amsinckia intermedia*), tansy mustard (*Descurainia pinnata*), prickly lettuce (*Lactuca serriola*), and black mustard (*Brassica nigra*). Velvet lupine (*L. leucophyllus*) was one of the few perennial forbs remaining.

Lupine samples were collected at roughly 2-wk intervals during the growing season in 2001, 2002, and 2003. Ten uniform plants were harvested during each collection period throughout the length of the pasture at approximately noon. They were separated into parts (leaf, stem, flower, pod, and seed), dried at 60°C for 48 hr, and ground through a cyclone mill, and 100 mg of the dried plant material was weighed into a 16-ml screw top glass vial. Alkaloids were isolated following standard acid/base extraction procedures with 1% hydrochloric acid, chloroform, and dilute ammonium hydroxide, and quantified by a gas chromatography (GC) (Gardner and Panter, 1993). Deviations from the previously described procedure included the use of caffeine as an internal standard, and concentrations of alkaloids were quantified against a six-point anagyrine standard.

Alkaloid concentrations were measured in plant parts, and profiles of the major alkaloids are presented over the growth stages of the plant. In addition, alkaloid pools, or absolute amount of alkaloid, was calculated by multiplying the concentration by the dry weight of the plant part. Pools are more useful in interpreting ontogenetic and environmental changes in synthesis and distribution of secondary compounds in plants (Koricheva, 1999). Plants produce and allocate quantities of compounds, whereas concentrations reflect the distribution of these quantities in plant tissues, and are therefore, functions of plant biomass.

Statistical Analysis

Concentration of the teratogenic alkaloid, anagyrine, and total alkaloids, were compared among plant parts and over years by a mixed model analysis of variance (SAS, 1999). Year and plant part were the fixed effects, and individual plants were the random effect. There was a year by plant part interaction for both anagyrine and total alkaloids; thus, the model was reduced, and each part was analyzed separately across years. Means were separated by the PDIFF function within the mixed model, comparing all possible combinations.

The concentration of anagyrine in plant parts was graphed over the growing seasons each year to express their phenological development. Anagyrine pools and standard errors for floral parts and leaf/stem were also graphed over the growing season to illustrate the total amount of the teratogenic alkaloid in the plant over the season and between years. Profiles of the six dominant alkaloids in this population of velvet lupine are also presented by plant part and over the growing season.

Results

The GC alkaloid profile of velvet lupine shows the presence of six major alkaloids and a number of minor alkaloids (Fig. 1). Three of the major alkaloids in velvet lupine were determined by GC retention time and mass spectrometric data to be 5,6-dehydrolupanine, lupanine, and anagyrine (Kinghorn and Balandrin, 1983; Wink et al., 1995). The alkaloids F (mw=246), T (mw=262), and N (mw=278) do not appear to correspond to any known alkaloids. We are in the process of separating and isolating enough of these compounds for structural determination.

Concentration of anagyrine and total alkaloids differed among years ($P<0.003$), plant parts ($P<0.001$), and there was a year × part interaction ($P<0.001$). Anagyrine con-

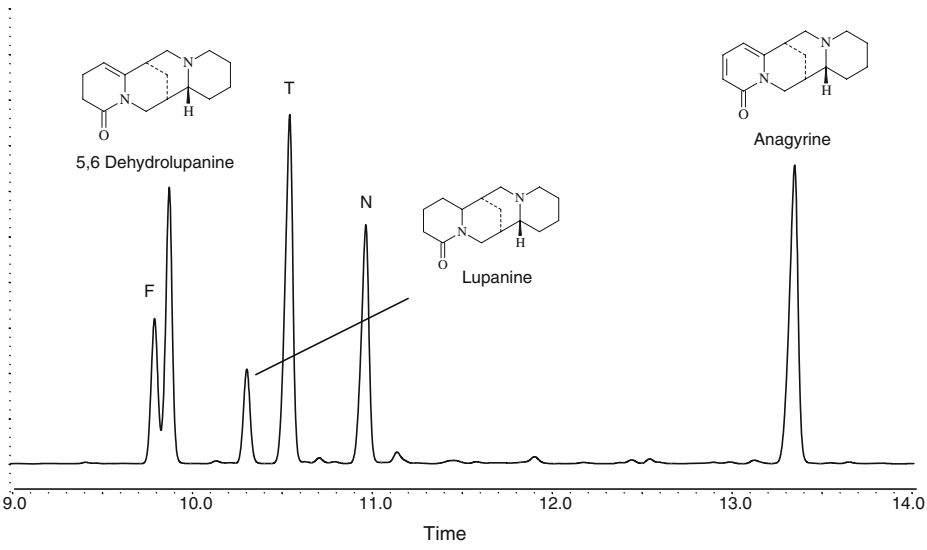

Fig. 1 Representative gas chromatogram showing quinolizidine alkaloids in velvet lupine

centration was greater in the floral heads than in the leaf and stem in each of the 3 yr (Table 1). Furthermore, the concentration of anagyrine in the floral head was greater in 2002 than the other 2 yr. Concentration of the total alkaloids was similar in the floral heads and leaves, but lower in the stem (Table 1). In addition, the total alkaloid content and the anagyrine content are not directly related in the different plant parts on a yearly basis. For example, the anagyrine concentration in floral heads was significantly higher in 2002 than in 2003, whereas the total alkaloid was similar in these 2 yr.

Anagyrine concentrations were greater in the floral parts than in the leaf and the stem throughout most of the growing season in all 3 yr (Fig. 2). The anagyrine concentration in the seed was two to three times greater than in the flower or pod. Anagyrine concentrations increased in the floral tissue until seed maturation and shatter, whereas its concentration in vegetative tissue remained constant or slightly decreased. After the seeds shattered from the pod around the first of July each year, anagyrine concentrations declined, suggesting that much of the anagyrine was contained in the seeds and/or catabolized as the seeds matured and shattered.

Anagyrine pools were calculated by multiplying the mass or weight of the plant part by the anagyrine concentration in the part. Anagyrine pools in the floral parts were greater than in the leaf and the stem through much of the growing season (Fig. 3). This results from the higher concentration of anagyrine in these parts and the increasing proportion of the plant's mass as the pods mature. Anagyrine pools in the floral parts steadily increased up to the point of seed ripening, which was subsequently followed by a significant decline after the seeds shattered from the pod. Anagyrine pools in the vegetative tissue remained constant or decreased.

Other Major Alkaloid Profiles

All of the other alkaloids were present in both floral, leaf, and stem tissue at some point within the growing season. Unknown F, 5,6-dehydrolupanine, and lupanine were present at higher levels in the leaves than in the floral parts (Fig. 4). Levels of these three alkaloids increased or stayed approximately the same from early growth to the point of seed maturity followed by a subsequent decline. Unknowns N and T were present in both the leaves and floral parts equally. They also increased in concentration as the plant matured, followed by

Table 1 Anagyrine and total alkaloid concentration of plant parts over years

a decline. Interestingly, anagyrine was the only alkaloid that showed greater levels in the floral parts than the other tissue parts.

In the stem, 5,6-dehydrolupanine is the dominant alkaloid (Fig. 5). Its concentration was two to three times greater than the other alkaloids in the stem during rapid growth and up to pod formation.

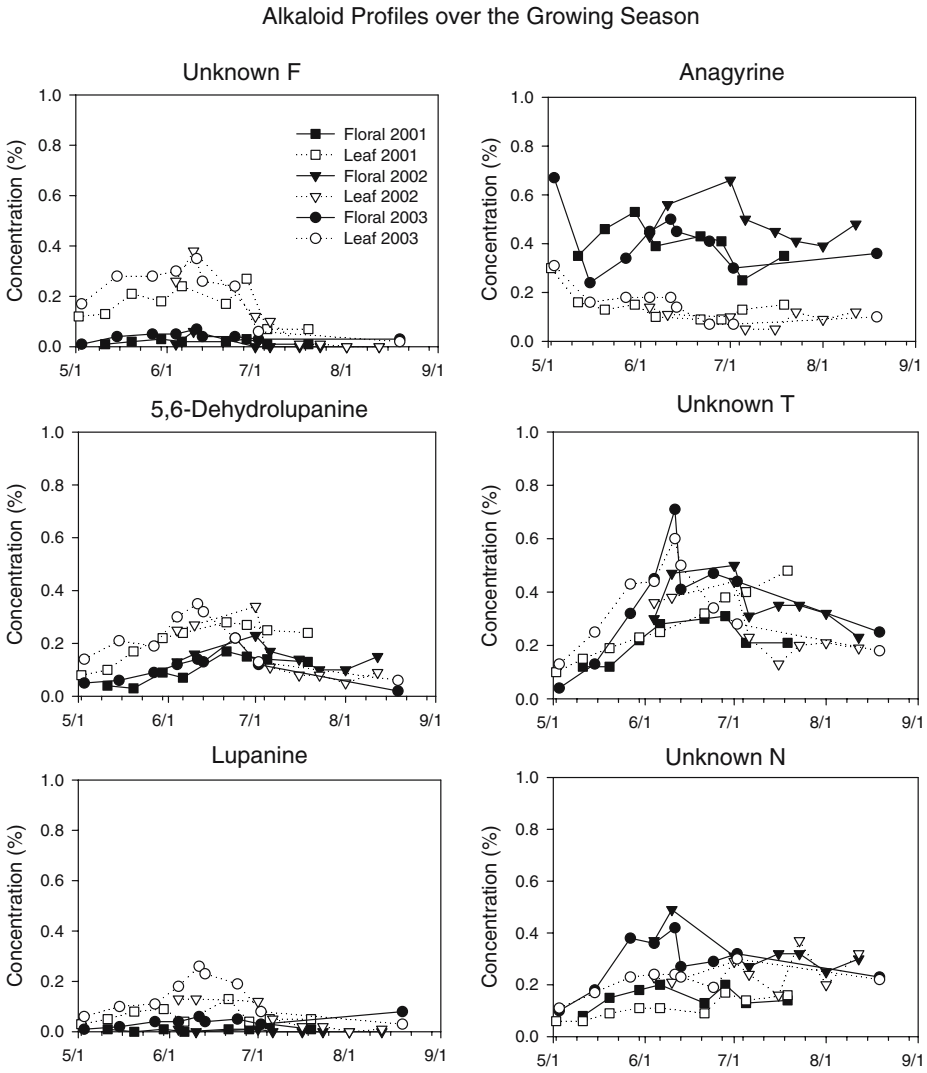

Fig. 4 Major alkaloids in floral parts and leaves over the growing season

Discussion

Velvet lupine contains a number of alkaloids that can be toxic and/or teratogenic to livestock. The concentrations of six alkaloids were evaluated throughout the growing season in different plant parts. Total alkaloids and anagyrine varied from year to year and in the different plant parts.

The teratogenic alkaloid anagyrine accumulates in the floral parts and reaches its highest concentration in the seeds. These results are similar to observations reported by Keeler (1976) in *L. caudatus* from different phenological growth stages. Furthermore, the anagyrine pools suggest that the majority of this toxic alkaloid is located in the floral parts. This is in contrast to lupanine and unknown F that accumulate to greater levels in

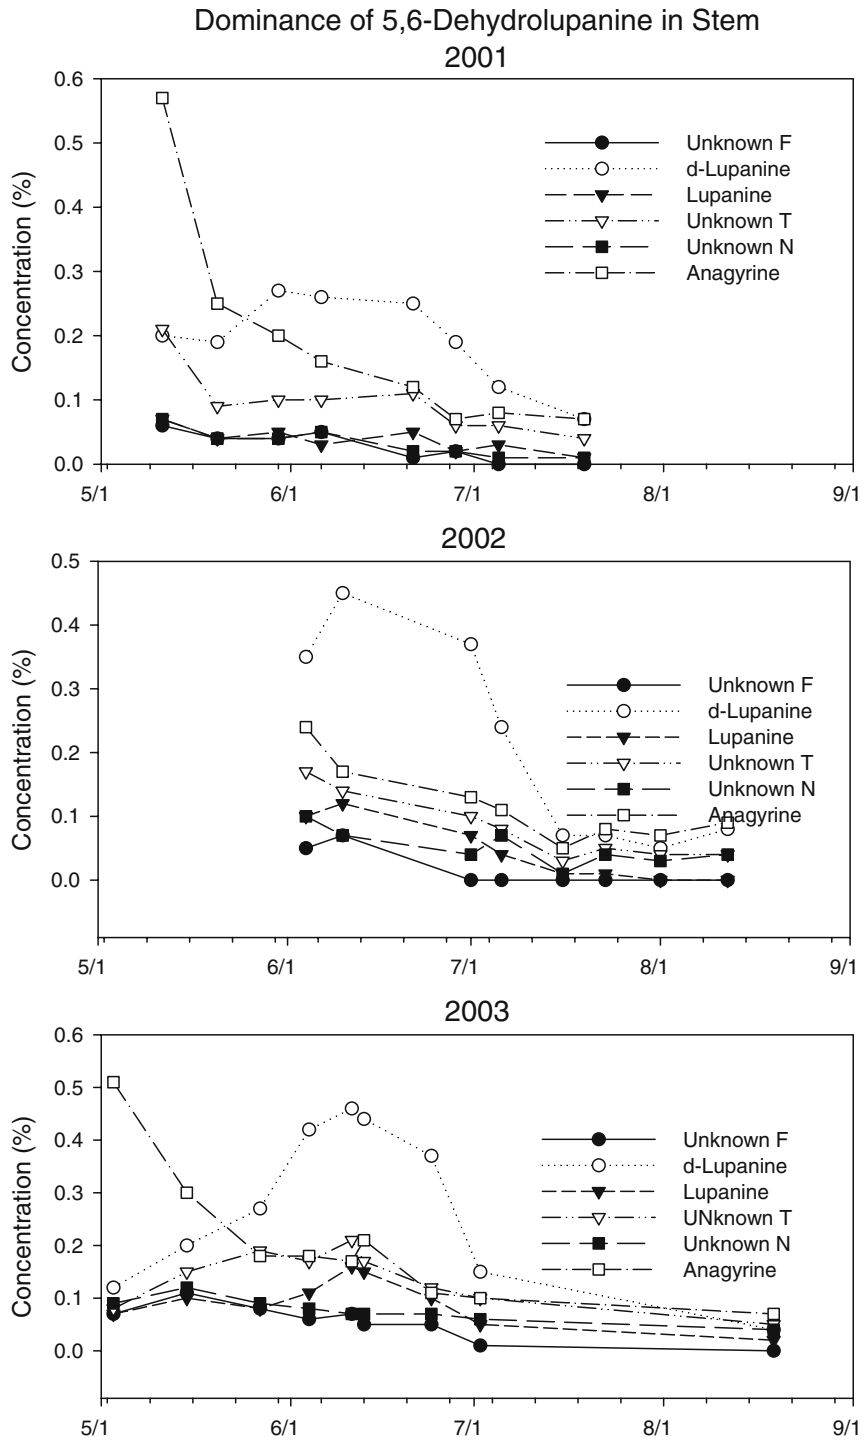

Fig. 5 Dominance of 5,6-dehydrolupanine (*d*-lupanine) in stems during rapid growth

leaves than the floral parts. In addition, 5,6-dehydrolupanine is the major alkaloid in the stem. The dominance of 5,6-dehydrolupanine in the stem suggests a transport function. Interestingly, it has been shown to be an intermediate metabolite in the biosynthesis pathways from lupanine to anagyrine (Cho and Martin, 1971). These results suggest that these compounds are in a metabolically dynamic state throughout the plant.

Wink and Witte (1984) reported that quinolizidine alkaloids in the annual lupine (*L. albus*) are synthesized in the chloroplast in leaves during the day, translocated through the phloem stream in the stem during the afternoon, are deposited in the pod and seeds, and decline during the night. This suggests that quinolizidine alkaloids are not waste products or end products of metabolism, but that they are metabolically dynamic compounds involved in defense from herbivory. In further support of this active metabolic process, it was observed that anagyrine in the seeds comprised only 13–38% of the total anagyrine pool in the floral head just before seed shatter. The results indicate that a significant portion of the pool of anagyrine remains in the empty pods and is then degraded and/or translocated from the middle of July to the first part of August. These results are consistent with a report from Wink and Hartmann (1981) that the concentration of quinolizidine alkaloids dropped 90% during senescence.

In summary, the quinolizidine alkaloids in lupine appear to be in a metabolically active state. The distribution of the individual alkaloids in the different tissues led us to speculate that unknown F and lupanine are synthesized in the leaf, transported in the phloem in the stem as 5,6-dehydrolupanine, and metabolized to anagyrine in the flowers, the pods, and the seeds. The teratogenic alkaloid anagyrine accumulates to its highest level in the floral parts and reaches its highest concentration in the seeds as they mature in late June. Anagyrine concentration drops dramatically as the seeds shatter in mid-July. The general breeding for cattle in the region where this study was performed is from May 1 to July (Ralphs et al., 2006). This puts the susceptible period of gestation to cause crooked calves (40–70 d of gestation) between approximately June 10 and October 8. Therefore, the high concentration of anagyrine in the mature seed overlaps the susceptible period of gestation, causing a high risk of crooked calf syndrome.

Abstract Cyanide production has been reported from over 2500 plant species, including some members of the Brassicaceae. We report that the important invasive plant, *Alliaria petiolata*, produces levels of cyanide in its tissues that can reach 100 ppm fresh weight (FW), a level considered toxic to many vertebrates. In a comparative study, levels of cyanide in leaves of young first-year plants were 25 times higher than in leaves of young *Arabidopsis thaliana* plants and over 150 times higher than in leaves of young *Brassica kaber*, *B. rapa*, and *B. napus*. In first-year plants, cyanide levels were highest in young leaves of seedlings and declined with leaf age on individual plants. Leaves of young plants infested with green peach aphids (*Myzus persicae*) produced just over half as much cyanide as leaves of healthy plants, suggesting that aphid feeding led to loss of cyanide from intact tissues before analysis, or that aphid feeding inhibited cyanide precursor production. In a developmental study, levels of cyanide in the youngest and oldest leaf of young garlic mustard plants were four times lower than in the youngest and oldest leaf of young *Sorghum sudanense* (cv. Cadan 97) plants, but cyanide levels did not decline in these leaves with plant age as in *S. sudanense*. Different populations of garlic mustard varied moderately in the constitutive and inducible expression of cyanide in leaves, but no populations studied were acyanogenic. Although cyanide production could result from breakdown products of glucosinolates, no cyanide was detected *in vitro* from decomposition of sinigrin, the major glucosinolate of garlic mustard. These studies indicate that cyanide produced from an as yet unidentified cyanogenic compound is a part of the battery of chemical defenses expressed by garlic mustard.

Introduction

Cyanide is a well-known inhibitor of respiratory electron transport that is produced by over 2500 plant species including many food plants (Jones 1998). Although substantial debate

exists on the role of cyanogenic compounds and cyanide in plants (Jones 1998; Gleadow and Woodrow, 2002), cyanide production has been invoked as an herbivore- and pathogen-resistance mechanism in many plants including clover, black cherry, and sorghum (Lindroth et al., 2000; Busk and Møller, 2002; Fitzgerald et al., 2002; Gleadow and Woodrow, 2002). In addition, cyanogenic compounds in plants like cassava appear to have roles in storage and mobilization of nitrogen (Gleadow and Woodrow, 2002; Jorgensen et al., 2005). Cyanide production in each of the aforementioned species typically reaches levels that can impact animal or human health (Jones 1998). Cyanide production has been reported in some members of the Brassicaceae, including *Brassica oleraceae*, *B. juncea*, *B. rapa*, *B. napus*, and *Raphanus sativus* (Sexton and Howlett, 2000; Chandra et al., 2004), but levels found thus far in plants in this family have been minimal and generally well below those considered to affect plant or animal health. In turn, the source of the detectable cyanide in brassicaceous plants is unknown, although the decomposition of glucosinolates, a ubiquitous group of defensive secondary compounds in this family, is one candidate (Sexton and Howlett, 2000).

Garlic mustard *Alliaria petiolata* [(M. Bieb) Cavara and Grande; Brassicaceae] is a Eurasian biennial herb that is an important invasive plant in North America. This plant has several known or presumed impacts on the flora and fauna in its invaded range that are apparently chemically mediated. These include allelopathic interactions with plants (Prati and Bossdorf, 2004), mycorrhizal fungi (Roberts and Anderson, 2001; Stinson et al., 2006), and herbivorous insects (Porter 1994; Haribal and Renwick, 1998; Haribal et al., 2001). Garlic mustard is also grazed little by mammalian or avian herbivores (D. Cipollini, personal observation). Like all brassicaceous plants, garlic mustard produces glucosinolates and defense proteins in both a constitutive and inducible fashion (Vaughan and Berhow, 1999; Cipollini et al., 2005). Garlic mustard is also rich in flavone gycosides, including isovitexin 6″-*O*-β-D-glucopyranoside, and it produces a novel cyanoallyl glycoside, alliarinoside; both have demonstrable effects on insect resistance (Haribal and Renwick, 1998; Haribal et al., 2001; Cipollini et al., 2005). It is likely that this suite of defenses contributes to the invasive success of this plant in novel habitats.

In this paper, we report that garlic mustard produces substantial quantities of cyanide from its tissues, an as yet undescribed component of the chemical arsenal of this plant. We first examined cyanide production in leaves and roots of young plants from a single population of garlic mustard, and then compared levels found in shoots to those of several members of the Brassicaceae. Second, we compared temporal variation in cyanide production in the youngest and oldest leaves of garlic mustard to that of a known cyanide producer, *Sorghum sudanense* (Sudan grass). Third, we examined leaf age-specific cyanide production in garlic mustard in the presence and absence of aphid herbivory. Fourth, we examined variation among garlic mustard populations in constitutive and inducible cyanide production. Finally, we examined whether the decomposition of sinigrin, the primary glucosinolate in garlic mustard (Vaughan and Berhow, 1999), could be the source of cyanide produced by this plant.

Methods and Materials

Experiment 1: Demonstration of Cyanide in Roots and Shoots of Garlic Mustard Seeds of garlic mustard were collected from plants growing naturally in the Wright State University forest preserve, cold stratified, and grown in the greenhouse in Pro Mix BX potting

medium, as described by Cipollini et al. (2005). Most experiments were conducted with the Wright State population, although experiment 5 includes several other populations. In this experiment, four plants were grown for 3 wk at which time all stems, leaves, and petioles present on each plant were collected and pooled for cyanide analysis, as described below. Roots of each plant were carefully extracted from the soil at the same time and rinsed free of soil with distilled water before cyanide analysis. Cyanide production by above-ground tissues was compared to that of roots with one-way analysis of variance (ANOVA) on SAS (version 9.1). Means were compared using Tukey's test in this and all other experiments.

Experiment 2: Comparisons of Cyanide Production in Leaves of Garlic Mustard with Other Brassicaceous Plants Seedlings of *Arabidopsis thaliana* (ecotype Columbia), *Brassica kaber* (wild collected), *B. rapa* (wild collected), and *B. napus* (cv. Westar), were grown from seed as described above, but without cold stratification. Garlic mustard was grown from cold-stratified seed as described above. All leaf material present on five 3-wk-old plants of each species was collected and pooled for analysis of cyanide. Cyanide production was compared among species with one-way ANOVA.

Experiment 3: Temporal Variation in Cyanide Production in Leaves of Garlic Mustard in Comparison to Sudan Grass This experiment was designed to compare variation in cyanide production in garlic mustard to a known cyanide-producing plant. Garlic mustard and Sudan grass [*S. sudanense* (cv. Cadan 97)] were grown from seed individually in pots in Pro Mix BX, as described above. Starting 2 wk after germination, the youngest fully expanded leaf and the oldest fully expanded leaf were collected from five plants of each species for cyanide analysis. Harvests continued in this manner from a subset of previously unsampled plants once per week for the next 8 wk, although the oldest leaves on each plant could be sampled for only 4 wk until they were too senescent to sample. This collection scheme isolates the effect of plant age on cyanide production in leaves of two distinct developmental stages. Cyanide production through time was compared between garlic mustard and Sudan grass with repeated-measures ANOVA, with time as the within-subject effect and species as the between-subjects effect. As the youngest leaves on each plant were sampled for 8 wk, and the oldest for only 4 wk, cyanide production was statistically examined separately for the youngest and oldest leaves.

Experiment 4: Leaf-specific Cyanide Production in the Presence of Aphid Herbivory This experiment examined within-plant variation in cyanide production among leaves in garlic mustard, but the plants were impacted by an outbreak of green peach aphids (*Myzus persicae*) in our greenhouse. When plants grown as described above were 40-d-old, we classified subsets of them as noninfested or infested (~20–30 aphids per plant). Infested plants were affected by aphids for approximately 2 wk at the time they were sampled. Fully expanded third (old), fourth (intermediate), and fifth (young) true leaves of garlic mustard plants were collected from 10–13 plants in each aphid infestation group for analysis of cyanide. Cyanide production was compared among aphid exposures and leaf ages by using two-way ANOVA, with aphid exposure and leaf age nested within aphid exposures as effects.

Experiment 5: Population Variation in Constitutive and Salicylic Acid-induced Levels of Cyanide Seeds of five populations of garlic mustard collected in the wild from Dalsland, Sweden; Marmontweg and Elderveld, the Netherlands; Hanau, Germany; and Ligonier, Pennsylvania, were cold-stratified and grown as described above. When plants were 8 wk

old, five plants from each population were sprayed with a 0.05-M solution of salicylic acid, as described by Cipollini et al. (2004). Salicylic acid induces many defense-related genes in plants (Mauch-Mani and Metraux, 1998), but its effect on cyanide production has never been examined. Leaf material was collected from the fully expanded fourth true leaf of each of these plants along with each of five control plants. Cyanide production was compared among populations and salicylate treatments with two-way ANOVA.

Experiment 6: Assessment of Sinigrin as a Source of Cyanide In this experiment, we evaluated the ability of sinigrin, the primary glucosinolate in garlic mustard (Vaughn and Berhow, 1999), to liberate cyanide upon enzymatic decomposition with thioglucosidase. We incubated 0.1 ml of sinigrin (Sigma Chemical, St. Louis, MO, USA) at concentrations of 0.125, 0.25, 0.5, 1.0, and 2.0 mg/ml with 0.1 ml of 3 mg/ml thioglucosidase (E.C. 3.2.3.1 from *Sinapis alba*; Sigma Chemical) suspended in sodium phosphate buffer in 25 ml center-well incubation flasks, and followed the protocol for cyanide trapping and analysis described below.

Cyanide Analysis We analyzed endogenous cyanide production in our tissues using a method modified from Lambert et al. (1975). Briefly, a weighed amount of fresh plant material (~0.02–0.05 g depending on tissue and species) was ground in a cold mortar with 0.5 ml of ice-cold 0.1-M sodium phosphate buffer. The homogenate was quickly transferred to a 25-ml center-well incubation flask, and the mortar was rinsed into the flask with an additional 0.5 ml of phosphate buffer. To trap cyanide in the flask, 0.2 ml of 0.1 M NaOH was placed in the center well, and the flasks were sealed and incubated at room temperature for 18 hr. To quantify cyanide present in the trap solution, 0.1 ml of 1 M acetic acid were added to the 0.2-ml trap solution (which was diluted as needed), followed by 1 ml of 0.25% succinimide/0.025% *N*-chlorosuccinimide reagent and 0.2 ml of 3% barbituric acid–pyridine solution. After incubation at room temperature for 10 min, absorbance at 580 nm was recorded for each sample in a spectrophotometer. Cyanide levels were quantified relative to a standard curve made with potassium cyanide and are expressed as milligram cyanide per kilogram tissue fresh weight (=ppm FW).

Results

Experiment 1 Three-week-old garlic mustard plants produced a mean level of 44.4 (±2.17) ppm cyanide from their aboveground tissues (including stems, leaves, and petioles) and 5.4 (±2.13) ppm from their roots. These levels were significantly different from one another ($F_{1,\ 6}$=212.5, P<0.001).

Experiment 2 Leaf cyanide production varied among the five brassicaceous species examined ($F_{4,\ 14}$=526.0, P<0.001, Table 1). Levels of cyanide in leaves of 3-wk-old garlic mustard plants were 25 times higher than in leaves of 3-wk-old *A. thaliana* plants and over 150 times higher than in leaves of 3-wk-old *B. kaber*, *B. rapa*, and *B. napus* plants.

Experiment 3 Changes in cyanide production through time by the youngest fully expanded leaf varied between garlic mustard and Sudan grass (time × species: $F_{7,\ 2}$=54.02, P=0.018, Fig. 1). Cyanide production in the youngest leaf of Sudan grass was five times higher than

Table 1 Mean (±1 SE) cyanide levels in leaves of 3-wk-old seedlings of five brassicaceous species

Species	Cyanide (ppm)
Alliaria petiolata	108.9 (7.82)[a]
Arabidopsis thaliana	4.19 (2.83)[b]
Brassica kaber	0.733 (0.571)[c]
Brassica rapa	0.617 (0.562)[c]
Brassica napus	0.433 (0.096)[c]

Means followed by different letters are significantly different at $P=0.05$.

in garlic mustard on the first sampling date, and it steadily declined to minimal levels through the 8-wk-time course as plants aged. In contrast, cyanide production declined little through time in garlic mustard, and by the fifth week of the time course through the end, cyanide levels in the youngest leaves of garlic mustard plants were significantly higher than in Sudan grass. A similar pattern was observed in cyanide production in the oldest fully expanded leaf of garlic mustard and Sudan grass through the 4-wk-time course (time × species: $F_{3,\ 6}=150.54$, $P<0.001$, Fig. 2). The decline in cyanide production in the oldest leaves in Sudan grass through time was even more dramatic than in the youngest leaves.

Experiment 4 Cyanide production varied among aphid-infested and noninfested plants ($F_{1,\ 64}=25.56$, $P<0.001$) and among leaf ages within each aphid treatment ($F_{4,\ 64}=10.72$, $P<0.001$, Table 2). Cyanide production was higher in young leaves than in older leaves in general and was lower in aphid-infested plants across all leaf ages.

Experiment 5 Significant variation in constitutive and salicylic acid (SA)-inducible cyanide production in leaves of 8-wk-old garlic mustard plants was detected among populations (pop: $F_{4,\ 40}=4.21$, $P=0.006$; pop × SA: $F_{4,\ 40}=8.4$, $P<0.001$, Table 3). Constitutive cyanide production was higher in plants from Dalsland, Marmontweg, and Elderveld than

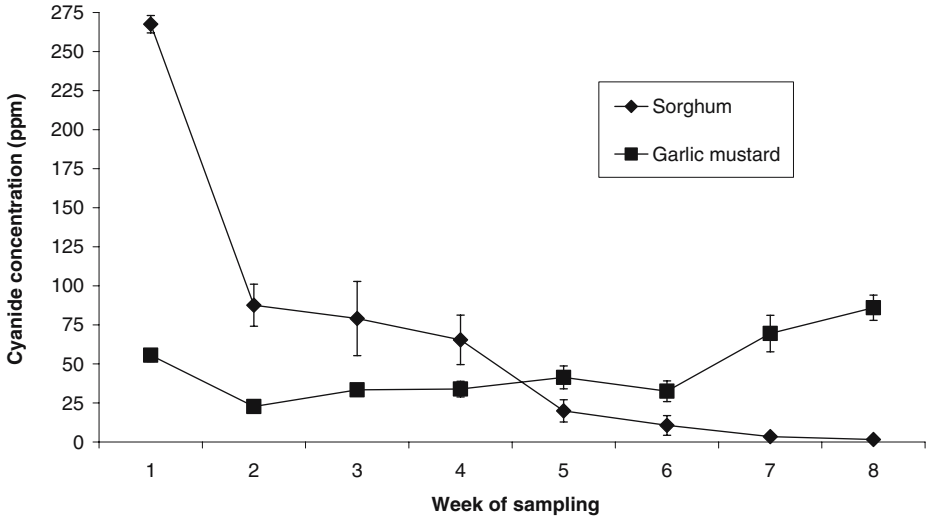

Fig. 1 Mean (±1 SE) cyanide levels in the youngest fully expanded leaf of garlic mustard and Sudan grass (*Sorghum sudanense*) through an 8-wk time course as plants aged. Plants were 2 wk old at the first sampling

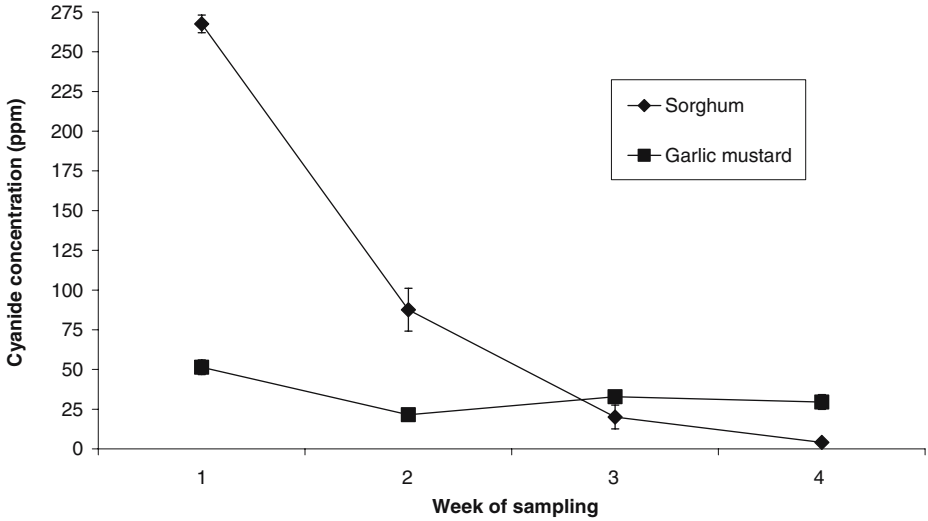

Fig. 2 Mean (±1 SE) cyanide levels in the oldest fully expanded leaf of garlic mustard and Sudan grass (*Sorghum sudanense*) through a 4-wk time course as plants aged. Plants were 2 wk old at the first sampling

in plants from Hanau and Ligonier. Although SA had little effect on cyanide production in plants from Dalsland, Marmontweg, and Ligonier, it strongly induced cyanide production in plants from Hanau and strongly reduced production in plants from Elderveld.

Experiment 6 Cyanide production was not detectable from the decomposition of sinigrin at any concentration in our experimental setup.

Discussion

Garlic mustard, an important invasive plant of forest understories throughout North America, produces a wealth of chemical defenses (e.g., Cipollini et al., 2005). We demonstrate for the first time here that garlic mustard produces substantial amounts of cyanide from its tissues.

Table 2 Mean (±1 SE) cyanide levels in young, intermediate, and old leaves of 5-wk-old seedlings of garlic mustard in the presence and absence of green peach aphids

Treatment	Leaf age	Cyanide (ppm)
Aphids absent	Young	66.2 (8.74)[a]
	Intermediate	38.7 (5.39)[b]
	Old	40.4 (5.00)[b]
Aphids present	Young	47.9 (6.68)[a]
	Intermediate	14.9 (2.13)[b]
	Old	16.9 (2.1)[b]

Means within an aphid treatment with different letters are significantly different at P=0.05.

Table 3 Mean (±1 SE) cyanide levels in leaves of 8-wk-old plants of five garlic mustard populations treated with 0.05 M salicylic acid or a control solution

Population	Salicylate Treatment	Cyanide (ppm)
Dalsland, Sweden	−	30.0 (4.2)[a]
	+	25.4 (4.3)
Elderveld, Netherlands	−	32.0 (4.6)[a]*
	+	11.4 (4.0)
Marmontweg, Netherlands	−	27.0 (4.7)[a]
	+	23.1 (4.1)
Hanau, Germany	−	14.4 (4.1)[b]*
	+	36.7 (4.3)
Ligonier, Pennsylvania	−	17.2 (4.0)[b]
	+	23.4 (4.6)

Means followed by different letters differ significantly at $P=0.05$ in the absence of salicylic acid. Means followed by asterisks indicate populations where salicylic acid significantly affected cyanide levels.

Cyanide contents reached by garlic mustard in some experiments were over 100 ppm FW in leaves, a level considered to be acutely toxic to humans (and other vertebrates) for plants like cassava (Jorgensen et al., 2005). In other experiments, levels in leaves ranged from 20 to 85 ppm, levels that are still considered to be moderately toxic (Jorgensen et al., 2005). As cyanide has known biological activity against animals, plants, and microbes (Jones 1998; Blenis et al., 2004; Gonzalez and Sotomayor, 2005), cyanide may contribute to some of the reported allelopathic effects of garlic mustard on other plants, insects, and mycorrhizal fungi (e.g., Porter 1994; Prati and Bossdorf, 2004; Stinson et al., 2006), and to its known deterrence of mammalian or avian herbivores (D. Cipollini, personal observation). It should be noted that we expressed cyanide content in garlic mustard per unit fresh weight, although many authors express cyanide content per unit dry weight (e.g., Lindroth et al., 2000). Expressing cyanide content in garlic mustard per unit dry weight would increase levels substantially, accounting for the average moisture content of leaves.

Within each plant, cyanide production was much higher in leaves than in roots and generally declined with leaf age. These findings are consistent with patterns of cyanide production in the foliage and roots of many other cyanogenic plants (e.g., Vickery et al., 1987; Busk and Møller, 2002; Fitzgerald et al., 2002; Jorgensen et al., 2005). In plants where the roots contain high levels of cyanide, like cassava, cyanide production by leaves is thought to be the source of cyanogenic compounds that are subsequently transported to roots (Jorgensen et al., 2005). Unlike *S. sudanense* studied here, cyanogenic potential in the youngest leaf of garlic mustard did not decline as plants aged. This indicates that garlic mustard consistently maintains the potential for cyanide toxicity in young leaves throughout much of its first season of growth, a pattern also seen in some other cyanogenic plants (e.g., Gleadow and Woodrow, 2000).

Interestingly, cyanide production was lower in aphid-infested plants across all leaf ages than in noninfested plants. Because we classified plants as infested or noninfested after the aphids had time to choose plants, it is possible that the patterns we observed resulted from aphid selection of the more weakly cyanogenic individuals in our experiment. However, as can be seen in the mean cyanide contents of the noninfested plants, individuals do not vary to a large extent in cyanide production in this population, which is known to be relatively genetically homogenous for other growth and defense characteristics (Cipollini 2002). Thus, it is more likely that aphid feeding somehow caused the differences in cyanide contents that we observed. For example, aphid feeding may have led to the volatilization of

cyanide from intact tissues before their analysis by enabling cyanide precursors and enzymes to mix *in planta*, thus lowering the cyanogenic potential of the tissue at the time of analysis. Alternatively, aphid feeding may have decreased cyanide precursor production either directly by downregulating gene expression or indirectly through nutrient limitation of precursor production. As cyanide production is increased by nitrogen fertilization in many plants (e.g., Busk and Møller, 2002; Jorgensen et al., 2005), aphid feeding may have reduced cyanide content by lowering tissue nitrogen content.

Populations varied to some extent in the constitutive and inducible production of cyanide, similar to other cyanogenic plant species (e.g., Lindroth et al., 2000; Schappert and Shore, 2000), but none of the six total populations studied here was acyanogenic. We have observed differences in defense production among populations of garlic mustard (Cipollini et al., 2005), but not enough populations were sampled in the current study to place our observations in an evolutionary or ecological context. Salicylic acid increased, decreased, or had no effect on cyanide production, depending upon the population studied. Salicylic acid is involved in the induction of numerous defenses in plants in response to biotic stimuli (Mauch-Mani and Metraux, 1998) and is known to induce cyanide-resistant respiration in plants (Kapulnik et al., 1992). Its effect on cyanide production has not been examined in any plant to our knowledge, but it has been shown to suppress the expression of dhurrinase mRNA in *Sorghum bicolor* (Salzman et al., 2005), which would presumably decrease cyanide production from the cyanogenic glycoside, dhurrin, found in these plants.

Garlic mustard produces substantially more cyanide than any brassicaceous plant studied to date (e.g., Sexton and Howlett, 2000; Chandra et al., 2004), including *A. thaliana* and the three *Brassica* species examined in this study. This appears to make garlic mustard unique among members of this family, which are characterized by their production of glucosinolates; cyanide production, however, has not been widely surveyed in this family. Only a few plant species are known as producers of both glucosinolates and cyanogenic glycosides, including *Carica papaya* in the Caricaceae family (Bennett et al., 1997), which is a member of the Capparales order along with members of the Brassicaceae family (Rodman et al., 1998). It has been suggested that glucosinolate production arose in an already cyanogenic species (Rodman et al., 1998; Halkier and Gershenzon, 2006), and it is perhaps surprising that so few members of the Brassicaceae have been confirmed to be cyanogenic.

Regardless of origin, cyanide production by garlic mustard may contribute to its unpalatability toward mustard specialist herbivores that typically prefer glucosinolate-containing plants (Porter 1994; Haribal and Renwick, 1998; Haribal et al., 2001) and some of its other allelopathic effects. We have noted anecdotally that treatment of garlic mustard leaves by freezing followed by subsequent thawing and incubation at room temperature makes them substantially more palatable and fosters better growth of larvae of the cabbage looper, *Trichoplusia ni* (D. Cipollini, unpublished data). This effect may be explained, in part, by the freezing-induced loss of cyanide from tissues. Interestingly, garlic mustard is also distinguished among members of its family by a characteristic garlic odor when its leaves are crushed (thus its common name). To our knowledge, the chemical profile and significance of this volatile blend has not been examined, but cyanide is certainly a part of it.

The source of cyanide in garlic mustard could not be determined in this study. The decomposition of glucosinolates has been suggested as a possible source in brassicaceous plants, but this does not appear to be the source in garlic mustard. Garlic mustard contains sinigrin (2-propenyl glucosinolate) as its primary glucosinolate (Vaughan and Berhow, 1999), but neither we nor Sexton and Howlett (2000) found that the thioglucosidase-

catalyzed hydrolysis of this compound could liberate cyanide *in vitro*. Moreover, the *Brassica* species and *A. thaliana* studied here are each well known as producers of glucosinolates (e.g., Cipollini et al., 2003, 2004; Chandra et al., 2004), yet each gave rise to negligible levels of cyanide in this study. The conversion of 1-amino-cyclopropane 1-carboxylic acid (ACC) into ethylene results in some cyanide production in plants, but levels seen here are much higher than those noted to be produced in this manner in other plant tissues (Yip and Yang, 1998). Although not initially considered a cyanogenic compound, garlic mustard contains a novel cyanoallyl glycoside, alliarinoside, with a –CN group as part of the molecule (Haribal et al., 2001). It is possible that either the enzymatic or nonenzymatic decomposition of this compound could yield volatile cyanide. If this compound is not the source of cyanide, then either other glucosinolates or an as yet undescribed cyanogenic compound may be the source.

Acknowledgments We thank Stephanie Enright for technical assistance, the Ohio Board of Regents for funding, and a simple curiosity that motivated this project. Martin Heil, Nicole van Dam, and Harriet Hillstrom kindly provided seeds of European garlic mustard plants. Two anonymous reviewers substantially improved the manuscript.

Interactive Effects of Leaf Damage, Light Intensity and Support Availability on Chemical Defenses and Morphology of a Twining Vine

Abstract In a greenhouse study, we evaluated the effect of the light environment and support availability on the induction of tropane alkaloids (TAs) after leaf damage in the twining vine *Convolvulus arvensis*. We also tested whether leaf damage modifies the phenotypic responses of the plant to shade and physical support. We found a consistent pattern of induction of TAs after leaf damage in each environmental condition. The induction of TAs was differentially affected by combinations of support and light treatments. In the sun, prostrate and climbing vines exhibited similar induced responses. In the shade, prostrate vines showed greater induced responses. Thus, vines showed the greatest chemical induction when damage occurred in a resource-poor environment (shade), and there was no cue (support) of future increase in resource uptake. Damaged plants showed reduced plasticity to shading in leaf shape and internodes and petiole length in comparison with control, undamaged plants. Herbivory and/or induced responses to herbivory may limit adaptive plant responses to the environment. Therefore, the negative consequences of herbivory on plant fitness might be magnified in a context of changing environments.

Keywords Climbing plants · Herbivory · Induced responses · Physical support · Shade

Introduction

Induced responses to herbivory in plants have been amply reported (Karban and Baldwin, 1997; Zangerl, 2003; Agrawal, 2005) and may be affected by environmental conditions (Gianoli and Niemeyer, 1996; Cipollini and Bergelson, 2001; Costa-Arbulú et al., 2001). The interplay between biotic and abiotic factors may thus determine plant phenotypic responses (Izaguirre et al., 2003, 2006; Cipollini, 2004). In the case of climbing plants, light intensity and support availability are environmental factors of fundamental importance

(Putz, 1984; Gentry, 1991; Ray, 1992). In this regard, forest lianas and herbaceous vines exhibit both morphological specializations and adaptive behaviors that allow a better exploitation of solar radiation (Darwin, 1875; Peñalosa, 1983; Lee, 1988; Putz and Mooney, 1991). There is evidence of induced responses to herbivory in climbing plants (Rausher et al., 1993; Schierenbeck et al., 1994; Fordyce, 2001; Heil, 2004). However, to our knowledge, no study in climbing plant species has addressed the interaction between plant responses induced upon damage and the availability of light and support. Within the theoretical context of plant resource allocation (Zangerl and Bazzaz, 1992), the expression of both induced responses and plastic responses to abiotic factors should depend on the ecological scenario. On one hand, induced responses to herbivory are thought to reduce costs of plant defense (Strauss et al., 2002) and hence are expected to be greater in resource-poor environments (Gianoli and Niemeyer, 1996). On the other hand, induced responses divert plant resources and hence herbivory may limit phenotypic plasticity to challenging environments (Quezada and Gianoli, 2006).

The field bindweed, *Convolvulus arvensis*, as is the case in many taxa from the Convolvulaceae, is a twining vine. Plants of this species that grow erect, i.e., climbing onto physical support, exhibit morphological differences from those growing prostrate (Gianoli, 2001). For instance, climbing individuals have shorter internodes and petioles (Den Dubbelden and Oosterbeek, 1995; Gianoli, 2001), and shaded plants show longer internodes and petioles, and have thinner leaves (Gianoli, 2001; González and Gianoli, 2004). The stems and leaves of *C. arvensis* contain tropane alkaloids (TAs) (Todd et al., 1995), which are toxic against insects and mammals (Krug and Proksch, 1993; Todd et al., 1995) and are inducible after herbivory (Khan and Harborne, 1990). Interestingly, it was recently shown that simulated herbivory on this twining vine enhances its climbing success, and that climbing individuals in the field suffer less herbivory than prostrate ones (Gianoli and Molina-Montenegro, 2005).

The present greenhouse study in *C. arvensis* had two main goals. First, we evaluated the effect of the light environment and support availability on the induction of TAs after leaf damage. Thus, in view of the recently described damage-induced twining that may reduce herbivory (Gianoli and Molina-Montenegro, 2005), we considered another damage-induced response of potential relevance for plant defense, further inquiring into its environmental modulation. In particular, we evaluated the hypothesis that induced responses should be of greater magnitude in resource-poor environments. Second, we tested whether leaf damage modifies the phenotypic responses to shade and physical support that have been described for *C. arvensis* and another convolvulaceous twining vine (Gianoli, 2001, 2002, 2003). Thus, we aimed at determining whether herbivory may limit plant phenotypic plasticity. This is of interest for the debate on the effects of herbivory on plant fitness (Marquis, 1992). Thus, if foliar damage constrains the capacity of plants to display functional responses to the environment, then the consequences of herbivory may be magnified in a context of changing environments.

Methods and Materials

Convolvulus arvensis L. (Convolvulaceae), the field bindweed, is a perennial herb with slender stems (0.5–2 m long) that are trailing or twining when physical support is available. Leaves (2–6 cm long) are simple, alternate, triangular to ovate-oblong. This species is typically found in cultivated fields and roadsides (Weaver and Riley, 1982). In central Chile, *C. arvensis* is often attacked by a leaf beetle (Gianoli, unpublished data), and there are reports of intense herbivory by insects elsewhere (Rosenthal and Hostettler, 1980; Weaver and Riley, 1982).

Seeds of *C. arvensis* were collected on the edge of cereal fields in central Chile in April 1999 from more than 40 mother plants. After acid scarification, seeds were germinated in the dark at room temperature (24±2°C). Seedlings were initially planted in 300-ml plastic pots filled with potting soil and placed outdoors. Two wk after seedlings attained the second true leaf, they were transplanted into 5-l pots filled with potting soil, and half of them received physical support (see below). Eight wk later, plants were transferred to the greenhouse, and light treatments were started (see below). Experiments were performed during 5 mo (November 2002–March 2003) at maximum and minimum temperatures of 23±2°C and 10±2°C, respectively.

Eight experimental treatments (N=12 plants per treatment) were applied after a factorial array of 2 light treatments (sun and neutral shade), 2 support conditions (with and without physical support, i.e., climbing and prostrate), and 2 damage treatments (undamaged and simulated herbivory). Sun = plants growing in the greenhouse (average light intensity at noon: 1120 and 1176 μmol m^{-2} sec^{-1} PAR for prostrate and climbing plants, respectively); Shade = plants growing under a double-layered black cloth hung at 2 m over the greenhouse benches (average light intensity at noon: 55 and 98 μmol m^{-2} sec^{-1} PAR for prostrate and climbing plants, respectively). Neutral shade has been shown to elicit plant phenotypic responses similar to those caused by neighboring vegetation (Peñalosa, 1983; Lee, 1988; Gianoli, 2001). Light intensity was recorded with a Li-250 light meter (LiCor, Lincoln, NE, USA). Support consisted of a plastic stake (0.8 cm diam, 1.2 m long) vertically placed in contact with the stem of seedlings. Damaged plants suffered 25% defoliation with scissors, 50% of leaf area being removed in half of the leaves; leaves were clipped along the mid vein. Foliar damage was applied twice during the experiment: 7 and 11 wk after plants were transferred to the greenhouse. At each time that foliar damage was applied, we did it so that defoliation level was kept at 25%. The 48 plants of each of the two light treatments were placed alternately on the greenhouse benches and rotated every 2 wk. Plants were watered with tap water every second day.

One wk after the last foliar damage we measured in each plant the length of 3 internodes and 3 petioles at midshoot (40–50 cm over soil pot level), and the length, width, thickness, and elevation angle of 3 intact leaves at midshoot. The choice of experimental leaves was done regardless of the proximity to damaged leaves. Morphological measurements were

done with a digital caliper (Mitutoyo; resolution, 0.01 mm). To determine the concentration of TAs we randomly chose 10 plants per experimental group, and for each individual we harvested 15 g of leaf fresh biomass from the upper third of the plant. We included both damaged and intact leaves. Samples were shredded and macerated in methanol (85%) for 72 h. The methanolic extract was concentrated in a rotavapor (Heidolph Instruments OB2000, Schwabach, Germany) with a water bath at 40°C. Three consecutive extractions with dichloromethane were made after adding water, chloridric acid (to pH 1), and sodium carbonate (to pH 12), respectively. All three extractions were blended, and a 10-μl aliquot was directly injected into a high-performance liquid chromatograph (Shimadzu SCL-10A, Kyoto, Japan; UV detector Shimadzu SPD-M10A). Flow rate was 1 ml min^{-1}. The concentration of TAs, specifically of tropine ($C_8H_{15}NO$), which has been earlier detected in *C. arvensis* aerial biomass (Todd et al., 1995), was determined by using a commercial

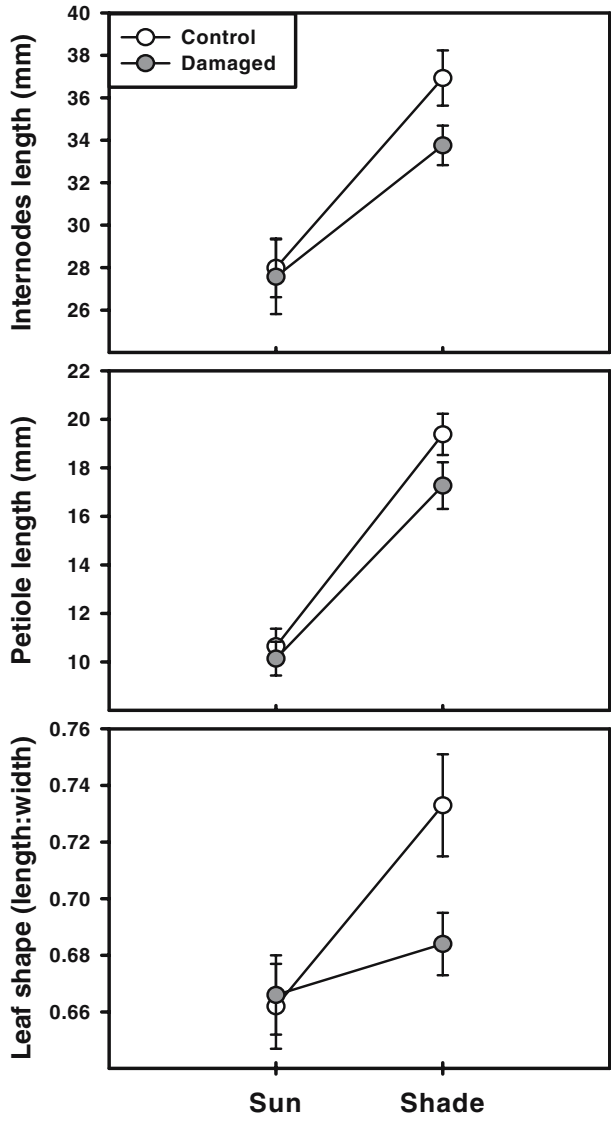

Fig. 2 Plasticity to shading in three morphological traits (mean ± SE) of undamaged (control) and clipped (damaged) plants of the twining vine *Convolvulus arvensis*. See Table 1 for the statistical significance of the Damage × Light interactions

tropine standard (Sigma-Aldrich Chemie, Steinheim, Germany). Detection of tropine was performed at 280 nm.

The effect of treatments on TAs and morphological traits was tested by a three-way ANOVA (main factors: Light, Support, and Damage). The significance of differences between means was determined by a Tukey test. To address the goals of the study, we examined the significance of interactions between Damage and the other main factors in the ANOVA. These results would show whether the light environment and support availability affect the induction of TAs after leaf damage, and whether leaf damage modifies the phenotypic responses of plants to shade and physical support.

Results

Overall, we did not find a significant effect of light or support treatments on the constitutive level of TAs, and there was a consistent pattern of induction of TAs after leaf damage in each environmental condition (Fig. 1). Although we failed to detect an effect of the light environment on the induction of TAs, there was a significant Support × Damage interaction, suggesting a differential effect of simulated herbivory on chemical defenses of prostrate and climbing plants (Table 1). However, it was clear that the latter was a result of the much greater induction of TAs observed in prostrate plants in the shade, whereas chemical induction was similar in prostrate and climbing plants growing in the sun (Fig. 1). Consequently, the main result for TAs with regard to the research goals was that there was a highly significant Light × Support × Damage interaction (Table 1). This means that the induction of TAs after leaf damage in *C. arvensis* was particularly affected by some combinations of light and support availability.

With the exception of leaf number, which was only affected by support, all the morphological traits evaluated responded to differences in the availability of both light and support (Table 1). Shorter internodes and petioles, and thicker leaves were found in climbing plants and in the sun (Table 2). Plants lacking support and growing in the shade showed a more ovate-oblong shape and a lower angle with the horizon (Table 2). Damage seemed to show a consistent effect on internodes and petiole length (Table 1). However, the tendency for damaged plants to have shorter internodes and petioles was statistically significant only in shaded and prostrate plants, and in shaded and climbing plants, respectively (Table 2). Interestingly, there were significant Light × Damage interactions for internodes and petiole length and leaf shape (Table 2). Particularly, damaged plants showed reduced plasticity to shading in these three traits in comparison with control, undamaged plants (Fig. 2).

Discussion

Induced responses to herbivory include short-term increases in chemical or physical defenses (Karban and Baldwin, 1997; Agrawal, 2005) and less rapid changes in resource uptake/allocation and growth patterns (Collantes et al., 1997; Strauss and Agrawal, 1999). In the case of climbing plants, there is evidence of changes in both chemical defenses and biomass allocation induced by herbivores (Schierenbeck et al., 1994; Fordyce, 2001). Recent findings in the twining vine *C. arvensis* (Gianoli and Molina-Montenegro, 2005) and related species (Atala and Gianoli, unpublished data) show that leaf damage induces an enhanced twining that, at least for *C. arvensis*, may reduce herbivory in the field (Gianoli and Molina-Montenegro, 2005). Induced defenses are thought to reduce costs of plant defense (Gianoli and Niemeyer, 1997; Heil, 2002; Heil and Baldwin, 2002; Strauss et al., 2002; Agrawal, 2005). Thus, greater induction might be expected in resource-poor or limiting environments compared with benign environments (Gianoli and Niemeyer, 1996). Accordingly, we found that vines showed the greatest induction of toxic TAs (Krug and Proksch, 1993; Todd et al., 1995) when damage occurred in a resource-poor environment (i.e., shade) and there was no cue (i.e., support) of future increase in resource uptake and/or escape from herbivores. This suggests that defensive responses in this vine species are adaptively tuned with the surrounding environment. It would be interesting to test how general is this induced responses pattern in climbing plants, particularly in those growing

in dynamic environments in terms of light and support availability such as rainforest understories.

Adaptive plant responses to shading and to herbivory have been studied widely and thoroughly, but there is little research on the interaction between plant phenotypic plasticity to both ecological factors (Cipollini, 2004). In *Chenopodium album*, induced responses to caterpillar herbivory did not affect subsequent responses to shading, and the magnitude of induced resistance (reduction of caterpillar mass) was similar in shaded and control light plants (Kurashige and Agrawal, 2005). Damaged plants of *Convolvulus demissus* are less plastic to experimental drought than undamaged control plants (Quezada and Gianoli, 2006). A study with genetically altered *Cucumis sativus* varieties reported some evidence that the constitutive expression of shade-avoidance response and resistance to herbivory are negatively related (McGuire and Agrawal, 2005). In the present study, damaged and hence induced vines showed reduced plasticity to shading in three morphological traits of functional significance for the enhancement of light capture. Plants receiving damage were less able to elongate internodes and petioles and to maximize leaf surface in comparison with undamaged plants. This shows a negative interaction between plant phenotypic responses to biotic and abiotic factors, as theory predicted (Cipollini, 2004). It is, therefore, verified that herbivory, in addition to its capacity to reduce plant fitness, may directly limit adaptive plant responses to the environment. Consequently, in the context of plant competition, (induced responses to) herbivory may affect the outcome of plant–plant interactions.

The evolution of a climbing habit constitutes a key innovation in flowering plants (Gianoli, 2004). Climbing plants are a typical element of rainforests. Despite the vast body of knowledge on herbivory in rainforests, the interaction between herbivory and the functional ecology of climbing plants has received little attention. This overlooked research line might provide insights into the current patterns of distribution and abundance of vines (Wright et al., 2004) as well as explanatory hypothesis for their evolutionary success (Gianoli, 2004).

Acknowledgement We thank Z. Rozas, S. Meneses, and V. Hernández for assistance during the chemical analysis, and M. González and P. Torres for help in the greenhouse. M. Heil and an anonymous reviewer made helpful suggestions for improvement of the manuscript.

Abstract Total and individual glucosinolate contents of broccoli cv Marathon were assessed at ambient CO_2 (430–480 ppm) and elevated atmospheric CO_2 (685–820 ppm) to determine the ecological relationship between changing atmospheric CO_2 concentrations and phytochemicals. Elevated atmospheric CO_2 concentration had a differing effect on individual glucosinolates and glucosinolate groups. Total glucosinolate content increased at elevated atmospheric CO_2 concentration as a result of a strong increase in both methylsulfinylalkyl glucosinolates glucoraphanin and glucoiberin. In contrast, indole glucosinolates simultaneously decreased, predominantly because of a reduction of glucobrassicin and 4-methoxy-glucobrassicin contents. We conclude that changes in N content and N/S ratios as well as alterations in photochemical processes at elevated atmospheric CO_2 concentration can influence total and individual glucosinolates contents of *Brassicaceae*, as demonstrated in the greenhouse, for broccoli.

Keywords Carbon dioxide · *Brassica oleracea* var. *italica* · Alkyl glucosinolate · Indole glucosinolate · Chlorophyll fluorescence

Introduction

Glucosinolates are found exclusively in plants of the order Capparales, including horticultural important crop plants of the *Brassicaceae* family (Halkier and Du, 1997). They are bioactive compounds responsible for many physiological effects functioning as feeding deterrents and protective compounds against herbivores (Mewis et al., 2005). In addition, they are important as flavor compounds and cancer-preventive agents (Mikkelsen et al., 2002).

Glucosinolates are known to confer health-promoting effects because of their assumed anticarcinogenic properties (Holst and Williamson, 2004). Broccoli is a *Brassica* vegetable

that has been recognized to be one component of a healthy diet, predominantly because of its high phytochemical content, in particular, glucosinolates (Brown et al., 2002; Schonhof et al., 2004; Zhang, 2004). With regard to current cancer incidence and global climate changes, it is of interest to determine to which extent glucosinolates might be affected by changing environmental factors, as glucosinolate content is influenced by numerous preharvest factors (Dekker and Verkerk, 2003). *Brassica* vegetables grown during different seasons exhibited varying glucosinolate contents, thereby establishing a distinct influence of environmental factors, such as temperature and radiation, on them (Shattuck and Wang, 1994; Schonhof et al., 1999; He et al., 2000; Krumbein and Schonhof, 2001; Schreiner, 2005). For example, the contents of glucoraphanin and glucoiberin in broccoli inflorescences increased at daily mean temperatures between 7 and 13°C combined with a moderate daily mean radiation of 10 to 13 mol m^{-2} d^{-1}, whereas the main indole glucosinolate glucobrassicin was reduced (Schonhof et al., in press). Atmospheric carbon dioxide concentration represents an environmental factor that is currently undergoing great changes from 280 ppm in preindustrial times to approximately 365 ppm at present (Craigon et al., 2002; Krupa, 2003), with peaks in urban areas of up to 480 ppm (Pataki et al., 2006). Climate simulations indicate a further ongoing increase up to double of today's concentration (Gerber et al., 2004; Norby and Luo, 2004). Increases in CO_2 concentrations have implications for agriculture and the environment as a whole. For example, elevated CO_2 levels enhance photosynthesis, leading to vigorous plant growth and higher yield (Maevskaya et al., 1990; Wurr et al., 1998, 2000; Amthor, 2001), which is a phenomenon also observed in *Brassica* vegetables (Mishra et al. 1999).

Glucosinolates are nitrogen- and carbon-containing compounds, and thus, could be affected by atmospheric CO_2 enrichment, as this enhances the plant's carbon supply, thereby diluting its nitrogen content (Cotrufo et al., 1998). In addition, synthesis of amino acids—the precursors of the amino acid-derived glucosinolates—from triosephosphates has been observed to increase because of increasing photosynthesis at elevated CO_2 (Habash et al., 1995), hence, affecting glucosinolate content. However, at present, only little information is available on the effect of elevated atmospheric CO_2 on glucosinolate content in *Brassica* vegetables. Karowe et al. (1997) and, more recently, Reddy et al. (2004) studied the CO_2 concentration-induced effect on glucosinolate content in *Brassica* seedling leaves; however, mature leaves, roots, and inflorescences, which are key components of the human diet, were not investigated.

Because of the problems resulting from dramatic and continuing increase in atmospheric CO_2 concentrations and unknown effects on plant physiology, including glucosinolate responses to elevated atmospheric CO_2 concentration, the objective of the present study was to determine the effect of ambient and elevated atmospheric CO_2 on total and individual glucosinolate contents in mature broccoli inflorescences. For this purpose, broccoli was chosen as a model crop because of its high level of aliphatic and indole glucosinolates compared to other *Brassicaceae* (Schreiner, 2005).

Methods and Materials

Plant Material and Experimental Design

Three experiments were carried out in a block design, each with three replicates: experiment I with planting on 10 September 2003 and harvest at the end of November

2003; experiment II with planting on 9 January 2004 and harvest at the end of March 2004; and experiment III with planting on 5 February 2004 and harvest at the end of April 2004. All experiments were conducted in a controlled greenhouse environment. Daily mean temperature and daily mean radiation were calculated from measurements taken every 2 and 5 min, respectively.

For each treatment and replication, 54 broccoli plants (*Brassica oleracea* var. *italica* Plenck) cv Marathon were used, with each plant grown in a soil-filled 40-l container spaced 0.6×0.7 m, resulting in a density of 2 plants m^{-2}. Plants at the three-leaf-stage were exposed to two different atmospheric CO_2 concentrations: ambient atmospheric CO_2 (430–480 ppm) or elevated atmospheric CO_2 (685–820 ppm).

Plants were grown between 14 and 15°C with radiation between 6.23 and 10.04 mol m^{-2} d^{-1}. Artificial radiation was applied with high pressure sodium lamps (SONT-T 400W, Philips) to compensate for the lower solar radiation in winter time. Plants were illuminated from sunrise to 20:00 hours when solar radiation in the greenhouse was <200 μmol m^{-2} s^{-1}.

After soil analysis, because of the nutrient demand of the broccoli, plants were fertilized twice: first at the 10-leaf stage and then after head induction. Plants were irrigated with tap water distributed via drip tubes after soil moisture was measured (soil moisture probes: FP/m; measuring device: FOM/m; Easy Test Ltd, Lublin Poland). Biological pest management was performed when necessary with common green lacewing (*Chrysoperla carnea*).

Chlorophyll Fluorescence

To determine changes in plant photochemistry, which could lead to changes in glucosinolate content, chlorophyll fluorescence parameters were measured. This was measured for six plants for each atmospheric CO_2 concentration. After 20 min of dark adaptation, chlorophyll fluorescence was measured for the two fullest developed leaves (four measurements per leaf from the upper part of the leaf area) nearest to the broccoli head and for the broccoli inflorescences (six measurements per head) using a Mini-Pam (Walz, Effeltrich, Germany). To assess the minimal fluorescence (Fo), a pulse-modulated actinic light source of about 0.02 μmol m^{-2} s^{-1} was used (Van Kooten and Snel, 1990). For the maximal fluorescence (Fm), a saturating light pulse (duration 30 s, intensity 3,000 μmol m^{-2} s^{-1}) was applied. This procedure was repeated after light adaptation, and the current fluorescence (F) and maximal fluorescence (Fm′) were then measured. The following derived functions were used to calculate the chlorophyll fluorescence values (Genty et al., 1989):

$$\text{Photochemical quenching coefficient qP} = (\text{Fm}' - F)/(\text{Fm}' - \text{Fo}) \quad (1)$$

$$\text{Nonphotochemical quenching coefficient qN} = (\text{Fm} - \text{Fm}')/(\text{Fm} - \text{Fo}) \quad (2)$$

Sample Preparation

To determine glucosinolate content, fully developed broccoli heads were harvested. Fresh matter taken from the heads was directly measured after harvest. A mixed sample of florets of each replicate was taken consisting of five heads. The plant material was immediately deep-frozen (−28°C), then freeze-dried before being finely ground. This dry matter (dm) was used for glucosinolate, N, and S analyses.

Compound Analyses

The high-performance liquid chromatography (HPLC) method reported by Krumbein et al. (2005) was used for glucosinolate determination. Duplicates of freeze-dried sample material (0.5 g) were heated to and incubated at 75°C for 1 min, extracted with 4 ml of a methanol/water mixture (v/v=7:3, T=70°C), and after adding 1 ml of 0.4 M barium acetate, centrifuged at 4,000 rpm for 10 min. For an internal standard, 200 µl of a 5-mM stock solution of sinigrin in methanol were added to one of the duplicates just before the first extraction. The residue was extracted twice with 3 ml of the methanol/water mixture (v/v=7:3, T=70°C). Supernatants were pooled and made up to 10 ml with the methanol/water mixture (v/v=7:3, T=70°C). From this, 5 ml of the extract were applied to a 250-µl DEAE-Sephadex A-25 ion-exchanger (acetic acid-activated, Sigma-Aldrich Chemie GmbH, Taufkirchen, Germany) and rinsed with 10 ml bidistilled water. Next, 250 µl of a purified solution of aryl sulfatase (Boehringer-Mannheim GmbH, Mannheim, Germany) were applied and left for 12 hr before the desulfocompounds were flushed with 5 ml of bidistilled water.

Desulfoglucosinolate analysis was conducted by HPLC (Merck Hitachi) using a Spherisorb ODS2 column (5 µm, 250×4 mm). A gradient of 0–20% acetonitrile in water was selected from 2 to 34 min, followed by 20% acetonitrile in water until 40 min, and then 100% acetonitrile for 10 min until 50 min. Determination was conducted at a flow of 1.3 ml min^{-1} and a wavelength of 229 nm. Desulfoglucosinolates were identified by HPLC–atmospheric pressure chemical ionization–mass spectrometry[3] using the Agilent 1100 series in the positive ionization mode (Krumbein et al., 2005). Glucosinolate content was calculated using sinigrin as internal standard and the response factor of each compound relative to sinigrin. Determination of glucosinolates was performed in duplicate.

For the nitrogen (N) and sulfur (S) analyses, finely ground samples were burned in the element analyzer Vario EL using Dumas' burning method (VDLUFA, 1991). Assessment of total N and S contents was also performed in duplicate.

Statistical Analyses

Results were evaluated using analysis of variance (ANOVA) and regression analysis. Using ANOVA, differences between treatments were analyzed by Tukey's HSD test (HSD, Honest Significant Difference). Linear regression analyses were performed with one independent variable x using the linear model $y = a + bx$. All tests were performed at a significance level of $P<0.05$. Calculations were carried out using the software package Statistica™ for Windows™ (version 6.1, Statsoft Inc., Tulsa, OK, USA).

Results and Discussion

The total glucosinolate content and the contents of individual methylsulfinylalkyl glucosinolates glucoraphanin and glucoiberin and the indole glucosinolates glucobrassicin, neoglucobrassicin, 4-methoxy-glucobrassicin, and 4-hydroxy-glucobrassicin were quantitatively determined in broccoli inflorescences. The predominant glucosinolate was glucoraphanin (Table 1).

Elevated atmospheric CO_2 concentration affected the contents of both individual glucosinolates and glucosinolate groups. Total glucosinolate content increased at elevated atmospheric CO_2 concentration because of the rise in methylsulfinylalkyl glucosinolates,

Table 1 Total and individual glucosinolate content (μg g^{-1} dm) in broccoli inflorescences cv Marathon grown at ambient CO_2 (430–480 ppm) and elevated CO_2 (685–820 ppm)

	Ambient CO_2	Elevated CO_2	HSD	*P* Value	*F* Value
Methylsulfinylalkyl glucosinolates	3.75	5.13	0.58	0.002[a]	14.73
Glucoiberin	0.52	0.71	0.07	0.007[a]	9.86

Sample size for each CO_2 treatment $N=9$; degrees of freedom $N=15$; critical F value 3.68

[a] Statistically significant

glucoraphanin, and glucoiberin. In contrast, indole glucosinolates simultaneously decreased, predominantly because of a sharp reduction in glucobrassicin and 4-methoxy-glucobrassicin (Table 1). Because the increase in the methylsulfinylalkyl glucosinolate content was stronger than the decrease in indole glucosinolates, overall total glucosinolate content was higher in broccoli inflorescences at elevated atmospheric CO_2 compared to ambient CO_2 (Table 1).

Apart from the effect of CO_2 concentration on glucosinolate content and composition, however, plant species is thought to play a role. As shown by cabbage, which also belongs to *B. oleracea*, there was a decrease in indole glucosinolate content. Aliphatic glucosinolate content remained unaffected at elevated concentrations (720 ppm) (Reddy et al., 2004). In contrast, other *Brassica* genotypes showed different CO_2 responses in glucosinolate content changes. In leaves of oilseed rape (*Brassica rapa* subsp. *oleifera*), there was a general increase in indole glucosinolate and aromatic gluconasturtiin contents. The aliphatic glucosinolate content consisting mainly of alkenyls and hydroxyalkenyls remained unchanged under enriched CO_2 conditions (720 ppm) (Reddy et al., 2004). Further, total glucosinolates in leaves of radish (*Raphanus sativus*) (major alkenyl glucosinolate: glucoraphasatin) and turnip (*Brassica rapa* subsp. *rapa*) (major alkenyl glucosinolates: gluconapin and glucobrassicanapin), appeared to be unaffected with rising atmospheric CO_2 level (724 ppm) (Karowe et al., 1997).

Moreover, the changing N content and N/S ratio in broccoli inflorescences under different atmospheric CO_2 concentrations could influence contents of total and individual glucosinolates. As demonstrated in both C3 and C4 plants, N is reduced in plant tissue under elevated CO_2 regimes (Cotrufo et al., 1998). We found that in broccoli inflorescences, N content was reduced by 10.1%, leading to a decrease in the N/S ratio at elevated CO_2 levels (Table 2); this was correlated to pronounced changes in total and individual glucosinolate contents (Table 3). N content decrease was not because of a dilution effect because fresh and dm of broccoli heads did not significantly differ between CO_2 regimes (Table 2). In contrast, the S content in broccoli inflorescences was unaffected by rising CO_2 levels (Table 2). However, in oak leaves—exposed to 700 ppm CO_2—diminished S contents as a result of decreased adenosine 5′ phosphosulfate reductase activity have been reported (Kopriva and Rennenberg, 2004), indicating genotypic differences in the acclimation of sulfate assimilation at elevated atmospheric CO_2 concentration.

Table 2 Inflorescence parameters of broccoli cv Marathon grown at ambient CO_2 (430–480 ppm) and elevated CO_2 (685–820 ppm)

Parameter	Ambient CO_2	Elevated CO_2	HSD	*P* Value	*F* Value
S content (% dm)	0.78	0.77	0.04	0.513	0.45
N content (% dm)	3.87	3.48	0.14	0.022[a]	6.52
N/S ratio	4.98:1	4.54:1	0.25	0.042[a]	4.94
Dry matter (%)	11.55	11.83	0.38	0.593	0.30
Fresh matter per head (g)	298.69	319.03	31.53	0.494	0.40

Sample size for each CO_2 treatment N=9; degrees of freedom N=15; critical F value 3.68

[a] Statistically significant

For aliphatic glucosinolate biosynthesis, sulfate assimilation in the form of cysteine, which is a key source of methionine-derived aliphatic glucosinolate, is a crucial step. Thus, the contents of the methylsulfinylalkyl glucosinolates glucoraphanin and glucoiberin increased with decreasing N content and decreasing N/S ratio at elevated CO_2 levels (Fig. 1, Table 3). The more the N/S ratio decreases because of diminished N content, the stronger the synthesis of sulfurous cysteine as a precursor of methionine seems to be (Hesse et al., 2004). Moreover, cysteine and methionine act as effective sulfur donors in thiohydroxamate formation in the synthesis of aliphatic and indole glucosinolates (Wetter and Chisholm, 1968; Mikkelsen et al., 2002); however, in our study, the indole glucosinolates glucobrassicin and 4-methoxyglucobrassicin decreased with reduced N content and reduced N/S ratio at elevated CO_2 levels (Fig. 1, Table 3). We assume that the synthesis of tryptophan-derived indole glucosinolates is not so strongly sulfur-dependent as the synthesis of methionine-derived alkyl glucosinolates, thereby explaining the positive correlation between indole glucosinolate content and N/S ratio and N content, respectively.

Changes in broccoli photochemistry could be another reason for the CO_2 concentration-induced effect on glucosinolates. Enhanced photochemical activity can result in the enhanced formation of ATP and reduction equivalents necessary for fixation and assimilation of CO_2 in the Calvin cycle, leading to the formation of a carbohydrate pool that forms the basis for the synthesis of further compounds, such as amino acids (Larcher,

Table 3 Correlation between total glucosinolate content, individual glucosinolate content, S content, N content, and N/S ratio in broccoli inflorescences cv Marathon

Correlation	Beta	R^2	*P* Value	*F* Value
N/S ratio per methylsulfinylalkyl glucosinolates	−0.56	0.31	0.019[a]	6.85

1994). Thus, enhanced amino acid formation could promote glucosinolate synthesis because glucosinolates are amino acid-derived compounds (Grubb and Abel, 2006).

With elevated CO_2 concentration in both plant organs—inflorescences and leaves—a greater portion of the absorbed light apparently was used for photochemical purposes, as indicated by the enhanced photochemical quenching coefficient (qP) at harvest date (Fig. 2), as well as that observed throughout the entire development of the broccoli head (data not shown). Simultaneously, as shown by the nonphotochemical quenching coefficient (qN), the portion of the absorbed photons diverting into the nonphytochemical pathway remained unaffected by varying CO_2 concentrations (Fig. 2). With a rising qP of broccoli leaves, indole glucosinolate content increased in the inflorescence tissue. In addition, rising qP values up to an optimum range of 0.4–0.5 were accompanied with increasing methylsulfinylalkyl glucosinolate content (Fig. 3), whereas no correlation was found between indole and methylsulfinylalkyl glucosinolate contents and the qP of the broccoli inflorescences (data not shown). This result demonstrates the large source capacity of the leaves in comparison with the inflorescences because of the pronounced photoassimilating leaf area.

Because glucosinolates are also formed in leaves of broccoli (Scheuner et al., 2005) and, as shown in *Arabidopsis thaliana*, are transported via the phloem (Chen et al., 2001; Chen and Andreasson, 2001), a glucosinolate exchange between individual plant organs is possible. In *A. thaliana*, the pattern of glucosinolate distribution corresponded to the transport of photoassimilates, which in turn was consistent with glucosinolate translocation in the phloem following the source–sink relationship (Chen et al., 2001). We assume that in broccoli, glucosinolate transport from leaves to inflorescences was affected by a changing source–sink relationship induced by enhanced demand for soluble carbohydrates of the stronger growing broccoli head (at the earlier stage of head formation, data not shown) at

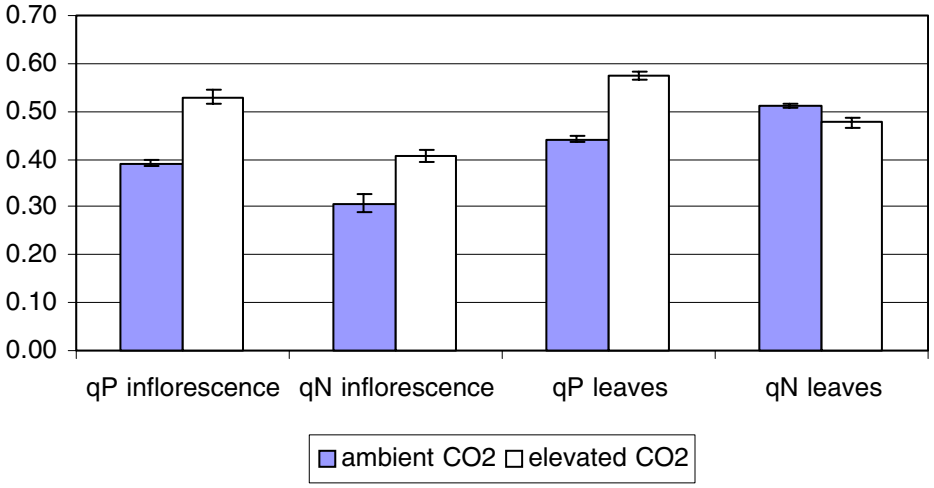

Fig. 2 Photochemical quenching coefficient (qP) and nonphotochemical quenching coefficient (qN) of broccoli inflorescences and leaves cv Marathon grown at ambient CO_2 (430–480 ppm) and elevated CO_2 (685–820 ppm). Values are the means of 36 (inflorescences) and 48 measurements (leaves), respectively. The bars represent the standard error

elevated CO_2. This would account for the especially enhanced methylsulfinylalkyl glucosinolate content in the inflorescences.

In summary, our results provide evidence that, in respect to predicted elevation of atmospheric CO_2 concentrations, secondary plant metabolism is affected by increasing CO_2 levels as demonstrated by glucosinolates. We have further demonstrated that different glucosinolate groups (methylsulfinylalkyl and indole) and individual glucosinolate contents

need to be assessed to have a clear picture of a plant's response to elevated CO_2 concentrations. We think that the CO_2 concentration-induced effect may be different for each *Brassica* species, and that changes in N content and N/S ratios as well as alterations in photochemical processes because of increased C content could influence the plant's total and individual glucosinolate contents.

Atmospheric CO_2 is both an important environmental and anthropogenic factor. It can enhance the health-promoting quality of broccoli because of induced glucosinolate content changes. Moreover, glucosinolates are involved in plant defense response against pathogen and herbivore attack (Mikkelsen et al., 2003). Because the variation in chemical defense by synthesis of structurally different aliphatic, aromatic, and indole glucosinolates can vary with the pathogen/herbivore (Mewis et al., 2005), changing of individual glucosinolate content by increasing atmospheric CO_2 levels could also result in a changing susceptibility to pathogen and herbivore attacks.

Abstract A detailed characterization of two humic fractions was performed: One with low relative molecular mass (LMr<3,500 Da) and one with high relative molecular mass (HMr >3,500 Da). Distinct ^{1}H NMR spectroscopic patterns were observed for the two fractions. HMr showed an aromatic proton region, an intense and broad region (3.0–5.0 ppm) attributed to sugar-like and polyether components, and an intense doublet at 1.33 ppm (identified as protons of the β-CH_3 in lactate). In contrast, LMr did not show resonances due to aromatic protons and was characterized by a broad unresolved region, assigned to sugar-like components. The ^{13}C NMR spectra showed that the LMr humic fraction was richer in carboxylic and aliphatic C groups compared to HMr fraction. These substances were fluorescein-labeled [fluorescein isothiocyanate (FITC)], and their interaction with carrot cells in culture was monitored for 10 d, and compared to FITC–indole-3-acetic acid (IAA) to clarify their mechanisms of biological activity. After different incubation times, fluorescein staining of carrot cells and decrease of fluorescein concentration in the culture medium were evaluated. Fluorescent membrane staining was only present in IAA and the LMr humic fraction treated cell cultures. A consequential decrease of fluorescein concentration in the culture media was also observed. Pretreatment of carrot cells with unconjugated IAA or LMr humic fraction markedly reduced fluorescein staining of both FITC–IAA and FITC–LMr humic fraction. Blocking tests gave indirect evidence of

possible binding of the LMr humic fraction to IAA cell membrane receptors. These results indicate that the two humic fractions behave differently. Only LMr humic fraction, like IAA, interacts with cellular membranes in carrot cell cultures.

Introduction

Humic substances (HS), the major components of soil organic matter, have multiple roles in plant growth (Tan, 1998), and are the subject of study in various areas of agriculture, such as soil chemistry, fertility, plant physiology, and environmental sciences. Many papers have shown that HS may improve physical and chemical soil properties, favor a higher concentration of ions in soil solution, and act as source and sink for nutrients, such as P, N, and K (Vaughan et al., 1985). In the rhizosphere, interaction between the root system and humic matter is possible when humic molecules present in the soil solution are small enough to flow into the apoplast and reach the plasma membrane. This event occurs in the vicinity of the root surface, where release of organic acids by roots enable dissociation of the humic macrostructure, and subsequent release of the otherwise unavailable bioactive fractions (Dell'Agnola and Nardi, 1987; Piccolo et al., 1992).

Many studies have shown that soil humic matter can affect plant growth and metabolism, by regulating plant biochemical and physiological processes (Vaughan et al., 1985), by nutrient absorption (Clapp et al., 2001; Varanini and Pinton, 2001), by enzyme activation or inhibition (Muscolo et al., 1993, 1996), and by inducing morpho-functional changes in root architecture (Canellas et al., 2002). In many cases, these effects are comparable to that induced by some plant growth regulators, e.g., the auxins. The complex biological activity of humic matter depends on its concentration, chemical characteristics, and molecular size and weight (Maggioni et al., 1987; Albuzio et al., 1993; Nardi et al., 1994; Muscolo and Nardi, 1997; Muscolo et al., 1998).

Muscolo et al. (1993, 1996) have shown that humic substances induce morphogenetic and biological changes in leaf explants of *Nicotiana plumbaginifolia*. They affect the patterns of peroxidase and esterase, enzymes that are involved in organogenesis, and may be indicators of somatic embryogenesis. These effects, peculiar to humic fraction with a low relative molecular mass (<3,500 Da), were similar to those produced by indole-3-acetic acid (IAA); whereas the humic fraction with a high relative molecular mass (>3,500 Da) had no effect on this system. A study on homogeneous carrot (*Daucus carota*) cell cultures compared the effects of the low relative molecular mass humic fraction to different auxins (Muscolo et al., 1999). This humic fraction caused an increase in carrot cell growth similar to that induced by 2,4-dichlorophenoxyacetic acid (2,4-D) and promoted morphological changes similar to those induced by IAA. The different biological activities of humic fractions, with high and low relative molecular mass, may be due to their chemical heterogeneity, polydisperse nature, and/or different conformational arrangements.

The mechanism by which soil HS stimulate plant biological activity is not yet clarified; this is, in part, due to the heterogeneity and complexity of HS that poses a serious impediment for characterization. Thus, attempts to relate humus structure to biological activity have produced contrasting results. The chemical structure of HS is not well-known. However, the main structure of humic matter has a polycyclic aromatic core linked with

side chain structures such as carbohydrates, phenolics, proteins, peptides, and metal ions (Cheshire et al., 1967). Considering that the genesis of HS involves combinations of several reaction pathways and a wide variety of chemical binding systems, it is difficult to define a clear concept of their composition (Hayes, 1997). Many of the original classical methods to understand the nature of HS were based on elemental composition, but the results obtained represent averages for agglomerations of molecules, and it is impossible to derive precise empirical formulae from these data. It is impossible to break the HS by hydrolysis or other chemical degradation techniques without producing denaturated substances, causing artificial results.

Considerable progress has been made in the last few years regarding some of the gross features of HS, by employing various spectroscopic procedures: infrared spectroscopy, electron spin resonance, Raman, ultraviolet-visible, fluorescence, and X-ray photoelectron spectroscopy. Considerable effort has been focused on ^{13}C-NMR and ^{1}H-NMR spectroscopy, the most powerful tools available to determine the structure of both organic and inorganic species.

In this study, two humic fractions with different relative molecular mass were extensively characterized by means of different spectroscopic techniques [diffuse reflectance infrared Fourier transforms (DRIFT), ^{13}C, ^{1}H nuclear magnetic resonance (NMR), and gas chromatography-mass spectroscopy (GC-MS)], for a better understanding of their chemical structure and physical–chemical properties.

These humic fractions were derivatized with fluorescein to observe their interaction with carrot cells in culture, with the aim of clarifying the mechanism of their biological activity.

Methods and Materials

Study Sites The study was carried out in the Ah horizon of a Calcaric Cambisol (CMc-F.A.O. classification) (FAO-UNESCO, 1990) of uncultivated couch grass (*Agropyron repens* L.) fields, located in the College of Agriculture Farm (University of Padua).

Preparation of Humic Fractions Humic substances were extracted from the air-dried samples with 0.1 N KOH (1:20 w/v) at room temperature for 16 hr under a N_2 atmosphere. Suspended material was removed by centrifugation at 7,000×*g* for 20 min. Humic extracts were transferred into 18,000 mol. wt cut-off dialysis tubing Visking (Medicell, UK) and dialyzed against double-distilled water. The retained solution was desalted by ion exchange on Amberlite IR 120 (H^+ form) and the pH adjusted to pH 2.1 with glacial acetic acid. The acidified solution was dialyzed through 3,500 mol. wt. cut-off Spectra/Por® 3 tubing (Spectrum, Gardena, CA) against distilled water. This procedure separated the total humic extract into high (>3,500 Da) and low (<3,500 Da) relative molecular mass (Mr) fractions. The HMr and LMr fractions were collected inside and outside the dialysis tubing, respectively. These solutions were freed from unreacted acetic acid and reduced in volume to about 50 ml by vacuum distillation (Nardi et al., 1991).

Diffuse Reflectance Infrared Fourier Transform (DRIFT) Spectroscopy For each analysis, 2 mg of dried sample was mixed with 148 mg KBr (FT-IR grade, Aldrich Chemical, Milwaukee, WI), so that the mixture became homogeneous. After grinding, the sample mixture was heaped over the top of the microsample cup. Any excess material was removed with a straight-edged tool. For the background, a microsample cup of pure KBr was

prepared. DRIFT spectra were recorded with 200 scans collected at 4 cm^{-1} resolution using a Nicolet Impact 400 FT-IR Spectrophotometer (Madison, WI) and fitted with an apparatus for diffuse reflectance (Spectra-Tech., Stamford, CT). DRIFT spectra are the average of 200 scans and the resolution was set at 4 cm^{-1} resolution.

^{1}H NMR Spectroscopy For each fraction, 20 mg of sample was dissolved in 0.5 ml D_2O (deuterium oxide). Spectra were recorded with a Bruker ACF 250 spectrometer (Karlsruhe, Germany) using a 5-mm multinuclear probe. ^{1}H spectra were accumulated with a 16-K data point, a one-pulse sequence, a 40°-pulse angle, a 3-sec relaxation delay, and a sweep width of 2.5 kHz. To obtain a satisfactory signal-to-noise ratio, 1,000–2,000 scans were needed. Gated irradiation was applied between acquisitions to presaturate the residual water peak. 3-(trimethylsilyl)propionic-2,2,3,3-d_4 acid, sodium salt was added to the samples to provide a chemical shift standard. Spectra were divided into three main regions: aromatic hydrogens (H_r) from 6.0 to 8.0 ppm; H attached to oxygen groups in carbon ($H_{C–O}$) from 4.2 to 3.0 ppm, and aliphatic H (Ha) from 3.0 to 0.5 ppm. In accordance with results obtained by Wilson et al. (1983), the $H_{C–O}$ region was attributed to protons largely arising from polysaccharides. Several research groups have demonstrated that the Ha region might be affected by the presence of protons attached to aromatic rings in α β γ positions (Wilson et al., 1983, Gil–Sotres et al., 1994, and Simpson et al., 1997).

GC-MS Analysis Methylated LMr or HMr humic fractions were prepared by treatment with acetyl chloride in methanol suspension. Humic fractions (30 mg dry weight) and methanol (7 ml) were mixed in a 100-ml flask in an ice bath. One ml of acetyl chloride was slowly added to the resulting suspensions. Flasks were shaken for 4 hr at 25°C. This procedure was repeated three times, except that the last reaction was carried out overnight. Suspensions were centrifuged for 30 min at 2,680×*g*. The clear brown solutions were dried in a rotary evaporator and dissolved in 10 ml of methanol. The methylated humic fractions were injected into the GC-MS for IAA detection. All measurements were performed using an HP 6890 Gas Chromatograph (Hewlett Packard, Palo Alto, CA) coupled with an HP 5973 N Quadrupole (Hewlett Packard, Palo Alto, CA). Chromatographic separation of analytes was obtained with an HP 5MS capillary column with the following dimensions: length, 30 m; ID, 0.25 mm, and film thickness, 0.25 μm. The column had a constant helium flow of 0.7 ml min^{-1}, and the temperature regime was 1 min at 150°C followed by an increase of 10°C min^{-1} to 250°C, which was held for 15 min. The injector temperature was 250°C. All injections were performed in splitless conditions for 0.5 min. The mass spectrometer was in SCAN acquisition mode to detect the ions produced by electron ionization (70 eV) at the ion source temperature of 230°C, in the mass range from 50 to 350 Da, with a scan rate of 4.72 scan sec^{-1}. Pure IAA from Sigma (St. Louis) was methylated as described above for humic fractions and subjected to GC-MS. IAA detection in the chromatogram of methylated humic fractions was accomplished by comparing retention time and mass spectra with those of the purified methylated IAA sample.

^{13}C NMR Spectroscopy The relative intensity observed for a given chemical shift value, expressed as a fraction of the total signal intensity acquired, represents the proportion of that type of C present in the sample (Baldock and Preston, 1995). Spectra were divided into chemical shift regions assigned to chemical group classes aliphatic C (0–48 ppm), peptide and carbohydrate C (48–105 ppm), aromatic C (105–145 ppm), phenolic C (145–165 ppm), and carboxylic C (165–190 ppm). These assignments were based, in part, on values given

in Candler et al. (1997). By integrating the signal intensity contained within each chemical shift region, the proportion of a given type of C was calculated.

IAA Content Determination The quantitative determination of IAA in the humic fractions was made by an enzyme-linked immunosorbent assay (ELISA) (Phytodetek-IAA, Sigma, St Louis, MO). Tracer and standard solutions were prepared following the manufacturers' instructions. To each well, 100 μl of standard or LMr or HMr and 100 μl of diluted tracer were added. After an incubation at 4°C for 3 hr, the wells were decanted and washed by adding 200 μl of wash solution and then 200 μl of substrate solution. After 60 min at 37°C, 50 μl of stop reagent was added to each well, and the absorbance at 405 nm was then read using a 450 Biorad microplater reader (Biorad, Hercules, CA).

Fluorescent Labeling Indole-3-acetic acid (IAA) and humic substances (LMr and HMr) were conjugated with fluorescein isothiocyanate (FITC), according to the procedure described by Nairn (1969). A 2-ml sample (IAA or humic substances) of a 2% solution was added to 0.5 mg FITC completely dissolved in 1 ml of 0.1 M Na_2HPO_4, in a 25°C water bath. The pH of the solution was rapidly adjusted to 9.5 with drops of 0.1 M Na_3PO_4, and then, 0.145 M NaCl was added to make a total volume of 4 ml. The reaction was allowed to proceed for 30 min at 25°C and then stopped in an ice-water bath. Removal of unreacted fluorescent material was accomplished by gel filtration on a Sephadex G-15 (Pharmacia Biotech, Uppsala, Sweden) column. The fluorescent fractions were eluted and stored at −20°C until use.

Cell Culture Carrot cell suspensions were selected to provide a simple and rapid means of in vitro screening of compounds for activity before testing on whole plant systems.

Suspensions of *Daucus carota* cells (cv S Valery) were grown in liquid Gamborg's B5 medium (Gamborg et al., 1968), supplemented with sucrose (20 g l^{-1}), 2,4-D (0.5 mg l^{-1}), and 6-benzylaminopurine (6-BAP, 0.25 mg l^{-1}). Cultures were kept on a M 301-OR rotary shaker (Tecnovetro, Monza, Italy) at 100 rpm under 16 hr light/8 hr dark, at 25°C. Subculturing was carried out every 14 days, by inoculating each flask (containing 70 ml complete fresh medium) with 14 ml cell-suspension culture. After 14 days of growth, the cells were washed (3×'s) with B5 medium free of 2,4-D and 6-BAP, and resuspended in the same medium. Two ml of this suspension was inoculated into 18 ml of medium containing FITC–IAA (2 mg l^{-1}), FITC–LMr (0.2 mg C l^{-1}), or FITC–HMr humic fraction (1 mg C l^{-1}) and incubated for 14 days. The humic fraction concentrations in the range 0.1–5.0 mg C l^{-1} were chosen according to the results of previous experiments (data not published) that indicated these concentrations stimulated maximum cell suspension growth.

Microscopic Observations and Residual Fluorescein in the Culture Medium After different incubation times (3, 6, 12, 24, 48, 72, and 240 hr), cell suspensions were collected in glass tubes and centrifuged at 2,000×*g* for 15 min. The sedimented cells were observed by UV fluorescence microscopy (Zeiss Axiovert 135, Oberkochen, Germany) assessing the percentage of stained cells. An indirect, but global, estimation of fluorescein binding to cells was obtained by testing the residual fluorescein concentration in the different culture media. Supernatants were analyzed fluorometrically with a Perkin Elmer MPF 44 A spectrofluorometer (Perkin Elmer, Norwalk, CT); emission was recorded at 520 nm with an excitation wavelength of 495 nm. Fluorescence intensity was monitored on an arbitrary mV scale.

Blocking Tests Blocking test is a technique based on the competition between labeled and unlabeled substances for the same receptors or binding sites. Fluorescein staining of carrot cells was considered specific if binding of FITC was abolished by pretreatment with unfluoresceinated compound (whatever the identity of receptors) at the same concentration of the labeled preparations (blocking tests). Membrane cell staining is inhibited if unconjugated substance is adsorbed onto a cell membrane first. The incubation time was 6 hr, using a concentration of FITC ten times higher than that used in cell cultures.

To evaluate the possible interference of LMr humic substances with IAA binding to cell membranes, we carried out competitive blocking tests by treating samples of carrot cells with unconjugated LMr before incubation with FITC–IAA or *vice versa*. Microscopic preparation of carrot cells was done without use of fixatives to avoid histological or cytological distortion.

Results

^{1}H NMR Spectroscopy Distinct spectroscopic patterns were observed for the two humic fractions (Fig. 1). HMr showed an aromatic proton region and an intense and broad region (3.0–5.0 ppm) attributed to sugar-like and polyether components (Wilson et al., 1983; Wershaw, 1985). Inspecting the aliphatic region revealed an intense doublet at 1.33 ppm that was the result of protons of the β-CH_3 in lactate (Wilson et al., 1988; Fan, 1996; Francioso et al., 2000). Other broad and intense resonances at 0.83 ppm and 1.3 ppm are due to protons of the terminal methyl groups of methylene chains, respectively (Malcolm, 1990). Two further intense resonances appeared at 2.9 and 3.40 ppm and were assigned to protons in α-CH_3 of acetoacetate and ether aliphatics, respectively (Aldrich Library, 1992;

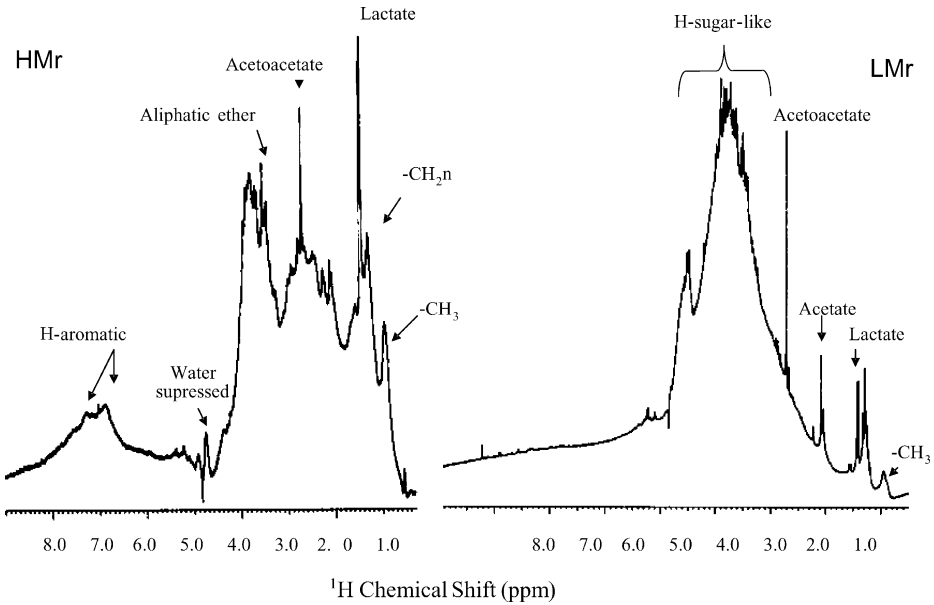

Fig. 1 ^{1}H NMR spectra (8.0–0.6 ppm) of humic substances extracted from the Ah horizon of a Calcaric Cambisol and separated in fractions corresponding to high (HMr) and low (LMr) relative molecular mass. The peaks are attributed according to Fan, 1996

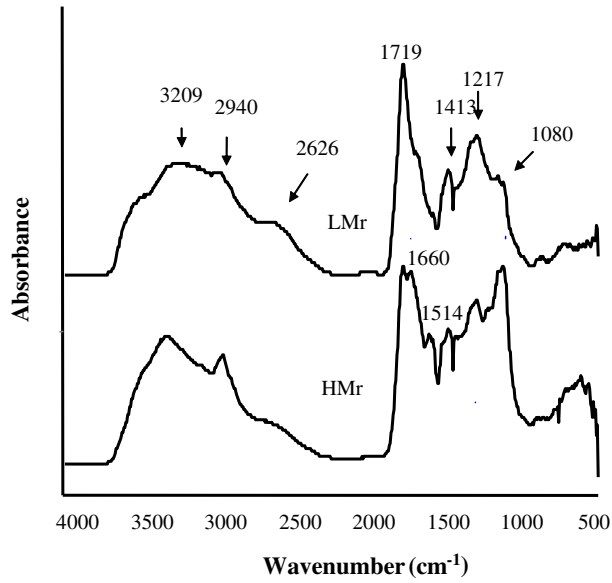

Fig. 2 DRIFT spectra of humic substances extracted from the Ah horizon of a Calcaric Cambisol and separated in high (HMr) and low (LMr) relative molecular mass fractions

Fan, 1996). In contrast, LMr did not show resonances due to aromatic protons and was characterized by a broad unresolved region, assigned to sugar-like components. However, the spectrum also contained some resonances due to the presence of low molecular weight organic substances, such as lactate (1.33 ppm), acetoacetate (2.9 ppm), and a singlet at 1.47 ppm, assigned to protons in β-CH_3 of alanine.

DRIFT Spectroscopy The interpretation of the DRIFT spectrum (Fig. 2) followed spectra published by Baes and Bloom (1989), Niemeyer et al. (1992), Stevenson (1994), and Francioso et al. (2001, 2002). The spectra of two humic fractions showed different structural modifications. In particular, in LMr appeared two strong bands at 1,719 and 1,217 cm^{-1} that are characteristic of C=O stretching (Rao, 1963; Niemeyer et al., 1992; Francioso et al., 1998, 2002) and C–O stretching motions in carboxyl acids, respectively. In addition, the broad band at 2,626 cm^{-1} suggested the formation of intermolecular hydrogen bonding between OH groups of COOH groups in acid dimers (Rao, 1963). In contrast, in HMr, the relative intensity of bands at 1,660 and 1,514 cm^{-1}, assigned to carbonyl C=O stretching and both N–H deformation and C–N stretching vibrations increased noticeably.

Table 1 Distribution of C intensity in different regions (ppm) of ^{13}C NMR spectra of high (HMr) and low (LMr) relative molecular mass humic fractions

Relative Intensity [Total Area Percentage (%)][a]					
Humic	0–48	48–105	105–145	145–165	165–190
Fraction	Aliphatic C	Peptidic and carbohydratic C	Aromatic C	Phenolic C	Carboxylic C
LMr	26.7±0.2	38.9±0.4	n.d.	n.d.	34.4±0.2
HMr	24.7±0.3	41.0±0.3	16.0±0.2	4.2±0.1	14.1±0.3

n.d. Not detected

[a] Values are mean ± SE (N=5)

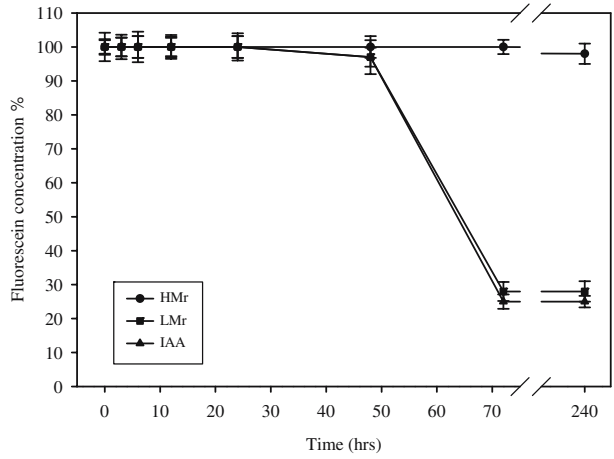

Fig. 3 Fluorescein concentration in solutions of carrot cells cultures supplemented with IAA, LMr, or HMr fractions

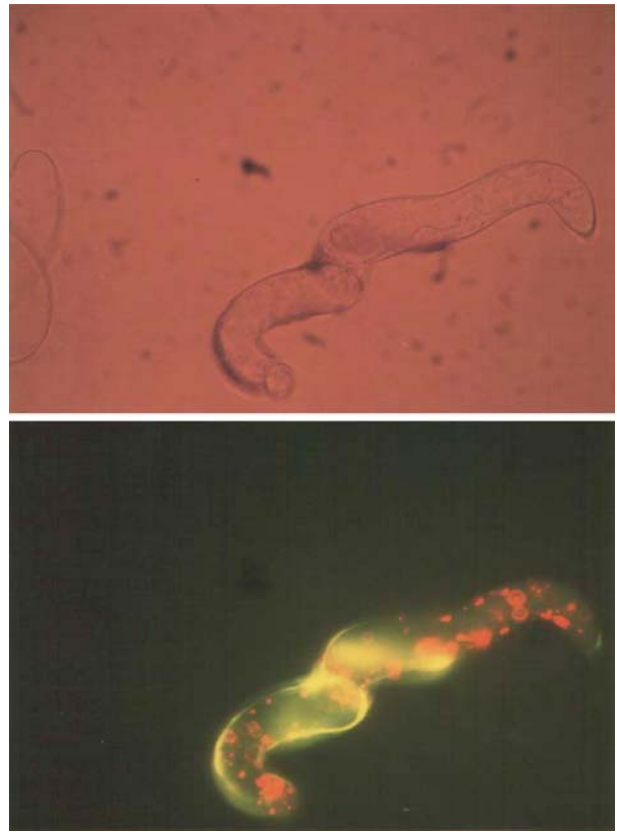

Fig. 4 Fluorescence labeling of bound IAA in carrot cell culture after 72 hr of incubation. In the carrot cells grown with FITC–IAA, 90% of cells were fluorescent after 72 hr of incubation. Fluorescence persisted through 240 hr

Moreover, these bands are due to C=C and C–C vibrations in aromatic rings, respectively. These results were supported by NMR spectra (Fig. 1).

GC-MS Analysis The IAA standard showed a GC retention time of 14.56 min and the mass spectrum had a base peak at 130 m/z, consistent with the ion formed by elimination of the $-CO_2$ Me radical from methylated IAA. This signal was not detectable in the spectrum for methylated humic fractions.

^{13}C NMR Spectroscopy Quantitatively, there were significant differences between spectra for the two humic fractions. The LMr humic fraction was richer in carboxylic and aliphatic C groups compared to the HMr fraction, whereas the HMr fraction had a higher content of peptidic-, carbohydratic-, aromatic-, and phenolic- groups (Table 1).

IAA Content The IAA content in the LMS and HMS fractions was determined to be 37 nmol mg^{-1} C.

Decrease in Fluorescence Intensity in B5 Medium Culture The fluorescence intensity was determined in the different experimental culture media after different incubation times (Fig. 3). At 72 hr, the fluorescein concentration in the culture media, added with FITC–IAA

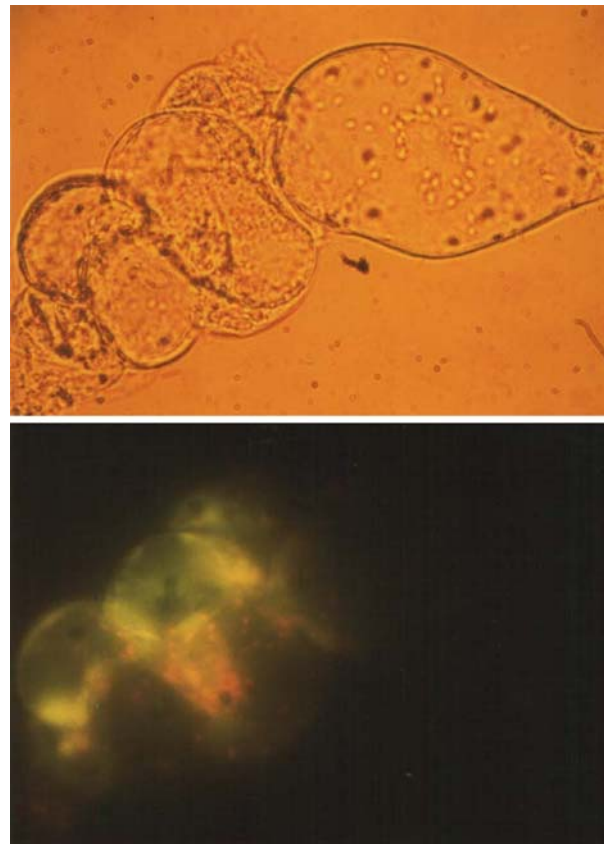

Fig. 5 Fluorescence labeling of bound LMr humic fraction in carrot cell culture after 72 hr of incubation. In the carrot cells grown with FITC–LMr humic fraction, 90% of cells were fluorescent after 72 hr of incubation and persisted through 240 hr

or FITC–LMr fractions, was markedly reduced, accounting in both about 30% of the baseline value. This decrease indicates an interaction of FITC compounds with carrot cells. On the other hand, the fluorescein content of the culture medium with HMr fraction was almost unchanged over 240 hr, suggesting a lack of interaction between this humic fraction and the carrot cells.

Microscopic Observations Cells grown in the presence of fluorescein-labeled IAA, LMr, and HMr were observed at different incubation times from 3 to 240 hr. Fluorescein staining, mainly of membranes, was observed in IAA and LMr treated cell cultures with a similar pattern. The staining was evident after 48 hr, but the highest fluorescence intensity, with more than 90% of carrot cells showing positive, was observed after 72 hr incubation, for both IAA and LMr treated cell cultures (Figs. 4 and 5). Membrane fluorescence persisted through 240 hr. Less than 10% of carrot cells grown in the presence of FITC–HMr were fluorescently stained at 72 hr, and this labile staining disappeared in cell specimens at longer incubation times (Fig. 6). Pretreatment with unconjugated IAA or LMr humic fraction blocked fluorescein staining of cells treated with both FITC–IAA (Fig. 7) or FITC–LMr humic fraction (Fig. 8). Blocking tests were considered positive if the number of fluorescent cells and the brightness of staining were decreased by 50% or more, with respect to the control samples.

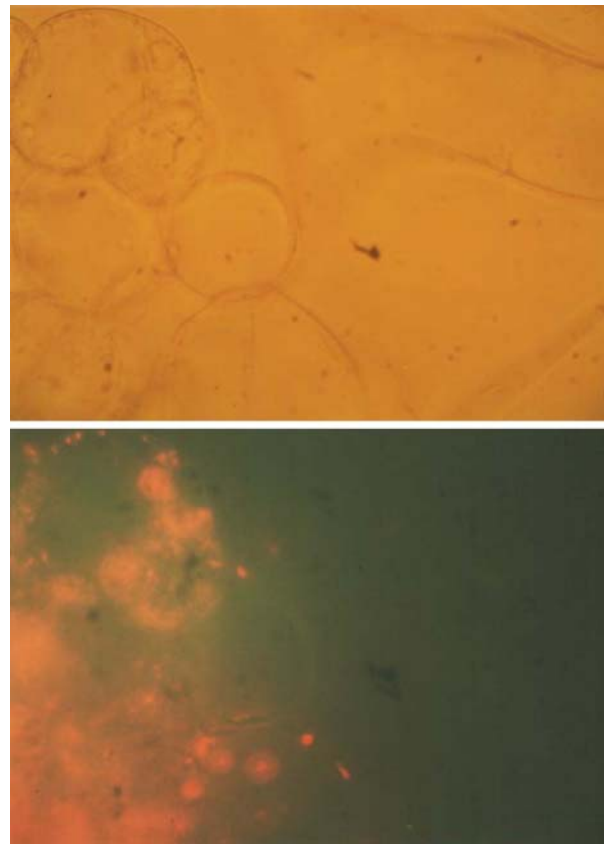

Fig. 6 Fluorescence labeling of bound HMr humic fraction in carrot cell culture after 72 hr of incubation. In the carrot cells grown with FITC–HMr humic fraction, less than 10% of carrot cells were fluorescently stained at 72 hr. This labile staining disappeared in cell specimens at longer incubation times

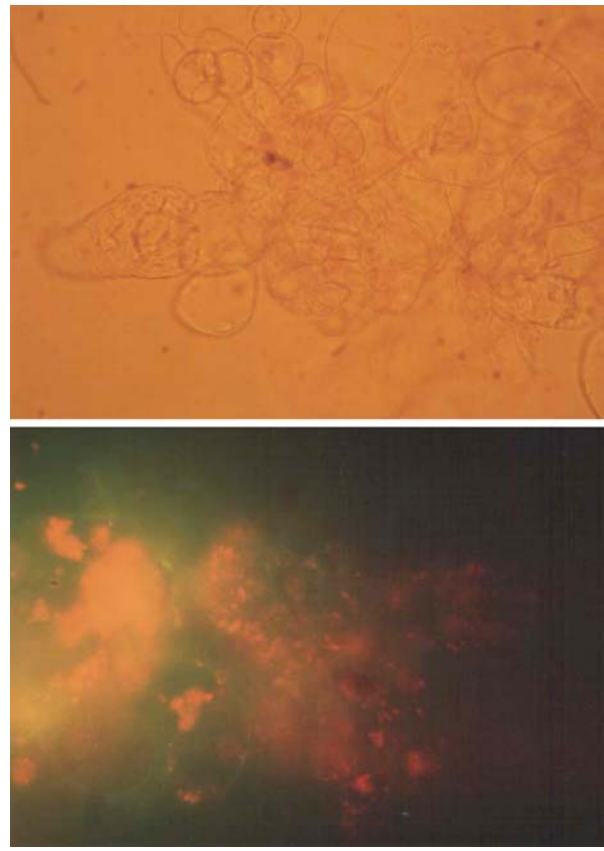

Fig. 7 Light and fluorescence microscopy of carrot cells pre-incubated with free IAA, to block auxin binding sites, and then, treated with FITC–LMr humic fraction. Pretreatment with free IAA blocked the fluorescence of carrot cell membranes. Granular staining is due to red auto-fluorescence

Discussion

Progress in research on HS has been considerably hampered by the lack of characterization of the humic fractions being used. A very detailed chemical characterization of the humic fractions used in this research had been undertaken by DRIFT, ^{1}H, ^{13}C NMR, and GC-MS. These substances were used to study their effects on carrot cell cultures and to evaluate their interaction with cell membranes.

In previous studies, the auxin-like biological effects of HS have been mainly attributed to the low relative molecular mass components of HS, such as LMr, in part, because of the ability of LMr to reach the plasma membrane of cells, whereas HMr is reported to be tightly bound to the cell wall (Vaughan, 1986). We have found marked differences in the structure of the two humic fractions. Comparing the DRIFT, ^{13}C, and ^{1}H MNR spectra of the two fractions revealed clear and significant differences. Quantitative ^{13}C NMR spectra showed the LMr fraction was rich in aliphatic- and carboxylic-C groups, whereas the HMr fraction had a higher content of peptidic-, carbohydratic-, aromatic-C, and phenolic-C groups. The higher content of aromatic groups in HMr was confirmed by ^{1}H NMR spectra that also

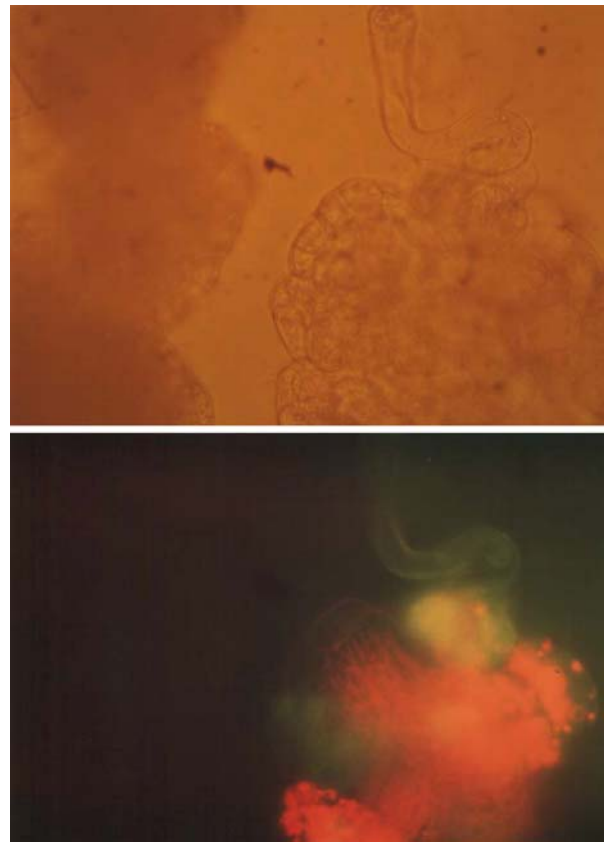

Fig. 8 Light and fluorescence microscopy of carrot cells pre-incubated with unconjugated LMr humic fraction and then treated with FITC–IAA. Pretreatment with unconjugated LMr humic fraction blocked the fluorescence of carrot cell membranes. Granular staining is due to red autofluorescence

suggested the presence of low molecular weight substances, such as lactate and acetoacetate, in both HMr and LMr. In HMr fraction, these substances are presumed to be bound to the macrostructure.

We demonstrate a direct binding of FITC–LMr humic fractions to cell membranes of *Daucus carota*. The morphological patterns and the intensity of fluorescent staining were similar to that observed in carrot cell cultures with FITC–IAA. The data obtained testing the decrease of fluorescein concentration in the media of cell cultures support these results; in fact, at 72 hr, there was good correlation between IAA or LMr interaction with plasma membrane and the maximum decrease of fluorescein concentration in the culture medium. The specificity of the binding is suggested by blocking test results. The blocking test is based on the competition between labeled and unlabeled substances for the same receptors or binding sites. Studies on the features of ABP1 showed an absence of change in conformation between auxin-bound and unbound (Woo et al., 2002), suggesting that the results obtained with the blocking test are not due to changes in conformation of the binding sites caused by the IAA pretreatment. Thus, the positive blocking competitive test between conjugated IAA and unconjugated LMr humic fraction or *vice versa* indicate that both substances interact in the same way with carrot cell membrane whatever the identity of auxin receptors is. These results cannot be related to the low content of IAA found in both fractions (0.5% w/w); in fact, it has been demonstrated that this amount of IAA is not able

to induce any biological actions on the vegetal systems utilized (entire plant, roots cells, and callus) (data not show). On the other hand, the FITC–HMr fraction, containing the same IAA amount (0.5% w/w) of the FITC–LMr fraction, did not show any interaction with the plasma membranes, and the fluorescein concentration in the culture medium did not change.

Several publications on the biological activity of humic material have shown the importance of the combination of a high content of both carboxyl, and phenolic groups, and low molecular size fractions (Muscolo et al., 1993, 1996; Nardi et al., 1994). The fraction with higher relative molecular mass was not effective on the biological activity of plant systems tested, but in soil, this fraction mainly contributes to the regulatory functions of humic fractions by encasing the strongly acidic LMr humic fraction in a macrostructure, thus, preserving it from leaching and degradation by microorganisms (Nardi et al., 1988). The dissociation of highly acidic and weakly acidic humic structures that takes place at the root–soil interface is, therefore, a prerequisite to any biological action of humic substances (Albuzio et al., 1993). Thus, the different interactions, and consequently, different biological activities of these humic fractions with the plant systems tested could be due to a different molecular mass associated with a different content of functional groups, in particular, the carboxylic groups that, as suggested by Rubery (1981) and Napier (2004), are needed for auxin bound.

In short, these results show that LMr and HMr humic fractions have a different interaction with carrot cell membranes, supporting the findings of previous studies of the effect of HS on plants, and in addition, it has been proven that the different biological activity of the two humic fractions tested is not due to the content of auxin, in that even though both humic fractions have the same amount of IAA, they do not induce the same biological activity.

Moreover, the interference in fluorescein staining of cell membranes between IAA and LMr humic fractions, as suggested by blocking competitive tests, suggests that IAA and LMr fractions richer in carboxylic groups, bind in the same way with carrot cell membranes, but do not give information about the structure of binding sites or the kind of bond because auxin specificity data have not yet been fully consistent with the characteristics for auxin receptors. Lately, affinity labeling has yielded a long list of proteins that do bind auxin, but for most (except for ABP1), their principal function is not a receptor (Napier et al., 2002, 2004); thus, many critical question about the molecular details and location of auxin binding sites remain to be answered (Woodward and Bartel, 2005).

Acknowledgments The authors thank Dr. Heather Macdonald for critical reading of the manuscript. This research was supported by the Università degli Studi "Mediterranea" di Reggio Calabria—Programmi di Ricerca Scientifica (ex Quota 60%).

Abstract Bark beetles (Coleoptera: Curculionidae, Scolytinae) have specialized feeding habits, and commonly colonize only one or a few closely related host genera in their geographical ranges. The red turpentine beetle, *Dendroctonus valens* LeConte, has a broad geographic distribution in North America and exploits volatile cues from a wide variety of pines in selecting hosts. Semiochemicals have been investigated for *D. valens* in North America and in its introduced range in China, yielding apparent regional differences in response to various host volatiles. Testing volatiles as attractants for *D. valens* in its native and introduced ranges provides an opportunity to determine whether geographic separation

promotes local adaptation to host compounds and to explore potential behavioral divergence in native and introduced regions. Furthermore, understanding the chemical ecology of host selection facilitates development of semiochemicals for monitoring and controlling bark beetles, especially during the process of expansion into new geographic ranges. We investigated the responses of *D. valens* to various monoterpenes across a wide range of sites across North America and one site in China, and used the resulting information to develop an optimal lure for monitoring populations of *D. valens* throughout its Holarctic range. Semiochemicals were selected based on previous work with *D. valens*: (*R*)-(+)-α-pinene, (*S*)-(−)-α-pinene, (*S*)-(−)-β-pinene, (*S*)-(+)-3-carene, a commercially available lure [1:1:1 ratio of (*R*)-(+)-α-pinene:(*S*)-(−)-β-pinene:(*S*)-(+)-3-carene], and a blank control. At the release rates used, (+)-3-carene was the most attractive monoterpene tested throughout the native range in North America and introduced range in China, confirming results from Chinese studies. In addition to reporting a more effective lure for *D. valens*, we present a straightforward statistical procedure for analysis of insect trap count data yielding cells with zero counts, an outcome that is common but makes the estimation of the variance with a Generalized Linear Model unreliable because of the variability/mean count dependency.

Introduction

Olfactory cues play a crucial role in host location by insects, often mediating intra- and interspecific interactions among insects (Visser 1986; Bernays and Graham, 1988). Interactions between bark beetles (Coleoptera: Curculionidae, Scolytinae) and their conifer hosts are of interest because many species colonize and kill apparently healthy trees, resulting in significant economic losses (Wood 1982b). Many species have specialized feeding habits and attack one or a few closely related host genera (Sturgeon and Mitton, 1982; Kelley and Farrell, 1998). Volatiles released from trees can provide long- and/or short-range cues for beetle attraction and, in some cases, synergize beetle aggregation pheromones (Wood 1982a; Byers 1995; Miller and Borden, 2000; Erbilgin and Raffa, 2000).

The role of monoterpenes in the ecology of bark beetles is of interest because some, such as α-pinene and myrcene, are precursors of the aggregation pheromone components of several bark beetle species (Hughes 1974; Renwick et al., 1976; Hendry et al., 1980; Byers 1989). Other studies have demonstrated *de novo* synthesis of pheromones in some species (Seybold et al., 1995b; Ivarsson et al., 1997).

The red turpentine beetle, *Dendroctonus valens* LeConte, is widely distributed in North America, extending from Nova Scotia (Canada) west to California (USA) and south to Honduras, except for the southeastern United States where its sibling species, *D. terebrans* (Oliv.), occurs (Wood 1982b). Although it is a relatively minor pest within its native range, *D. valens* occasionally kills young ponderosa pines in plantations in the western USA (Eaton and Rodríguez Lara, 1967; Rappaport et al., 2001) and may predispose trees to subsequent lethal attacks by other species (Klepzig et al., 1996; Owen et al., 2005). Drought-stressed trees appear to be more susceptible to attack by *D. valens* (Smith 1961), and there is concern that global climate change may exacerbate damage caused by this insect. Larvae feed and develop in the phloem of host trees, and galleries often overlap spatially and temporally with larvae of other members of the subcortical-feeding guild of

insects (Wood 1982b; Erbilgin and Raffa, 2002). *D. valens* was introduced into China around 1985, and has caused extensive mortality of *Pinus tabuliformis* Carrière and other pine species in north central China (Li et al., 2001). Although *D. valens* has widely been considered a secondary pest in North America (Furniss and Carolin, 1977), it has been shown to act as a primary tree-killer in China. The reasons underlying the greater tree mortality in China are not known, but could include a lack of evolutionary adaptation with this new insect/host association (Sakai et al., 2001) and/or differences in host physiology, stand structure, or climate. Considering its wide host range and geographic distribution in North America and the abundance of suitable pine hosts throughout Eurasia (Critchfield and Little, 1966), the host range and distribution of *D. valens* in the Palearctic region are expected to increase.

D. valens exploits volatile pine monoterpenes as kairomones to locate host trees, and several monoterpenes have been tested for attraction of *D. valens* in both North America and China, revealing different responses in populations from different regions. Hobson et al. (1993) reported that traps baited with (+)-α-pinene, (+)-3-carene, and (−)-β-pinene were the most attractive monoterpenes tested in California, with (−)-β-pinene by far the most attractive for *D. valens*. They showed a positive dosage–response relationship in tests of (−)-β-pinene at high release rates. Fettig et al. (2004) showed positive response by *D. valens* to the standard three-component commercial lure consisting of a 1:1:1 ratio of (*R*)-(+)-α-pinene:(*S*)-(−)-β-pinene:(*S*)-(+)-3-carene (Phero Tech, Inc., Delta, BC, Canada) in California populations, but they did not test individual monoterpenes for relative attraction. Erbilgin and Raffa (2000) showed attraction of *D. valens* to (+)-3-carene and both enantiomers of α-pinene in Wisconsin. In China, (+)-3-carene was the most attractive monoterpene for *D. valens*, with beetles showing a dose-dependent increase in attraction to (+)-3-carene, but not to (−)-β-pinene (Sun et al., 2004).

These differences were puzzling, but it was not possible to make reasonable inferences about geographic variation in response because test conditions, notably release rates, varied widely among these earlier studies. Studies conducted in California, for example, used release rates several hundreds of times higher than those in China (Hobson et al., 1993; Sun et al., 2004). Other semiochemicals cause dose-dependent differences in insect behavior (Miller and Borden, 2000), so it is reasonable to question whether the behavioral differences reported in earlier studies resulted from differences in release rate rather than divergence in behavioral response of the Chinese populations from the indigenous North American populations. On the other hand, other widespread insect species use semiochemical "dialects" in disparate parts of their ranges (Wood 1982a; Seybold et al., 1995a; Erbilgin et al., 2001; Miller et al., 1997), so we could not rule out geographic variation in behavioral response to host monoterpenes by *D. valens*, especially considering the localized source of populations introduced into China from the Pacific Northwestern United States (Cognato et al., 2005). These apparent differences prompted us to conduct a systematic evaluation of *D. valens* response to host monoterpenes throughout its native range in North America and its introduced range in China, by using standardized (i.e., with equivalent release rate) lures containing individual host monoterpenes. These were compared with a three-component commercial lure used widely in North America.

Testing host volatiles as attractants for species with wide host and geographical ranges provides us with an opportunity to compare semiochemical-mediated host selection behavior in native and introduced ranges. Furthermore, understanding the ecological aspects of host selection is important for developing semiochemicals to monitor beetles (Wood 1982a; Schlyter and Birgersson, 1999). Our objective was to investigate the responses of *D. valens* to various monoterpenes across a wide range of sites across North

America and China and to assess the potential behavioral divergence of the populations. Our practical goal was to develop optimal blends or single-component lures, appropriate for each locality, for monitoring populations of *D. valens* throughout its Holarctic range.

The project, involving nine separate trapping studies, also provided an opportunity to describe an approach for estimating treatment differences in data sets with many "zero count" cells. Data sets with zero count cells have long been a problematic area for entomological researchers (Reeve and Strom, 2004) because it is not possible to estimate the standard errors of cells with no observations. We can, however, calculate theoretical confidence intervals for the expected means for these cells, allowing Bonferroni-adjusted comparisons (Miller 1991) between means from zero count cells and means from cells with nonzero observations. This problem has been addressed in the past by either recommending exclusion of zero-count cells from the analysis, adding a small constant to each count, or creating a "dummy variable" with a low mean and variance (Agresti 1996; Reeve and Strom, 2004). In contrast, our approach was to calculate Bonferroni-adjusted confidence intervals for means with zero observations to permit comparison with nonzero cells with a given level of certainty, thus using real data rather than "dummy" variables.

Methods and Materials

Study Sites The experiments were conducted in 2003, 2004, and 2005 at 6 sites spanning the range of *D. valens* in North America and at one site in China. These were in the following forests: a *P. resinosa* Ait. stand in Jackson Co. (Central WI, USA); an east side *P. ponderosae* Laws plantation in Siskiyou Co. (Northern CA, USA); a Sierra mixed conifer forest where *D. valens* colonizes *P. lambertiana* Dougl and *P. ponderosa*, in Blodgett Forest Research Station (Central CA, USA); a mixed conifer forest where *D. valens* colonizes *P. jeffreyi* Grev. & Balf. and *P. coulteri* D. Don, in the Laguna Mountains in San Diego Co. (Southern CA, USA); a mixed hardwood and conifer forest where *D. valens* colonizes *P. strobus* L. and *P. resinosa* at Raccoon Creek State Park in Beaver Co. (Western PA, USA), a natural *P. leiophylla* Schl. et Cham. stand in San Francisco Zentlalpan (Estado de México, México), and a *P. tabuliformis* plantation in Shanxi Province, China.

Experimental Design We selected semiochemicals based on previous work with *D. valens* (Hobson et al., 1993; Erbilgin and Raffa, 2000; Sun et al., 2004). Four single-monoterpene baits [(*R*)-(+)-α-pinene, (*S*)-(−)-α-pinene, (*S*)-(−)-β-pinene, and (*S*)-(+)-3-carene], the standard commercial red turpentine beetle lure, hereafter referred to as the "RTB lure," which consists of a 1:1:1 ratio of [(*R*)-(+)-α-pinene:(*S*)-(−)-β-pinene:(*S*)-(+)-3-carene; Phero Tech Inc.], and a blank control were replicated at each site (Table 1). Trapped beetles were collected periodically, but the number of collections ("sampling periods" in Table 1) varied from site to site for reasons of local logistics. The number of replicates at each site was constant throughout the entire sampling period for each study. All of the analytical models accommodated these repeated measures, and in cases where the number of sampling periods was small (e.g., Pennsylvania), the number of replicates was increased to reduce the effect of overdispersion of counts.

Chemicals (all with purity >95%) were obtained from Sigma-Aldrich (St. Louis, MO, USA) and from Phero Tech. Single-monoterpene release devices consisted of 15-ml polyethylene bottles (Phero Tech), each filled with 8 ml of the monoterpene. The high cost of enantiopure monoterpenes prohibited the use of the full measure of 15 ml per vial. To

ensure that the entire contents of each vial were exposed to the release surface, the bottles were squeezed until the liquid reached the shoulder, then were tightly capped leaving the bottles slightly collapsed. Each bottle also contained 100 mg BHT (butylhydroxytoluene) (Sigma-Aldrich) as an antioxidant. Each chemical maintained a sustained release of 103.4± 11.3 mg/d at 20±4.3°C with 6.2±2.3 km/hr wind velocity for at least 30 d in the field. Release rates of chemicals (determined by daily weight loss) under the same conditions did not vary significantly ($F_{4,3}$=1.23, P=0.45). The RTB lure contains 15 ml of the three-component blend (5 ml of each of the three monoterpenes) mixed with undefined stabilizers and antioxidants, and it releases at a slightly higher rate, 110 mg/d, under similar environmental conditions (personal communication, B. Thompson, Phero Tech). We concluded that this slight difference in release rate would have no significant effect on our overall inferences, especially considering the ambient release of monoterpenes from trees in a typical forest stand (Wilt et al., 1993; Schade and Goldstein, 2003).

Lures were attached to multiple-funnel traps (Phero Tech) or panel traps (Advanced Pheromone Technologies, Marylhurst, OR, USA) designed for trapping bark beetles. Propylene glycol antifreeze or a plastic insecticidal strip saturated with 2,2-dichlorovinyl dimethyl phosphate (Hercon Vaportape II Insecticidal strips; Hercon Environmental Co., Emigsville, PA, USA) was put in each collection cup to prevent predation. The experimental design was a completely randomized design with repeated measurements, with the exception of the Wisconsin site, which was a randomized complete block design. For some sites, traps were rerandomized at sampling time, and for other sites the trap was left at the same location for the entire time of the experiment. Statistical models for analysis were designed to account for these minor differences in design. The numbers of replications and sampling periods per treatment are shown in Table 1. Beetles captured in each trap were identified, counted, and recorded; voucher specimens were stored at the USDA Forest Service Institute of Forest Genetics (Placerville, CA, USA), Universidad Autónoma Chapingo (Texcoco, México), or Chinese Academy of Sciences (Beijing, China) according to site.

Statistical Analyses Trap counts were analyzed with Poisson Regression Models for overdispersed Poisson distributed responses (counts) to address potential overdispersion arising from the repeated measurements (McCulloch and Searle, 2001). The overdispersion error was assumed to be normally distributed for some sites according to sampling design.

The Maximum Likelihood Ratio test with the Bonferroni adjustment was used for multiple comparisons for an experimentwise error rate of 0.05. The SAS (2005) NLMIXED procedure was used to estimate parameters and their differences. Mean counts for treatments with nonzero observations were estimated the using the computing routines described above. For the treatments with zero observations, the mean counts were estimated as zero, and precision was estimated by a Bonferroni-adjusted confidence interval from 0.0% to 99.7% $(100 \times [1 - 0.05/\{15 = \text{number of comparisons}\}])$, where the upper confidence bound was calculated by using rules for multiplication and addition of probabilities (Hoel et al., 1971). We thereby created a way to determine, with a given level of certainty, the range of the treatment means with zero observations. We compared nonzero count treatment means by using the standard method of testing significance, but for zero-count treatment means we used the overlap between the calculated Bonferroni-adjusted confidence intervals for zero counts and the Bonferroni-adjusted confidence intervals of the nonzero treatment means. Even though this approach is occasionally conservative, it yields a more sensitive test of treatment differences. In general, it works best if the lower confidence bounds of the nonzero count treatment levels are not close to zero.

Procedure for Calculating the Upper Bound for Treatments with Observed Zero Counts Upper bounds are developed as follows. We present a $1 - \alpha$ upper bound for three count distributions: the Poisson distribution and two overdispersed Poisson distributions (Poisson-Gamma = Negative Binomial and Poisson-Normal).

Let α be the given level; therefore, a $1 - \alpha$ upper bound for expected count for a treatment is given by:

$$P(x > 0) = 1 - [P(x = 0)]^{n_{\text{reps}}} \leq 1 - \alpha,$$

where n_{reps} is the number of replications.

(A) Suppose x has the Poisson distribution with mean λ_T (not overdispersed) for a given treatment level T, then

$$P(x > 0) = 1 - \left[e^{-\lambda_T}\right]^{n_{\text{reps}}} \leq 1 - \alpha.$$

Therefore, the upper bound for expected mean count is given by

$$\lambda_T \leq -\frac{1}{n_{\text{reps}}} \log(\alpha), \tag{1}$$

where log indicates logarithm.

The next two techniques [Eqs. (2) and (3)], which assume the Poisson-Gamma or the Poisson-Normal distribution, can be problematic to calculate if the software is not available. If so, then a close approximation of the upper bound can be made by using just the Poisson distribution [Eq. (1)], since the α level and number of replicates are the only pieces of information required for that calculation.

(B) Suppose x has an overdispersed Poisson distribution with mean λ_T, and with a Gamma distributed overdispersion error (McCulloch and Searle, 2001). Therefore, x has the Negative Binomial distribution (k). In this case,

$$P(x > 0) = 1 - \left[(1 - k\lambda_T)^{-\frac{1}{k}}\right]^{n_{\text{reps}}} \leq 1 - \alpha,$$

and the upper bound is given by

$$\lambda_T \leq \frac{\alpha^{\frac{-k}{n_{\text{reps}}}} - 1}{k} \tag{2}$$

The parameter k can be estimated by SAS NLMixed or Glimmix procedures.

(C) Suppose, for a given treatment, x has an overdispersed Poisson distribution $P(\lambda_T)$ with mean $\lambda_T = e^{T+\sigma\varepsilon}$, and a normally distributed overdispersion error ε (McCulloch and Searle, 2001.). If ε is $N(0,1)$ (Standard Normal) distributed, and σ is the standard deviation of the overdispersion error, then

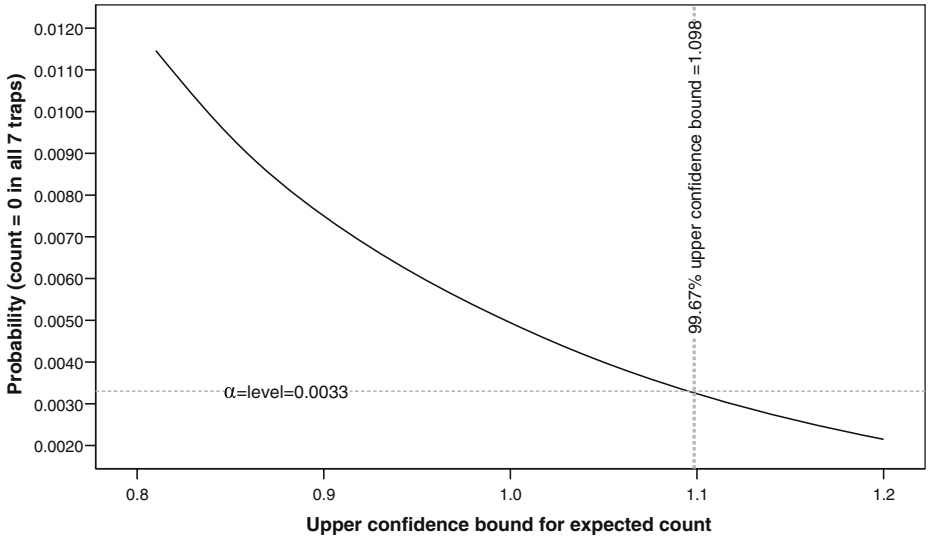
$$P(x>0) = 1 - \left[\int_{-\infty}^{+\infty} \frac{e^{-e^{T+\sigma\varepsilon}} e^{-\frac{\varepsilon^2}{2}}}{\sqrt{2\pi}} d\varepsilon\right]^{n_{\text{reps}}} \leq 1-\alpha,$$

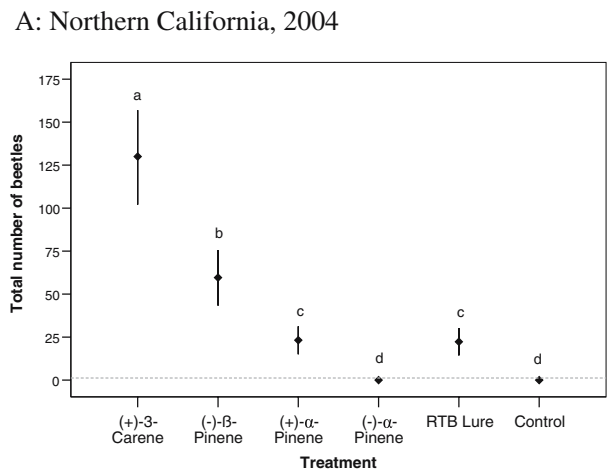
where $\int$ is the integration symbol. In this case, the upper bound does not have a closed formula. However, it can be approximated by numerically calculating this probability for several values of T for the following function:

$$f(T) = \left[\int_{-\infty}^{+\infty} \frac{e^{-e^{T+\sigma\varepsilon}} e^{-\frac{\varepsilon^2}{2}}}{\sqrt{2\pi}} d\varepsilon\right]^{n_{\text{reps}}} \tag{3}$$

The numerical solution of the integral can be done with Mathematica (Wolfram 1999). Fig. 1 depicts the function $f(T)$ for possible upper bound values for several values of T. The value of T for a given $f(T)=0.05/15=0.0033$ is equal to 1.098 (the upper 99.7% confidence limit). Fig. 1 diagrams the method for the Central California site; the upper bound for the treatment levels with zero counts for this site can be compared with the lower bounds of other treatments at the same α level ($\alpha=0.0033$).

Panels A–D, F, and G of Fig. 2, each of which contains at least one zero-count cell, all illustrate this approach for making multiple comparisons with treatments with zero counts (the upper Bonferroni-adjusted confidence limit for multiple comparisons is indicated by a dotted line on those figures). The calculated upper bound for the treatment levels with zero counts can be compared to the lower bounds of other treatments at the same α level ($\alpha=$





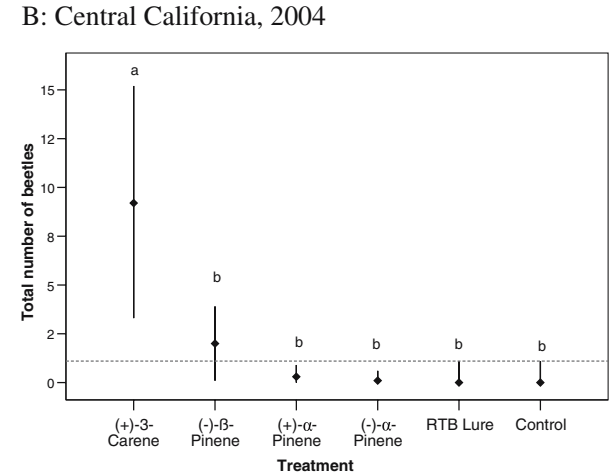


Fig. 1 Calculated upper Bonferonni-adjusted confidence limit for cells with zero counts (example using results from central California, 2004)

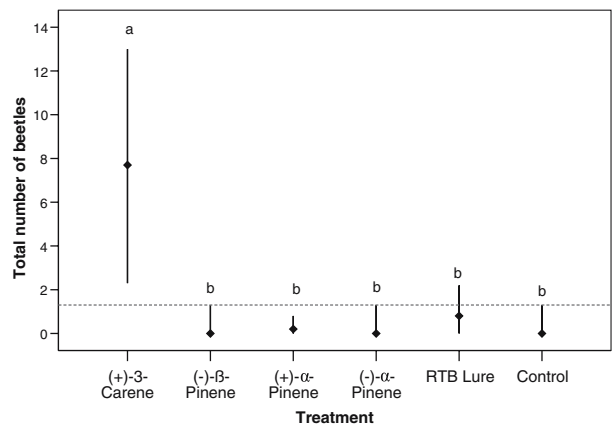

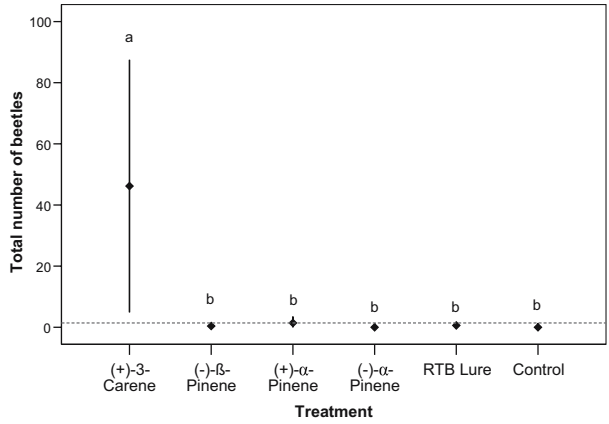

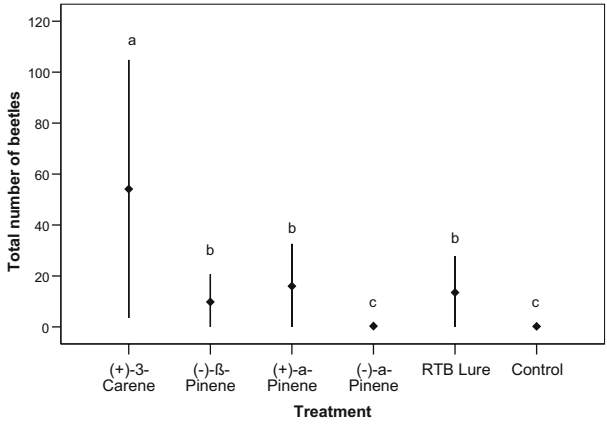

Fig. 2 (A-I) *Dendroctonus valens* response to pine monoterpenes at nine different localities and/or years in North America and China. Dates (location codes) for experiments: May 22–June 10 for Northern California (CA North); September 21–October 10 for Central California (CA Central); August 28–September 6 and May 20–August 26 for Southern California (CA South); May 3–May 18 for Wisconsin (WI); May 2–May 15 for Pennsylvania (PA); June 27 for Mexico (MX); May 2–June 20 for China 2003 (CH 2003) and May 4–August 2 for China 2004 (CH 2004). Data show mean numbers (lower=99.7% lower confidence bound, upper=99.7% upper confidence bound) of insects per trap summed over sampling period. Means followed by the same letter in a column are not significantly different from each other. Dotted lines indicate 99.7% calculated upper confidence bound for treatments with zero observations

0.0033). If they do not touch, then the treatment levels are significantly different. If they overlap, then there is not enough evidence to reject the null hypothesis. Mexico has two calculated upper bounds because each treatment level had eight replications except for the control, which had only four (and thus a greater upper bound). Fig. 2E, H, and I, which do not contain zero count cells, are handled in the traditional manner.

Results

Trap counts were estimated as mean numbers of beetles per trap summed over the sampling intervals (Table 1, Fig. 2A–I). The mean counts of beetles summed over sampling intervals are not comparable among sites because the sites had different sampling time ranges, from 1 wk for Mexico to nearly 3 mo for China and southern California in 2004 (Table 1).

California In northern California (Fig. 2A), (+)-3-carene was the most attractive compound tested, followed by (−)-β-pinene. The number of *D. valens* trapped was not different between (+)-α-pinene and the RTB lure, nor between (−)-α-pinene and the control. In central California (Fig. 2B), the numbers of *D. valens* were relatively lower than those in northern California, but the pattern of attraction was similar; only (+)-3-carene attracted significantly more *D. valens* than the control. In southern California (Fig. 2C and D), the results were identical to those of central California. In two consecutive years, only (+)-3-carene attracted a significantly higher number of *D. valens* than the control.

Wisconsin (+)-3-Carene was significantly more attractive than the remaining treatments, whereas (+)-α-pinene, (−)-β-pinene, and the RTB lure were more attractive than (−)-α-pinene and the control (Fig. 2E). There were no significant differences between mean numbers of *D. valens* caught in traps baited with (−)-α-pinene and the control, nor between (+)-α-pinene, (−)-β-pinene, and the RTB lure.

Pennsylvania (+)-3-Carene was the most attractive compound tested and was significantly different from the control, the (−)-α-pinene, and the RTB lures (Fig. 2F). Attraction of (−)-β-pinene and (+)-α-pinene were not different, and both were greater than the attraction of either (−)-α-pinene or the control.

Mexico None of the treatments in Mexico were significantly different from one another (Fig. 2G). However, there was only one sampling interval, and the number of beetles was low, with a median close to zero for all treatments except for (+)-3-carene and the RTB lure.

China (+)-3-Carene was the most attractive lure in both 2003 (Fig. 2H) and 2004 (Fig. 2I), but only in 2004 was it significantly more attractive than the RTB lure, which was the second most attractive lure in both years of testing. The mean number of *D. valens* caught by the RTB lure was not significantly different from that caught by (−)-β-pinene in both 2003 and 2004. The mean number of *D. valens* caught in (−)-β-pinene traps was significantly higher than for the control. (+)-α-Pinene, (−)-α-pinene, and the control were not significantly different from one another in 2003. Results for 2004 were identical except that (−)-α-pinene caught more insects than the control.

General Observations With the exception of the tests conducted in Wisconsin (Fig. 2E) and China (Fig. 2H and I), where beetle populations were among the highest, the total number of beetles trapped in unbaited traps was zero. There were significant differences among treatments in the mean numbers of *D. valens* caught in all sites and all years except for Mexico (2005), where beetle numbers were low and there was only one sampling interval (Fig. 2G). (+)-3-Carene was the most attractive treatment at all sites, and the difference between (+)-3-carene and the second most attractive treatment was significant in most cases, i.e., northern California (Fig. 2A), central California (Fig. 2B), southern California (both years) (Fig. 2C and D), Wisconsin (Fig. 2E), and China (both years) (Fig. 2H and I). In Pennsylvania (Fig. 2F), (+)-3-carene attracted 65% more beetles than did (−)-β-pinene, but this difference was not significant. In Mexico (Fig. 2G), (+)-3-carene tied with the RTB lure for most attractive treatment. The RTB lure, which also contains (+)-3-carene as a component, was generally the second most attractive lure, although in most cases it was not significantly more attractive than the third-ranking treatment. In three cases, however (northern California, central California, and Pennsylvania), (−)-β-pinene was the second most attractive compound tested, but only in northern California was this difference significant. In Wisconsin, (+)-α-pinene was the second most attractive treatment but it was not significantly different from (−)-β-pinene or the RTB lure. (−)-α-Pinene was not significantly different from the control in any case except for China in 2004.

Discussion

(+)-3-Carene was the most attractive monoterpene tested throughout the native range of *D. valens* and in China. These results confirm studies conducted recently in China, where (+)-3-carene has been shown to be the dominant attractant among pine host monoterpenes (Sun et al., 2004; J.H. Sun, personal communication). (+)-3-Carene is, thus, broadly applicable for monitoring *D. valens* in both China and North America. This uniform preference for the same signal over such a broad geographical range differs from responses by certain other bark beetle species to their pheromones, which vary geographically (Wood 1982a; Seybold et al., 1995a; Miller et al., 1997).

The practical, pest management implication of this finding is clear: a single-component lure will likely be the most cost-effective and biologically efficient one for *D. valens* across its range in the Holarctic, whether in its native range in North America or in its introduced range in Asia. Preferential attraction of *D. valens* to (+)-3-carene suggests that it is the key stimulus from its host trees, and plays role in host selection. Differences between this and earlier studies (Hobson et al., 1993; Erbilgin and Raffa, 2000) may result from differences in release rates of the compounds. For example, in the work of Hobson et al. (1993), where (+)-3-carene was less attractive than other monoterpenes, release rates were more than 200 times those used in this study. In other words, (+)-3-carene may become repellent or inhibitory at higher release rates relative to the other monoterpenes studied.

(+)-3-Carene constitutes varying proportions of the resins of *Pinus* species and other coniferous genera in North America (Mirov 1961; Hobson et al., 1993; Smith 2000; Erbilgin et al., 2001), but it is generally the predominant monoterpene in its most widely distributed host in North America, ponderosa pine (Smith 2000). *P. tabuliformis*, the primary host of *D. valens* in China, has a needle monoterpene composition that is similarly high in (+)-3-carene (Jin et al., 1994). Several other forest Coleoptera respond to 3-carene as an attractant or synergist. For example, the pine shoot beetle, *Tomicus piniperda*, utilizes

(+)-3-carene as a kairomone along with (±)-α-pinene and terpinolene to locate and assess the susceptibility of its host, *P. sylvestris* L. (Byers et al., 1985; Lanne et al., 1987; Byers 1992). Likewise, *Pityogenes chalcographus* (L.) utilizes α-pinene, β-pinene, and (+)-3-carene to locate and colonize hosts (Byers et al., 1988). In another study, (+)-3-carene synergized the attraction of *Conophthorus ponderosae* Hopkins to its sex pheromone in a ponderosa pine seed orchard in northern California (Gillette et al., unpublished data). (+)-3-Carene also influenced the attraction of bark beetles and their predators to bark beetle pheromones (Miller and Borden, 2003).

Although host monoterpenes are crucial in the *D. valens* host selection process, it is difficult to relate levels of emission from our lures to natural emissions from forest stands. For example, monoterpene concentrations in pines vary in response to drought (Lorio et al., 1995), fungal infection of roots (Klepzig et al., 1995), and defoliation (Wallin and Raffa, 1999). Emissions from foliage vary depending on state of decomposition (Wilt et al., 1993). Furthermore, boring activities initiated by beetles rapidly alter monoterpene concentrations and release rates of attacked trees (Paine and Stephen, 1987; Cook and Hain, 1988; Raffa and Smalley, 1995). On a broader scale, estimations of volatile emissions from forests are more difficult to make. For example, natural emission of α-pinene from ponderosa pine plantations at the Blodgett Forest Research Station is about 0.1 $mg/m^2/hr$ during the daytime in summer, and it changes as an exponential function of temperature (Schade and Goldstein, 2003). Monoterpene emissions from the same pine forest were enhanced about 40 times during a mechanical thinning operation. Previous reports indicate that bark beetle populations tend to increase following fire and tree thinning (Furniss and Carolin, 1977), and higher emissions of monoterpenes may explain such increases in populations of *D. valens* and other bark beetle species.

The broad host and geographical range (Kelley and Farrell, 1998), highly specialized olfactory responses (White and Hobson, 1993), and cryptic nature (Bernays and Graham, 1988) of *D. valens* may all have contributed to its successful establishment in China. Other factors, such as host susceptibility and a lack of competition and natural enemies (Sakai et al., 2001), undoubtedly also played a role. Although many species of *Dendroctonus* are restricted to one of four confamilial genera of conifers (Sturgeon and Mitton, 1982), *D. valens* can colonize almost three times as many hosts as its congeners (Kelley and Farrell, 1998), suggesting that it may have greater intrinsic capacity for adaptation to new hosts. Recently, Cognato et al. (2005) reported significant haplotype variation in *D. valens* in its native and introduced ranges. We initially expected that behavioral differences seen in earlier studies might be explained by genetic variability, but this variation was not reflected in behavioral differences in responses to host compounds.

The recent introduction of *D. valens* to China and its rapid establishment on pines indigenous to Asia demonstrate that *D. valens* can colonize and reproduce on new host species within the same genus as its ancestral hosts in North America. This new association may have resulted from adaptation to diverse secondary chemicals during colonization of ancestral hosts (Byers 1995; Kelley and Farrell, 1998), and/or close association with particular host volatiles that result in gaining access to chemically similar host species in new biogeographic areas (Futuyma et al., 1995; Becerra 1997). Recognition of common host volatiles, e.g., (+)-3-carene, may be the first phase of colonization of new host species by *D. valens*, since the dominant volatiles of its hosts are mainly monoterpenoids (Mirov 1961; Juuti et al., 1990; Smith 2000). However, the presence of the same attractive compounds in nonhost trees (Hobson et al., 1993) or the presence of inhibitory nonhost, e.g., green leaf, volatiles (Zhang and Schlyter, 2004) in the same forest suggests that host

location by this beetle species must rely on multiple factors, such as the relative and absolute release rates of host and nonhost compounds, timing of response elicitation, and other life history aspects. Indeed, Pureswaran et al. (2004a, b) presented extensive evidence for several beetle/host combinations supporting the hypothesis that scolytid beetles utilize quantitative, as well as qualitative, differences in host odor blends in the process of host selection. Such a strategy would optimize host selection and minimize the risks associated with response to nonhost cues in the process of host location. In China, *D. valens* is faced with many new pine hosts that provide a continuous corridor for its spread from its region of introduction in northeastern China across Eurasia to Europe (Critchfield and Little, 1966). For example, *D. valens* colonizes *P. sylvestris* planted in North America (Wood 1982b); thus, it could be predicted that *D. valens* will infest naturally occurring *P. sylvestris* throughout Eurasia. Effective semiochemical lures are of increasing importance as this introduced pest expands its range in the Palearctic. If, as predicted, *D. valens* becomes more of a primary tree killer as a result of the effects of global warming, such methods will also become more important in its native range in the Nearctic.

Acknowledgement This study was supported by the USDA Forest Service, Forest Health Technology Enterprise Team (Morgantown, WV, USA), the National Natural Science Foundation of China (Project 30471403 and 30525009), the College of Natural Resources, University of California, Berkeley, and the College of Agricultural and Life Sciences, University of Wisconsin, Madison, Universidad Autonóma Chapingo (Texcoco, Mexico), and the Chinese Academy of Sciences, Institute of Zoology (Beijing, China). Abstract Six known pentacyclic triterpenes possessing oleanane, lupane, or taraxerane-type skeletons were isolated from the leaves of *Sebastiania adenophora* (Euphorbiaceae) and are reported for the first time in this species. These compounds include 3-*epi*-β-amyrin, β-amyrinone, 3-*epi*-lupeol, lupenone, taraxerol, and taraxerone. Structures were elucidated by comparison with literature data. The bioactivities of these compounds were tested on the root growth of *Amaranthus hypochondriacus*, amaranth (Amaranthaceae), *Lycopersicon esculentum*, tomato (Solanaceae), and *Echinochloa crus-galli*, barnyard grass (Poaceae). All six triterpenes were selectively bioactive. An important stimulatory effect was observed on amaranth root growth (23% to 56%) for almost all tested triterpenes (250 μg/ml). These triterpenes significantly inhibited the root growth of barnyard grass (28% to 78%) and tomato (23% to 49%). Aqueous leachate and organic extracts of *S. adenophora* leaves significantly inhibited the root growth of all test species. The possible ecological role of the allelochemicals isolated is discussed.

Introduction

Sebastiania adenophora Pax & K. Hoffm (Euphorbiaceae), commonly known as "zak chechén," "k'aan chunup," or "chechén blanco" is a tree up to 8–15 m high from the Peninsula of Yucatan, Mexico, Guatemala, and Belize (Martínez, 1994; Flores and Espejel-Carvajal, 1994). This tree is the main component of the *S. adenophora–Plumeria obtusa* var. *cericifolia–Agave angustifolia* forest community in Quintana Roo State. This community covers approximately 90% of the tropical forest area of this Mexican state (Sánchez-Sánchez and Islebe, 2002).

Sebastiania comprises over 101 species; 71 of them have been reported in the Peninsula of Yucatan, Mexico (Sousa and Cabrera, 1983). The empirical medicinal use of *S. adenophora* in this area is related to the use of the highly toxic latex of this tree. Two to three drops of it are used as a cathartic; a higher amount can cause death. In addition, *S. adenophora*'s wood is considered as rare and is appreciated in floors and furniture.

Phytochemical and pharmacological studies of *Sebastiania* species have yielded several phenolic compounds (Penna et al., 2001; Godoy et al., 1991; Calixto et al., 1990), steroids, and triterpenoids (Khera et al., 2003; Branco and Pizzolatti, 2002; Gaertner et al., 1999; Yunes et al., 1990). Some of these compounds have biological activity such as antimicrobial (Khera et al., 2003; Penna et al., 2001; Haraguchi et al., 1999; Godoy et al., 1991), antiviral (Kott et al., 1999), analgesic (Luzzi et al., 2000; Gaertner et al., 1999), or antispasmodic (Yunes et al., 1990; Calixto et al., 1990).

In a previous study (Romero-Romero et al., 2002), we reported the allelochemical effect of an aqueous leachate (1%) from the leaves of *S. adenophora* on the root growth and cytoplasmic protein synthesis patterns of maize, bean, squash, and tomato. The aqueous leachate exhibited a selective effect on root growth of the test species. Tomato roots were inhibited (70%) and squash roots were stimulated (49%). In addition, cytoplasmic protein pattern of all test plants was altered by *S. adenophora* aqueous leachate.

To continue with our studies on the allelochemical potential of *S. adenophora*, we isolated and identified the main secondary metabolites from leaves and searched for the compounds responsible for the differential effect on the growth of some plants.

Methods and Materials

Plant Material Leaves of *S. adenophora* were collected in Quintana Roo, Mexico, in February of 2004. Leaves were air-dried in the shade. A voucher specimen was deposited at the Herbarium of the University of Yucatan, Mexico.

Test Seeds Phytotoxicity of the aqueous leachate, organic extracts, and pure compounds from *S. adenophora* leaves were tested on the root growth of two dicotyledonous species: *Amaranthus hypochondriacus* L. (Amaranthaceae), amaranth, and *Lycopersicon esculentum* Mill. (Solanaceae) var. Pomodoro, tomato; and one monocotyledonous plant, *Echinochloa crus-galli* L. (Beauv.) (Poaceae), barnyard grass. We chose these three species to obtain rapid and more homogeneous results in bioassays. Amaranth seeds were purchased from a local market in Tulyehualco, Mexico, D.F. Barnyard grass seeds from Valley Seed Service, Fresno, California, USA and tomato seeds from Semillas Berentsen, Celaya, Guanajuato, Mexico.

Bioassays with Aqueous Leachate Two grams of *S. adenophora* dry leaves were soaked for 3 hr in 100 ml of distilled water. The leachate was filtered through Whatman paper (no. 4)

and then a sterile Millipore membrane (0.45 μm). The osmotic potential was measured with a freezing-point osmometer (Osmette A. Precision System), and the values ranged from 20 to 26 mosm/l=−0.045 to −0.059 MPa.

Aqueous leachate (2%, w/v) was mixed (1:1 v/v) with agar (2%) to obtain a 1% test solution. Pure agar (1%) was used as a negative control, and agar with 100 μg/ml of 2,4-D as a positive control. Seedling root growth bioassays for the aqueous leachate were carried out according to procedures published previously (Anaya et al., 2003). Bioassays were set up in 6-cm Petri dishes. Ten seeds of each test plant were sown directly on the agar of each Petri dish following a completely random design with 4 replicates per treatment. Petri dishes were kept in darkness at 27°C. Root lengths were measured 24 hr after treatment for amaranth, 48 hr for barnyard grass, and 72 hr for tomato. Data were analyzed by ANOVA and Tukey's tests (Mead et al., 2002).

Bioassays with Organic Extracts and Pure Compounds Bioassays with organic extracts (100 μg/ml) and pure compounds (250 μg/ml) were set up using the same conditions as for aqueous leachate, but with filter paper as a substrate. The filter paper (Whatman 42) was impregnated with 1.5 ml of the solutions or 2,4-D (250 μg/ml) as a positive control. After complete evaporation of solvents, filter papers were moistened with 1.5 ml of distilled water. Filter paper with only distilled water was used as negative control. Test seeds and time of harvesting for these bioassays were the same. IC_{50} (50% inhibitory concentration) values for 3-*epi*-β-amyrin (**1**), taraxerol (**5**), and the mixture of the six triterpenes (**E2** fraction), were calculated by probit analysis based on root growth bioassays where treatments were evaluated at 125, 250, and 500 μg/ml.

Extraction and Isolation of Allelochemicals in Leaves Plant material (2.0 kg) was sequentially extracted with hexane and CH_2Cl_2–MeOH at room temperature for 9 d. Evaporation to dryness under reduced pressure of the two extracts afforded a dark green residue.

The CH_2Cl_2–MeOH extract (40.1 g) was fractioned by column chromatography on silica gel (60, 70–230 mesh, Merck) using *n*-hexane–CH_2Cl_2–MeOH mixtures of increasing polarity, yielding 180 fractions (400 ml) that were reduced to 13 fractions (**A-M**) after comparison by thin layer chromatography (TLC) (pre-coated silica gel 60 F254 plates, Merck). Fraction **E** was selected for further fractionation because it had the highest activity in root growth bioassays with the dicotyledonous species amaranth and tomato, and the monocotyledonous species barnyard grass. From this primary fraction **E** (eluted with 30% *n*-hexane and 70% CH_2Cl_2), taraxerol (14-taraxeren-3-ol) [**5**] (4.2 mg) spontaneously crystallized (Sakurai et al., 1987; Ogihara et al., 1987). The mother liquors from this bioactive fraction were purified by silica gel column chromatography eluted with *n*-hexane, CH_2Cl_2, and MeOH in increasing polarity. The resulting fractions were combined according to TLC monitoring to give eight fractions (**E1**–**E8**). Bioactivity on plant growth was found in fraction **E2**. From this fraction (eluted with 60% *n*-hexane and 40% CH_2Cl_2), a mixture of the pentacyclic triterpenes **1**–**6** spontaneously crystallized. The mixture was resolved by preparative TLC and was eluted with CH_2Cl_2–MeOH (99.5:05) to give band I and II. Both bands were purified by successive preparative TLC (impregnated with a 10% $AgNO_3$ solution) eluted with CH_2Cl_2–MeOH (99.5:05). Band I yielded, 3-*epi*-β-amyrin (3α-hydroxyolean-12-ene) [**1**] (12.1 mg) [Tamai et al., 1989; Reyes et al., 1983] and 3-*epi*-lupeol (3α-hydroxylup-20(29)-ene) [**3**] (8.7 mg) [Carvalho and Seita, 1995; Waterman and Ampofo, 1985]. Band II yielded β-amyrinone (3-oxoolean-12-ene) [**2**] (7.6 mg) [Yan et al., 1989; Kikuchi et al., 1977], lupenone (3-oxolup-20(29)-ene) [**4**] (6.1 mg) [Carpenter et al.,

1980; Appleton and Enzell, 1971], and taraxerone (14-taraxeren-3-one) [**6**] (6.8 mg) [Parveen et al., 1988; Sakurai et al., 1987]. From the inactive fractions **H** and **L**, spontaneously crystallized β-sitosterol (45.3 mg) and β-D-glucositosterol (177 mg), respectively.

In contrast, the hexane extract (37 g) was subjected to silica gel column chromatography eluting with a gradient of *n*-hexane–CH_2Cl_2–MeOH. One hundred sixty fractions (200 ml each) were collected and pooled on the basis of their TLC profiles to yield 14 major fractions (**I**–**XIV**). Root growth bioassay showed one active pool (**VIII**). From fraction **VIII**, eluted with 30% *n*-hexane and 70% CH_2Cl_2, 26.0 mg of taraxerol (**5**) spontaneously crystallized and was recrystallized from a CH_2Cl_2–MeOH solution. The mother liquors from bioactive fraction **VIII** were also subjected to column chromatography on silica gel using *n*-hexane–CH_2Cl_2–MeOH mixtures of increasing polarity. This column yielded 125 fractions (50 ml each) that were reduced to 10 fractions (**VIII–1**–**VIII–10**) after comparison of their Rf's by TLC. According to the root growth bioassay, bioactivity was concentrated in secondary fraction **VIII–6**. From this fraction following TLC and elution with CH_2Cl_2–MeOH (99.5:05) 3-*epi*-β-amyrin (**1**) (8.2 mg) and taraxerol (**5**) (3.2 mg) were isolated.

General Experimental Procedures Melting points were determined on a Fisher–Johns apparatus and are uncorrected. IR spectra were obtained using KBr disks on a Perkin-Elmer 599-B spectrophotometer. UV spectra were obtained on a Shimadzu 160 UV spectrometer in MeOH solution. Optical rotations were taken on a JASCO DIP 360 polarimeter. NMR spectra was recorded on a Bruker DMX500, in $CDCl_3$, either at 500 (^{1}H) or 125 (^{13}C) MHz, using tetramethylsilane (TMS) as an internal standard. EI mass spectra were performed using a Hewlet-Packard 5890 mass spectrometer.

Results and Discussion

Effects of Aqueous Leachate and Organic Extracts on Plant Root Growth The bioactivity of the aqueous leachate and organic extracts of the dry leaves of *S. adenophora* were determined (100 μg/ml) on the root growth of *A. hypochondriacus* (Amaranthaceae), amaranth; *L. esculentum* (Solanaceae), tomato; and *E. crus-galli*, (Poaceae) barnyard grass using 2,4-D (2,4-dichlorophenoxyacetic acid) as a positive control (Fig. 1).

The aqueous leachate of *S. adenophora* dry leaves inhibited root growth of tomato (63%) and amaranth (25%), with no effect on barnyard grass. The hexane extract inhibited root growth of amaranth (40%) and barnyard grass (35%), with no effect on tomato. The CH_2Cl_2−MeOH (1:1) extract inhibited root growth of amaranth (49%), barnyard grass (39%), and tomato (42%). These results led to selection of the hexane and CH_2Cl_2–MeOH (1:1) extracts for biodirected fractionation.

Isolation and Characterization of Compounds from S. adenophora Leaves Bioactivity-guided fractionation of the hexane and CH_2Cl_2–MeOH (1:1) extracts led to the isolation of six known pentacyclic triterpenes: 3-*epi*-β-amyrin (**1**), β-amyrinone (**2**), 3-*epi*-lupeol (**3**), lupenone (**4**), taraxerol (**5**), and taraxerone (**6**) (Fig. 2). This is the first report of these compounds in leaves of *S. adenophora*. Triterpenes **2** to **6** are reported for the first time in the genus *Sebastiania*. The spectral properties of oleanane, lupane, and taraxerane-type triterpenes, including IR, ^{1}H NMR, and ^{13}C NMR data, were identical to those previously reported in the literature (Carvalho and Seita, 1995; Yan et al., 1989; Tamai et al., 1989;

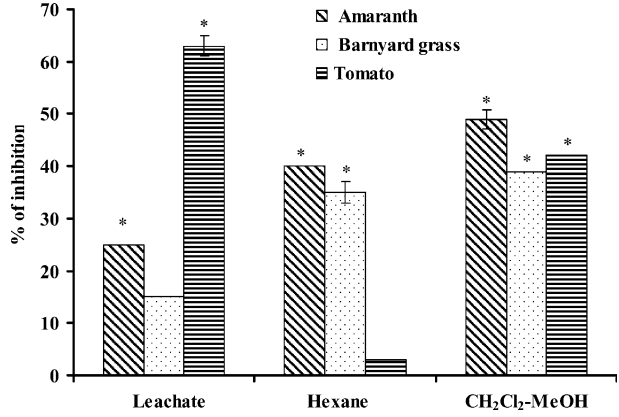

Fig. 1 Effect of aqueous leachate (1%), hexane, and CH_2Cl_2–MeOH extracts (100 μg/ml) of *Sebastiania adenophora* leaves on the root growth of amaranth, barnyard grass, and tomato. Vertical bars represent SD, $N=4$; $^*P<0.05$

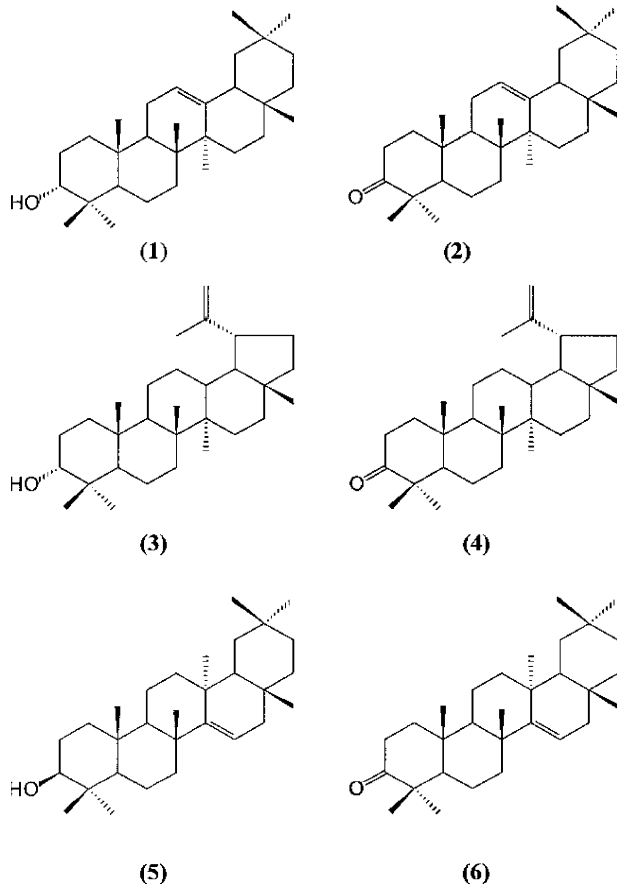

Fig. 2 Structures of pentacyclic triterpenes from *Sebastiania adenophora*: 3-*epi*-β-amyrin (**1**), β-amyrinone (**2**), 3-*epi*-lupeol (**3**), lupenone (**4**), taraxerol (**5**), and taraxerone (**6**)

Parveen et al., 1988; Sakurai et al., 1987; Ogihara et al., 1987; Waterman and Ampofo, 1985; Reyes et al., 1983; Carpenter et al., 1980; Kikuchi et al., 1977; Appleton and Enzell, 1971).

Langenheim (2003) mentioned that triterpenes dominate the nonvolatile composition of resins in some tropical families, particularly Burseraceae, Dipterocarpaceae, and Anacardiaceae. Resins of the Burseraceae typically have tetracyclic euphane/tirucallane, and pentacyclic lupane, ursane, and oleanane triterpene skeletal types. Resin is often listed as a component of latex in members of some families (e.g., Euphorbiaceae and Convolvulaceae). In the present study, we found that similar triterpenes were common in *S. adenophora* leaves, and they could be important components of its latex.

Bioactivity of Pentacyclic Triterpenes The bioactivity of triterpenes (250 μg/ml=5.9×10^{-4} M) was evaluated on root growth of amaranth, barnyard grass, and tomato (Fig. 3).

Six pentacyclic triterpenes stimulated amaranth root growth. The most effective compounds were 3-*epi*-β-amyrin (**1**) (55%), 3-*epi*-lupeol (**3**) (48%), and taraxerol (**5**) (39 %). These compounds contain a hydroxyl group at C-3. In contrast, pentacyclic triterpenes possessing oleanane and taraxerane-type skeleton showed phytotoxic effects on barnyard grass. Taraxerol (**5**) and taraxerone (**6**) were the most inhibitory on barnyard grass (77% and 42%, respectively). Root growth of tomato was inhibited by all triterpenes, particularly taraxerone (**6**) (50%) and taraxerol (**5**) (42%).

3-*epi*-β-amyrin (**1**), taraxerol (**5**), and the mixture of the six pentacyclic triterpenes (Fraction **E2**) were evaluated for their effect on root growth of amaranth, barnyard grass, and tomato at three different concentrations (125 μg/ml=2.9×10^{-4} M; 250 μg/ml=5.9×10^{-4} M; and 500 μg/ml=1.2×10^{-3} M). Figure 4 shows the effects of the different concentrations of these three treatments on the test plants. In general, 3-*epi*-β-amyrin (**1**), taraxerol (**5**), and the mixture of the six pentacyclic triterpenes (**1**–**6**) were stimulatory when tested on amaranth root growth. The effect increased with concentration. We estimate the 50% stimulatory concentration (SC_{50}) (required to stimulate 50% root growth) on amaranth for **1**, **5**, and **1**–**6** mixture (fraction **E2**) to be: 5.1×10^{-4} M, 7.6×10^{-4} M, and 372.4 μg/ml, respectively. The same three compounds inhibited root growth of barnyard grass and tomato in a concentration-dependent manner. Barnyard grass was inhibited most and taraxerol (**5**) produced the greatest inhibition on root growth of these two plants. The IC_{50} for barnyard grass was 4.38×10^{-4} M and for tomato, it was 6.23×10^{-4} M. IC_{50} values of

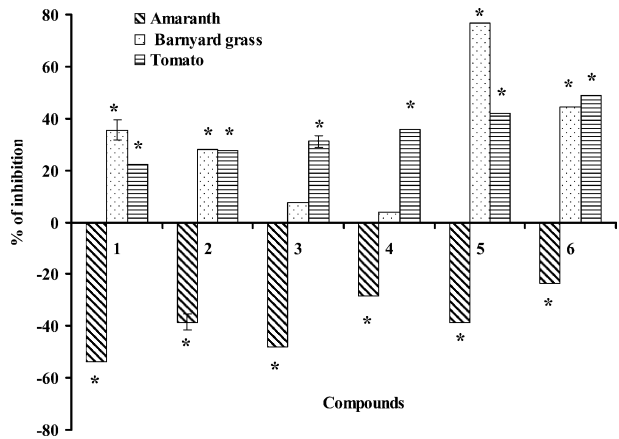

Fig. 3 Effect of the pentacyclic triterpenes (250 μg/ml or 5.9×10^{-4} M) isolated from *Sebastiania adenophora* leaves on the root growth of amaranth, barnyard grass, and tomato. A positive value represents inhibition; a negative value represents stimulation. Vertical bars represent SD, N=4; *P<0.05

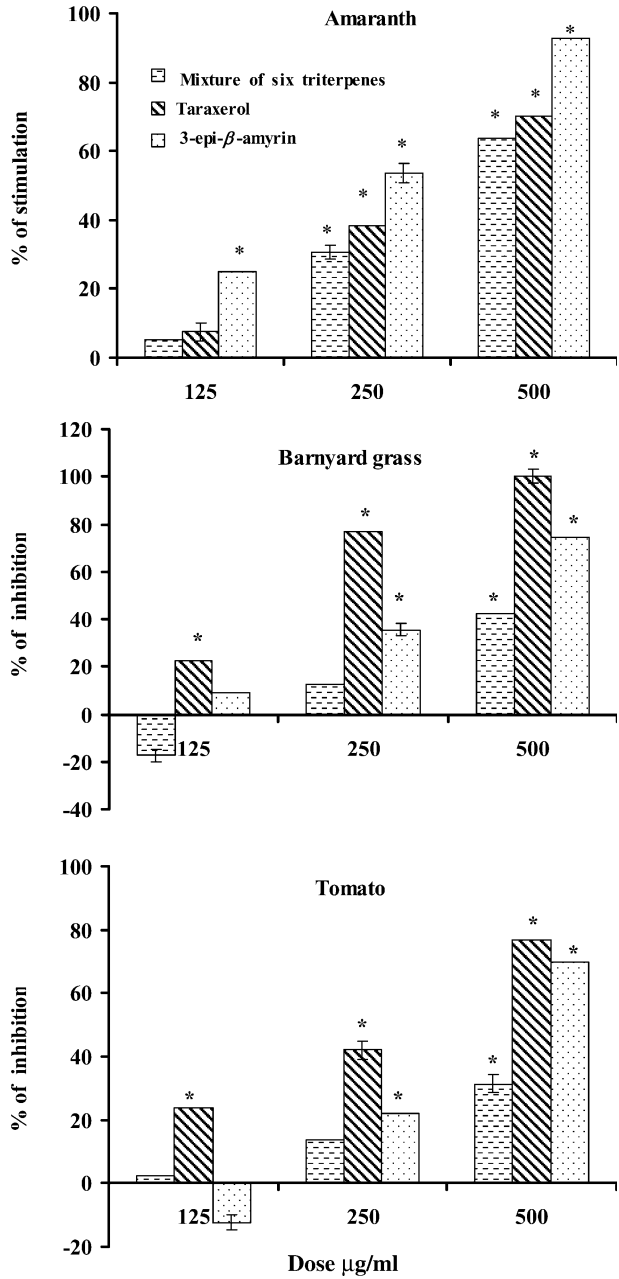

Fig. 4 Selective effects of 3-*epi*-β-amyrin (**1**), taraxerol (**5**), and the mixture of the six triterpenes at 3 different concentrations: [125 μg/ml (2.9×10^{-4} M); 250 μg/ml (5.9×10^{-4} M); 500 μg/ml (1.2×10^{-3} M)] on the root growth of amaranth (stimulatory effect); barnyard grass and tomato (inhibitory effects). Vertical bars represent SD, N=4; *P<0.05

the positive control 2,4-D were 1.88×10^{-4} M for barnyard grass and 2.3×10^{-4} M for tomato. The IC_{50} values for 3-*epi*-β-amyrin (**1**) were 7.30×10^{-4} M for barnyard grass and 8.72×10^{-4} M for tomato. The mixture of six triterpenes (fraction **E2**) had inhibited these two plants only at 500 μg/ml.

In previous studies, lupane and oleanane-type triterpenes exhibited clear selective bioactivity. These compounds could stimulate or inhibit germination or radical growth of

dicotyledonous and monocotyledonous species at concentrations ranging between 10^{-4} and 10^{-9} M. Root growth of the test plants responded differently, depending on the species and the substance tested. In general, triterpenes either stimulated germination of *Allium cepa* or inhibited root growth of this plant. In *Hordeum vulgare*, triterpenes inhibited germination of this monocotyledonous plant and stimulated its root growth (Macías et al., 1994, 1997, 1998a).

Macias et al. (1998b) found that some bioactive norsesquiterpenes isolated from *Helianthus annuus* exhibited clear selectivity on monocotyledon species with an average of inhibition of 45% on the germination of *A. cepa* and an average of stimulation of 50% on the root growth of *A. cepa* and *H. vulgare* in a range of concentrations of 10^{-5}–10^{-9} M.

The mechanism of allelopathic action of triterpenes is unknown. Duke and Oliva (2004) mentioned that the phytotoxic triterpenes holacanthone, chaparrinone, and glaucarubolone (quassinoids) inhibited some stages of mitosis. The former and the latter one also reduced chlorophyll accumulation. In addition, some saponins have effects on membrane properties because of their detergent-like activity.

Different plant species produce sesquiterpenoids and triterpenoids as defense compounds against pathogens (phytoalexins) and/or herbivores. Puglisi et al. (2004) found that aqueous and EtOAc extracts of the green alga *Penicillus capitatus* showed a strong inhibitory effect on the marine fungal pathogen *Lindra thallasiae*. Using *L. thallasiae* in bioassay-guided fractionation, they isolated two new cycloartane triterpene sulfate esters, capisterones A and B. Furthermore, Dutton et al. (2002) investigated the changes in apple leaf chemistry after infestation by leafminers and their effect on both host and habitat location of the generalist parasitoid *Pholetesor bicolor*. Chemical analysis of leaf solvent extracts from healthy and leafminer-damaged leaves revealed that herbivory increased the amount of the triterpene squalene ($C_{30}H_{50}$) that is an intermediate in the biosynthesis of sterols and triterpenes. Parasitoids performed a characteristic ovipositional probing more often on mine-damaged than on the healthy leaves.

Zinov'eva et al. (2001) mentioned the involvement of triterpenes in plant adaptation to stress induced by parasitic nematodes and pointed out that most studies were devoted to the biological activity of azadirachtin isolated from the neem tree (*Azadirachta indica* L., Meliaceae). This compound possesses insecticidal and antifeedant properties and inhibits the growth and molting of insects. Root exudates and lipid-containing extracts from neem seeds also suppress hatching and have nematocidal activity for some nematode larvae. Water extracts of leaves inhibit gall formation and fecundity of the nematode *Meloidogyne javanica* in tomato plants, but stimulate growth and productivity of these plants. The nortriterpenoid glycinoeclepin A derived from roots of common beans (*Phaseolus vulgaris* L., Fabaceae) and applied at a concentration of 6–10 mg/ml *in vitro* stimulates hatching of *Heterodera glycines* (Ichinohe) larvae.

Members of the cycloartane, lupane, ursane, oleanane, friedelane (especially quinone methides), dammarane, cucurbitacin, and limonoid triterpenoids, have anti-proliferative activity on various cancer cell lines (Setzer and Setzer, 2003).

In the present study, we described triterpenes **1–6** in *S. adenophora* leaves (**2–6** for the first time in *Sebastiania* genus) and confirm their selective bioactivity on the root growth of plants. Otherwise, the bioactivity of the mixture of allelochemicals in organic extracts and aqueous leachate of the leaves were phytotoxic, possibly due to a synergetic effect of the compounds present. Further study on the modes of action of these triterpenes will contribute to understanding the selective bioactivity on plants and on the physiological processes that result in inhibition or stimulation responses of plants.

Based on our results, we hypothesize that triterpenes and other allelochemicals that may be in the mixtures could play a multifunctional role in *S. adenophora*. These compounds act as alellopathics or as chemical defenses against herbivores, and may contribute to adaptation to the hostile environment of the dry tropical forest where this plant lives.

Abstract The bird cherry-oat aphid, *Rhopalosiphum padi* (L.), and the damson-hop aphid, *Phorodon humuli* (Schrank), migrate at the same time of year and colonize closely related *Prunus* spp. as primary hosts, but utilize (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol and (1*RS*,4a*R*,7*S*,7a*S*)-nepetalactol, respectively, as sex pheromones. Interactions between these sex pheromones and benzaldehyde and methyl salicylate, plant volatiles common to primary hosts of both species, were investigated to assess whether they confer reproductive isolation between these species. Female autumn migrants (gynoparae) and males of these two species were caught in the field with water traps baited with their respective sex pheromones. *Rhopalosiphum padi* gynoparae and males also responded positively to benzaldehyde. Release of either benzaldehyde or methyl salicylate with the conspecific sex pheromone increased catches of both species of aphid. However, releasing both plant volatiles with the sex pheromone of *R. padi* increased catches of gynoparae and males, but reduced those with the sex pheromone of *P. humuli*. These results support the hypothesis that specific plant volatiles synergize responses of autumn migrating aphids to their sex pheromone. Because these interactions are species-specific, they may be important in allowing males to discriminate between conspecific sexual females (oviparae) and those of other aphid species.

Introduction

The interaction between host-plant volatiles and sex pheromones of phytophagous insects, including aphids, is well established (Landolt and Phillips, 1997; Powell and Hardie, 2001). In many insect species, the response of males to a female-produced sex pheromone is directly influenced by host-plant volatiles. Host-plant volatiles may synergize the response to the sex pheromone, as has been shown for several species of Lepidoptera and Coleoptera with the simple addition of one or more green leaf volatiles (Light et al., 1993; Ruther et al., 2000, 2002; Reinecke et al., 2002a,b). Examples also exist where host-plant volatiles other than green leaf volatiles, or intact host plants, act synergistically with pheromones (Landolt and Phillips, 1997).

In contrast to the Lepidoptera and Coleoptera, for which many hundreds of species-specific sex pheromone components have been identified, of the 12 species of aphids for which sex pheromones are known, only three sex pheromone components have been identified (Hardie et al., 1999). There is also conflicting evidence as to whether male aphids can discriminate between the sex pheromone produced by conspecific sexually reproducing egg-laying females (oviparae) and those produced by oviparae of other species (Marsh, 1975; Eisenbach and Mittler, 1987; Steffan, 1990; Hardie et al., 1990, 1992).

The limited range of aphid sex pheromone components, and inconclusive evidence that aphids can discriminate between them, led Steffan (1987) and Guldemond (1990) to argue that the primary host plant may be important in promoting reproductive isolation. Subsequently, Powell and Hardie (2001) suggested that a more important role of host-plant volatiles may be to synergize the response of male aphids to sex pheromones. Gynoparae (female parthenogens that uniquely produce the sexually reproducing oviparae) of several species of aphid are known to respond to odors from primary host plants (Powell and Hardie, 2001) as do those and males also of the bird cherry-oat aphid, *Rhopalosiphum padi* (L.) and the damson-hop aphid, *Phorodon humuli* (Schrank). In olfactometer studies, gynoparae and males of *R. padi* responded positively to crushed buds of bird cherry, *Prunus padus* L., the primary host of this species (Pettersson, 1970). Subsequently, benzaldehyde was identified as an active component in the odor of bird cherry, eliciting positive behavioral responses on its own (Pettersson, 1970; Park et al., 2000). In contrast, in the field neither a steam distilled extract of bird cherry or benzaldehyde increased numbers of male *R. padi* caught in water traps (Hardie et al., 1994). However, when the steam distilled extract or benzaldehyde were released simultaneously with (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**I**), the sex pheromone of this species, significantly more males were trapped than with the pheromone alone, indicating a significant interaction. *Phorodon humuli* males responded positively to leaf and twig material from myrobalan, *Prunus cerasifera* Ehrhart, one of its primary hosts, as well as a bark extract from the same host in an olfactometer and in the field (Campbell et al., 1990). In a second study, steam distilled extracts of two other primary hosts, sloe (*Prunus spinosa* L.) and plum (*P. domestica* L.), also increased catches of gynoparae, but not males, in clear water traps (Lösel et al., 1996b). In addition, release of extracts from these hosts increased catches of gynoparae and males to the sex pheromone produced by conspecific oviparae, (1*RS*,4a*R*,7*S*,7a*S*)-nepetalactol (**III**) (Campbell et al., 1990; Lösel et al., 1996a,b).

These results suggest that primary host-plant volatiles elicit positive responses, both on their own and through synergistic interactions with sex pheromones, in autumn migrants of *R. padi* and *P. humuli*. However, gynoparae and males of *R. padi* and *P. humuli* migrate to closely related species of *Prunus*, which may provide similar olfactory cues. In addition, because the migrations occur at similar times of the year, there is no temporal separation. Thus, these two species of aphid respond to different sex pheromones but are presented with similar olfactory cues from their respective host plants. The responses of gynoparae and males of these species to their respective sex pheromones presented together with plant volatiles common to their primary hosts may provide insight into how aphids are able to make species-specific responses with such a limited range of sex pheromone components.

The present study investigated responses of gynoparae and males of *R. padi* and *P. humuli* to combinations of **I**, **III**, benzaldehyde, and methyl salicylate. The headspace profiles of *Prunus padus*, the primary host of *R. padi*, and *P. spinosa*, *P. domestica*, and *P. cerasifera*, primary hosts of *P. humuli*, are rich in volatile compounds including benzaldehyde and methyl salicylate (Pettersson, 1970; Pettersson et al., 1994; Pope, unpublished data). Benzaldehyde alone, as outlined above, is known to elicit positive responses in *R. padi* autumn migrants and to synergize responses to **I**. Methyl salicylate has been shown to evoke negative behavioral responses in spring migrants of both *R. padi* and *P. humuli*, which suggests some role for these specific compounds in primary host plant recognition (Campbell et al., 1993; Pettersson et al., 1994; Lösel et al., 1996a; Ninkovic et al., 2003).

Methods and Materials

Chemicals (4a*S*,7*S*,7a*R*)-Nepetalactol (**I**) was prepared from an extract of the catmint *Nepeta cataria* (L.) (see Dawson et al., 1987). A 7:3 mixture of the 1*S*- and 1*R*-diastereoisomers of (4a*R*,7*S*,7a*S*)-nepetalactol (**III**) was prepared from *N. racemosa* (syn. *mussinii*) (see Campbell et al., 1990, 2003). Benzaldehyde (**B**) and methyl salicylate (**MS**) were purchased from Sigma-Aldrich (Poole, UK) (purity 99% and 98%, respectively).

Field Experiments Randomized block factorial experiments were conducted in plantations of dwarf hops growing on 2.4-m-high trellises at East Malling Research (EMR) in 1996, 2000, and 2001. The experimental design consisted of two, four, and two blocks in 1996, 2000, and 2001, respectively. Water traps were made from transparent plastic Petri dishes (14 cm diam×2 cm deep) as described by Hardie et al. (1997). Traps were filled with a dilute solution of Lipsol, a nonionic detergent. Pheromones (10 mg) in 50 µl Et_2O and **B** (50 mg) were placed into individual glass vials (08-CPV Chromacol), with a 1-mm hole drilled through the cap. The antioxidant butylatedhydroxytoluene (BHT, 5 mg), was added to vials containing 50 mg of **B**. **MS** (41 mg) was placed into closed polyethylene vials (WP/5, Fisons) with four 1-mm holes drilled through the cap. Control vials were added as necessary so that all traps presented an identical visual image. Vials were suspended 1 cm above the surface of the water. The traps were spaced 3 m apart and 60 cm above the ground and sited centrally in the 3-m-wide alleys between the rows of hops. Traps were emptied and their positions rerandomized daily. Trapped *P. humuli* and *R. padi* gynoparae and males were counted in the laboratory.

The release rates of **B** and **MS** were determined by suspending vials within a fume cupboard with an air flow of 0.6 m sec^{-1} at 18±2°C. Weight changes in vials were recorded over a 7-d period and the release rates were calculated (mean±SE) as 1.03±0.02 mg day^{-1} for **B**, and 0.81±0.16 mg day^{-1} for **MS**.

The experiments were conducted from October 8 to 25, 1996, from October 14 to 30, 2000, and from September 22 to October 26, 2001. A complete factorial design was used in 1996 with each chemical at two levels (present and absent). The treatments were (1) **III**, (2) **B**, (3) **MS**, (4) **III**+**B**, (5) **III**+**MS**, (6) **B**+**MS**, (7) **III**+**B**+**MS**, and (8) control. Incomplete factorial designs were used in 2000 and 2001; all treatments that combined both sex pheromones were omitted. Therefore, the treatments in both years were (1) **I**, (2) **III**, (3) **B**, (4) **MS**, (5) **I**+**B**, (6) **I**+**MS**, (7) **III**+**B**, (8) **III**+**MS**, (9) **B**+**MS**, (10) **I**+**B**+**MS**, (11) **III**+**B**+**MS**, and (12) control.

Data Analysis Data were analyzed by analysis of variance (ANOVA). To stabilize variances, daily counts were transformed to square roots ($n^{0.5}$) and summed for the whole sampling period. A two-way classification of treatments within blocks was used for first-step analyses, with differences between means compared against the least significant difference (LSD) only if the overall treatment terms were significant. The data were then reanalyzed with the variance partitioned into factorial contrasts. Separate terms for block-to-block variance, main effects of each chemical individually, two- and three-chemical interactions, and residual variance for the incomplete factorial designs in 2000 and 2001 were accumulated into analysis of variance from regressions using GenStat 5 (Payne, 2000).

Results

A total of 2120 *P. humuli* gynoparae and 9764 males were caught in the 1996 experiment (Table 1). *P. humuli* gynoparae and males were more numerous in traps baited with **III** than in traps without pheromone. Furthermore, traps baited with **III** together with either **B** or **MS** caught significantly more gynoparae and males (1.9–2.1 and 2.5–2.7 times as many respectively) than did traps baited with **III** alone. The factorial ANOVA of these data showed that *P. humuli* gynoparae and males responded significantly to **III** (gynoparae, $F_{1,7}$= 71.57, P<0.001; males, $F_{1,7}$=162.93, P<0.001). The three-way interactions between **III**, **B**, and **MS** were also significant for both morphs (gynoparae, $F_{1,7}$=5.73, P<0.05; males, $F_{1,7}$=11.27, P<0.05). Both morphs responded positively to the plant volatiles, but only in the presence of **III** (**III**+**B** vs. **III**, gynoparae, t=2.95, P<0.05, males, t=3.69, P<0.01; **III**+**MS** vs. **III**, gynoparae, t= 3.11, P<0.05, males, t=3.98, P<0.01), but the response was negated when both plant volatiles were presented with **III** (**III**+**B**+**MS** vs. **III** gynoparae, t=1.33, males, t=0.82).

Table 1 Total numbers of *Phorodon humuli* gynoparae and males caught in water traps releasing benzaldehyde, methyl salicylate, and (1*RS*,4a*R*,7*S*,7a*S*)-nepetalactol (**III**) in 1996

Treatment	*P. humuli*	
	Gynoparae	Males
Control	110d	201c

Benzaldehyde (**B**)	122cd	160c
Methyl salicylate (**MS**)	96d	177c
III+**B**	488a	3039a
III+**MS**	534a	3278a
B+**MS**	127cd	154c
III+**B**+**MS**	391ab	1542b

Numbers in a column followed by the same letter are not significantly different at P<0.05 based on two-way ANOVA of $n^{0.5}$ transformed counts.

Few gynoparae of *R. padi* and *P. humuli* were caught in the year 2000 experiment (29 and 1, respectively), which was conducted after the peak migration period for that morph. Totals of 441 *R. padi* and 368 *P. humuli* males were caught (Table 2). Males of *R. padi* responded significantly to their own pheromone (**I**) irrespective of the presence of the two plant volatiles, and more males responded to **I** released with **B**±**MS** (1.6–2.3 times as many) than to **I** alone. In contrast, catches of males in traps releasing **III** were no different from controls. The factorial ANOVA confirmed that *R. padi* males responded to **I** compared with either no pheromone (t=7.48, P<0.001) or **III** (t=6.24, P<0.001), as did gynoparae (**I** vs. control, t=2.16, P<0.05; **I** vs. **III**, t=2.27, P<0.05; **III** vs. control, t=0.11; data not shown). *Rhopalosiphum padi* males also responded to **B** (F=9.45, P<0.05) but not to **MS**. Although the two- and three-way interactions between pheromones, **B**, and **MS** were not significant at the 5% probability level, the two-way interaction between pheromones and **B** were close for both morphs (males, F=2.90, P=0.069; gynoparae F=2.63, P=0.087). Although these results must be treated with caution owing to the borderline significance of the F ratios, almost twice as many males responded to **B** when released with **I** compared with **I** alone (t=3.32, P<0.01) and a similar proportion to **B** alone compared with control (t=2.04, P<0.05). Gynoparae also responded to **B** when released together with **I**, as compared with **I** alone (t=2.58, P<0.05), but not otherwise.

The results for *P. humuli* males in 2000 were similar to those in 1996. They responded to **III**±**B** and **III**±**MS**, but the release of both plant volatiles with **III** halved the response. Males did not respond to **I**. The factorial ANOVA of these data confirmed that male *P. humuli* responded to **III** (**III** vs. control, t=7.25, P<0.001; **III** vs. **I**, t=7.22, P<0.001). Although the three-way interaction was not significant, an examination of the means showed that release of plant volatiles together with **III** reduced responses of males (**III** vs. **III**+**B**+**MS**, t=3.09, P<0.01).

Totals of 629 *R. padi* gynoparae and 606 males together with 104 *P. humuli* gynoparae and 597 males were caught in the 2001 experiment (Table 3). Owing to a shortage of pheromone, only two blocks of the experiment were deployed, and the distribution of *P. humuli* was skewed positionally with 94% of males and 80% of gynoparae trapped in one experimental block. This positional disparity increased the error variance and contributed to large differences in numbers trapped between treatments being not statistically significant. No such disparity in distribution was observed with *R. padi*. In comparison with **I** alone, 1.6–4.7 times as many gynoparae and 20–45 times as many males responded to **I** released with plant volatiles. The factorial ANOVA of these data confirmed that *R. padi* gynoparae

Table 2 Total numbers of *Phorodon humuli* and *Rhopalosiphum padi* males caught in water traps releasing benzaldehyde, methyl salicylate, and (4a*S*,7*S*,7a*R*)-nepetalactol (**I**)) or (1*RS*,4a*R*,7-*S*,7a*S*)-nepetalactol (**III**) in 2000

Numbers in a column followed by the same letter are not significantly different at $P<0.05$ based on two-way ANOVA of $n^{0.5}$ transformed counts.

responded significantly to **I** compared either with no pheromone ($t=4.29$, $P<0.01$) or with **III** ($t=3.72$, $P<0.01$). *Rhopalosiphum padi* gynoparae responded to **B** as in previous trials ($F=10.54$, $P<0.01$), but not to **MS**. The factorial ANOVA showed that males of *R. padi* also responded to **I** compared either with no pheromone ($t=6.72$, $P<0.001$) or with **III** ($t=6.97$, $P<0.001$), but did not respond to **III**. In contrast to the 2000 experiments, *R. padi* males also responded to **MS** in 2001 ($F=9.17$, $P<0.05$), but not to **B**. The significant two-way interaction between pheromones and **MS** ($F=10.49$, $P<0.01$) showed that males responded to **MS** only when it was released with **I** (**I**+**MS** vs. **I**, $t=5.49$, $P<0.001$; **I**+**MS** vs. **MS**, $t=7.42$, $P<0.001$). The three-way interaction between pheromones and plant volatiles was not significant.

Gynoparae of *P. humuli* responded only to **III** in 2001 (Table 3). The factorial ANOVA of these data confirmed that gynoparae responded to **III** irrespective of the plant volatiles (**III** vs. no pheromone, $t=2.58$, $P<0.05$; **III** vs. **I**, $t=2.50$, $P<0.05$). Trap catches were unaffected by the presence of **I**. The two- and three-way interactions between pheromones, **B**, and **M** were not significant. Although the response of males to **III**+**B** was the only treatment combination greater than the control by two-way ANOVA, the factorial analysis showed that significantly more males were trapped in response to **III** than either to no pheromone ($t=2.81$, $P<0.05$) or to **I** ($t=2.67$, $P<0.05$). Gynoparae did not respond to either **B** or **MS**.

Discussion

Autumn migrants of both *R. padi* and *P. humuli* responded to the plant volatiles when the latter were released individually with their conspecific sex pheromone. The strength of these interactions differed between aphid species, with benzaldehyde inducing a stronger effect on *R. padi* than *P. humuli*. *Rhopalosiphum padi* males and gynoparae responded

significantly to the release of benzaldehyde in 2000 and 2001, and catches of both morphs were enhanced by the release of benzaldehyde with **I**. These results confirm those of Hardie et al. (1994), where extracts from bird cherry synergistically increased the number of males caught in the field in response to **I**, as did the release of benzaldehyde with **I**.

In contrast, *P. humuli* autumn migrants responded to benzaldehyde only when it was released with **III**, and then only in one of three years. Interestingly, in 1996, when responses to benzaldehyde were recorded, far more *P. humuli* were trapped in the 12.2 m Rothamsted Insect Survey suction trap at Wye (approximately 48 km from EMR) than in the two subsequent years of this study. The suction trap results showed that catches of *P. humuli* in 1996 were approximately 30 times greater than in 2000 or 2001.

Methyl salicylate elicited responses from *R. padi* and *P. humuli* only when released with the conspecific sex pheromone. In addition, responses were inconsistent, with methyl salicylate significantly increasing catches of *R. padi* males in 2001, and *P. humuli* gynoparae and males in 1996. Despite this, the responses of autumn migrants to methyl salicylate in the present study contrasts with the lack of response of spring migrants recorded previously (Campbell et al., 1993; Pettersson et al., 1994; Lösel et al., 1996a; Ninkovic et al., 2003). Therefore, our results offer moderate support for the suggested role of methyl salicylate as a cue allowing *R. padi* migrants to discriminate between primary and secondary hosts.

In contrast to the positive responses of the two aphid species to individual plant volatiles, responses of *P. humuli* males were reduced by the release of both plant volatiles with the conspecific sex pheromone. The same pattern was also evident for males in 2001. In addition, this response appeared to be species-specific because similar numbers of *R. padi* responded to the three-way combination and each two-way combination.

It is interesting to note that in spring, production of methyl salicylate by hop plants was increased from plants infested with *P. humuli* spring migrants (Campbell et al., 1993). Methyl salicylate acted as an antiaggregant, negating previously identified positive behavioral responses to (*E*)-2-hexenal and (−)-β-caryophyllene. Similarly, primary hosts of *P. humuli* also produced more methyl salicylate when infested with gynoparae (Wadhams, unpublished data.). Therefore, methyl salicylate may have a similar antiaggregation role in the response of *P. humuli* autumn migrants to **III** as does, for example, verbenone as an antiaggregant for the spruce bark beetle, *Ips typographus* (L.) (Zhang, 2003; Zhang and Schlyter, 2003).

The effect on catches of *P. humuli* males of releasing the plant volatiles with **III** depended upon whether benzaldehyde and methyl salicylate were released individually or together. Both of these plant volatiles are produced by primary hosts of *P. humuli*, and extracts of these hosts enhanced catches of gynoparae and males to **III** (Campbell et al., 1990; Lösel et al., 1996a,b). Therefore, the importance of other factors such as the ratio of compounds must be considered. Indeed, there is some evidence to suggest that aphids are able to discriminate between different ratios of **I** and (4a*S*,7*S*,7a*R*)-nepetalactone (Marsh, 1975; Eisenbach and Mittler, 1987; Steffan, 1990; Hardie et al., 1990, 1992). Aphids also discriminate between ratios of their common alarm pheromone, (*E*)-β-farnesene (EBF), and specific plant volatiles (Dawson et al., 1984). Dawson et al. (1984) noted that although hop plants also produce EBF, they are readily colonized by aphids, and that it was the corelease of (−)-β-caryophyllene by hop plants that allowed several aphid species, including *P. humuli*, to discriminate the source of EBF.

Rhopalosiphum padi and *P. humuli* are, to date, the only aphid species for which host-plant volatiles have been found to increase responses to sex pheromones (Campbell et

al., 1990; Hardie et al., 1994; Lösel et al., 1996a,b). The host-plant extracts used in those studies would have contained many of the same volatiles, given that the hosts are closely related species of *Prunus*, and likely included both methyl salicylate and benzaldehyde. The results presented here indicate that both benzaldehyde and methyl salicylate can affect the responses of *R. padi* and *P. humuli* autumn migrants to their respective sex pheromones, but show also that these responses are species-specific. Our results also provide some support for assertions that host plant volatiles and their interactions with aphid sex pheromones may be important in promoting reproductive isolation (Steffan, 1987; Guldemond, 1990; Powell and Hardie, 2001).

Abstract We investigated the influence of juvenile hormones (JH) on the composition of cuticular hydrocarbons (CHCs) and the division of labor in colonies of the African ant *Myrmicaria eumenoides*. CHCs have long been implicated in nestmate recognition in social insect colonies. In *M. eumenoides*, the CHC profiles also vary with the task performed from brood-tender-type to forager type. The endocrine factors regulating the task allocation as well as the intracolonial recognition cues are not well understood, but JHs are prime candidates. Only JH III was identified in the hemolymph of *M. eumenoides* workers. Foragers had significantly higher JH III titers than brood tenders. The application of exogenous JH III and a JH analogue (methoprene) to *M. eumenoides* workers did not result in an observable acceleration of task change in our study. However, longevity of the focus workers, and thus the observational period, was reduced by the applications. Changes from a brood-tender-type to a forager-type CHC profile were accelerated by the application of JH III and methoprene, resulting in brood-tending workers that displayed forager-type CHC profiles. We present the first data supporting that recognition cues of an eusocial Hymenopteran are influenced by JH III, which could thus play a major role in the regulation of the dynamic nature of social insect colonies. JH III is connected to at least two key processes: the acceleration of CHC changes and the more long-term modulation of task shifting. Moreover, this indicates that changes in CHC recognition cues do not trigger task allocation in social insect colonies.

Introduction

Ants (Formicidae) are ecologically among the most dominant organisms in the world (Hölldobler and Wilson, 1990). They are also highly social animals, and an important feature of social organization are the caste systems (Hölldobler and Wilson, 1990). Two basic castes are found in ants: reproductive females and males (fertile caste), and nonreproductive female workers (sterile caste; Wilson, 1971).

In some ant species, the sterile caste can be further subdivided into morphologically disparate subcastes, e.g., in *Pheidole dentata* (Johnston and Wilson, 1985) and *Atta cephalotes* (Wilson, 1983). Each subcaste is responsible for one or more particular tasks, resulting in polyethism (division of labor). However, caste polyethism is far less prevalent in ants than temporal polyethism (Hölldobler and Wilson, 1990), where the adult workers change tasks as they grow older. Usually, tasks inside the nest (e.g., brood tending) are executed early in life, whereas out-of-nest tasks (e.g., foraging) are performed later in life (Wilson, 1971). In the ant species *Pogonomyrmex barbatus*, workers can distinguish between nestmates engaged in tasks inside and outside the nest (Greene and Gordon, 2003). The nestmate recognition cues have been suggested to come from the cuticle (reviewed by Bradshaw and Howse, 1984).

The insect cuticle is covered by a thin lipid layer consisting to a large extent of hydrocarbons, and a fundamental function of this is to prevent water loss (Hadley and Schultz, 1987; Hadley, 1994; Blomquist et al., 1998). However, an additional major function of these cuticular hydrocarbons (CHCs) is to serve as recognition cues (reviewed by Howard and Blomquist, 2005). CHCs are involved in nestmate and species recognition in social insects (Jutsum et al., 1979; Nowbahari et al., 1990; Dahbi and Lenoir, 1998; Lahav et al., 1999; Wagner et al., 2000; Kaib et al., 2004). Direct experimental evidence supports the involvement of CHCs in nestmate recognition (Lahav et al., 1999; Thomas et al., 1999; Wagner et al., 2000). Furthermore, other studies have demonstrated that CHC profiles of workers within a colony are not uniform and may vary temporally (Nielsen et al., 1999; Cuvillier-Hot et al., 2001), with diet (Liang and Silverman, 2000), and with task (Kaib et al., 2000; Greene and Gordon, 2003), thus linking temporal polyethism and CHC recognition cues.

Both the development of fertile and sterile castes and the temporal division of labor in social insects are thought to be regulated by endocrine factors. Juvenile hormones (JH) play an important role in the reproductive division of labor in Hymenoptera (*Bombus terrestris*, Bloch et al., 2000; Bortolotti et al., 2001; *Apis mellifera*: e.g., Rembold et al., 1992), and Isoptera (*Zootermopsis angusticollis*, Brent et al., 2005).

In the Hymenoptera, JH also appears to be involved in temporal polyethism, e.g., in *Apis mellifera* (e.g., Robinson, 1985; Huang and Robinson, 1995), *A. cerana* (Huang et al., 2001), and *Polistes canandensis* (Giray et al., 2005). Numerous studies document the correlation between hemolymph JH titers and task performance in *A. mellifera*: the JH titer is low in brood tenders and high in foragers (e.g., Fluri et al., 1982; Huang et al., 1994; Huang and Robinson, 1995). Additionally, JH has been implicated in the production of foragers in *A. mellifera* (Bloch et al., 2002) and polybiine wasps (O'Donnell and Jeanne, 1998). In contrast, Cameron and Robinson (1990) could not find such a correlation in bumblebees, a species that does not exhibit a strong age polymorphism.

Because there is a correlation between task and CHC profiles, this suggests that JH also may be implicated in the composition of CHCs. It already has been shown that one or more steps of pheromone biosynthesis in blattodean and coleopteran species is influenced by JH (reviewed by Tillman et al., 1999). Thus, the aim of this investigation was to determine if JH plays a role in the temporal division of labor in *Myrmicaria eumenoides* colonies. This

was carried out in a two-pronged approach. First, the JH hemolymph titers of workers in particular task categories were measured, and second, the CHC profile changes with task in nontreated and hormone-treated workers were recorded, along with their behavioral development. The amalgamation of these results sheds some light on how the compositions of CHCs and task allocation in *M. eumenoides* colonies are governed.

Methods and Materials

Focus Colony, Marking, and Behavioral Observations

The *M. eumenoides* (Formicidae; Myrmicinae) focus colony was collected in the Kwale District of Kenya in June 1995. In the laboratory, the colony was maintained under constant conditions (25°C, 70% RH, 12:12 L/D) as described by Kaib et al. (2000). Relative humidity and temperature were similar inside and outside the "nest". Dots of various colors of acetone-based nail varnish in quantities of 0.3–0.6 μl were applied to the thorax of newly eclosed workers (callows) to individually mark them. These were then observed for 5 min every 24 to 48 hr (focal sampling) during their lifetime. All observations took place during the light phase between 0900 and 1900 hr, with location, behavior, and task being noted. Three task categories (brood tenders, "reserves", and foragers) and a developmental category (callows) were defined and observed.

Chemical Analysis

The noninvasive solid-phase microextraction (SPME) (Arthur and Pawliszyn, 1990) was used to extract CHCs from live *M. eumenoides* workers. A fiber with a 7 μm nonpolar polydimethylolsiloxane (PDMS) coating (Supelco; Sigma-Aldrich Chemie, Munich, Germany), which has been used successfully in other CHC profile studies on ants (Monnin et al., 1998; Cuvillier-Hot et al., 2001; Liebig et al., 2000; Dietemann et al., 2003), was used. CHC profiles were obtained by rubbing the fiber on the fourth tergite of the gaster for 5 min.

Samples were analyzed with a Hewlett-Packard 5890 Series II gas chromatograph (GC) equipped with a DB1 capillary column and flame ionization detector (FID) as described by Kaib et al. (2000) with a temperature program of 130°C 1 min, then rising to 180°C at 8°C/min, and finally to 300°C at 2°C/min. To ensure correct peak allocation a standardized *n*-alkane mixture (ThetaKit®, AccuStandard, CT, USA) was sampled at regular intervals.

Peaks were quantified by using the HP ChemStation® software. Fifty-one CHC components integrated and quantified across all individuals were chosen for statistical analysis. Coeluting components were treated as one component. The structural identification of *M. eumenoides* CHCs was previously carried out by Kaib et al. (2000) by using gas chromatography-mass spectrometry (GC-MS) and dimethyl disulfide (DMDS) derivatization.

CHC profiles of 14 untreated workers were sampled continuously across the three task categories in order to observe the general pattern of CHC profile changes in the colony.

JH Titer Determination

Pooled hemolymph samples from the task categories brood tender, "reserve", and forager (15–25 workers per sample; not the SPME-sampled workers) were used for the identification and quantification of JH. Hemolymph was collected with calibrated glass capillaries (Lamag, VWR, Germany), content to the nearest 0.1 μl was visually estimated

and the capillary was emptied into a conical vial containing 100 μl MeOH (HPLC-grade; Sigma-Aldrich Chemie, Schnelldorf, Germany) isooctane (HPLC-grade; Fluka, Taufkirchen, Germany) (1:1, v/v). The solvent/hemolyph ratio was at least 10:1 in all samples. Hemolymph sample preparation was carried out according to the method of Westerlund and Hoffmann (2004). The sample was centrifuged (2 times at 9,500*g*, for 15 min) in order to precipitate hemolymph proteins. The extracts were then concentrated and analyzed using liquid chromatography-mass spectrometry (LC-MS) on a Shimadzu mass spectrometer (LCMS-2010A) coupled to an Eldex MicroPro HPLC (Westerlund and Hoffmann, 2004). Separation was carried out with a C_{18} reverse-phase column (150× 2.0 mm, ReproSil-Pur ODS-3, 5 μm; Dr. Maisch GmbH, Ammerbuch, Germany) H_2O/MeOH at a flow rate of 200 μl/min. Total run time was 15 min; 0–5 min isocratic at 30% MeOH, 5–10 min from 30% to 100% MeOH, 10–12 min from 100% back to 30% MeOH. The column temperature was kept constant at 37°C. The mass spectrometer was operated in electrospray (ESI) positive ion mode with a gas flow (N_2) of 3.76 L/min, a curved desolvation line (CDL) temperature of 250°C, and a heat block temperature of 200°C. The system was operated in Q-array scan mode. Peaks were integrated by using the "LC-MS Solution by Shimadzu" program, and quantified by using an external calibration curve based on known amounts of JH III across several orders of magnitude. The limit of detection was determined to be 6 pg.

Juvenile hormone detection and identification was carried out by matching of retention times with those of authentic standards, as well as the monitoring of the following diagnostic ions: *m/z* 289, 267 (JH III [M + Na^+]+ and [M + H]+ adducts), *m/z* 303, 281 (JH II [M + Na^+]+ adducts), and *m/z* 317, 295 (JH I [M + H]+ adducts). Only JH III was identified in our samples.

JH III and Methoprene Application

For topical applications, the JH analogue methoprene [isopropyl (2*E*,4*E*)-11-methoxy-3,7,11-trimethyl-2,4-dodecadienoate] and racemic JH III [methyl-(2*E*,6*E*)-10,11-epoxy-3,7,11-trimethyl-2,6-dodecadienoate; Fluka, Steinheim, Germany] were dissolved in acetone (HPLC grade; Sigma-Aldrich, Taufkirchen, Germany). The applied dose of JH III was 50 pmol (0.13 pg), whereas that of methoprene was 1.77 nmol (0.55 μg). A CHC profile (to serve as reference profile) was taken from each focus worker prior to the first application. One μl of acetone (control), JH III, or methoprene solution was then applied twice a week to the head of the focus workers. These were kept individually in ventilated Petri dishes for 30 min after application of the solutions to ensure all the acetone had evaporated. The age of the workers at the first application was standardized to 4±1 d.

Data Analyses

Data were analyzed using the Statistica 5 (1997) package. Where the properties of the data sets allowed (Lilliefors Normality Test, and Levene's Homogeneity of Variances Test passed) Analyses of variance (ANOVAs) were carried out. Where necessary, *post-hoc* comparisons were then made using Tukey's HSD test. Where the assumptions of normal distribution and variance homogeneity were not met, data were subjected to the nonparametric Kruskal–Wallis *H* test, or a Kruskal–Wallis ANOVA. In this case, the *post-hoc* comparisons were carried out by using the Critical Difference Test for mean ranks: critical $\text{difference}_{0.05} = 2.394\sqrt{(N(N+1)/12 * (1/n_1 + 1/n_2))}$, where N is the total number of subjects in the experiment, and n_1 and n_2 are the number of subjects in the groups compared.

Calculations to estimate the contribution of individual peaks to the total variance between CHC profiles were carried out using the variance components module contained in the Statistica 5 (1997) package. A maximum likelihood approach was used to estimate the variance components. The statistical theory underlying maximum likelihood variance component estimation techniques is detailed by Searle et al. (1992).

The percentage contribution (relative concentration) of each component to the total CHC fraction was calculated to allow multivariate analyses. A similarity index (Nei distance 072, Nei, 1972; see also Nowbahari et al., 1990) for pairwise comparisons between each CHC profile was calculated and this was then subjected to a principal components analysis (NT-SYS 2.02). The first three principal components were taken as an estimate of CHC variation, and the number of dimensions responsible for the estimate of CHC profile variation was reduced from three to one by calculating the Euclidean distances between the relevant profiles (Statistica 5, 1997).

The first CHC profile after eclosion of each focus worker (equivalent to $x=0$, $y=0$, $z=0$) was taken as the reference point from which the Euclidean distances to other CHC profiles of this worker were calculated. Hence, the resulting one-dimensional CHC variation measurement ("chemical distance") represents vectors from zero. Low chemical distances stand for CHC profiles similar to the reference profile, and *vice versa* for high chemical distances.

Results

Temporal Polyethism and CHC Profile Variation

We identified three distinct task categories in the behavioral development of *M. eumenoides* workers. Workers carried out brood-tending duties early in life (up to 8 wk), and then went through an intermediate "reserve" phase (characterized by a high degree of inactivity) before eventually changing to foraging duties (Fig. 1). This behavioral transition was continuous and took place in a similar fashion in all focus workers, thereby confirming the presence of temporal polyethism in colonies of *M. eumenoides*. However, the time required for the transition from interior to exterior work varied from worker to worker; this parallels the findings of Otto (1962) on *Formica polyctena* workers. The CHC profiles of the workers were shown to gradually change in and parallel to this task transition.

The CHC profiles consist of a complex mixture of substances representing a series of *n*-alkanes, alkenes, and alkadienes with a chain length of 21–36 C atoms. The mean of CHC profiles collected during repetitive sampling of each focus worker in a particular task category was calculated. We found a large intraindividual variation in CHC profiles of individual workers performing different tasks (Fig. 1). To assess this variation, the mean "chemical distances" of the profiles were calculated by using the callows group centroid as reference, and a global significance was found when the three task groups were compared (repeated-measures ANOVA, $N=42$, $F=41.69$, $P<0.001$). The CHC profiles of the brood tenders (mean ± SD: 0.155±0.043, $N=14$) changed continuously and in a synchronous fashion as a function of time towards a "reserve"-type CHC profile (0.341± 0.069, $N=14$). This change is significant (Tukey's HSD test, $P<0.001$), but the change from a "reserve"-type CHC profile to a forager-type CHC profile (0.357±0.086, $N=14$) was not (Tukey's HSD test, $P=0.805$). This means that the interindividual CHC profile variation within the brood-tending task category was lower than the intraindividual variation between each of the brood tenders and their profiles during the "reserve" or foraging phases, respectively.

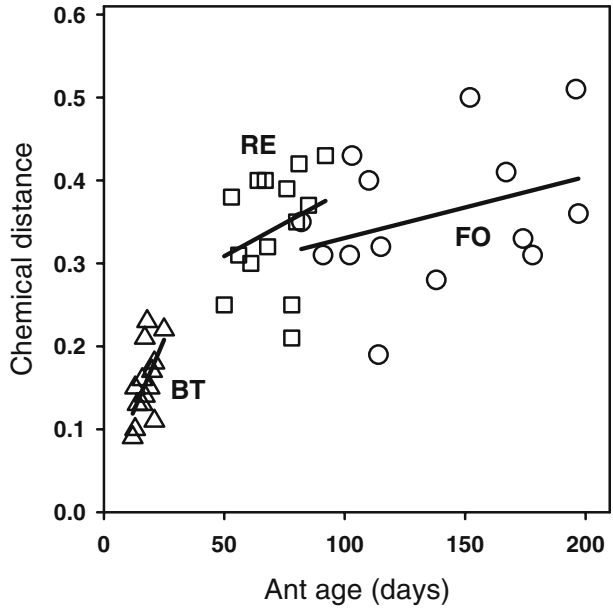

Fig. 1 Variation of CHC profiles in 14 *M. eumenoides* workers as a function of age and task. The brood tender (BT, ▵), "reserve" (RE, □), and forager (FO, ○) symbols represent the mean number of days post eclosion plotted against the mean chemical distances of all CHC profile samples taken from each individual in that task category (r^2_{BT}= 0.34, r^2_{RE}=0.08, r^2_{FO}=0.12). Chemical distance is the Euclidean distance to the callows group centroid; black lines are linear regressions for the CHC profiles of the three different task categories

All task groups were shown to have the same 51 CHCs—this means that the CHC profile change from brood tender to forager was only quantitative. Using variance components analysis, the difference between the CHC profiles of brood tenders and foragers was shown to be more than 98% due to only 10 components: four *n*-alkanes, two alkenes, and four alkadienes (Table 1, series I). In terms of relative abundance, these 10 components were classed as major- and mid-sized components.

Juvenile Hormone Identification and Hemolymph Titers

Only JH III was identified in the hemolymph samples of all workers. A global significance was found when the JH III titers (expressed in pg/μl hemolymph) of the brood tenders, "reserves", and foragers were compared (ANOVA, N=30, F=6.45, P=0.005) (Fig. 2). Foragers (N=10, 32.6 ±10.9) had a significantly higher JH III hemolymph titer (Turkey's HSD test, P=0.003) than brood tenders (N=10, 15.4±7.5). JH III titers of "reserves" (N= 10, 23.2±13.0) were intermediate. Differences were not significant when brood tenders and "reserves", or foragers and "reserves" were compared (Turkey's HSD test, P=0.24 and P= 0.14, respectively). This demonstrated the existence of a task-related difference in JH III hemolymph titers among *M. eumenoides* workers. The JH III titers of hormone- and hormone analogue treated workers were not measured because the workers would have had to be killed in order for us to carry out the tests. Thus, they would no longer have been available for the continuous SPME sampling of CHCs during their entire life span.

Effects of the Application of JH III and Methoprene on Behavioral Development

All application treatments including the control had detrimental effects on the longevity of the test subjects, reducing their life expectancy to only 4–6 wk after the first application. None of the treated individuals were observed to forage at any point. Thus, the mean

Values for BT and FO are given as mean ± SD of the relative abundance, and variance values state the % contribution to the total variance.

[a] Series I represents a comparison of CHC profiles of untreated brood tenders and foragers.

[b] Series II represents a comparison of CHC profiles of untreated brood tenders and brood tenders applied with JH III leading to forager-type CHC profiles (JH-appl. BT).

number of days post first application that a worker started to show "reserve" behavior was recorded (control, 31.5±7.5; 50 pmol JH III, 28.1±7.8; methoprene, 28.4±9.5) as a representative measure of behavioral development. When the hormone-treated groups were compared to the control group, no difference regarding the start of the "reserve" phase was found (ANOVA; N=22, F=0.724, P=0.33).

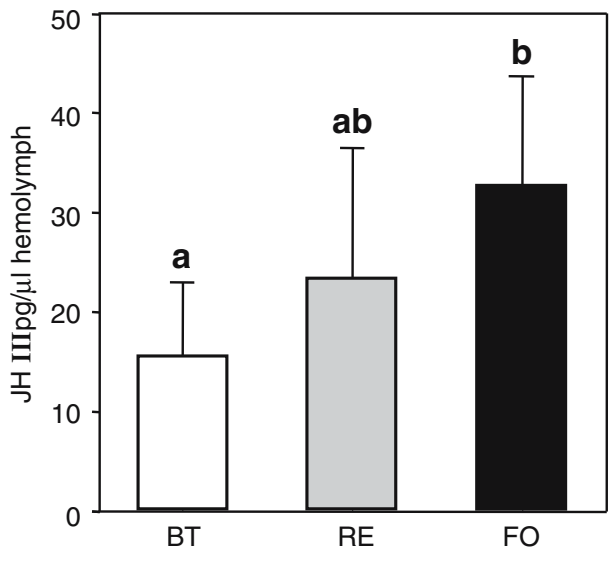

Fig. 2 The JH III hemolymph titers (mean ± SD) of brood tenders (BT), "reserves" (RE), and foragers (FO). Each category is represented by 10 pooled samples. Different letters denote significant differences at the P<0.05 level

Effects of the Application of JH III and Methoprene on CHC profiles

Effects of the application of JH III and methoprene on CHC profiles were documented in terms of days post first application, although none of the treated workers changed from brood tending to foraging. The five different time brackets (Fig. 3) were analyzed, and in the first no significant difference in comparison to the control group was found (Kruskal–Wallis $ANOVA_{1-10}$; $N=19$, $H=2.16$, $P=0.34$). However, in the other four time brackets significant differences were found (Kruskal–Wallis $ANOVA_{11-20}$; $N=21$, $H=8.62$, $P=0.013$, Kruskal–Wallis $ANOVA_{21-30}$; $N=21$, $H=9.87$, $P=0.007$, Kruskal–Wallis $ANOVA_{31-40}$; $N=18$, $H=8.08$, $P=0.017$, Kruskal–Wallis $ANOVA_{41-60}$; $N=14$, $H=9.00$, $P=0.011$).

The application of 50 pmol JH III resulted in increased chemical distances (measurement of magnitude of CHC profile change) in all time brackets, but significant differences between JH III treated workers and controls were only found from days 21 to 30 (Critical $Difference_{0.05}$, $P<0.05$), and from days 41 to 60 (Critical $Difference_{0.05}$, $P<0.05$). For days 31–40, the value obtained was below the critical difference value (Critical $Difference_{0.05}$, $P>0.05$) and was thus not significant, but due to the highly conservative nature of the *post-hoc* test used this result is nevertheless viewed as presenting a clear trend. The application of methoprene also resulted in increased chemical distances in all time brackets, and these were significant in comparison to the control group from day 11 post application onwards (Critical $Difference_{0.05}$, $P<0.05$ in all cases). In sum, these results suggest that the CHC composition in *M. eumenoides* workers is influenced by JH III.

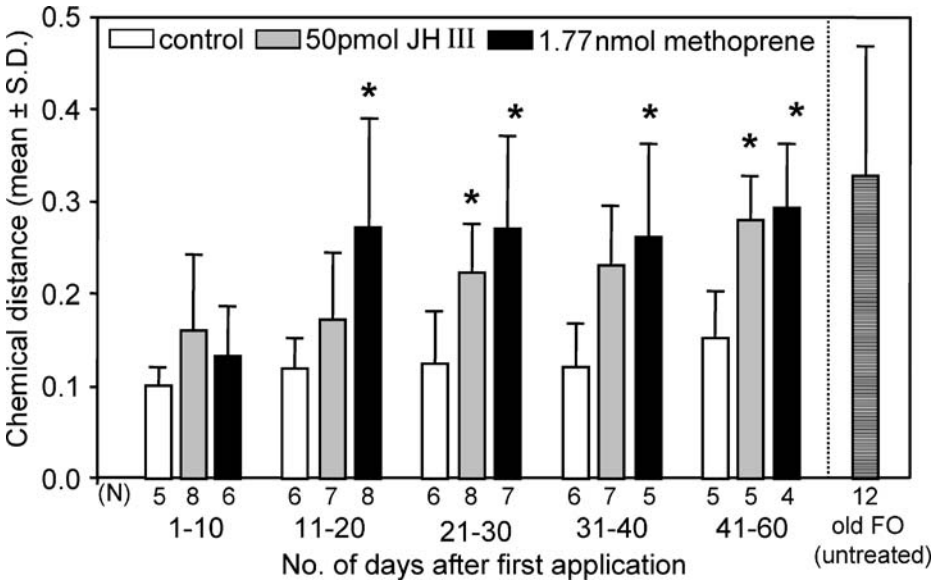

Fig. 3 Effects of application of 50 pmol JH III, 1.77 nmol methoprene, or acetone controls, on the CHC profiles of individual workers as a function of time. Chemical distance is the Euclidean distance to the first CHC profile taken from a focus worker prior to the first application. Thus the mean chemical distance of CHC samples in each time bracket was first calculated per individual, then for each application group. The number of individuals (N) used in the analysis is denoted in each time bracket for each application category. Asterisks indicate differences at the $P<0.05$ level between that specific application group and the acetone control group in the same time bracket. The "old foragers" (old FO) group was included for comparison

Analysis of Application-Induced CHC Profile Changes

Variance components analysis showed that CHC profiles of the control group (performing brood-tending duties) can be differentiated from CHC profiles of the treated brood tenders altered through JH III and methoprene application on the basis of only 10 components (Table 1, series II). These 10 compounds made up more than 98% of the total variation between the CHC profiles. Moreover, these were the same compounds that were shown to summarize the differences between brood-tender-type and forager-type CHC profiles observed during the course of the normal behavioral development in untreated workers. This suggests that the application of JH III, as well as its analogue methoprene, resulted in a precocious shift from brood-tender-type towards forager-type CHC profiles.

Discussion

We investigated the influence of JH III and its analogue methoprene on CHC profile changes and the division of labor in *M. eumenoides*. The endocrinological control of the division of labor in social insect colonies has already been the subject of several studies (Sasagawa et al., 1989; Huang et al., 2001; Schulz et al., 2002). However, to the best of our knowledge, this marks the first time that the endocrinological basis of CHC profile changes has been investigated specifically and parallel to age-related task changes in the same workers.

Our results showed that behavioral transitions took place during the life of all untreated focus workers. These carried out brood-tending duties early in life, and then went through the "reserve" phase before eventually changing to foraging duties. The CHC profiles of workers changed parallel to the task transitions. These results therefore suggest a strong correlation of CHC profiles and task allocation in the ant *M. eumenoides*, in agreement with the findings of Kaib et al. (2000). Our data also showed that foragers have higher JH III hemolymph titers than brood tenders, and thus a strong correlation between CHC profile changes and JH III titers exists in *M. eumenoides.* When we topically applied JH III and methoprene, we found that the CHC profiles of workers changed towards a forager-type CHC profile after the applications. However, we did not observe that task change was affected when focus workers were treated with JH III and methoprene.

Unfortunately, we found that the life span of workers was greatly reduced by the application of acetone (solvent) during the application experiments. The toxic effects of organic solvents at the cellular level are well known, but only poorly documented. However, it is generally agreed that the cell membrane is the primary target, and that changes in permeability lead to increased mortality (e.g., Stevens and Hofmeyr, 1993). In addition, the life span of workers was further reduced by high doses of JH; this type of toxic effect has been previously noted (e.g., Kuhr and Cleere, 1973; Meola et al., 2001; Orth et al., 2003). Thus, our applied concentrations represented a trade-off between worker longevity and the amounts of JH III that we were planning to apply (within the range of the hemolymph titers).

The type of behavioral transition observed in untreated *M. eumenoides* workers is in good agreement with the basic temporal polyethism pattern observed in eusocial Hymenopterans. This has been described as strikingly similar from species to species (Hölldobler and Wilson, 1990): tasks inside the nest are executed early in life, whereas out-of-nest tasks are performed later in life. This has been thoroughly investigated in the honeybee, *Apis mellifera* (Giray and Robinson, 1994; Giray et al., 1999), as well as the ants

P. barbatus (Wagner et al., 1998) and *Diacamma ceylonense* (Cuvillier-Hot et al., 2001). We also found that in *M. eumenoides* the time required for the transition from interior to exterior work (the "reserve" phase) varied from worker to worker (data not presented here), paralleling findings by Otto (1962) on *F. polyctena*.

The factors regulating temporal polyethism, i.e., task allocation, in social insect colonies have as yet not been determined, but increasing evidence indicates the involvement of JH (Robinson and Vargo, 1997; Hartfelder and Emlen, 2005). It is generally accepted that JH III is the only form of JH found in Hymenoptera (Gäde et al., 1997). Our results support this; we only found JH III in *M. eumenoides* workers, regardless of the task performed. In addition, several published studies showed that high JH III hemolymph titers are associated with foraging, whereas low JH III titers are associated with within-nest duties such as brood tending in, e.g., *B. terrestris* (Bloch et al., 2000), *Diacamma* spp. (Sommer et al., 1993), and *A. mellifera* (Robinson, 1987; Huang et al., 1991). Again, our results parallel these findings, because the JH III hemolymph titers of foragers were shown to be significantly higher than those of brood tenders. Studies on the honeybee *A. mellifera* showed that JH III and methoprene treatments promoted a precocious switch from activities in the nest to foraging (Robinson, 1985; Robinson et al., 1989; Sasagawa et al., 1989). In contrast, a study on *B. impatiens* and *B. bimaculatus* reported that application of 250 μg methoprene, and the injection of 250 μg JH I did not lead to precocious foraging (Cameron and Robinson, 1990), possibly because these two *Bombus* spp., unlike *A. mellifera* and most of the Formicidae, do not exhibit strong age-related polyethism.

We did not see a precocious task switch when we applied both JH III and its analogue methoprene to *M. eumenoides* workers, a species demonstrating a strong temporal polyethism. This discrepancy might be explained by the fact that the concentrations of JH III (0.13 pg/μl) and methoprene (0.55 μg/μl) applied in our study were between 2 and 4 orders of magnitude lower than those administered in the above study, and might have been too low to have any effect on task allocation. As stated earlier, higher concentrations of JH III would have markedly reduced the period of survival of the treated workers, and would have made the collection of CHCs from individual workers over longer periods impossible.

Alternatively, it has been suggested that JH III may only act as a "behavioral pacemaker" and is not necessary for the onset of foraging behavior *per se* (Robinson and Vargo, 1997; Sullivan et al., 2000). Such a "pacemaker" effect is likely to take place over a longer period, and we may not have been able to observe this due to the application-related premature deaths of the focus workers. In our study, JH III- and methoprene-treated workers survived for only 4–6 wk posteclosion, whereas nontreated workers started to forage roughly 18 wk after eclosion.

Besides playing a role in the temporal division of labor, our data provide evidence that JH III is also involved in regulating chemical communication in social insects. Signaling in the Hymenoptera appears to be primarily based upon CHCs (reviewed by Howard and Blomquist, 2005). Numerous studies have shown the involvement of CHCs in nestmate recognition, especially in the ants (Lahav et al., 1999; Thomas et al., 1999; Wagner et al., 2000; Lucas et al., 2005). Task-related CHC profiles are also thought to occur in *A. mellifera* (Francis et al., 1989), and several studies have documented the close correlation between hemolymph JH III titers and task in this species (Robinson et al., 1989; Huang and Robinson, 1995). This correlation gives an indication that CHC profiles in eusocial Hymenoptera workers are influenced by JH III. In our study, we also found that CHC profiles of *M. eumenoides* workers varied with the task performed (brood tending, foraging), and also strongly correlated with their hemolymph JH III titers. In addition, our study is the first to document the effects of topically applied JH III and methoprene on CHC

profile changes. Compellingly, we found that the application of these substances to *M. eumenoides* workers resulted in a general, precocious shift of the CHC profiles from brood tender type to forager type, resulting in brood-tending workers that displayed clear forager-type CHC profiles. These artificially induced CHC profile changes took place in a continuous fashion, altered the CHC profile within a short period, and intensified with increasing numbers of applications. Moreover, these changes were induced at concentrations roughly 1 order of magnitude below the physiological JH III titers of the workers, and several orders of magnitude below the concentrations applied or injected in comparative studies (regarding the effect of JH III on temporal polyethism).

In untreated *M. eumenoides* workers, the CHC profile changes took place in a continuous fashion from a brood-tender-type to a forager-type profile, and only quantitative involved changes. A quantitative shift of 10 saturated and unsaturated components (*n*-alkanes, alkenes, and alkadienes) within the whole CHC profile typified the change from a brood-tender-type to a forager-type CHC profile. The CHC profile changes induced by the application of JH III and methoprene involved the same 10 components documented in the CHC profile changes of untreated workers. The resulting CHC profiles were indistinguishable from the "normal" forager-type CHC profiles produced during the behavioral transitions that take place over much longer periods. This indicates that the same underlying biosynthetic pathways are affected when JH III is applied, and suggests the involvement of JH III in the CHC profile changes, and thus in signaling.

In contrast to the general hydrocarbon biosynthesis pathways in insects (reviewed by Howard and Blomquist, 2005), there is no information on how JH III could mould the CHC composition in social insects. From studies on pheromones of nonsocial insects, there are indications that JH III may act directly via a receptor-mediated gene induction for a key enzyme at some point along the biosynthesis pathway (Schal et al., 1994, 2003; Tillman et al., 1998; Tittiger et al., 2003). However, in contrast to these pheromones, which usually consist of only one or a few substances, the CHCs of social insects constitute a far more complex system of recognition cues. Thus, the fact that CHC profile changes in hormone-treated workers parallel the "normal" CHCs shift with task in nontreated workers (i.e., a change in the same 10 components) suggests that enzymes responsible for chain elongation, desaturation, and polydesaturation are affected by JH III. Thus JH III may exert its influence at several points along the biosynthetic pathway.

Another likely regulatory point is at the CHC transport level: high-density lipophorin (HDLp) has been hypothesized to play a key role in the transportation of CHC from the site (s) of synthesis to the cuticle (reviewed in Schal et al., 1998). Additionally, HDLp has a specific, high-affinity JH III binding site in Hymenoptera (Sevala et al., 1997). Because *M. eumenoides* individuals carrying out different tasks have altered relative proportions of the same CHCs, it is conceivable that JH III regulates the loading and/or unloading of CHCs into HDLp. Interestingly, it was recently demonstrated that the HDLp-bound hydrocarbons in the ant *Pachycondyla villosa* are quantitatively and qualitatively similar to the CHCs (Lucas et al., 2004).

Finally, our data also showed that "task signaling" takes place in colonies of *M. eumenoides*, paralleling findings from several other ant species (*Camponotus vagus*, Bonavita-Cougourdan et al., 1993; *P. barbatus*, Wagner et al., 1998, 2001; *Diacamma ceylonense*, Cuvillier-Hot et al., 2001). It appears that these task-specific CHC profiles allow workers to determine the tasks performed by nestmates during brief antennal encounters. Greene and Gordon (2003) demonstrated that workers perceive and respond to task-related CHC differences in the red harvester ant *P. barbatus*. In light of the results obtained in our study, this suggests a JH III-mediated, task-based recognition cue system in

M. eumenoides colonies. Such an endocrinologically controlled recognition system could allow each worker to assess the workforce involved in the various tasks on a small spatial scale (i.e., a subsample of the colony). This would allow individual workers to assess the colony requirements using CHCs as simple, localized cues, and to adjust their own behavioral development and signal composition accordingly. Tentative evidence is provided by Gordon and Mehdiabadi (1999), who demonstrated that rates of brief antennal contact (involving the perception of CHCs) influence task decisions in the ant *P. barbatus*. Altogether, this would result in a dynamic network that efficiently regulates a colony's behavior (Greene and Gordon, 2003) without any central or hierarchical control. Although this type of scenario may constitute the backbone of temporal polyethism in eusocial Hymenopterans, it is likely that other environmental and social cues also play a role in the "task decisions" made.

In summary, our investigation has shown that hemolymph JH III titer, task, and cuticular recognition cues in *M. eumenoides* workers are linked, but apparently two independent processes exist. First, short-term JH III application only leads to CHC profile changes, and acts at low JH III hemolymph concentrations. Second, a more long-term process that perhaps requires higher JH III concentrations modulates the task shift from brood tender to forager. Furthermore, these results also indicate that changing the task-specific CHC signals is not a prerequisite for temporal polyethism.

Acknowledgment We thank Antje Halwas for help and support during the investigations, and we are grateful to Konrad Fiedler for advice regarding statistical problems. This study was supported by the Deutsche Forschungsgemeinschaft as part of the Graduiertenkolleg 678 at the University of Bayreuth.

Abstract Quantitative stir bar sorptive extraction methodology, followed by gas chromatography-mass spectrometry (GC-MS) and element-specific atomic emission detection (AED) were utilized to analyze seasonal changes in volatile components of preen oil secretions in *Junco hyemalis*. Juncos were held in long days to simulate breeding conditions, or short days to simulate nonbreeding conditions. Linear alcohols (C_{10}–C_{18}) were the major volatile compounds found in preen oil, and in both sexes their levels were higher when birds were housed on long as opposed to short days. Methylketones were found at lower levels, but were enhanced in both sexes during long days. Levels of 2-tridecanone, 2-tetradecanone, and 2-pentadecanone were also greater on long days, but only in males. Among carboxylic acids (C_{12}, C_{14}, and C_{16}), linear but not branched acids showed some differences between the breeding and nonbreeding conditions, although the individual variation for acidic compounds was large. Qualitatively, more sulfur-containing compounds were found in males than females during the breeding season. Functionally, the large increase in linear alcohols in male and female preen oil during the breeding season may be an indication of altered lipid biosynthesis, which might signal reproductive readiness. Linear alcohols might also facilitate junco odor blending with plant volatiles in the habitat to distract mammalian predators. Some of the volatile compounds from preen oil, including linear alcohols, were also found on the wing feather surface, along with additional compounds that could have been of either metabolic or environmental origin.

Introduction

In birds, the uropygial (also called "preen") gland produces lipids, much like those produced by mammalian sebaceous glands. These lipids are spread over the feathers as the bird uses its bill to preen. As an example, the junco first rubs its bill against the gland located on its rump, and then applies the secretions as it runs individual feathers between its upper and lower mandibles (Schrock, personal observation). Among other functions, the oils may protect the feathers from wear (Stettenheim, 1972), aid in waterproofing (Elder, 1954; Fabricius, 1959; Elowson, 1984), or protect against dermatophytes (Jacob et al., 1997) including lice (Moyer et al., 2003).

Traditionally, the composition of preen oil gland secretions has focused on nonvolatile compounds and has been investigated by hydrolyzing the waxes (mostly nonvolatile compounds) under basic conditions into acids, acid esters, and alcohols. Long-chain and branched acids and their esters were thus found to be the main components in hydrolyzed wax collected from the preen gland of the mute swan (*Cygnus olor*) (Odham, 1965) and also from waterfowl belonging to the avian family *Anatidae* (Odham, 1967). Even carbon-numbered long-chain alcohols were also recovered from hydrolyzed preen wax in a shorebird, the red knot (*Calidris canutus*) (Dekker et al., 2000).

Several investigations of the waxy composition of preen gland secretions have compared the nonbreeding and breeding seasons and reported shifts from monoester to diester waxy components in sandpipers (*Scolopacidae*) and in male and female Mallard ducks (*Anas platyrhynchos*) (Bohnet et al., 1991; Reneerkens et al., 2002). It was hypothesized for the sandpipers (*Scolopacidae*) that a shift from more volatile monoester preen waxes in winter to less volatile diester preen waxes in spring and summer may reduce the "odor" of the bird's feathers causing it to transfer less of this odor to the nest when incubating, and thus making the nest less noticeable to olfactorily sensitive mammalian nest predators (Reneerkens et al., 2002). Alternatively or in addition, the diester waxy preen oil during summer may alter the sandpiper's appearance, perhaps by influencing UV reflectance or other aspects of visual attractiveness, and thus play a role in mate choice (Reneerkens et al., 2002). Bohnet et al. (1991) suggested that compounds from the preen gland, when spread over the feathers, may also influence mate choice through a potential sex pheromone action. Preen oil may even have a role in advertising the allelic status of an individual's MHC genes to potential mates via a particular odor (Freeman-Gallant et al., 2003).

Recently, in studies with the great snipe (*Gallinago media*), which is a lekking bird species, a correlation between the MHC lineage and a mating success has been confirmed (Ekblom et al., 2004). The olfaction-mediated functions in birds, more than was previously appreciated, are plausible in light of new evidence for a stronger role for olfaction in passerines and other avian orders (see Roper, 1999 for a review).

Junco hyemalis is a classic species for the study of seasonality, as it was the first wild species shown to respond to changes in day length (summarized in Nolan et al., 2002). *J. hyemalis* is a socially monogamous, ground-nesting bird. Plasma testosterone levels have been reported to vary seasonally in both males and females (Schoech et al., 1998; Ketterson et al., 2005). Although the female builds the nest and does all the incubation, the male also provides parental care by delivering food to the young in the nest (Nolan et al., 2002).

To date, relatively few studies of any bird species have reported the composition of the volatile fraction of the preen oil. As with the contents of waxy compounds, the composition of volatile compounds reported in preen gland secretions and feathers also appears to differ greatly depending on the bird species. A "citrus odor" found on the feathers of the crested

auklet (*Aethia cristatella*) has been found to contain a group of aldehydes (hexanal, octanal, decanal, Z-4-decenal, and 12-carbon unsaturated aldehyde) that act as the major volatile chemosignals (Douglas et al., 2001). It was originally suggested that these aldehydes are capable of repelling invertebrate species, bacteria, and fungi, and consequently might signal an individual's health and vigor in the mate selection process.

A more recent study has shown that the crested auklet feather aldehydes are effective as mosquito repellants (Douglas et al., 2005). In addition, Hagelin et al. (2003) established that the "tangerine odor" in volatile secretions (octanal and *cis*-4-decenal) of the crested auklet feathers act as social odors to present to conspecifics. Partner-specific olfactory recognition was also observed between Antarctic prions (*Pachiptila desolata*) by Bonadonna and Nevitt (2004), but the specific compounds involved were not identified. Foul-smelling preen gland secretions (consisting of acids, aldehydes, ketones, amines, and dimethyl sulfide) in the green woodhoopoe (*Phoeniculus purpureus*) serve as a multifunctional tool, repelling predators and warding off feather-degrading bacteria (Burger et al., 2004).

In this paper, we report on the volatile and semivolatile chemical composition of the preen gland secretions of male and female dark-eyed juncos (*J. hyemalis*) during the breeding and nonbreeding seasons. Sorptive stir bar extraction methodology (Soini et al., 2005) with gas chromatography-mass spectrometry (GC-MS) was utilized in the investigation of the preen oil compositions. A novel *in situ* stir bar sampling method (Soini et al., 2006) was also applied to study volatile compounds on the surface of the wing feather.

Methods and Materials

Preen Oil Collection Sample secretions were collected from captive juncos in breeding and nonbreeding conditions. The juncos were originally captured near Pembroke, VA, USA and were held thereafter at the Kent Farm Bird Observatory in Bloomington, IN, USA. Their diet consisted of millet seed and a pureed mixture of dog chow, hard-boiled eggs, and carrots supplemented with vitamins and mealworms, and was available *ad libitum*. A total of 20 individuals were used, including 10 males and 10 females, and each individual was sampled first under short days and then under long days in a repeated measures design. Both short- and long-day conditions were maintained for 8 wk before the sample collection. The short-day birds (8L:16D) are referred to as "nonbreeding," whereas the long-day birds (16L:8D) are referred to as "breeding." In fact, neither group bred, but the long-day birds exhibited indicators of reproductive readiness, i.e., males developed large cloacal protuberances and females developed brood patches (defeathered areas on the ventral surface that transfer heat to developing embryos). Air temperature also differed by season: nonbreeding, short-day birds were held at −2–4°C, whereas in the breeding-season, long-day birds were held on at 18–20°C. Temperature conditions are typical temperatures juncos would experience in the wild population at Mountain Lake Biological Station in Virginia during the normal seasonal cycle.

Preen gland contents were collected by gently squeezing the area around the gland until a small amount of oil was discharged (Kolattukudy et al., 1987). The preen oil was then collected with a 100-μl microcapillary glass pipette that was weighed before and after sampling to determine how much was collected. The experimental procedures were approved by the Bloomington Institutional Animal Care and Use Committee of Indiana University. The samples (1.3–1.8 mg) were frozen at −20°C for the gas chromatography-

mass spectrometry (GC-MS) and gas chromatography-atomic emission detection (GC-AED) analyses.

Reagents and Materials All compound identifications were verified through authentic standards. The standard compounds and ammonium sulfate (99% +) were purchased from Aldrich Chemical Company (Milwaukee, WI, USA). The stir bars (Twister™, 10 mm, 0.5-mm film thickness, 24-μl polydimethylsiloxane, PDMS volume) used for the sorptive extraction were purchased from Gerstel GmbH (Mülheim an der Ruhr, Germany).

Preparation of Preen Oil Samples Volatile and semivolatile compounds were extracted from the preen oil samples by placing a 100-μl glass capillary containing the sample in a 20-ml capped glass vial with 2 ml of water (high-purity OmniSolv® water from EM Science, Gibbstown, NJ, USA), 100 mg of ammonium sulfate, and a Twister™ stir bar. As an internal standard, 8 ng of 7-tridecanone (Aldrich) was added in 5 μl volume of methanol to each vial. The stirring speed was 800+ rpm on the Variomag Multipoint HP 15 stirplate (H+P Labortechnic, Oberschleissheim, Germany) for a 60-min extraction time. Before extraction, all glassware was washed with acetone and dried at 80°C. After extraction, the stir bars were rinsed with a small amount of distilled water, dried gently on the paper tissue, and placed in the TDSA autosampler tube (a product of Gerstel) for the GC or GC-MS analysis.

Collection of Volatile Compounds from Surface of the Wing Feather A rolling stir bar method (Soini et al., 2006) was applied in the collection of wing feather volatiles from the live bird wings. A wing feather of a single junco was sampled, rolling a stir bar gently over about 4 cm^2 surface area of its length. Sample-containing stir bars were subsequently stored in a refrigerator. The analyses were performed within 48 hr after collection. Stir bars were placed in the thermal desorption autosampler (see the description of equipment) without any further sample manipulation.

Analytical Instruments The GC equipment for quantitative analyses consisted of the Agilent 6890N gas chromatograph connected to a 5973i MSD mass spectrometer (Agilent Technologies, Inc., Wilmington, DE, USA) with the Thermal Desorption Autosampler and Cooled Injection System (TDSA-CIS 4 from Gerstel). Positive electron ionization (EI) mode at 70 eV was used with the scanning rate of 2.47 scans/sec over the mass range of 40–350 amu. A MSD transfer line temperature was set at 280°C. The ion source and quadrupole temperatures were set at 230°C and 150°C, respectively. The separation capillary was DB-5MS (20 m×0.25 mm, i.d., 0.25 μm film thickness) from Agilent (J&W Scientific, Folsom, CA, USA).

Samples were thermally desorbed in a TDSA automated system, followed by injection into the column with a cooled injection assembly, CIS-4. TDSA operated in a splitless mode. Temperature program for desorption was 20°C (0.5 min), then 60°C/min to 250°C (3 min). Temperature of the transfer line was set at 280°C. CIS was cooled with liquid nitrogen to −80°C. After desorption and cryotrapping, CIS was heated at 12°C/sec to 280°C, with the hold time of 10 min. CIS inlet was operated in the solvent-vent mode, a vent pressure of 14 psi, a vent flow of 50 ml/min, and a purge flow of 50 ml/min. The temperature program in the GC operation was 50°C for 2 min, then increasing to 200°C at the rate of 3°C/min (hold time, 10 min). The carrier gas head pressure was 14 psi (flow rate, 1.1 ml/min at the constant flow mode).

Element-selective compound profiling was performed using a GC 6890 instrument equipped with an Atomic Emission Detector (AED, model G2350A) from Agilent Technologies (Wilmington, DE, USA) and a Thermal Desorption Autosampler-Cooled Injection System (TDSA-CIS-4 from Gerstel). The separation capillary was an HP-5MS (30 m× 0.25 mm, i.d., 0.25 μm film thickness) from Agilent. Samples were thermally desorbed in a TDSA automated system, followed by injection into the column with a cooled injection assembly under the same conditions as described above for the GC-MS analysis, except that the CIS was cooled with liquid nitrogen to −60°C. The temperature program in the GC operation was 50°C for 2 min, then increasing to 200°C at the rate of 3°C/min. The final temperature was held for 12 min. The carrier gas head pressure was 14 psi (flow rate, 1.2 ml/min). The GC unit was operated at the constant flow mode. The emission lines for carbon (193 nm), sulfur (181 nm), and nitrogen (174 nm) were monitored during the atomic plasma emission detection.

Quantitative Comparisons A total of 24 samples were quantitatively analyzed by GC-MS, six from each group (breeding and nonbreeding females and males). Four other samples from each of the 4 groups were qualitatively screened for the sulfur compounds by the GC-AED method. Of the approximately 100 compounds detected in chromatographic profiles of the preen oil by GC-MS, about 40 were tentatively identified. All major compounds were positively identified through comparison of their mass spectra and retention times to those of standard substances. Peak areas of the identified compounds were used to make quantitative comparisons between the long- and short-day groups of each sex. Peak areas were integrated either from the TIC (total ion current) profiles or from the postrun, selected ion current (SIC) profiles at *m/z* 55, *m/z* 58, and *m/z* 60. Peak areas of the internal standard were integrated from the *m/z* 113 profiles. Peak areas of the compounds of interest were normalized by dividing each peak area by that of the internal standard in corresponding runs. Reproducibility of the internal standard peak area was 13% (relative standard deviation, RSD, $N=12$).

Statistical Analyses Statistical comparisons of the normalized peak areas were calculated by using nonparametric, two-tailed Mann–Whitney matched pairs *U* tests for seasonal comparisons within sex and simple Mann–Whitney *U* tests for sex comparisons within a season. Statistically significant values of $P<0.05$ were accepted.

Results and Discussion

The volatile compound GC-MS profiles (collected under the scan mode over 40–350 amu) were complex when viewed as total ion current chromatograms (TICs). The profiles consisted of the major components (peak intensity 50–2,000 times over the detection limit), along with a large number of minor components (peak intensity 10–50 times over the detection limit). Because of this degree of complexity, not all compounds were fully resolved in the GC separation. Figure 1 illustrates a compound pattern that is representative of the "raw" volatile compound profiles. To facilitate more precise comparisons of the peak area integrations, we employed a postrun modification of the TIC profiles known as selected ion current (SIC) profiles, which allowed us to view the data "one ion" at a time.

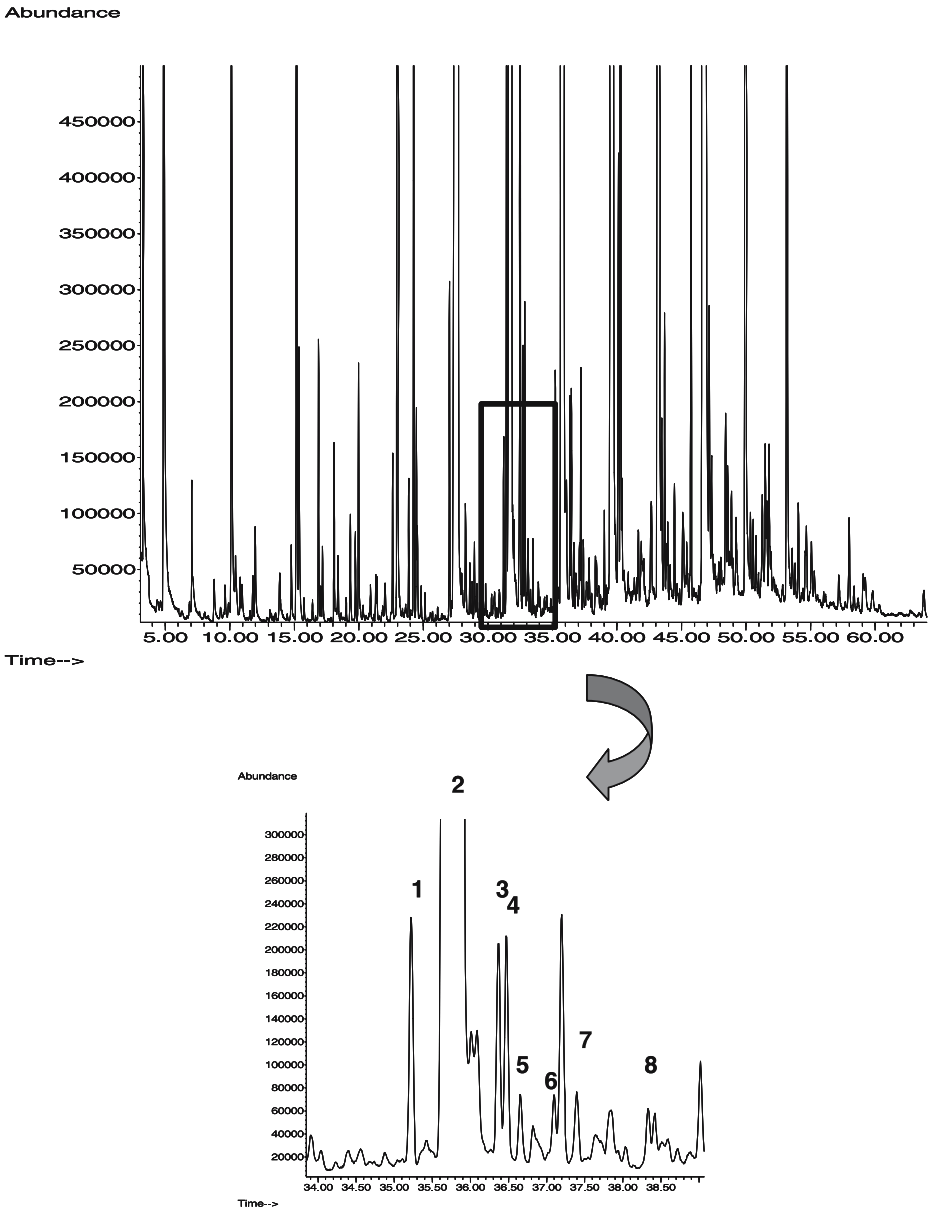

Fig. 1 A representative GC–MS TIC (total ion chromatogram) of the volatile compound profile extracted from preen oil. The enlargement of the framed area shows complexity of the profile leading to a partial co-elution of compounds. Numbers indicate the compounds 1: a methyl carboxylic acid, 2: 1-tridecanol, 3: 1-hexadecene, 4: 2-tetradecanone, 5: hexadecane; 6: 1-tetradecanol, 7: benzophenone, 8: a branched hydrocarbon

In addition to the TIC profiles, ions *m/z* 55, 58, and 60 were chosen to monitor peak areas of alcohols and aldehydes (*m/z* 55), a series of methylketones (*m/z* 58), and fatty acids (*m/z* 60). In Fig. 2, we demonstrate typical simplified profiles for *m/z* 55 and *m/z* 60. Six females and 6 males were investigated during both breeding and nonbreeding conditions

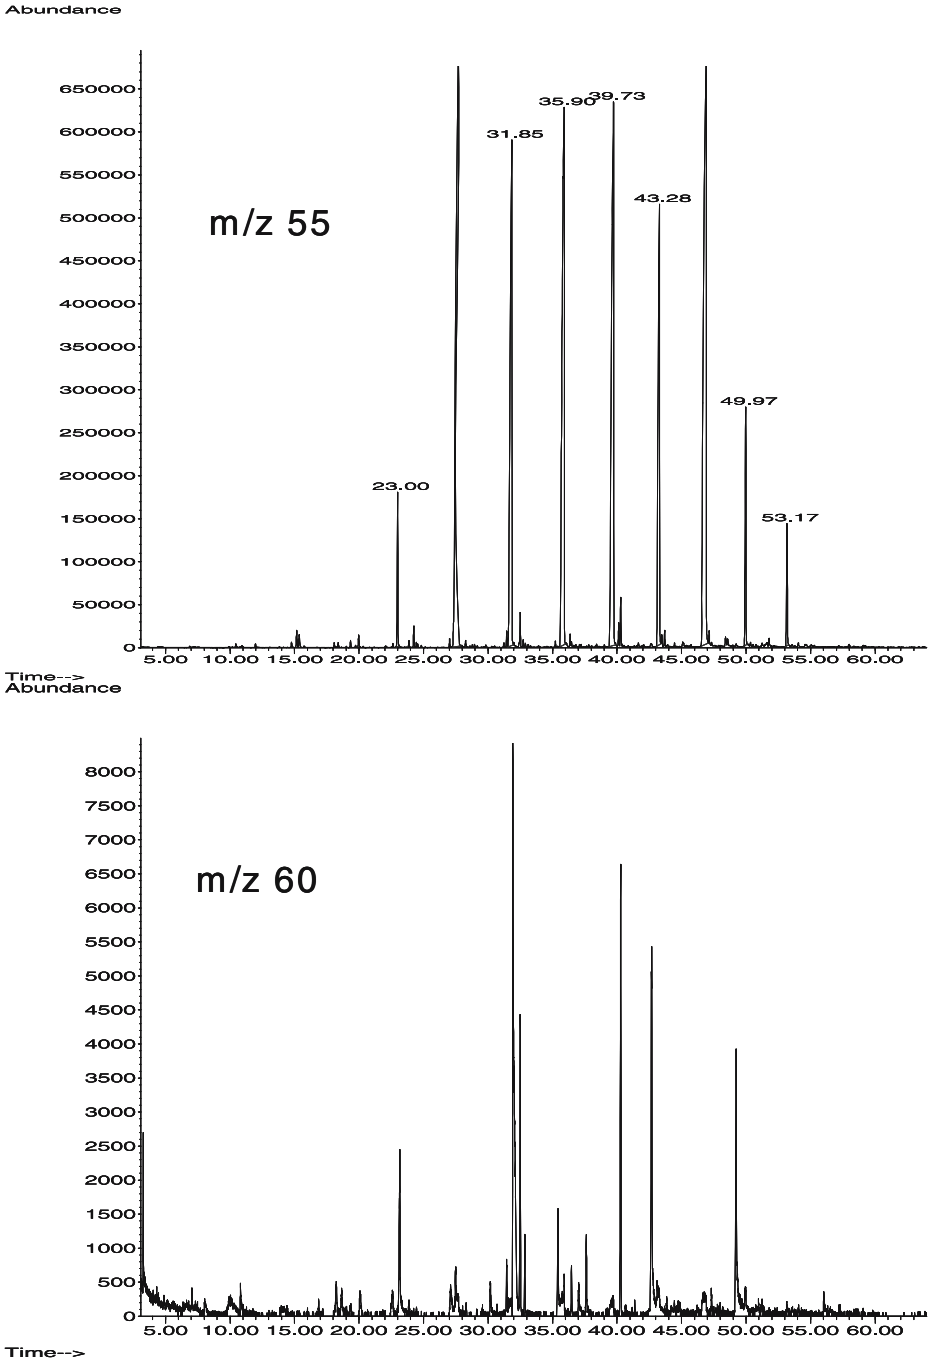

Fig. 2 Simplified selected-ion chromatograms (SICs) for extracted ions at m/z 55 and m/z 60 in a representative preen oil sample

through qualitative and quantitative comparisons. Table 1 lists the identified compounds together with their retention times and statistical significance classified by both season and sex. The compounds found prominently in preen oil samples included a homologous series of linear alcohols (C_9–C_{18}) as the major components in all samples (peak areas 100–1,000

times larger than minor compounds). Additionally, the series of aldehydes, acids, and methylketones were included in such volatile profiles. Among the minor components, some branched acids and saturated and unsaturated hydrocarbons were notably detected (see also Fig. 1).

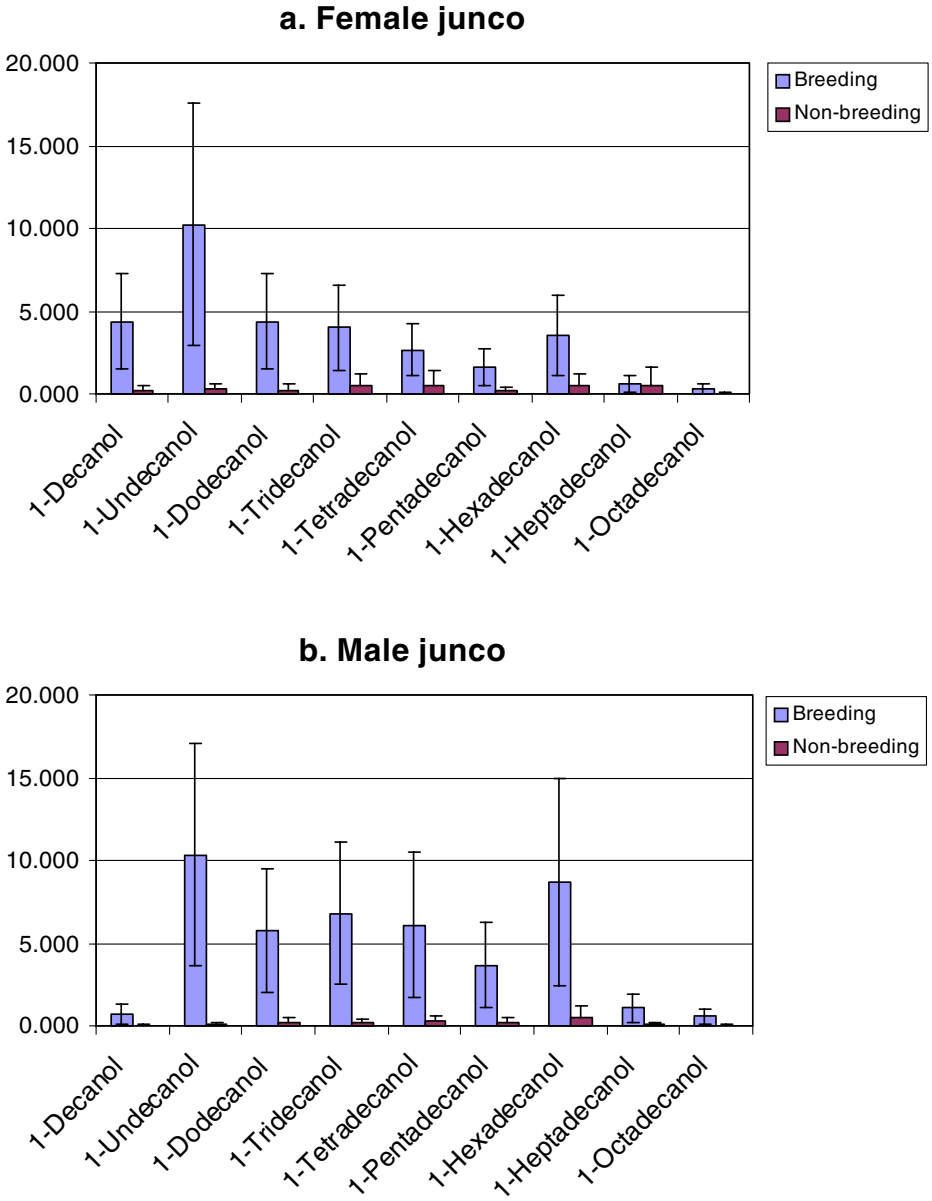

Fig. 3 (a) Averages of the normalized peak areas of C_{10}–C_{18} alcohols in female junco preen oil samples (N=6) in breeding and nonbreeding conditions. Error bars indicate individual variation (standard deviation, SD). (b) Averages of the normalized peak areas of C_{10}–C_{18} alcohols in male junco preen oil samples (N=6) in breeding and nonbreeding conditions. Error bars indicate individual variations (standard deviation, SD)

Linear Alcohols The highest levels of *n*-alkanols were detected as C_{10}–C_{18} (from decanol to octadecanol). Also, 1-nonanol, was detected at lower concentrations. Using the extracted ion profiles for *m/z* 55 (see Fig. 2), the peak areas of alcohols were measured and normalized with the peak area of the internal standard (*m/z* 113). In Fig. 3, we show the plotted normalized peak areas for the major alcohols of female and male juncos, respectively. In the breeding condition, as compared to the nonbreeding condition, both junco sexes showed elevated levels of these alcohols, although their individual variations appeared relatively large, as indicated by the error bars in Fig. 3.

Except for 1-heptanol in the female group, all *n*-alcohols, from 1-decanol to 1-octadecanol, showed statistically significant seasonal increases ($P<0.05$) in both males and females under long days. As seen in Table 1, based on their smaller *P* values, the differences tended to be larger in males than females. The compound 1-decanol was an exception in that it appeared more elevated in breeding females than in breeding males, but the sex difference was only marginally significant ($P<0.052$). During the nonbreeding season, concentrations of the linear alcohols did not differ between females and males.

Linear *n*-alcohols, such as those seen here as the major volatile components in the preen oil of the dark-eyed junco, have been reported as effective natural antimicrobial and antifungal substances for a wide spectrum of gram-positive bacteria, molds, and yeasts (Kubo et al., 1993, 1995, 2003). Indeed, these alcohols could have multiple functions during a junco breeding season as antimicrobial and antifungal agents. Juncos are high-latitude and high-altitude birds, and during winter their environments tend to be cold enough to suppress growth of both bacteria and fungi. However, warmer temperatures increase microbial growth, and alcohols may be a response to increased exposure, serving to promote healthy feathers and conditions at the nest.

In addition, plant leaves typically contain linear alcohols (Vioque and Kolattukudy, 1997). Increased levels of *n*-alcohols in preen oil during summer may help both female and

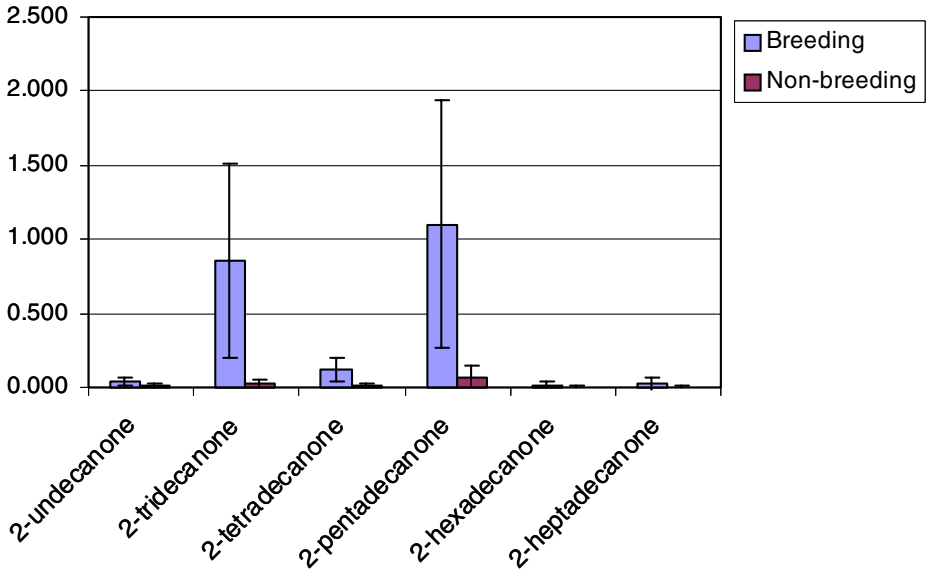

Fig. 4 Averages of the normalized peak areas of methylketones in male junco preen oil samples ($N=6$) in breeding and nonbreeding conditions. Error bars indicate individual variations (standard deviation, SD)

male juncos to blend their odors with the background odors of the plants in their environment (odor blending), for example, when the female with incubating eggs in a ground nest or the male is approaching the nest with food. Junco's eggs and young are a common prey of mammalian predators such as mice, chipmunks, and raccoons, so odor camouflage could provide a significant advantage (Nolan et al., 2002; Clotfelter et al., 2004).

Linear Methylketones A pattern of linear methylketones was seen in all preen gland samples (both male and female juncos). Comparing their peak areas to those of *n*-alkanols, methylketones were minor components. The peak areas for these compounds were measured using the extracted ion at *m/z* 58.

2-Tridecanone and 2-pentadecanone levels were higher than the remaining 2-ketones for the breeding male juncos, as shown in Fig. 4. A statistically significant increase (compared to nonbreeding season), was found for 2-tridecanone ($P<0.002$), 2-tetradecanone ($P<0.002$), and 2-pentadecanone ($P<0.004$) (see also Table 1). Female juncos showed an increase during the breeding season for 2-tridecanone and 2-pentadecanone levels, although these levels were somewhat lower than in males, and the changes were only close to statistical significance as a result of the large individual variations ($P<0.051$). A comparison between the male and female levels of 2-ketones showed only slight tendency for higher 2-pentadecanone levels in breeding males vs. breeding females ($P<0.186$).

Methylketones are also commonly found components in mammalian epidermis, including human skin (Penn et al., 2006). In birds, similarly to *n*-alcohols, methylketones may be promoting healthy feather conditions by acting as chemical defense compounds. Methylketone activity has previously been shown to provide plants with protection from herbivores and fungal pathogens, having been reported as a chemical defense compound in tree bark (McDowell et al., 1988), and as protection against the spider mite in wild and cultivated tomato plants (Chatzivasileiadis et al., 1999). Perhaps they provide similar protection for feathers.

Fatty Acids Preen samples contained linear and branched carboxylic acids at relatively low levels. The linear acid concentrations were higher than for the branched acids. The linear-

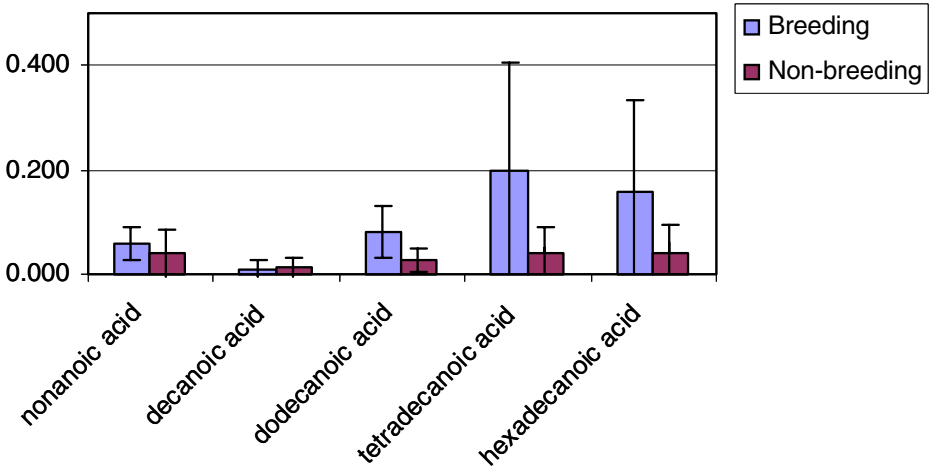

Fig. 5 Averages of the normalized peak areas of linear acids (C_9, C_{10}, C_{12}, C_{14}, C_{16}) in female junco preen oil samples ($N=6$) in breeding and nonbreeding conditions. Error bars indicate individual variations (standard deviation, SD)

acid peak areas were measured by using the extracted ion at *m/z* 60. Individual variation within all acid concentrations in the samples was quite large, as shown in Fig. 5, for the female juncos. Moreover, for this class of compounds, the differences between the breeding and nonbreeding conditions were not clear. However, in both female and male junco samples, tetradecanoic and hexadecanoic acid (even number fatty acids) levels were elevated more than for similar constituents (shown in Fig. 5) in the breeding condition. In both sexes, a statistically significant increase during breeding was found only for hexadecanoic acid ($P<0.044$ for females and $P<0.010$ for males). Additionally, the seasonal increase in dodecanoic acid was significant: for females, dodecanoic acid ($P<0.028$) and for males tetradecanoic acid ($P<0.044$). However, the acid concentrations did not differ statistically between females and males during the seasons.

Branched fatty acids were detected at lower levels than linear fatty acids, but also with large individual variations (data not shown). Their levels did not differ significantly by season in either male or female juncos.

Human sebum and circulating lipids contain a large number of different linear and branched fatty acids. It was suggested long ago that the ratios of the acidic constituents in mammalian skin lipids may carry an olfactory signature of an individual (Nicolaides, 1974). Interestingly, mammalian wax monoester biosynthesis involves fatty acids as starting materials, followed by reduction to linear alcohols (fatty alcohols) by a specific reductase enzyme. A wax synthase enzyme converts fatty alcohols finally to wax monoesters (Cheng and Russell, 2004a, b). Similarly, wax ester synthesis via linear alcohols was suggested for algae even earlier (Kolattukudy, 1970).

In our current study, the levels of nonvolatile wax monoesters were not of a direct interest. Whether their levels vary seasonally in the preen oil is not currently known. However, although fatty acid compositions were variable among the individuals across the seasons, the levels of linear alcohols (possibly fatty acid reduction products) increased dramatically. Accordingly, one might postulate that the wax ester synthesis route may slow down during the breeding season, yielding more *n*-alcohols as fatty acid reduction products.

One of the more interesting implications of volatile preen gland secretions is that the odors they create could serve to signal identity, condition, relatedness, or other information about an individual. This information might be utilized by conspecifics to make an assessment of the signaler. Compounds with large individual variation may be particular candidates as signals. The MHC gene products, for example, have been hypothesized both to facilitate immune responses (Apanius et al., 1997, Penn and Potts, 1999) and to produce recognizable odors (Penn and Potts, 1998, Spehr et al., 2006). Furthermore, some studies have speculated that these odors might be used to promote adaptive mate choice, as they allow individuals to assess their relatedness and regulate their degree of inbreeding (Potts and Wakeland, 1990; Brown and Eklund, 1994; Penn and Potts, 1999).

Interestingly, *CD1* genes (evolutionary predecessors of the MHC genes) which have been found in humans, have also been identified in birds. Correspondingly, these genes code for proteins that present antigens such as fatty acids and glycolipids to T cells, rather than the more typical presentation of peptides (Miller et al., 2005; Salomonsen et al., 2005). These genes might also play a role in regulating similar fatty acid compositions as found in preen gland secretions (Porcelli and Modlin, 1999). Enhanced detection of variation in the *MHC* or *CD1* genes might also be useful for dark-eyed juncos, particularly for those that breed in the Appalachian Mountains where natal philopatry is high (Nolan et al., 2002) and thus the potential for inbreeding is also high. Individuals able to detect variation at the MHC and, possibly CD1 loci, could potentially benefit from inbreeding avoidance and increased offspring fitness by maintaining immunogenetically important MHC or CD1 heterozygosity.

Comparisons of the other compounds, which appeared at low levels (e.g., *p*-cymene, saturated and unsaturated hydrocarbons, and some aldehydes) did not result in clear differences by sex or between the breeding and nonbreeding conditions (data not shown).

Sulfur Compound Profiles Several individuals from each group of breeding and nonbreeding males and females were qualitatively screened using the ultrasensitive sulfur compound detection (GC-AED). The sorptive stir bar extraction method has been previously shown to recover efficiently sulfur compounds at picogram quantities from biological samples (Soini et al., 2005). In this study, the breeding males consistently showed a higher number of low (picogram level) sulfur compounds than nonbreeding males and females (breeding or nonbreeding). No identifications could be made because of the low levels detected in the sulfur detection mode (data not shown).

Volatile Compound Profiles on the Feather Surface Among the volatile compounds collected from the wing surface were several compounds, including *n*-alcohols, which were obviously shown as originating from the preen oil (see Fig. 6). Additionally, numerous compounds not found previously in preen oil were detected on the feather surface. These compounds may be originating from the bird epidermal lipids (Menon and Menon, 2000), their surface-catalyzed conversions, or environmental sources. A large porous surface area on feathers is known to be efficient in enriching airborne particulates, including metals. Several studies have utilized bird feather surface for a biological monitoring of environmental heavy metal pollutants (for review see, Burger, 1994; Veerle et al., 2004).

In summary, the volatile compounds found in *J. hyemalis* preen gland secretions were found to have increased during the breeding season in both sexes, and the seasonal variations may reflect a number of possible functions for these components including defense against bacteria and fungi, odor camouflage in relation to nest predators, or information to

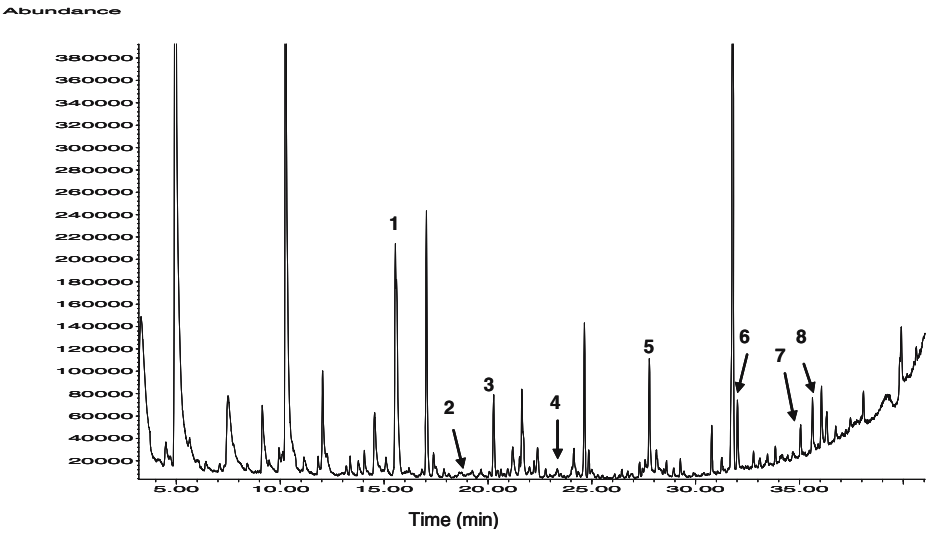

Fig. 6 A volatile compound GC–MS TIC profile collected directly from the surface of the male junco wing feather. Compounds, which were also found in the preen oil, are marked by numbers 1: nonanal, 2: 1-nonanol, 3: decanal, 4: 1-decanol, 5: 1-undecanol, 6: 1-dodecanol, 7: dodecanoic acid, 8: 1-tridecanol

be communicated to conspecifics, such as chemosignals about condition (appearance) or genotype (degree of relatedness). A large individual variation in the volatile compound levels could even indicate their regulation by *MHC* or *CD1* genes. More experiments are needed to test possible functions of the linear alcohols, methylketones, and linear carboxylic acids whose concentration increased during the breeding. Such experiments will require a carefully controlled design of behavioral and hormonal conditions.

Acknowledgments This work was jointly sponsored by the METACyt Initiative at Indiana University, and the Lilly Chemistry Alumni Chair funds (to M.V.N.) and the National Science Foundation grant NSF BSC 05-19211, 2005–2008 (to E.D.K.). We thank Mr. Michael Wigen for technical assistance.

More Rare Males in *Ostrinia*: Response of Asian Corn Borer Moths to the Sex Pheromone of the European Corn Borer

Charles E. Linn Jr. · Callie J. Musto · Wendell L. Roelofs

Received: 21 June 2006 / Revised: 5 September 2006 / Accepted: 12 September 2006 /

Abstract A previous flight tunnel study showed that 3–5% of European corn borer (ECB) moths, *Ostrinia nubilalis* (*Z*/*E*11-14:OAc), could fly upwind and make contact with sources releasing the sex pheromone of the related Asian corn borer (ACB), *Ostrinia furnacalis* (2:1 *Z*/*E*12-14:OAc). In this study, we show that rare males (3–4%) are also present in South Korean ACB that respond to the sex pheromone blends of the ECB UZ (97:3 *Z*/*E*11-14:OAc) and BE (1:99 *Z*/*E*11-14:OAc) pheromone races. We also show that the upwind flight response of a significant proportion of male ACB was antagonized by the addition of 1% *Z*9-14:OAc to the ACB blend, a compound that also antagonizes the upwind flight of ECB males. Male ACB flight behavior was not, however, affected by adding either of the ECB blends to the ACB blend, or by the addition of 50% 14:OAc, a compound identified from female pheromone glands of ACB and a number of other *Ostrinia* species. Additional flight tunnel tests with ACB to study the comparative aspects of ECB and ACB pheromone response specificity showed that male ACB exhibited maximal levels of upwind flight and source contact with doses of pheromone (30 and 100 μg on rubber septum sources) that also elicited maximal levels in the two ECB pheromone races. The maximal level of source contact for ACB (66%) was lower than observed with the UZ race of ECB to its pheromone blend (>95%), but comparable to those for the BE race of ECB (65–70%). Male ACB also flew upwind in high proportions to a broader range of ratios of *Z*/*E*12-14:OAc (80:20 to 20:80) than was previously observed for either of the ECB races.

Introduction

The genus *Ostrinia* (Lepidoptera: Crambidae) is composed of 20 species, including two of agricultural importance, the European corn borer (ECB), *Ostrinia nubilalis* (Hübner), and the Asian corn borer (ACB), *Ostrinia furnacalis*. The ECB has been studied more extensively and exists in Europe and North America as two distinct pheromone races (Kochansky et al., 1975; Roelofs et al., 1985). Most populations (Z race) use a 97:3 blend of (*Z*)-11- and (*E*)-11-tetradecenyl acetates (*Z*11/*E*11-14:OAc), but occur in some areas sympatrically with an E race that uses the opposite 1:99 *Z*/*E* blend. In New York state, three different races of ECB, based on the sex pheromone blend and the number of generations (voltinism), have been described: bivoltine Z (designated BZ), univoltine Z (UZ), and bivoltine E (BE) (Roelofs et al., 1985). Studies of the genetic basis of the ECB pheromone system have shown that there are three genes responsible for the differences (Roelofs et al., 1987; Löfstedt et al., 1989; Cossé et al., 1995).

The ACB, which occupies the ecological niche in Asia equivalent to that occupied by ECB in Europe (Ishikawa et al., 1999a), uses mixtures of (*Z*)-12- and (*E*)-12-tetradecenyl acetates (*Z*12/*E*12-14:OAc) that vary from 1:1 in the Philippines, mainland China, Taiwan, and some parts of Japan (Klun et al., 1980; Cheng et al., 1981; Du et al., 1986; Kou et al., 1992) to 2:1 in the southernmost part of Japan (Ando et al., 1980; Huang et al., 1998) and South Korea (Boo and Park, 1998).

In studies on the desaturase enzymes involved in controlling pheromone biosynthesis, Roelofs et al. (2002) discovered that the female pheromone gland of the ECB contains the expected desaturase gene that makes Δ11-14:Acid for production of its pheromone components, but the gland also contains the gene for a Δ14-16:Acid desaturase used by the ACB. The ACB pheromone gland likewise contains the same two desaturase genes, but only expresses the Δ14 desaturase, which it uses for its pheromone components. Roelofs et al. (2002) proposed that a saltational event occurred in an ancestral *Ostrinia* moth population and gave rise to a new pheromone and new species, the ACB. A possible pseudogene that had been unexpressed for millions of years in the genome of *Ostrinia* became functional and generated pheromone precursor fatty acids that differed in double-bond position and chain length. The resulting pheromone acetates then possessed a double bond in the Δ12 position instead of the Δ11 position. The desaturase studies raised the possibility that a new pheromone communication system can arise as a result of changes in regulatory pathways controlling gene expression. However, for the new pheromone to be effective in mate location it is necessary for some males to be able to detect and respond to the new blend. Subsequent flight tunnel studies showed that some males (3–5%) in the UZ and BE *O. nubilalis* races did, in fact, respond to both species' pheromone blends (Linn et al., 2003).

In this study, we report the results of flight tunnel experiments showing that there also are rare ACB males from a population originating in South Korea that respond to one or both of the ECB blends. We show further that the upwind flight of ACB males to their pheromone is antagonized by the addition of *Z*9-14:OAc, as it occurs with ECB, but not by the addition of the ECB blends to the ACB mixture. We also provide support for the claim that tetradecyl acetate (14:OAc), although present in the pheromone glands of many *Ostrinia* species, including ACB, does not enhance or disrupt levels of upwind flight.

Methods and Materials

Insects

Colonies of the UZ and BE races of *O. nubilalis* from New York state were maintained in separate walk-in environmental chambers. Mating and larval rearing conditions were as described in Roelofs et al. (1987) at a constant temperature of 25°C and 16:8 L/D photoperiod. Pupae were sexed and the male pupae were placed on a layer of vermiculite in plastic and screen emergence cages inside a walk-in environmental chamber (25°C, 16:8 L/D photoperiod). Cages of adults were separated daily so that individuals of known age could be used for flight tunnel tests.

The ACB were obtained from Jin Kyo Jung, National Institute of Crop Sciences, South Korea, and maintained on the same diet and environmental conditions in the lab in New York as were the ECB populations.

Chemicals

*Z*11-14:OAc, *E*11-14:OAc, *Z*12-14:OAc, *E*12-14:OAc, *Z*9-14:OAc, and 14:OAc were obtained from the Pherobank (http://www.pherobank.nl), and mixtures were prepared in high-performance liquid chromatography grade hexane and applied to red rubber septa (Thomas Scientific, Swedesboro, NJ, USA; Glover et al., 1989; Linn et al., 1997).

Flight Tunnel

Adults were tested in the sustained flight tunnel during their second to third night after ecolosion under standard conditions for *O. nubilalis* (Glover et al., 1989; Linn et al., 1997): 20–21°C, 60–65% RH, 0.50 m/sec air flow, and illumination of 11 lux of red light at the tunnel floor during the third to sixth hour of scotophase. Adults were taken to the room housing the flight tunnel 1 hr before the start of the eighth hour of scotophase and placed individually in screen release cages so they could acclimate to the flight tunnel room environment. The temperature during the 1-hr period of acclimation, in photophase, was 25°C, then, when lights off occurred the temperature dropped to 20–21°C. Adult moths were tested individually, and a positive response was counted if the male exhibited upwind flight in the odor plume and made contact with the rubber septum source.

Six experiments were conducted, each designed to address a different question about the comparative response specificity of ACB and ECB males. In some cases, individual males were tested to more than one treatment during each test period. After recapture, males were removed from the flight tunnel and allowed a minimum period of 15 min before retesting to a different blend. Previous experiments have demonstrated that ECB can be tested up to four times in a daily testing period without adverse affects on performance (Cossé et al., 1995). Preliminary experiments indicated that ACB could also be tested three times during a single testing period with no adverse affects on levels of upwind flight.

Experiment 1: Response of ACB Males to a Dose Series of Pheromone

ACB males were tested to a dose series of the 2:1 *Z*/*E*12-14:OAc blend: 1, 3, 30, 100, and 300 μg/septum. During each testing period, a minimum of 10 ACB males were tested to at

least two of the five doses, with each dose tested a minimum of four different testing periods (days).

Experiment 2: Response of ACB Males to Different Blends of *Z*/*E*12-14:OAc

ACB males were tested to 30-μg doses of the following *Z*/*E*12-14:OAc blends: 4:1, 2:1, 1:1, 1:2, and 1:4. During each day of testing, a minimum of 10 males were tested to three of the blends, with treatment blends rotated over subsequent days to achieve approximately the same number of males tested to each blend.

Experiment 3: Are There Rare ACB Males that Respond to the ECB Blends?

Two protocols were used for this experiment. In the first, ACB males and UZ race ECB males were tested to a 30-μg dose of the 2:1 *Z*/*E*12-14:OAc blend (ACB blend) and to a 30-μg dose of the 97:3 *Z*/*E*11-14:OAc UZ ECB blend (UZ blend). Males of each species were tested during each daily test period, beginning with the ACB blend for UZ males and the UZ blend for ACB males. In the second protocol, ACB males were tested to 30-μg doses of the UZ blend, 1:99 *Z*/*E*11-14:OAc BE ECB blend (BE blend), and the ACB blend. Each male was tested sequentially to the three blends in the same testing period, beginning with either of the ECB blends and ending with the ACB blend.

Experiment 4: Effect of *Z*9-14:OAc on Male ACB Response to the ACB Pheromone Blend

ACB males were tested to a 30-μg dose of the ACB blend alone, or with 1% *Z*9-14:OAc added to the mixture. The 1% value was chosen based on previous studies (Glover et al., 1989). For comparison, male ECB of the BE race were also tested on each day to a 30-μg dose of the BE blend alone, or with 1% *Z*9-14:OAc added to the mixture.

Experiment 5: Response of ACB Males to the Combined ACB/ECB Blends

ACB males were tested to a 30-μg dose of the ACB blend alone or with a 30-μg dose of the UZ or BE blends added.

Experiment 6: Response of ACB Males to the ACB Blend with 14:OAc Added

Previous studies with ACB have shown that 14:OAc is present in female pheromone glands, but has never been shown to enhance trap capture of moths (Boo and Park, 1998). In our experiment, ACB males were tested to a 30-μg dose of the ACB blend alone, or with 50% of the compound 14:OAc added. The 50% value was relative to the amount of *Z*12-14:OAc in the blend and was selected based on the study by Boo and Park (1998) showing that female glands from 2- to 3-d-old females contained a mean ratio of 0.74:1:1.36 for 14:OAc, *E*12-14:OAc, and *Z*12-14:OAc, respectively.

Statistical Analysis

For each experiment the number of moths in each treatment that exhibited upwind flight to the source was combined for all testing periods and converted to a percent for graphical display.

Chi-square analysis or post hoc pairwise comparisons using Fisher's exact tests were implemented according to the JMP statistical analysis program for Macintosh $P<0.05$).

Results

Experiment 1: Response of ACB Males to a Dose Series of Pheromone

The greatest percentage of source contacts by ACB males occurred with the 30-μg dose of the ACB blend (66%, $N=40$; Fig. 1a). This value was not significantly different from the lower percentages with the 3-μg (53%, $N=53$; Fisher's exact test $P=0.273$, $df=1$) and 100-μg (63%, $N=44$; Fisher's exact test $P=0.825$, $df=1$) doses. However, with the 1-μg

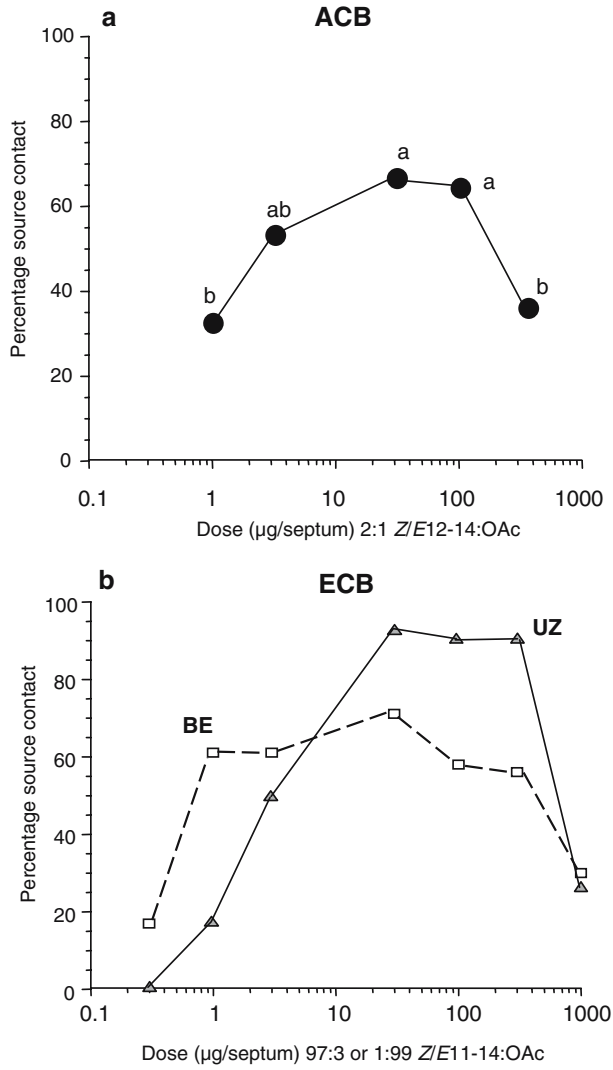

Fig. 1 Percentage source contact by ACB males tested to a dose series (1, 3, 30, 100, and 300 μg; $N=63$, 64, 60, 65, and 62, respectively) of the 2:1 *Z*/*E*12-14:OAc ACB pheromone (**a**). Data points with different letters are significantly different ($P<0.05$) according to selected post hoc Fisher's exact tests (see text). For comparison, response values for ECB males (UZ males to 97:3 and BE males to 1:99 *Z*/*E*-11-14:OAc) are presented in subpanel **b**, modified from Linn et al. (1997)

(32%, N=43) and 300-μg (35%, N=42) doses, there were significant reductions in the percentages of source contacts compared with the 100-μg dose (Fisher's exact test P= 0.004, df=1 for 3 μg vs. 100 μg). Based on these results, the 30-μg dose of the ACB blend was used for the other experiments. Previous results with two populations of ECB also showed that 30-μg of the 97:3 or 1:99 Z/$E$11-14:OAc blends elicited maximal response levels (Fig. 1b; modified from Linn et al., 1997; see also Glover et al., 1989). Maximal response levels were lower for the BE (72%, 30 μg) and ACB (66%, 30 μg) populations than for UZ males (93%, 30 μg) (Fig. 1b).

Experiment 2: Response of ACB Males to Different Blends of Z/$E$12-14:OAc

There were no significant differences in the response levels of ACB males to the 30-μg dose of five ratios of Z/$E$12-14:OAc (Fig. 2a; χ^2=5.296, P>0.05). Interestingly, ACB

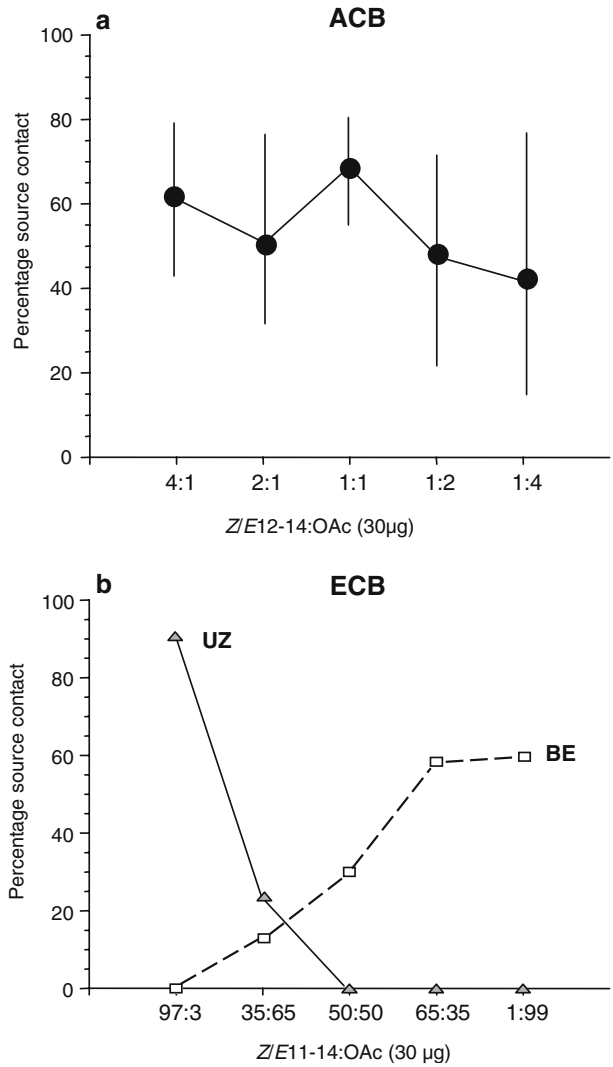

Fig. 2 Percentage source contact by ACB males tested to 30-μg doses of five different ratios (4:1, 2:1, 1:1, 1:2, and 1:4 Z/E; N=63, 67, 64, 67, and 62, respectively) of the ACB pheromone (**a**). There were no significant differences in the response values (χ^2, P>0.05), and lines above and below data points indicate the range of values obtained over 6 d of testing. For comparison, response values for UZ and BE race, ECB males to different ratios of Z:$E$11-14:OAc are presented in subpanel **b**, modified from Linn et al. (1997)

males flew upwind in the greatest percentage to the 1:1 *Z*/*E*12-14:OAc ratio (69%), and not the 2:1 mixture that occurs in the glands (Boo and Park, 1998). The measurement of 50% for source contacts with the 2:1 ratio in this experiment was the lowest measurement for that blend in all of the other experiments (generally in the 60–70% range, see below). For most of the ratios, there was considerable variability in the male preference for blend quality over the 6-d testing period (Fig. 2a).

Comparative data from Linn et al. (1997) for the upwind flight response of UZ and BE ECB males to a range of *Z*/*E*11-14:OAc ratios show that ACB males displayed a much lower preference for odor quality than did ECB males (Fig. 2b). UZ males displayed a high specificity for the 97:3 *Z*/*E*11-14:OAc blend that occurs in the glands, with >90% reaching the source, but only 24% flying upwind to a 35:65 *Z*/*E* ratio, and none to the 50:50 blend. Although BE males also displayed a preference for the identified 1:99 *Z*/*E*11-14:OAc blend, they also reached the source in approximately equivalent proportions with a 65:35 *Z*/*E*11-14:OAc mix, and 12% of the tested males exhibited complete flights to a source, releasing a 35:65 *Z*/*E*11-14:OAc mix. The combined results from experiment 2 and previous studies of ECB suggest that with respect to specificity for odor quantity and quality, the three populations can be ranked: UZ > BE > ACB.

Experiment 3: Are There Rare ACB Males that Respond to the ECB Blends?

Rare males were found in the ACB population that exhibited complete flights to the UZ ECB pheromone source (30 μg, Fig. 3). Of 525 ACB males tested to the UZ blend, 3%

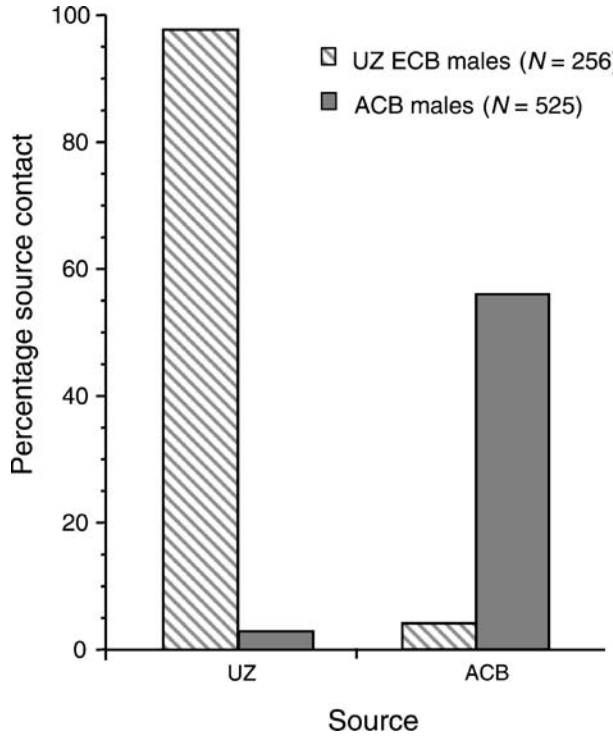

Fig. 3 Percentage source contact of male UZ ECB and male ACB to the 30-μg source of the UZ (97:3 *Z*/*E*11-14:OAc) and 30-μg source of the ACB (2:1 *Z*/*E*12-14:OAc) pheromone blends. For UZ ECB, 256 males were tested to the ACB blend, with 4% (*N*=10) reaching the source. Of the UZ males that did not fly upwind to the ACB blend 213 were then tested to the UZ blend, with 97% (*N*=207) reaching the source. For ACB, 525 males were tested to the UZ blend, with 3% (*N*=16) reaching the source. Of the ACB males that did not fly upwind to the UZ blend 250 were then tested to the ACB blend, with 56% (*N*=140) reaching the source

(16 males) made source contact. These same 16 males also flew upwind to the 30-μg dose of the ACB blend. Additionally, of the 509 ACB males tested to the UZ blend that did not fly upwind to that source, 250 were also tested to the ACB blend, with 56% (N=140) making source contact.

For UZ males, 256 were tested to the 30-μg dose of the ACB blend, with 4% (10 males) reaching the source (Fig. 3). These same 10 males also flew upwind to the 30-μg dose of the UZ blend. Additionally, of the UZ males tested to the ACB blend that did not fly upwind to that source, 213 were also tested to the UZ blend, with 97% (N=207) making source contact.

In a second testing protocol to detect the presence of rare ECB blend-responding ACB males, ACB males were tested to 30-μg doses of the UZ and BE blends, and to 30 μg of the ACB blend. Of 460 males tested, 61% (N=281) made contact with the ACB source; 4% (N=18) reached the UZ and ACB sources; 3% (N=14) reached the BE and ACB sources; and 1% (N=5) flew upwind to all three sources (Fig. 4).

Experiment 4: Effect of *Z*9-14:OAc on Male ACB Response to the ACB Pheromone Blend

The percentage of ACB males flying upwind to the 30-μg dose of the ACB blend was reduced when 1% *Z*9-14:OAc was added to the ACB blend (Fig. 5; Fisher's exact test $P<0.001$, df=1). With the ACB blend alone, 66% (N=129) of the males reached the source, but only 30% did so when 1% *Z*9-14:OAc was added. In comparison, 77% of ECB males from the BE colony reached the source in response to the BE blend (30 μg) alone, but only

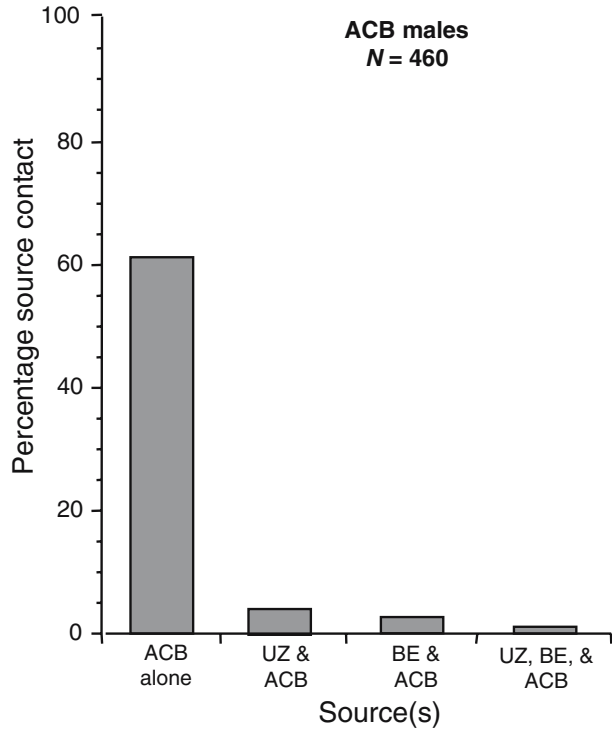

Fig. 4 Percentage source contact by male ACB (N=460) tested in sequence to the BE (1:99 *Z*/*E*11-14:OAc; 30 μg), UZ (97:3 *Z*/*E*11-14:OAc; 30 μg), and ACB (2:1 *Z*/*E*12-14:OAc; 30 μg) pheromone blends. Response values show percentage of males reaching the source of the ACB blend alone (61%, N=281), those reaching the ACB and UZ sources (4%, N=18); those reaching the BE and ACB sources (3%, N=14); and those flying upwind to all three blends (1%, N=5). None of the ACB males flew upwind to one or both of the ECB blends, but not to ACB blend

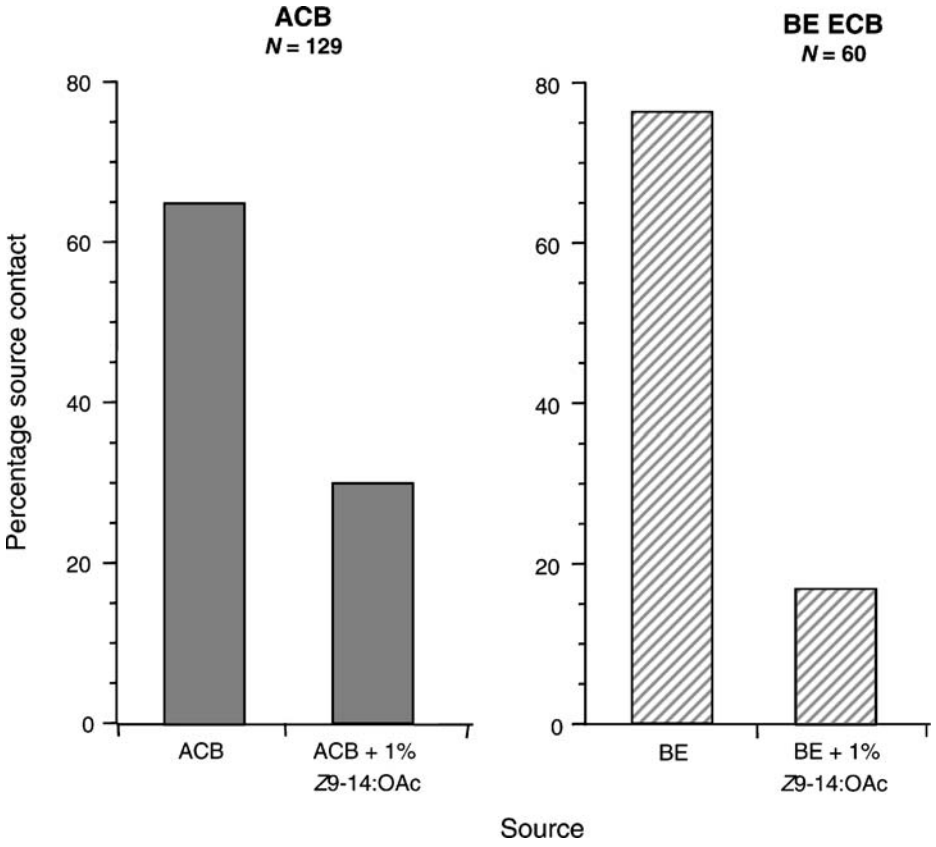

Fig. 5 Percentage ACB (N=129) and BE ECB (N=60) making source contact with the 30-μg ACB (2:1 *Z*/*E*12-14:OAc) or the BE (1:99 *Z*/*E*11-14:OAc) blend and then to the ACB blend with 1% *Z*9-14:OAc added, or the BE blend with 1% *Z*9-14:OAc added

17% did so when 1% *Z*9-14:OAc was added to the blend (Fig. 5; Fisher's exact test $P<0.001$, $df=1$).

Experiment 5: Response of ACB Males to the Combined ACB/ECB Blends

The upwind flight response of ACB males to a 30-μg dose of the ACB blend was unaffected by the addition of the UZ or BE blend (30 μg). With the ACB blend alone, 66% of the tested males (N=64) reached the source, and when the UZ or BE blend was added 68% (N=60; Fisher's exact test $P=0.894$, $df=1$) and 57% (N=65; Fisher's exact test $P=0.368$, $df=1$) of ACB males, respectively, reached the source.

Experiment 6: Response of ACB Males to the ACB Blend with 14:OAc Added

The upwind flight response of ACB males to the ACB blend also was unaffected by the addition of 14:OAc. With the 30-μg dose of the ACB blend alone, 64% of the tested males

(N=55) reached the source, and when 50% 14:OAc was added to the ACB blend, 60% (N=50; Fisher's exact test P=1.000, df=1) reached the source.

Discussion

Our results provide several important findings concerning the response specificity of ACB males for their pheromone, and allow comparisons with previously published results for the closely related ECB. First, there are rare ACB males that respond to their own pheromone and to one or both of the ECB blends. Second, the upwind flight response of ACB males was antagonized by the addition of *Z*9-14:OAc to the pheromone blend, similar to ECB, but was unaffected by addition of either of the ECB blends. Third, ACB males responded in high proportions to a wider range of blend ratios than did ECB males. Fourth, addition of 14:OAc, a previously identified compound in ACB pheromone glands, did not affect the upwind flight response of ACB males to the 2:1 *Z*/*E*12-14:OAc blend.

Rare ACB Males Responding to the ECB Pheromone Blends

Male ACB were found that responded to the ECB UZ blend (4%), the BE blend (3%), and to both the UZ and BE blends (1%), in addition to the ACB blend. The upwind flight percentages are comparable with levels of 3–5% for ECB males of the UZ and BE races that responded to the ACB blend (Linn et al., 2003). The finding that some ACB males can detect and respond to the ECB pheromone blends adds to a growing list of cases involving the presence of broadly responsive individuals in moth populations (Baker, 2002) that have the capacity to process information about pheromone components utilized by related species in an agonistic manner. The adaptive value of being a broad responder is that these individuals have the potential to exploit new communication channels, as has been proposed for the ACB (Baker, 2002; Roelofs et al., 2002). The finding also is not entirely unexpected given the proposed phylogenetic relationships in the *Ostrinia* (Ishikawa et al., 1999a, b). Most of the *Ostrinia* species in Asia, from which the ACB were derived (Roelofs et al., 2002), utilize *Z*/*E*11-14:OAc mixtures (Ishikawa et al., 1999a) and, thus, there presumably exists the genetic capacity in ACB to express the ECB receptors. The finding of rare males in both ECB and ACB also affords the opportunity to explore the peripheral processing of these compounds in rare and normal individuals in both species (Domingue et al., 2006).

Functional Role of *Z*9-14:OAc and the Evolution of Pheromone Communication in *Ostrinia*

Similar to ECB, the upwind flight response of significant numbers of male ACB was antagonized by the addition of *Z*9-14:OAc to the ACB blend. Glover et al. (1989) showed that addition of 1% *Z*9-14:OAc reduced the level of upwind flight by BE ECB males from 73% to 18%, which is similar to the values reported here for BE males (77% reduced to 17%, Fig. 5). The addition of 1% *Z*9-14:OAc to the ACB blend also resulted in a reduction of upwind flight levels by ACB from 66% to 30%.

The observed antagonist effect of *Z*9-14:OAc on ACB upwind flight is of interest because of its impact on discussions on the phylogenetic relationships within *Ostrinia*, as proposed by Ishikawa et al. (1999a, b). In a study of the host plants and sex pheromones of

Ostrinia species in Japan, Ishikawa et al. (1999a) showed that all species use the Δ11 pheromone components, similar to those of ECB, except for the ACB populations, which use the Δ12 pheromone components. It was proposed that the ACB populations are derived from one of the closely related *Ostrinia* populations that use the Δ11 components. Support for this hypothesis comes from a study of the reductases of ACB. Evolution of the unusual pheromone components of ACB should require a change in the desaturase and a change in the specificity of the reductase for Δ12 instead of Δ11 compounds. However, a study of the ACB reductases (Zhao et al., 1995) revealed that their Δ12 reductase was able to convert *Z*11-14:Acid to the corresponding alcohol more efficiently than it did for the Δ12-14:Acids (with which it seemed to favor the *E* isomer). This suggests a possible close linkage to a *Z*11 strain of *Ostrinia*.

In the study by Ishikawa et al. (1999a), two phylogenies were proposed. In the first, based on morphological data (Mutuura and Munroe, 1970), the group III trilobed uncus species group is divided into two subgroups: one containing ACB, ECB, and *Ostrinia orientalis*; and a second containing *Ostrinia scapulalis*, *Ostrinia zaguliaevi*, and *Ostrinia zealis*. In the second proposed phylogeny, based on mitochondrial COII gene sequence analysis (Ishikawa et al., 1999b; Kim et al., 1999), the subgroups of group III are not supported, and ACB is placed basal to the remaining five species. Based on the existing knowledge about the pheromone systems in *Ostrinia*, the following sequence of changes were proposed to have occurred: (1) the most ancestral form (as yet unidentified) most likely utilized *E*11-14:OAc alone, based on the fact that one of the most basal species, *Ostrinia latipennis*, uses only *E*11-14:OH; (2) species evolved that used mixtures of *Z*/*E*11-14:OAc, such as *Ostrinia palustralis*; (3) species evolved using *Z*/*E*11-14:OAc + *Z*9-14:OAc as a three-component blend (*O. zaguliaevi* and *O. zealis*); (4) species evolved, such as ECB and *O. scapulalis*, in which *Z*9-14:OAc has switched functionality and is an antagonist component of the communication system. Within this scheme, the ACB is hypothesized to be ancestral to the group that includes *O. zaguliaevi* and *O. zealis*, that is, before the incorporation of *Z*9-14:OAc into the pheromone as an agonist component, and in agreement with the second phylogeny based on COII gene sequence analysis. However, if this scheme is correct, then our result, showing that *Z*9-14:OAc also is an antagonist of upwind flight in ACB, implies that the role of *Z*9-14:OAc arose earlier than previously thought, and further that the functionality of this component has switched more than once. Alternatively, our result suggests that species using the three-component pheromone constitute a group that is ancestral to ACB, ECB, and *O. scapulalis* in which *Z*9-14:OAc is an antagonist. This hypothesis is more in agreement with the phylogenetic relationships based on morphological data (Mutuura and Munroe, 1970; Ishikawa et al., 1999a), and the idea that agonist functionality precedes the emergence of antagonism in the evolution of pheromone systems (Linn and Roelofs, 1995; Baker, 2002).

Finally, the addition of the ECB blends did not affect the upwind flight of ACB males to the ACB blend. This result supports the hypothesis that the lack of response of ACB males to the ECB pheromone in experiment 3 was not because of antagonistic properties of the ECB pheromone components, but rather threshold differences between rare ECB-responding ACB males compared with nonresponding ACB males to the ECB blends.

Response Specificity and Additional Pheromone Components for ACB

Male ACB displayed a relatively low level of specificity with respect to blend quality, compared with ECB, evidenced by the similar levels of upwind flight and source contact

(45% to 66%) that occurred with a range of ratios (4:1 to 1:4) of *Z*/*E*12-14:OAc, and the variability in response over the course of the experiments. Previous studies with ECB (Figs. 1b and 2b; Linn et al., 1997) showed that UZ males exhibited a greater specificity for blend ratio than did BE males, with no UZ males flying upwind to a 50:50 ratio. BE males responded to a wider range of ratios (1:99 to 35:65 *Z*/*E*11-14:OAc). With respect to odor quantity, lower specificity was also evidenced by the fact that the maximal level of upwind flights by ACB males was 66%, a value that is considerably less than routinely observed with the UZ ECB males (>90%; see Linn et al., 1997, 2003), but comparable to maximal levels observed with the BE ECB race to their 1:99 *Z*/*E*11-14:OAc mixture (65% to 70%).

Results of other studies with ACB suggest that throughout Asia a range of *Z*/*E*12-14:OAc mixtures are produced by females and result in trap captures of males (Ando et al., 1980; Klun et al., 1980; Cheng et al., 1981; Yeh et al., 1989; Boo and Park, 1998). Field trapping studies and analysis of female pheromone glands at sites in Japan led Huang et al. (2002) to hypothesize that there was a pheromone polymorphism, with populations in the north preferring a blend containing 36% to 39% *E*12-14:OAc, and in the south 44% *E*12-14:OAc. Analysis of field trapping studies in South Korea showed that high numbers of moths were captured with ratios from 3:1 to 1:3 *E*/*Z*12-14:OAc (Boo and Park, 1998).

One explanation for the relatively lower response levels and lack of specificity in ACB is that because the pheromone is made up of unusual Δ14 compounds, there is less pressure from interspecies encounters that could lead to mating mistakes, as might occur in other *Ostrinia* that utilize Δ11 compounds. It also could be the case that other pheromone components are involved in the communication system. Boo and Park (1998) reported the presence of 14:OAc in hexane extracts of female abdominal tips from 2- to 3-d-old females that contained a mean ratio of 0.74:1:1.36 for 14:OAc, *E*12 and *Z*12-14:OAc, but the compound did not elicit an EAG response and was not used in field trials. The field trials showed that among 12 blends tested, the greatest capture occurred with the 2:1 *Z*/*E* mix, but as noted above there was significant variability among sites and in the range of blends capturing high numbers of moths. At one site, a ginger field, maximal captures were reported with a 5:1 *E*/*Z* mixture. Kou et al. (1992) also reported the presence of 14:OAc in the pheromone gland analysis of moths in Taiwan. However, in field trials there was no difference between the three- and two-component mixtures, or a 3:2 *Z*/*E*12 formulation identified in Japan (Ando et al., 1980). Finally, 14:OAc was reported in pheromone gland tips of females in China (Cheng et al., 1981), but when added to the 1:1 *Z*/*E*12 mix at the reported gland content (1.8×sum of isomers), it resulted in reduced trap capture. Our results also suggest that lower levels of upwind flight were not because of a lack of 14:OAc as a potential pheromone component.

Acknowledgements We thank Kathy Poole for help in maintaining the ACB and ECB colonies, and Satoshi Nojima and Shannon Olsson for preparing the solutions for flight tunnel tests. The project was funded by NSF IBN #034340.

RAPID COMMUNICATION

Chemical Deterrence of a Cyanobacterial Metabolite against Generalized and Specialized Grazers

Edwin Cruz-Rivera · Valerie J. Paul

Abstract Pitipeptolide A is the major secondary metabolite in a persistent population of the cyanobacterium *Lyngbya majuscula* from Guam. Because this cyanobacterium is of low preference to many sympatric consumers, we tested the hypothesis that this compound acted as a chemical defense. Pitipeptolide A was deterrent to urchins, two species of amphipods, and small herbivorous crabs, whereas it did not deter feeding by the sea hare *Stylocheilus striatus*, which readily consumes cyanobacteria. Although our comparison included various small invertebrates, which are often tolerant to algal chemical defenses, this cyanobacterial compound proved deterrent at natural concentrations to all but one of the consumer species tested. Thus, the production of defensive secondary metabolites is likely related to the common occurrence of *L. majuscula* on this coral reef despite the abundance of diverse grazers.

Keywords Chemical defense · Cyanobacteria · Guam · *Lyngbya majuscula* · Mesograzers · Pitipeptolide

Introduction

Marine benthic filamentous cyanobacteria have provided natural products chemists with a wealth of novel compounds. This is particularly true for cyanobacteria of the genus *Lyngbya* (Paul et al., 2001). *In vitro* activities of many of these compounds have been studied as part of screening programs in drug discovery, and a number of potent toxins are known. Yet, out of hundreds of compounds isolated and purified, few studies have addressed the ecological roles (Paul et al., 2001; Cruz-Rivera and Paul, 2002).

Because these benthic cyanobacteria can form extensive blooms that can have detrimental effects on marine life, fisheries and (sometimes) human health, the study of bottom–up *versus* top–down controls of these blooms is important (e.g., Thacker et al., 2001). Herbivory is a strong top–down ecological force controlling the structure and dynamics of marine macroalgae and has favored the evolution of a variety of chemical defenses in seaweeds (Hay and Steinberg, 1992; Paul et al., 2001). Some evidence suggest that chemical defenses could also mediate the persistence of benthic cyanobacteria in areas of high herbivory such as coral reefs (Paul et al., 2001; Cruz-Rivera and Paul, 2002). However, tests of individual compounds against diverse grazers are scarce. This is important because studies testing crude extracts alone (e.g., Cruz-Rivera and Paul, 2002) cannot discern whether the observed deterrence is the result of individual metabolites, or of additive or synergistic interactions among different chemicals. Also, since intraspecific variation in the production of secondary metabolites is well documented for cyanobacteria (Paul et al., 2001), testing individual compounds might provide information on redundancy of roles for diverse compounds endemic to specific populations of the same cyanobacterial species.

In this study, we test a natural role of the major secondary metabolite from a persistent population of the cyanobacterium *Lyngbya majuscula* as a feeding deterrent to sympatric consumers from Guam. We hypothesize that chemical defenses allow mats of this cyanobacterium to persist in an area of high herbivore density and diversity.

Methods and Materials

Lyngbya majuscula was collected from Piti Bomb Holes in Guam, Mariana Islands (13°30′ N, 144°45′E). Large mats of the cyanobacterium were collected by snorkeling, brought to the laboratory, freeze-dried, and extracted in 1:1 ethyl acetate/methanol. After extracting ×3, crude extract was concentrated by using rotary evaporation and partitioned between ethyl acetate and water. The concentrated organic phase was separated by Si Bond-Elut column, and pitipeptolide A eluted with hexane/ethyl acetate (1:3). The mixture was dried and further separated by semipreparative normal-phase HPLC (Econosil Silica) by using an isocratic system of hexanes/ethyl acetate (3:7) (Luesch et al., 2001).

Artificial diets were made following the methods described in Hay et al. (1998), with 4 g of freeze-dried, ground *Ulva* (=*Enteromorpha*) *clathrata*, 0.72 g of agar, and 36 ml deionized water per batch of food. *Ulva* spp. (a number of which were formerly classified under the genus *Enteromorpha*) are routinely used in marine chemical ecology for testing the palatability of compounds because of their lack of chemical or structural defenses that might interact with tested metabolites (Hay et al., 1998). The species used here is readily consumed by a variety of grazers from Guam (Cruz-Rivera and Paul, 2002). Treatment foods were made by coating *U. clathrata* with pitipeptolide A at the natural concentration of 0.8% of dry mass (Pangilinan, 2000). This was accomplished by dissolving the compound in enough ethyl ether to thoroughly soak the powdered alga and then removing the solvent with rotary evaporation. Control foods were made with *U. clathrata* treated with ethyl ether alone. Control or treatment *Ulva* were homogeneously mixed with hot agar and poured individually onto plastic screen mesh to produce food strips. Upon cooling, food-covered screen mesh was cut to desired sizes. For small consumers, the foods were lightly pressed onto strips of screen mesh. For urchins, which consume larger amounts, foods were poured onto molds that were pressed against plastic screen (Hay et al., 1998). Consumption was quantified as the number of squares cleared of food by the grazers.

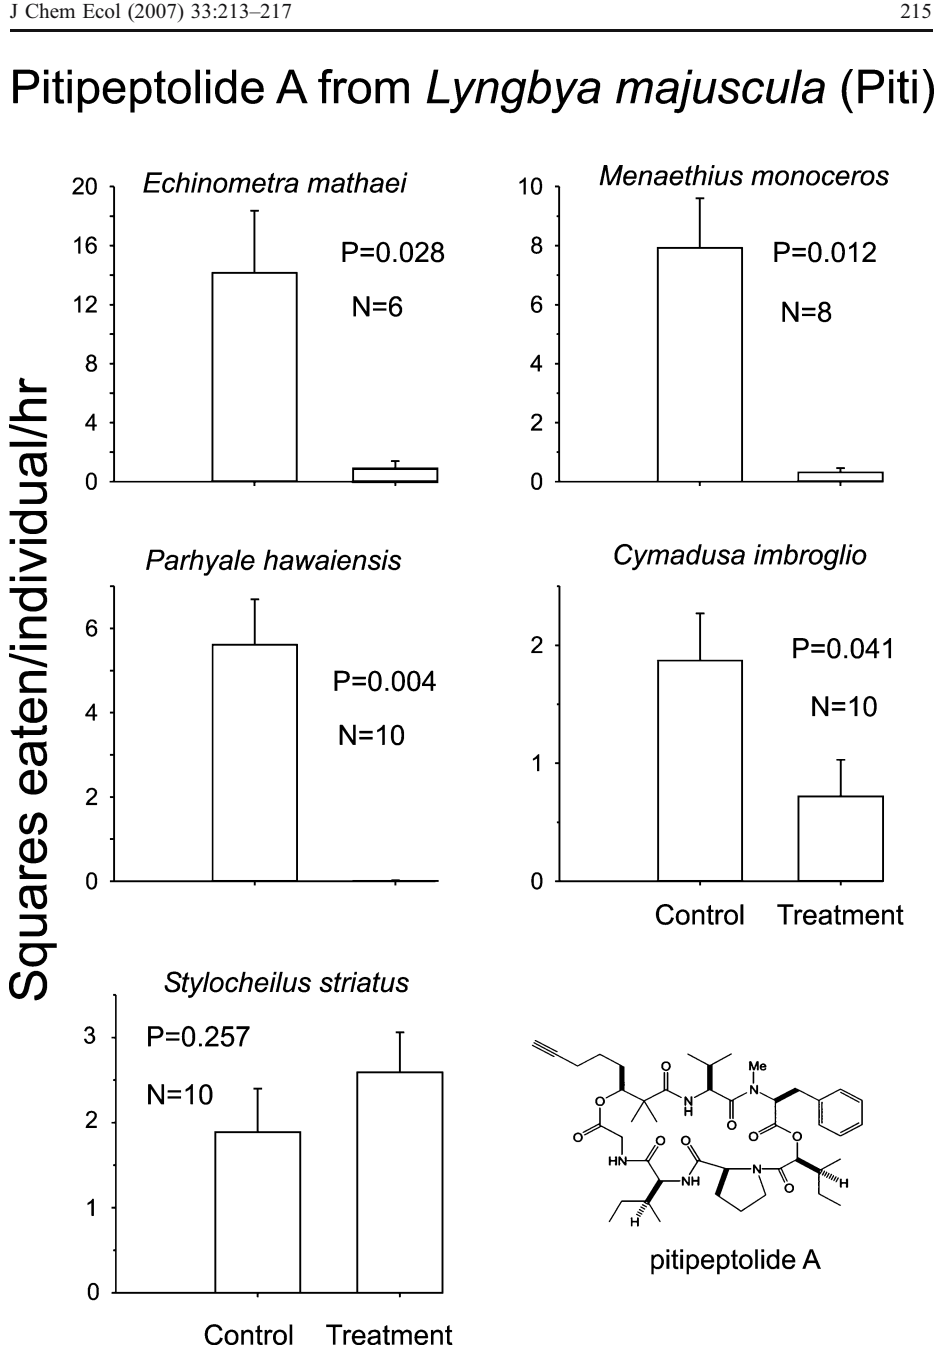

Fig. 1 Consumption of artificial diets containing or lacking pitipeptolide A by five invertebrate consumers from Guam. Bars represent mean (±1 SE) amount of food eaten by individuals per hour (see Methods and Materials). Analyses are by paired *t*-tests

Treatment and control foods were simultaneously offered to five invertebrate consumers: the sea urchin *Echinometra mathaei*, the small majid crab *Menaethiusmonoceros*, the gammaridean amphipods *Parhyalehawaiensis* and *Cymadusa imbroglio*, and the small sea hare *Stylocheilus striatus* (= *S. longicauda*; see Rudman, 1999). Grazers were obtained from algal and cyanobacterial mats collected by snorkeling at Piti Bomb Holes, Pago Bay, and from flow-through tanks at the University of Guam Marine Laboratory. The tanks receive unfiltered water from the adjacent reef, and organisms continuously recruit from the field.

Experiments with urchins were conducted in flow-through 20-l tanks (N=10). For all other smaller consumers, 16 cm (diam)×6 cm (height) dishes were used (N=10). Replicates contained single individuals of each consumer species except for the amphipods. Because *P. hawaiensis* would invariably form precopulatory pairs, and mate guarding could influence feeding behavior, we used four males or four females per replicate. For *C. imbroglio*, the smallest of the consumers tested, five individuals were placed in each replicate. Experiments were monitored over 24 hr, and replicates were scored when more than 50% of either treatment or control foods were eaten. Paired t-tests were used to analyze data (squares eaten/individual/hr). Replicates in which no food was consumed after 24 hr were eliminated from the analyses as they offered no information of feeding preference.

Results

Pitipeptolide A at natural concentrations deterred feeding in all but one of the invertebrates grazers tested. The urchin *E. mathaei*, the small algal-dwelling crab *M. monoceros*, and the amphipods *P. hawaiensis* and *C. imbroglio* all consumed significantly more of the control algal food (without pitipeptolide A) than of the treatment food (P=0.004–0.41, Fig. 1). The exception to this pattern was the small sea hare, *S. striatus*, which was not deterred by natural concentrations of the compound (P=0.257, Fig. 1).

Discussion

While hundreds of compounds have been isolated from marine benthic cyanobacteria, and *L. majuscula* in particular, only a handful of studies have addressed the ecological roles of cyanobacterial secondary metabolites (reviewed in Paul et al., 2001). In this work we demonstrate a defensive role for the main secondary metabolite produced by a specific *L. majuscula* population from Guam. Pitipeptolide A was deterrent at natural concentrations against urchins as well as three smaller algal/cyanobacterial-dwelling grazers. Previous studies have shown that *L. majuscula* from this population is also a low preference food for sympatric fishes, suggesting that its chemical defenses might act against a broad array of consumers (Cruz-Rivera and Paul, 2002).

The exception to this pattern of deterrence was the small gastropod *S. striatus*. This sea hare has been collected from at least six cyanobacterial genera and will readily consume cyanobacteria (Cruz-Rivera and Paul, 2002, 2006). It will also accumulate compounds from *L. majuscule*, and their role as potential sequestered chemical defenses has been discussed (Paul et al., 2001; Capper et al., 2005). While it could be expected that this grazer would not be deterred by *Lyngbya* extracts or compounds, studies have shown that different *L. majuscula* compounds and their varying concentrations may stimulate or deter feeding by *S. striatus*, which does not appear to be completely adapted to *L. majuscula* secondary

metabolites (Paul et al., 2001; Cruz-Rivera and Paul, 2002). In this study, however, the natural concentration of pitipeptolide A did not deter feeding by this sea hare.

Other consumers tested here are more generalized than *S. striatus* and will eat macroalgae, sometimes as much as cyanobacteria (Cruz-Rivera and Paul, 2002, 2006). Mesograzers such as the amphipods and crabs used here are often better adapted to secondary metabolites of macroalgae. Living on chemically defended hosts can reduce predation from fishes, although closely related mesograzers can vary greatly in their ability to use a chemically defended host (Hay and Steinberg, 1992; Paul et al., 2001). It is possible that similar advantages are experienced by small consumers preferring, or specializing on, chemically defended cyanobacteria as *S. striatus* does (Cruz-Rivera and Paul, 2002, 2006). If so, then tropical benthic cyanobacteria could fill similar niches as chemically defended macroalgae (as food and shelter) for small marine consumers that have adapted to live, and feed, on benthic cyanobacterial mats (Cruz-Rivera and Paul, 2002).

Acknowledgments Funding for this study was provided by an NIH Postdoctoral Supplement (to E. Cruz-Rivera) to NIH grant CA 53001 (J. Horwitz, P.I.). We thank the reviewers whose comments improved this manuscript. This is contribution # 589 of the University of Guam Marine Laboratory and contribution # 670 from the Smithsonian Marine Station at Fort Pierce.

RAPID COMMUNICATION

Lichen Substances Affect Metal Adsorption in *Hypogymnia physodes*

Markus Hauck · Siegfried Huneck

Received: 1 October 2006 / Accepted: 13 November 2006 /
Published online: 29 November 2006

Abstract Lichen substances are known to function as chetators of cations. We tested the hypothesis that lichen substances can control the uptake of toxic metals by adsorbing metal ions at cation exchange sites on cell walls. If true, this hypothesis would help to provide a mechanistic explanation for results of a recent study showing increased production of physodalic acid by thalli of the lichen *Hypogymnia physodes* transplanted to sites with heavy metal pollution. We treated cellulose filters known to mimic the cation exchange abilities of lichen thalli with four lichen substances produced by *H. physodes* (physodic acid, physodalic acid, protocetraric acid, and atranorin). Treated filters were exposed to solutions containing seven cations (Ca^{2+}, Cu^{2+}, Fe^{2+}, Fe^{3+}, Mg^{2+}, Mn^{2+}, and Na^{+}), and changes to the solution concentrations were measured. Physodalic acid was most effective at influencing metal adsorption, as it increased the adsorption of Fe^{3+}, but reduced the adsorption of Cu^{2+}, Mn^{2+}, and Na^{+}, and to a lesser extent, that of Ca^{2+} and Mg^{2+}. Reduced Na^{+} adsorption matches with the known tolerance of this species to NaCl. The results may indicate a possible general role of lichen substances in metal homeostasis and pollution tolerance.

Introduction

Lichens are notable for the production of unique lichen substances, including more than 800 aliphatic, cycloaliphatic, aromatic, and terpenic compounds (Huneck and Yoshimura, 1996). Lichens are also sensitive to a variety of air pollutants and are widely used as

biomonitors of air quality. Recently, Białońska and Dayan (2005) linked lichen secondary chemistry with the use of lichens as biomonitors in a study of the common lichen *Hypogymnia physodes*. This lichen has often been employed as a model species in ecophysiological and biomonitoring studies because of its abundance and its moderate sensitivity to SO_2 and heavy metals. In Europe, *H. physodes* has declined in many areas with significant pollutant load. Białońska and Dayan (2005) found that thalli of *H. physodes* transplanted to areas polluted with heavy metals and inorganic S compounds exhibited significantly lower concentrations of atranorin, physodic acid, and 3-hydroxyphysodic acid and significantly higher concentrations of physodalic acid. They postulated that physodalic acid might participate somehow in the stress response of *H. physodes* to toxic effects of heavy metals and acidic inorganic S compounds. This was the first time that the content of lichen substances had been linked to pollution tolerance. However, the authors did not provide any mechanistic hypothesis to explain any such relationship.

Our hypothesis is that the presence of lichen compounds significantly reduces toxic effects of heavy metals to living cells by controlling their extracellular adsorption and thereby influencing their intracellular uptake. Specifically, we tested the hypothesis that physodalic acid affects the adsorption of metal ions at cation exchange sites and thereby contributes to the heavy metal tolerance of *H. physodes*. To test our hypothesis, we used cellulose filters coated with physodalic acid and other lichen substances of *H. physodes* (atranorin, physodic acid, and protocetraric acid) as a standardized model system containing numerous hydroxyl groups as cation exchange sites (Hauck et al., 2007). Lichen cell walls and exopolysaccharide matrices harbor many hydroxylic and carboxylic binding sites for cations, from which delayed intracellular uptake is possible (Hauck et al., 2006). Metal ions chosen for the study included the transition metals Cu^{2+}, Fe^{2+}, Fe^{3+}, and Mn^{2+} and the alkaline earth metals Ca^{2+} and Mg^{2+}, which (1) occurred in measurable concentrations in the stemflow of trees with *H. physodes* in ecosystem studies conducted in Europe and North America (Hauck, 2003); (2) are essential macro- or micronutrients; and (3) are, in the case of the transition metals, toxic to *H. physodes* when concentrations significantly exceed the amount required for nutrition (Hauck, 2003). The alkali metal Na^{+} was studied in addition, as it is often the most common metal in precipitation.

If our hypothesis is correct, the presence of lichen compounds on cellulose filters will significantly alter the adsorption of metal cations from solution. We were especially interested in the effects of physodalic acid on cation uptake inasmuch as this compound was specifically mentioned by Białońska and Dayan (2005) to be involved in the stress response of *H. physodes*.

Methods and Materials

Hypogymnia physodes (L.) Nyl. is a common foliose lichen of the temperate and boreal zones of the northern hemisphere, which primarily occurs as an epiphyte (McCune, 2002). Seven lichen substances have been identified in *H. physodes* (McCune, 2002), which are either located in the cortex (atranorin, chloroatranorin) or in the medulla (physodic, 3-hydroxyphysodic, physodalic, protocetraric, 2′-*O*-methylphysodic acids). The two latter substances are found only in minor amounts (McCune, 2002). The cortical lichen substances of *H. physodes* are depsides, whereas the medullary ones belong to the depsidones (Huneck and Yoshimura, 1996).

Pure atranorin, physodic acid, physodalic acid, and protocetraric acid from the collection of S. Huneck were dissolved in acetone (2.5 mM) and applied to ash-free cellulose filter

paper (Blue Ribbon Filters, Schleicher & Schuell, Dassel, Germany) by shaking filter strips (ca. 20 cm^2, 160 mg) in the lichen substance solution for 1 hr. Cellulose filters consist of randomly interlaced fibers that are littered with exchange sites that bind to metal ions, similar to the cell wall surfaces of lichens (Hauck et al., 2007). Untreated filter strips were used as controls. Two strips of impregnated filters per replicate were exposed for 1 hr to 25 ml of micromolar solutions of $CuCl_2$, $FeCl_2$, $FeCl_3$, $MnCl_2$, $CaCl_2$, $MgCl_2$, or Na_2SO_3; the concentrations applied (Table 1) referred to the optimum measuring range of the AAS (Vario 6, Analytik Jena, Jena, Germany; Cu, Fe, Mn, Ca, Mg) or inductively coupled plasma-atomic emission spectrometry (Spectraflame, Spectro Analytical Instruments, Fitchburg, MA, USA; Na) used for chemical analysis. After incubation, the filter paper was removed with forceps and metal concentrations in the solution were analyzed. The experiment was run in five replicates. Statistical analyses were conducted with SAS 6.04 software (SAS Institute, Cary, NC, USA). Duncan's multiple range test was applied to test for significance of differences between means after testing for normal distribution with the Shapiro–Wilk test.

Results

For all but one of the cations studied, the presence of lichen compounds on filter strips resulted in significantly reduced removal of the cations from solution, indicating that lichen compounds prevent the binding of cations to exchange sites on the filters. Physodalic acid was especially inhibitory inasmuch as filters coated with this lichen compound adsorbed from solution significantly less Cu^{2+}, Mn^{2+}, Na^{+}, Ca^{2+}, and Mg^{2+} than control samples of filters not soaked with a lichen substance (Table 1). Adsorption of Mn^{2+} was also reduced by protocetraric acid, as was that of Ca^{2+} by atranorin. All studied lichen substances also inhibited the adsorption of Na^{+}. Lichen compounds caused significantly enhanced adsorption of only one metal cation, and this was Fe^{3+}. While the concentrations of Fe^{2+}

were not affected by any of the lichen substances, Fe^{3+} was nearly completely removed from solution by filters coated with physodalic acid. Physodic and protocetraric acids significantly increased removal of Fe^{3+} from the incubation medium by 43–44% (Table 1).

Discussion

Our results provide a mechanistic explanation for the hypothesis of Białońska and Dayan (2005) that enhanced synthesis of physodalic acid in polluted areas is a stress response of *H. physodes* to heavy metal pollution. High ambient concentrations of both Cu^{2+} and Mn^{2+} have been shown to limit the abundance of *H. physodes* in the field (Hauck, 2003; Hauck and Paul, 2005). An inhibition of the adsorption of these ions in the apoplast would, therefore, increase the tolerance of *H. physodes* to Cu^{2+} and Mn^{2+}.

The strong reduction of the Fe^{3+} concentration in the incubation medium by physodalic acid suggests that this lichen substance forms complexes with Fe^{3+}. Evidence for the existence of such complexes with Fe^{3+} has been found for several lichen substances (Engstrom et al., 1980; Hauck et al., 2007) belonging, like physodic acid, to the depsidones (fumarprotocetraric and norstictic acids), the depsides (divaricatic acid), the pulvinic acid derivatives (pulvinic and rhizocarpic acids), or the anthraquinones (parietin). Complex formation with transition metals has also been established for other combinations of lichen substances and metal ions (e.g., Cu^{2+}) and was mostly discussed in the light of immobilization of potentially toxic ions (Takani et al., 2002).

Occurrence of Fe^{3+}-adsorbing lichen substances in lichens of sites with low Fe availability, but lack in most lichen species of Fe-rich substrate, suggests that Fe^{3+} bound in complexes with lichen substances is subsequently taken up into the cytoplasm (Hauck et al., 2007). The only Fe^{3+} adsorbing lichen substances known, so far, from lichen species of Fe-rich substrate, viz. norstictic and rhizocarpic acids, simultaneously reduce the adsorption of Fe^{2+} (Hauck et al., 2007). Increased uptake of Fe^{3+} in *H. physodes* by physodalic acid and other lichen substances would increase its tolerance to Mn^{2+}, as Mn-related damage depends on the Mn/Fe ratio (Hauck and Paul, 2005).

If our hypothesis is correct, the increased production of physodalic acid by *H. physodes* in polluted areas observed by Białońska and Dayan (2005) is a response to pollution stress. However, the reduced concentration of other lichen substances (atranorin, physodic acid, and 3-hydroxyphysodic acid) also requires explanation. The decline of physodic acid in thalli of *H. physodes* transplanted to sites with heavy metal pollution could be due to conversion into the chemically related physodalic acid. Protocetraric acid, which is even more closely related to physodalic acid than physodic acid (Huneck and Yoshimura, 1996), was not included in the analyses of Białońska and Dayan (2005) and should be investigated for possible stress responses. Inhibition of Na^{+} adsorption by all investigated lichen substances (Table 1) agrees with the known tolerance of *H. physodes* to NaCl (Punz, 1979).

The putative ability of physodalic acid to increase heavy metal tolerance would explain why *H. physodes* was less subject to pollutant-caused declines in the past than other European *Hypogymnia* species, including *Hypogymnia farinacea*, *Hypogymnia tubulosa*, and *Hypogymnia vittata*, as *H. physodes* is the only European species with physodalic acid (McCune, 2002). The assumed protective effect of physodalic acid in *H. physodes* is probably limited because this substance is primarily produced by the fungal hyphae of the medulla and the algal layer (McCune, 2002), while the cortical atranorin did not affect the adsorption of transition metals (Table 1). The absence of a protective lichen substance from the cortex would explain the moderate heavy metal tolerance of *H. physodes* (Hauck, 2003;

Hauck and Paul, 2005). *Lecanora conizaeoides*, a markedly Mn-tolerant lichen (Hauck and Paul, 2005), contains the depsidone fumarprotocetraric acid in the entire thallus. This substance also reduces Mn^{2+} adsorption and is even more effective at adsorbing Fe^{3+} than physodalic acid (Hauck et al., 2007). Though our experiment suggests a protective role of physodalic acid, it has to be kept in mind that adsorption rates on fungal and algal cell walls might differ from that of cellulose fibers. Moreover, other mechanisms including immobilization in polyphosphate bodies and phytochelatines are involved in the heavy metal tolerance of lichens (Hauck and Paul, 2005).

Acknowledgments The study was supported by a grant of the Deutsche Forschungsgemeinschaft to M. Hauck (Ha 3152/8-1). Inductively coupled plasma analyses were carried out in the Institute of Soil Science and Forest Nutrition, University of Göttingen (Dr. Norbert Lamersdorf). Dr. James D. Lawrey, George Mason University, Fairfax, VA, is warmly thanked for extensive comments on the manuscript and for checking the English language.

Abstract Benzoxazolinone detoxification is similar in plants grown under sulfur deficiency conditions and in control plants grown with an optimal S supply. However, when S-deficient plants were treated with metolachlor before benzoxazolin-2(3H)-one (BOA) incubation, detoxification was reduced, as indicated by a lower accumulation of the detoxification products BOA-6-*O*-glucoside and glucoside carbamate and by a loss of BOA-6-OH glucosyltransfease activity. Root colonizing microorganisms and the endophytic fungus *Fusarium verticillioides* participated in benzoxazolinone detoxification by converting the compound to 2-acetamidophenol (AAP) or *O*-hydroxyphenyl malonamic acid (OHPMA), a process accompanied by the appearance of phenoxazinone. Maize roots, however, absorbed AAP and OHPMA only in traces. Absorbed traces of OHPMA stimulated maize radicle growth, and traces of AAP stimulated cress. Phenoxazinone inhibited the growth of cress radicles at

concentrations higher than 500 μM, whereas maize radicles were hardly affected. *F. verticillioides* did not convert benzoxazolinone to any known microbial degradation product when the medium of maize seedlings was inoculated with the fungus under sterile condition. Plant–fungus interactions seem to be important in plant survival of allelopathic attacks. This study points to a complicated network of allelopathic interactions that are influenced by biotic and abiotic factors, including herbicides.

Introduction

Allelopathic interactions between plants are known to be complex depending on both biotic and abiotic factors that influence them. Soil microorganisms are an important component of allelopathic interactions, underlying environmental influences that change seasonally. Studies of allelopathy under field conditions, therefore, often involve uncontrolled variables and often produce unpredictable or irreproducible results, leading to misinterpretations. The use of model systems reduces the complexity and allows a more precise and defined characterization of molecular events and responses of a plant on treatments with allelochemicals. Current opinion in allelopathy holds that the inhibitory or stimulating effects of allelochemicals become more evident when combined with additional biotic and abiotic stress situations experienced by plants during development (Einhellig 2003).

Benzoxazinones, secondary products of several monocots such as rye, wheat, and maize and of some dicots such as several *Lamium* species, are biologically active compounds that are relatively phytotoxic (Gierl and Frey, 2001; Sicker and Schulz, 2002; Alipieva et al., 2003; Macias et al., 2005). As aglucones, they become unstable and are converted to benzoxazolin-2 (3H)-ones (BOAs), which have a reduced phytotoxicity in comparison to the original compounds. The benzoxazolin-2(3H)one, for instance, is a known allelopathic compound thought to be mainly responsible for the phytotoxic properties of rye mulch that suppresses several weeds common in North America (Barnes et al., 1986). The mechanism of action of the benzoxazolinones as phytotoxins is unknown, but effects have been found on *in vivo* protein and nucleic acid synthesis. However, some plants are able to overcome the negative effects because they have developed mechanisms to detoxify the compounds. In *Arabidopsis thaliana*, for instance, 158 genes are induced by BOA, many of them potentially involved in detoxification processes (Baerson et al., 2005).

Benzoxazolin-2(*3H*)-one has been used in model systems to elucidate the detoxification capacity of monocotyledonous and dicotyledonous weeds and crops found in European field communities (Schulz and Wieland, 1999, Sicker et al., 2000). Existing variations in the detoxification efficiencies are thought to be jointly responsible for the differences often observed among dicots and monocots in their sensitivity to BOA. The most important detoxification product accumulating temporarily in cereals and several other Poaceae after BOA incubations was identified as glucoside carbamate (Sicker et al., 2001; Wieland et al., 1999) (Fig. 1). This product, not toxic to higher plants such as cress up to 1 mM concentrations, can be subsequently modified in maize to the corresponding gentiobioside or to 1-(2-hydroxyphenylamino)-6-*O*-malonyl-1-deoxy-β-glucoside 1,2-carbamate (malonyl glucoside carbamate (Hofmann et al., 2006). A second important metabolite has been identified as BOA-6-*O*-glucoside (Wieland et al., 1998; Sicker et al., 2003; Schulz et al., 2006). This compound is the major detoxification product found in most of the dicots, where glucoside

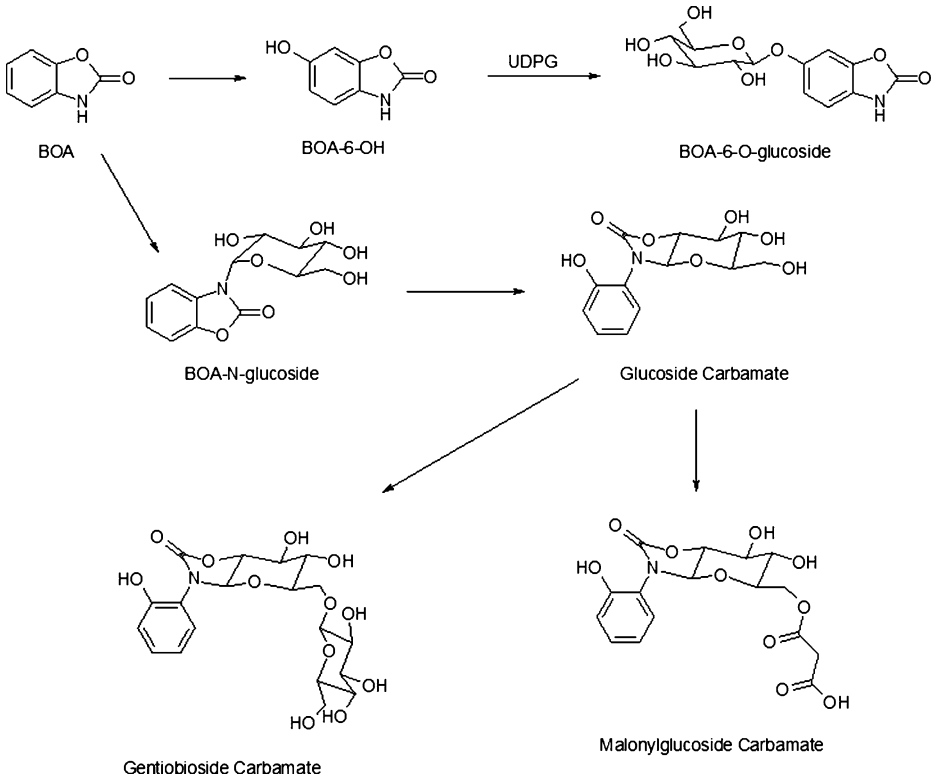

Fig. 1 Detoxification pathways in maize roots

carbamate was produced only in traces or not at all. Accumulation of extractable detoxification products was transient in maize. At least a portion of them was exuded by the roots following partial or complete BOA absorption or after a change to BOA-free medium. The roots are the most important plant organ for BOA detoxification, and shoots are only involved when roots are overloaded. Among the 30 species tested for BOA detoxification capacity, *Zea mays* was the most effective (Schulz and Wieland, 1999). Application of 125 μmol BOA to 30 6-day-old seedlings never led to an accumulation of any detoxification products in the shoot.

Maize was chosen to address the question whether BOA detoxification is affected when additional stress conditions act on the plant. With regard to induced or up-regulated enzymes important for detoxification reactions, such as glucosylation, protein synthesis should be a critical process in the efficiency of detoxification. As sulfur deficiency affects protein synthesis, it was chosen as a stress condition that might influence BOA detoxification. As an additional stress factor, treatment with the synthetic herbicide metolachlor was performed.

Methods and Materials

Plant Cultivation Maize (*Zea mays* L. cv. Nicco) seeds were planted 2 cm deep in pots (diameter 17 cm) filled with perlite (Perligran G; Germany; granulometric composition: 0–3 mm). Seven days after sowing, extra plants were removed to leave four uniform seedlings

per pot. Plants were grown in a greenhouse at 20°C during the light period and a minimum temperature of 16°C at night. Pots were watered daily with diluted nutrient solution. Over a period of 2 wk, the following amounts of fertilizers were applied: 1,660 mg K (K_3PO_4, K_2SO_4, or K_2HPO_4), 654 mg P (K_3PO_4, Na_2HPO_4, NaH_2PO_4, or K_2HPO_4), 500 mg N (NH_4NO_3), 103 mg Mg ($MgCl_2$), 100 mg Fe ($FeCl_3$), 20 mg Mn ($MnCl_2$), 20 mg Zn ($ZnCl_2$), 20 mg Cu ($CuCl_2$), 5 mg B (H_3BO_3), 5 mg Mo (Na_2MoO_4), 5 mg Co ($Co(NO_3)_2$), and 1,000 mg Ca ($CaCO_3$) per pot. Two different S-levels according to the fertilized amount of S per pot were applied: 0 mg S (S_0) and 200 mg S (S_{200}) as SO_4^{2-}. Plants were grown for 3 wk.

In one series of experiments, S_0 and S_{200} plants were treated with metolachlor, (DualGold®; 0.4% v/v spray concentration) 3 wk after sowing. Another application was given 2 d later. Treatment with BOA was started 24 hr after the second metolachlor application.

For incubations, experiments with 2-acetamidophenol (AAP) or *O*-hydroxyphenyl malonamic acid (OHPMA) and for fungus identification, maize seedlings were grown aeroponically on cheesecloth. Seedlings (5 d old) were used for uptake analysis and for cultivation on agar to isolate the fungus.

Sulfur Determination in Seeds After drying seeds of *Zea mays* at 90°C and grinding with an attrition mill, the S contents were analyzed by a C/N/S-Elemental-Analyser (Euro EA).

Incubation and Extraction of Maize Plants with Allelochemicals Plants were carefully removed from the pots and incubated with 500 μM BOA (Sigma) incubation medium as described by Schulz and Wieland (1999) for 24 hr. After incubation, the roots were harvested, mortared with quartz sand, and extracted with 50% methanol. Homogenates were centrifuged at 20,000×*g* for 15 min and at 4°C. Supernatants were used for high performance liquid chromatography (HPLC) analysis. The incubation medium was treated with ethyl acetate, the resulting organic phases and the water phases were evaporated to dryness, and the residues were dissolved in methanol. After centrifugation, the solutions were analyzed by HPLC.

For incubation experiments with 100 μM 2-acetamidophenol (Aldrich) or with 100 μM *O*-hydroxyphenyl malonamic acid for 24 and for 48 hr, respectively, 5-d-old seedlings were incubated. Seedlings were separated into roots and shoots and extracted with methanol as described above. Extracts were analyzed by HPLC.

HPLC analyses were performed with a Beckman Coulter pump module 126 and a diode array detector 166. For separation, an Ultraphere ODS 18 RP column was used. Elution was performed with 0.1% trifluoro acetic acid in H_2O as eluent A and methanol as eluent B with the following gradient: 1 min: 100% A; 1–21 min 20% B in A, linear; 21–41 min 100% B, linear; 43 min 100% B. The detection wavelengths were 280 and 405 nm.

Further allelochemicals used for incubations and as reference substances were BOA-6-OH (Wieland et al., 1999) and *O*-hydroxyphenyl malonamic acid (Friebe et al., 1998). 2-Amino-3*H*-phenoxazin-3-one (phenoxazinone) was synthesized as described in Friebe et al. (1996) but extraction of the methanolic solution was performed with chloroform.

Glucosyltransferase Assay Roots were extracted at 4°C with 100 mM 2-morpholinoethanesulfonic acid monohydrate (MES) pH 6.0 containing 10% glycerol, 1% Na-ascorbate, and 1 mM dithiothreitol (DTT) (1:3 w/v) and 1% protease inhibitor cocktail (Sigma) by mortaring with quartz sand. The homogenate was centrifuged at 20,000×*g* (4°C) for 20 min, the supernatant was used as crude protein extracted for enzyme assays. The assay consisted of 68 μl protein solution, 50 mM Tris, 2.5 mM Uridine diphosphate glucose (UDPG), and

200 μM of synthetic BOA-6-OH (Wieland et al., 1999) in a total volume of 100 μl. After incubation at 30°C for 30 min, the reaction was stopped by boiling for 10 min. The mixture was centrifuged at 20,000×*g* for 5 min and analyzed by HPLC.

Identification of the Endophytic Fungus Maize roots were cut into pieces and transferred to Petri dishes containing Czapek Iprodione Dicloran agar (CZID-agar according to Abildgren et al., 1987) and incubated in the dark at 25°C. Mycelium appearing on agar medium was purified and transferred onto Czapek Dox agar for identification.

All other *Fusarium* isolates utilized in this study were taken from the Fungal Collection (Institute of Microbiology and Virology by D.K. Zabolotny, Ukraine) and maintained on Czapek Dox agar.

For microscopic characterization of *Fusarium* sp. isolated from maize roots, the fungus was cultivated on synthetic nutrients agar (SNA) for 14 d at 25°C under near UV-light to allow spore formation (Nirenberg, 1976). Spores were observed microscopically with a Leitz DMRB microscope equipped with Normanski interference and using the key given by Nelson et al. (1983).

Polymerase chain reaction (PCR) parameters: after 7 d of culture on Czapek Dox agar, the isolated *Fusarium* sp. was used for species-specific identification with molecular techniques. Fungal cells were scraped off agar plates and used for PCR amplification. PCR was accomplished in 25-μl PCR mixtures containing species-specific primers 53-6F/53-6R (Möller et al., 1999) and FOF1/FOR1 (Mishra et al., 2003), Taq DNA Polymerase (1.25 U, Fermentas), KCl-buffer, $MgCl_2$ (25 μM), deoxyribonucleotide triphosphates (dNTPs) (10 mM, Amersham) and performed as follows: one cycle at 95°C for 5 min; 35 cycles at 95°C for 30 sec, 65°C (primer pair 53-6F/53-6R) and 58°C (primer pair FOF1/FOR1) for 30 sec, and 72°C for 2 min 30 sec; followed by a 7-min extension at 72°C; and hold at 4°C. Amplification products were separated on a 1% agarose gel run at 100 V and visualized by ethidium bromide staining of the agarose gel.

Incubation of Fusarium verticillioides with Allelochemicals Mycelial plugs from agar plates (discs 5 mm diameter with 0.5–1 mg mycelium) were transferred into 250-ml flasks with 100 ml sterilized, liquid Czapek medium. The incubations were performed at 27°C in the dark without and with addition either of 2-acetamidophenol, *N*-(2-hydroxyphenyl) malonamic acid (each 10 μmol), or 2-amino-3H-phenoxazin-3-one (1 μmol). The structures of the compounds are presented in Fig. 4.

Cultures were analyzed after 2 wk of cultivation. Mycelia were separated from the liquid by filtration through a 200-μm nylon net and weighed, and the incubation media were extracted with ethyl acetate. The organic and aqueous phases were evaporated to dryness, and the residues were dissolved in 70% methanol. The resulting solutions were analyzed by HPLC.

Radicle Growth Tests Radicle growth tests were conducted in Petri dishes (12 cm diameter), (Schulz and Wieland, 1999). Filter paper in the Petri dishes was saturated with 2 ml methanol or with 2 ml chloroform only, or with 2 ml of solutions of 100, 250, 500, and 1,000 μM *N*-(2-hydroxyphenyl) malonamic acid, 2-acetamidophenol (both dissolved in methanol) and 2-amino-3H-phenoxazin-3-one (dissolved in chloroform). After complete evaporation of the solvent, 15 imbibed maize caryopses were placed on the filter paper and watered with 2 ml tap water. The Petri dishes were sealed with parafilm. The length of the radicle was determined 3 d after germination at 25°C in the dark. Determinations of radicle growth were also

performed with *Lepidium sativum*, cress (30 seeds per Petri dish). Conditions were the same as described with maize. The tests were repeated six times.

Incubation of Sterilized Maize Seedlings Inoculated with F. verticillioides Isolated from Maize Roots and/or Doratomyces stemonitis in the Presence of BOA Sterilized maize caryopses were germinated on Murashige and Skoog (MS) medium in Petri dishes under sterile conditions in a growth chamber at 25°C and a photoperiod of 16 hr. When the seedlings had developed one to two leaves, they were transferred to tubes filled with l0 ml sterilized liquid MS medium containing 100 or 740 μM BOA. The medium was inoculated with *D. stemonitis*, used as a nonpathogenic control, or *F. verticillioides*, respectively, or with both fungi. After 10 days, the liquid was collected and dried by vacuum centrifugation. The residue was dissolved in 50% methanol, the resulting solution was centrifuged and the supernatant used for HPLC analysis.

Results

Plant Detoxification of BOA Three-week-old plants suffering from sulfur deficiency showed reduced growth and reddish leaves due to anthocyanin accumulation, which indicates stress reactions. The appearance of the S_0 plants was an indicator that the low sulfur reserves of the caryopses (0.074–0.076 S%) were depleted during growth and that SO_2 uptake from the air was not sufficient to cover the sulfur requirement. Metolachlor-treated S_0 and S_{200} plants developed necrotic spots on the leaves, but there was no visible additional deterioration when plants were finally incubated with 500 μM BOA for 24 hr.

HPLC analysis of the methanolic root extracts revealed no differences in the content of BOA-6-*O*-glucoside regardless of whether plants were grown under optimal or deficient sulfur supplies (Table 1). Compared to the S_{200} variant, the glucoside carbamate content was slightly higher in roots of sulfur-deficient plants. However, metolachlor treatment strongly affected detoxification, and differences could be observed between metolachlor-treated S_{200} and S_0 plants. In the S_0 variant, the content of BOA-6-*O*-glucoside and glucoside carbamate dropped compared to that of S_0 plants without metolachlor treatment. In S_{200} plants, glucoside carbamate accumulation was slightly diminished, whereas BOA-6-*O*-glucoside production was higher than that found in S_{200} plants without metolachlor treatment.

The accumulation pattern of BOA-6-*O*-glucoside is in accordance with the UPDG-glucosyltransferase activity involved in BOA-6-OH glucosylation. The enzyme responds to BOA and metolachlor treatments. The enzyme activity was apparently affected by metolachlor in both sulfur-deficient and S_{200} plants (Table 2). There was no increase of the enzyme activity when S_{200} plants were treated with metolachlor only. In sulfur-deficient

plants, the constitutive glucosyltransferase activity was similar to that determined in roots extracts of S_{200} plants, but BOA incubation induced no increase in activity in sulfur-deficient plants. Application of metolachlor, however, resulted in less enzyme activity in S_0 plants and BOA plus metolachlor cut activity more than 60% (Table 2). *N*-glucosylation was not determined because with protein crude extracts, glucoside carbamate is converted to several other, partly unstable, products that hydrolyze and complicate the determination of enzyme activity.

Analyses of Incubation Media Besides phenoxazinone, AAP and OHPMA were found in most of the incubation media. Furthermore, the incubation media contained MBOA, but none of the known plant detoxification products. Table 3 presents the amounts of AAP, OHPMA, and phenoxazinone accumulation of representative experiments after 24 hr of incubation.

The presence of OHPMA prompted us to elucidate the existence of endophytic fungi in the roots of seedlings and adult plants. As expected, a fungus could be isolated from cut roots. The extent of infection with the fungus varied considerably from root to root. In one sample, *Aspergillus flavus* was found, and in all samples bacteria were found, which were not further determined.

A single fungal strain was identified by microscopic examinations as *F. verticillioides*, formerly known as *F. moniliforme*. Identification on the species level of this *Fusarium* strain was also proved by PCR. Both primer pairs (53-6F/53-6R; FOF1/FOR1) were successfully applied and showed high specificity and selectivity of amplified fungal DNA. PCR with the primer pair 53-6F/53-6R resulted in a specific amplification and generated a

fragment for the *Fusarium* species originating from maize root tissue determining the strain as *F. verticillioides* (Fig. 2).

As methanolic extracts from the roots neither contained AAP nor OHPMA in detectable amounts, seedlings were incubated with 100 μM solutions of the compounds for 24 hr and for 48 hr to ascertain that absorption of the compounds is negligible. Even after 48 hr, only traces up to 1% of the applied concentration of AAP or OHPMA could be found in the root extracts. Thus, in contrast to BOA, the compounds are absorbed only in traces. Radicle growth tests with the two compounds indicated, however, that traces of OHPMA had a stimulating effect on maize radicle elongation (Fig. 3), whereas AAP had only a significant effect when filter papers were soaked with 250 μM of the compound. Phenoxazinone stimulated maize radicle growth at 250 μM, but had no effect at higher concentrations. The tests were repeated with cress as a representative of dicotyledonous plants. A stimulation of radicle growth was observed with AAP, whereas OHPMA had only a slight effect, and phenoxazinone induced radicle growth at low concentration but was strongly inhibitory at higher concentrations.

Metabolization of AAP, OHPMA, and Phenoxazinone by Fusarium verticillioides To investigate whether the different degradation and detoxification products accumulate over time in the media or whether they are further metabolized by *F. verticillioides*, the fungus was incubated with AAP, OHPMA (both 10 μmol), and 2-amino-3*H*-phenoxazin-3-one (1 μmol). The weight of the mycelia was determined after 2 wk of incubation, and the incubation media was analyzed for the compounds. The fungus was able to use phenoxazinone as a C-source, but growth was reduced (phenoxazinone: 14% in comparison to the control: 100%). Metabolization of phenoxazinone was indicated by loss of the yellowish-orange color of the medium during the incubation time. AAP and OHPMA were both strongly inhibitory to fungal growth (2.3 and 3.4% of the control). AAP, 2.5 μmol, was metabolized, in contrast to OHPMA, where the whole amount applied was regained after 2 wk of incubation.

Experiments with Surface-Sterilized Maize Seedlings

HPLC analysis of the liquid culture medium revealed the presence of plant detoxification products in several samples (Table 4). With *D. stemonitis*, small amounts of gentiobioside carbamate and glucoside carbamate were identified after application of 740 μM BOA. With 100 μM, only glucoside carbamate could be found. Inoculation with *F. verticillioides* led to gentiobioside carbamate and glucoside carbamate accumulation in the medium. When inoculation was performed with both fungi, neither gentiobioside nor glucoside carbamate was

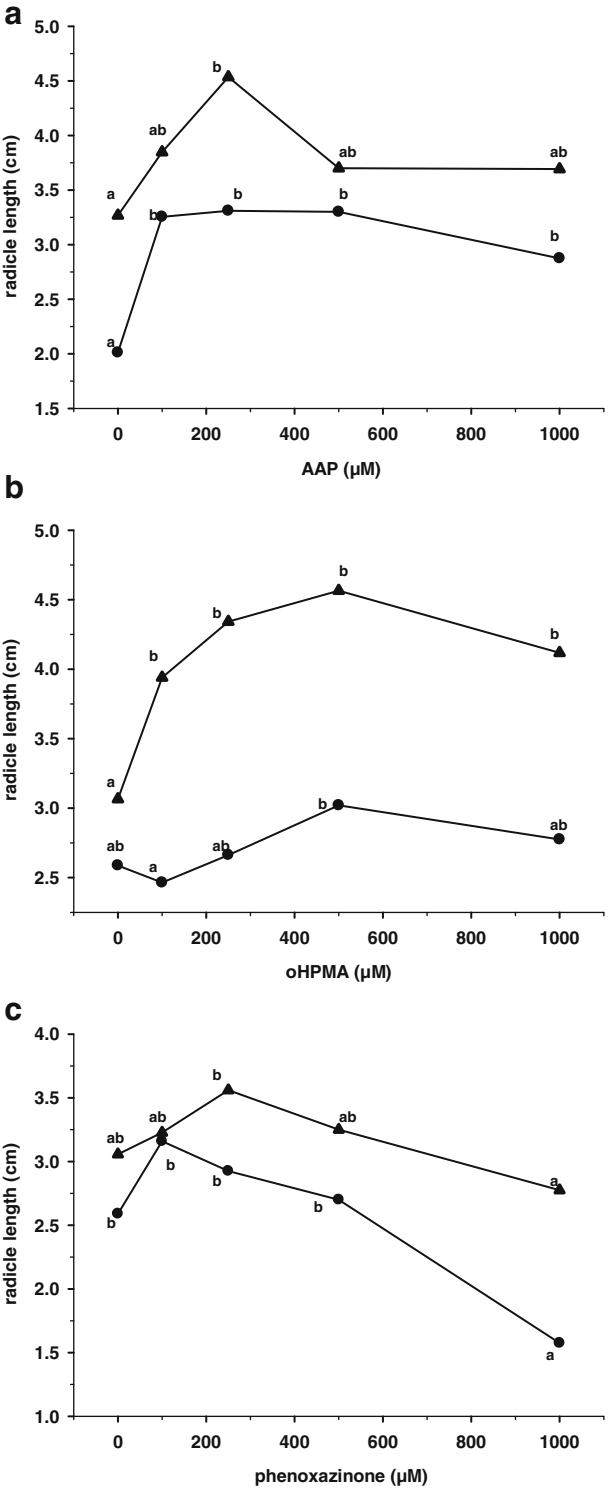

Fig. 3 Radicle growth in presence of AAP (**a**), OHPMA (**b**), and phenoxazinone (**c**). ▲ maize; • cress. Different superscripts for datum points for a particular species denote significant differences ($P<0.05$) (ANOVA SPSS windows version 12.0)

Table 4 Gentiobioside and glucoside carbamate accumulation in the liquid media of sterilized maize plants inoculated with *Doratomyces stemonitis* as nonpathogenic control and *Fusarium verticillioides* after application of 100 or 740 μM BOA

Species μM BOA	Gentiobioside Carbamate (nmol)	Glucoside Carbamate (nmol)
Doratomyces stemonitis		
100 μM BOA	n.d.	181.15±14.15
740 μM BOA	18.3±6.1	69.6±23.2
Fusarium verticillioides		
100 μM BOA	11.45±3.9	90.53±36.8
740 μM BOA	73.9±12.75	478.4±164.8
D. stemonitis/F. verticillioides		
100 μM BOA	n.d.	n.d.
740 μM BOA	n.d.	457.63±64.65

(N=3)

detectable after application of 100 μM BOA. With 740 μM BOA, only glucoside carbamate was found. Surprisingly, none of the samples contained even traces of the microbial degradation products AAP and OHPMA, or phenoxazinone.

Discussion

Although sulfur deficiency results in dramatic growth reductions of the maize plants, BOA-detoxification pathways are not affected, indicating that detoxification of BOA and phytotoxins is important to the plant. The glucosyltransferase involved in BOA-6-OH glucosylation plays an important role in this process. The identification of the enzyme will be published elsewhere.

However, a reduction in BOA detoxification appeared in S_0 plants when metolachlor application was used as an additional stress factor before BOA incubation. In S_{200} plants, metolachlor treatment suppressed an increase of the enzyme activity, but no breakdown appeared. Thus, increasing coincidence of several stress factors results initially in no effect, followed by an increase, and finally, in a reduction of the enzyme activity. The extent and course of time of these reactions should be dependent on plant health, fitness, and genotype.

The analysis of the incubation media demonstrated that a considerable amount of BOA is not absorbed and detoxified by the roots but converted by microorganisms. OHPMA, synthesized via 2-aminophenol, has been described as a characteristic BOA detoxification product of several fungi, e.g., *F. verticillioides* (*F. moliniforme*) *Fusarium subglutinans*, and *Gaeumannomyces graminis* varieties (Friebe et al., 1998; Yue et al., 1998; Glenn et al., 2001, 2003), whereas AAP is supposed to present a branch product of BOA detoxification by *F. verticillioides*. Phenoxazinone, resulting from spontaneous oxidative dimerization of 2-aminophenol, is a known component of BOA degradation initiated by heterocycle cleavage, not only due to fungal but also to bacterial activities. In the incubation studies presented here, *F. verticillioides*, known as an important endophytic fungus of maize (Bacon and Hinton, 1996), is thought to be mainly responsible for OHPMA and at least partly for AAP production, whereas several microorganisms including *F. verticillioides* should be involved in BOA degradation to 2-aminophenol. Thus, endophytic and rhizosphere organisms participate in BOA degradation, which might be regarded as a mechanism that protects the plant, which is important for their own existence. For the plant, energy costs to perform detoxification reactions are lowered, and the time of exposure with harmful effects on biomembranes and cell organelles is shortened.

One of the resulting transformation products, OHPMA was found to be absorbed by maize seedlings only in traces, but the low amounts stimulated maize radicle growth. This compound had only slight stimulatory effects on cress, in contrast to AAP that stimulated cress but maize only at 250 μM. The concentrations used in the bioassays do not present the true concentration of molecules that are in contact with the root. Rather, only molecules within the narrow space of the root absorption tissue are available for uptake. Thus, the true amount of compounds causing stimulation or inhibition of radicle growth should be below the applied concentration. The mechanism of induction is unknown. In this complex interaction, it cannot be excluded that growth stimulation is a secondary effect due to other compounds not related to BOA. Nevertheless, the final effect, a stimulated radicle growth, enhances the chance to escape from BOA-contaminated soil (and to open up new sulfur sources), which is important for further plant growth and associated microorganisms.

Different reactions of cress and maize were also observed with phenoxazinone. This compound was inhibitory for cress only at higher concentrations, while maize radicle growth was not severely affected. Whether endophytic *F. verticillioides* in maize roots may be the cause for the difference is still speculative.

The fungus is a pathogen but can live within the plant without the development of symptoms. As long as the pathogenic character is not manifested, its life as a heterotrophic endophyte is dependent on sustenance by the intact plant. It was unexpected that in the liquid MS medium from sterilized maize seedlings inoculated with *F. verticillioides* and/or *D. stemonitis* that none of the microbial degradation products could be detected. From another study, it is known that the fungi are able to consume exuded plant detoxification products (Voloshchuk et al., unpublished data). In this plant–fungus relationship under sterile conditions, where *F. verticillioides* does not appear as an endophyte, the fungi do not start to degrade BOA not yet absorbed by plants. A possible explanation might be the necessity of bacterial initiation of BOA cleavage. On the other hand, fungi perform the degradation when they are grown in pure culture, a situation in which they are not fed by a plant. Under sterile growth conditions with the plant, a competition with root colonizing bacteria is not occurring. Perhaps the lack of this competition may explain the inactivity of the fungi that require glucosylated plant detoxification products.

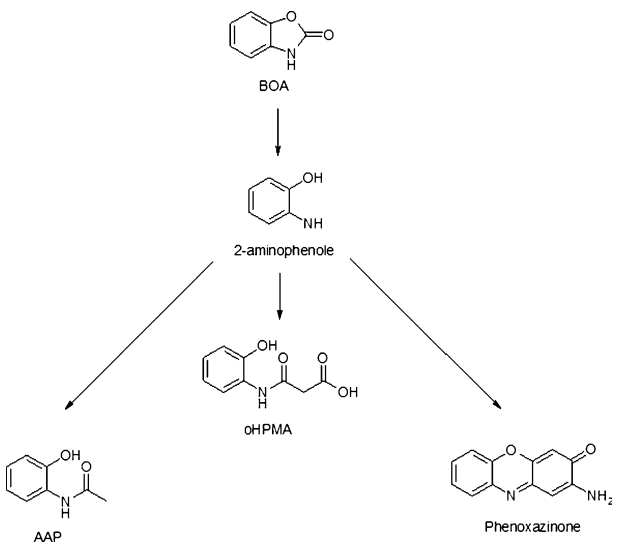

Fig. 4 BOA and its microbial detoxification products

As the media of non-sterile plant incubation with BOA did not contain any plant detoxification products, exuded products also may be consumed by the fungi under non-sterile conditions. In an earlier study with a different experimental arrangement, plant detoxification products (Fig. 1) were exuded after transferring plants to BOA-free medium (Sicker et al., 2001). Thus, the interactions might be more complex when the participation of additional, rhizosphere-colonizing microorganisms is also considered. The complexity of rhizosphere biology has been recently highlighted by Walker et al. (2003).

Our results can be summarized as follows: (1) BOA detoxification is reduced in metolachlor-treated plants suffering from sulfur deficiency. (2) Endophytic *F. verticillioides* and probably other microorganisms participate in BOA detoxification, as indicated by the appearance of the microbial degradation products AAP, OHPMA, and phenoxazinone. *F. verticillioides* seems to be able to degrade phenoxazinone. However, when the medium of sterilized maize plants is inoculated with the fungus, microbial products do not accumulate. (3) AAP and OHPMA are absorbed by maize roots only in traces. OHPMA stimulates maize radicle growth, AAP stimulates cress radicle growth. Phenoxazinone (1 mM) inhibits only cress significantly.

The results imply that allelochemical interactions are affected when maize plants are exposed to combined stress factors. The application of metolachlor likely causes negative effects by weakening detoxification processes in sulfur-deficient plants. Our findings underline the importance of microorganisms involved in the degradation of BOA as partners of a complicated ecological network. The role of endophytic *F. verticillioides* as a supporter in BOA detoxification has to be elucidated by further experiments using plants not infested with the fungus. Plant–fungus interactions seem to be important in plant survival of allelopathic attacks. A disturbance of the sensitive ecological balance by herbicide application can have broad-ranging effects under stress conditions.

Abstract 3-(3′,4′-Dihydroxyphenyl)-L-alanine (L-DOPA), which is synthesized in velvet bean (*Mucuna pruriens*), inhibits plant growth. The concentration of L-DOPA in soil is reduced by adsorption and transformation reactions, which can result in the reduction of its plant-growth-inhibitory activity. To determine which part of the L-DOPA structure is involved in the adsorption and soil transformation reactions, we compared the kinetics of L-DOPA disappearance in a volcanic ash soil with that of L-phenylalanine (3-phenyl-L-alanine) and L-tyrosine (3-(4′-hydroxyphenyl)-L-alanine), compounds that are similar in structure to L-DOPA but do not have a catechol (*o*-dihydroxybenzene) moiety. L-Phenylalanine and L-tyrosine were not adsorbed and transformed in the soil at equilibrium pH values between 4 and 7. These results suggest that the adsorption and transformation reactions of L-DOPA in the soil involve the catechol moiety and not the amino and carboxylic acid groups, which are common to all three compounds. Like L-DOPA, (+)-catechin, another allelochemical that contains a catechol moiety, underwent adsorption and soil transformation reactions. Thus, we concluded that the concentrations of allelochemicals bearing a catechol moiety in soils will decrease rapidly owing to adsorption and transformation reactions, and this decrease will be faster in soils with a high pH value or high adsorption ability. Owing to this decrease in concentration, allelopathic phenomena may not occur.

Keywords Allelopathy · Catechin · *Mucuna* · Velvet bean · Volcanic ash soil

Introduction

Velvet bean (*Mucuna pruriens*) inhibits the growth of neighboring plants by releasing the phytotoxic substance 3-(3′,4′-dihydroxyphenyl)-L-alanine (L-DOPA, Fig. 1) (Fujii et al., 1991, 1992; Fujii, 2000). L-DOPA content in fresh leaves and roots of velvet bean ranges

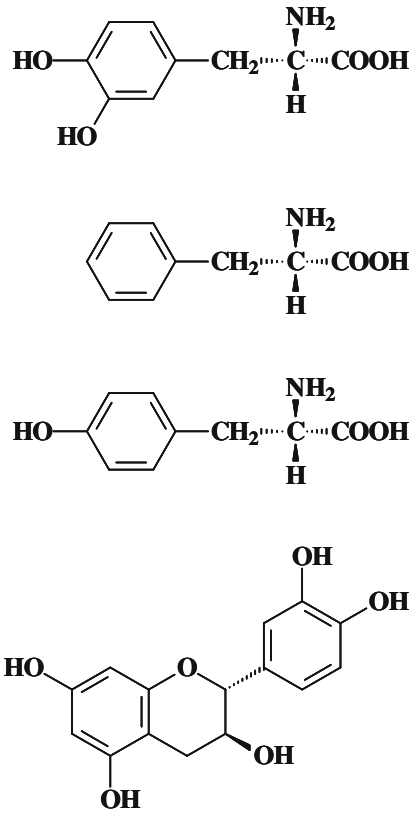

Fig. 1 Chemical structures of 3-(3′,4′-dihydroxyphenyl)-L-alanine (L-DOPA), 3-phenyl-L-alanine (L-phenylalanine), 3-(4′-hydroxyphenyl)-L-alanine (L-tyrosine), and (+)-catechin

from 0.5 to 1.5%, and the yield of fresh leaves and stems ranges from 20 to 30 t ha^{-1} (Fujii et al., 1991). Therefore, velvet bean could produce 100–450 g ha^{-1} (0.05–0.23 mol m^{-2}) of L-DOPA. Because plant-growth-inhibitory activity of L-DOPA in the absence of soil has been observed at concentrations of at least 1×10^{-4} to 1×10^{-5} M (Fujii et al., 1991; Nishihara et al., 2004; Furubayashi et al., 2005; Hiradate et al., 2005), L-DOPA released from velvet beans may inhibit the growth of neighboring plants if L-DOPA persists in soil environments.

Shibuya et al. (1994) observed plant-growth-inhibitory activity of L-DOPA in a granitic sandy soil ("Masa" soil) but not in an Andosol, probably because of the high ability of the Andosol to adsorb L-DOPA. Furubayashi et al. (2005) showed that the concentration of L-DOPA in a soil-water mixture decreases over time, owing to (i) adsorption on the soil, (ii) chemical transformation, and (iii) microbial degradation. Hiradate et al. (2005) reported that the adsorption mechanism involves a ligand exchange reaction in an Andosol, and that the soil components catalytically accelerate the transformation of L-DOPA. Hiradate et al. (2005) also demonstrated that the adsorbed and transformed forms of L-DOPA exhibit no plant-growth-inhibitory activity. Furubayashi et al. (2005) determined the amount of L-DOPA adsorbed and the rate of transformation at equilibrium pH values between 4 and 7 in three soil types (volcanic ash, alluvial, and calcareous soils). The amount of adsorbed L-

DOPA and the rate of transformation at equilibrium pH 6 in the presence of volcanic ash soil were 0.068 mol kg^{-1} soil and 0.057 mol kg^{-1} soil d^{-1}, respectively, and these values indicate that L-DOPA can be expected to disappear rapidly in this type of soil.

L-DOPA contains a catechol moiety, and catechol is easily oxidized in soils, especially under alkaline conditions (Kumada, 1981). Like catechol, L-DOPA may undergo soil oxidation reactions. Many other allelochemicals also contain a catechol moiety. For example, robinetin, myricetin, and quercetin are produced by *Robinia pseudo-acacia* L. (Iqbal et al., 2004); caffeic and chlorogenic acids are present in wild perennial buckwheat (*Fagopyrum cymosum* M.; Tsuzuki and Yamamoto, 1987); digallic and ellagic acids have been detected in soils under the canopy and in the litter of a lowland forest (Lodhi, 1976); (±)-catechins are secreted by spotted knapweed (*Centaurea maculosa*; Bais et al., 2002, 2003); and (+)-catechin has been isolated from buckwheat (Iqbal et al., 2003). All these compounds show plant-growth-inhibitory activity, but their concentrations in soils may be reduced owing to the presence of the catechol moiety in their structures, which we suspect is involved in their adsorption and soil transformation reactions.

In the present study, to elucidate the role of the catechol moiety in L-DOPA adsorption and soil transformation reactions, we investigated the kinetics of the disappearance of L-phenylalanine and L-tyrosine (Fig. 1), which have chemical structures similar to the structure of L-DOPA but lack the catechol moiety, at various equilibrium pH values in a volcanic ash soil. We also investigated whether (+)-catechin underwent adsorption and transformation reactions in a volcanic ash soil and whether the decrease of (+)-catechin concentration in soil solutions corresponded to the reduction of plant-growth-inhibitory activity. We expect this information to be useful in understanding the chemical behaviors of phytotoxic catechol compounds in soils.

Methods and Materials

Soil Samples Samples of a volcanic ash soil (Silandic Andosol, FAO, 1998; Melanudand, Soil Survey Staff, 1999) and an alluvial soil (Anthrosol, FAO, 1998; Aquept, Soil Survey Staff, 1999) were collected from the A_p horizons of an upland agricultural field and a paddy field, respectively, in Tsukuba, Japan (Hiradate and Uchida, 2004). A sample of a calcareous soil (Chromic Luvisol, FAO, 1998; Hapludalf, Soil Survey Staff, 1999) was collected from the A_p horizon of an upland agricultural field in Yomitan, Okinawa, Japan. The soil samples were air-dried and then ground and finely sieved (<0.5 mm).

Analysis of Soil Components Particle size analysis was performed by the pipette method (Day, 1965). Total organic components were determined by a dry combustion method (Sumigraph NC analyzer NC-900, Sumika Chem. Anal. Service, Japan). Determination of soil pH in H_2O was performed with a pH meter with a glass electrode. To determine the pH(H_2O) values, 10.0 g of air-dried soil were mixed with 25 ml of deionized water. The mixture was allowed to stand over 12 hr with occasional shaking, and the pH was measured in the suspension.

Chemicals L-Phenylalanine and L-tyrosine were purchased from Wako Pure Chemical Industries (Osaka, Japan). (+)-Catechin was purchased from Spectrum Chemical (Gardena, CA, USA).

Kinetics of L-Phenylalanine, L-Tyrosine, and (+)-Catechin Disappearance in the Presence of the Volcanic Ash Soil Fifty milligrams of the volcanic ash soil sample (oven-dry basis)

were placed in a 12-ml glass centrifuge tube. Deionized water, 1.0 ml of a 1-M NaCl solution (background electrolyte), 50 μl of chloroform (an antibiotic), and a dilute HCl or NaOH solution (for pH adjustment) were added to the tube to obtain a liquid-phase volume of 3.0 ml and equilibrium pH values between 4 and 7. The tube was capped with a screw-on Teflon-sealed cap and shaken overnight to establish equilibrium. Then, 2 ml of a 5-mM L-phenylalanine or (+)-catechin solution were added to the soil suspension (0.2 mol L-phenylalanine or (+)-catechin kg^{-1} soil). The resulting mixture was shaken at 100 rpm for 1–120 hr at 30°C in the dark. The same procedure was applied to another 50 mg of soil samples, but 0.25 ml of 4 M NaCl and a dilute HCl or NaOH solution were added to the tube to obtain a liquid-phase volume of 1.0 ml and equilibrium pH values between 4 and 7. Then, instead of 2 ml of 5 mM L-phenylalanine or (+)-catechin, 4 ml of 2.5 mM L-tyrosine were added to reach the same final concentration (0.2 mol L-tyrosine kg^{-1} soil).

After filtration of the soil suspension through a cellulose acetate filter membrane (pore size, 0.2 μm; Advantec Toyo Kaisha, Tokyo, Japan), the equilibrium pH was determined with a pH meter with a glass electrode, and the concentration of the test chemical was determined with a high-performance liquid chromatograph (HPLC: pump, L-6200; UV–vis detector, L-4200H; autosampler, AS-2000; column oven, L-5025; chromatogram integrator, D-2500; Hitachi, Tokyo, Japan) equipped with a reversed-phase analytical column (Inertsil ODS-3, 5 μm, 4.6-mm i.d., 250-mm length, GL Sciences, Tokyo, Japan). L-Phenylalanine and L-tyrosine were eluted with a solution of 0.1 M phosphate buffer (pH 2) and methanol (L-phenylalanine, 8:2 v:v; L-tyrosine, 9:1 v:v) at a flow rate of 1 ml min^{-1} at a column temperature of 40°C; the detection wavelength was 200 nm. (+)-Catechin was eluted with a mixed solution of deionized water and methanol (7:3 v:v) at a flow rate of 1 ml min^{-1} at a column temperature of 40°C; the detection wavelength was 200 nm. L-Phenylalanine, L-tyrosine, and (+)-catechin eluted at 6.2, 6.0, and 5.4 min, respectively.

Calculation of L-Phenylalanine, L-Tyrosine, and (+)-Catechin Disappearance at Constant Equilibrium pH Value in the Presence of the Volcanic Ash Soil To adjust accurately the equilibrium pH at the end of the reaction time was difficult because the equilibrium pH of the soil mixture changed gradually over the reaction period, owing to the buffering action of the soil and the reaction of the test chemicals. Therefore, we calculated the amounts of chemicals at equilibrium pH values of 4, 5, 6, and 7 by plotting the relationship between the amounts of the test chemicals and equilibrium pH values of the solutions after filtration through the cellulose acetate membrane. This calculation method is similar to that used for L-DOPA in our previous work (Furubayashi et al., 2005).

Kinetics of L-Phenylalanine and (+)-Catechin Disappearance in the Absence of Soil To clarify the effects of solution pH on the stability of L-phenylalanine and (+)-catechin in the absence of soil, we prepared a 5-ml solution of 2 mM L-phenylalanine or (+)-catechin in a 12-ml glass centrifuge tube in the presence of 0.1 M phosphoric acid–sodium phosphate solution buffered at pH values between 4 and 7. After the tube was shaken at 100 rpm for 1–120 hr at 30°C in the dark, the test solution was passed through a cellulose acetate filter membrane (pore size, 0.2 μm; Advantec Toyo Kaisha). Then, the equilibrium pH and the concentrations of the test chemicals in the filtrate were measured by using a pH meter and an HPLC system, as described above.

Kinetics of L-DOPA Disappearance in the Presence and Absence of Soil We measured the kinetics of the disappearance of L-DOPA in the presence and absence of the volcanic ash

soil in a previous study (Furubayashi et al., 2005) under experimental conditions identical to those used in the present study. The kinetic data from the previous study were used for comparison with the data obtained in this study.

Measurement of the Plant-Growth-Inhibitory Activity of (+)-*Catechin in the Presence of Three Types of Soil* A 500-mg portion (oven-dry basis) of the soil (volcanic ash soil, calcareous soil, or alluvial soil) was placed in each well (15.6-mm i.d., 17-mm high, 1.9-cm^2 growing area) of a 24-well plate (Nunclon, NalgeNunc, Denmark). Then, 1.0 ml of a solution containing 10^{-6}–10^{-2} M (+)-catechin in the presence of 0.75% agar (gelling temperature, 30 to 31°C; Nacalai Tesque, Kyoto, Japan) at 40°C was added to each soil-containing well. After the soil suspension was stirred with a stick and incubated at 30°C for 24 hr in the dark, four lettuce seeds (*Lactuca sativa* cv. Great Lakes 366) were placed on the gelled agar–soil mixture. The lettuce seeds were grown for 72 hr at 20°C in the dark, and the inhibitory activity was determined by measuring root elongation and comparing it with that of the control (without (+)-catechin, but in the presence of the corresponding soil). This experiment was replicated three times.

Results and Discussion

In the presence of volcanic ash soil, L-DOPA disappeared over time at equilibrium pH values between 4 and 7, and in the absence of soil, L-DOPA disappeared only at pH values higher than 7 (Fig. 2). Hiradate et al. (2005) previously reported that L-DOPA disappeared in soils because of adsorption and transformation reactions. In contrast, the amounts of L-phenylalanine and L-tyrosine in the presence and absence of soil remained stable at equilibrium pH values between 4 and 7 during the experimental period (1–120 hr; Fig. 2), which indicates that L-phenylalanine and L-tyrosine were neither absorbed nor transformed by the soil.

In our previous work (Furubayashi et al., 2005), we found that when L-DOPA is incubated with soils, it disappears by means of two chemical processes (Fig. 3). The rapid and sudden reduction of L-DOPA concentration observed during the first 4-hr period was attributed to adsorption. The second process was characterized by a constant rate of disappearance caused by catalytic transformation reactions. The adsorption process ends within 8 hr, and after that time, only the catalytic transformation reactions contribute to the disappearance of L-DOPA (Fig. 3; Furubayashi et al., 2005). The amount of L-DOPA disappearing after 8 hr can be expressed by the following linear equation:

$$Y = aX + b, \tag{1}$$

where Y is the amount of L-DOPA disappeared (mol kg^{-1} soil), a is the rate of L-DOPA disappearance by the transformation reactions (mol kg^{-1} soil hr^{-1}), X is the reaction time (hr), and b is the amount of L-DOPA disappeared by adsorption (mol kg^{-1} soil). The rate of transformation (a) and the amount of L-DOPA adsorbed (b) were calculated by using Eq. 1, and the values obtained were plotted against the equilibrium pH values (Figs. 4 and 5).

The presence of volcanic ash soil increases adsorption of L-DOPA (Fig. 4). The amounts of L-DOPA adsorbed by the soil range from 0.020 to 0.068 mol kg^{-1} soil at equilibrium pH values between 4 and 7, and the amounts increased with increasing equilibrium pH. In

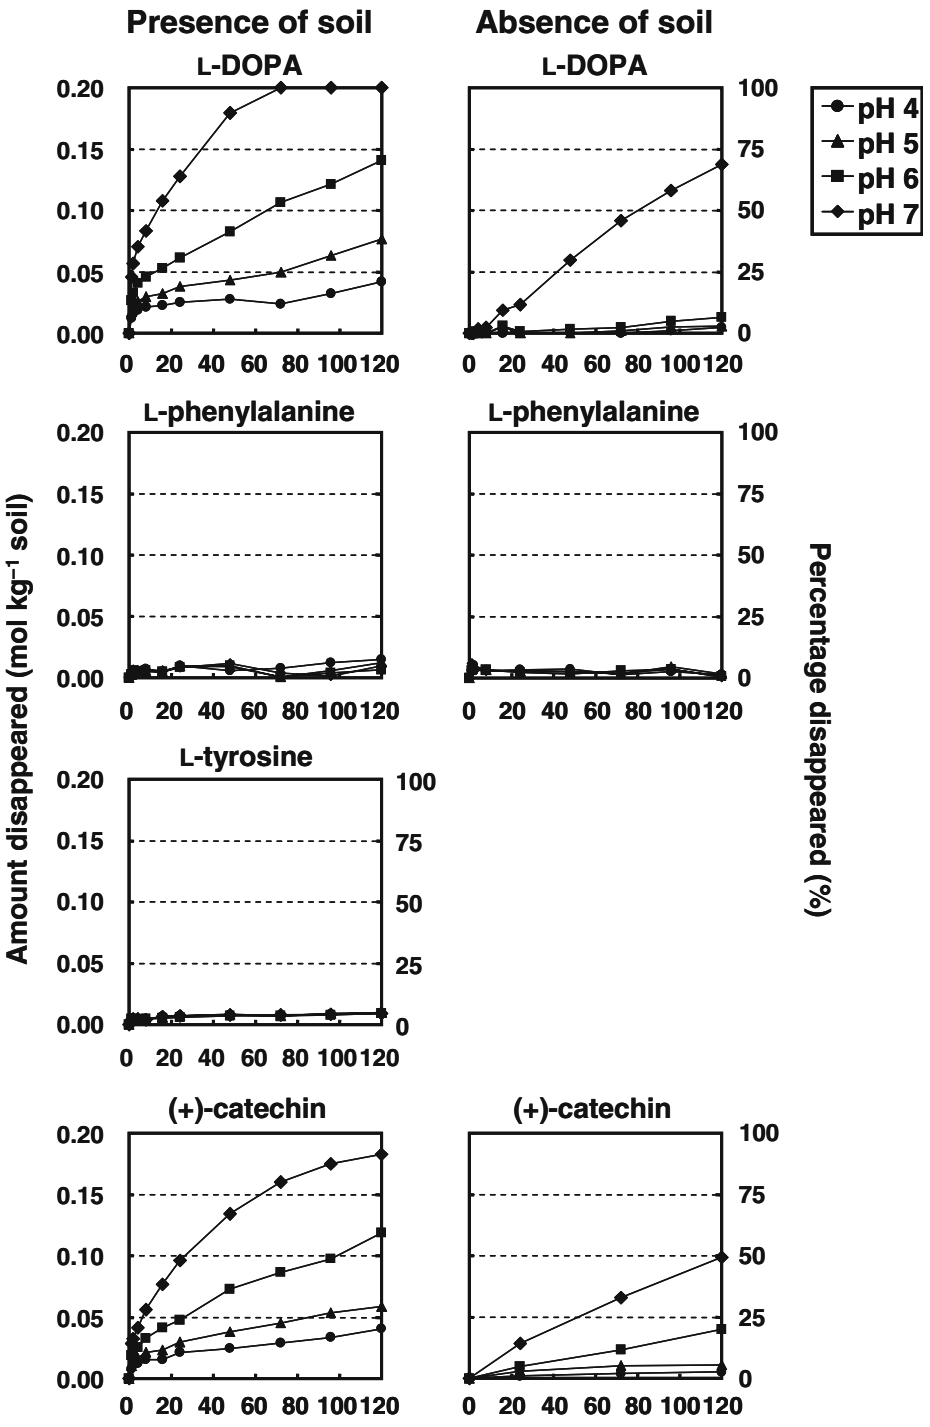

Fig. 2 Kinetics of L-DOPA, L-phenylalanine, L-tyrosine, and (+)-catechin disappearance in the presence (left) and absence (right, excluding L-tyrosine) of a volcanic ash soil at equilibrium pH values of 4, 5, 6, and 7

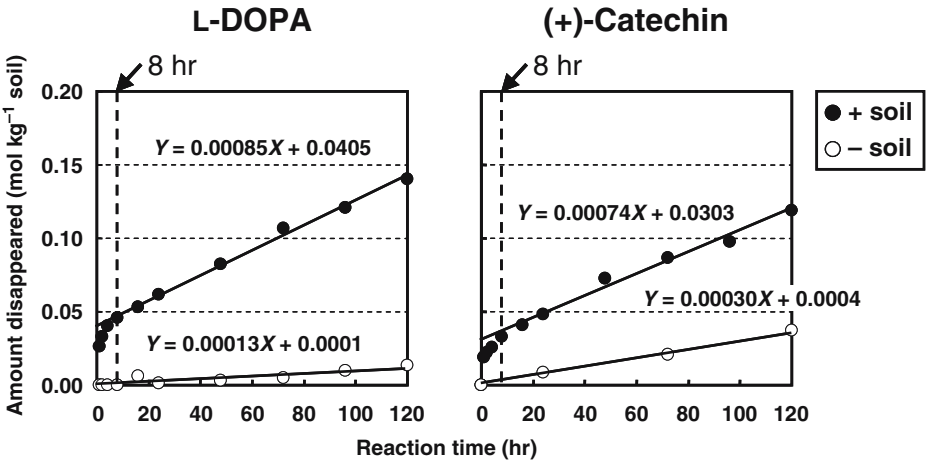

Fig. 3 Determination of the transformation rate and the amount of adsorption of L-DOPA (left) and (+)-catechin (right) using the first-order regression curve $Y=aX+b$, where Y is the amount of L-DOPA or (+)-catechin lost (mol kg^{-1} soil), a is the rate of L-DOPA or (+)-catechin disappearance by transformation (mol kg^{-1} hr^{-1}), X is the reaction time (hr), and b is the amount of L-DOPA or (+)-catechin lost by adsorption (mol kg^{-1}). For the regression analysis, data between 8 and 120 hr of reaction time were used for each series. The reaction experiments were conducted at an equilibrium pH value of 6.0 in the absence (○) and presence (●) of a volcanic ash soil

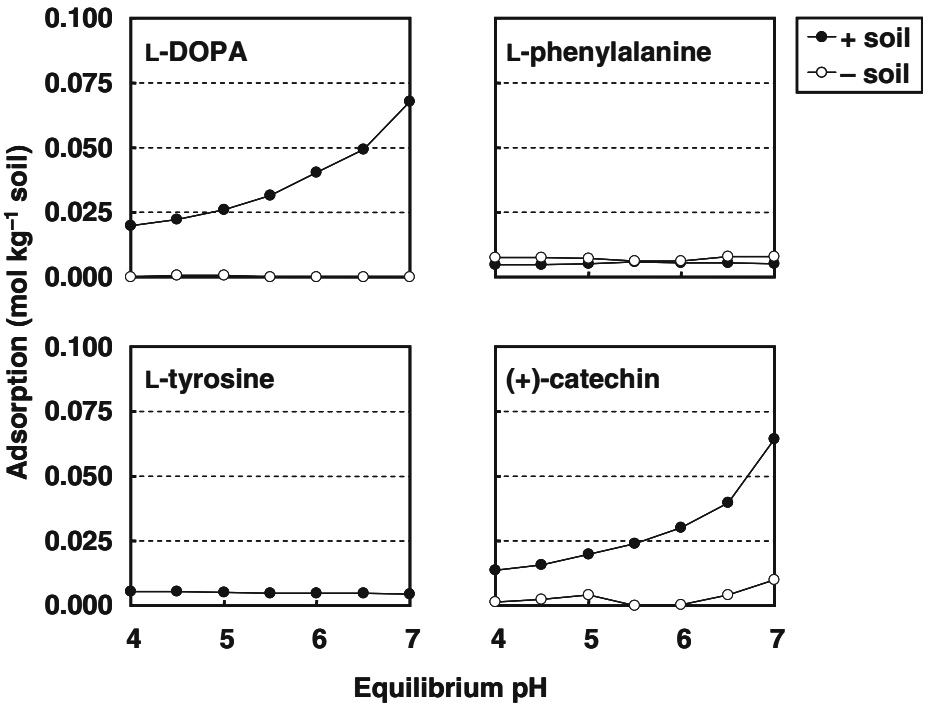

Fig. 4 Adsorption of L-DOPA, L-phenylalanine, L-tyrosine, and (+)-catechin at equilibrium pH values between 4 and 7 in the absence (○) and presence (●) of a volcanic ash soil

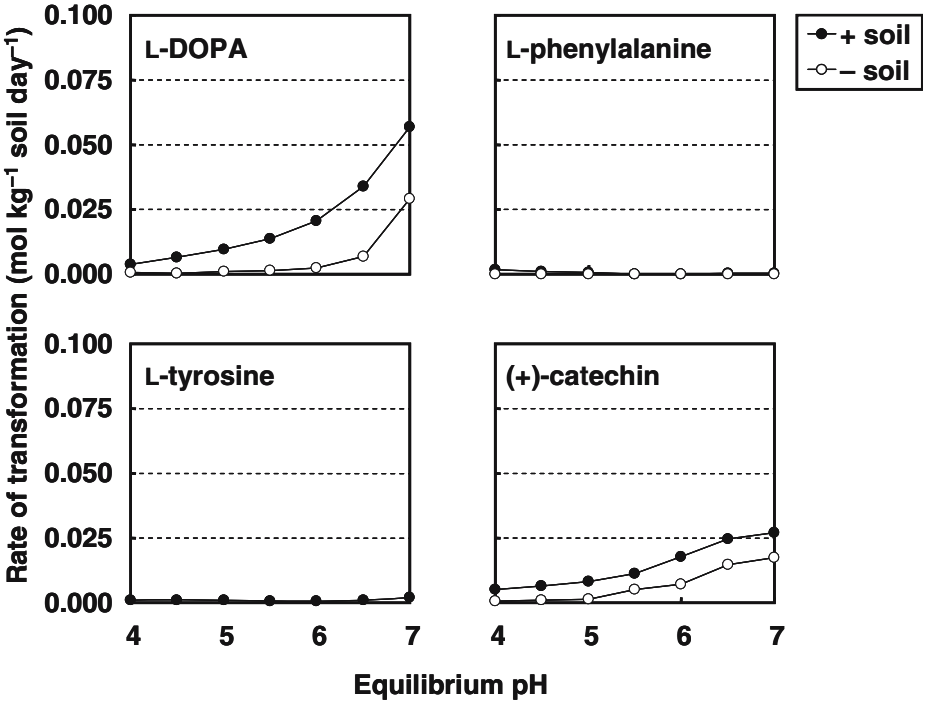

Fig. 5 Transformation rate of L-DOPA, L-phenylalanine, L-tyrosine, and (+)-catechin at equilibrium pH values between 4 and 7 in the absence (○) and presence (●) of a volcanic ash soil

contrast, the amounts of adsorbed L-phenylalanine and L-tyrosine were negligible. The differences in adsorption among the three compounds cannot be attributed to the amino and carboxylic acid groups, which are common to all three structures, and are instead attributable to the number and positions of the hydroxyl group on the benzene rings: L-DOPA has 3′ and 4′ hydroxyl groups, L-tyrosine has a 4′ hydroxyl group, and L-phenylalanine has no hydroxyl groups (Fig. 1). Therefore, we concluded that the 3′,4′-dihydroxyphenyl moiety (that is, the catechol moiety) is responsible for the adsorption.

In both the presence and the absence of soil, the rate of L-DOPA transformation is faster at higher pH values, whereas the transformation rates of L-phenylalanine and L-tyrosine were negligible at equilibrium pH values between 4 and 7 (Fig. 5). In the absence of soil, the rate of L-DOPA transformation is almost zero at equilibrium pH values lower than 6.0, but the rates increase to 0.007 and 0.029 mol kg^{-1} soil d^{-1} at equilibrium pH 6.5, and 7.0, respectively. Hiradate et al. (2005) reported that L-DOPA is automatically transformed into polymerized forms in the absence of soils at equilibrium pH values higher than 6.5 and that this transformation is accompanied by the consumption of OH^-. In the presence of the soil, the L-DOPA transformation rates increase to 0.003 and 0.028 mol kg^{-1} soil d^{-1} at equilibrium pH 4 and 7, respectively. Hiradate et al. (2005) also reported that an Andosol and its components catalytically accelerate the transformation of L-DOPA into heterogeneous components, such as humic substances, as indicated by their spectrum in the proton nuclear magnetic resonance. In contrast, L-phenylalanine and L-tyrosine, which lack the catechol moiety, remained stable both in the absence and in the presence of the

soil, which indicates that the catechol structure, rather than the amino group or the carboxylic acid group, is responsible for L-DOPA adsorption and soil transformation reactions.

L-DOPA content in fresh leaves and roots of velvet bean has been reported by Fujii et al. (1991). If the estimated total production of L-DOPA from velvet bean were added to a soil of 10-cm depth, the maximum amount of L-DOPA in the soil would range from 0.0005 to 0.0023 mol kg^{-1} soil. If a certain amount, close to the above estimated value of 0.0023 mol kg^{-1} soil of L-DOPA, is added to a volcanic ash soil, the concentration of L-DOPA is markedly reduced after 24 hr of reaction time (Fig. 2). Furubayashi et al. (2005) likewise reported that at a concentration of 10^{-3} M (0.002 mol kg^{-1} soil), the plant-growth-inhibitory activity of L-DOPA in the presence of the three soils (volcanic ash, calcareous, and alluvial) is less than 25%. In the presence of these soils, therefore, allelopathic phenomena caused by L-DOPA released from velvet bean may not be observed.

To clarify the influence of the catechol moiety on the adsorption and soil transformation reactions of these compounds, we examined the adsorption and transformation reactions of another catechol-containing allelochemical, (+)-catechin (Fig. 1), both in the presence and in the absence of the volcanic ash soil. When (+)-catechin was incubated with the soil, it disappeared rapidly during the first 4 hr, and then the rate of disappearance slowed and become constant, just as is the case for L-DOPA (Fig. 2). We attributed the disappearance of (+)-catechin in the presence of the soil to adsorption and transformation reactions, as for L-DOPA (Fig. 3). The amount of (+)-catechin adsorbed and the rate of (+)-catechin transformation were calculated by using Eq. 1. (+)-Catechin adsorption on the soil increased with increasing equilibrium pH: 0.013 and 0.054 mol kg^{-1} soil were adsorbed at equilibrium pH 4 and 7, respectively (Fig. 4). The rate of (+)-catechin transformation in the presence of the soil increased with increasing equilibrium pH, to 0.005 and 0.027 mol kg^{-1} soil d^{-1} at equilibrium pH 4 and 7, respectively (Fig. 5). In the absence of soil, the rate of (+)-catechin transformation was negligible at equilibrium pH values lower than 5, but the transformation rate was clearly detected at equilibrium pH values between 5.5 and 7.0 (0.005 and 0.018 mol kg^{-1} soil d^{-1}, respectively). The kinetics of the disappearance of (+)-catechin in the absence and presence of the soil were similar to those of L-DOPA, which indicates again that the presence of the catechol moiety, common to L-DOPA and (+)-catechin, was involved in the adsorption and soil transformation reactions. Oszmianski and Lee (1990) reported that the enzymatic oxidation reaction products of catechin and chlorogenic acid are mainly polymers, and that the production of these is associated with browning. In our study, the gradual change of the (+)-catechin solutions from colorless to yellowish brown likely indicates that (+)-catechin was transformed by oxidative polymerization. Shindo and Huang (1984) found that dihydroxybenzene compounds (hydroquinone, resorcinol, and catechol) are converted into humic acid through semiquinones during the catalytic oxidative reduction of Mn(IV) and Fe(III) oxides. The catechol moieties of L-DOPA and (+)-catechin probably underwent similar reactions in our study.

We investigated the plant-growth-inhibitory activity of (+)-catechin in three soil types (volcanic ash, calcareous, or alluvial). Under natural pH conditions (without pH adjustment, Table 1), (+)-catechin activity became markedly weaker in the presence of soils, whereas in the absence of soils, growth inhibition of at least 50% was observed at initial concentrations higher than 10^{-3} M (Fig. 6). At initial concentrations lower than 3×10^{-3} M (0.006 mol kg^{-1} soil), the inhibitory activity was negligible in the presence of the soils. When 0.006 mol (+)-catechin kg^{-1} soil was incubated with volcanic ash soil at pH 5.8 (no pH adjustment), the (+)-catechin concentration was markedly reduced after 24 hr (Fig. 2). As a result of the

Table 1 Particle size analysis and selected chemical properties of soils used in this study

Soil sample	Particle size analysis			Textural class	Total organic components [a]		pH (H_2O)
	% Sand	% Silt	% Clay		C (g kg^{-1})	N (g kg^{-1})	
Volcanic ash soil	19.7	37.3	43.1	LiC	71.9	4.5	5.8

disappearance of (+)-catechin, almost no plant-growth-inhibitory activity was observed. In the environment, allelochemicals are released from living plants at a fairly constant rate during the growth season, and, therefore, the amounts of these chemicals deposited in the soils remain fairly constant. However, adsorption and transformation reactions would prevent the accumulation of the highly toxic allelochemicals L-DOPA and (+)-catechin.

Dalton et al. (1983, 1989) extensively studied the role of clays and organic matter in similar reactions of ferulic acid in soils. These workers found that organic matter was the most active soil component involved in the irreversible retention of ferulic acid in sterile soil. In our study, the clay contents of the soils decreased in the order calcareous soil > volcanic ash soil > alluvial soil, and the organic matter contents decreased in the order volcanic ash soil > calcareous soil > alluvial soil (Table 1). However, we could not confirm the influence of variations in the clay and organic matter contents of the soil on adsorption and transformation reactions of catechin, because the plant-growth-inhibitory activity of (+)-catechin was extremely low in the presence of the soils. In a previous study (Furubayashi

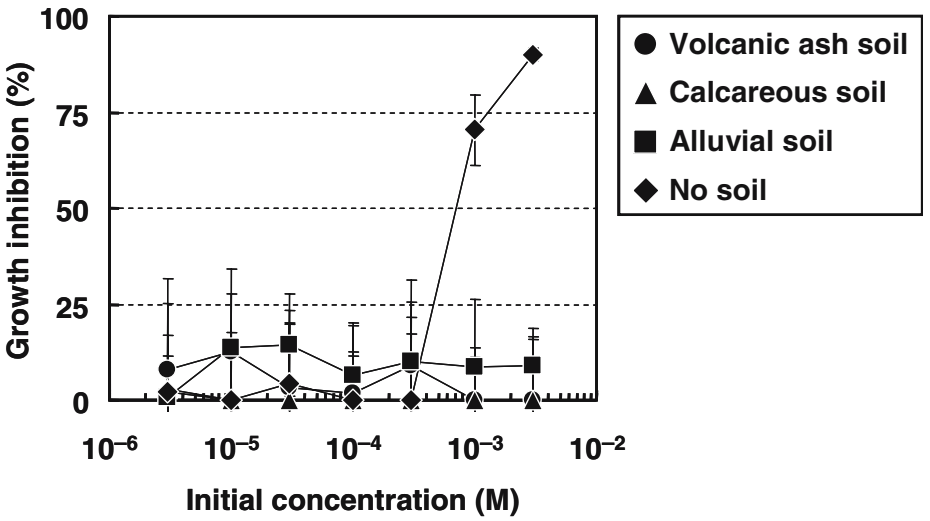

Fig. 6 Inhibitory activity of (+)-catechin, measured in terms of root elongation of lettuce (*Lactuca sativa* cv. Great Lakes 366) grown in agar media in the absence (♦) and presence of soils (●; volcanic ash soil, ▲; calcareous soil, ■; alluvial soil), at various initial concentrations. Inhibition of root growth was detected by measuring root elongation and comparing it with that of the control (with no (+)-catechin, but in the presence of the corresponding soil) after incubation for 72 hr at 20°C in the dark. Bars indicate standard deviation (n=12)

et al., 2005), we observed the largest amount of L-DOPA adsorption in the presence of the volcanic ash soil, which has the highest organic matter content of the three soil types, but the influence of variations in clay content on the adsorption and transformation reactions of L-DOPA was not clear. However, we suspect that the influence may be small because L-DOPA is more polar than ferulic acid and dissolves readily in water. Hiradate et al. (2005) and Furubayashi et al. (2005) have reported that volcanic ash soil, which has high P-retention ability, a high pH (NaF) value, and large amounts of Fe and Al (hydr)oxides, absorbs large amounts of L-DOPA, which suggests that the mechanism of the adsorption of L-DOPA involves a ligand exchange reaction. The mechanisms of the adsorption and transformation reactions of both L-DOPA and (+)-catechin in soils and the effect of variations in clay and organic matter soil contents on their disappearance require further study.

Blum et al. (1987) reported that the retention of ferulic acid (i.e., by adsorption, polymerization, etc.) by clay and organic matter in nonsterile soil is secondary to microbial utilization and uptake by cucumber roots. Likewise, Weidenhamer and Romeo (2004) reported that certain allelochemicals (gallic acid, hydroquinone, arbutin, and benzoquinone) from *Polygonella myriophylla* are degraded rapidly by soil microbes. In our previous study of the behavior of L-DOPA in soil sterilized with chloroform and in nonsterile volcanic ash soil (Furubayashi et al., 2005), we found that L-DOPA disappears after 72 hr, owing to degradation caused by the soil microbes. Therefore, biodegradation by soil microbes, in addition to adsorption and transformation reactions, is a significant factor in the disappearance of L-DOPA and (+)-catechin in soils. In volcanic ash soil environments, the plant-growth-inhibitory activity of L-DOPA and (+)-catechin can be expected to be reduced quickly mainly because of adsorption and transformation reactions that occur rapidly (within 24 hr). The disappearance might be even faster in high-microbial-activity soil than in low-microbial-activity soil because all three processes will occur. The importance of adsorption and transformation reactions relative to that of microbial activity in reducing the concentrations of these compounds in soils also requires further study.

Bais et al. (2003) used methanol to extract natural rhizosphere soil of spotted knapweed in Montana, and estimated that the concentration of (−)-catechin in the soil is about 1.1 mg g^{-1} soil (0.004 mol kg^{-1} soil), and that (−)-catechin inhibits the growth and germination of native species in field soils at natural concentrations. However, they did not report the soil pH, and the extraction method they used was different from our method, making comparison with our results difficult. Under the soil conditions used for the present study, we estimate that the rates of transformation of (+)-catechin were 0.013 and 0.054 mol kg^{-1} soil d^{-1} at equilibrium pH 4 and 7, respectively, and these values indicate that the occurrence of allelopathic phenomena of spotted knapweed in the field would require the release of catechin at the rate of 0.013 mol kg^{-1} soil d^{-1} or more. Blair et al. (2005) demonstrated a rapid decline of catechin concentration within 24 hr after its addition to wet North Carolina soil (Loamy sand/sand, pH 5.2), and those results support ours. We expected, therefore, that the occurrence of allelopathic phenomena caused by catechin and L-DOPA would be low in a soil such as volcanic ash soil, calcareous soil, or alluvial soil at pH values between 4 and 7, because in this range, the rate of transformation of catechin and L-DOPA would be high. Many other phytotoxic allelochemicals contain a catechol moiety (e.g., caffeic acid, digallic acid, ellagic acid, robinetin, myricetin, quercetin, and (−)-catechin). These compounds may disappear rapidly by means of mechanisms similar to those responsible for the disappearance of L-DOPA and (+)-catechin. We conclude that the phytotoxicity of all catechol-bearing compounds released from plants into soils is likely to be substantially reduced by adsorption and transformation reactions, and that the soil concentrations of these

compounds can be expected to be reduced more quickly in soils with high pH values or high adsorption ability. Therefore, allelopathic phenomena may not be observed under such conditions.

Abstract The aim of this study was to investigate the phytotoxic effect of sunflower on physiological and biochemical processes during germination of mustard seeds (*Sinapis alba* L. cv. Nakielska). To exclude the involvement of osmotic stress in seed reaction to phytotoxic compounds, we compared the effect of 10% (w/v) water extract from sunflower (*Helianthus annuus* L. cv. Ogrodowy) leaves and 28.4% (w/v) polyethylene glycol (PEG) 8000 solution characterized by an equal $\Psi = -1$ MPa. We evaluated (1) the amount of hydrogen peroxide (H_2O_2); (2) activities of antioxidant enzymes: superoxide dismutase, catalase, and glutathione reductase; (3) membrane permeability; and (4) level of malondialdehyde (MDA). Both, sunflower compounds and PEG solutions inhibited mustard seed germination, but only phytotoxins caused an increase in the cell membrane permeability, MDA level, H_2O_2 concentration, and alterations in activities of antioxidant enzymes. Our results demonstrate that despite the activation of the antioxidant system by sunflower phytotoxins, reactive oxygen species accumulation caused cellular damage, which resulted in the decrease of germinability and gradual loss of seed vigor. It seems that the negative effect of sunflower on germination of mustard seeds is mostly because of its toxicity and not to its contribution to osmotic potential.

Introduction

Allelopathic interactions refer to both natural and agroecosystems. Most effects reported have been identified as being caused by inhibitors of physiological and biochemical processes in plants from chemicals released from living plants into the environment through root exudation, leaching, and volatilization, and passively through decomposition of plant residues. In recent years, a wide selection of plants has been studied for phytotoxic potential. Among them, *Helianthus annuus* L. actively influences the growth of surrounding plants (Irons and Burnside, 1982; Shon and Einhellig, 1982; Leather, 1983; Azania et al., 2003). Phytotoxicity of sunflower residues against *Sorghum vulgare*, *Zea mays*, *Pennisetum americanum*, and *Cyamopsis tetragonoloba* has been reported by Batish et al. (2002). Foliar extracts of sunflower contain chlorogenic and isochlorogenic acids, naphthol derivatives, and scopolin (Wilson and Rice, 1968). In addition, more than other 50 compounds from the active fraction of sunflower extracts have been isolated by Macias et al. (1993, 1996, 1997, 1999, 2000, 2002). Those allelochemicals are mainly terpenoids. Sesquiterpenes are the most abundant, and two new skeletal types, heliannuols and heliespirones, are known.

Like other stress factors, allelochemicals have several molecular targets, and some of their physiological processes or modes of action have been reviewed (Peng et al., 2004; Weir et al., 2004; Gniazdowska and Bogatek, 2005). They include disruption of membrane permeability (Galindo et al., 1999), ion uptake (Lehman and Blum, 1999), inhibition of electron transport in both photosyntetic and the respiratory chain (Peñuelas et al., 1996; Abrahim et al., 2000; Czarnota et al., 2001), alterations of enzyme activities (Cruz-Ortega et al., 1990; Politycka, 1998), and inhibition of cell division (Cruz-Ortega et al., 1988; Anaya and Pelayo-Benavides, 1997). It has also been postulated that allelopathy stress might lead to an imbalance between antioxidant defenses and the amount of reactive oxygen species (ROS), resulting in oxidative stress (Cruz-Ortega et al., 2002; Bais et al., 2003; Romero-Romero et al., 2005).

Although the role of the antioxidant system in plants in response to environmental stresses has received attention (Bowler et al., 1992; Scebba et al., 1998; Yu et al., 2003; Foyer and Noctor, 2005), our understanding about its putative involvement in response to phytotoxic agents is so far not well documented. The scavenging of the superoxide radical $\left(O_2^{\cdot-}\right)$ is achieved through an upstream enzyme, superoxide dismutase (SOD), which catalyses the dismutation of $\left(O_2^{\cdot-}\right)$ to hydrogen peroxide (H_2O_2) and plays a role in protecting cells against the toxic effects of those radicals produced in different cellular compartments (del Rio et al., 2002). Furthermore, the intracellular level of H_2O_2 is regulated by a wide range of enzymes, the most important being catalase (CAT) (Blokhina et al., 2003). Synthesis of SOD and CAT as an adaptive response to oxidative stress has been reviewed (Mittler, 2002). In addition, effective resistance to prolonged stress would necessitate an augmented capacity for ascorbate regeneration, a process at least partly dependent on the tripeptide thiol (glutathione) in higher plants (Foyer et al., 1995). An important role in glutathione oxidation to glutathione disulfate is played by the latter enzyme in the ascorbate–glutathione cycle, glutathione reductase (GR). Transgenic plants, which have threefold higher GR activity than the control, have also increased tolerance to oxidative stress induced by paraquat (Inze and Montagu, 1995).

The phytotoxicity of sunflower extracts makes them good candidates as a source of a natural herbicide against weed species (Azania et al., 2003 and references therein). In this study, we studied the effect of an aqueous extract from sunflower leaves (*H. annuus* L. cv. Ogrodowy) on mustard (*Sinapis alba* L. cv. Nakielska) seed germination, a common dicotyledonous weed species. Extract from sunflower leaves has a low water potential;

therefore, we compared the effect of sunflower water extract and polyethylene glycol (PEG) solution (characterized by an equal $\Psi = -1$ MPa) on mustard seed germination.

In view of the increasing evidence on the role of ROS and the contribution of some antioxidant enzymes (CAT, SOD, and GR) to various physiological processes during stress conditions, it was of a particular interest to investigate whether H_2O_2 and related oxidative damage i.e. lipid peroxidation and membrane injuries, might play a role in seed responses to sunflower phytotoxic compounds.

Methods and Materials

Preparation of Sunflower Extract Leaves from field grown sunflower (*H. annuus* L. cv. Ogrodowy) were harvested at the beginning of the flowering stage. Tissue (leaves) was air-dried, and ground to obtain a fine powder. Leaf powder (10 g dry weight [DW]) was extracted for 24 hr in 100 ml of distilled water at 20°C. The obtained 10% (w/v) extract was filtered through filter paper and used as a source of phytotoxins (Bogatek et al., 2006; Kupidłowska et al., 2006).

Plant Material and Germination Tests Germination assays of mustard seeds (*S. alba* L. cv. Nakielska) were performed by placing seeds (four replicates of 100 seeds each) in 9-cm petri dishes (25 seeds per dish) containing filter paper moistened with distilled water (control), 28.4% (w/v) PEG (−1 MPa) solution or 10% (w/v) sunflower extract (−1 MPa) at 20°C in darkness. Seeds were considered to have germinated when the radicle had pierced the envelope. Dry matter of mustard seeds was determined by oven drying at 105°C for 48 hr.

Viability Seed viability was estimated with a tetrazolium test. Seeds were cut longitudinally and incubated in 1% solution of 2,3,5-triphenyltetrazolium chloride for 2 hr at 20°C in darkness (Moore, 1973). Seeds in which the embryo exhibited no carmine staining were scored as nonviable.

Biochemical measurements were carried out on mustard seeds after 18 hr and 2, 4, 6, and 8 d of treatment with sunflower extract. For the control and seeds germinated in the presence of 28.4% (w/v) PEG (−1 MPa), measurements were carried out only after 18 hr of germination because longer durations of imbibition allowed radicle protrusion (seeds in all combinations were at the same physiological stage).

H_2O_2 Concentration Hydrogen peroxide contents of seeds were determined according to the method described by O'Kane et al. (1996). Mustard seeds (0.5 g, fresh weight [FW]) were ground with a mortar and pestle in liquid nitrogen. Samples were homogenized with 10 ml of perchloric acid (0.2 M). After 15 min of centrifugation at 11,000×*g* at 4°C, the resulting supernatant was neutralized to pH 7.5 with KOH (4 M), and then centrifuged at 5,000×*g* for 3 min at the same temperature to remove insoluble potassium perchlorate. The obtained supernatant was used for spectrophotometric determination of H_2O_2. The reaction mixture contained 50 µl of the collected supernatant, 12.5 mM of dimethylaminobenzoic acid, 1.25 mM of 3-methyl-2-benzothiazolidone hydrazone, and 20 µl (0.25 U) of horseradish peroxidase for a total volume of 1.5 ml. The reaction started with the addition of peroxidase. Increase in absorbance at 590 nm was monitored after 5 min at 25°C and compared with the absorbance obtained with known amounts of H_2O_2, detected for 5 min at 590 nm. Results are expressed as micromoles per gram of DW and correspond to the means of the values ± SD obtained with three replicates from three independent experiments.

Electrolyte Leakage Germinated seeds (on water, PEG solution, or extract from sunflower leaves) were rinsed with distilled water, and solute leakage was determined. Twenty seeds were placed in 15 ml of distilled water at 20°C in darkness. Conductivity in the medium was measured with a conductivity meter after 2 hr of incubation period. Results are expressed as percent of total leakage from seeds boiled for 20 min in water and represent the means ± SD of the values obtained with three measurements carried out on five replicates.

MDA Content Lipid peroxidation was estimated by measuring spectrophotometrically malondialdehyde (MDA) contents of seeds. The tissue (five seeds) was ground in 5 ml distilled water and homogenized with an equal volume of 0.5% (w/v) 2-thiobarbituric acid in 20% (w/v) trichloroacetic acid. The homogenate was incubated for 30 min at 95°C in a water bath and then cooled quickly on ice and centrifuged at 16,000×*g* for 30 min. The supernatant was used for MDA determination according to Heath and Parker (1968) as described by Bailly et al. (1996). MDA equivalent was calculated from the difference in absorbance at 532 and 600 nm using an extinction coefficient of 155 mM^{-1} cm^{-1}. Results are expressed as nanomoles per gram of DW and represent the mean of 3 replicates ± SD.

SOD, CAT, and GR Extraction Enzyme activities were determined from the extract prepared according to the method of Bailly et al. (1996). All steps of the extraction were carried out at 4°C. Seeds (1 g FW) were homogenized in a cold mortar in 10 ml of 0.1 M potassium phosphate buffer (pH 7.8) containing 2 mM α-dithiothreitol, 0.1 mM EDTA, 1.25 mM PEG 4000, and 0.2 g polyvinylpyrrolidone and mixed for 15 min. The homogenate was centrifuged at 11,000×*g* for 15 min, and the supernatant was filtered through Miracloth, desalted on a PD 10 column (Amersham Biosciences). The obtained extract was immediately used for determination of enzyme activities.

Total SOD (EC 1.15.1.1) Activity of SOD was determined by inhibition of *p*-nitroblue tetrazolium chloride (NBT) photoreduction (Giannopolitis and Ries, 1977). The assay was conducted at 25°C in a total volume of 3 ml of 0.1 M potassium phosphate buffer (pH 7.8) containing 1.3 μM riboflavine, 13 mM methionine, 63 μM NBT, and 50 μl of enzymatic extract, as described by Bailly et al. (1996). Absorbance was monitored at 560 nm after 15 min of illumination, using a spectrophotometer Pharma Spec UV-1700 (Shimadzu, Japan). One unit of SOD is defined as the amount of enzyme that inhibits NBT photoreduction to blue formazan by 50%, monitored at 560 nm. Superoxide dismutase activity of the extracts was expressed as units of SOD per milligram of protein.

CAT (EC 1.11.1.6) Catalase activity was determined according to Clairbone (1985) with some modifications (Bailly et al., 1996). The assay was carried out in a total volume of 3 ml of 50 mM potassium phosphate buffer (pH 7.0) containing 37.5 mM of H_2O_2 and 200 μl of enzyme extract. The decrease in absorbance at 240 nm because of degradation of H_2O_2 ($\varepsilon = 39.4\ mmol^{-1}\ cm^{-1}$) *was monitored every 3 sec for 2 min, using a spectrophotometer, Pharma Spec UV-1700 (Shimadzu). Catalase activity was expressed as nanomoles of* H_2O_2 *decomposed per milligram of protein per minute.*

GR (EC 1.6.4.2) Glutathione reductase activity was determined in 800 μl of 0.1 M potassium phosphate buffer (pH 7.8) containing 0.5 mM β-nicotinamide adenine dinucleotide 2′-phosphate, reduced form (2′-NADPH); 10 mM glutathione, oxidized form; 3 mM $MgCl_2$; and 50 μl enzymatic extract (Bailly et al., 1996). The decline in absorbance

because of NADPH oxidation was recorded at 340 nm every 30 sec for 6–8 min using a spectrophotometer, Pharma Spec UV-1700 (Shimadzu). Glutathione reductase activity was expressed as nanomoles of NADPH oxidized per milligram of protein per minute. All results correspond to the means ± SD of the values obtained with three measurements carried out in three independent experiments.

Protein Determination Protein content in the enzymatic extracts was determined by using a Bradford reagent (Bradford 1976). Bovine serum albumin (Sigma) was used as a calibration standard.

Measurement of Water Potential WP4 Dewpoint Potential Meter (Decagon Devices, Inc., Pullman, WA, USA) was used to measure water potential (Ψ) of 10% (w/v) sunflower extract and 28.4% (w/v) PEG 8000 solution. Samples of both solutions were monitored at 20°C. Results correspond to the means ± SD of the values obtained with three measurements carried out for three of each independent prepared solutions.

Statistical Analysis The values of germinability and viability were represented as means ± SE from four independent experiments, whereas the remaining data were means ± SE from three replicates from three independent experiments. Significant differences between values of H_2O_2 concentration, membrane injury, MDA concentration, and enzyme activities, which were measured in dry mustard seeds and germinating mustard seeds in the presence of water, PEG solution, and sunflower extract, were determined at $P \leq 0.05$ according to Duncan's multiple range test.

Results

Germination and Viability Almost all (95%) mustard seeds germinated on water (control) within 3 d at 20°C and produced typical etiolated seedlings 7–8 cm long after 8 d (Fig. 1).

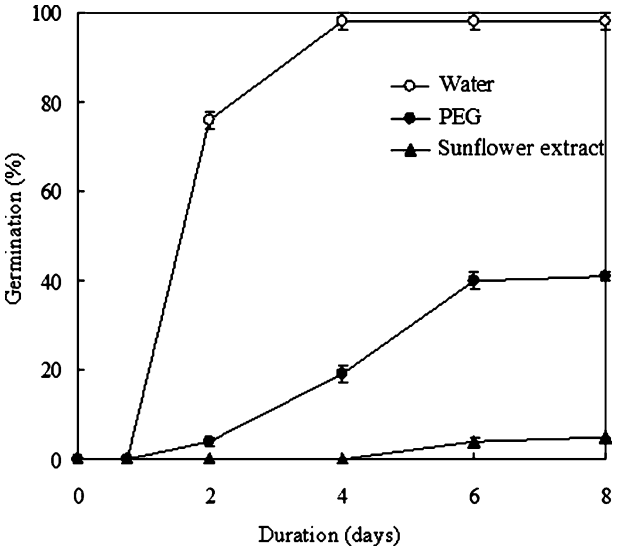

Fig. 1 Mustard seed germination in the presence of water, PEG, and sunflower extract. Data are means ± SD from four independent experiments

The water potential of 28.4% (w/v) PEG equaled that of the 10% (w/v) sunflower extract and reached −1 MPa. Germination on 28.4% PEG solution (Ψ=−1 MPa) was inhibited by almost 50%; after 8 d of incubation on PEG solution, only 48% of seeds germinated and produced etiolated seedlings 5–6 cm long (Fig. 1). The water extract from sunflower leaves (10% w/v, −1 MPa) strongly affected germination of mustard seeds. After 8 d of exposure to phytotoxic compounds, only 5% of seeds germinated (Fig. 1) and failed to develop into normal seedlings (data not shown). For the duration of the test, in the presence of sunflower toxins, no radicles pierced the seed envelope, nor was seedling growth noticed. Those seeds, throughout the course of the experiment, remained at the stage comparable to seeds immersed in water after 18 hr. Therefore, seeds after 18 hr (0.75 d) of imbibition in water were regarded as a potential control for comparative purposes, owing to their similar morphological and physiological growth stage to treated seeds.

Results of the tetrazolium test (Fig. 2) showed that almost all seeds incubated on water were viable. During the time of germination, control seed viability was not changed and we obtained 95% viable seeds (Fig. 2). Similarly, the viability of seeds treated by PEG reached 92% and was constant till the end of the experiment (Fig. 2). During the first 4 d of germination in the presence of sunflower extract, 84% of the seeds remained viable (Fig. 2), although they did not germinate (Fig. 1). A longer treatment with sunflower extract was lethal, and the tetrazolium test showed that seed viability decreased progressively to 65% at the eight day and to 2% of viable seeds after 14 d (Fig. 2).

H_2O_2 Concentration Hydrogen peroxide concentration (Fig. 3) in dry seeds and seeds imbibed with water was 0.11 and 1.33 μmol g^{-1} DW, respectively. Similar values of H_2O_2 level (1.05 μmol g^{-1} DW) were observed in seeds germinated on PEG solution (Fig. 3). Sunflower phytotoxic compounds increased H_2O_2 concentration in mustard seeds. After 18 hr, it was more than three times as high (3.9 μmol g^{-1} DW) as in the control and seeds imbibed on PEG, and increased progressively, reaching 5.78 μmol g^{-1} DW at the fourth day and 7.12 μmol g^{-1} DW at the eight day (Fig. 3).

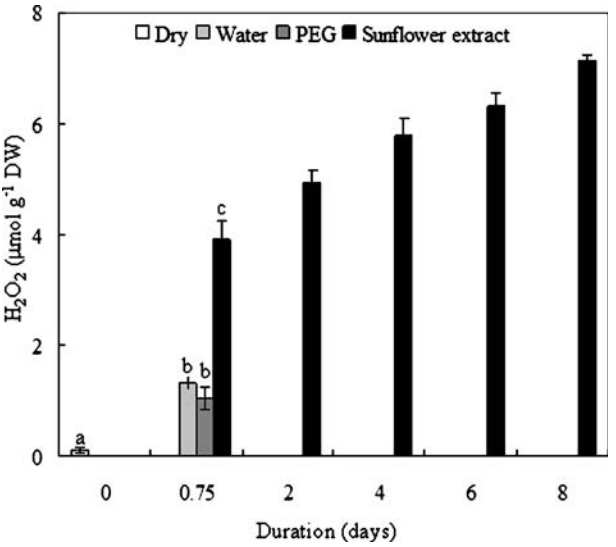

Fig. 3 H_2O_2 concentration in dry mustard seeds and germinating mustard seeds in the presence of water, PEG, and sunflower extract. Data are means ± SD from three replicates from three independent experiments. Significant differences *a*, *b*, and *c* at the 5% level between mustard seeds germinated in the presence of water, PEG solution, and sunflower extract ($P \leq 0.05$, according to Duncan's multiple range test)

Electrolyte Leakage Ion leakage (Fig. 4) from dry mustard seeds or after 18 hr of imbibition on water and PEG solution was low (0.5, 4, and 5% of total leakage, respectively). Treatment of seeds by sunflower extract led to a rapid and marked increase in electrolyte leakage. It represented 19.5% of total leachable electrolytes after 18 hr and increased continuously during the experiment. After 8 d of incubation of mustard seed in the presence of sunflower compounds, electrolyte leakage reached 33% of total electrolyte leakage (Fig. 4).

MDA Content The level of MDA (Fig. 5) in dry seeds was 1.3 nmol g^{-1} DW. After 18 hr of imbibition on water, PEG solution, or sunflower compounds, the MDA content of mustard

Data are means ± SD from three replicates from three independent experiments. Significant differences *a*, *b*, and *c* at the 5% level between mustard seeds germinated in the presence of water, PEG solution, and sunflower extract ($P \leq 0.05$, according to Duncan's multiple range test)

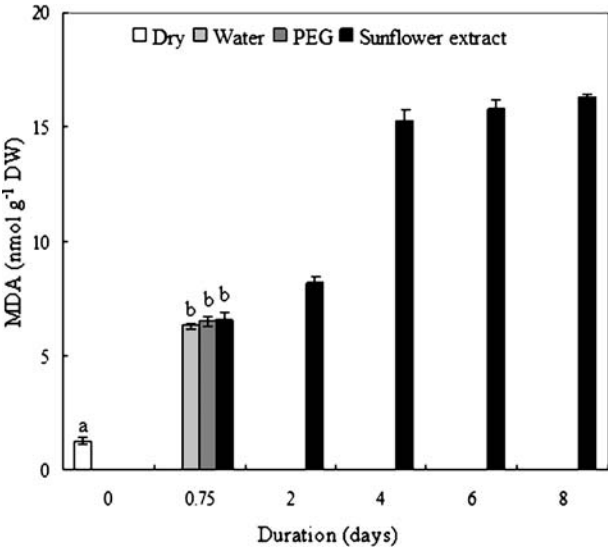

Fig. 5 Malondialdehyde (MDA) concentration in dry mustard seeds and germinating mustard seeds in the presence of water, PEG, and sunflower extract. Data are means ± SD from three replicates from three independent experiments. Significant differences *a* and *b* at the 5% level between mustard seeds germinated in the presence of water, PEG solution, and sunflower extract ($P \leq 0.05$, according to Duncan's multiple range test)

seeds increased to ca. 6.3, 6.5, and 6.6 nmol g^{-1} DW, respectively. Prolonged phytotoxic stress was associated with an increase of MDA concentration until the fourth day, and it remained at a constant value, close to 15.3 nmol g^{-1} DW till the end of the experiment.

Activities of Antioxidant Enzymes Superoxide dismutase activity (Table 1) in dry mustard seeds was 4.61 U mg^{-1} protein. Eighteen hours of imbibition on water, PEG solution, or sunflower extract resulted in an increase of SOD activity to values 7.28, 6.60, and 7.32 U mg^{-1} protein, respectively. The prolonged treatment by sunflower extract increased SOD activity, and after 8 d of germination it was almost doubled, compared to seeds in the imbibed in water, and reached a value 12.11 U mg^{-1} protein.

Table 1 Antioxidant enzyme activities in dry mustard seeds and germinating mustard seeds in the presence of water, PEG solution, and sunflower extract

Combination	Enzyme Activity			
	Days	SOD (units mg^{-1} protein)	CAT (nmol H_2O_2 mg^{-1} protein min^{-1})	GR (nmol NAPDH mg^{-1} protein min^{-1})
Dry	0	4.61±0.14[a]	0.01±0.005	ND
Water	0.75	7.28±0.22[a]	0.95±0.03	2.11±0.06[a]
PEG	0.75	6.60±0.20[a]	1.34±0.04	1.84±0.05[a]
Sunflower extract	0.75	7.32±0.22[a]	1.17±0.03	0.31±0.01[a]
	2	9.33±0.28	1.84±0.05	1.37±0.04
	4	11.03±0.33	4.63±0.09	1.52±0.05
	6	11.33±0.34	6.03±0.12	1.64±0.05
	8	12.11±0.36	9.17±0.27	2.06±0.06

Data are means ± SD from three replicates from three independent experiments.

[a] Significant differences at the 5% level between mustard seeds germinated in the presence of water, PEG solution, and sunflower extract ($P \leq 0.05$, according to Duncan's multiple range test).

ND = not detected

Catalase activity (Table 1) in dry seeds was 0.01 nmol H_2O_2 mg^{-1} protein min^{-1}. After 18 hr of imbibition, it increased similarly in each three combinations (control, PEG solution, and sunflower extract), reaching values of 0.95, 1.34, and 1.17 nmol H_2O_2 mg^{-1} protein min^{-1}, respectively. The prolonged seed incubation on sunflower extract resulted in a further increase of CAT activity. After 8 d of exposure to phytotoxins, it achieved 9.17 nmol H_2O_2 mg^{-1} protein min^{-1}.

Glutathione reductase activity (Table 1) in dry mustard seeds was not detected but during 18 hr of imbibition on water and PEG solution it increased significantly (2.11 and 1.84 nmol NADPH mg^{-1} protein min^{-1}, respectively). However, GR activity in seeds imbibed 18 hr on sunflower extract was eight times lower than that measured in control or seeds treated by PEG solution. Subsequent imbibition of seeds imbibed in the present of sunflower toxins resulted in increase of GR activity. After 8 d of phytotoxin treatment, it increased to a value similar to that observed in the control and osmotic stressed seeds after 18 hr of incubation, and reached 2.06 nmol NADPH mg^{-1} protein min^{-1}.

Discussion

The most widely used biological assays for the action of phytotoxins are seed germination and seedling growth studies. The delay and reduction of seed germination and/or inhibition of root and shoot growth are usually the first visible symptoms of phytotoxic stress (Dayan et al., 2000). It was previously demonstrated that sunflower produces different allelochemicals that exhibit phytotoxicity against many plant species (Macias et al., 1999, 2002) and, therefore, might be used as an alternative strategy for weed control (Leather, 1983, Azania et al., 2003). Our previous study confirmed that the effect of aqueous sunflower foliar extracts on mustard seed germination is dose-dependent (Bogatek et al., 2006). Germination of mustard seeds is almost fully inhibited by 10% (w/v) water extract of sunflower leaves (Fig. 1). The osmotic potential of sunflower extract used in our experiment was determined to be close to −1 MPa, and for that reason PEG solution characterized by the same osmotic potential was used to determine whether the inhibition of germination resulted from limited water availability. Imbibition of seeds on PEG solution did not fully inhibit their germination but delayed radicle protrusion and finally allowed 48% of seeds to germinate (Fig. 1). Thus, the inhibitory effect of sunflower foliar extracts on germination cannot be explained by a limitation in water availability, but rather by a toxic effect of the extract, as shown by the viability test (Fig. 2).

Many identified allelochemicals inhibit or delay seed germination. (−)-Catechin, the allelochemical from root exudates of *Centaurea maculosa* inhibited germination of *Festuca idahoensis* and *Koelaria micrantha* (Bais et al., 2003). Different phenolic compounds (vanillic, *p*-coumaric, and protocatechuic acids) used at concentrations from 10^{-5} to 10^{-6} M reduced germination of *Pinus laricio* seeds (Musculo et al., 2001). Capsaicin isolated from *Capsicum* spp. at the concentration 10–90 mM suppressed germination of lettuce (*Lactica sativa*), crabgrass (*Digitaria sanguinalis*), timothy (*Phleum pretense*), and ryegrass (*Lolium multiflorum*) (Kato-Noguchi and Tanaka, 2003–2004). Although allelochemicals act as inhibitors of seed germination, their mode of action often remains unclear. Recently, it was proposed that oxidative stress could play a role in phytotoxic phenomenon (Weir et al., 2004). The exposure of cucumber roots to ferulic and *p*-coumaric acids resulted in increased H_2O_2 concentration in the tissue (Politycka, 1996). Bais et al. (2003) showed that

(−)-catechin elicits a burst of ROS in susceptible plant roots, and the kinetics of ROS induction was similar to the patterns of cell death induced by (−)-catechin. The toxicity of many quinones and phenols can largely be attributed to the formation of semiquinone radicals that donate electrons to molecular oxygen, forming superoxide anions $\left(O_2^{\cdot-}\right)$ (Weir et al., 2004). Our results show that an increase in H_2O_2 content occurs early during mustard seed imbibition in sunflower extract (Fig. 3). We demonstrate that the detrimental effect of sunflower on germination of mustard seeds is not strictly associated with water stress (comparison of PEG and phytotoxins treatment) but rather with the imposition of a precocious oxidative stress.

One of the best known cellular targets of oxidative stress is lipid peroxidation, which is a free-radical chain process leading to the deterioration of polyunsaturated fatty acids (PUFAs). Lipid peroxidation is likely to degrade PUFAs present in membranes, leading to severe damage to membranes or to reserve lipids of oily seeds (Scandalios, 1993; Foyer et al., 1994). One of the indicators of plasma membrane damage is electrolyte leakage measurement. After 8 d of incubation of mustard seed on sunflower compounds, ion leakage reached 35% of total leachable electrolytes, thus suggesting damage to plasma membranes (Fig. 4). This observation is in agreement with that obtained with cucumber cotyledons treated with natural sesquiterpenolide, dehydrozaluzanin C, causing a dramatic and rapid plasma membrane leakage (Galindo et al., 1999). In the present paper, symptoms of membrane injuries occurred concomitantly to H_2O_2 accumulation (Fig. 3) and preceded an increase in the content of MDA, a compound that reveals the occurrence of measurable processes of lipid peroxidation (Fig. 5). Lipid peroxidation, therefore, seemed to occur when seeds started to die, i.e., after 4 d of treatment by phytotoxins (Fig. 2), and thus refers to deep damage of the seed lipid component that may concern either membrane or reserve lipids. Storage materials in mustard seeds are mainly proteins (ca. 60%) and lipids (ca. 40%), depending on the variety and environmental conditions. Increased lipid peroxidation in the presence of phytotoxins has also been shown in tomato roots (Cruz-Ortega et al., 2002) and in cucumber roots (Politycka, 1996). Damage of the whole membrane system of different plants (rape, cucumber, corn, and sorghum) analyzed at the biochemical and ultrastructural level has been detected in the presence of secalonic acid F, produced by *Aspergillus japonicus* (Zeng et al., 2001). Allelochemicals can damage cell membranes through direct interaction with a constituent of the membrane, or can result in an impairment of some metabolic processes necessary for the maintenance of membrane function.

With regard to the possible roles of oxidative stress in phytotoxicity, the changes in the main antioxidant enzymes have been investigated during seed imbibition on sunflower leaf extract. During the first 2 d of sunflower treatment, SOD and CAT activities did not evolve significantly and were similar to those measured in seeds imbibed in water (Table 1). However, GR activity was transiently and dramatically reduced by sunflower foliar extract (Table 1), which may account, at least in part, for the increase of H_2O_2 in the treated seeds (Fig. 3). Glutathione reductase is known to play a role in the control of endogenous H_2O_2 through its participation in the ascorbate–glutathione cycle and through the formation of reduced glutathione, a compound able to scavenge ROS (Goel et al., 2003). Its impairment would alter the scavenging ability of the cellular ROS and lead to an unbalanced accumulation of H_2O_2. Longer treatment of seeds by allelochemicals, i.e., from the fourth to eight day, was associated with a stimulation of CAT and SOD activities and with the recovery of GR activity (Table 1). Indeed, ROS are known to regulate the expression of many genes. One commonly cited possibility concerns the activation of transcription factors by redox status changes (Foyer and Noctor, 2003). Alternatively, gene

promoter regions may possess antioxidant response elements suspected to play a role in either H_2O_2 or antioxidant sensing, as in the case of the maize CAT *Cat1* gene (Scandalios et al., 1997). We cannot exclude the possibility that sunflower phytotoxins may influence synthesis of CAT isoforms. Western blot analysis showed that enhancement of CAT activity is associated with synthesis of CAT 5 and CAT 6 isoforms in seeds treated by sunflower extract (Oracz, personal communication). The results provide evidence that the effect of phytotoxins is not direct but occurs through regulation of ROS level in cells of mustard seeds. However, this stimulation of the cell antioxidant system was insufficient to avoid H_2O_2 accumulation (Fig. 3) or to prevent lipid peroxidation (Fig. 5) and did not prevent cell death (Fig. 2). Our data are consistent with those of Yu et al. (2003), which showed that exposure of cucumber roots to phytotoxic compounds significantly increased SOD activity. An increased CAT activity in response to allelochemicals has also been demonstrated in germinating cucumber seeds treated by different benzoic acids (Maffei et al., 1999). Romero-Romero et al. (2005) observed increased CAT activity in tomato affected by phytotoxins from *Sicyos deppei*. However, regarding the complex composition of sunflower leaves extract (Macias et al., 2002) it is not possible to conclude that there is a specific effect of phytotoxic compounds on antioxidant enzymes. Furthermore, it is known that activity and expression of most antioxidant enzymes is stimulated by ROS accumulation (Vranova et al., 2002; de Gara et al., 2003; Apel and Hirt, 2004). The first effect of sunflower phytotoxicity is a dramatic increase in H_2O_2 concentration and an inhibition of GR activity. It is thus highly probable that the observed stimulation of antioxidant enzymes does not result from a direct effect of sunflower compounds but is rather a consequence of the oxidative burst that occurs during the first hours of seed imbibition.

The presented data show that although some disturbances in seed metabolism during the germination process are common in both phytotoxic and osmotic stress, the markedly different response is a dramatic increase in the concentration of H_2O_2 and changes in GR activity. Therefore, we conclude that despite the similar effect caused by both stresses (inhibition/delay of germination), the mode of their action is different at the biochemical level, as was previously suggested by Romero-Romero et al. (2005).

Our results bring together several lines of evidence, indicating that the deleterious effect of phytotoxins on germination may occur through the imposition of an oxidative stress. The specific effect of sunflower compounds on GR activity explains, in part, the accumulation of H_2O_2, but future studies will have to deal with the precise mechanisms of ROS production during this treatment.

Abstract L-3,4-dihydroxyphenylalanine (L-DOPA), an allelochemical exuded from the roots of velvet bean [*Mucuna pruriens* (L.) DC. var. *utilis*], presents a highly inhibitory action to plant growth. The effects of L-DOPA on phenylalanine ammonia-lyase (PAL, EC 4.3.1.5) and peroxidase (POD, EC 1.11.1.7) activities, and phenolic compound and lignin content in soybean [*Glycine max* (L.) Merr.] roots were investigated to determine the possible phytotoxic mechanism. Three-day-old seedlings were cultivated in half-strength Hoagland nutrient solution (pH 6.0), without or with 0.1 to 1.0 mM L-DOPA in a growth chamber (25°C, 12-hr light to 12-hr darkness photoperiod, irradiance of 280 μmol m^{-2} s^{-1}) for 24 hr. In general, the length, fresh weight, and dry weight of the roots decreased, whereas PAL and POD activities and phenolic compound and lignin content increased after L-DOPA treatments. Results showed the susceptibility of soybean to L-DOPA and reinforce the role of this nonprotein amino acid as a strong allelochemical. The present findings also suggest that L-DOPA-induced inhibition in soybean roots may be because of a cell wall stiffening process related to the formation of cross-linking between cell wall polymers linked to lignin production.

Keywords Allelopathy · L-DOPA · Lignin · Peroxidase · Phenolic compounds · Phenylalanine ammonia-lyase · Root growth · Soybean · Nonprotein amino acid

Introduction

For years, it was known that plants release organic compounds into the environment from their aerial or subaerial parts as exudates, volatiles, and/or decomposition residues. These compounds may accumulate in the soil environment and affect the growth and development

of neighboring plants, an interaction called allelopathy (Einhellig, 1995). Velvet bean [*Mucuna pruriens* (L.) DC. var. *utilis*] is one such species that was long cultivated in tropical regions as a soil-improving crop, a cover crop to control weeds, green manure, and a forage plant (Anaya, 1999; Tarawali et al., 1999; Vargas-Ayala et al., 2000).

Using *in vitro* bioassays and field studies, Fujii et al. (1991) identified secondary chemical agents produced and released by the leaves and roots of *Mucuna*. The main phytotoxic compound encountered was the nonprotein amino acid L-3,4-dihydroxyphenylalanine (L-DOPA), which represented about 1% of the fresh tissues. L-DOPA exudes from *Mucuna* roots to the soil (Furubayashi et al., 2005), and its concentration may reach 1 ppm in water culture solution and 50 ppm in the vicinity of roots (Nishihara et al., 2005). This concentration is enough to affect the growth of neighboring plants by reducing seed germination and suppressing root growth more than shoots of other plant species (Fujii et al., 1991; Fujii, 1999; Nakajima et al., 1999; Nishihara et al., 2004, 2005; Hachinohe et al., 2004). L-DOPA's physiological mechanism in plants, however, is poorly understood. In animals, L-DOPA is a precursor of the neurotransmitter dopamine and the most effective therapeutic agent for the symptomatic relief of Parkinson's disease (Mercuri and Bernardi, 2005). In plants, L-DOPA is a precursor of many alkaloids, catecholamines, flavonoids, melanin, and phenylpropanoids (Hahlbrock and Scheel, 1989).

The phenylpropanoid pathway is an important metabolic pathway as it is involved in the synthesis of phenolic compounds and a wide range of secondary products in plants, including lignin. Phenylalanine ammonia-lyase (PAL) is the first rate-limiting enzyme of the phenylpropanoid pathway leading to the synthesis of the phenolic acids, and later, monolignols (Boerjan et al., 2003). Peroxidase (POD) within the cell wall, in either the free or bound state, is associated with monolignol polymerization and, therefore, in lignin synthesis (Passardi et al., 2005). To date, no reports on the effects of exogenous L-DOPA on soybean roots are available. Because of the important role of lignification in root growth, the question in the current research was whether L-DOPA affects PAL and POD activities and/or phenolic compound and lignin content of soybean roots.

Methods and Materials

General Procedures Soybean [*Glycine max* (L.) Merr. *cv.* BRS-133] seeds, surface-sterilized with 2% sodium hypochlorite for 5 min and rinsed extensively with deionized water, were dark-germinated (at 25°C) on three sheets of moistened filter paper. Twenty-five 3-d-old seedlings of uniform size were supported on an adjustable acrylic plate and transferred into a glass container (10×16 cm) filled with 200 ml of half-strength Hoagland's solution (pH 6.0), without or with 0.1 to 1.0 mM L-DOPA. The container was kept in a growth chamber (25°C, 12-hr light to 12-hr darkness photoperiod, irradiance of 280 μmol m^{-2} s^{-1}). Roots were measured at the beginning and end of the experiments (24 hr). The fresh root weight was determined immediately after incubation, and the dry weight was estimated after oven-drying at 80°C for 24 hr. L-DOPA was purchased from Sigma Chemical Co. (St Louis, MO, USA), and all other reagents used were of the purest grade available or chromatographic grade.

Enzymatic Assays After incubation, all treated or untreated seedling roots were detached, and enzymes were extracted. Phenylalanine ammonia-lyase (PAL) was extracted as described by Ferrarese et al. (2000). Fresh roots (2 g) were ground at 4°C in 0.1 M sodium borate buffer

(pH 8.8). Homogenates were centrifuged (2,200×*g*, 15 min), and the supernatant was used as the enzyme preparation. The reaction mixture (100 μmol sodium borate buffer, pH 8.7, and a suitable amount of enzyme extract in a final volume of 1.5 ml) was incubated at 40°C for 5 min for the PAL activity assay. Fifteen micromoles of L-phenylalanine were added to start the reaction, which was stopped after 1 hr of incubation by the addition of 50 μl of 5 N HCl. Samples were filtered through a 0.45-μm disposable syringe filter and analyzed (20 μl) with a Shimadzu® Liquid Chromatograph (Tokyo, Japan) equipped with an LC-10AD pump, a Rheodine® injector, an SPD-10A UV detector, a CBM-101 Communications Bus Module, and a Class-CR10 workstation system. A reversed-phase Shimpack® GLC-ODS (M) column (150×4.6 mm, 5 μm) was used at room temperature, with an equivalent pre-column (10× 4.6 mm). The mobile phase was methanol to water (70%:30%) with a flow rate of 0.5 ml min^{-1}. Absorption was measured at 275 nm. Data collection and integration were performed with Class-CR10 software (Shimadzu®, Tokyo, Japan). *t*-Cinnamate, the product of PAL, was identified by comparing its retention time with standard values. Parallel controls without L-phenylalanine or with *t*-cinnamate (added as an internal standard in the reaction mixture) were performed as described elsewhere (Ferrarese et al., 2000). PAL activity was expressed as μmol *t*-cinnamate hr^{-1} g^{-1} of fresh weight.

Peroxidase (POD) was extracted from fresh roots (0.5 g) with 67 mM phosphate buffer (5 ml, pH 7.0). The extract was centrifuged (2,200×*g*, 5 min, 4°C), and the supernatant was used to determine the activity of soluble POD. For cell wall-bound POD isolation, the pellet was washed with deionized water until no soluble POD activity was detected in the supernatant. The pellet was then incubated in 1 M NaCl (2 ml, 1 hr, 4°C), and the homogenate was centrifuged (2,200×*g*, 5 min). The supernatant contained the cell wall (ionically)-bound POD. Guaiacol-dependent activities of the soluble and cell wall-bound POD were determined according to Cakmak and Horst (1991), with slight modifications. The reaction mixture (3 ml) contained 25 mM sodium phosphate buffer, pH 6.8, 2.58 mM guaiacol, and 10 mM H_2O_2. The reaction started by adding the enzyme extract into the phosphate buffer. The guaiacol oxidation was followed for 5 min at 470 nm, and enzyme activity was calculated from the extinction coefficient (25.5 mM^{-1} cm^{-1}) for tetraguaiacol. The blank consisted of a reaction mixture without enzyme extract, and its absorbance was subtracted from the mixture with enzyme extract. POD activities were expressed as μmol tetraguaiacol min^{-1} g^{-1} fresh weight.

Absorption of L-DOPA by Soybean Roots Exogenous L-DOPA-treated or untreated roots (0.1-g dry weight) were put into 5 ml of deionized water in 30 ml polypropylene tubes. Extraction was performed by immersing the tubes into a sonication bath for 5 min (St-Laurent et al., 2002). Extracts were then centrifuged at 2,200×*g* for 2 min and diluted (1:1) in the chromatographic mobile phase containing water to methanol to phosphoric acid (97.5:2:0.1). The solution was filtered through a 0.45-μm disposable syringe filter and analyzed (20 μl) with a Shimadzu® Liquid Chromatograph (Tokyo, Japan), as described earlier. A reversed-phase Shimpack® GLC-ODS (M) column (150×4.6 mm, 5 μm) was used, at room temperature, with an equivalent pre-column (10×4.6 mm). The mobile phase was applied with a flow rate of 0.5 ml min^{-1}. Absorption was measured at 280 nm. Data collection and integration were performed with Class-CR10 software (Shimadzu®, Tokyo, Japan). L-DOPA was identified by comparing its retention time with that of the standard. The L-DOPA concentration in the sample = standard concentration × peak area of the sample / peak area of the standard. L-DOPA absorption was expressed as mg g^{-1} of dry weight.

Phenolic Compound Quantification Dry root (0.25 g) was boiled for 30 min in 5 ml of 2 N HCl. After cooling, the homogenate was filtered through a Whatman® paper, and the filtrate was used to determine the total phenolic compound content. Samples (5 ml) were mixed with 0.75 ml of 1.9 M Na_2CO_3 plus 0.25 ml of Folin-Ciocalteau phenol reagent. This mixture was kept in the dark at room temperature (23–25°C) for 1 hr before its absorption was read at 750 nm (Blum et al., 1991). Ferulic acid was used as the standard. As L-DOPA absorbed by the roots might lead to overestimated results, data obtained by high performance liquid chromatography (HPLC) (described earlier) were subtracted from the total phenolic compound content. Results were expressed as mg total phenolic compound content g^{-1} dry weight.

Lignin Quantification After the incubation period, dry roots (0.3 g) were homogenized in 50 mM potassium phosphate buffer (7 ml, pH 7.0) with a mortar and pestle and transferred into a centrifuge tube (Ferrarese et al., 2002). The pellet was centrifuged (1,400×*g*, 4 min) and washed by successive stirring and centrifugation as follows: twice with phosphate buffer pH 7.0 (7 ml); 3× with 1% (v/v) Triton® X-100 in pH 7.0 buffer (7 ml); 2× with 1 M NaCl in pH 7.0 buffer (7 ml); 2× with distilled water (7 ml); and 2× with acetone (5 ml). The pellet was dried in an oven (60°C, 24 hr) and cooled in a vacuum desiccator. The dry matter obtained was defined as a protein-free cell wall fraction. Further, all dry protein-free tissue was placed into a screw-cap centrifuge tube containing the reaction mixture (1.2 ml of thioglycolic acid plus 6 ml of 2 M HCl) and heated (95°C, 4 hr). After cooling at room temperature, the sample was centrifuged (1,400×*g*, 5 min), and the supernatant was discarded. The pellet contained the complex lignin–thioglycolic acid (LTGA). The pellet was washed 3× with distilled water (7 ml), and the LTGA was extracted by shaking (30°C, 18 hr, 115 oscillations min^{-1}) in 0.5 M NaOH (3 ml). After centrifugation (1,400×*g*, 5 min), the supernatant was stored. The pellet was washed again with 0.5 M NaOH (3 ml) and mixed with the supernatant obtained earlier. The combined alkali extracts were acidified with concentrated HCl (1.8 ml). After precipitation (0°C, 4 hr), LTGA was recovered by centrifugation (1,400×*g*, 5 min) and washed 2× with distilled water (7 ml). The pellet was dried at 60°C, dissolved in 0.5 M NaOH, and diluted to yield an appropriate absorbance for spectrophotometric determination at 280 nm. Lignin was expressed as mg LTGA g^{-1} dry weight.

Statistical Design The experimental design was completely randomized, and each plot was represented by one glass container with 25 seedlings. Data are expressed as the mean of three to six independent experiments±SE. Significant differences were verified by the one-way analysis of variance with *GraphPad Prism*® package (Version 2.0, GraphPad Software Inc., USA, 1995). Differences between parameters were evaluated by the Dunnett's multiple comparison test, and P values < 0.05 were considered as statistically significant.

Results

To evaluate if L-DOPA had been absorbed by the roots, soybean seedlings were incubated with this compound (0.1 to 1.0 mM) for 24 hr. Fig. 1 shows that L-DOPA was progressively absorbed by the roots. After exogenous 0.1-mM treatment, L-DOPA content determined in

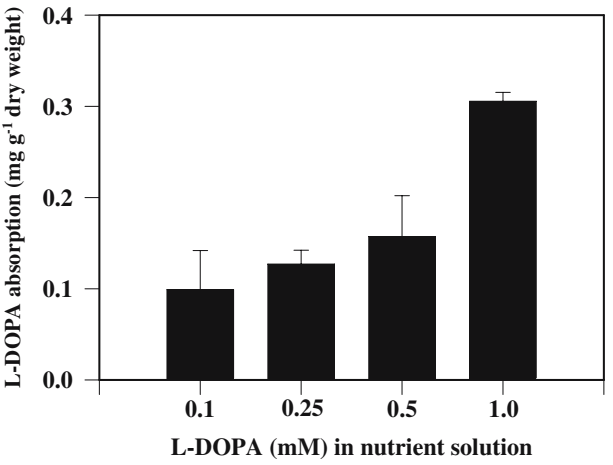

Fig. 1 Absorption of L-DOPA by roots treated exogenously with the allelochemical (0.1 to 1.0 mM) for 24 hr. Mean values±SE from three independent experiments with 25 seedlings for each determination are shown

the roots reached 0.099-mg g^{-1} dry weight, whereas at 1.0 mM, the content amounted to 0.306-mg g^{-1} dry weight.

Root lengths and root fresh and dry weights decreased with increasing concentrations in soybean seedlings grown during short-term exposure (24 hr) in nutrient solution containing L-DOPA (Fig. 2). Mean total root lengths (Fig. 2a) were 20.9, 72.5, and 76.7% less than the control (2.15±0.101 cm) for 0.25, 0.5, and 1.0 mM treatments, respectively. Low concentration (0.1 mM) did not impair root length. Root fresh weight (Fig. 2b) decreased 11.2 and 14.3% at 0.5- and 1.0-mM treatments, respectively, when compared to the control (2.58±0.012 g). A similar trend was also evident in root dry weights (Fig. 2c) determined as 16.1 and 14.9% less than the control (0.174±0.001 g) with 0.5 and 1.0 mM L-DOPA.

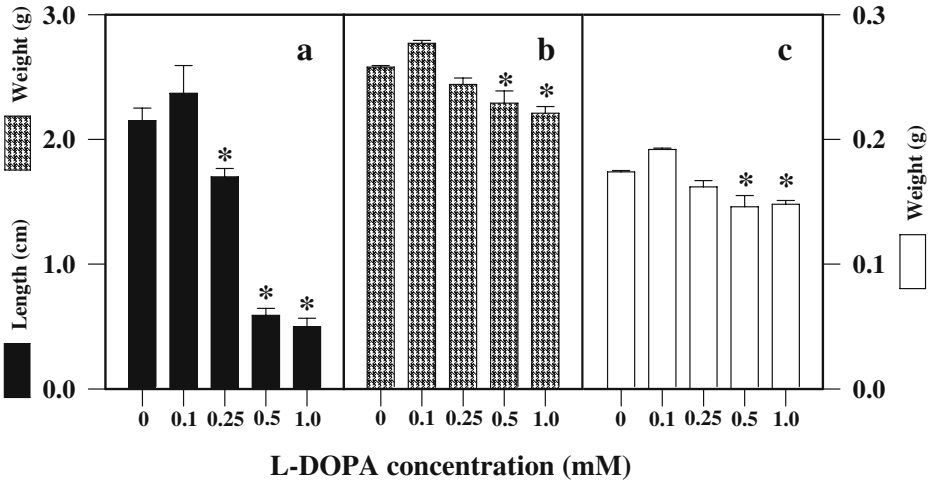

Fig. 2 Effects of L-DOPA on root length (**a**), root fresh (**b**), and dry (**c**) weights of soybean seedlings. Mean values±SE from five independent experiments with 25 seedlings for each determination are shown. *Significant at $P<0.05$ level as compared with the control seedlings

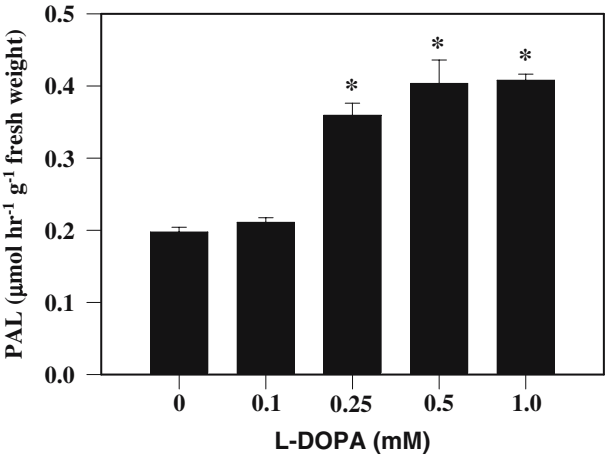

Fig. 3 Effects of L-DOPA on phenylalanine ammonia-lyase (PAL). Mean values±SE from four independent experiments with 25 seedlings for each determination are shown. *Significant at $P<0.05$ level as compared with the control seedlings

No significant differences in the fresh and dry weights of roots exposed to L-DOPA at low concentrations (≤0.25 mM) were recorded.

L-DOPA-affected PAL activities were significantly different from the controls (Fig. 3). The allelochemical increased the enzymatic activities from 82 to 106% after 0.25- to 1.0-mM treatments. No significant change was observed in PAL activity after 0.1 mM L-DOPA exposure. Soluble POD activities (Fig. 4a) increased around 39%, and cell wall-bound POD activities (Fig. 4b) increased around 31% regardless of L-DOPA concentrations, when compared to control conditions.

The phenolic compound content was significantly increased from 86% (at 0.1 mM) to 150% (at 1.0 mM) when compared to untreated roots (Fig. 5). Finally, data revealed that the

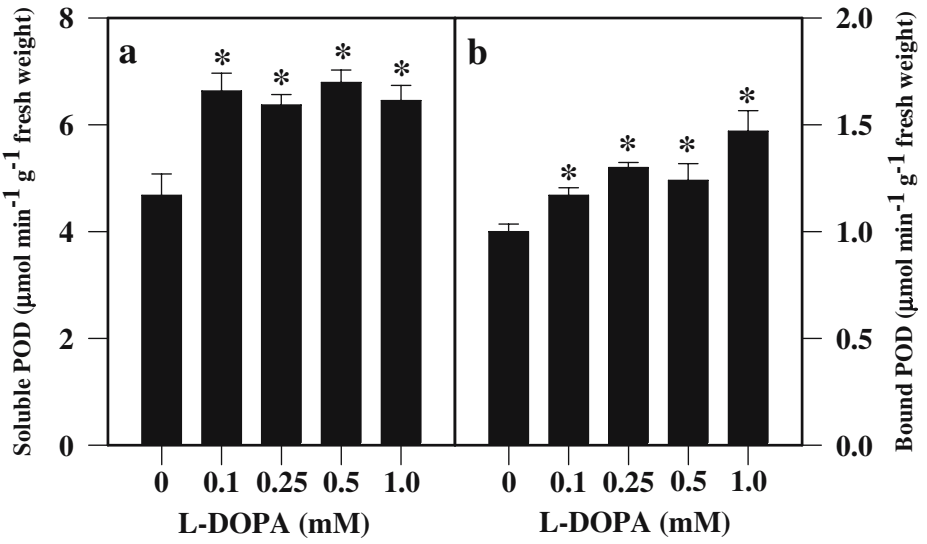

Fig. 4 Effects of L-DOPA on soluble (**a**) and cell wall-bound (**b**) peroxidases (POD). Mean values ± SE from five independent experiments with 25 seedlings for each determination are shown. *Significant at $P<0.05$ level as compared with the control seedlings

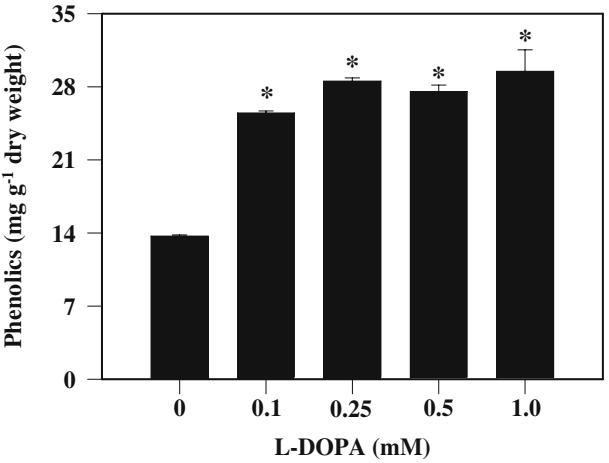

Fig. 5 Effects of L-DOPA on total phenolic compound content. Mean values ± SE from four independent experiments with 25 seedlings for each determination are shown. *Significant at $P<0.05$ level as compared with the control seedlings

lignin content increased around 56% from 0.25- to 1.0-mM L-DOPA, whereas no significant change was recorded at 0.1-mM treatment when compared to untreated roots (Fig. 6).

Discussion

The main finding revealed in the current research is that root growth (length and weight) decreased (Fig. 2) after L-DOPA absorption (Fig. 1), whereas PAL and POD activities and phenolic compound and lignin content increased (Figs. 3 to 6). Another finding is that there is no dose dependency (Dayan et al., 2000). No significant differences among the L-DOPA concentrations (0.25 to 1.0 mM, for example) were recorded for most of the variables analyzed. Therefore, dose-response curves indicating the inhibition threshold for root growth (Fig. 2) or the lowest concentration that completely activates all other variables (Figs. 3 to 6) could not be accurately determined.

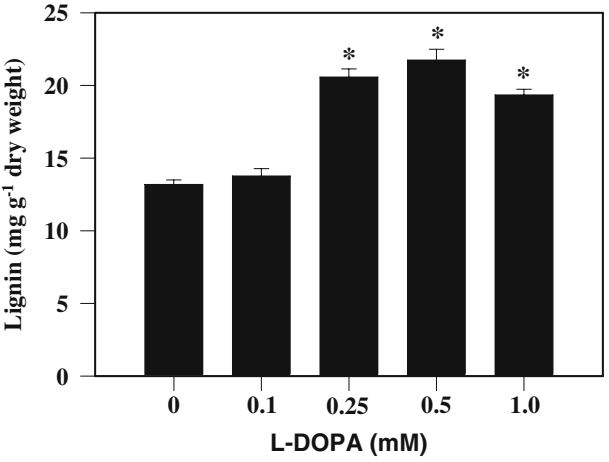

Fig. 6 Effects of L-DOPA on lignin contents. Mean values ± SE from six independent experiments with 25 seedlings for each determination are shown. *Significant at $P<0.05$ level as compared with the control seedlings

Reduction of root growth by L-DOPA was reported in several plant species. Nishihara et al. (2004) used a treatment of 250 μg/ml (about 1.27 mM) and showed that L-DOPA strongly inhibited (<25% of control) root growth of cabbage (*Brassica oleraceae*), komatsuna (*Brassica campestris*), qing gin cai (*Brassica chinensis*), baby blue eyes (*Nemophila menziesii*), watercress (*Nasturtium officinale*), pumpkin (*Cucurbita moschata*), lettuce (*Lactuca sativa*), and cucumber (*Cucumis sativus*). However, tall fescue (*Festuca arundinacea*), perennial ryegrass (*Lolium perenne*), creeping bentgrass (*Agrostis palustris*), red clover (*Trifolium pratense*), milk vetch (*Astragalus sinicus*), hairy vetch (*Vicia villosa*), and corn (*Zea mays*) were less inhibited (>75% of control) and suggested a possible resistance to L-DOPA. The effect of L-DOPA (0.01 or 0.1 mM) on root growth of 32 species was examined at the germination stage (Hachinohe et al., 2004). Root growth was <50% of the control value for 7 of the 19 species treated with 0.01 or 0.1 mM L-DOPA, respectively. Barnyard grass (*Echinochloa crus-galli*) was more tolerant than lettuce, one of the most susceptible species (about 80% inhibition by 0.1 mM L-DOPA). As L-DOPA reduced the soybean root growth and fresh and dry weights (Fig. 2), its susceptibility was indicated, and the amino acid's role as a strong allelochemical was reinforced.

Investigations of the absorption of L-DOPA in plant species are scanty. Using ^{14}C-L-DOPA, Hachinohe et al. (2004) reported that this compound was largely absorbed and metabolized by the roots of barnyard grass and lettuce. The authors verified that metabolites (dopamine, phenylalanine, and tyrosine) derived from ^{14}C-L-DOPA are not directly involved in L-DOPA phytotoxicity. As results reported in the present work indicate that L-DOPA was effectively absorbed by soybean roots (Fig. 1), reduction of root growth by L-DOPA verified after 24-hr treatments (Fig. 2) may be because of this active form in the roots.

The discovery that L-DOPA stimulated lignin production (Fig. 6) is of particular interest. Reduction of seedling roots was associated with premature allelochemical-induced lignification of the cell walls accompanied by increases in phenolic compound content and PAL and POD activities. PAL participates in root growth reduction of maize (Devi and Prasad, 1996), cucumber (Politycka, 1999), and soybean (Herrig et al., 2002; Santos et al., 2004) under stress of cinnamic and benzoic acids derivatives. In these cases, the increase in PAL activity was associated with lignin production. Likewise, higher activities of PAL (Fig. 3) in soybean root tissues were accompanied by an increase in phenolic compound content (Fig. 5) after L-DOPA treatments.

Phenolic compounds play a vital role in plant growth and regulation and also in protecting plants from abiotic and biotic stresses. They are known for their antioxidative properties of scavenging free radicals (Appel, 1993). Phenolic compounds are derived originally by enzymatic deamination of phenylalanine and tyrosine via nitrogen-free skeletons of cinnamate or *p*-coumarate. Once formed, the latter compounds are converted, within the phenylpropanoid metabolism, into a broad range of secondary metabolites such as caffeic, ferulic, and sinapic acids, and eventually, lignin (Boerjan et al., 2003). PAL and POD are involved in this pathway, and the production of phenolic compounds was often observed when levels of phenylpropanoid pathway intermediates or end products are artificially increased. Stress caused by the addition of exogenous allelochemicals (ferulic and vanillic acids) in soybean stimulates the accumulation of phenolic compounds and lignin (Herrig et al., 2002; Santos et al., 2004).

As mentioned earlier, L-DOPA is a precursor of phenylpropanoids. L-DOPA-treated roots of cucumber accumulate nontoxic amino acids (phenylalanine and tyrosine) supposedly because of the oxidation of the allelochemical (Nakajima et al., 1999). In contrast,

dopamine (a product of enzymatic decarboxylation of L-DOPA), tyrosine (the substrate of tyrosine decarboxylase to form dopamine), and phenylalanine (the substrate of PAL in the first reaction of the phenylpropanoid pathway) failed to increase in lettuce roots after exogenous L-DOPA treatments (Hachinohe et al., 2004). In the authors' opinion, these metabolites are not directly involved in the phytotoxicity of L-DOPA as they may be further metabolized into other compounds. It is known that phenylalanine and tyrosine are precursors of phenylpropanoids and lignin (Boerjan et al., 2003). As reported here, soybean is susceptible to L-DOPA (Fig. 2). Although phenylalanine and tyrosine were not monitored in soybean roots treated with L-DOPA, it is reasonable to suppose that the increases in PAL activity (Fig. 3) and phenolic compound content (Fig. 5) may be because of the utilization of these amino acids in the phenylpropanoid pathway.

Increased activities of soluble POD (Fig. 4a) associated with reduced root growth (Fig. 2) induced by L-DOPA are consistent with one of the several functions of this enzyme in plants. Soluble POD mediates the oxidation of L-DOPA to form dopaquinone, and further, melanin (Albrecht and Kohlenbach, 1990; Takahama and Egashira, 1991; Nishihara et al., 2004). Melanin biosynthesis is linked to the production of reactive oxygen species (ROS) or other L-DOPA oxidation products such as semiquinone radicals, quinones, and metal ion-L-DOPA complexes (Kruk et al., 1999; Pattison et al., 2002). In general, ROS and quinones have the potential to interact with many cellular components, triggering stresses in plants, leading to membrane damage, blocking of nutrient uptake and hindering of root growth (Appel, 1993; Einhellig, 1995). Hachinohe and Matsumoto (2005) have recently reported that L-DOPA increases the levels of melanin and thiobarbituric acid-reactive substances (TBARS) in lettuce, which suggests that this action is because of ROS released during melanin synthesis. As the soybean radicle becomes light brown or black after 0.1 and 1.0 mM L-DOPA treatments, respectively, it is reasonable to suppose that the increase in soluble POD activities (Fig. 4a) may be because of oxidation of L-DOPA, and possibly, to melanin formation.

L-DOPA also increased cell wall-bound POD activities (Fig. 4b). One of the noteworthy features of cell wall-bound POD is its association with growth-restricting conditions linked to cell wall stiffening (Passardi et al., 2005). This enzymatic form polymerizes monolignols from phenolic compounds such as ferulic, *p*-coumaric, and caffeic acids. This process requires oxidative coupling and is dependent on H_2O_2. If cell wall-bound POD regulates cell wall stiffening and lignin polymerization (Boerjan et al., 2003), there must be a sufficient supply of H_2O_2. This relatively stable form of ROS may be released during oxidative transformation of L-DOPA into melanin (Kruk et al., 1999). As observed here, increased activities of cell wall-bound POD were associated with a significant decrease in the root length and fresh and dry weights (Fig. 2), and an increase in the lignin content (Fig. 6). Thus, L-DOPA may decrease the root growth because of premature cell wall lignification induced by cell wall-bound POD.

It has become clear from this study that L-DOPA treatment of soybean seedlings results in an increase of PAL activity and increased phenolic compound content. Furthermore, H_2O_2-dependent POD reactions convert phenolic substances into phenoxyl radicals that may produce lignin monomers. These monomers form a complex network that solidifies the plant cell wall and subsequently restricts root growth. According to the results of the current research, it is probable that L-DOPA-induced inhibition in soybean roots may be because of a cell wall stiffening process related to the formation of cross-linking among cell wall polymers and lignin production. If this is the working mode of L-DOPA, the cell wall may be a site for allelopathic action and may indicate how the compound affects the growth of

plant species. One may ask whether these effects are exclusively because of L-DOPA itself or to products of its metabolism. Notwithstanding the fact that L-DOPA was absorbed by roots (Fig. 1), its metabolism was not explored in soybean seedlings. However, Hachinohe and Matsumoto (2005) evaluated the L-DOPA metabolism in other plant species and suggested that its phytotoxicity was because of metabolism and not to its absorption. Therefore, the possibility cannot be discarded that data reported here are results of L-DOPA-induced oxidative stress because of ROS released during its transformation into melanin and/or because of its auto-oxidative breakdown. Further studies are required to elucidate the L-DOPA metabolism in soybean roots and to identify ROS generated during this pathway. This is the challenge of a new study in progress.

Abstract Competition is an important factor that has been extensively reported in the Mediterranean area. There is evidence that leaf terpene accumulation may vary between plants growing on calcareous and siliceous soils. In the present study, leaf terpene emissions from potted seedlings of *Pinus halepensis, Cistus albidus*, and *Quercus coccifera*, growing under natural environmental conditions on calcareous and siliceous substrates, were studied by using a bag enclosure method. In both substrates, seedlings were potted alone and in intraspecific competition, to examine the effect of substrate type and that of intraspecific competition on terpene emissions. The results showed that competition favored: (i) overall monoterpene and sesquiterpene emissions from *Q. coccifera*; (ii) overall monoterpene emissions from *P. halepensis*; (iii) overall sesquiterpene emissions from *C. albidus*. Substrate type affected terpene emissions to a limited extent and in a species-specific way. Whereas for *Q. coccifera*, the overall monoterpene emissions and that of Allo-aromadendrene were favored on siliceous substrate, no significant changes were found in emissions from *P. halepensis*. Only the release of AR-curcumene from *C. albidus* was higher on siliceous substrate. We also found high variability in terpene emission composition from the study species, particularly for *P. halepensis* and *Q. coccifera*. These two species released both monoterpenes and sesquiterpenes, instead of monoterpenes only, as shown in previous studies.

Introduction

Emission of biogenic volatile organic compounds (BVOC) from leaves is an important mechanism through which plants modify air quality on a global (Guenther et al., 1995), regional

(Fuentes et al., 2000), and local scale (Simon et al., 2001). In particular, oxidation of terpenes contributes to both ozone (O_3) and secondary organic aerosols (Guenther, 2002). In addition, these natural emissions may increase the life span of greenhouse gases, such as CH_4, which are related to the pattern of global climatic change (Guenther et al., 1995). Consequently, there is interest in understanding which environmental factors affect terpene emissions from plants. This especially concerns Mediterranean regions, as such emissions are directly implicated in O_3 concentration even on a local scale (Simon et al., 2005), and this secondary pollutant exceeds the European tolerated limits several times per year (Millan et al., 1996). Although the scientific community has devoted considerable effort to understand the effect of environmental factors on BVOC in the Mediterranean Region, estimates of these compounds are still uncertain (Staudt et al., 2000). This is partly because of the range of factors controlling these emissions.

With regard to abiotic factors, few studies have addressed the issue of soil nutrient effects on terpene emissions, whereas the effect of climate-related factors is well documented. In contrast to released terpenes, studies dealing with soil nutrient effects on stored or accumulated terpenes within leaves have been more frequent (e.g., Kainulainen et al., 1996; Close et al., 2004). However, those studies were performed on the basis of different fertilizer treatments (Harley et al., 1994; Litvak et al., 1996), and they show inconsistent results. Only a few studies have shown that plant emissions vary on soils of different natural fertility, such as calcareous and siliceous soils. Robles and Garzino, (1998) and Flamini et al. (2004) showed that some terpene content from Mediterranean species varied according to soil type. However, other studies have shown that there is no correlation between terpene content and emissions (Gershenzon et al., 2000). The degree of dependency of terpene emissions on soil type will not necessarily be the same as that found for terpenes stored within leaves.

With regard to biotic interference on emissions, terpenes are currently associated with: (i) attractant compounds that favor pollination or seed dispersal (Caissard et al., 2004); (ii) herbivore and pathogen deterrents (Holopainen, 2004); and (iii) plant to plant communication (Gniazdowska and Bogatek, 2005).

Plant to plant competition is common under natural conditions (Goldberg and Barton, 1992), and one prevalent interaction is competition for limited resources. As soils are often nutrient-poor in Mediterranean regions, the study of competition is of particular interest. Moreover, plant biomass and growth are especially sensitive to competition (Ramseier and Weiner, 2006; Midoko-Iponga et al., 2005), and these factors may explain some BVOC variability among plants of the same species (Batten et al., 1995). Nevertheless, the effect of this factor remains almost wholly unexplored, as only a single study is available on terpene emission response to competition (Peñuelas and Llusià, 1998).

The aim of this work was to examine whether terpene emissions change when plants grow: (i) on calcareous or siliceous substrate, and (ii) alone or in intraspecific competition. We also analyzed whether these two factors interact, as it has been reported that competition for nutrients is more intensive when nutrient availability is high (Vila and Sardans, 1999).

Methods and Materials

Species Studied Terpene emissions from *Pinus halepensis* Mill. (Pinales, Pinaceae), *Cistus albidus* L. (Malvales, Cistaceae), and *Quercus coccifera* L. (Fagales, Fagaceae), which are typical of the Mediterranean area, were studied. The tree species studied, *P. halepensis*, is representative throughout the Mediterranean Basin, where it is widespread (Quézel, 2000). *P. halepensis* (Orshan, 1989) and *C. albidus* (Passama, 1970) grow both on calcareous and siliceous substrates even if they are mainly calcicole species. *Q. coccifera* is rarely found on

siliceous soils (Bornand et al., 1997). All study species form both monospecific and mixed stands in Mediterranean ecosystems. However, they often form dense and abundant monospecific stands in areas that have been previously disturbed by recurrent fire (*Q. coccifera*, Larcheveque et al., 2005; *C. albidus*, Robles, 1998; *P. halepensis*, Barbero et al., 1990).

Experimental Setup The study was performed on 2-yr-old potted seedlings. Seedlings were obtained from plant collections of the nursery garden (Luberon, Lambesc, southern France). For each species, four seedlings were potted alone (four pots, four seedlings) and four other seedlings were potted with another seedling of the same species (in intraspecific conditions) (four pots, four seedlings). In both cases, seedlings were potted on siliceous and on calcareous substrates, thus making a total of 16 seedlings per species. All seedlings were irrigated similarly and regularly to avoid any water stress. Substrates came from natural garrigue sites (of southern France) from the first 25 cm of the soil layer. Soils were sampled in May 2003 and then potting took place over several weeks in summer 2003.

The main physical and chemical properties of calcareous and siliceous substrates were analyzed (Table 1). Calcareous substrate was mainly characterized by higher values of N, Ca^{2+}, TOC (total organic carbon), K^{+}, pH, clay, and silt (Table 1), whereas siliceous substrate showed mainly higher values of Mg^{2+} and sand.

Terpene emission sampling was performed from 15–19 April 2004, from 11:00 to 15:30 (solar time). Experimentation was carried out under natural environmental conditions. During the study period, air temperature varied between 23 and 27°C, PAR (Photosynthetically Active Radiation) ranged from 800 to 1,000 μmol m^{-2} s^{-1}, wind speed was negligible, and air humidity was less than 30%. Weather was typical of the spring season, with alternative cloudy and sunny sky.

Terpene Sampling A semidynamic bag enclosure system, made of Teflon film (FEP), was applied to enclose a single healthy twig per plant. The health of leaves was visually checked. Sun- and shade-exposed leaves, as well as primary and secondary leaves, were considered. The emission rate obtained through this method may be taken as a representation of the mean emission rate. The system consisted of 16 bag enclosures. Each (0.5 l) was designed with two air streams, inlet and outlet.

Table 1 Physical and chemical properties of the calcareous and siliceous substrates studied

Properties	Siliceous Substrate	Calcareous Substrate
pH (H_2O)	6.18±0.20	7.22±0.09
TOC (total organic C) (%)	1.80±0.28	5.96±0.35
Total N (%)	0.084±0.005	0.334±0.005

[a] Values are mean ± SE. N=8.

Before samples were taken, the bag air was renewed, and each bag was continuously flushed with nonpolluted air (Alphagaz, 99.99% purity, Type 1) through a Tygon tube (Tygon® Fuel and lubricant tubing; o.d: 11.2 mm, i.d: 8 mm), especially designed for hydrocarbon transport. Inflowing air (Qe) was measured with a digital mass-flow controller (Aalborg® CFC17, 0–500 ml). Qe was 110±20 ml min^{-1} and was maintained for 15 min, so that the bag air was renewed three times. After air renewal, terpene sampling took place (while inflowing air was maintained). The outgoing terpenes from each bag enclosure were collected on glass sorbent tubes filled with preconditioned Tenax TA (Varian®: 20–35 mesh, 150 mg, 160×5×3 mm), using a pumping system (Edwards®) placed downstream of the Tenax TA. One sorbent tube per bag was used. We previously demonstrated in the laboratory that there were no significant differences between trapped terpene concentrations in four Tenax TA placed simultaneously at different air stream outlets of the same bag enclosure. Outflowing air (Qs) at each bag enclosure was measured with a bubble flow meter (0–280 ml/min, GPE Meterate 314-140/084), placed immediately after each sorbent tube. Flow meters were specially designed to allow connection to a tube, as each bubble flow meter was linked to the pump by means of a reinforced flexible antioxidant PVC tube (i.d. 0.8 mm). Terpene sampling took place for 10 min at Qs=80±30 ml min^{-1}. Constancy of Qs at each bag enclosure was verified every 2 min. Of the 16 bag enclosures constructed, only 14 were directly used to sample terpene emissions; one was always allocated to a blank with no twig in the gas exchange system, and another was used for measurements of air temperature inside the enclosure. After measurements, each sampled twig was cut off and stored in a portable refrigerator at +4°C until being stored at −20°C in the laboratory. Leaves from each twig were separated and lyophilized to measure dry mass (DM).

Terpene Analyses Adsorbed terpenes in Tenax TA were analyzed through thermal desorption by gas chromatography (GC) fitted with a Flame ionization detector (FID) (HP®5890 series II). Before thermal desorption, a preflush phase was run (3 min, 10 ml min^{-1}, 60°C), to allow humidity in Tenax TA to be evacuated. This phase was also necessary to accurately analyze sesquiterpene adsorbed compounds. Then, thermal desorption (Thermal Desorption Cold Trap injector, Varian®, CP4020-TCT model) was carried out through nitrogen carrier gas (10 min, 50 ml min^{-1}, 250°C) and cryogenic concentration in a silica capillary trap, cooled with liquid nitrogen at −100°C. Finally, compounds were separated in the nonpolar chromatographic column (Ultra 2, 50 m× 0.2 mm×0.25 μm).

The identity of terpenes was confirmed by comparison with standards of high purity (Aldrich-Firminich). Calibration of monoterpene and sesquiterpene factor response, used to calculate their concentrations, was performed periodically throughout the sampling period. In a few cases, when standards were not available, peak identification was achieved by injection of previously extracted terpenes from each species, in Tenax TA. The identity of these compounds was determined by means of a GC (HP®6890) coupled with a mass spectrometer (MS) (HP®5973 Network Mass Selective Detector).

Statistical Analyses and Standard Terpene Emission Calculation Statistical treatments were applied to standardized emissions. In the case of *P. halepensis* and *C. albidus*, standardization at 30°C was carried out with the algorithm proposed by Tingey et al. (1980), as temperature is considered to be the main factor controlling emissions from these storing species in the short-term (Llusià and Peñuelas, 2000). As *Q. coccifera* is a nonstoring species, emissions were standardized at 30°C and 1,000 μmol s^{-1} m^{-2} according to the model of Guenther et al. (1995). Temperature and light are currently agreed to be the

main factors controlling monoterpene emissions from nonstoring species (Staudt et al., 2000). Thus, all emission data presented throughout this study represent standard emissions, expressed as mean ± SE.

Two-factor analysis of variance (ANOVAs) was applied to test the effect of both substrate type and intraspecific competition, and possible interacting effects between factors. This statistical test was performed for the overall monoterpene and sesquiterpene emissions, and for the major compounds released from each species. Data were log-transformed, when necessary, to meet normal requirements for ANOVAs analysis. Statistical analyses were performed by using Statistical Graphics® version 4.1.

Results

P. halepensis mainly emits monoterpenes (Table 2). Overall monoterpene emission rate is 3.12±0.75 μg h^{-1} $g_{DM}{}^{-1}$, whereas that of sesquiterpenes is only 0.29±0.04 μg h^{-1} $g_{DM}{}^{-1}$.

The major released compounds are α-pinene and Δ^3-carene. Substrate type does not significantly modify either the overall monoterpene and sesquiterpene emissions (ANOVAs, $P>0.05$; Fig. 1) or those of any major compound (ANOVAs, $P>0.05$; Table 3). Whereas substrate type has no effect on terpene emissions from *P. halepensis*, its overall monoterpene emissions (ANOVAs, $P<0.05$; Fig. 1) and emissions of all major monoterpenes, except those of β-pinene (ANOVAs, $P>0.05$; Table 3), increase significantly in conditions of intraspecific competition, irrespective of substrate type. By contrast, the overall sesquiterpene emissions do not change in competition (ANOVAs, $P>0.05$; Fig. 1)

C. albidus is mainly a sesquiterpene emitter (Table 2). Sesquiterpene emission rate is about threefold that of monoterpenes (4.44 ± 1.08 μg h^{-1} $g_{DM}{}^{-1}$). The major sesquiterpenes emitted are α-zingiberene, followed by AR-curcumene and allo-aromadendrene (Table 3). Among the monoterpenes, only α-pinene shows high emission rates. Neither the overall monoterpene, nor the overall sesquiterpene emission rates, show significant changes on calcareous and siliceous substrates (ANOVAs, $P>0.05$; Fig. 1). Only emissions of AR-curcumene rise when seedlings of *C. albidus* grow on siliceous substrate (ANOVAs, $P<0.05$; Table 3). By contrast, emissions from *C. albidus* are markedly dependent on competition, irrespective of substrate type. The overall sesquiterpene emissions (Fig. 1), and those of β-bourbonene and β-caryophyllene, are significantly higher when this species grows in competition (ANOVAs, $P<0.05$; Table 3).

Finally, *Q. coccifera* releases monoterpenes and sesquiterpenes similarly (Table 2). This species shows the lowest emission rate of species examined here (Fig. 1). The major monoterpenes released are α-pinene, followed by β-pinene and sabinene (Table 3). The major sesquiterpenes released are α-caryophyllene and allo-aromadendrene (Table 3). Emission of the overall monoterpenes is significantly higher when *Q. coccifera* grows on siliceous substrate (*ANOVAs*, $P<0.05$; Fig. 1). This is caused by α-pinene, which is the only major monoterpene emitted in higher amounts when seedlings grow on siliceous

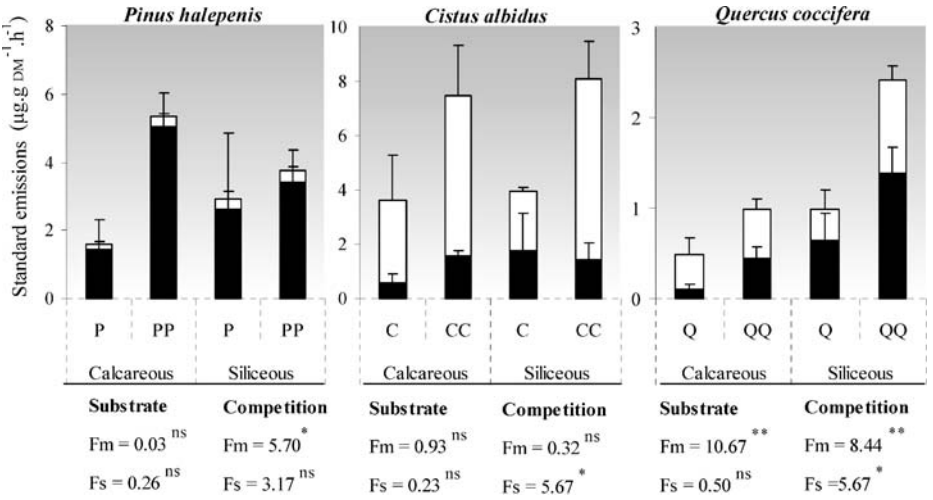

Fig. 1 Monoterpene and sesquiterpene standard emissions from *P. halepensis, C. albidus*, and *Q. coccifera* on calcareous and siliceous substrates, isolated and in intraspecific competition. Values are mean ± SE ($N=4$). Bars indicate the standard error. P, C, Q: isolated seedlings. PP, CC, QQ: seedlings in intraspecific competition. Results of the two-way ANOVAs (substrate and competition) are also shown. *Fm, Fs*: test values for monoterpenes and sesquiterpenes, respectively; ns: not significant at 95% of confidence; *$0.01<P<0.05$; **$0.001<P<0.01$

substrate (*ANOVAs*, P<0.05; Table 3). The overall sesquiterpene emissions do not significantly change according to substrate type (*ANOVAs*, P>0.05; Fig. 1). Only emissions of α-caryophyllene are higher when seedlings are potted on siliceous substrate (*ANOVAs*, P<0.05; Fig. 1). With regard to competition, the overall monoterpene and sesquiterpene emissions are higher when *Q. coccifera* grows in intraspecific competition (*ANOVAs*, P< 0.05; Fig. 1), both on calcareous and siliceous soils. Emissions of all major compounds, except those of β-pinene, are also higher in competition (*ANOVAs*, P<0.05; Table 3).

Discussion

The aim of the investigation was to extend our understanding of the dependency of terpene emissions on environmental factors. The effect of both substrate type and intraspecific competition, and their potential interaction, were explored on emissions from seedling plants. Despite the recognized importance of competition for different aspects of plant development (e.g., biomass, growth, phenology), little attention has been paid to the impact this biotic factor may have on terpene emissions. The results showed that even if calcareous and siliceous substrates differed in their nutrient resources, competition had a positive effect on terpene emissions among all species irrespective of the substrate type. Thus, this biotic factor had a positive effect on terpene emissions from *P. halepensis* (monoterpenes), *C. albidus*

(sesquiterpenes), and *Q. coccifera* (monoterpenes and sesquiterpenes). Only Peñuelas and Llusià (1998) have previously dealt with the effect of competition on terpene emissions. These authors found similar results to those reported here. They observed that when two seedlings of *P. halepensis* grew together, monoterpene emissions were favored. However, they reported the opposite response for *Q. ilex* where seedlings growing alone showed higher emission rates. Hence, the pattern shown here for *Q. coccifera* in intraspecific competition is different from that reported for *Q. ilex*. Both *Quercus* are long-lived, perennial, and angiosperm species, with a broad edaphic tolerance. Moreover, their emissions have been shown to vary similarly with light and temperature (Niinemets et al., 2002). A possible explanation for the apparent difference in impact of intraspecific competition on terpene emissions between *Q. ilex* and *Q. coccifera* is that Peñuelas and Llusià (1998) added nutrients to substrates during the sampling period, whereas nutrients were not added in our study.

This is the first investigation into plant emissions on calcareous and siliceous substrates, and it shows that, in contrast to intraspecific competition, substrate type affects terpene emissions in a species-specific way. On one hand, monoterpene emissions from *Q. coccifera* were considerably higher on siliceous substrate. On the other, emissions from *P. halepensis* showed similar rates on calcareous and siliceous substrates. Finally, a single major compound released by *C. albidus* showed higher emission rates on siliceous substrate. We think that the higher terpene emissions reported in this study for *Q. coccifera* on siliceous soils is the consequence of stress, as this is a calcicole species that is rarely found on siliceous soils (Bornand et al., 1997).

This study also showed that sesquiterpenes have been neglected, in particular with regard to emissions from *Q. coccifera*, although they may constitute an important fraction of total emitted compounds. The lack of sesquiterpene emission data in previous studies for *Q. coccifera* and *P. halepensis* might, however, be explained by differences in sampling methodology and analysis protocols. Moreover, as sesquiterpenes may alter the tropospheric balance, notably by favoring aerosol formation (Guenther, 2002), their isoprenoids should not be excluded either from terpene emission inventories or from models designed for predicting secondary pollutant concentrations and climate change.

In summary, this study was carried out to contribute to a better understanding of environmental factors that modify the release of terpenes by plants. The results presented could be taken into account: (i) to update terpene emissions from these species in current terpene emission inventories, as sesquiterpenes have not so far been considered; (ii) as input in models commonly used for predicting terpene emissions from plants to obtain more accurate estimations; (iii) to obtain better insight into factors that modify the secondary metabolism of plants. In a broader perspective, it might be of interest to examine whether terpene emissions from these and other Mediterranean species show the same response to the factors analyzed here over the whole seasonal cycle.

Acknowledgments This research was primarily funded by the French Agriculture Minister (DERF), the Environmental agency (ADEME), and PACA region (Presence-Alpes-Côte d'Azur). We thank Sylvie Dupouyet for collaboration in measurement campaigns. We are grateful to Christine Ballini for advice on soil analysis. We are also grateful to Patrice Brahic, the director of the national nursery garden "Aix Les Milles," and Michael Paul for improvements in the English.

Do Elevated Temperature and CO_2 Generally Have Counteracting Effects on Phenolic Phytochemistry of Boreal Trees?

Abstract Global climate change includes concomitant changes in many components of the abiotic flux necessary for plant life. In this paper, we investigate the combined effects of elevated CO_2 (720 ppm) and temperature (+2 K) on the phytochemistry of three deciduous tree species. The analysis revealed that elevated CO_2 generally stimulated increased carbon partitioning to various classes of phenolic compounds, whereas an increase in temperature had the opposite effect. The combined effects of both elevated CO_2 and temperature were additive, i.e., canceling one another's individual effects. Obviously, the effects of global climate change on leaf chemistry must simultaneously consider both temperature and CO_2. If these results are generally applicable, then the counteracting effect of the temperature is likely to play a major role in alpine, boreal, and arctic zones in determining the balance between populations of plants and herbivores.

Keywords Climate change · Secondary compounds · Metabolism · *Betula* · *Salix* · Phenolics

Introduction

Global climate change, considered as an increase in atmospheric CO_2 and temperature, can influence interactions between plants and their herbivores by changing the quality of plants as food by making them more stoichiometrically unbalanced for their herbivores (Loladze 2002; Sterner and Elser, 2002). For example, a review of the literature on CO_2 elevation by Bezemer and Jones (1998) revealed that leaf nitrogen concentration decreased on average

by 15%, whereas carbohydrates and plant phenolics increased by 47% and 31%, respectively. Zvereva and Kozlov (2006), in their metaanalysis of the consequences of the simultaneous elevation of CO_2 and temperature on plant traits, made similar conclusions about CO_2 effects, but concluded that temperature alone typically had opposite effects, whereas temperature and CO_2 combined had negligible effects. Both reviews concluded that insects from different feeding guilds generally responded to CO_2-mediated changes in host-plant quality by compensating for decreased nitrogen levels and increased phenolic levels in the plant tissues by increasing their food consumption, but suffered lowered food conversion efficiencies, and longer larval development.

General circulation models (GCM) indicate that, especially in arctic, alpine, and boreal zones, elevated temperatures will accompany rising levels of CO_2 (Prentice et al., 1992; IPCC 1996). In these geographic zones, the effects of elevated temperature may be especially important because the growth of most plants is typically temperature-limited. Although the effects of elevated atmospheric CO_2 on plant physiological processes has long been studied, the combined effects of elevated temperature and CO_2 are only poorly known. The growth-differentiation balance model of plant development suggests elevated CO_2 may generally increase carbon partitioning to secondary metabolites like phenyl propanoids because it typically increases plant source strength (rates of photosynthate accumulation) more than sink strength (Herms and Mattson, 1992; Mattson et al., 2005). However, the effects of elevated temperature are much less predictable because it is not fully obvious how that will simultaneously influence both source and sink processes and thus the crucial source-sink carbon balance over plant development.

Temperature increases generally raise the rates of biochemical reactions, but such reactions also depend on the supplies of available substrates and enzymes to sustain them. If plant sink (growth) processes are more sensitive to ameliorative changes in temperature than is photosynthesis (Mattson and Haack, 1987a,b; Herms and Mattson, 1992), then the plant's source-sink balance may generally decline with rising temperatures because sink demands will outpace source supplies. This could lead to reduced carbon partitioning to facultative secondary metabolism. Although this reasoning is obviously elementary, as a starting point it suggests that under favorable growing conditions (i.e., adequate nutrients and water), the effects of elevated CO_2 and temperature might be counterbalancing, as was evident in the Zvereva and Kozlov (2006) metaanalysis. However, metaanalysis indicates only pattern or a trend combined from completely separate studies and tells very little about the metabolic processes lying behind the phenomena. In this study, we go a layer deeper to understand better those partitioning processes affected by elevated CO_2 and temperature treatments by using a dataset coming from one controlled experimental system (Kellomäki et al., 2000). Here, we use graphic vector analysis (GVA), which allows us to analyze if the target phytochemical response is associated with changes in total dry weight, or target chemical content, or is some combination of these two partitioning alternatives.

We argue that to predict the effects of global climate-change-mediated responses in phytochemistry and plant–herbivore relationships, the CO_2 × temperature interaction must be more fully considered.

Methods and Materials

Analytical Procedures We employed graphic vector analysis (GVA) for representing and interpreting the fundamental changes in the plants' growth and phytochemical components

in response to different treatments (Timmer and Stone, 1978; Haase and Rose, 1995; Koricheva, 1999). This method, although laborious, has been proposed as an alternative to simply examining phytochemical concentrations to understand environmental effects on carbon partitioning to the synthesis of the target compounds (Koricheva, 1999). If GVA is more insightful than simply evaluating changes in concentrations of target compounds, it is because GVA also requires measuring and evaluating total plant (or organ) growth that is necessary to construct the axes. GVA is, in fact, three-dimensional plotting of target compound concentration (Y axis), total plant (organ) content (X axis), and total plant (organ) size (Z axis). Instead of using raw values, the data are converted to their relative values, using the control as the standard in the following manner:

$$(elevated\ value - control\ value) \times control\ value^{-1}$$

Total relative dry weight growth of a plant is the inverse of the slope of the aforementioned plot of Y vs. X variables, and all such plotted plant-relative dry weights will lie on diagonal lines corresponding to the Z axis (Fig. 1.). If the goal is to measure and evaluate treatment effects on plant carbon partitioning to a target phytochemical compound, there are two basic responses, either increased or decreased relative partitioning, as indicated on the Y axis by relative concentrations being greater or less than 1, respectively. If, however, one also considers how treatments affect relative plant organ size (presented here as specific leaf weight) in addition to partitioning to the target compound, there are eight possible outcomes (Fig. 1, Table 1): increased relative synthesis and a) decreased or b) increased specific leaf weight (*i.e.*, gm^{-2}); decreased synthesis and c) decreased or d) increased specific leaf weight; no change in synthesis and either e) decreased or f) increased specific leaf weight; and finally, g) increase or h) decrease in synthesis, but no change in specific leaf weight.

The use of relative values allows one to present the results of several plant species, and treatments on the same graph. Each point represents the relative mean value of each plant species for each compound in question. We did not test the data statistically, because that was already done in the studies from which these data were extracted (Lavola and

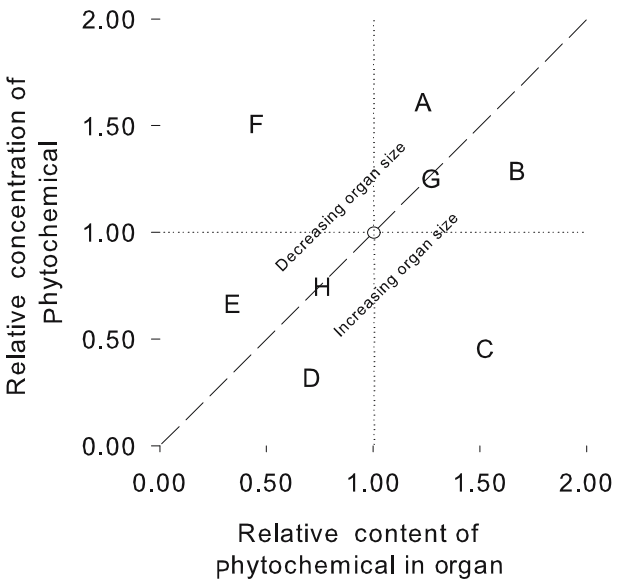

Fig. 1 Interpretation of directional shifts in chemical concentration, chemical content, and specific leaf weight. Modified from Timmer and Stone (1978), Haase and Rose (1995), and Koricheva (1999). Dotted lines represent reference lines for no change in phytochemical character in question. Dashed line indicates relative plant unit biomass, reference point (control sample) has values (1, 1, 1). Letters refer to quadrants in Table 1

Table 1 Interpretations of quadrants in Fig. 1

Julkunen-Tiitto, 1994; Lavola et al., 1998; Kuokkanen et al., 2001, 2003; Veteli et al., 2002; Veteli 2003; Veteli, unpublished). The direction and magnitude of the vectors from reference or control (1, 1, 1) are used to interpret the effects of the treatments (Fig. 1, Table 1). There are four quadrants in a vector diagram with the diagonal (Z axis = 1) bisecting the upper right and lower left. All vector points to the left of the dashed diagonal are cases where the treatment plants are smaller than control, and all vector points to right of the diagonal are cases where treatment plants are larger. All changes in phytochemical concentrations (Y axis) are the result of shifts in the relative rates of synthesis of both phytochemical content and plant biomass. We avoid the GVA parlance of "diluting" and "concentrating," etc. with respect to the target compound(s) because we believe that it is misleading and inappropriate. Growing plants are continuously adjusting their carbon partitioning based on their unfolding developmental programs, source-sink balances, environmental conditions, and stochastic events. This implies that a target compound is simply being diluted or concentrated in response to treatments and environments, and it is misleading because it suggests a passive process. Instead, carbon partitioning alternatives are of physiological and ecological import to the plant. Having a substantial capacity for changing carbon partitioning at a given time and circumstance is crucial to plant fitness.

Treatments and Studies Included The treatment conditions used in these studies were: (i) control CO_2 and temperature, (ii) elevated CO_2 and control temperature, (iii) control CO_2 and elevated temperature, and (iv) elevated CO_2 and temperature. The mean control and elevated CO_2 concentrations were 360 and 720 ppm, respectively. The elevated temperature was obtained by raising the ambient air temperature by 2 K, on average, from that of the control chambers to correspond to the climate warming scenarios predicted after a doubling of the atmospheric CO_2 concentrations (IPCC 1996). Treatments were done at the Mekrijärvi Research Station, University of Joensuu (62°47′N, 30°58′E, and 145 m a.s.l.), eastern Finland. Sixteen closed-top climate chambers were divided in four CO_2 and temperature treatments (as above), with four replicates in each (Kellomäki and Wang, 1998). Outdoor climate chamber studies (Kuokkanen et al., 2001, 2003; Veteli et al., 2002; Veteli 2003; Veteli, unpublished) and results from indoor chamber studies in which the CO_2 levels were as above (Lavola and Julkunen-Tiitto, 1994; Lavola et al., 1998) were included in the vector analysis.

The tree species used in these experiments (*Betula pubescens*, *B. pendula*, and *Salix myrsinifolia*) are species that are widely distributed and common in boreal zone. Their responses to various environmental factors have been extensively studied and, therefore,

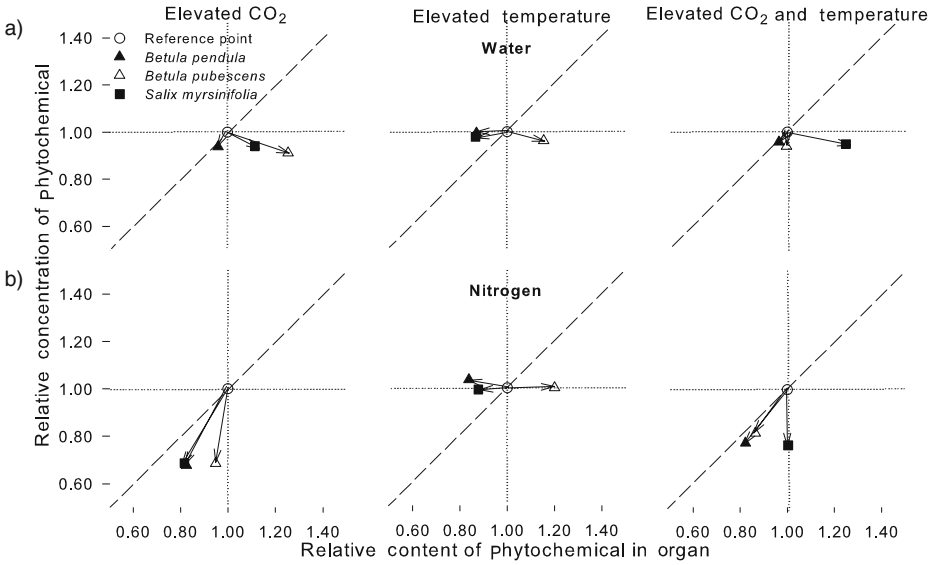

Fig. 2 Directional shifts in A) water and B) nitrogen in relation to climate change factors. The first figure in the column indicates the effect of elevated CO_2, second the elevated temperature, and the third their interaction

provide a fruitful basis for this study. Sampling and chemical analysis are described in detail by Lavola and Julkunen-Tiitto (1994); Lavola et al. (1998); Kuokkanen et al. (2001), (2003); Veteli et al. (2002); and Veteli (2003).

Results

Graphic vector analysis (GVA) shows that specific leaf mass responded rather consistently to treatments. CO_2 enrichment by itself resulted in heavier leaves per area unit on all three tree species (Figs. 2, 3, 4, and 5, first figure in a row). In contrast, elevated temperature by

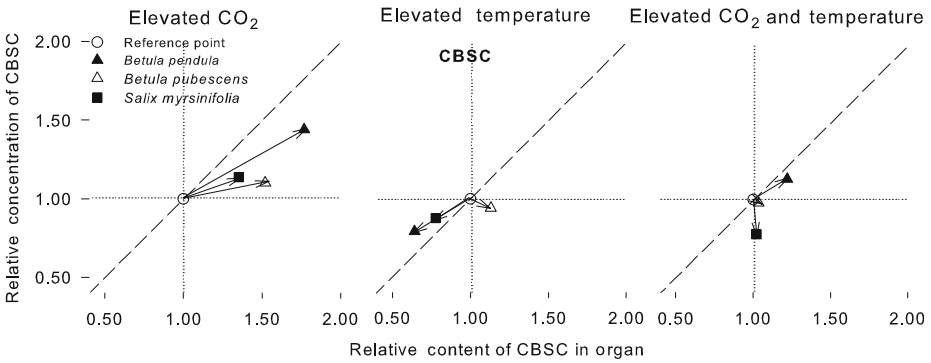

Fig. 3 Directional shifts in detected carbon-based secondary compounds in relation to climate change factors. The first figure in a column indicates the effect of elevated CO_2, second the elevated temperature, and the third their interaction

itself reduced specific leaf weights on two species, but increased that of *Betula pubescens* (Figs. 2, 3, 4, and 5, second figure in a row) The combination of elevated CO_2 and temperature resulted in no net change in specific leaf weight, except for *Salix* where it increased, as if CO_2 overwhelmed the temperature effect (Figs. 2, 3, 4, and 5, third figure in a row).

With respect to foliar chemicals, all graphs generally suggest that there is a counteracting effect between elevated CO_2 and temperature, although the effect is weakest for water and N (Figs. 2, 3, 4, and 5). In the case of water, elevated CO_2 generally increased specific leaf weights but not water uptake, and water concentrations fell. Elevated temperature had negligible effect on water concentrations, whereas the combined effect of CO_2 and temperature caused all plants to have slight decreases in water concentrations, although no declines or even increases in total leaf water content (Fig. 2a). In the case of N, elevated CO_2 generally reduced assumed N uptake and N concentration in all three species (Fig. 2b). Elevated temperature, however, had no effect on foliar N concentrations, although total N content both increased and decreased (Fig. 2b). On the other hand, the combination of CO_2 and temperature caused reduced N uptake and concentrations (Fig. 2b).

With respect to phenolic secondary metabolites, elevated CO_2 generally elicited increased synthesis of detected total carbon-based secondary compounds (CBSC) and thus increased concentrations (Fig. 3). The pattern was the same for most of the component synthetic groups such as phenolic acids, salicylates, flavonoids, and condensed tannins (Figs. 4 and 5). On the other hand, elevated temperature generally elicited diminished synthesis and concentration of total CBSC, and most of the component molecular groups. Tannins were an exception because they were diminished in only *B. pendula*. The combined treatments of CO_2 and temperature elicited steady states or small change in concentrations

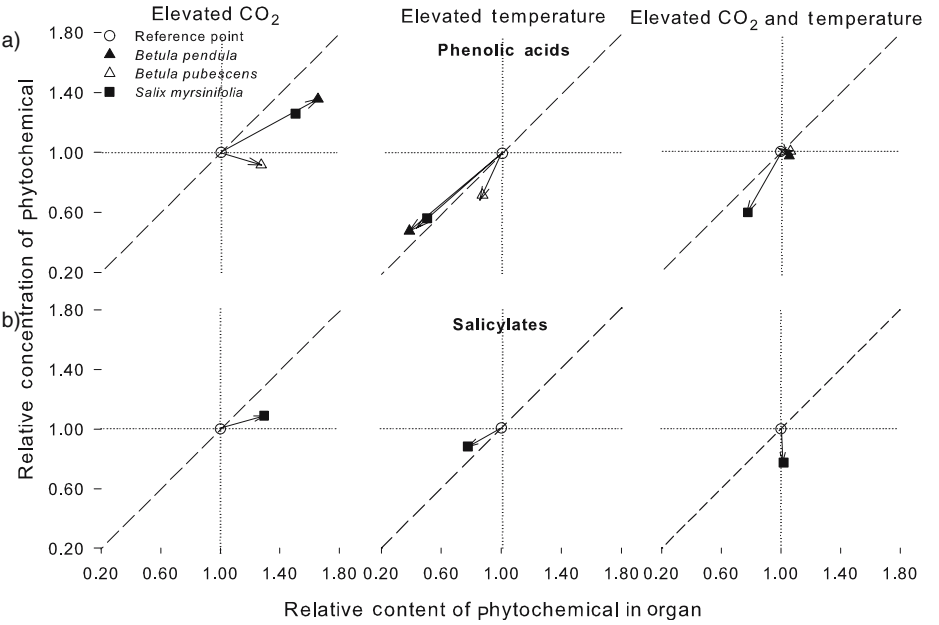

Fig. 4 Directional shifts in A) phenolic acids and B) salicylates in relation to climate change factors. The first figure in a column indicates the effect of elevated CO_2, second the elevated temperature, and the third their interaction

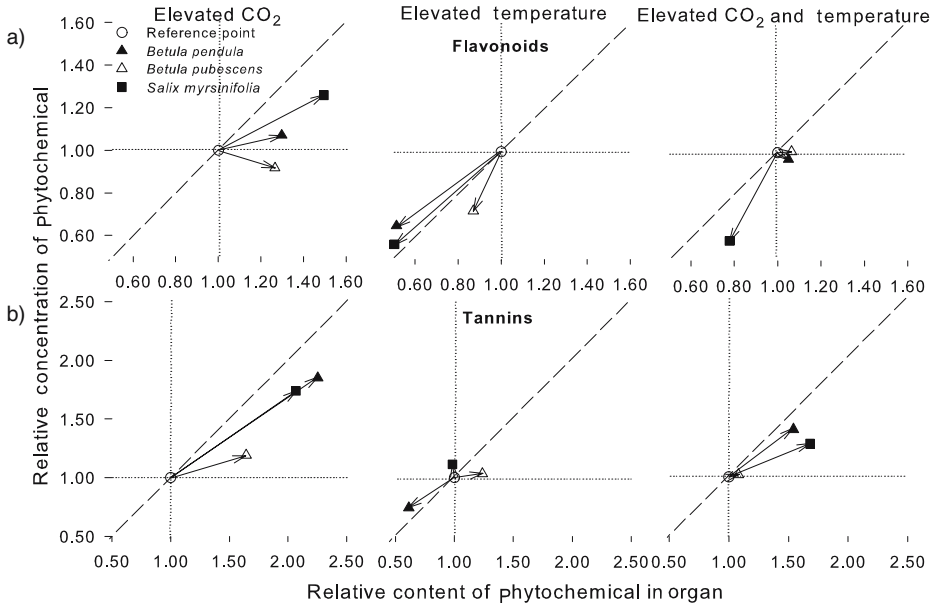

Fig. 5 Directional shifts in A) flavonoids and B) tannins in relation to climate change factors. Notify different scaling in figures A) and B). The first figure in a column indicates the effect of elevated CO_2, second the elevated temperature, and the third their interaction

of secondary compounds in most instances for the two *Betula* species. However, *S. myrsinifolia* was much more responsive. Elevated CO_2 and temperature generally caused substantially reduced concentrations of most phenolics (Figs. 3, 4, and 5a), except for tannins which increased, as was also true for *B. pendula* (Fig. 5b). The data suggest that heightened temperatures generally reduced the magnitudes of the changes that were elicited by elevated CO_2 (Fig. 5b).

Discussion

We showed that the interactions between elevated CO_2 and temperature are typically additive and generally cancel one another. Generally, elevated CO_2 increased the accumulation of total CBSC and specific carbon-based secondary compounds as has been proven in previous studies (Lincoln et al., 1993; Bezemer and Jones, 1998; Hunter, 2001; Zvereva and Kozlov, 2006). However, the climate changes predicted also include rising temperatures, and in this study, changes of only 2 K eliminated the effect of elevated CO_2 on analyzed carbon-based secondary compounds within the leaves. It could be assumed that CO_2 enhancement either increased the synthesis or decreased the turnover rate, and that temperature elevation caused the opposite. For almost all of the plant species previously studied, the carbohydrate concentrations of leaves have been reported to rise by an average of 47% in response to elevated CO_2 (Bezemer and Jones, 1998). In the present study, the carbohydrate concentrations were not measured, but specific leaf weights increased under enriched CO_2, which may be a result of starch accumulating in the leaves. The effect was present also in the combination of the treatments, although not so intense. Starch may or

may not enhance the herbivore's ability to digest leaves, whereas structural carbohydrates (cellulose, hemicellulose), as well as lignin, will very likely interfere with feeding and digestion, especially that of small larvae (Lincoln et al., 1993; Reavey, 1993).

The accumulation of nonstructural carbohydrates under elevated CO_2 in leaves has been reported in many studies (e.g., Johnson and Lincoln, 1991; Lindroth et al., 1993; Hall et al., 2005), but this alone does not explain the reduction in nitrogen concentration observed in this study because total leaf N content also declined. The higher C/N ratio implies perhaps a surfeit of C during leaf ontogeny, thereby allowing more partitioning to facultative synthesis of secondary metabolites. Likewise, both N concentrations and total leaf N were lower in the foliage from the combined treatments, although leaf size was unaffected for the two *Betula* species, but larger for *S. myrsinifolia*. Their C/N ratios were lower than in the CO_2 treatment but higher than in the elevated temperature treatments that were the same as control. Because insect herbivores tend to be nitrogen-limited (Mattson, 1980), possible reductions in nitrogen concentration may substantially reduce insect performance. Thus, it could be expected that the consequences of reduced nitrogen will also prevail in the boreal zone after modest temperature elevation, possibly having a reducing effect on herbivory (see, e.g., Hall et al., 2005). In total, however, the positive effect of temperature may have an ameliorating or even enhancing effect on the growth rates of insects (e.g., Lindroth et al., 1997; Holopainen and Kainulainen, 2004).

Our results here and earlier suggest that elevated CO_2 and temperature can enhance the growth of plants (Kuokkanen et al., 2001, 2004; Veteli et al., 2002; Veteli 2003) while lowering the levels of nitrogen and water in leaf tissue. The effects of elevated CO_2 on levels of CBSC are quite variable depending on the species and compound in question (see, e.g., Agrell et al., 2004; Hall et al., 2005), whereas temperature elevation tends to lower CBSM levels in these species, which is also shown as a general trend in Zvereva and Kozlov's (2006) study. These differing reactions are probably caused by different source–sink interactions: if enhanced plant growth demand is not more than matched by enhanced photosynthesis, there may be a subsequent diminution in available carbon for facultative secondary metabolism. The effect of rising temperature may be similar to the nonlinear effect of fertilization on CBSCs (Herms and Mattson, 1992; Herms, 2002). Some insect species feeding on these plants have increased consumption and reduced growth (e.g., Bezemer and Jones, 1998; Veteli et al., 2002; Zvereva and Kozlov, 2006), and, therefore, may be subjected to natural enemies for a longer time under elevated CO_2. Higher temperatures, on the other hand, may directly compensate for some of the negative effects of increased CO_2; increasing temperatures affect the distribution of some species by shifting ranges poleward and altitudinally upward (e.g., Parmesan et al., 1999; Battisti et al., 2005). The reason for these observed species range shifts can be a result of reducing extreme winter temperatures, increasing thermal sum, or subsequent changes in properties of the host plants.

Hence, we argue that in alpine, boreal, and arctic areas the effect of the rising temperature in addition to levels of atmospheric CO_2 should be taken into account in making any predictions about the effects of climate change on phytochemistry and plant–herbivore–natural enemy interactions (Mattson and Haack 1987a,b). The GCM predicts that in these areas the most important factor of climate change is temperature elevation. We conclude that when studying the effects of climate change we must consider both the effects of enriched CO_2 and elevated temperature. This is especially true in alpine, boreal, and arctic environments where temperature is often the most important factor limiting growth.

Abstract *Brugmansia suaveolens* (Solanaceae) contains tropane alkaloids (TAs), which can act as chemical defenses. Selective pressures might modulate the allocation of alkaloids within the plant, as postulated by optimal-defense theory. By tracing scopolamine, the most abundant TA in this species, we found that scopolamine in an artificial diet, in concentrations similar to those in leaves of *B. suaveolens*, increased mortality and prolonged developmental time of the larvae of the generalist noctuid moth *Spodoptera frugiperda*. A diet of undamaged leaves of *B. suaveolens* also showed a large negative effect on the growth of larvae of *S. frugiperda* compared to a diet of leaves of *Ricinus communis*, a species that did not have negative effects on this moth; more valuable plant parts, such as young leaves, flowers, and unripe fruits with seeds, have higher scopolamine concentrations than other tissues; leaves of *B. suaveolens* increase their content of scopolamine after artificial damage. The highest induction was found 24 hr after the damage, and after that, scopolamine content decreased to constitutive levels. This increase represented a cost, because in another experiment, a treatment with methyl jasmonate, an elicitor hormone, increased scopolamine production 9.5-fold and decreased leaf growth 2.3-fold; a diet of artificially damaged leaves of *B. suaveolens* showed a negative effect on the growth of larvae of *S. furgiperda* compared to undamaged leaves, suggesting that damage by herbivores induces resistance. Our data are in line with the optimal-defense theory, but experiments in the field with herbivores that share an evolutionary history with *B. suaveolens* must be undertaken to understand the dynamics of TA allocation in response to herbivory.

Introduction

Plant defenses are costly, and optimal-defense theory, originally outlined by McKey (1974) and later elaborated by Rhoades (1979), predicts that defenses should be preferentially allocated to more valuable plant parts, resulting in a spatial and temporal allocation. Changes in resistance to herbivores of plants following damage, induced responses, are a saving–cost strategy, where the responses and response-associated costs are increased only when the benefit can be realized, e.g., in the presence of the damage (Zangerl and Bazzaz, 1992; Karban and Baldwin, 1997). These responses can be morphological (Young, 1987) or chemical (Zangerl and Bazzaz, 1992; Karban and Baldwin, 1997, and references therein). The latter are generally due to an increase in protease inhibitors or compounds of secondary metabolism. Green and Ryan (1972) made pioneer studies on chemical induced responses, showing that simulated herbivory increases the content of protease inhibitors in leaves of young potato and tomato. Induced responses are also associated with biotic responses of the third throphic level, such as ants (Agrawal, 1998; Romero and Izzo, 2004). The last three decades have shown an increase in studies focusing on chemical induced responses by herbivory, reporting a broad spectrum of secondary metabolites that are inducible (see Karban and Baldwin, 1997, and references therein). Few studies have reported on the induction of tropane alkaloids (TAs) in plants. Andries, cited in Rhoades (1979), found an increase in TA content in *Datura* sp. after nutrient stress. Khan and Harborne (1990) showed, after artificial damage or herbivory by mollusks, that leaves of *Atropa acuminata* (Solanaceae) increased the TA content by 160%. However, Shonle and Bergelson (2000) did not find an induction of these compounds in insect-damaged *Datura stramonium* leaves. TAs are reported to be effective against many herbivorous insects (Hsiao and Fraenkel, 1968; Krug and Proksch, 1993; Wink, 1993; Shonle, 1999). Hyoscyamine, scopolamine, and other esters of tropine constitute a distinctive group of secondary metabolites of the Solanaceae (Griffin and Lin, 2000). They have been found in the subfamilies Schizanthoideae, Solanoideae, and Nicotianoideae, and are especially abundant in certain tribes, e.g., Datureae, Hyoscyameae, and Mandragoreae. In Physaleae, Solaneae, and Solandreae, only a limited number of taxa produce these alkaloids, which are completely absent in other tribes and subfamilies (Wink, 2003).

Brugmansia suaveolens (Humb. & Bonpl. Ex Willd.) Bercht. & J. Presl. (Solanaceae: Solanoideae: Datureae) produces TAs (Freitas et al., 1996). This plant is a small tree native to South America, 2–5 m high, with leaves ovate to narrowly elliptic; large, 20–30-cm-long white flowers; and 10–15-cm-long fusiform fruits. The genus is closely related to *Datura* (Olmstead and Palmer, 1992; Griffin and Lin, 2000; Wink, 2003). In the field, *B. suaveolens* has been reported to be used as host plant by larvae of the specialist ithomiine butterflies *Placidula euryanassa* (=*Placidina euryanassa*, Lamas, 1999) and *Miraleria cymothoe* (Freitas, 1993; Freitas et al., 1996).

In the present work, we investigated whether chemical defense strategies of *B. suaveolens*, involving TAs, matched optimal-defense theory (McKey, 1974, 1979; Rhoades, 1979). We predicted that (1) TAs defend *B. suaveolens* against herbivores, (2) TAs have differential distributions in plant organs according to value for the plant in each phenological phase, (3) TAs are costly, and (4) TAs increase when the plants are subject to herbivore attack. To test these predictions, we performed experiments to verify the effect of scopolamine on the performance of a model of generalist insect herbivore; we analyzed the amount of the TA scopolamine in different plant organs in each phenological phase; we artificially damaged leaves of *B. suaveolens* and verified changes of scopolamine content; we tested whether artificially damaged leaves decreased the performance of a generalist

herbivore; and we verified whether an increase in scopolamine content, thorough elicitation by the phytohormone methyl jasmonate, represented a metabolic cost to *B. suaveolens*. We analyzed scopolamine as a representative TA of *B. suaveolens* because this alkaloid is the major one found in *B. suaveolens* (Freitas et al., 1996), and, biosynthetically, scopolamine is one of the more derived TAs (Croteau et al., 2000). In an escalating arms-race scenario between plants and herbivores, the more derived compound could be expected to be more active against herbivory (Berenbaum, 1983).

Methods and Materials

Plant material Individuals of *B. suaveolens* were collected in semidecidous mesophyll forest, along stream edges in the Serra do Japi, Jundiaí, São Paulo State, Brazil (from 23° 13′21.9″S, 46°58′14.0″W to 23°13′15.1″S, 46°58′5.2″W). A voucher specimen was deposited at the Herbarium of the Institute of Biology (UEC 35387) and at the Herbarium of the Centro Pluridisciplinar de Pesquisas Químicas, Biológicas e Agrícolas (CPQBA 171). Stem cuttings (several clones of each individual) of 10 different individuals of *B. suaveolens* were rooted for 20 d in flasks containing 0.1% of benomyl solution inside an acclimatized chamber at 25±2°C with a light intensity of 40 μmol/m^2s and a 12-hr photoperiod. Rooted cuttings were transferred to 2-l pots containing a mixture of soil and sand (3:1). Each pot was supplied once with 100-ml full Hoaglands nutrient solution (Hoaglands and Arnon, 1950) to enhance root production and to help in establishment of plants in the pots.

Herbivores Larvae of first instars of the polyphagous noctuid moth *Spodoptera frugiperda* were obtained from Bug Biological Agents, Piracicaba, São Paulo, Brazil (http://www.bugbrasil.com.br/eng/index2.htm), and maintained in an acclimatized chamber (L12:D12, 25±1°C, and about 70% RH). Larvae were reared individually in plastic pots, 4 cm in diam, 5 cm high, on artificial wheat germ diets (Ferraz, 1991).

Performance of a generalist herbivore insect on scopolamine diet To verify negative effects of scopolamine on the performance of generalist herbivore insects, we use as an herbivore model the polyphagous pest insect *S. frugiperda*. Although this generalist noctuid does not share its evolutionary history with *B. suaveolens*, this species or related ones are commonly used as models for generalist insect herbivores to make predictions (e.g., Blau et al., 1978; Miller and Feeny, 1983; Krug and Proksch, 1993; Bultman and Bell, 2003; Dyer et al., 2003; Macel et al., 2005). Second instars of *S. frugiperda* were maintained in an acclimatized chamber (L12:D12, 25±1°C, and about 70% RH), and were reared individually in individual plastic pots, 4 cm in diam, 5 cm high, on artificial wheat germ diets containing the treatments 0, 0.05, 0.25, 0.5, and 2.5% dry weight of commercial scopolamine during their entire development. Before use, scopolamine hydrobromide trihydrate Across™ was basified and extracted ×3 with $CHCl_3$, yielding the free-base scopolamine. We used free-base scopolamine because the form in which this compound occurs in plants containing TAs is controversial. Choi et al. (1999) suggested that both the salt form and free base were present in *Scopolia japonica*. In a recent report of TAs in seeds and leaves of *D. stramonium* var. *tatula*, Mroczek et al. (2006) showed that scopolamine and hyoscyamine were present in the free-base form. Rearing pots were cleaned daily, and fresh food was added. The percentage of surviving larvae, larval development times, and weights of pupae (sexed after the emergence of adults) were recorded. The percentage of

surviving larvae was correlated with scopolamine concentrations by Sperman rank correlation and also compared by comparison for multiple proportions (Zar, 1999). The other two variables, larval development times and weight of pupae, were tested by one-way and two-way ANOVA, respectively, with a *post hoc* Tukey test (Zar, 1999).

Allocation of scopolamine in B. suaveolens One month after the transference to pots, four clones of each of the 10 genotypes, in cutting stage, were planted randomly in the experimental field of the Centro Pluridisciplinar de Pesquisas Químicas, Biológicas e Agrícolas, Universidade Estadual de Campinas, at a spacing of 2×2 m, and they received normal agricultural treatments (irrigation, weeding, and fertilization). In each of the phenological stages (cuttings, 1 month after the transference to the field; vegetative stage, 3 to 6 months; flowering stage, and fruiting stage, more than 6 months) one clone of each genotype was harvested and its organs [roots, fully expanded young leaves (from first to fourth leaves), old leaves (from eighth leaf), stems, flowers, and unripe fruits, when present] were separated and dried at 40±2°C in a mechanical convection oven, ground in a mill, and stored at −5°C for extraction of scopolamine. At the stage of flowers, four genotypes were lost in the extraction procedure. The concentration of scopolamine was compared within phenological stages by one-way ANOVA with a *post hoc* Tukey test (Zar, 1999).

Costs of induction of scopolamine To assess the effect of an increase of scopolamine content in leaves of *B. suaveolens* on fitness, we conducted an experiment where we increased the scopolamine production by the wound hormone methyl jasmonate. We compared leaf-relative growth rate (LRGR) of control and treated plants. Nine 3-month-old genotypes of *B. suaveolens* (three clones for each individual) were subjected to 3 different treatments (modified from Baldwin, 1998) in a controlled environment (see conditions above): (a) 5.0 μg of methyl jasmonate (MeJA—Aldrich™) suspended in 10 ml of water was applied with a syringe inserted below the soil surface at the base of the shoot, with 5 ml applied to each side of each plant; (b) 50 μg MeJA as above; and (c) control with 10 ml distilled water was applied as above. Twelve days after application, leaves were sampled, and the concentration of scopolamine was measured as below. LRGR [LRGR=[((final leaf area 12 d after the application − initial leaf area)/initial leaf area)×100] for each treatment was calculated by measuring the initial and final leaf areas, with a Licor LI-3000 leaf area meter (Li-Cor Biosciences). Both scopolamine concentration and LRGR were compared between treatments by one-way ANOVA, with a *post hoc* Tukey test (Zar, 1999).

Induced response of scopolamine in leaves by leaf artificial damage Fourteen days after the development of the first 16 leaves, six genotypes growing in 2-l pots (five clones per genotype), maintained in an acclimatized chamber as above, were submitted to artificial damage as follows: At time zero, five clones of each genotype had half their leaf area removed with a pair of scissors (hereafter, distal half leaf or undamaged leaf) and were harvested and stored until chemical analysis (see below). At time zero, and after 24, 48, 96, and 192 hr (concerning to first to fifth clones, respectively), the remaining half leaf (hereafter, proximal half leaf or damaged leaf) was harvested. Both proximal and distal half leaves were dried individually in an oven at 50°C for 2 d, ground to a powder, and maintained at −10°C until extraction and measurement of scopolamine (see below). The induction ratio, which expresses how scopolamine varies after the artificial damage, was calculated by dividing the concentration of scopolamine at any time treatment (0, 24, 48, 96, or 192 hr) in the proximal half leaf (artificial damage treatment) by the concentration of scopolamine at time zero in distal half leaf (control). The half leaf was delimited by half of

the length along the principal vein. The areas of distal leaf halves (76.70±5.91 cm, $\overline{X} \pm SE$), measured with a Licor LI-3000 leaf area meter (Li-Cor Biosciences), were not significantly different from the area of proximal leaf halves (77.81±6.47 cm) (paired *t*-test, $t=0.905$, $df=9$, $P=0.389$). Because scopolamine concentration in *B. suaveolens* did not show significant hourly fluctuations (one-way ANOVA, $F_{11,72}=0.324$, $P=0.977$), the experimental design as used by van Dam et al. (1993) was not necessary. Preliminary experiments did not show significant differences in scopolamine content between proximal (1.76±0.15 mg/g) and distal (1.71±0.16 mg/g) leaf halves (paired *t*-test, $t=0.3620$, $df=9$, $P=0.726$) and, therefore, no correction in the calculation of the induction ratio was necessary. To compare the induction ratio at different times, one-way repeated-measure ANOVA, with a *post hoc* Tukey test, was used (Zar, 1999).

Induced resistance to a generalist herbivore To determine whether artificial damage altered resistance (*sensu* Karban and Baldwin, 1997) of plant leaves against generalist herbivores, we use as model the fourth instar of the polyphagous noctuid moth *S. frugiperda* (see above). Larvae were reared as above and allowed to starve for 24 hr. After starvation, larvae received food *ad libitum* in three different treatments during 24 hr in an acclimatized chamber (L12:D12, 25±1°C, and about 70% RH) as follows: (1) control: intact leaves of *Ricinus communis* (Euphorbiaceae) that did not show negative effects on the larval performance of *S. frugiperda* in previous work (Ferraz, 1991), (2) distal halves of leaves of *B. suaveolens* (see above), and (3) proximal half leaves of *B. suaveolens*, 24 hr before harvesting (see above). Only one genotype of *B. suaveolens* was used to carry on this assay. This individual had 0.14 mg/g of scopolamine in the distal half and 0.37 mg/g of scopolamine in proximal half leaves. To assess the role of undamaged (distal half) and damaged (proximal half) leaves of *B. suaveolens* on larval performance of *S. frugiperda* in relation to control leaves of *R. communis*, the relative consumption rate (RCR) and relative growth rate (RGR) were calculated following Miller and Feeny (1983) and Blau et al. (1978). Compounds in *B. suaveolens* in damaged or undamaged leaves may alter the consumption rate and the growth rate of *S. frugiperda*. When growth rate is plotted against consumption rate, a positive slope is expected if no inhibitory or toxic compounds are present. If compounds are toxic, a higher RCR would result in an even lower growth rate, and a negative slope is expected. If compounds inhibit feeding, RCR is expected not to be related to RGR (Blau et al., 1978). To compare the regression lines, we first tested the significance of each one; because the regression line of treatment 2 was not significant (see Fig. 2), ANCOVA was not done (Zar, 1999). Instead, one-way ANOVA, with a *post hoc* Tukey test, was carried out by comparing either RCR or RGR among the treatments (Zar, 1999).

Extraction, GC-flame ionization detector and GC-MS analysis of scopolamine Samples of plant material (~2.0g) were homogeneized in 5 ml EtOH and centrifuged at 4,000 rpm for 10 min. This procedure was repeated ×3, and the EtOH supernatants were combined and evaporated under vacuum. TAs were purified from the EtOH extract by acid–base work up and analyzed by GC-MS as given in Freitas et al. (1996). For scopolamine quantification, a GC-flame ionization detector (FID) analyses was carried out by using a Hewlett Packard 5890 GC with a FID coupled with a Hewlett Packard (HP 3396-A) electronic integrator, with SA-1 (100% polydimethyl siloxane) capillary column (30 m×0.25 mm×0.25 μm). The GC-FID conditions were as follows: injection temperature 250°C; temperature program 150–300°C, 4°C/min; split ratio 1:100; and carrier gas He 1 ml/min. An aliquot of 1 μl of the alkaloidal extracts was redissolved in 200 μl of a 2-mg/ml MeOH solution of stearic

acid methyl ester was injected as an internal standard. We used methyl stearate as the internal standard because its retention time (RT) did not overlap the RT of the TAs, used as a commercial alkaloid (the pyrrolizidine monocrotaline).

Results and Discussion

Performance of larvae of S. frugiperda on scopolamine diet Diets containing scopolamine affected the larvae of *S. frugiperda* negatively. Developmental time increased with greater scopolamine concentration in the diet (Table 1), and the percentage of individuals surviving on diets was negatively affected by an increase in scopolamine concentrations (Table 1). Concentrations of 0.25% dry weight were effective, and these are comparable with scopolamine concentrations found in plant parts (Fig. 1). Weight of pupae for both sexes decreased marginally with an increase of scopolamine concentration; there was no interaction between sex and diets (Table 1).

Although the generalist noctuid *S. frugiperda* does not share its evolutionary history with *B. suaveolens*, based on the results with this generalist herbivore model, we can suggest that scopolamine may be a factor acting as antifeeding on generalist insects. TAs have been reported to be effective against many generalist herbivorous insects (Hsiao and Fraenkel, 1968; Krug and Proksch, 1993; Wink, 1993; Shonle, 1999), but none of these shared their evolutionary history with the bioassayed host plants. Additionally, other TAs are presented in *B. suaveolens*, but in lower concentration than scopolamine (Freitas et al., 1996), and the role of these in plant resistance remains to be studied. Does this compound also act against generalist insects that share an evolutionary history with *B. suaveolens* or as specialists? To our knowledge, only two specialist butterflies feed on leaves of *B. suaveolens*, *P. euryanassa* and *M. cymothoe*; the former sequesters TAs from leaves, but the latter does not (Freitas et al., 1996), and no record of generalists in the field has been observed by us. Specialists can be attracted to a compound that formally may have been a feeding deterrent for generalists (van der Meijden, 1996, and see references in Shonle and Bergelson, 2000), and although our data suggest an antiherbivore defense against specialists by scopolamine, it remains an open question whether this compound or other TAs in general act as an antiherbivore defense against specialists.

Allocation of scopolamine in B. suaveolens The scopolamine concentration changed according to the organs investigated and with the phenological stage of the plant (Fig. 1). In the cutting stage, young leaves and stems had a higher concentration than roots (one-way ANOVA, $F_{2,27}=59.497$, $P<0.001$). In the expanded leaf stage, stems had a higher concentration than other plant parts ($F_{3,36}=117.828$, $P<0.001$). In the flowering stage, the highest scopolamine concentrations were found in the flowers, young leaves, and stems; old leaves and roots had the lowest ($F_{4,25}=188.340$, $P<0.001$). In the fruiting stage, scopolamine had the highest concentrations in unripe fruits ($F_{5,54}=400.679$, $P<0.001$).

The allocation of scopolamine to different tissues of *B. suaveolens* in different phenological states is as predicted by optimal-defense theory: more valuable structures, in terms of fitness, receive greater defenses (McKey, 1974, 1979; Rhoades, 1979). Young leaves, flowers, and mainly unripe fruits with seeds have progressively higher scopolamine concentrations than other tissues. Zangerl and Bazzaz (1992) suggest that fruits; seeds; and, to a lesser extent, flowers, are more heavily defended than vegetative plant parts. This differential allocation of potential defensive compounds has been found in many plants. Van Dam et al. (1996) found that young leaves of *Cynoglossum officinale* contain higher

Table 1 Performance of *Spodoptera frugiperda* fed on artificial diets with different concentrations of scopolamine

	Control (0%)	0.05%	0.25%	0.5%	2.5%	Statistical Tests

For each variable, different letters mean significant differences at 5%.

[a] The number in parentheses represents the sampled number.

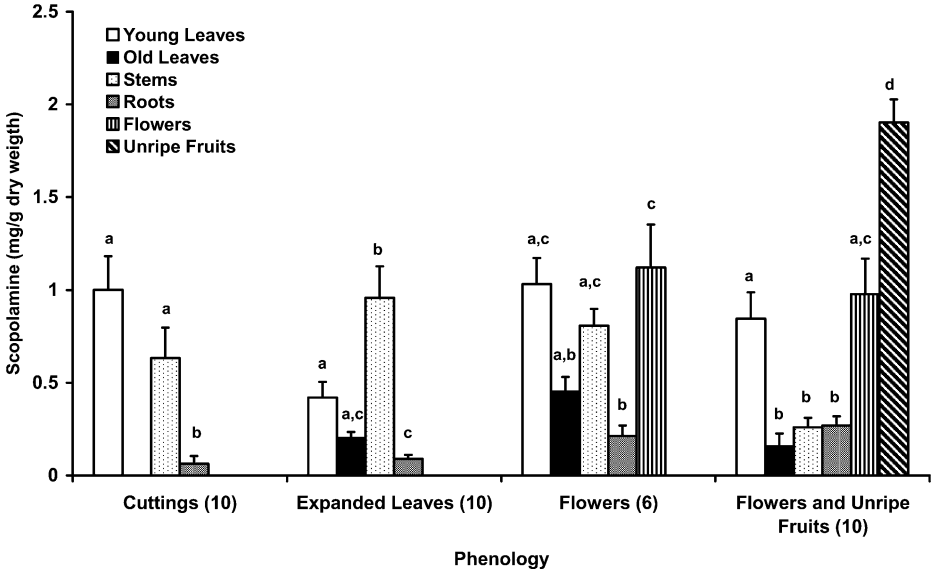

Fig. 1 Concentration of scopolamine (mean ± SE, mg/g dry weight) of different organs in different phenological stages of *Brugmansia suaveolens*. One-way ANOVA was performed within each phenological state. Different letters mean significant differences at 5% (*post hoc* Tukey test)

concentrations of pyrrolizidine alkaloids than old leaves. Wink (1985) reported that fruits in *Lupinus polyphyllus* had about 100 times more quinolizidine alkloids than other tissues. The same pattern was also found for furanocoumarins in *Pastinaca sativa*; the concentration of xanthotoxin being highest in fruits, lowest in roots, and intermediate in leaves (Zangerl and Rutledge, 1996, and references therein). Shonle (1999) found that scopolamine reduced the growth of the generalist *Spodoptera exigua*, but did not have any effect on either the generalist *Heliothis zea* or the specialist *Manduca sexta*. No natural generalist or specialist herbivore insect sharing an evolutionary history with *B. suaveolens* was tested in our work, but based on literature (see above) and these results (see Table 1), the suggestion is that this compound (maybe together with the other TAs) protects *B. suaveolens* against generalist natural enemies. However, what about ripe fruits? A high content of distasteful compounds in ripe fruits would be deterrent for dispersers. Cipollini and Levey (1997) and Cipollini (2000) suggested that when seeds from ripe fleshy fruits are dispersed by vertebrates, the allocation of distasteful compounds in their pulp represents a compromise between defensive and attractive functions (defense-tradeoff hypothesis). Nevertheless, *B. suaveolens*, which is common on the edge of rivers, has a ripe dry dehiscent fruit, and the seeds are water-dispersed (J.R. Trigo, personal observation). In this case, distasteful compounds, if present in ripe fruits, do not represent any ecological costs for this species because they do not affect disperser vertebrates.

Costs of induction of scopolamine At 50 μg/plant, the MeJA application significantly increased the concentration of scopolamine in leaves of *B. suaveolens* to about 9.5 times the concentration in controls (one-way ANOVA, $F_{2,24}$=15.670, P<0.001, Fig. 2). Similarly, these plants showed a leaf production decrease by a factor of 2.3 times, and this is significantly lower than that of control plants (one-way ANOVA, $F_{2,24}$=9.142, P=0.001,

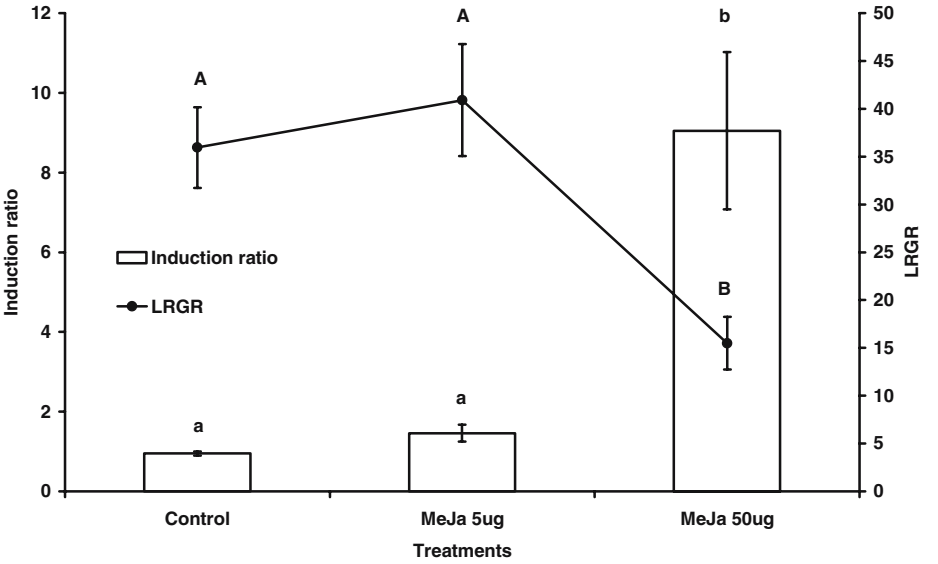

Fig. 2 Induction ratio in leaves and LRGR ($\overline{X} \pm SE$) of *Brugmansia suaveolens* with roots treated with MeJA. For each variable, different letters mean significant differences at 5% (*post hoc* Tukey test)

Fig. 2). A lower concentration of MeJA (5 μg/plant) neither increased the concentration of scopolamine nor showed significant differences in LRGR in relation to control plants (Fig. 2).

The treatment with MeJA hormone increased the production of scopolamine and decreased the LRGR in *B. suaveolens*. MeJA is known to inhibit protein biosynthesis, which is essential for growth, and acts as elicitor for several secondary metabolic pathways

Table 2 RCR and RGR ($\overline{X} \pm SE$) of *Spodoptera frugiperda* larvae in a 24-hr feeding trial on distal (undamaged) and proximal (artificially damaged) halves of leaves of *Brugmansia suaveolens*

Treatments	RCR	RGR
Control (leaves of *Ricinus communis*) (n=33)	0.424±0.109[a]	0.193±0.048[a]
Undamaged leaves (n=24)	1.379±0.106[b]	−0.102±0.022[b]
Artificial damaged leaves (n=24)	1.380±0.092[b]	−0.246±0.022[c]
One-way ANOVA	$F_{2,78}$=29.801, P<0.001	$F_{2,78}$=38.520, P<0.001

For each variable, different letters mean significant differences at 5% (*post hoc* Tukey test).

(see Reinbothe et al., 1994 for a review). As discussed by Baldwin (1998), this experiment showed a decrease in growth due to jasmonate induction, but it is not clear which jasmonate-inducible responses were responsible for the growth reduction. Scopolamine induction was a component of this response. Although LRGR may only be an indirect measure of fitness, with seed production and/or seed viability being a better measure, a reduced foliage production in the field might seriously alter competition for light and therefore have an impact on fitness. Induced plant responses to herbivory are considered to be cost-saving strategies, as pointed out by optimal-defense theory, but costs are hard to detect because multitrophic interactions involving many trade-offs may participate in the plant environment (Dicke and van Loon, 2000; Heil and Baldwin, 2002; van Dam et al., 2003).

Induced response of scopolamine in leaves by leaf artificial damage The highest induction (3.40±0.54 times) was recorded 24 hr after artificial damage; subsequent periods showed a rapid decrease in induction rate, reaching the control level at 96 hr (one-way repeated-

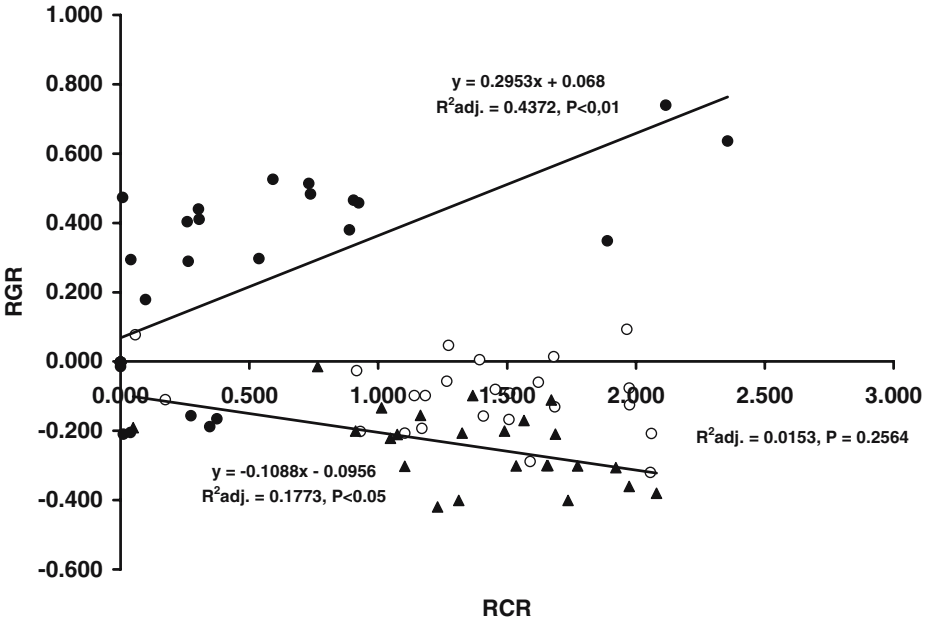

Fig. 4 RGR as a function of RCR for the fourth larval instar of *Spodoptera frugiperda* fed with *Ricinus communis* undamaged leaves (control, *black circles*) and undamaged (*white circles*) and artificially damaged (*triangles*) leaves of *Brugmansia suaveolens*. The regression line was shown only when it was significant

measure ANOVA, $F_{4,20}$=10,103, P<0.001, Fig. 3). Leaves of *B. suaveolens* increase their content of scopolamine after artificial damage. This induced response has been demonstrated for different organs in several species (see Karban and Baldwin, 1997, for a review). The highest induction rate for *B. suaveolens* was found 24 hr after the damage; after this, the rate decreased to constitutive levels. This relaxation timing has also been described for several species, and the duration of the phenomenon varies within hours or days after damage (Green and Ryan, 1972; Underwood, 1998) or even years (Haukioja, 1980). Nevertheless, Shonle and Bergelson (2000) reported no induction of TAs after damage in the taxonomically close *D. stramonium*. They analyzed damaged leaves 5 d after the damaging treatments; in this period, the level of alkaloids may have already decreased to their constitutive levels. Rapid induction after damage followed by a rapid relaxation to constitutive levels follows the predictions of optimal-defense theory, and may save costs associated with self-toxicity and biosynthesis of high levels of defensive substances (Karban and Baldwin, 1997).

Induced resistance to larvae of S. frugiperda due to mechanical damage of B. suaveolens Feeding on intact leaves of *B. suaveolens* had an adverse effect on larvae of the generalist noctuid moth *S. frugiperda*. Although the RCR increased in relation to control diet (1.379±0.106), the RGR showed significant negative values (−0.102±0.022). RGR became even more negative when *S. frugiperda* fed on artificially damaged leaves (−0.246±0.022), although it remained similar to that on intact leaves (1.380±0.092) (Table 2, Fig. 4).

The diet of undamaged leaves of *B. suaveolens* showed a negative effect on the RGR of the generalist insect *S. frugiperda*. Artificially damaged leaves increased this effect. There is a reduction in RGR, but not in RCR, when the diets with undamaged and artificially damaged leaves are compared (Table 2). As pointed out by Blau et al. (1978), this must occur when ingested compounds are toxic to herbivores. Compounds present in undamaged *B. suaveolens* leaves may be toxic for herbivorous insects and the toxic effect may have increased after artificial damage. Nevertheless, we cannot exclude that the toxic effect may also be due to compounds other than scopolamine or TAs. Artificial damage can also lead to the induction of compounds such as phenolics, terpenes, and defense-related proteins (Karban and Baldwin, 1997). Additionally, the impact of induced response on natural populations of herbivores, either specialists or generalists, such as population fluctuations and regulation (Haukioja, 1980; Edelstein-Keshet and Rausher, 1989; Lundberg et al., 1994), or the increase of induced susceptibility in herbivores counteracting the benefits of induced response (Underwood, 1998), remains to be investigated.

Acknowledgments We thank Flávia Tavares Colpas, Keith S. Brown, Klaas Vrieling, Rodrigo Cogni, Suzana de Fátima Alcântara, and two anonymous reviewers for comments on the manuscript. The research was supported by a Fundação de Amparo à Pesquisa do Estado de São Paulo grant for JRT (98/01065-7). We thank also the Prefeitura Municipal de Jundiaí for permission to work in Serra do Japi. This work is part of the Ph.D. dissertation of MNA at Pós-Graduação em Biologia Vegetal, Instituto de Biologia, Universidade de Campinas.

Abstract The mushroom genus *Amanita* has a spectrum of chemical compounds affecting survival and performance of animals. Ibotenic acid is one of such compounds found in some *Amanita* mushrooms. We studied the effects of ibotenic acid and its derivative, muscimol, on egg-to-pupa survival, pupation time, and pupal size in five *Drosophila* species (Diptera: Drosophilidae), *Drosophila bizonata*, *Drosophila angularis*, *Drosophila brachynephros*, *Drosophila immigrans*, and *Drosophila melanogaster*. The first three species are mycophagous and use a wide range of mushrooms for breeding, whereas *D. immigrans* and *D. melanogaster* are frugivorous. We reared fly larvae on artificial medium with 500, 250, 125, and 62.5 μg/ml of ibotenic acid and/or musimol. The three mycophagous species were not susceptible to ibotenic acid, whereas the two frugivorous species were affected. In experiments with *D. melanogaster*, muscimol was less toxic than ibotenic acid.

Keywords Ibotenic acid · *Amanita* · *Drosophila* · Susceptibility · Mycophagy

Introduction

A wide variety of secondary metabolites occur in fungi (Martin, 1979), many of which are potentially harmful to insects that consume them. Several are toxic to both invertebrates and vertebrates. Besl et al. (1987) studied the effects of 127 species of fungi on the development of *Drosophila melanogaster* Meigen and observed that six of eight *Amanita* (Agaricales, Amanitaceae) species impaired the development of the fly. In contrast, mycophagous species, *Drosophila kuntzei* and *Drosophila phalerata*, were not susceptible to amatoxins of *Amanita phalloides* (Fr.) Link (Besl et al., 1987). Jaenike et al. (1983) studied mycophagous and nonmycophagous species of *Drosophila* for tolerance to α-amanitin, a potential inhibitor of RNA polymerase II, and observed that mycophagous species were tolerant, whereas nonmycophagous species were intolerant.

We studied the effects of ibotenic acid and its derivative, musimol, found in *Amanita pantherina* (DC.:Fr.) Krombh.; *Amanita ibotengutake* T. Oda, C. Tanaka & Tsuda; and *Amanita muscaria* (L.: Fr.) Pers. on survival and performance of mycophagous (*Drosophila bizonata* Kikkawa and Peng, *Drosophila angularis* Okada, and *Drosophila brachynephros* Okada) and nonmycophagous species (*Drosophila immigrans* Sturtevant and *D. melanogaster*). Among them, *D. bizonata* was observed to breed abundantly on *A. pantherina* and *A. ibotengutake* in Kyoto, central Japan (Yamashita et al., unpublished data). The three mycophagous species use a wide variety of mushroom species for breeding, whereas *D. immigrans* and *D. melanogaster* are frugivorous, although *D. immigrans* sometimes feeds and breeds on mushrooms (Kimura et al., 1977; Nishiharu, 1980; Tuno, 2001; Takahashi et al., 2005).

Materials and Methods

Flies Laboratory stocks of *D. bizonata*, *D. angularis*, *D. immigrans*, and *D. melanogaster* were established from females collected in Tokyo, central Japan, and a stock of *D. brachynephros* was from females collected in Sapporo, northern Japan. They were maintained on poison-free laboratory medium for at least three generations before the test.

Experiments Test medium was prepared as follows. A mixture of cornmeal (2.5 g), malt (3.5 g), sugar (5 g), dry yeast (3 g), and agar (1 g) was added to water to make up 60 ml. Thirty grams of ground commercial mushroom [*Flammulia velutipes* (Curt.: Fr.) Sing.] were added. The medium was boiled for 15 min and 0.45 ml of propionic acid was added. To this medium, ibotenic acid (Tocris Cookson, St. Louis, MO, USA) or muscimol (0.25 H2O; Wako Chemical, Osaka, Japan) dissolved in NaOH (0.1 N) solution was added to make final concentrations of 500, 250, 125, and 62.5 μg/ml. The concentration of NaOH in the test medium was standardized to 0.01 N by the addition of NaOH solution. The rearing of larvae was made by using vials (6 ml vol) with test medium (440 or 1,000 μl) and a cotton plug.

Eggs were collected from laboratory fly stocks, sterilized in 70% ethanol for 15 min, and placed in vials with test medium (ten eggs per vial). The vials were kept at 23°C. Five to ten replicates were used. When pupae were formed in the vials, they were counted daily to determine pupation time (i.e., days from egg to pupation), and then they were measured for size.

Two experiments were conducted. In experiment 1, the effects of ibotenic acid and muscimol were compared with *D. melanogaster*; in experiment 2, the effect of ibotenic acid on four different *Drosophila* species was investigated. The effect of the chemicals on the

egg-to-pupa survival was analyzed using logistic regression; the effect on pupation time was analyzed using Cox's regression analysis (Cox, 1972); the effect on pupal size was determined with standard regression analysis. If a significant effect was observed in these regression analyses, pairwise comparison was made between experimental treatments and control; i.e., values at 62.5, 125, 250, or 500 μg/ml value in control. The pairwise comparison was made using Fisher's exact test for survival, with Cox's regression analysis for pupation time, and Dunnett's test for pupal size. The sequential Bonferroni correction was made for the results of these multiple comparisons. Statistical analyses were performed using JMP version 5.0.1.2 (SAS Institute, Cary, NC, USA).

Results

Table 1 shows the effects of ibotenic acid and muscimol on egg-to-pupa survival, pupation time, and pupal size in *D. melanogaster*. The effects of these two chemicals on egg-to-pupa survival and pupation time were significant (logistic regression for survival, $P<0.001$; Cox's regression for pupation time, $P<0.001$); i.e., survival decreased and pupation time was prolonged with the increase of concentration. According to pairwise comparisons with control, the effect of ibotenic acid became significant at a concentration of 62.5 μg/ml,

whereas the effect of muscimol became significant at a concentration of 125 μg/ml in survival and at a concentration of 250 μg/ml in pupation time (two-tailed Fisher's exact test on survival, $P<0.05$; Cox regression analysis on pupation time, $P<0.01$) (Table 1). Survival was significantly lower in individuals treated with ibotenic acid than in those treated with the same concentration of muscimol at a concentration of 125 μg/ml or higher (two-tailed Fisher's exact test, $P<0.001$). Ibotenic acid seemed to cause high mortality in the earlier developmental phases, because almost no trace of crawling or feeding of larvae was observed at concentrations of 125, 250, and 500 μg/ml. On the other hand, the effects of ibotenic acid and muscimol on pupation time were different only at a concentration of 250 μg/ml or higher (Cox's regression analysis, $P<0.001$). On pupal size, ibotenic acid had only a weak effect (regression analysis, $P=0.043$) and muscimol had no significant effect (regression analysis, $P>0.05$).

Table 2 shows the effects of ibotenic acid on four other *Drosophila* species, *D. bizonata*, *D. angularis*, *D. brachynephros*, and *D. immigrans* (the results on *D. melanogaster* are also shown as a reference), and Table 3 shows the results of regression analyses. Ibotenic acid did not show any detrimental effect on mycophagous species *D. bizonata*, *D. angularis*, and *D. brachynephros*. In contrast, *D. immigrans* was affected by this chemical, although less seriously than *D. melanogaster*; the effects on egg-to-pupa survival and pupation time on *D. immigrans* were significant at a concentration of 125 μg/ml or higher (Fisher's exact test on survival, $P<0.05$, Cox's regression on pupation time, $P<0.05$; Table 2). In this species, the effect of ibotenic acid on pupal size was not significant (Dunnett's test, $P>0.05$).

Discussion

Tsunoda et al. (1993) reported that fruit bodies of *A. muscaria*, a species closely related to *A. pantherina* and *A. ibotengutake*, on average, contain ibotenic acid at a concentration of 343 μg/ml. In this study, it appeared that ibotenic acid had no effects on survival, pupation

time, or pupal size in mycophagous *Drosophila* species, *D. bizonata*, *D. anguralis*, and *D. brachynephros*, even at a concentration of 500 μg/ml. In contrast, it had deleterious effects on frugivorous species, *D. melanogaster* and *D. immigrans*, at concentrations of 125 or 250 μg/ml. Thus, ibotenic acid in mushrooms may have a defensive function at least against nonmycophagous insects. On the other hand, muscimol was less harmful than ibotenic acid. Muscimol, detected at low concentrations, is assumed to be an inevitable byproduct of ibotenic acid. Tsunoda et al. (1993) reported that fruit bodies of *A. pantherina* and *A. ibotengutake* contain this chemical at a concentration of 22 μg/ml, but Stømer and Janak (2004) failed to detect muscimol from fresh fruit bodies of *A. muscaria*. Thus, it is not likely that muscimol has a defensive function.

It is unclear why mycophagous *Drosophila* species have evolved such high tolerance to ibotenic acid. These species use a wide variety of mushrooms (Kimura et al., 1977; Nishiharu, 1980; Tuno, 2001; Takahashi et al., 2005), and mushrooms containing ibotenic acid (e.g., *A. pantherina* and *A. ibotengutake*) are expected to be only a small part of their food resources. Therefore, they would be able to maintain their populations without *Amanita* mushrooms.

A similar situation has been reported in American mycophagous drosophilids. They are highly tolerant to α-amanitin, another poison of *Amanita* mushrooms that is harmful to all kinds of eukaryotes, although they use a wide variety of mushrooms lacking α-amanitin (Jaenike, 1985). Jaenike (1985) argued that a primary selective advantage of α-amanitin tolerance is that it allows drosophilids to breed in mushrooms that are free of nematodes. Nematodes are abundantly found in many fungi, and they infest drosophilids, breeding on them and rendering them infertile. However, nematodes are absent in mushrooms containing amanitin.

Amanita mushrooms may avoid predation because they may appear to generate ibotenic acid. However, mycophagous maggots are often seen feeding on mushroom tissue without disturbing the growth of mushrooms. It is possible that maggot attack has little effect on host fitness. Poisonous mushrooms may serve as a refuge for mycophagous flies that are less harmful to host fungi. We need to investigate animal consumption of mushrooms in nature to clarify the relevance of mushroom poisons.

Acknowledgement We thank Dr. John Romeo for his patient help and advice. We thank Prof. M. T. Kimura for improving the manuscript and the members of the Department of Ecology and Genetics, Graduate School of Environmental Earth Science, Hokkaido University, for their technical support. Spectrum of Cyanide Toxicity and Allocation in *Heliconius erato* and *Passiflora* Host Plants

Mirian Medina Hay-Roe · James Nation

Abstract The larvae of three races of *Heliconius erato* were fed various species of *Passiflora* containing varying levels of cyanoglucosides. The mortality rate of larvae and pupae rose when larvae were fed species of *Passiflora* capable of releasing larger quantities of cyanide. When larvae were fed species of *Passiflora* with these properties, the resulting adult butterflies also released higher levels of cyanide. This may serve as a defense mechanism. The compounds responsible for the release of cyanide were not evenly distributed throughout the adult butterfly's body. The thorax contained the highest concentration of cyanogenic substances, followed by the head, wings, and abdomen. The younger tissues of *Passiflora* plants had higher levels of cyanide-releasing compounds than stems and mature leaves. Cyanogenic glycoside distribution within the plants is consistent with optimal allocation theory. The levels of cyanide-releasing substances in plants varied depending on the season.

Keywords *Heliconius erato cyrbia* · *Heliconius erato favorinus* · *Heliconius erato demophoon* · *Passiflora* · Cyanogenic glycosides · β-glucosidase · Cyanide · Ecuador · Peru · Panama

Introduction

The genus *Heliconius* comprises a large group of tropical butterflies whose larvae specialize in feeding upon members of the *Passiflora*. Within this genus, *Heliconius erato* is a common species that inhabits second growth and disturbed forest of Central and South

America and is adapted to altitudes ranging from sea level to 1,600 m. *Heliconius erato* has radiated into numerous geographic races that are members of local mimicry groups. Each race feeds upon a different species of *Passiflora*, and the plants are, to a greater or lesser extent, cyanogenic. The adult butterflies are unpalatable to predators (Chai 1996) due to the accumulation of cyanogenic glycosides as larvae (Spencer 1988). Cyanogenesis has been found in both insects and plants containing cyanogenic glycosides that break down upon tissue injury to yield cyanide. Cyanide is released when the enzyme β-glucosidase hydrolyzes a cyanogenic glycoside-generating cyanohydrin, which then rapidly breaks down at normal cell pH to a carbonyl compound and cyanide. In addition, some tissues contain the enzyme α-hydroxynitrile lyase that acts upon the cyanohydrin to release cyanide and the aglycone (Höesel 1981).

In *Heliconius* butterflies, cyanogenic compounds are found in the cuticular part of the integument (Nahrstedt and Davis, 1983, 1985; Davis and Nahrstedt, 1985). The location of β-glucosidase is unknown, but it is separated from the cyanoglucoside (Nahrstedt and Davis, 1983). All stages in the life history of Heliconiinae have been examined, and the highest concentrations of cyanide-releasing compounds occur in the egg stage. The concentrations in the larval and pupal stages do not vary greatly from each other, but cyanogenic compound concentrations increase in adults as a result of cyanoglucoside biosynthesis during the adult stage (Nahrstedt and Davis, 1985).

Potential variations in levels of cyanogenic glycoside concentrations within body parts of *Heliconius* adults, as related to their host plants, has not been previously explored. For this paper, levels of cyanide liberated from different body parts of various races of *H. erato* that were fed natural *Passiflora* host plants were examined. Analyses of cyanogenesis were performed over two seasons (summer and fall) on separate parts of *Passiflora* plants (young leaves, mature leaves, and stems). Roots, fruits, and flowers were not included in the analysis because *Heliconius* larvae rarely feed upon these tissues. Cyanide liberated from plant tissues was correlated with the cyanide liberated from tissues of adults that fed on the plants. The discussion addresses the costs and benefits of allocating cyanogens as a defense mechanism to different body parts of this species and the implications of these variations on the palatability of this butterfly and on its mimetic relationships.

Methods and Materials

Plant Growth and Insect Rearing This study was conducted at the University of Florida in Gainesville with butterfly colonies that were raised in Lord & Burnham glass houses (5×8 m). *Heliconius erato favorinus* was collected in Tingo Maria, Huanuco, Peru, located on the eastern side of the Andes, whereas *Heliconius erato cyrbia* was collected in Pichincha, Ecuador, located on the western side of the Andes, and *Heliconius erato demophoon* in Soberania National Park, Panama.

Most of the *Passiflora* plants began as cuttings that were propagated in pots for use in this research. All vouchers for *Passiflora* plants used for this study are deposited at the Missouri Botanical Garden, St. Louis, MO, and identification of the plants was confirmed by Dr. John MacDougal, an expert in systematics of the family Passifloraceae.

Larvae, Experimental Design, and Treatments *Heliconius erato favorinus*, *H. e. cyrbia*, and *H. e. demophoon* larvae were raised in environmental chambers under controlled temperature (27°C), humidity (78%), and photoperiod (14 hr light/10 hr dark). The three races were fed only their natural host plants. All of these host plants possess complex

cyclopentenoid glycosides (Olafsdottir et al., 1989; Hay-Roe 2004). *Heliconius erato favorinus* (*N*=19, 13 males and 6 females) was fed *Passiflora trifasciata*. *Heliconius erato cyrbia* (*N*=14, seven males and seven females) was fed *Passiflora punctata* and *Passiflora rubra* (*N*=12, six males and six females), and *H. e. demophoon* (*N*=10, five males and five females) was fed *Passiflora biflora*. Males and females of *H. e. cyrbia* and *H. e. favorinus* were examined separately, and for each specimen, the head, thorax, abdomen, and wings were examined separately. The head, thorax, and abdomen of *H. e. demophoon* were examined as a unit but the wings separately. Excreta from caterpillars that were fed different host plants were also examined for cyanogenesis.

Temporal Cyanide Quantification of Passiflora Plants *Passiflora* plants were examined during the summer (July–August) and fall (September–October) of 1999 (Table 1). All plants were potential host plants of *H. erato* in different geographical areas of Brazil, Costa Rica, and Ecuador. The analyses were performed on young leaves, mature leaves, and stems.

All analyzed *Passiflora* plants were subjected to the same environmental conditions (humidity, temperature, and natural photoperiod) in the greenhouses. None of the plants examined was exposed to herbivores.

Quantitative Determination of Cyanide Cyanogenesis was quantified by the Lambert procedure (Lambert et al., 1975) as modified by Brinker and Seigler (1989, 1992). In short, plant or butterfly samples were ground to a fine powder in liquid nitrogen. The powdered plant or butterfly tissue was added to a 10-ml vial containing 0.1 M phosphate buffer (pH 6.8). A 5-ml vial containing fresh 1 M NaOH solution was then placed inside the 10-ml vial, and the 10-ml vial was stoppered tightly. Samples were prepared quickly to avoid loss of HCN. Vials were incubated at 37°C overnight. During incubation, HCN released from tissue was trapped in the NaOH solution, and formed NaCN.

After incubation, cyanide was quantified in a spectrophotometer (Spectro 22; Labomed, Culver City, CA, USA) after a sequential addition of a series of reagents detailed in Brinker and Seigler (1989). Addition of exogenous β-glucosidase [linamarase from flax seed, courtesy of David Jones; sulfatase type IV from limpets (Sigma, St. Louis, MO, USA); almond-β-glucosidase (Sigma); and β-glucosidase that we extracted from *P. biflora* and *Passiflora coriacea*] was used when samples initially tested acyanogenic. A standard curve was prepared following the methods of Brinker and Seigler (1989).

	Xerogona	*rubra*	Ecuador	12	0

All plants are used by *H. erato* in different geographical areas

After cyanide release and assay, the remaining plant or insect tissue was dried at 65°C to constant weight (approx. 6 d) and weighed. Dry weight was used to calculate the micrograms of CN^- released per gram of dry weight of plant tissue or butterfly body tissue.

Statistical Analysis Two-way analysis of variance was performed with the statistical program SYSTAT 10. Some of the data were not normally distributed, and the data were subjected to square root transformation to compensate for increasing variation associated with larger mean values (Zar 1996). However, the statistical results with transformed data did not vary significantly from the raw data, so the results of the raw data are reported here. A Tukey test was used for multiple comparisons. Linear regression was used to test the correlation of cyanide released by butterfly tissues with cyanide released by tissues of *Passiflora* host plants.

Results

Cyanide Quantification in H. erato Fed Natural Host Plants The amount of cyanide released per given weight of tissue varied among the races (F=29.90; df=1, 139; P<0.001). *Heliconius erato cyrbia* released greater amounts of cyanide than *H. e. favorinus*. There were differences in cyanide released between the sexes (F=8.26; df=1, 139; P<0.005) and by different body parts (F=8.14; df=3, 139; P<0.001).

Differences in host plant utilization resulted in differences in cyanide released from individuals of *H. e. cyrbia* fed on *P. rubra* and *P. punctata* (F=10.02; df=1, 97 P<0.002). When *H. e. cyrbia* fed on *P. rubra* (Fig. 1), the butterflies released greater amounts of cyanide per gram of tissue compared to butterflies fed on *P. punctata* (Figs. 1 and 2). Males and females of this race differed in the quantity of cyanide released (F=5.68; df=1, 97; P< 0.025). Females concentrated higher amounts of cyanide-releasing compounds in their bodies when fed *P. rubra* as larvae. Furthermore, the cyanogenic compounds were stored differently within the body parts (F=7.32; df=3, 97; P<0.001) (Fig. 1), with higher levels

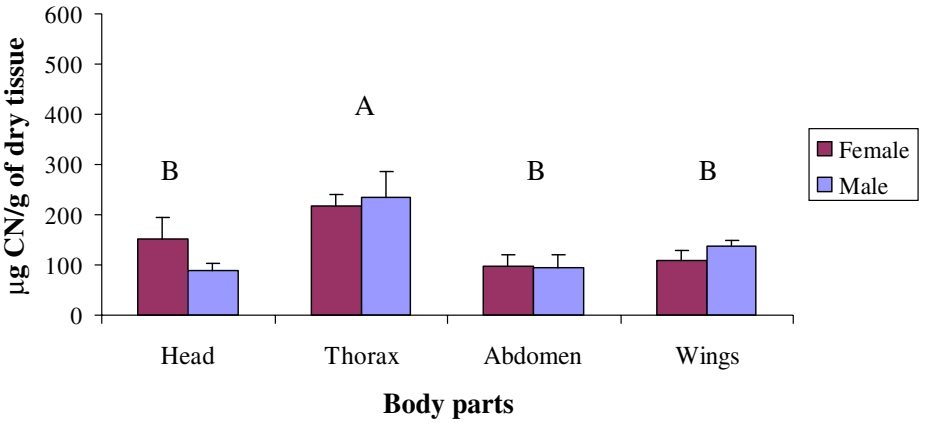

Fig. 2 Cyanide liberated from body parts of male and female *H. e. cyrbia* fed *P. punctata*. *Different letters* indicate significant differences between means (Tukey HSD-test). *Bars* indicate standard error

of cyanide released from the thorax. When *H. e. cyrbia* was fed *P. punctata* (Fig. 2), cyanide concentrations released from the sexes did not differ. The thorax and the head released greater amounts of cyanide per unit weight of tissue than the abdomen and wings (F=12.31; df=3, 52; P<0.001) (Fig. 2).

Low levels of cyanide were released from the body of *H. e. favorinus* fed *P. trifasciata*, and there were no differences in cyanide-releasing activity in the male and female thorax and head. The wings and abdomen released the lowest concentrations. More males than females were examined because more than 50% of the males examined were negative. Only five males and four females were cyanogenic, and the addition of exogenous β-glucosidase did not promote the release of cyanide, indicating that cyanide release was not due to the

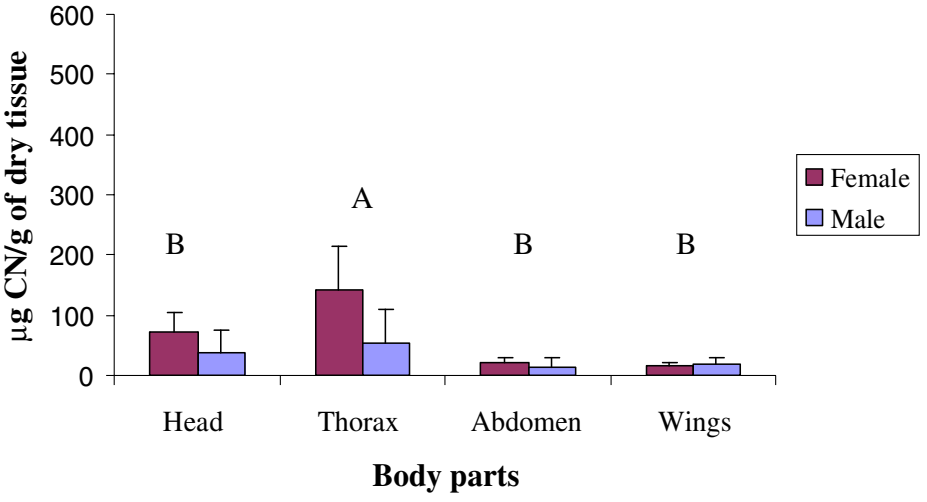

Fig. 3 Cyanide liberated from body parts of male and female *H. e. favorinus* fed *P. trifasciata*. *Different letters* indicate significant differences between means (Tukey HSD-test). *Bars* indicate standard error

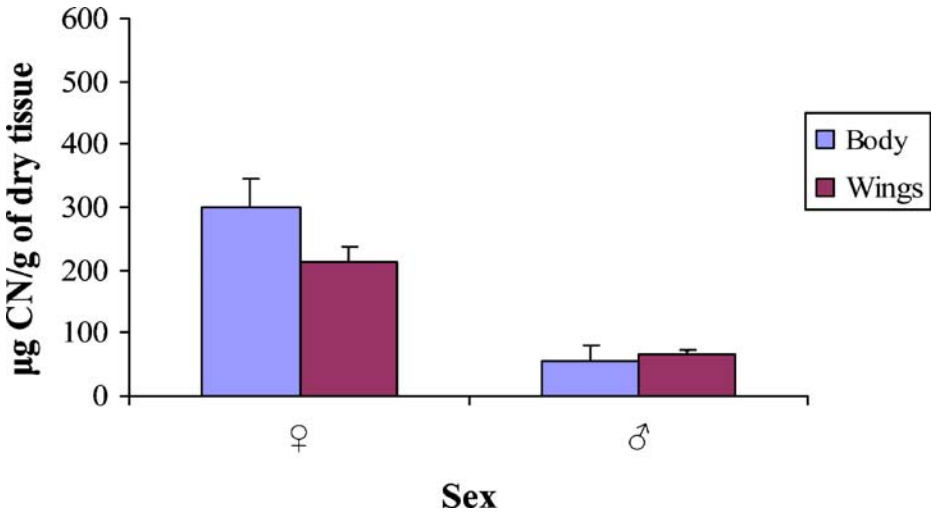

Fig. 4 Cyanide liberated from male and female *H. e. demophoon* fed *P. biflora*. *Bars* indicate standard error

lack of the enzyme. The most probable reason for lack of cyanide release was a very low, or no, amount of cyanogenic glycosides within the butterfly's body (Fig. 3).

Low levels of cyanide release were found in male *H. e. demophoon* fed on *P. biflora*, its natural host plant. Furthermore, cyanide concentrations varied between body parts. In general, the body (which in these samples includes the head, thorax, and abdomen) released more cyanide per unit of tissue than the wings (F=7.21; df=9,19; P=0.003) (Fig. 4).

Mortality of H. erato Fed Natural Host Plants High mortality during the larval stage was observed in *H. e. cyrbia* fed *P. rubra*. In all cases, larvae died during the early instars (Table 2). During the pupal stage, 12% of the individuals fed as larvae on *P. punctata* died. For the rest of the treatments, mortality rate was low. *Heliconius erato favorinus* showed no mortality when fed *P. trifasciata*.

Temporal Variation of Cyanide Release in Passiflora Plants The amount of cyanide released per weight of plant tissue varied between the two analyzed seasons (F=129.95; df=1, 388; P<0.001) (Fig. 5a and b). In the fall, cyanide released per unit tissue increased to approximately double the amount released in summer. *Passiflora rubra* was not examined in the fall; however, *Passiflora capsularis*, a close relative (Table 1), follows this

Table 2 Mortality in different stages of the life history of *H. e. favorinus*, *H. e. cyrbia*, and *H. e. demophoon* feeding on natural host plants

Race of *H. erato*	Total *N*	Host plant	Larvae		Pupae		Adult	
			N dead	% dead	*N* dead	% dead	*N* dead	% dead
favorinus	25	*P. trifasciata*	0	0	0	0	0	0
cyrbia	25	*P. punctata*	1	4.0	3	12.0	0	0
	48	*P. rubra*	20	41.7	2	4.2	2	4.2
demophoon	25	*P. biflora*	1	4.0	0	0	0	0

same pattern of variation in toxicity and possesses the same cyanogenic glycoside as *P. rubra* (Hay-Roe 2004). There was a difference in cyanide-releasing capacity between host plants examined (F=45.06; df=6, 388; P<0.001) (Table 1) and plant parts (F=131.83; df= 2, 388; P<0.001). The release of cyanide was always higher from new leaves, and this value differed significantly from the cyanide released from mature leaves and stems. The cyanide-releasing capacity of mature leaves and stems did not follow a constant pattern and varied according to the species (Fig. 5a, b).

The regression line in Fig. 6 indicates that 68% of the variation in cyanide concentration released from tissue of *Heliconius* butterflies is explained by the ability of their host plants to release cyanide, which we assume to be due to cyanogen concentration in the host plant tissues.

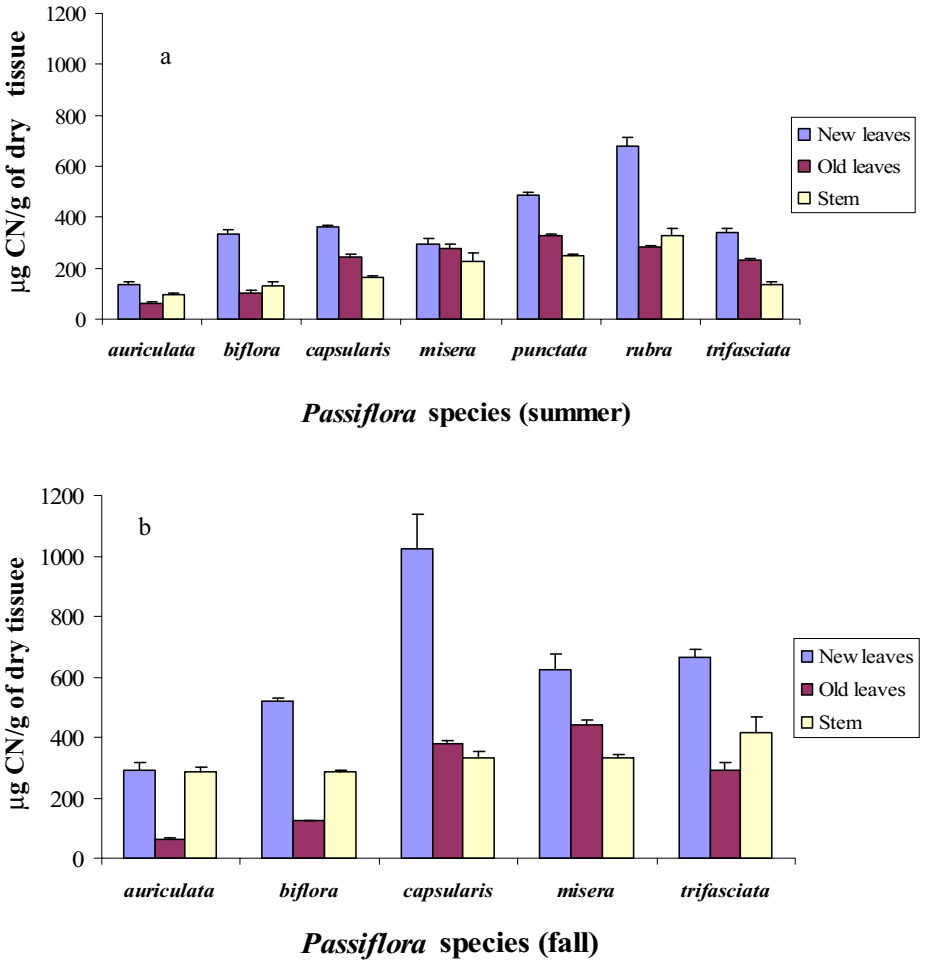

Fig. 5 Cyanide liberated from *Passiflora* plants in the **a** summer and **b** fall seasons. *Bars* indicate standard error

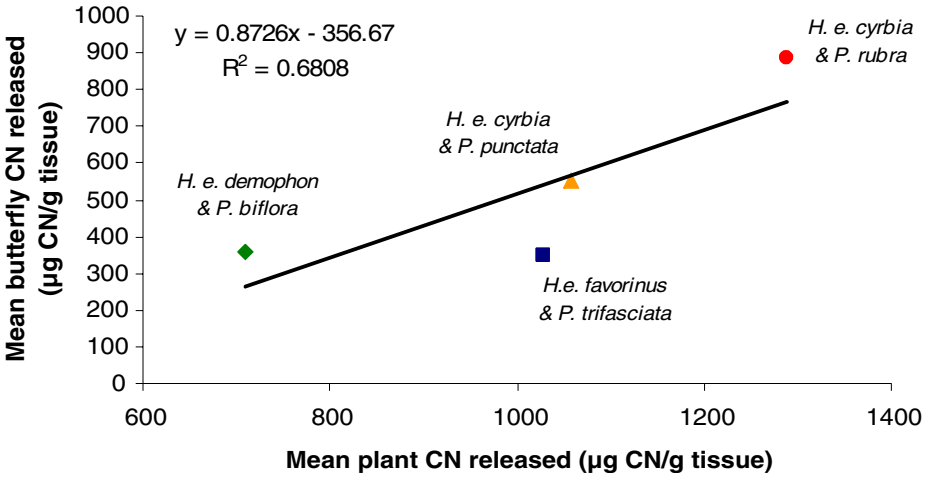

Fig. 6 Regression of the mean cyanide released from *H. erato* vs. the mean cyanide released from the natural *Passiflora* host plants upon which larvae fed

Discussion

Cyanogenic Concentrations in H. erato Fed Passiflora Host Plants and its Implications for Palatability The host plant consumed was the main reason for the variation in cyanide released by different races of *H. erato*. Different levels of cyanogenic compounds in the larvae might be due to both differing levels of cyanogenic substances in the host plants eaten and to detoxification mechanisms in the larvae (Hay-Roe 2004). The thorax and the head were the body parts that released greater amounts of cyanide per unit weight of tissue, which suggests greater accumulation of cyanogenic compounds in these body parts. These results did not follow the patterns of cardenolide accumulation reported for monarch butterflies, which possess higher concentrations of cardenolides in wings (Brower and Glazier, 1975). Low levels of cyanide released from the wings and abdomen might be the result of low levels of hemolymph-containing β-glucosidase in the former and low levels of sclerotized cuticle in the latter.

Cyanogenesis in *Heliconius* butterflies probably functions as an alert signal to predators to reinforce the memory of toxicity, also called aide-mémoire mimicry (Rothschild 1984). Under this assumption, it is not necessary for selection to favor highly cyanogenic wings because low levels of HCN will be enough to trigger the recall of experiences of the bad taste and smell of HCN and aglycone compounds formed during cyanogenesis. A naive predator can quickly learn to avoid feeding on that particular pattern of wing coloration (Chai 1988) and flight (Srygley and Chai, 1990), and the members that constitute a Müllerian ring will benefit from it. The selection for belonging to the ring's common pattern will be reinforced (a similar mechanism of avoidance is likely found for the larval stage; however, a definitive test was not run). Achieving a high degree of unpalatability has a negative aspect, as was demonstrated by the mortality rates. Members of *H. e. cyrbia* fed with *P. rubra* benefit by becoming distasteful, but there was a high cost paid for this benefit: individuals feeding on *P. rubra* had a higher mortality rate and spent a longer period feeding on the host (Hay-Roe 2004), which increases the time they are exposed to

parasitoids. At least for *H. e. cyrbia*, there is a limiting range of potential toxicity to a predator because of high mortality at the larval stage caused by ingested cyanide. On average, adult butterflies that fed as larvae on cyanogenic plants are slightly smaller in size than comparable butterflies feeding on other less-cyanogenic host plants (Hay-Roe 2004).

Heliconius erato favorinus seems to be better adapted to detoxifying and tolerating different chemicals in *Passiflora* plants (Hay-Roe 2004), probably due to more efficient degradative enzymatic activity, or by possessing higher tolerance of chemicals, for example, by having a target-site insensitivity (Brattsten, 1979; Lindroth and Weisbrod, 1991). Differences between strategies for coping with cyanogenic compounds probably reflect genetic variation among the races of *H. erato*. Some insects, for example, *Trichoplusia ni* and *Heliothis virescens*, excrete ingested nicotine rapidly as a detoxification mechanism. We did not find cyanide released from excreta of the caterpillars examined in this study.

Temporal Variation in Cyanide in Passiflora Plants Considerable variation in cyanide released was found among *Passiflora* examined over two seasons (summer and fall). The amount of cyanide released per gram in the fall was almost double the amount observed in the summer season. Variation in cyanogenic glycosides has been linked to herbivore presence (Cooper-Driver et al., 1977) and to altered climatic conditions such as temperature (Ellis et al., 1977; Rammani and Jones, 1985; Jones and Rammani, 1985). In this study, the biotic and abiotic conditions were similar for all analyzed *Passiflora* species in the greenhouse because temperature and light were the same for all plants. An environmental factor that might be responsible for the variation is the difference in photoperiod due to seasonal change. A study of seasonal variation in flavonoid concentration performed on temperate-zone *Alliaria* plants (Haribal and Renwick, 2001) showed that flavonoid concentrations were lower in the summer and higher in the fall. It would be interesting to see how this variation in cyanogenic glycoside concentration correlates to the survival rates of larvae and/or adults of *Heliconius* species.

Higher release of cyanide occurred from the new growth of *Passiflora* plants and followed the same pattern of variation between the summer and fall seasons. Similar temporal variation of cyanogen accumulation in passionvines could occur during the dry and rainy seasons in the tropical rainforest. The distribution of cyanogens within the plant is consistent with optimal allocation theory (McKey 1974), which states that vulnerable plant tissues and organs are defended more than older senescing ones. It has been demonstrated elsewhere that for several cyanogenic species, young developing tissues contain the highest amounts of cyanogenic glycosides (Conn 1981).

Implications of Cyanogenic Compounds for Mimicry Different precursors of toxic substances within a butterfly's body produce a palatability spectrum (Brower et al., 1967), which in turn affects the conditioning of avian predators towards their prey (Brower et al., 1967; Pough et al., 1973). *Heliconius erato* and its comimic *Heliconius melpomene* are members of a Müllerian mimicry ring of races in the South and Central America rainforests. There is some disagreement as to whether *erato* or *melpomene* is the model for this ring, but Mallet (1999) listed three different reasons for favoring *erato* as the model. The first is that *erato* is more abundant in the areas where it coexists with *melpomene*; second, *erato* has a broader geographical distribution; and third, *erato* has a broader habitat than *melpomene*.

If *H. e. favorinus* in Tingo Maria, Huanuco, is less palatable, then this species is, in fact, a weak model. We should then expect that this would directly affect the presence of the less

common *H. melpomene*. This would be true if *P. trifasciata* were the only host plant used by *H. e. favorinus* in the area. It was certainly the most common in Tingo Maria. However, *Passiflora auriculata* (which is the host plant of *Heliconius sara*), *Passiflora laurifolia*, *Passiflora tricuspis*, *P. rubra*, and *Passiflora vespertilio* have been found in Huanuco (Brako and Zarucchi, 1993) and are potential host plants for *H. e. favorinus*.

Recently, doubts have been raised with regard to the existence of the classical Müllerian mimic. Instead, some have proposed a new term, "quasi-Batesian mimicry" (Huheey 1976; Speed and Turner, 1999), as an alternative explanation for some types of polymorphism associated with mimicry. Quasi-Batesian mimicry states that if members of a Müllerian mimicry complex are not equally distasteful, then the presence of individuals that are less distasteful would lead to an increase in predation on the models, and this will result in an overall weakening of the Müllerian mimicry. In this model, predator learning and memorization of the degree of distastefulness of the prey is assumed. However, more recent models have argued that the assumptions that lead to quasi-Batesian mimicry may not be met in most real situations, casting doubt on the model (Mallet and Joron, 1999; Kokko et al., 2003).

Males of *H. e. favorinus* that fed on *P. trifasciata* had a very low ability to release cyanide. They probably get protection from the presence of more unpalatable conspecifics (females or other conspecifics that do not feed on *P. trifasciata*). It is likely that females will be more affected by potential male palatability because females are probably more exposed to predators, particularly during oviposition and while searching for host plants.

Abstract Jasmonic acid (JA) and salicylic acid (SA) are key molecules in the initiation of plant defensive responses to attack by herbivores and pathogens, respectively. Our previous work has shown that JA occurs at high concentrations in eggs and neonates of lepidopteran species. Here, we extend our analyses to eggs of 15 non-lepidopteran insect species spanning eight orders, again screening for JA, but also including SA and one of its metabolic precursors, benzoic acid. We detected all three compounds in eggs of almost all the species examined. Moreover, concentrations of these compounds were variable across species, suggesting that species accumulate and/or utilize the compounds differently. Eggs of the fruit-feeding fly *Rhagoletis pomonella* contained the greatest concentrations of all three compounds, which appear to be common in fruit. The presence of these plant-derived compounds in eggs may serve defensive or other functions for insects, and could conceivably trigger plant defensive responses after oviposition.

Keywords Benzoic acid · Jasmonic acid · Salicylic acid · Phytohormone · Plant defenses

Introduction

The phytohormones jasmonic acid (JA) and salicylic acid (SA) initiate plant defensive responses to attack by herbivores and pathogens (Walling, 2000). Jasmonate is derived from linolenic acid via the octadecanoid pathway and activates defensive genes that initiate "induced systemic resistance" against some insect herbivores and the release of volatile compounds that attract natural enemies to herbivore-infested plants (Walling, 2000). Salicylate appears to be produced by at least two pathways, one via phenylalanine, cinnamic acid, and benzoic acid (BA), and the other via isochorismate (Métraux, 2002; Delaney, 2005). Salicylic acid initiates defensive response against pathogens and some insect herbivores resulting in "systemic acquired resistance" (Walling, 2000; Métraux, 2002). Molecules of both JA and SA can be produced at sites of insect damage and are

ingested by feeding herbivores, activating detoxification genes that appear to provide "early-warning" signals indicating imminent production by plants of toxic defense compounds (Li et al., 2002).

We recently reported that lepidopteran eggs and neonates can harbor high concentrations of JA (Tooker and De Moraes, 2005). We detected JA in all nine lepidopteran species that we screened. This JA may have been derived from the larval diets of ovipositing mothers, although the presence in two species of significantly greater quantities of JA in unfed neonates than in eggs suggests that some lepidopteran species may synthesize JA *de novo*. Because of the consistent presence of JA in lepidopteran eggs and neonates, we postulated that JA may play an unknown functional role in lepidopterans and, perhaps, in insects in general (Tooker and De Moraes, 2005).

In this paper, we expand on our previous analyses of JA in insect eggs, extending our analyses to non-lepidopteran eggs and screening for SA and one of its metabolic precursors, BA. As with JA, the presence of these plant-derived compounds in insect eggs seems counterintuitive because of their roles in initiating plant defensive responses (Walling, 2000; Delaney, 2005). Previous studies have shown that eggs laid on plants can trigger a hypersensitive response (Shapiro and DeVay, 1987; Balbyshev and Lorenzen, 1997; Garza et al., 2001), which is SA-mediated (McDowell and Dangl, 2000; Walling, 2000; Ollerstam and Larsson, 2003); however, to our knowledge, there have been no previous reports of SA in insect eggs. Similarly, we are unaware of any investigations of BA in insect eggs despite its being a component of defensive secretions in some insect species and of sex pheromones in others (e.g., Classen and Dettner, 1983; Nishida et al., 1996). We present data from analyses of eggs from 15 insect species in eight orders. We report levels of JA, BA, and SA for eggs of individual species and also analyze data based on groupings of species with similar trophic positions, diets, or feeding styles.

Methods and Materials

Insect and Diet Samples We obtained eggs of 15 species representing 8 insect orders (Table 1). Two species were field collected, and the exact composition of their diets is unknown. The other 13 species were colony reared on plants or artificial diets, and we were able to obtain samples of diet for 10 of these 13 (Table 1). We collected 50–250 mg of each diet (five samples per diet) or eggs directly into FastPrep® tubes (Qbiogene, Carlsbad, CA, USA) containing 1 g of Zirmil beads (1.1 mm; Saint-Gobain ZirPro, Mountainside, NJ, USA) and froze them at −80 °C until processing (see below). Because of the low mass of eggs (<1 mg for most species), we combined multiple eggs (2–20 depending on mass) into single samples, processing 5–10 samples for each species (total eggs analyzed per species: 10–100). For the phasmid *Extatosoma tiaratum* (MacLeay), eggs were large enough (~40 mg each) to process only two eggs per sample (we analyzed 10 eggs), and for the cockroach *Periplaneta americana* L., we processed one ootheca per sample, and each ootheca contained 16 eggs (we analyzed 80 eggs). For the cecidomyiid *Mayetiola destructor* (Say), eggs were so small that we were unable to obtain accurate masses even when 20 eggs were combined in each sample; therefore, we were unable to include this species in some of our statistical analyses (see below).

Extraction and Quantification of JA, BA, and SA To extract and detect JA, BA, and SA, we used a previously described method (Tooker and De Moraes, 2005) modified slightly from

[c] Field collected.

Schmelz et al. (2003, 2004). Briefly, we derivatized carboxylic acids to methyl esters, which were isolated by using vapor phase extraction and analyzed by GC-MS with isobutane chemical ionization with selected-ion monitoring. We quantified amounts of methyl jasmonate (meJA), methyl salicylate (meSA), and methyl benzoate (meBA) by using standard curves made with the pure compounds (Sigma-Aldrich, St. Louis, MO, USA) and relying on internal standards to confirm derivatization and recovery. We also processed samples without the derivatization agent to verify that the meJA, meBA, and meSA we recovered were not themselves present in eggs, but were derived from the carboxylic acids. To confirm the identity of meJA, meBA, and meSA in our samples, we analyzed extracts by GC-MS with electron ionization with selected-ion monitoring of characteristic fragments by comparing retention times and spectra with those of pure compounds (*m*/*z* ratio of characteristic fragments—meJA: 27, 41, 67, 83, 151, 224; meBA: 51, 77, 105, 136; meSA: 15, 39, 65, 92, 120, 152). We used electron ionization in the "selected-ion" mode rather than the "scan" mode because mass spectrometry using the former mode has greater sensitivity.

Statistical Analyses We analyzed amounts of JA, BA, and SA on a "per-gram-fresh-weight" basis as well as a "per-egg" basis because of disparate egg masses ranging from <0.01 mg (*M. destructor*) to ~40 mg (*E. tiaratum*). To stabilize variance, we added one to each value to control for zeros and square-root transformed the data, making between-species comparisons of JA, BA, and SA levels and egg mass by analysis of variance (ANOVA) and comparing individual means with Tukey's honestly significantly different (HSD) means separation test (Sokal and Rohlf, 1995; Statistix, 2003). Because JA, BA, and SA in insect eggs are likely to be derived from the nymphal or larval diet of the ovipositing mothers (Tooker and De Moraes, 2005), we also used ANOVA to compare levels of JA, BA, and SA (transformed as above) in diets and among 4 feeding-based groupings of the species (sucking herbivores, chewing herbivores, fruit feeders, and predators; Table 1). Not all species were represented in this latter analysis because we only used functional groupings comprising at least two species. Lastly, we used regression analysis to test for linear relationships between variables (Sokal and Rohlf, 1995; Statistix, 2003).

Results

We detected JA, BA, and SA in eggs of almost all the insect species and diet samples that we screened, with the exceptions that eggs of the seed bug *Oncopeltus fasciatus* Dallas did not yield SA, and its diet yielded neither SA nor JA. Retention times and selected-ion mass spectra of meJA, meBA, and meSA recovered from eggs and diets were nearly identical to those of pure standards, confirming the identity of JA, BA, and SA in our samples. Moreover, we did not recover the 3 compounds in absence of the derivatization agent, verifying that the methyl esters we measured were derivatized from JA, BA, and SA and were not themselves present in samples.

For the diets we were able to analyze, we found significant differences across the diets for all three compounds (Table 2). The diet of *E. tiaratum*, *Pyracantha coccinea* M. Roemer (Rosaceae), contained the greatest amount of JA, which was significantly greater than all of the other diets (Tukey's HSD $P<0.05$). The remaining diets were statistically similar and intermediate in concentration relative to *P. coccinea* and the sunflower-seed diet

Table 2 Concentrations of JA, BA, and SA in insect diets

[e] Statistics were performed on transformed data (see text for details).

of *O. fasciatus*, which did not yield detectable JA (Table 2). Benzoate and salicylate from the 7 diets showed statistical patterns similar to each other with the diets of *Anastrepha ludens* (Loew) and *P. americana*, respectively, having significantly greater concentrations than the other diets, which were similar to each other (Table 2).

Amounts of JA on a "per-gram" basis varied across insect species (Fig. 1a; ANOVA $F_{13,\ 80}$= 6.5, P<0.001). Eggs of the fly *Rhagoletis pomonella* (Walsh) had the highest levels of JA, significantly greater than concentrations in eggs of 10 of the other species (Tukey's HSD P< 0.05), whereas *A. ludens* eggs had a concentration that was similar to that of *R. pomonella* (Tukey's HSD P>0.05), but greater than that of the eggs of *P. americana*, *Tenodera aridifolia* Saussure, *Nezara viridula* L., and *O. fasciatus* (Tukey's HSD P<0.05). All remaining species were statistically similar to each other (Fig. 1a; Tukey's HSD P>0.05).

Benzoate levels also differed across species on a "per-gram" basis (Fig. 1b; ANOVA $F_{13,\ 80}$=15.8, P<0.001). Similar to our results for JA, eggs of *R. pomonella* had the greatest concentrations of BA, significantly greater than eggs of all the other species except *A. ludens* (Fig. 1b; Tukey's HSD P<0.05). Eggs of *A. ludens* had concentrations of BA that were higher than eggs of 5 species (Fig. 1b; *E. tiaratum*, *T. aridifolia*, *P. americana*, *O. fasciatus*, *N. viridula*; Tukey's HSD P<0.05). Eggs of *E. tiaratum*, *P. americana*, and *T. aridifolia* contained the lowest amounts of BA, which were statistically lower than the eggs of 6 other species (Fig. 1b, Tukey's HSD P<0.05). Eggs of the remaining species had similar levels of BA (Fig. 1b; Tukey's HSD P>0.05).

"Per-gram" levels of SA also varied among species (Fig. 1c; ANOVA $F_{13,\ 80}$=3.7, P= 0.001). Unfortunately, many species showed considerable variation among samples, resulting in statistical differences only between eggs of *R. pomonella* and the eggs of *E. tiaratum*, *T. aridifolia*, *Zootermopsis nevadensis* (Hagen), *N. viridula*, *O. fasciatus*, and the 4 species of *Diabrotica* (Fig. 1c, Tukey's HSD P<0.05). Levels of SA in eggs of the remaining species were intermediate and similar to levels found in eggs of all the other species (Tukey's HSD P>0.05).

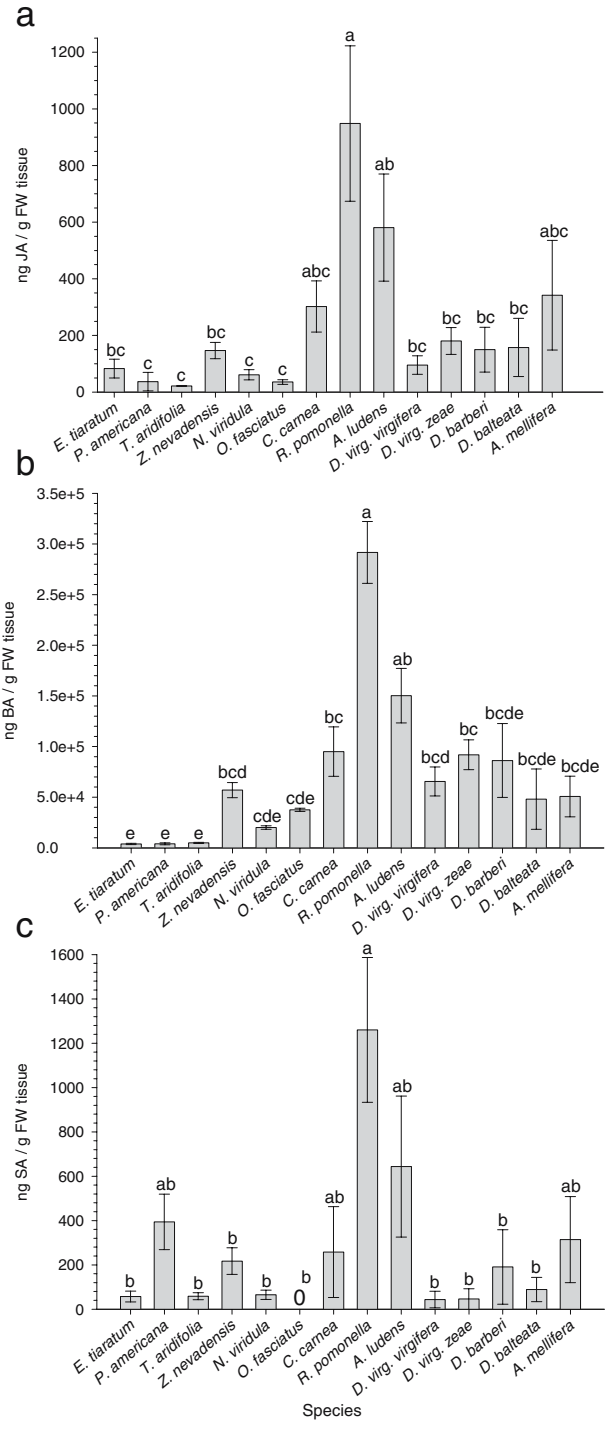

Fig. 1 (a) JA, (b) BA, and (c) SA per gram FW tissue recovered from eggs of 14 insect species. Bars marked with different letters are significantly different from each other (Tukey HSD $P<0.05$; see text for details on statistics)

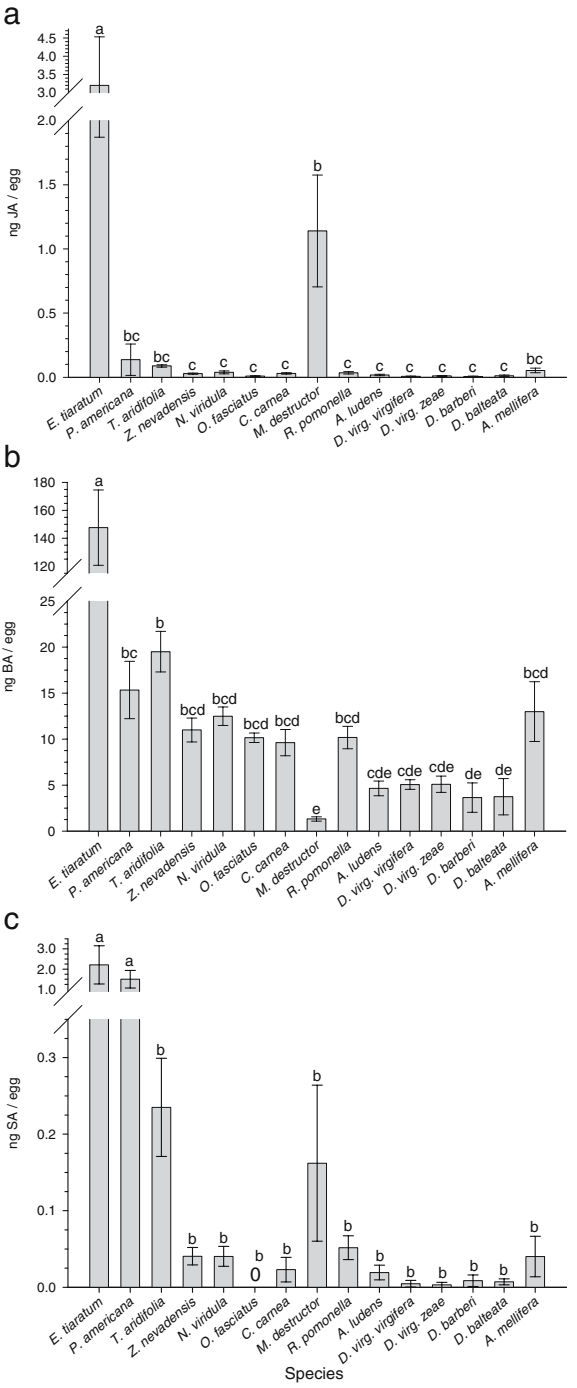

Fig. 2 (a) JA, (b) BA, and (c) SA per egg recovered from eggs of 15 insect species. Bars marked with different letters are significantly different from each other (Tukey HSD $P<0.05$; see text for details on statistics)

When considered on a "per-egg" basis, JA varied among eggs of different species (Fig. 2a, ANOVA $F_{14, 85}$=9.0, P<0.001). Eggs of *E. tiaratum* contained greater amounts of JA than all the other species, whereas eggs of *M. destructor* (Say) had the next highest amount, statistically greater than the levels detected in the eggs of all but 3 species (*P. americana*, *T. aridifolia*, and *Apis mellifera* L.; Tukey's HSD P>0.05). Benzoate also varied on a 'per-egg' basis, but the pattern was more complicated (Fig. 2b, ANOVA $F_{14, 85}$= 46.2, P<0.001). As with JA, eggs of *E. tiaratum* had a concentration that was greater than all other species (Tukey's HSD P<0.05). Eggs of the gall midge *M. destructor* had the lowest amounts of BA, whereas the remaining species were more or less intermediate (Fig. 2b). Salicylate also varied among species (Fig. 2c; ANOVA $F_{14, 85}$=10.2, P<0.001), showing a slightly different pattern than JA and BA. Eggs of *P. americana* and *E. tiaratum* had similar amounts of SA (Tukey's HSD P>0.05) that were greater than eggs of all other species (Tukey's HSD P<0.05).

Because *E. tiaratum* eggs, the largest of the species sampled, contained the greatest amounts of JA, BA, and SA, we suspected that amounts of these plant compounds might be related to egg size. Egg mass varied across species (ANOVA $F_{13, 80}$=1577, P<0.001) with *E. tiaratum* eggs being the heaviest and larger than eggs of all other species (38.1±0.9 mg/egg; Tukey's HSD P<0.05). Eggs of *P. americana* and *T. aridifolia* were the next largest and were similar in mass (4.1±0.4, 4.0±0.1 mg/egg, respectively; Tukey's HSD P>0.05) and larger than eggs of the remaining species (Tukey's HSD P<0.05). Eggs of the 11 remaining species (excluding *M. destructor*) had similar masses (ranging from 0.03 to 0.60 mg; Tukey's HSD P>0.05). Linear regression revealed that "per-gram" amounts of JA, BA, and SA were not statistically related to the mass of individual eggs (r^2≤0.07, P> 0.05); however, on a "per-egg" basis, JA, BA, and SA were positively related to mass of individual eggs, suggesting that larger eggs contain greater amounts of these plant-derived compounds (ng JA/egg vs. egg mass: r^2=0.58, P<0.001, best fit regression line Y=85.3X− 0.03; ng BA/egg: r^2=0.87, P<0.001, Y=3711X+7.01; ng SA/egg: r^2=0.45, P<0.001, Y= 59.2X+0.09). Therefore, we avoid any further consideration of "per-egg" data because it is undoubtedly confounded by egg mass.

Regression analysis also revealed that "per-gram" amounts of JA, BA, and SA were positively related to each other ("per-gram" statistics—ng SA/g vs. ng BA/g: r^2=0.49, P< 0.001, Y=0.004X−22.6; ng JA/g vs. ng BA/g: r^2=0.62, P<0.001, Y=0.003X−25.9; ng SA/g vs. ng JA/g: r^2=0.72, P<0.001, Y=1.11X+21.4). These relationships indicate that insect species that had high concentrations of one of these compounds in their eggs tended to have higher concentrations of the other two as well. Finally, linear regression revealed no statistical relationship between the amounts of JA, BA, and SA in eggs of different insect species and amounts of these compounds in their diets (r^2≤0.07, P>0.55), indicating that factors other than dietary concentrations influence the amounts of these compounds in eggs.

When we compared amounts of JA, BA, and SA in eggs of herbivores and predators, we found no statistical differences on a "per-gram" basis (262.7±52.3 and 162.0±63.2 ng JA/g for herbivores and predators, respectively, ANOVA $F_{1, 80}$=0.5, P=0.48; 84,368±11,738 and 49,949±18,910 ng BA/g, ANOVA $F_{1, 80}$=1.14, P=0.29; 319.9±67.8 and 158± 102.5 ng SA/g, ANOVA $F_{1, 80}$=0.76, P=0.39). When we divided the insect species into more specific functional groups based on nymphal or larval feeding habits, we found a consistent pattern for all three compounds: eggs of the fruit feeders had higher concentrations than eggs of species in other functional groups, which were statistically similar to each other (Fig. 3; ng JA/g: ANOVA $F_{3, 70}$=22.3, P<0.001; BA: ANOVA $F_{3, 70}$=24.9, P<0.001; SA: ANOVA $F_{3, 70}$=12.9, P<0.001).

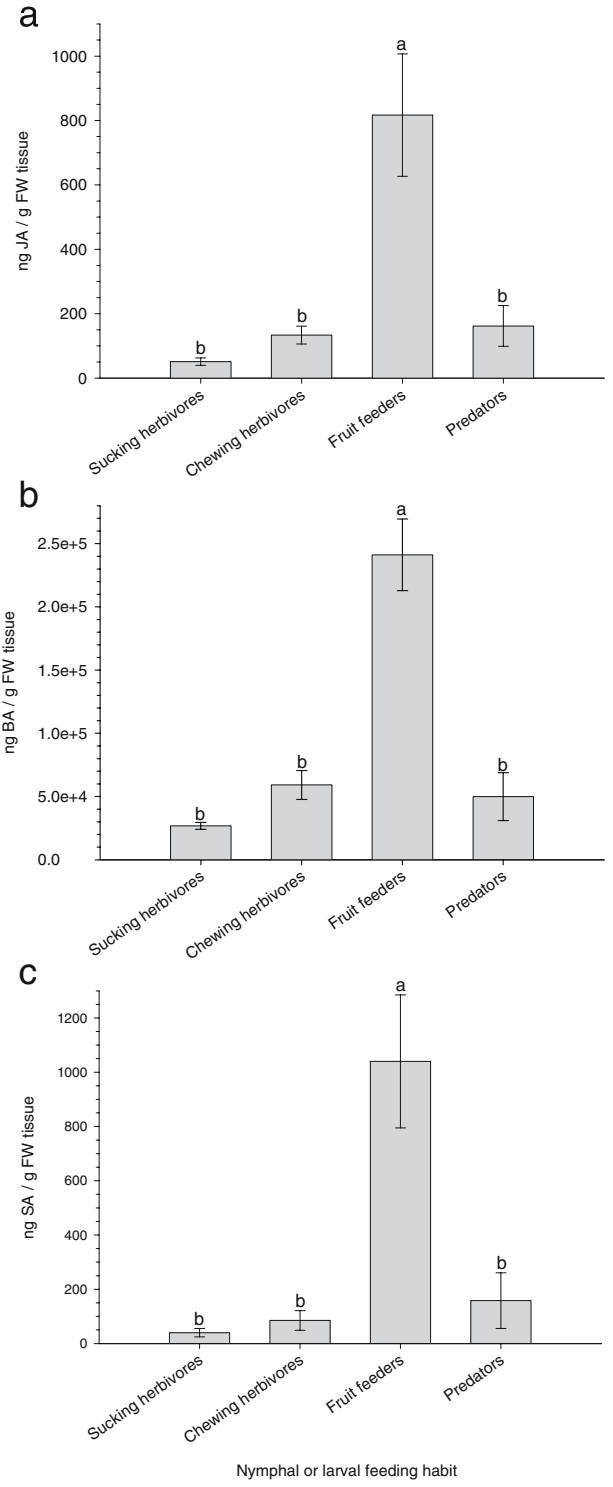

Fig. 3 (a) JA, (b) BA, and (c) SA per gram FW in eggs of four different functional groups based on nymphal or larval diets and represented by at least two species (see Table 1). Bars marked with different letters are significantly different from each other (Tukey HSD $P<0.05$; see text for details on statistics)

Discussion

All the diets we analyzed contained substantial amounts of BA (>1 μg/g diet FW), and all but one contained JA and SA. The exception was the sunflower-seed diet used to rear *O. fasciatus* (Table 2), whose eggs were the only ones analyzed that did not contain detectable amounts of SA (Fig. 1c), suggesting that SA (and JA and BA) in insect eggs is at least partially obtained from the nymphal or larval diets of their mothers. Thirteen of the species that we screened were either reared directly on plant material or plant-based artificial diets, and most of their diets contained all three compounds, sometimes in extremely high concentrations (Table 2). The two remaining species were predators: the lacewing *Chrysoperla carnea* was reared on a proprietary chicken egg-based artificial diet, and the plant-derived compounds could have originated in plant-based chicken feed; eggs of the mantid *T. aridifolia* were field collected, and JA, BA, and SA in mantid eggs could have originated from herbivores eaten as prey. Despite diets being the likely sources of plant-derived compounds, we found no clear relationship between amounts of JA, BA, or SA in the diet and "in-egg" concentrations. These findings agree with levels of JA detected in lepidopteran eggs and diet (Tooker and De Moraes, 2005) and indicate that other factors may play a role in determining the amounts of these compounds in eggs. Some evidence suggests that insect species may be capable of synthesizing these typically plant-derived compounds (Tooker and De Moraes, 2005). Similarly, we did not detect JA from sunflower seeds, but did detect JA in eggs of *O. fasciatus*, suggesting that this phytohormone may be produced by the insects themselves, although the possibility remains that JA was present in sunflower seeds, but was bound or otherwise undetectable by our methods.

The consistent presence of JA, BA, and SA in insect eggs across taxa suggests that these compounds may serve some function for eggs or developing insects. Moreover, species-specific concentrations suggest that insect species vary in their accumulation and/or use of these compounds. We have previously suggested that JA might perform an unidentified function in lepidopteran eggs, drawing on commonalities between plant and animal signaling systems and the structural similarity of JA and prostaglandins, which mediate a variety of functions in insects (Tooker and De Moraes, 2005). Our discovery of JA in eggs of eight more orders reinforces this idea. The JA concentrations for non-lepidopteran eggs that we report here span a lower range (20–950 ng JA/g FW) than those we reported for lepidopteran eggs (500 ng–600 μg JA/g FW; Tooker and De Moraes, 2005), but considerable overlap remains in the concentrations across different taxa. We are uncertain why lepidopteran eggs appear to contain more JA than eggs of other insect species, but perhaps, the physiological needs of caterpillars for JA are greater. Alternatively, chewing caterpillars may elicit a stronger JA response from plants causing JA to accumulate to a greater degree in their bodies and eggs.

Among non-lepidopteran species, eggs of the apple maggot *R. pomonella* contained the greatest "per-gram" concentrations of JA, BA, and SA (Fig. 1). Similarly, when we considered amounts across functional groupings, fruit feeders (comprising *R. pomonella* and *A. ludens*; Table 1) had the highest "per-gram" concentrations of JA, BA, and SA (Fig. 3). This finding was unexpected because most research on these three compounds has focused on "in-leaf" concentrations rather than levels in fruits, giving the impression that leaf concentrations are more significant; however, all three compounds appear common in fruit, including apples (Meyer et al., 1984; Peña-Cortés et al., 2005), the food for *R. pomonella*, and the fruit-mimicking diet used to rear *A. ludens* (Table 2). In fact, concentrations of JA in fruit of some plant species can greatly exceed concentrations found

in other plant tissues (Meyer et al., 1984). Jasmonate in fruit appears to play a role in ripening in addition to its role as a defensive phytohormone (Peña-Cortés et al., 2005). It should be noted, however, that whereas JA levels of *R. pomonella* eggs were the greatest among all species we screened (Fig. 1a), levels of JA in the diet were among the lowest we detected (Table 2), indicating that insects accumulate JA while they feed as larvae, and/or the species may be capable of producing JA on their own.

Benzoate and salicylate are also found in fruit (Table 2; Robertson and Kermode, 1981; Zuo et al., 2002). Salicylate is ingested by herbivores, providing a signal that warns of production of toxic plant compounds (Li et al., 2002). Moreover, when ingested by humans, BA- and SA-containing fruit can elevate levels of BA and SA in plasma (Zhang and Zuo, 2004). Perhaps frugivory also enriches these compounds in insects, favoring passive or active incorporation into eggs.

On a "per-egg" basis, the phasmid *E. tiaratum* had the highest levels of JA, BA, and SA, but this result likely reflected the size of *E. tiaratum* eggs (Fig. 2). In fact, significant linear relationships between amounts of JA, BA, and SA and the mass of individual eggs suggest that larger eggs tended to have high concentrations of these compounds, and this relationship likely explained any other "per-egg" patterns. It is worth noting, however, that we did not find a similar pattern for JA in lepidopteran eggs, whose masses spanned a much smaller range (0.05–3.0 mg/egg; unpublished data; Tooker and De Moraes, 2005). It is also worth noting that *E. tiaratum*, among the 15 insect species that we screened, has the mode of feeding that is most similar to leaf-feeding lepidopterans. However, on a "per-gram" basis, the concentrations of JA in *E. tiaratum* eggs (~85 ng JA/g) were considerably lower than the lowest concentration we found among lepidopteran eggs (~500 ng JA/g for *Manduca sexta*; Tooker and De Moraes, 2005). It seems likely that amounts of JA (or BA and SA) found in eggs of herbivores are a function of the insect species involved, the strength of the plant response to herbivory, and possibly, the insects' physiological usage of JA. The strength of the induced plant response appears to be influenced by host plant species, the tissue being attacked, and the mode of feeding, including content of the oral secretions of the insect species (Karban and Baldwin, 1997). Interactions among these various factors may explain why sucking and chewing herbivores had similar amounts of JA, BA, and SA, although chewing insects tend to elicit a stronger JA response from plants than sucking herbivores, which tend to elicit a stronger SA response (Walling, 2000).

As with JA (see above and Tooker and De Moraes, 2005), the presence of BA and SA in insect eggs is not easily explained. Both compounds have antimicrobial and antifungal properties that may confer some protection from pathogens (Krebs et al., 1983; Cowan, 1999). Moreover, SA can attenuate in both plants and animals the virulence of some pathogens (Prithiviraj et al., 2005), suggesting that insect eggs could gain similar protection from its presence. As phenolic compounds, BA and SA might protect eggs and developing insects by blocking harmful free radicals from oxidizing important biological molecules, including DNA (Zuo et al., 2002). Also, BA is a component of defensive secretions of some insect species (e.g., Classen and Dettner, 1983) and could conceivably deter egg predators.

At the same time, concentrations in eggs of SA and its precursor BA seem counterintuitive given their roles in initiating plant defenses against pathogens and some insect species (Walling, 2000; Delaney, 2005). Their presence in herbivore eggs that are laid on plants could provide a plausible mechanism for triggering an SA-mediated hypersensitive response in leaves (e.g., Shapiro and DeVay, 1987; Balbyshev and Lorenzen, 1997; Garza et al., 2001). Similarly, JA in insect eggs could play a role in volatile defensive

responses of plants against insect eggs (Meiners and Hilker, 2000; Tooker and De Moraes, 2005). However, it seems maladaptive for endogenous compounds of eggs (i.e., JA, BA, or SA) to facilitate such plant defense responses, and natural selection would likely not favor their inclusion under these circumstances in the absence of some other function (Tooker and De Moraes, 2005). Moreover, in preliminary work, we have not been able to detect measurable JA, BA, or SA after solvent washes of the exterior of eggs that are laid on plants (e.g., *M. destructor* eggs; unpublished data); however, different species and/or different extraction methods might yield a different result. Nevertheless, at least for hypersensitive responses after oviposition, no other triggering mechanisms appear to have been proposed, and possible roles for BA and SA in eggs warrant investigation.

In summary, the phytohormones JA and SA, and a precursor of salicylate, BA, appear common in insect eggs. The function of these in eggs is unclear, but they could serve signaling or defensive roles. It is also conceivable that they could play a role in triggering plant defenses after oviposition on plants. Further research is underway to clarify the exact role of the plant-derived compounds in insect eggs.

Evaluation of Pheromones and a New Trap for Monitoring *Agriotes lineatus* and *Agriotes obscurus* in the Fraser Valley of British Columbia

R. S. Vernon · M. Tóth

Received: 12 September 2005 / Revised: 16 September 2006 / Accepted: 11 October 2006 /
Published online: 27 December 2006

Abstract A prototype ground-based pheromone trap design, baited with various pheromone lures, was field tested for effectiveness in trapping male *Agriotes obscurus* and *Agriotes lineatus* click beetles in British Columbia. Pheromone dispensers containing geranyl octanoate and geranyl hexanoate in a 1:1 ratio caught the greatest numbers of *A. obscurus*, whereas those containing geranyl octanoate and geranyl butanoate in a 9 or 10:1 ratio caught high numbers of *A. lineatus*. Some differences in *A. obscurus* attraction to traps were observed between dispensers according to the manufacturer and the number of dispensers deployed in traps. The trap design and optimal pheromone dispensers tested would be suitable for monitoring or surveying *A. obscurus* and *A. lineatus* populations in North America.

Introduction

The most economically important European wireworm species are in the genus *Agriotes* (Coleoptera: Elateridae) and include: *Agriotes brevis* Candeze; *Agriotes rufipalpis* Brulle; *Agriotes sordidus* Illiger; *Agriotes ustulatus* Schaller; *Agriotes sputator* L.; *Agriotes obscurus* L.; and *Agriotes lineatus* L. (Furlan et al., 2001a). Of these, *A. lineatus* and *A. obscurus* have been introduced to Atlantic Canada, British Columbia (BC), and Washington state in the USA (Eidt, 1953; Vernon and Päts, 1997; Vernon et al., 2001) whereas *A. sputator* has been reported in Nova Scotia (Eidt, 1953). These wireworms were probably introduced into North America at least a century ago with infested nursery stock

and/or through the dumping of soil ballast in port areas (Eidt, 1953; Wilkinson, 1963). Where they have become established in Canada, *A. sputator, A. obscurus*, and *A. lineatus* have often become the dominant wireworm species and major economic pests of several crops (i.e., potatoes, corn, strawberries, cereal crops).

Surveys of European wireworm species in North America have traditionally relied upon habitat searches or devices such as pitfall traps for the click beetle stage (Vernon and Päts, 1997). Field surveys of *Agriotes* spp. wireworm stages are not usually considered due to the extensive labor and time required and difficulties in differentiating larvae of *A. obscurus* from *A. lineatus* (Wilkinson, 1963). However, the identification of sex pheromones for several *Agriotes* species (Yatsynin and Lebedeva, 1984; Kudryavtsev et al., 1993; Yatsynin et al., 1980, 1986, 1991, 1996; Borg-Karlson et al., 1988; Tóth et al., 2002a,b) offers a new tool for surveying and monitoring these economic elaterids. They were successfully used to survey the distribution of five species (*A. ustulatus, A. litigiosus, A. sputator, A. obscurus*, and *A. lineatus*) across the former Union of Soviet Socialist Republics (USSR) (Kudryavtsev et al., 1993), and surveys for eight species (*A. ustulatus, A. litigiosus, A. sputator, A. obscurus, A. lineatus, A. rufipalpis, A. sordidus*, and *A.brevis*) were carried out in several European countries between 1999 and 2001 (Furlan et al., 2001b). Studies are also underway in Europe to determine whether pheromone traps can be used as monitoring tools to determine the risk of wireworm attack at the field level (e.g., Furlan et al., 2001a).

The availability of sex pheromones for *A. obscurus, A. lineatus*, and *A. sputato*r would greatly enhance the scope and efficacy of surveys to determine the current geographic distribution of these species in North America. The objectives of this paper were to: (1) determine whether various pheromone lures produced by manufacturers in Hungary and Canada are effective in attracting *A. obscurus* and *A. lineatus* populations in BC; and (2) develop a ground-based pheromone trap for the general survey or in-field monitoring of *Agriotes* species in North America.

Methods and Materials

Pheromones and release devices *Agriotes lineatus* and *A. obscurus* females produce a sex pheromone composed of (*E*)-3,7-dimethyl-2,6-octadienyl [=geranyl] esters. *A. lineatus* females produce primarily geranyl octanoate (G8) with geranyl butanoate (G4) as a trace component, whereas *A. obscurus* females produce both geranyl octanoate (G8) and geranyl hexanoate (G6) (Borg-Karlson et al., 1988; Yatsynin et al., 1996; Tóth et al., 2003). Dispensers containing a 10:1 ratio of G8:G4 were effective in attracting male *A. lineatus* to flight traps in Europe (Tóth, unpublished data). A 1:1 ratio of G8:G6 caught male *A. obscurus* in Russia, but an analysis of female pheromone glands suggested that a 10:1 ratio might be more effective (Tóth, unpublished data). Consequently, various ratios of G8:G6 and G8:G4 were tested for attractiveness to *A. obscurus* and *A. lineatus*, respectively, in BC in 1999. In these trials, two types of dispensers were used. The first, from the pheromone Group (Budapest, Hungary), consisted of 0.7-ml polyethylene vials with lids (No. 730, Kartell Co., Italy). Active ingredients were added in 50% hexane solutions, with load volumes of 60 or 33 µl (1:1 and 10:1 G8:G6 ratios) for *A. obscurus* baits, and 33 µl (10:1 G8:G4 ratios) for *A. lineatus* baits. After the hexane was allowed to evaporate, each dispenser was closed and individually wrapped in aluminum foil sachets. Dispensers provided by Phero Tech Inc. (Delta, BC, Canada) consisted of 400-µl centrifuge tubes (Evergreen Scientific, Los Angeles, CA, USA) with load volumes of 50 µl. In 2000, the Phero Tech centrifuge tube dispensers (2 per trap) were compared to bubble cap dispensers

(Phero Tech Inc.) in *A. obscurus* traps, with load volumes of 175 μl in the bubble caps (1:1 ratio of G8:G6). All dispensers were stored separately at −20°C before deployment in the field.

Pheromone trap design A portable plastic exclusion trench (United States Patent # 5,926,999) developed to mass trap Colorado potato beetles (Hunt and Vernon, 2001) captured large numbers of *A. obscurus* in a fallowed field in Agassiz, BC in 1998 (R.S. Vernon, unpublished data). Using reconfigured components of the exclusion trench, a prototype ground-based trap was constructed to house pheromone dispensers and crawling *A. obscurus* and *A. lineatus* were collected (Fig. 1). The trap consists of two converging ramps (separated at the top by a 1-cm wide gap), which curved downwards at the apex to ensure that click beetles would slide into the enclosed cavity within. The ramps had 0.2-mm high elevated ridges, spaced 2 mm apart to assist beetles in climbing. A retractable flat tray, extending into the enclosed cavity from one of the two flat sides, was fitted with a 10× 15 cm yellow sticky card (Phero Tech Inc.) to catch and hold click beetles falling into the trap. A removable lid prevented water and larger beetles from entering the trap. The pheromone dispenser(s) was centered along the underside of the lid using double-sided tape, parallel to and 1 cm above the ramp opening.

Traps were installed so the floor of the trap was flush with the soil surface to afford a smooth transition to the ramps. For consistency, a 1-m square area around the traps was kept free of weeds, and traps were always oriented with ramps facing north–south. Traps

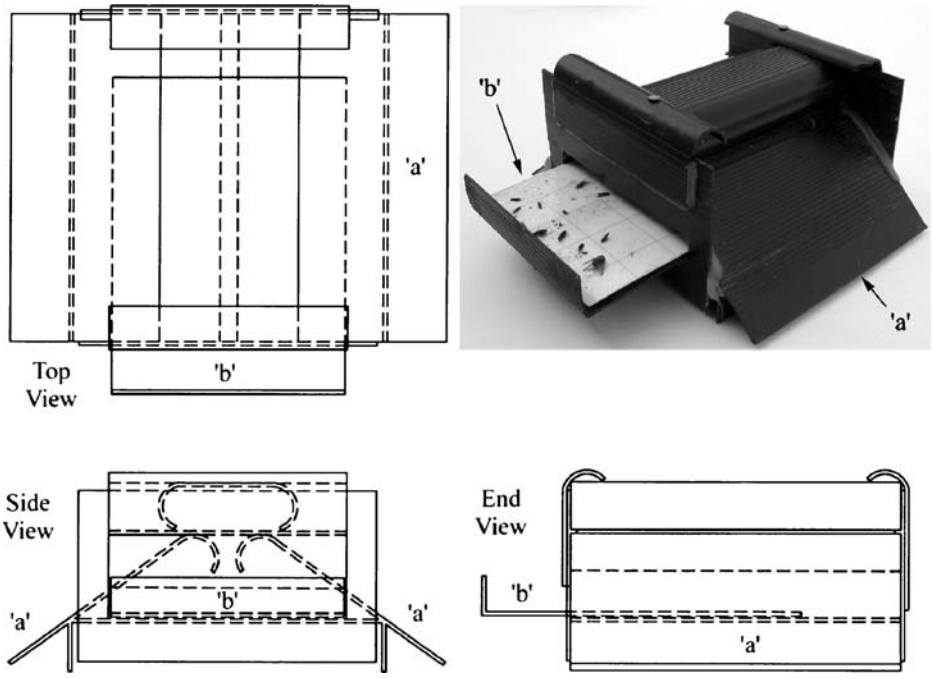

Fig. 1 Photograph and drawings of top, side, and end views of a ground-based pheromone trap developed for collecting crawling *Agriotes obscurus* and *A. lineatus* click beetles in 1999 and 2000. The opposing ramps (**a**) and partially extruded retractable tray with sticky trap (**b**) are indicated

were inspected by removing the tray and counting beetles on the sticky cards. At the end of each study, beetles on sticky cards were counted, as were any additional beetles that escaped the cards into the trap cavity. All elaterids captured were identified to species and subsamples of *A. obscurus* and *A. lineatus* identified to sex.

1999 Field Studies In 1999, experiments were conducted in fallow fields in Agassiz known to contain almost exclusively *A. obscurus* and in Delta in the lower Fraser valley of BC where *A. lineatus* was the predominant species (Vernon and Päts, 1997).

The first study conducted in Agassiz (5–13 May) tested the efficacy of prototype pheromone traps baited with 1:1 or 10:1 ratios of G8:G6), with dispensers produced in Hungary or Canada. The second (11–25 June) tested the efficacy of pheromone traps (1:1 ratio of G8: G6) baited with single (Hungary or Canada) or multiple (Canada) dispensers. Randomized complete block designs were used in both studies, with 5 m between traps in blocks and at least 20 m between blocks. Blocks were always arranged in consecutive linear arrays.

The first study conducted in Delta (10–21 May) tested prototype pheromone traps baited with dispensers (produced in Hungary or Canada) containing various ratios of G8:G4. The second (11–25 June) tested the efficacy of pheromone traps (9 or 10:1 ratios of G8:G4) baited with single (Hungary and Canada) or multiple (Canada) dispensers. Randomized complete block designs were used in both studies, with 5 m between traps in blocks and 10 m between blocks. Blocks were arranged in a linear array parallel to and about 10 m away from a grassy ditch alongside the fallowed field.

2000 Field Study A new 'bubble cap' dispenser developed by Phero Tech Inc. was tested for *A. obscurus* trapping efficacy in the prototype pheromone trap in Agassiz between 28 March and 1 May, 2000. This was compared with two Phero Tech centrifuge tube dispensers (all lures containing a 1:1 ratio of G8:G6), the most attractive to *A. obscurus* in 1999. The bubble cap and centrifuge tube dispensers were placed in the center of the sticky cards on the retractable trays inside the traps. The two traps were placed 5 m apart at four locations (20 m between replicates) along a 10-m wide fallowed strip of field adjacent to a grassy ditch.

Data Analysis The mean number of beetles collected in each trap were transformed $\left(y = (x + 0.5)^{1/2}\right)$ for analysis. Transformed means were compared using a single-factor analysis of variance (ANOVA) (proc GLM in SAS vers. 8.2, SAS Institute, Cary NC), followed by a Tukey–Kramer honestly significant difference test (α=0.05), or Duncan's multiple range test (trial 2, Table 1b).

Results

General observations With the more effective pheromone traps (Tables 1 and 2), adult click beetles of either *A. obscurus* (Agassiz studies) or *A. lineatus* (Delta studies) could be seen entering traps within minutes after trap installation. Subsamples of beetles that were sexed were predominantly male in the various studies, although some females (<1% of total) were also taken.

1999 Field Studies, Agassiz There were significant differences between various treatments in the first Agassiz study (ANOVA $F_{(4,24)}$=34.9, P<0.001). Traps baited with dispensers

1:1 ratio of G8:G6 were all more attractive to *A. obscurus* than the unbaited traps (Table 1b). However, there was no effect of the origin or number of lures (Table 1b).

2000 Field Studies, Agassiz Traps with bubble cap dispensers caught twice the number of *A. obscurus* as traps with two centrifuge tube dispensers (Canadian manufacturer) (mean= 134.0+30.9 vs. 64.3+15.1), although the difference was only marginally significant (ANOVA $F_{(1,7)}=7.3$, $P=0.07$).

1999 Field Studies, Delta In the first study, traps baited with the various ratios of G8:G4 were more attractive to *A. lineatus* than the unbaited traps (ANOVA $F_{(4,24)}=22.7$, $P<0.001$) (Table 2a). However, neither the ratios nor the origin of the lure affected trap efficacy (Table 2a). In the second study, all pheromone baited traps were more attractive to *A. lineatus* than the unbaited traps (ANOVA $F_{(4,19)}=32.6$, $P=0.001$). Increasing the number of dispensers improved beetle catch, with four Canadian dispensers catching significantly more beetles than traps with one dispenser from either Canada or Hungary (Table 2b).

Discussion

In the former USSR, it was shown that geographically isolated populations of *A. sputator, A. obscurus, A. lineatus*, and *A. ustulatus* may exhibit quantitative differences in major and minor pheromone components in pheromone gland extracts (Yatsynin et al., 1996). It was suggested that the presence of pheromone 'dialects' in *Agriotes* might lead to variability in response to pheromone traps in different geographic areas. In Canada, *A. lineatus* and *A. obscurus* probably became established in BC and certain Maritime provinces about a century ago (Eidt, 1953; Wilkinson, 1963), and at that time, established geographically isolated populations from their unknown European point(s) of origin. In the current study, *A. lineatus* responded optimally to a 9 or 10:1 ratio of G8:G4, and *A. obscurus*, to a 1:1 ratio of G8:G6, the same component ratios that have been successfully used to survey these species in several European countries (Furlan et al., 2001b; Tóth et al., 2003). These results suggest that these ratios would also be effective for surveying introduced populations of *A. lineatus* and *A. obscurus* in other parts of North America.

The current studies also show that trapping efficacy can be affected by the type and quantity of dispensers used. For example, traps baited with bubble cap dispensers caught more *A. obscurus* than those baited with two centrifuge tube dispensers (Canada). This may be due to differences in release rate, a parameter that was not measured in this study. In the case of *A. lineatus*, trap catch increased significantly when the number of dispensers was increased from one to four. However, as optimum trap efficacy is not a necessity for determining the presence or absence of these species, single centrifuge-style dispensers would be adequate and cost effective. Where greater efficacy is required, such as in a mass trapping program, either bubble cap dispensers (*A. obscurus* and probably *A. lineatus*), or multiple centrifuge tube dispensers (*A. lineatus*), could be used.

Pitfall traps were used in earlier *A. obscurus* and *A. lineatus* surveys in the lower Fraser valley of BC (Vernon and Päts, 1997). In a preliminary comparison at Agassiz in 1999, prototype pheromone traps (baited with dispensers from Hungary containing a 1:1 ratio of G8:G6) caught approximately 200 times more *A. obscurus* adults than pitfall traps (R.S. Vernon, unpublished data). Thus, as pheromone traps are far more effective than pitfall traps, they should be the method of choice in general surveys for *A. obscurus* and *A.*

lineatus (and possibly *A. sputator*) in North America. The potential use of these pheromone traps as mass trapping devices, or for estimating the risk of wireworm damage by *A. lineatus* and *A. obscurus*, is currently being investigated in fields in the lower Fraser valley of BC.

Abstract The mate attraction signal of *Heliothis subflexa* (Hs) females consists of a multicomponent sex pheromone blend. In this study, we assessed the intraspecific importance of three groups of compounds found in Hs pheromone glands: three acetate esters (Z7-16:OAc, Z9-16:OAc, and Z11-16:OAc), two 14-carbon aldehydes (14:Ald and Z9-14:Ald), and one 16-carbon alcohol (Z11-16:OH). Because the relative importance of pheromone components may vary in different regions, we conducted experiments in Eastern US (North Carolina) and Western Mexico (Jalisco). Our experiments in Eastern US showed that when the acetates were omitted from a 7-component blend in rubber septa, fewer males were caught in cone traps. Subsequent experiments conducted both in Eastern US and Western Mexico indicated that the addition of Z9-16:OAc alone does not increase attraction of male Hs, while Z11-16:OAc does. The Hs male response to Z7-16:OAc differed between the two regions. In Eastern US, significantly more males were attracted to a minimal three-component blend to which Z7-16:OAc was added, but this was not the case in Western Mexico. The two 14-carbon aldehydes also showed differential attraction between the two regions. 14:Ald and Z9-14:Ald appeared not to play any role in the sexual communication of Hs in Eastern US, but reduced trap catches in Western Mexico. The alcohol Z11-16:OH was tested in two concurrent dose–response studies with Hs males in Western Mexico, one using a minimal blend and one using a complete blend. The minimal three-component blend provided a more discriminating tool for delineating dose–response effects of Z11-16:OH than the seven-component blend. In the minimal blend, the optimal dose of Z11-16:OH was 1%, while in the complete blend similar numbers of males were caught when the alcohol ranged from 1 to 25%.

Introduction

The evolution of premating signals is generally shaped by both intra- and interspecific selection. In moths, the predominant premating signals consist of multicomponent sex pheromone blends produced by females to which only conspecific males are attracted. To delineate the direction and magnitude of selection exerted on multicomponent pheromone blends, it is important to define the role of each constituent. The behavioral significance of pheromone compounds may vary geographically, and geographic variation in moth pheromone blends has been found in several species (e.g., Klun and Cooperators, 1975; Cardé et al., 1977; Guerin et al., 1984; Gemeno et al., 2000; McElfresh and Millar, 1999, 2001; Gries et al., 2001; El-Sayed et al., 2003). Such variation may be due to drift or to communication interference between closely related species in areas of sympatry. When closely related species with similar pheromone blends cooccur, kairomonal effects of specific compounds in a blend that inhibit attraction of closely related males may be important (Cardé et al., 1977; Löfstedt, 1990, 1993; Löfstedt et al., 1991; Butlin, 1995; Gries et al., 1996; Potting et al., 1999).

Heliothis subflexa (Guenée 1852) (Hs) (Lepidoptera: Noctuidae) is a New World specialist herbivore, and as it only feeds on species in the genus *Physalis* (McElvare 1941; Sheck and Gould, 1995, 1996) its occurrence is limited to habitats where these plants occur. In the US, *Physalis* species (e.g., ground cherry) are weedy plants, growing in disturbed habitats along roadsides and in agricultural fields. However, one species, tomatillo (*Physalis philadelphica* Lam.), is grown commercially in almost every state in Mexico. Thus, Hs appears to be patchily distributed in the US, while it is abundant in Mexico.

The intraspecific importance of each compound in Hs pheromone glands has not been firmly established (Table 1). Some of these compounds may merely be by-products of the pheromone biosynthetic pathway (Teal and Tumlinson, 1987; Jurenka and Roelofs, 1993; Jurenka, 1996, 2004) but most have not been tested systematically. For example, none of the three acetate esters has been tested separately, and research to date has generated contrasting results. Teal et al. (1981) found an increase in trap catch when all three acetates were added to a binary blend of Z11-16:Ald and Z9-16:Ald, whereas Vickers (2002) did not find a change in attraction in a wind tunnel when Z11-16:OAc was added to a three-component blend of Z11-16:Ald, Z9-16:Ald, and Z11-16:OH. We recently found a significant positive relationship between the relative percentage of acetates (sum of Z7-16:OAc, Z9-16:OAc, and Z11-16:OAc) in the pheromone glands of Hs females and the number of males attracted to them in the field (Groot et al., 2006). However, this relationship requires confirmation with synthetic blends, and it remains to be determined whether all three acetates are (equally) important.

At least three heliothine species are sympatric with Hs in parts of North America: the tobacco budworm *Heliothis virescens* (Hv) (Fabricius 1777), the corn earworm *Helicoverpa zea* (Hz) (Boddie), and *Heliothis phloxiphaga* (Hp) Grote & Robinson. Hv and Hz are both highly polyphagous species and are important agricultural pests (Laster, 1972; Sparks et al., 1979; Hartstack et al., 1979; Lopez et al., 1994; Parajulee et al., 2004). Hp is an innocuous oligophagous species feeding on asters and *Castilleja indivisa* (Texas

[a] Z7-16:Ald and Z9-16:Ald could not be separated on GC in some studies.

+: increased attraction, - : decreased attraction, 0 : did not affect attraction, no sign: only tested as part of a whole blend, thus a specific function cannot be inferred.

1 Teal et al., 1981 (tested different combinations of blends; found a significant decrease in attraction when 48% Z9-16:OH and 40% Z11-6:OH (relative to Z11-16:Ald) were added to a five-component blend); *2* Klun et al., 1982 (in the field no males were caught in traps with the two-component blend (Z11-16:Ald and Z9-16:Ald; these were tested in different ratios), while the 11-component blend caught males); *3* Heath et al., 1990 (varied the percentage of Z11-16:OH; attraction of Hs males was increased when 0.9–3.5% was released from the septa, but decreased when release rate was higher); *4* Heath et al., 1991; *5* Vickers and Baker, 1997; *6* Vickers, 2002; *7* Groot et al., 2004

paintbrush) (Eger et al., 1982), and it occurs only in the western part of North America (Forbes, 1954; Eger et al., 1982). Females of all four species produce overlapping multicomponent sex pheromone blends (Table 2), so that interspecific cross-attraction may occur at low frequencies (e.g., Chapin et al., 1997; Groot et al., unpublished research). Recently, we found that Hv can exert an impressive selection force on the production of acetate esters in Hs females (Groot et al., 2006).

In this study, we concentrated on three specific questions that emerge from studies on Hs pheromones: (a) What is the intraspecific role of each of the acetate esters found in the pheromone glands of Hs females? (b) Do 14:Ald and Z9-14:Ald, which are present in the Hs pheromone gland, play a role in the attraction of Hs males? (c) Are Hs males differentially attracted to blends with varying amounts of Z11-16:OH and does this response change when tested in a complete blend versus a minimal blend?

In the context of evolution of pheromone blend variants, we hypothesized that the value of pheromone components may differ regionally in response to interspecific interactions with species that have overlapping chemical communication channels. Thus, we reasoned that if the importance of the three acetate esters, 14:Ald, Z9-14:Ald, and Z11-16:OH, in the pheromone communication of Hs depends on the abundance of other heliothine moths and the probability of communication interference, then the following regional differences may be predicted. In areas where Hz and Hv are abundant (North America), Hs males are more likely to be attracted to blends containing the acetates and/or Z11-16:OH because their presence is indicative of, and unique to, the volatile blend of Hs females (Heath et al., 1991). Moreover, both the acetates and the alcohol will be important to antagonize attraction of Hv and Hz males (Hartstack et al., 1980; Vetter and Baker, 1983; Vickers and Baker, 1997; Fadamiro and Baker, 1997; Quero and Baker, 1999). In contrast, Hs males

should be less attracted to blends containing 14:Ald and Z9-14:Ald in areas with large Hv populations because they risk the possibility of being attracted to Hv females that produce these two compounds in higher amounts (Roelofs et al., 1974; Tumlinson et al., 1975, 1982; Klun et al., 1979, 1980a; Teal et al., 1986).

Methods and Materials

Pheromone Lures Pheromone components were obtained from *PHERO*BANK (Wageningen, The Netherlands), Shin-Etsu Chemical (Tokyo, Japan) and Bedoukian Research (Danbury, CT, USA). The following synthetic compounds were tested (% purity by GC indicated): Z11-16:Ald (98.0%; 16:Ald was the largest contaminant at 0.20%), 14:Ald (>98%), Z9-14:Ald (95.5%), 16:Ald (>98%), Z7-16:Ald (98.5%), Z9-16:Ald (96.6%), Z7-16:OAc (97.8%), Z9-16:OAc (99.2%), Z11-16:OAc (95%), and Z11-16:OH (95%).

Compounds were dissolved (*w*/*v*) in dichloromethane (2003) or *n*-hexane (2004 and 2005). Treatment blends were made relative to the primary component, Z11-16:Ald, which was loaded onto rubber septa at 100 μg (2003) or 300 μg (2004 and 2005). The ratios of all other compounds were based on Heath et al. (1991), who determined the release ratios of each of the *H. subflexa* pheromone components from septa similar to those used in this study. BHT was added at 1% (w/*v*) to all solutions, and ratios were confirmed by GC-FID on a DB-WAXETR (extended temperature range) column (30 m×0.25 mm×0.5 μm), which adequately separated Z7-16:Ald and Z9-16:Ald.

Rubber septa (#1780J07, Thomas Scientific, Philadelphia, PA, USA) were first ultrasonicated for 6 hr in hexane, then extracted ×3 with hexane, and air-dried in a fume

hood for at least 48 hr before loading. Each septum was first loaded with 100 µl of one of the treatment solutions, air-dried, then 100 µl of solvent were added to the septum well, air-dried again, and then stored in glass vials at −20°C until used. The septa were hung on a metal paper clip attached to a metal wire with a binder clip at each end, so that they could be positioned in the center of the trap opening without touching any trap surface. All septa were replaced at the same time, every 1–2 wk.

Field Sites Three different field sites were used in Eastern US: the North Carolina State University field station in Clayton, NC (35° 39′ 58″ N, 78° 30′ 36″ W), a commercial soybean field site in Smithfield, NC, USA (35° 30′ 42″ N, 78° 21′ 08″ W, ±20 km south of Clayton), and a commercial tomatillo field site in Oxford, NC (36° 13′ 12″ N, 78° 41′ 16″ W), ~100 km north of Clayton). In Western Mexico, commercial tomatillo fields in the state of Jalisco at Chamela (19° 31′ 49″ N, 105° 03′ 47″ W), Hidalgo (19° 21′ 37″ N, 104° 52′ 28″ W, ~25 km south of Chamela), and Autlán (19° 46′ 03″ N, 104° 20′ 59″ W, ~100 km northeast of Chamela) were used. Table 3 provides a summary of the site(s) used for each experiment.

Species-Specificity To determine species-specificity of the Hs and Hv blends, the following treatments were compared concurrently (Table 4): (1) the complete 7-component Hs blend (HsC treatment), based on Heath et al. (1990, 1991), (2) HsC minus the three acetate esters (HsC minAcs treatment), (3) the complete 7-component Hv blend (HvC treatment), based on Teal et al. (1986) and Heath et al. (1991), (4) HvC plus the three acetate esters (HvC+ Acs treatment), and (5) the control, in which rubber septa were loaded only with solvent and 1% BHT. For all septum loadings, the ratios of all compounds, except Z11-16:OH, were rounded off to the nearest 5% from the ratios reported by Heath et al. (1990). This experiment was conducted twice in both 2003 and 2004 (Table 3). The cotton and soybean

Control											0.022±0.015	–	2

The experiment was conducted twice in 2003 and twice in 2004 (Table 3). Statistical analysis showed a significant date effect but not a significant year effect; therefore, we combined all data for further analysis. The treatment names are explained in the text, while their composition is shown in the table (the numbers refer to the percentages of each compound relative to Z11-16:Ald). Different letters indicate significant differences in mean number of males caught (ANOVA, Tukey's adjustment for multiple comparisons, $P < 0.05$). HvC treatment was not included in the analysis because no Hs males were caught in traps baited with this blend. The control treatment was omitted from the analysis because the specific question was whether the attraction of the treatments differed from each other.

fields in Clayton were about 100 m apart, and about 150 m from a field in which *Physalis* species had been planted to attract and generate an Hs population. Hartstack cloth traps (Hartstack et al., 1979) were arranged 15–20 m apart in a completely randomized Latin square design consisting of three replicates (rows), for a total of 15 traps in each field. These traps consist of a conical base leading to a removable top in which males are trapped. The five treatments were rotated every 3–4 d, the tops were replaced and males caught in the traps during 3–4 nights were sorted by species under a microscope.

Role of Each of the Acetate Esters To specifically determine whether Z7-16:OAc, Z9-16:OAc, or Z11-16:OAc are important in the attraction of conspecific males, an experiment consisting of five treatments was conducted in 2005 (see Fig. 1): a treatment consisting of the primary component Z11-16:Ald and the two secondary sex pheromone components Z9-16:Ald and Z11-16:OH, considered the Hs minimal blend (HsM) (based on Vickers, 2002); three treatments in which each of the three acetate esters was added to HsM (HsM+7Ac, HsM+9Ac, HsM+11Ac), and one treatment in which all three acetates were added (HsM +Acs). This experiment was conducted both in Eastern US and Western Mexico to investigate possible geographic differences in response to the different treatments. In Eastern US, the experiment was conducted in a field planted with *P. angulata*, *P. pubescens*, *P. cordata*, and *P. heterophylla* at Clayton (Table 3). Two replicates per treatment were used and the treatments were rotated every 2–3 d. In Autlán, Western Mexico, the experiment

Fig. 1 The effect of adding three acetate esters, separately and in combination, to the minimal blend on the attractiveness of lures to male *Heliothis subflexa* in Eastern United States and Mexico. A significant increase in number of Hs males caught is indicated by asterisks in a, b, and c. Asterisks in d indicate a significant difference between Eastern US and Western Mexico in the elevated attraction of Hs males compared to the minimal blend (i.e., the addition of Z7-16:OAc and the three acetate esters resulted in a significantly higher increase in attraction in Eastern US than in Western Mexico). ns represents "not significant", the error bars show +SEM, and numbers within bars indicate total number of Hs males caught. Each blend is represented at the bottom of the figure by percentages of each compound relative to Z11-16:Ald

consisted of three replicates per treatment, rotating the treatments every day. In addition to the complete experiment, an additional experiment was conducted in Hidalgo, Western Mexico, where HsM+7Ac and HsM+11Ac were compared with HsM. This experiment was replicated twice (Table 3), once with two replicates per treatment and once with three replicates per treatment, rotated every day.

Role of 14:Ald and Z9-14:Ald To determine whether 14:Ald and Z9-14:Ald are important in the attraction of Hs males, an experiment was conducted in 2005 comparing HsC and HsC with 14:Ald and Z9-14:Ald added (HsC+14Alds). This experiment was conducted at Clayton, using five replicates per treatment that were rotated every 3–4 d, eight times in total, and in Oxford, where both treatments were rotated every 2 d. This experiment was also conducted in Hidalgo, Western Mexico, where both treatments were replicated four times and rotated every 1–2 d, four times in total.

Dose–Response Test of Z11-16:OH To determine the effect of Z11-16:OH at different doses, two dose–response experiments were conducted concurrently. In Chamela, Z11-16:OH was varied from 0 to 50% in the minimal blend (HsM), while in Hidalgo the same doses were tested when added to the complete blend, HsC (see Fig. 2). In both experiments, two replicates per treatment were used and all treatments were rotated daily over 5 d.

Statistical Analyses The number of males caught per treatment in each experiment were square-root transformed, when needed, to normalize the variance. To determine the role of each of the acetate esters, a mixed model ANOVA was carried out using proc GLM in SAS

Fig. 2 Dose–response experiment with Z11-16:OH in Hidalgo and Chamela, Western Mexico. a: Z11-16:OH added to the minimal three-component blend, b: Z11-16:OH added to the complete seven-component blend. Different letters within each graph indicate significant differences in mean number of males caught and the error bars show +SEM. Numbers within bars indicate total number of males caught. Each blend is represented by percentages of each compound relative to Z11-16:Ald

9.1 with "treatment" and "day" as fixed effects, and "replicate" and "replicate by treatment" as random effects. To determine whether the addition of each of the acetate esters to HsM increased attraction, the number of Hs males captured in each treatment was compared to the number attracted to HsM alone, using Dunnett's procedure with "replicate by treatment" as the error term.

Geographic differences in attraction between Eastern US and Western Mexico to the acetate treatments were compared after normalizing the trap catches relative to those in HsM baited traps for each region. Subsequently, the increase in attraction to each blend in Eastern US was compared to the increase in attraction to each blend in Western Mexico, using proc MIXED in SAS 9.1, where "treatment", "region", and "day" were considered fixed factors, and "replicate", "trap position" and "treatment by trap position" per site were considered random effects.

Differences in attraction of (a) the species-specific blends, (b) the HsC and HsC+14Alds, and (c) the alcohol treatments, were compared using ANOVA (proc MIXED in SAS 9.1). Within each experiment, the numbers of males attracted to the different treatments were compared, where "treatment" and "day" were considered fixed factors, and "replicate" and "trap position" were regarded as random. The treatment means were then separated using Tukey's adjustment for multiple comparisons.

Results

Species-Specificity The HsC blend attracted significantly more Hs males than the HsC minAcs blend, while the Hv blend, with or without the acetates, did not differ from the control (Table 4).

Role of Each of the Acetate Esters Significantly more Hs males were caught in traps with HsM+11Ac and HsM+Acs than in traps with HsM alone in both regions, while the addition Z9-16:OAc did not increase attraction (Fig. 1a, b). In the case of HsM+7Ac, trap catches only increased in Eastern US (Fig. 1a). The lack of attractiveness of Z7-16:OAc for Mexican Hs males was confirmed in independent trials (Fig. 1b, c).

After normalizing the relative trap catches to that of the minimal blend, there were significant effects of region, treatment, day and their interactions (see Table 5), and there were contrasts between Eastern US and Western Mexico when a) HsM+7Ac, and b) HsM+Acs were compared (Fig. 1d). In both cases, more Hs males were caught in Eastern US than in Western Mexico.

Table 5 Type 3 tests of fixed effects when *H. subflexa* trap catches of the five acetate treatments were compared between Eastern US and Western Mexico

Effect	Degrees of Freedom	*F* value	Pr>*F*
Region	1	8.27	0.027
Treatment	4	33.26	<0.001
Region×treatment	4	5.69	<0.001
Day	7	5.92	<0.001
Region×day	7	10.13	<0.001
Treatment×day	28	1.68	0.031
Region×treatment×day	28	1.50	0.072

Role of 14:Ald and Z9-14:Ald In Eastern US, the addition of 14:Ald and Z9-14:Ald did not increase the attractiveness of the HsC blend (Table 6). However, in Western Mexico, more Hs males were caught in traps baited with the HsC (N=166) than those with HsC+14Alds (n=110, P=0.014).

Dose–Response of Z11-16:OH Trap catches of Hs males showed a nonmonotonic function in relation to increasing Z11-16:OH doses in both HsC and HsM blends, represented by parabolic, or inverted U-shaped curves (Fig. 2). Omission of the alcohol, as well as high doses of it, suppressed trap catch, whereas intermediate doses increased trap catch. However, the specific effective doses depended upon whether the alcohol was in the minimal or complete blend. Similar numbers of Hs males were caught with 1 to 25% Z11-16:OH in HsC, whereas significantly more males were only caught in traps baited with HsM and 1% Z11-16:OH (Fig. 2).

During these experiments, we also deployed pheromone traps in both Eastern US and Western Mexico to estimate the relative abundance of *H virescens*. A comparison of traps baited HvC and HsC in Eastern US showed that there were similar, or more, Hv males as Hs males caught in all 3 yr (Fig. 3). In contrast, in Western Mexico only three Hv males were captured in fields of commercially grown *Physalis*, compared with 785 Hs males.

Discussion

A thorough evaluation of the contribution to mating success of each pheromone compound found in the glands of *H. subflexa* females is critical to our goal of understanding the evolutionary diversification of heliothine moth pheromone signals (Groot et al., 2004, 2006; Sheck et al., 2006) In this study, we assessed the importance of several compounds whose roles in Hs sexual communication were equivocal.

The importance of pheromone compounds may differ geographically when their behavioral significance partly depends on the presence and/or abundance of closely related species that are attracted to similar pheromone blends. Of the common heliothines in

Table 6 Effects of 14:Ald and Z9-14:Ald on *H. subflexa* trap catches in Eastern US and Western Mexico

Treatment Name	Treatment Composition										Hs Males Caught Per Trap (mean±SEM)	
	14:Ald	Z9-14:Ald	16:Ald	Z7-16:Ald	Z9-16:Ald	Z11-16:Ald	Z7-16:OAc	Z9-16:OAc	Z11-16:OAc	Z11-16:OH	Eastern US	Western Mexico
HsC			5		50	100	5	10	20	10	3.63±0.46 a (N=232)	10.38±1.47 a (N=166)
HsC+14Alds	2	2	5		50	100	5	10	20	10	3.48±0.45 a (N=230)	6.88±0.78 b (N=110)

Different letters within region indicate significant differences in mean number of males caught (P<0.05). Each blend is represented by percentages of each compound (w/v) relative to Z11-16:Ald. HsC is the complete seven-component blend, and HsC+14Alds represents the addition of 14:Ald and Z9-14:Ald to the complete blend.

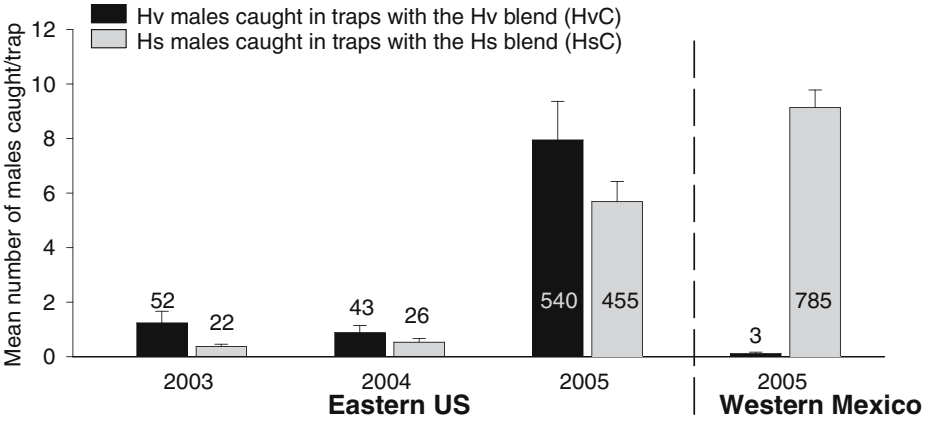

Fig. 3 Mean number of Hv and Hs males caught in traps with their respective pheromone lure during the trapping experiments conducted in Eastern US (years 2003–2005) and Western Mexico (2005). Numbers above/in bars indicate total number of males caught and the error bars show +SEM

Eastern US, Hv is the most closely related species to Hs (Mitter et al., 1993). Females of both species elicit interspecific precopulatory behavior from males in close proximity (Klun et al., 1982), and they can be hybridized in the lab, producing sterile male, and less fit fertile female, offspring (Laster, 1972; Sheck and Gould, 1995). However, males of these two species are rarely attracted to heterospecific females in the field (Groot et al., 2006). Trap catches in pheromone traps baited with the complete Hv blend confirm our supposition that Hv is much less abundant in Western Mexico than in Eastern US. Therefore, the chance of communication interference—that is, the likelihood of Hs females attracting heterospecific Hv males—is much greater in Eastern US than in Western Mexico.

Role of the Acetate Esters The species-specificity experiments conducted in Eastern US showed that one or more of the three acetate esters contribute to greater attraction of Hs males (Table 4). This experiment supports our finding that backcross Hs females who produce a very low amount of the acetate esters (<5% relative to all compounds present in the gland) were less attractive to Hs males than those with higher amounts (Groot et al., 2006). Notably, the context in which the acetates are presented is important as adding the three acetates to an HvC blend failed to attract more Hs males.

Of the three acetate esters emitted by calling Hs females, Z9-16:OAc does not appear to play a role in the long distance attraction of conspecific males in either Eastern US or Western Mexico. Hence, the presence of this compound in the Hs pheromone gland may just be a by-product of the biosynthetic pathway that produces the critical secondary pheromone component Z9-16:Ald, or may serve an antagonistic function to suppress attraction of other species, as has been found for Z11-16:OAc.

The addition of Z7-16:OAc to the HsM blend increased captures of Hs males in Eastern United States, whereas in Western Mexico HsM and HsM+7Ac gave similar results (Fig. 1). This geographic difference was even more evident when normalized trap catches were contrasted between the two regions (Fig. 1d).

The HsM+Acs lure was more attractive than HsM in both sites (Fig. 1a, b) but the addition of all three acetate esters resulted in a greater increase in Eastern US than in Western Mexico (Fig. 1d). This finding confirmed our prediction, based on our earlier

observations (Groot et al., 2006), that in Eastern US, where Hv and Hz are abundant, the acetates would not only function to enhance intraspecific communication but also to prevent the attraction of heterospecific males. Where the probability of communication interference with Hv and Hz is low, as in Western Mexico, selection pressure to produce acetates may be attenuated and Hs males may be more finely tuned to the other pheromone components (Z11-16:Ald, Z9-16:Ald, and Z11-16:OH). It will be interesting to investigate the interspecific interaction between Hs and Hp because their pheromone blends are more similar to each other than to Hv or Hz (Table 2), and one or more of these acetate esters might serve to reduce interspecific attraction of Hp males. However, Hp is an innocuous nonpest species and its population densities may be relatively low in areas where tomatillo is a major agricultural crop. In Western Mexico, no Hp males were caught in traps regardless of the Hs lure used in this study, suggesting that the species was not present at the time of our experiments.

Role of 14:Ald and Z9-14:Ald Both 14:Ald and Z9-14:Ald are found in the pheromone glands of Hv and Hs, and Z9-14:Ald is the critical secondary sex pheromone component of Hv (Table 2) (Roelofs et al., 1974; Tumlinson et al., 1975, 1982; Klun et al., 1979, 1980a, 1982; Teal et al., 1986; Groot et al., 2005). It is not known, however, whether they are released by calling Hs females, and their contribution to conspecific attraction had not been investigated. Vickers (2002) showed that 0.05–50% Z9-14:Ald (relative to Z11-16:Ald) failed to attract Hs males in a wind tunnel, but in his experimental design Z9-14:Ald replaced the critical secondary pheromone component Z9-16:Ald. Since Hv is abundant in Eastern US and scarce in Western Mexico, we expected blends containing 14:Ald and Z9-14:Ald to be less attractive to Hs males in the former site, if these compounds are used by Hs males to distinguish Hs from Hv blends. However, while their addition did not affect catches in the Eastern United States, they significantly reduced the attractiveness of lures in Western Mexico (Table 6). This suggests that these do not to function as pheromone components for the intraspecific attraction in either region, but it would be instructive to conduct dose-response studies with each of these compounds in HsM to rule out the possibility that they only function optimally at very precise release ratios.

Role of Z11-16:OH In Western Mexico, the response of Hs males to different doses of Z11-16:OH to the lure depended on whether it was added to the HsC or HsM blend (Fig. 2). In the minimal blend, 1% Z11-16:OH caught more Hs males than any other treatment, while in the complete blend a range of doses between 1 and 25% Z11-16:OH caught similar numbers of Hs males. These results suggest that males respond more precisely to component ratios when tested in a minimal blend in the field, whereas in a more complex blend, males respond to broader component ratios as there might be some redundancy of components (Linn and Roelofs, 1989). We, therefore, suggest that the importance of heliothine pheromone compounds may be better discerned when compounds are added singly to a minimal blend in dose–response studies, rather than when compounds are omitted from a complete blend. This approach will be used in future studies to elucidate the optimal percentage of Z11-16:OH needed to attract Hs males in Eastern US, as well as the role of other compounds, such as 16:Ald and Z7-16:Ald, that are present in Hs pheromone glands.

Our results confirm the importance of Z11-16:OH to Hs males, but differ from previously published data. Vickers (2002) found no difference in male responses when Z11-16:OH varied from 1 to 50% in HsM on filter papers in wind tunnel assays, but it is

possible that more replications would be needed to delineate subtle dose-response effects in no-choice wind-tunnel tests. In the field, Heath et al. (1990) reported significantly higher attraction of HsC to rubber septa when Z11-16:OH was loaded between 3 and 6%. The broader range we observed may be related to close-range male orientation. We used Hartstack traps that captured males before they reach the pheromone source, whereas Heath et al. (1990) used sticky and bucket traps, which require that males land close to the lure to be captured. The requirement for close-range orientation to sticky traps may produce sharper dose–response curves, even to the complete blend. In addition, the climatic conditions in Western Mexico at the time that we conducted our experiments may have been different from those when Heath et al. (1990) ran their experiments in Florida, which could differentially affect the release rates of compounds.

Geographic variation in the response of pest moths to sex pheromone blends has important practical implications. Pheromone traps are widely used to monitor pest moth populations with the catch data being used to determine if and when insecticide applications are needed. Geographic differences in male response have led to the development of region-specific pheromone lures for several other moth species (e.g., Klun and Cooperators, 1975; Arn et al., 1983; Hansson et al., 1990; Cork et al., 1992; Tóth et al., 1992; McElfresh and Millar, 1999, 2001; Gemeno et al., 2000; Gries et al., 2001; El-Sayed et al., 2003). Our finding of geographic variation in Hs male response indicates that the development of region-specific lures is an important consideration for heliothine moths as well. Monitoring the presence of Hs with pheromone traps can be a first step towards improved management of Hs populations, especially in tomatillo fields where it is an important pest. Understanding the evolution of pheromone communication in this context is critical because changes in population densities may result in shifts in both the pheromone blend and behavioral responses of males.

Abstract Trail pheromones mediate communication among western subterranean termites, *Reticulitermes hesperus* Banks. Repetitive passages of ≥28 termites were required to establish a pheromone trail and trails needed to be reinforced because they lasted <48 hr. The minimal threshold concentration for inducing responses from termite workers and secondary reproductives was between 0.01 and 0.1 fg/cm of (3*Z*,6*Z*,8*E*)-dodecatrien-1-ol (henceforth, dodecatrienol). Workers showed optimal trail-following behavior to dodecatrienol at a concentration of 10 fg/cm. Trails with concentrations >10 pg/cm were repellent to workers. Workers did not detect pheromone gradients, responding equally to increasing or decreasing gradients of dodecatrienol, and termite workers were not able to differentiate between different concentrations of dodecatrienol. Termites preferred dodecatrienol trails to 2-phenoxyethanol trails. Antennae played a key role in trail pheromone perception. Dodecatrienol acted as an arrestant for worker termites (10 fg/cm^2) and male alates (5 ng/cm^2), whereas sternal gland extracts from females attracted male alates. Workers and alates, upon contact with filter paper disks treated with higher doses (10 fg/cm^2 and 5 ng/cm^2, respectively) of dodecatrienol, were highly excited (increased antennation and palpation) and repeatedly returned to the treated disks. Dodecatrienol did not act as a phagostimulant when offered on a paper towel disk. *Reticulitermes hesperus* is highly responsive to dodecatrienol, and it may play an important role in orientation of workers and alates.

Introduction

Semiochemicals play important roles in termite colonies, where they mediate caste regulation, reproduction, nestmate recognition, and behaviors associated with defense and foraging (Prestwich, 1988; Pasteels and Bordereau, 1998). In the subterranean termites *Reticulitermes*

virginicus Banks, *Reticulitermes lucifugus grassei* Clement, *Reticulitermes speratus* Kolbe, *Reticulitermes santonensis* Feytaud, and *Coptotermes formosanus* Shiraki, the trail pheromone or at least one of its components has been identified as (3*Z*,6*Z*,8*E*)-dodecatrien-1-ol (henceforth, dodecatrienol) (Matsumura et al., 1968, 1969; Honda et al., 1975; Laduguie et al., 1994a; Tokoro et al., 1994; Wobst et al., 1999). In addition, wood degraded by the fungus *Gloeophyllum trabeum* Persoon is reported to be attractive to subterranean termites (Watanabe and Casida, 1963; Matsumura et al., 1969; Rust et al., 1996; Su, 2005), and extracts of the infested wood were found to contain dodecatrienol (Matsumura et al., 1969). Termites other than *Reticulitermes* spp. display trail-following behavior in response to dodecatrienol (Matsumura et al., 1972; Howard et al., 1976; Yamaoka et al., 1987; Tokoro et al., 1989, 1994; Bordereau et al., 1991; Laduguie et al., 1994a, b; Batista-Pereira et al., 2004) and its aromatic analogs (Tai et al., 1971; Prestwich et al., 1984). *Coptotermes formosanus* and *Reticulitermes* spp. also exhibit trail-following behavior toward 2-phenoxyethanol (Chen et al., 1998), a component in ballpoint pen ink. However, the importance of this compound to termites in their natural habitats remains unknown.

After fractionation of extracts of the fourth and fifth sternites of *Reticulitermes hesperus* workers, Grace et al. (1995) demonstrated that a single major component was responsible both for induction of trail following and for orientation of termites on the trail. Studies suggest that other minor components in trail pheromones may lead to qualitative and quantitative differences in the actual trail laid down by worker termites (Howard et al., 1976; Kaib et al., 1982; Runcie, 1987; Tokoro et al., 1994; Cornelius and Bland, 2001; Arab et al., 2004). It has been suggested that time, number of termites laying the trail, and presence or absence of a food source also has an effect on trail quality and longevity (Runcie, 1987; Cornelius and Bland, 2001). Different aspects of termite trail-following behavior have been studied using trails made from natural pheromone (sternal gland extracts [SGE]), synthetic dodecatrienol, and 2-phenoxyethanol (Traniello, 1982; Grace et al., 1988, 1995; Grace, 1991; Chen et al., 1998; Appel and Hu, 2005; Fe et al., 2005). Minor components might also provide the basis for species- and caste-specific responses (Affolter and Leuthold, 2000; Gessner and Leuthold, 2001), and quantitative differences in the concentration of trail pheromone were proposed for differential response in the recruitment behavior of soldiers and worker termites in *Nasutitermes costalis* Holmgren (Traniello and Busher, 1985).

Trail pheromones have been reported to have secondary roles as sex pheromones in various termite species. In *R. santonensis* Feytaud (Laduguie et al., 1994b) and *Cornitermes bequaerti* Emerson (Bordereau et al., 2002), it has been suggested that dodecatrienol is a component of the alate female's sex pheromone. The analogous alcohol, (3*Z*,6*Z*)-dodecadien-1-ol, has been identified as a sex and trail pheromone in *Ancistrotermes pakistanicus* Ahmad (Robert et al., 2004). So far, dodecatrienol has not been shown to be either a trail or sex pheromone of *R. hesperus*, and we did not detect dodecatrienol by GC/mass spectroscopy (MS) analysis of solid phase microextraction extracts of workers and female alates of *R. hesperus* (unpublished data). However, *R. hesperus* has been shown to be very responsive to dodecatrienol, which has been reported to elicit trail-following behavior at a threshold of 6 fg/cm (Matsumura et al., 1972). Grace (1986) was able to isolate trail pheromone from excised sternites by sequential high-performance liquid chromatography fractionation. Based on a GC and subsequent MS analysis of the active fraction and synthetic standards [(6*E, 8Z*- and 6*E,8E*)-dodecadien-1-ol], Grace (1986) concluded that an unsaturated dodecatrienol was present in the active fraction. However, its structure could not be elucidated because of the minute quantities. We also were unable to

detect dodecatrienol in solvent extracts of sternal glands of workers by GC-MS analysis, almost certainly because of the minute quantities of dodecatrienol produced by and present in sternal glands. However, previous studies across several species of subterranean termites indicate that dodecatrienol elicits trail-following behavior and is likely a trail pheromone component. Thus, we tested behavioral responses of workers and males to dodecatrienol with the goal of investigating the role of dodecatrienol as a possible pheromonal signal for *R. hesperus*. Our specific objectives were: (1) to study the preferences and minimal thresholds for trails of natural pheromone (SGE), synthetic trail pheromone (dodecatrienol), and 2-phenoxyethanol; (2) to determine whether termites could detect increasing or decreasing gradients of dodecatrienol; (3) to determine the potential role of dodecatrienol as a feeding stimulant and arrestant; and (4) to assess the responses of alate and dealate adults to synthetic dodecatrienol and to SGE from females.

Methods and Materials

Termites

Western subterranean termites, *R. hesperus* Banks, were collected on the University of California, Riverside Campus in polyvinyl chloride (PVC) traps buried in the ground and provisioned with rolls of corrugated cardboard. Termites were gently removed and maintained in the laboratory in a plastic container (43.3×29.9×17.7 cm, Rubbermaid Inc., Wooster, OH, USA) at 24°C and 98% RH. Pieces of brown paper towel (Fort James Corp., Deerfield, IL, USA) were regularly provided as a food source. Undifferentiated larval termites [mean weight 1.6±0.44 mg (N=50)] were used for bioassays (Thorne, 1996). All worker and soldier termites used in bioassays were from the same colony.

Reticulitermes hesperus alates used in the study were collected from the PVC traps before they swarmed and during swarms. The wings of alates collected from the traps 2–3 d before a swarming event were still wet, grayish-white in color, and the alates were unable to fly. Alates collected from active swarms were kept in the dark inside a plastic petri dish provisioned with a moistened brown paper towel to avoid desiccation. Alates were allowed to acclimate for 1 hr, and individuals that shed their wings (dealates) were used for bioassays.

Termites were starved by confining them inside a plastic petri dish (5.0×0.9 cm, Falcon, BD Biosciences, Franklin Lakes, NJ, USA) containing 5 g of sand moistened with 1 ml of deionized water. One hundred termites were transferred to each of five dishes. Termites were held without food for 24, 48, 72, 96, and 120 hr. Control dishes were provisioned with brown paper towel disks (3.0 cm diam.) as a food source. All the petri dishes were transferred to a plastic container and held at 100% RH. Humidity indicator strips (Sude-Cheme Performance Packaging, Colton, CA, USA) were taped to the walls of the container to ensure that RH remained at 100% throughout the studies. To ensure that termites did not feed on dead individuals, we removed dead or moribund termites regularly during the starvation period.

Sternal Gland Extracts

Fifty worker termites were frozen at −20°C for 5 hr. Sternal glands were dissected from the fourth and fifth abdominal sternites under a binocular stereoscopic microscope (Grace et al., 1988). Dissected glands was transferred to a 2-ml amber glass vial with a Teflon-lined cap

(Wheaton, Millville, NJ, USA) kept at 0°C. The combined glands were extracted overnight in 1 ml *n*-hexane. The supernatant was used for bioassays, with 20 µl considered one termite SGE equivalent. Sternal gland extract from the female alates (N=50) was obtained following the same procedure.

Production of Natural Trails

To determine how many termites were required to establish a pheromone trail, individual termites were placed at one end (release end) of a Y-maze (described under "Choice Bioassays") and were allowed to walk on one arm of the maze. At the intersection, a surgical blade was inserted halfway (0.5 mm) inside one of the two Y-arms to ensure that termites walked only on one arm. To test for trail pheromone, the surgical blade was removed and a termite was placed at one end of the Y-maze and allowed to walk up the trail. Thirty termites were tested, recording the arm chosen by each individual. The test was repeated using trails laid by 5, 10, 15, 20, 25, and 30 termites on the treatment arm. The passage of 30 termites generated a significant response. To narrow the range, we repeated the tests by increasing the number of termites in increments of 1 after 25 termites. The procedure was repeated on the other arm of a new Y-maze to avoid any directional biases.

All Y-mazes treated with different treatments and naturally laid trails were stored separately in sealed plastic containers at room temperature to avoid any direct effects of light on the laid trails. The mazes were tested when the trails were 0.1, 24, 48, and 60 hr old.

Straight-line Bioassays

Straight-line bioassays were conducted to determine the concentration (fg/cm) of dodecatrienol to which termites exhibited optimal trail-following responses. Lines were drawn (27 cm long, <1 mm wide) with a 0.5-mm mechanical pencil on a piece of white printer paper (21.6×27.9 cm, Boise™ X-9™, Boise, ID, USA). The line was lightly marked with a pencil 1 cm from each end of the 27-cm line. This 25-cm-long section was used as the walking distance for each bioassay. These lines were drawn very lightly, and preliminary runs were conducted to ensure that termites did not use them as guidelines. A 10-µl syringe (Hamilton Company, Reno, NV, USA) was used to treat these lines (27 cm) with hexane solutions of test treatments at the desired concentration (wt/cm) of a particular treatment.

For each test run, 100 termites were transferred to a plastic petri dish (3.5×1.0 cm) provisioned with a moistened brown paper towel disk. Termites were allowed to acclimate for ~30 min. A small acrylic paintbrush (no. 3/0 Round Red Sable, M. Grumbacher, NJ, USA) was used to gently put a termite at one end of the treated line. A stopwatch was used to record the time taken by termites to reach the other end of the trail. Timing began as soon as the termite's abdomen crossed the marked starting point of the 25-cm treated section of the trail, and ended as soon as it crossed the opposite end point. The number of termites that did not walk to the end of the trail, left the trail, or reversed their direction was recorded. Time recordings of these termites were not included in the rate of movement analysis.

Seven concentrations of dodecatrienol (0.01 fg/cm, 0.1 fg/cm, 1 fg/cm, 10 fg/cm, 100 fg/cm, 1 pg/cm, and 10 pg/cm) were tested with 30 termites per concentration. To ensure that termites did not detect any natural pheromone from a previous run, a new sheet of paper and a dodecatrienol trail were used for every run.

Gradient Bioassays

To determine whether termites responded to increasing or decreasing dodecatrienol concentration gradients, trails were drawn on printer paper as described above. The 25-cm long section was further divided into five equal sections. We selected a range of concentrations between 1 and 10 fg/cm to construct the gradient trail. Each 5-cm section was treated with an increasing concentration of dodecatrienol (1, 2, 5, 8, and 10 fg/cm). A single termite was placed at either the low concentration (increasing gradient) or the high concentration end (decreasing gradient). The termite's walking speed, pauses, and reversals in direction and the number of termites leaving the trail were observed. A new gradient trail was constructed on a new sheet of paper for each run. Thirty termites were tested on increasing and decreasing gradient trails.

Choice Bioassays

To study different aspects of trail-following behavior of termites, natural trails (laid down by worker termites), SGE trails, and artificial trails with dodecatrienol were used. A Y-maze was designed from a cardboard sheet (1 mm thick), with each arm of the Y-maze being 120° apart, 5 cm in length, and 3 mm in width (Fig. 1). All the Y-mazes were cut on a die-cutting machine such that each maze had a well-perforated margin. A no. 7 insect mounting pin (Ward's Natural Science, Rochester, NY, USA) was gently inserted in the Y-maze at the center at the junction of the three arms. The other end of the pin was inserted into a Styrofoam block. The Styrofoam served as a base to hold the Y-maze stable so that the arms were level. A 10-µl syringe was used to treat the surface of one arm with solutions of the desired concentration (wt/cm) of a particular treatment. The other arm of the maze was treated with acetone or hexane only. Three concentrations of SGE (TE = termite equivalent) (0.002, 0.02, and 0.2 TE/cm) and seven concentrations of dodecatrienol (0.01 fg/cm, 0.1 fg/cm, 1 fg/cm, 1 pg/cm, 0.01 ng/cm, 0.1 ng/cm, and 1 ng/cm) were tested. In other studies, different concentrations of dodecatrienol were applied to the two arms of the Y-maze to determine termites' ability to discriminate between different concentrations. Similarly, 2-phenoxyethanol

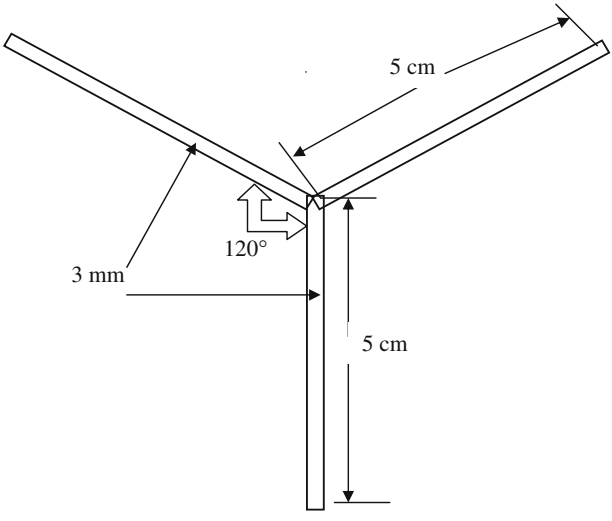

Fig. 1 Diagram of the Y-maze used for choice bioassays. Each arm is 120° apart, 5 cm long, and 3 mm wide

[ethylene glycol phenyl ether, (90+ percent purity), Aldrich Chemical Company, Inc., Milwaukee, WI, USA] trails were laid down using three concentrations (0.02 ng/cm, 0.2 ng/cm, and 10 μg/cm) on one arm and compared with the untreated arm as well as with different dodecatrienol concentrations.

The same acrylic paintbrush described above was used to gently put a termite at the end of one of the untreated arms, and the worker walked up to the intersection and chose between the treated or untreated arm. The run was considered complete when the termite walked to the end of one 5-cm arm. A new termite was used for each run, and 30 runs were made for each test. To control for directional biases, 15 runs were conducted with the left arm treated and 15 runs with the right arm treated. A new Y-maze was used for each run. All bioassays were performed in a room (6.70×3.65×3.35 m) illuminated by four 32-W white fluorescent tubes. We conducted preliminary runs in the absence of light and determined that light did not influence the trail following ability of *R. hesperus* workers (without functional eyes) and male and female dealates.

Detection of Trail Pheromone

To determine how termites detect trail pheromone, termites were tested on a bilevel Y-maze arena. A Y-maze with one arm treated as described above was inverted and rested upon three insect-mounting pins inserted in a Styrofoam sheet so that the Y-maze was level (Fig. 2). The arms of another Y-maze were cut such that each arm measured 4 cm. A no. 7 pin (cut to 3.7 cm in length) was inserted through a cork such that the pointed end was about 2 cm out on the other side. The pin and cork assembly was carefully pressed onto the center of the shorter Y-maze so that it securely held the shorter Y-maze. The shorter Y-maze was put directly under the inverted Y-maze (one arm treated) described above (Fig. 2). The distance between the untreated surface of the arms of the shorter Y-maze and the inverted Y-maze above it was ~1.0 cm. A single termite was placed on the end of the bottom Y-maze. The termite's behaviors were observed when it came to the intersection, specifically looking for any antennal response toward the treated arm above its head. The run was terminated when a termite walked to the end of the 4-cm arm of the shorter Y-maze (Fig. 2). For the series of assays, the distance (4 to 10 mm) between the treated inverted Y-maze and untreated smaller Y-maze surfaces was adjusted by inserting 1-mm-thick disks (2.5 cm diam.) of cardboard under the cork holding the smaller Y-maze.

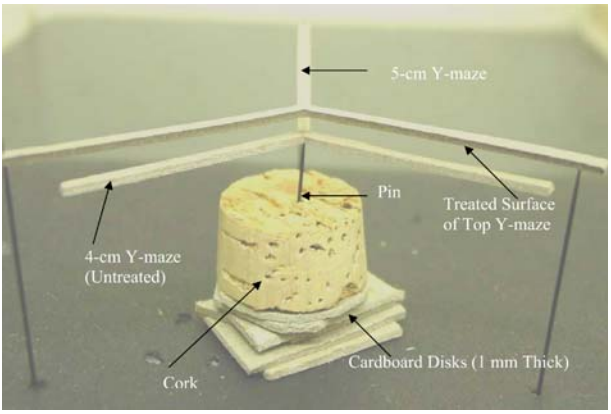

Fig. 2 A bilevel Y-maze used to determine whether the antennae or palpi detected the trail pheromone. One arm of the top Y-maze (each arm 5 cm long) was treated with acetone solutions of dodecatrienol and the other with acetone only. The arms of the shorter Y-maze were not treated. The distance between the top and bottom Y-mazes was adjusted by putting 1-mm-thick cardboard disks under the wooden cork

Arrestant Bioassays

To determine whether dodecatrienol or SGE arrested termite movement, four separate bioassays were conducted with workers and male dealates. The bottom of a plastic petri dish (9.0 cm diam.) was completely covered with a filter paper disk (Whatman no. 1, Whatman International Ltd., Maidstone, UK). For the first bioassay, a small filter paper disk (2.1 cm diam., Whatman no. 1) was treated with 10 μl of a solution of dodecatrienol in acetone (3.46 pg/ml) using a 10-μl syringe (Hamilton). The resulting concentration of dodecatrienol on the treated disk was 10 fg/cm^2. Another filter paper disk (2.1 cm diam.) was treated with 10 μl of acetone only. Both disks were allowed to dry for 5 min under a laminar flow hood and then glued to the bottom of the larger disk (9.0 cm diam.) so that they were 5 cm apart (between their center points). Individual workers were released in the center of the arena. The amount of time each termite (N=15) spent contacting each disk was recorded for 5 min. Their gnawing and palpation behaviors on the treated disk were also observed. New disks were used for each run.

In the second bioassay, the attractiveness of dodecatrienol to male dealates (N=15) was tested. Preliminary bioassays at different concentrations ranging from 10 fg/cm^2 to 10 ng/cm^2 were tested, and 5 ng/cm^2 was selected for a full experiment. The amount of time spent by male dealates contacting each disk was recorded for 5 min. Their palpation, excitement, and gnawing behaviors on treated vs. untreated disks were visually observed. The third bioassay was carried out using SGE from female dealates (1 female alate equivalent) on one disk and hexane (control) on the other disk. Male dealates (N=15) were released in the arena one at a time as described above. The amount of time each male spent contacting each disk was recorded for 5 min. Their palpation, excitement, and gnawing behaviors on treated vs. untreated discs were visually observed. The fourth bioassay was conducted to compare attractiveness of dodecatrienol with that of female SGE, for male dealates (N=15). The amount of time each male spent contacting each disk was recorded for 5 min. Their palpation, excitement, and gnawing behaviors on treated vs. untreated discs were visually observed. Termite workers used in the first bioassay were taken from the lab colony in cohorts of 50 termites, and were transferred to a plastic petri dish (3.5 cm diam.). The disk was provisioned with a moistened brown paper towel disk. Termites were allowed to acclimate for 30 min. Termites were used only once. The alates used were collected from an active swarm. They were immediately transferred to a plastic container provisioned with moistened brown paper towel, and dealates separated by sex were used for bioassays.

Feeding Bioassays

To determine whether dodecatrienol acted as a phagostimulant, workers were tested in a feeding choice bioassay. Small disks of brown paper towel (2.5 cm diam.) were cut in half, and both halves were weighed. One half was designated as treated (T) and the other as control (C). A calculated volume of dodecatrienol solution in acetone was applied to the treated half disk with an Eppendorf micropipetter to provide the desired concentration (pg/cm^2). The untreated half was treated with the same volume of acetone. Both disk halves were dried under a laminar flow hood for 5 min and were then weighed again. Concentrations of 0.01, 0.1, 1, and 10 pg/cm^2 and 1 ng/cm^2 were tested. After drying, treated and untreated half disks were stuck back together with a small strip of Scotch tape (3M®, St. Paul, MN, USA). The intact disk was placed in a plastic petri dish (3.5 cm diam.×1 cm, Falcon, BD Biosciences) with the taped side facing down. All the petri dishes with disks were then transferred to a plastic container (43.3×29.9×17.7 cm) and were maintained at 100% RH.

Forty termites of similar size and weight were transferred to each petri dish, the dishes were covered with lids to keep moisture high, and the dishes were held in the container for 5 d. Appropriate controls were used to check for mortality and amount of feeding on disks treated with acetone only. Five replicates were conducted for each concentration. At day 5, the termites were removed, and the two halves of the disk were separated, cleaned by gently brushing the fecal material and dirt from them, and dried in a laminar flow hood for 24 hr. The half disks were weighed again. Net feeding was calculated after subtracting amount of feeding on control halves from the feeding on treated halves.

Statistical Analyses

Statistical analyses of choice tests on Y-mazes were based on a binomial distribution, using a chi-square test ($P<0.05$) (SAS Institute, 1999). Results of termite feeding and straight-line bioassays were analyzed with the general linear model analysis of variance (ANOVA) procedure (SAS Institute, 1999). Means were separated using Tukey's honestly significant difference (HSD) test for significance at $P<0.05$. Arrestant bioassay data were analyzed by paired *t*-tests.

Synthesis of (3*Z*,6*Z*,8*E*)-Dodecatrien-1-ol (Fig. 3)

Unless otherwise stated, reactions were run under argon atmosphere. Tetrahydrofuran (THF) was dried by distillation from sodium-benzophenone ketyl. Solutions were dried over anhydrous Na_2SO_4 and concentrated with rotary evaporation under reduced pressure, unless otherwise stated. NMR spectra were taken on a Varian INOVA 400 NMR spectrometer, and mass spectra were taken with a Hewlett-Packard 6890 gas chromatograph interfaced to a Hewlett-Packard 5973 mass selective detector, using electron impact ionization at 70 eV. Reaction yields have not been optimized.

*(E)-1-Iodo-1-pentene (**3**)* Diisobutylaluminum hydride in hexanes (1 M, 100 ml, 100 mmol) was added dropwise to a solution of 1-pentyne **2** (7.5 g, 110 mmol) in hexanes chilled to −40°C. The resulting mixture was stirred 30 min, then slowly warmed to room temp over 3 hr, and stirred overnight. The mixture was warmed to ~50°C for 4 hr, then cooled to

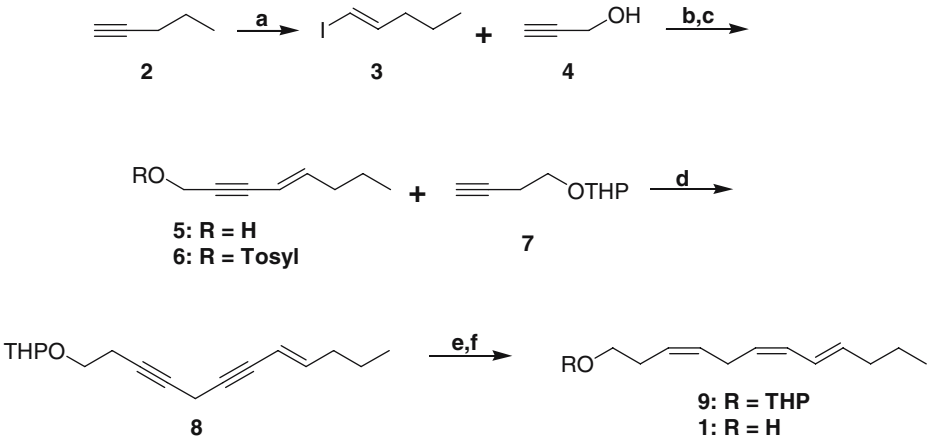

Fig. 3 Synthesis of dodecatrienol

−40°C, and a solution of iodine (25.4 g, 100 mmol) in THF (100 ml) was added dropwise over 30 min. The resulting dark brown suspension was allowed to warm to room temperature with stirring overnight, producing a clear pale yellow solution. The solution was cooled in an ice bath, and slowly quenched by dropwise addition of ice-cold H_2SO_4 (20%, 50 ml) (CAUTION: EXOTHERMIC) with vigorous stirring. After stirring for 30 min, the layers were separated, and the organic layer was washed with dilute $NaHSO_3$ solution and brine, and dried over $MgSO_4$. The resulting pale yellow solution was filtered through a 2.5-cm pad of silica, rinsing with pentane, then concentrated by rotary evaporation without heating. The resulting pale orange oil **3** (28.9 g, 88.8% pure) was contaminated with isobutyl iodide (8.7%), 1-iodo-1-pentyne (0.8%), and iodopentane (1.8%), but appeared to be isomerically pure. The crude material was used without further purification. MS: *m/z* (%): 196 (M+, 40), 167 (22), 154 (28), 127 (13), 69 (20), and 41 (100).

*(E)-Oct-4-en-2-yn-1-ol (**4**)* A 250-ml three-neck flask fitted with a thermometer was flushed with Ar and loaded with bis(triphenylphosphine)palladium (II) dichloride (1 g, 1.4 mmol), 0.5 g CuI (2.6 mmol), and pyrrolidine (50 ml). The mixture was stirred and cooled in an ice bath, and crude (*E*)-1-iodo-1-pentene **3** (14.5 g, ~50 mmol) was added dropwise, followed by dropwise addition of propargyl alcohol **4** (3.5 ml, 60 mmol). The mixture was slowly warmed to room temperature, at which point a rapid exothermic reaction commenced, necessitating external cooling with an ice bath. After cooling the mixture to room temperature, checking the mixture revealed a clean reaction with complete consumption of iodoalkene **3** and production of a single product. The reaction mixture was worked up by pouring into an ice-cold 1:1 mixture of saturated aqueous NH_4Cl and 2 M HCl (300 ml), and extracting several times with ether. The combined ether extracts were washed with a small portion of the NH_4Cl and HCl mixture and brine, dried and decolorized with a mixture of anhydrous Na_2SO_4 and decolorizing charcoal, filtered through a plug of celite, and concentrated. The resulting viscous orange oil was Kugelrohr-distilled (oven temp ~70°C, 1 mmHg), yielding 3.5 g of clear oil (56%). MS: 124 (M+, 96), 109 (15), 95 (42), 91 (40), 81 (100), 79 (40), 77 (34), 67 (40), 65 (41), 55 (28), 54 (26), 53 (31), 41 (48). ^{1}H NMR: 6.14 (dt, 1H, J=15.97, 7.04 Hz, H-5), 5.48 (dtt, 1H, J=15.97, 2.05, 1.5 Hz, H-4), 4.35 (d, 2H, J=2.05 Hz, H-1), 2.09 (overlapped tdd, 2H, J~7.5, 7.1, 1.5 Hz, H-6), 1.91 (br s, 1H, OH), 1.41 (overlapped qt, 2H, J~7.5, 7.3 Hz, H-7), and 0.89 (t, 3H, J =7.3 Hz, H-8). ^{13}C NMR: 145.8, 109.1, 85.8, 84.8, 51.8, 35.3, 22.1, and 13.8.

*(E)-Oct-4-en-2-yn-1-ol Tosylate (**6**)* Enynol **5** (3.1 g, 25 mmol) and *p*-toluenesulfonyl chloride (5.4 g, 28 mmol) were dissolved in 100 ml of ether, and the solution was cooled to ~−10°C in an ice–salt bath. With vigorous stirring, powdered KOH (16.8 g, 300 mmol) was added in portions over 30 min, and the resulting mixture was warmed to ~ 0°C and stirred until the starting alcohol had been completely consumed (~1 hr). The mixture was then poured into 100 ml of ice water, stirred for 10 min, and the layers were separated. The aqueous layer was extracted again with ether, and the combined ether extracts were washed with brine, dried, concentrated, and then pumped under high vacuum (~0.2 mmHg) for 1 hr to remove traces of solvent, yielding the tosylate as a gold oil (6.32 g). This was used immediately in the next step without further purification.

Isopropyl magnesium chloride (2 M, 16 ml, 32 mmol) was added dropwise at room temperature to a solution of THP-protected 3-butyn-1-ol **7** (4.62 g, 30 mmol) in 75 ml THF. The mixture was stirred for 2 hr at room temperature, then cooled to 0°C, and CuI (0.5 g,

2.6 mmol) was added. After stirring for 15 min, crude tosylate **6** (3.2 g, ~12.5 mmol) in 20 ml of THF was added dropwise. The mixture was warmed slowly to room temperature overnight in an insulated bath, then worked up by addition of saturated NH_4Cl and extraction with hexane. The hexane extract was washed with brine and dried over Na_2SO_4, filtered, concentrated, and Kugelrohr-distilled (oven temperature <90°C, 0.2 mmHg) to remove the excess THP-protected butynol. The residue was then purified by vacuum flash chromatography (7.5% ethyl acetate [EtOAc] in hexanes), yielding the protected endiynol **8** (1.06 g), which was used immediately in the next step.

A solution of dicyclohexylborane was prepared by addition of cyclohexene (2.43 ml, 24 mmol) dropwise to a THF solution (20 ml) of borane-dimethylsulfide complex (2 M, 6 ml, 12 mmol) maintained at <−10°C in an ice–salt bath. After the addition was complete, the mixture was slowly warmed to room temperature over 3 hr, yielding a white slurry. The mixture was cooled to <−10°C again, and the protected enediynol (0.78 g, 3 mmol) in 10 ml THF was added dropwise. The solution was slowly warmed to 0°C over 3 hr, and stirred at 0°C for a further 3 hr, yielding a cloudy orange solution. Acetic acid (3 ml, 50 mmol) was then added dropwise, and the solution was warmed to room temperature overnight. The next morning, the mixture was cooled to 0°C again, and a solution of 4 g NaOH in 20 ml H_2O was added over 10 min, followed by dropwise addition of 1.4 ml of 30% H_2O_2 (EXOTHERMIC). The resulting mixture was warmed to room temperature and stirred for 30 min, poured into water, and extracted with hexane. After washing with brine, drying over Na_2SO_4, and concentrating, the residue was purified by vacuum flash chromatography (5% EtOAc in hexane). The resulting yellow oil **9** was dissolved in MeOH (15 ml) containing ~50 mg *p*-toluenesulfonic acid, and stirred at room temperature for 3 hr. The mixture was then poured into aqueous $NaHCO_3$ and extracted twice with hexane. The combined hexane extracts were washed with saturated $NaHCO_3$ and brine, then dried over a mixture of anhydrous Na_2CO_3 and Na_2SO_4. After filtration and concentration, the residue was purified by flash chromatography (22% EtOAc in hexane). The purified trienol **1** was Kugelrohr-distilled (oven temperature ~80–90°C, 0.2 mmHg), yielding 280 mg of trienol **1**, >99.5% pure by GC. MS: 180 (29), 137 (8), 133 (10), 119 (25), 105 (48), 93 (41), 91 (100), 79 (73), 77 (37), 67 (40), 55 (28), and 41 (30). ^{1}H NMR: 6.31 (ddq, 1H, J=15.1, 11.0, 1.3 Hz, H-8), 5.97 (br t, 1 H, J=11.1 Hz, H-7), 5.69 (dt, 1H, J=15.1, 7.0 Hz, H-9), 5.56 (ddt, 1H, J=10.7, 7.3, 1.5 Hz, H-4), 5.43 (ddt, 1H, J=10.7, 7.3, 1.5 Hz, H-3), 5.25 (dd, 1H, J=10.8, 7.5 Hz, H-6), 3.66 (br q, 2H, J=6.3 Hz, H-1), 2.95 (br t, 2H, J=7.3 Hz, H-5), 2.37 (br q, 2H, J=6.8 Hz, H-2), 2.09 (br q, 2H, J~7.1 Hz, H-10), 1.42 (overlapped tq, 2H, J~7.3, 7 Hz, H-11), and 0.91 (t, 3H, J=7.3 Hz, H-12). All spectra were in accord with literature values (Eya et al., 1990; Argenti et al., 1994).

Results

Termites (N=30) walked on the Y-maze at an average speed of 0.73±0.12 cm/sec on the untreated arm of the Y-maze where they were released. Once the termites reached the intersection of the maze and turned toward the dodecatrienol treated arm (1 fg/cm), they traveled significantly faster (t=8.08, df=29, P<0.05) with fewer delays toward the end than on nontreated controls. The average speed on the treated arm was 1.05±0.18 cm/sec (N=30).

Production of Natural Trails

Individual termites laid trails that could be detected by other termites in significant numbers only after about 28 termites walked along the given Y-maze treatment arm compared to the

other control arm (χ^2=13.34, *df*=1, *P*<0.001). This trail lasted for 1 d when the maze was held inside a sealed container at room temperature (Table 1). By day 2, the trail no longer elicited a significant response.

Straight-line Bioassays

Termites showed optimal responses to trails of 0.1 to 10 fg/cm dodecatrienol in our bioassays. When exposed to trails made with the various concentrations of dodecatrienol, they did not show significant differences in their mean walking speed on the trail except for the 10 fg/cm trail (*F*=6.91, *df*=5, 29, *P*<0.001; Table 2), on which they walked more quickly (1.15 cm/sec) than they did with most of the other concentrations. The percentage of termites that walked the entire distance of the treatment trails was lower at higher concentrations of dodecatrienol (*F*=17.91, *df*=5, 29, *P*<0.001; Table 2) compared with lower concentrations (≤10 fg/cm).

Gradient Bioassays

There was no difference in trail-following behavior of the termites when they were exposed to increasing or decreasing gradients of dodecatrienol. Their speed walking up or down gradients was not significantly different, with termites covering the distance in about 24 sec (increasing gradient 24.7±5.0 sec and decreasing gradient 23.7±4.5 sec). Similarly, no differences were observed in the percentages of termites (88 to 90%) that completed the gradient trails compared to nongradient trails.

Choice Bioassays

A minimum of 0.02 TE/cm (worker SGE) was required for trail following (Table 3). The threshold concentration of 2-phenoxyethanol to elicit significant levels of trail following on a Y-maze was 0.2 ng/cm. For dodecatrienol the threshold concentration was between 0.01

Table 1 The number of *R. hesperus* walking on the Y-maze arm before other termites followed the trail

10 pg/cm	38.5d	27.4±5.4a

Mean values with the same letter in a column are not significantly different (Tukey's HSD test, $P<0.05$).

and 0.1 fg/cm. Thus, *R. hesperus* workers were 10^7 times more responsive to dodecatrienol than they were to 2-phenoxyethanol (Table 3).

Sternal gland extracts at 0.2 TE/cm elicited significant trail following for only 24 hr after application (Table 3), whereas a 2-phenoxyethanol trail at 0.2 ng/cm on a Y-maze lasted for 24 hr, and a 1 fg/cm trail of dodecatrienol was active for at least 48 hr.

Threshold concentrations for trail following on dodecatrienol trails were similar for workers and secondary reproductives (Table 4). Soldiers and alate males of *R. hesperus* were not able to follow trails at 0.1 fg/cm dodecatrienol (Table 4). Both workers and soldiers followed the 2-phenoxyethanol trails at equivalent threshold levels (0.2 ng/cm). Workers,

SGE = sternal gland extract, TE = termite equivalent, SGE alate (F) = sternal gland extract of female alates, SR = secondary reproductive

[a] Chi-square (χ^2) analysis is based on a binomial probability of 1:1 for a null hypothesis of no difference between the control and treated arms, and χ^2 values less than 3.84 are not significant at the 0.05 level of significance.

secondary reproductives, and soldiers readily followed the trails of 0.02 TE of SGE/cm of worker termites. Male alates followed the trails of 0.2 female alate SGE/cm (Table 4).

Starvation appeared to have no effect on the sensitivity of termites to dodecatrienol. Those starved for 120 hr were still capable of following 0.1 fg/cm dodecatrienol trails on the Y-maze (χ^2=6.54, *df*=1, *P*<0.013; Table 5). However, those starved up to 120 hr were not able to differentiate between 1 fg/cm vs. 10^4 fg/cm dodecatrienol trails (χ^2=2.13, *df*=1, *P*<0.18; Table 5).

Termites were not able to differentiate between different concentrations of fresh trails of dodecatrienol or SGE when offered simultaneously on each of the two arms of the Y-maze (Table 6). Even when the differences in concentrations of dodecatrienol were as great as 10^4, they did not show any preference. However, significantly more followed the higher concentration trail after it aged for 48 hr.

When given a choice between 2-phenoxyethanol and dodecatrienol, workers generally preferred the latter (Table 7). Only when the concentration of 2-phenoxyethanol was 10^{11} (0.1 mg/cm) or 10^{12} (1 mg/cm) times greater than dodecatrienol (1 fg/cm) did they show significantly higher preference for the 2-phenoxyethanol trails (Table 7). Unlike

Table 5 Trail-following behavior of *R. hesperus* workers starved for different durations

Starvation Period (hr)	Conc. (fg/cm)	Control/Treatment	Chi-square[a]

	0.1	8/22	6.54
	0.01	14/16	0.13
120	1.0 vs. 10^4	11/19	2.13

[a] Chi-square (χ^2) analysis is based on a binomial probability of 1:1 for a null hypothesis of no difference between treated and control arms, and χ^2 values less than 3.84 are not significant at the 0.05 level of significance.

dodecatrienol (0.01 to 1 ng/cm, Table 3), at a higher concentration 2-phenoxyethanol (1 mg/cm, Table 7) was not repellent to termite workers.

Detection of Trail Pheromone

In this experiment, a treated Y-maze was placed directly above the untreated Y-maze upon which the test animal walked. Neither the antennae nor the mouthparts of the termites could touch the treated surface of the Y-maze above them. When the distance between the treated and untreated surfaces of the two Y-mazes was reduced to 4 mm, termites were able to detect and follow the treated arm (Table 7). When the distance between the two mazes was reduced to less than 4 mm, they were able to touch the upper Y-maze surface and in few cases were able to climb up the maze over their heads. Dodecatrienol has relatively low vapor pressure (estimated as 3.73×10^{-4} Torr at 25°C; Chemical Abstracts, 2005), and termites were only able to detect it when their antennae were about 1–2 mm from the trail. Increasing the concentration of dodecatrienol did not alter the distance over which it was perceived by the antennae (Table 8). Concentrations as high as 1 ng/cm were not repellent to workers in this setup.

Table 6 Ability of *R. hesperus* workers to differentiate between different concentrations of synthetic dodecatrienol and SGE on the Y-maze

Concentration/cm[a] of Arm A vs. Arm B	Time (hr)	A/B	Chi-square[b]

1	10^{12}	8/22	6.54

2-P = 2-phenoxyethanol.

[a] Chi-square (χ^2) analysis is based on a binomial probability of 1:1 for a null hypothesis of no difference between two treated arms, and χ^2 values less than 3.84 are not significant at the 0.05 level of significance.

Arrestant Bioassays

Both worker termites and male dealates spent more time on disks treated with 10 fg/cm^2 and 5 ng/cm^2 dodecatrienol, respectively, than on control disks (Fig. 4A, t=4.45, df=14, P <0.05; Fig. 4B, t=3.61, df=14, P<0.05). Male dealates also spent more time (t=10.62, df= 14, P<0.05) on disks treated with female alate extract (SGE, 0.28 TE/cm^2) than on control disks (Fig. 4C). When female alate SGE was directly compared to dodecatrienol, male dealates spent more time (t=6.10, df=14, P<0.05) on SGE-treated disks (0.28 termite equivalent/cm^2) than disks treated with dodecatrienol (5 ng/cm^2, Fig. 4D).

Feeding Bioassays

The total amount of feeding on treated and untreated paper combined at various dodecatrienol concentrations was not significantly different (F=2.45, df=5, 24, P=0.06). Total feeding on the treated and control halves combined ranged from 5.9 to 3.9 mg 40 termites^{-1} 5 d^{-1}. Net feeding on the treatments was determined by subtracting the amount of feeding on the control half of the disk from feeding on the treated half. Net feeding on treated halves ranged from −1.6 to +1.9 mg 40 termites^{-1} 5 d^{-1}. No consistent trend of feeding on either the control or treated half was observed. There were no significant differences in the amount of net feeding on paper towel disk halves treated with different concentrations of dodecatrienol (F=1.92, df=5, 20, P=0.15).

Table 8 Detection of trail pheromone by *R. hesperus* workers on the double Y-maze arms

Weight/cm on Y-maze Arm	Distance Between Arms (mm)	Control/Treatment	Chi-square[a]
1 fg	10	12/18	1.2
1 fg	5	11/19	2.13
1 fg	4	6/24	10.8
1 ng	5	10/20	3.34
1 ng	4	7/23	8.54

[a] Chi-square (χ^2) analysis is based on a binomial probability of 1:1 for a null hypothesis of no difference between two treated arms, and χ^2 values less than 3.84 are not significant at the 0.05 level of significance.

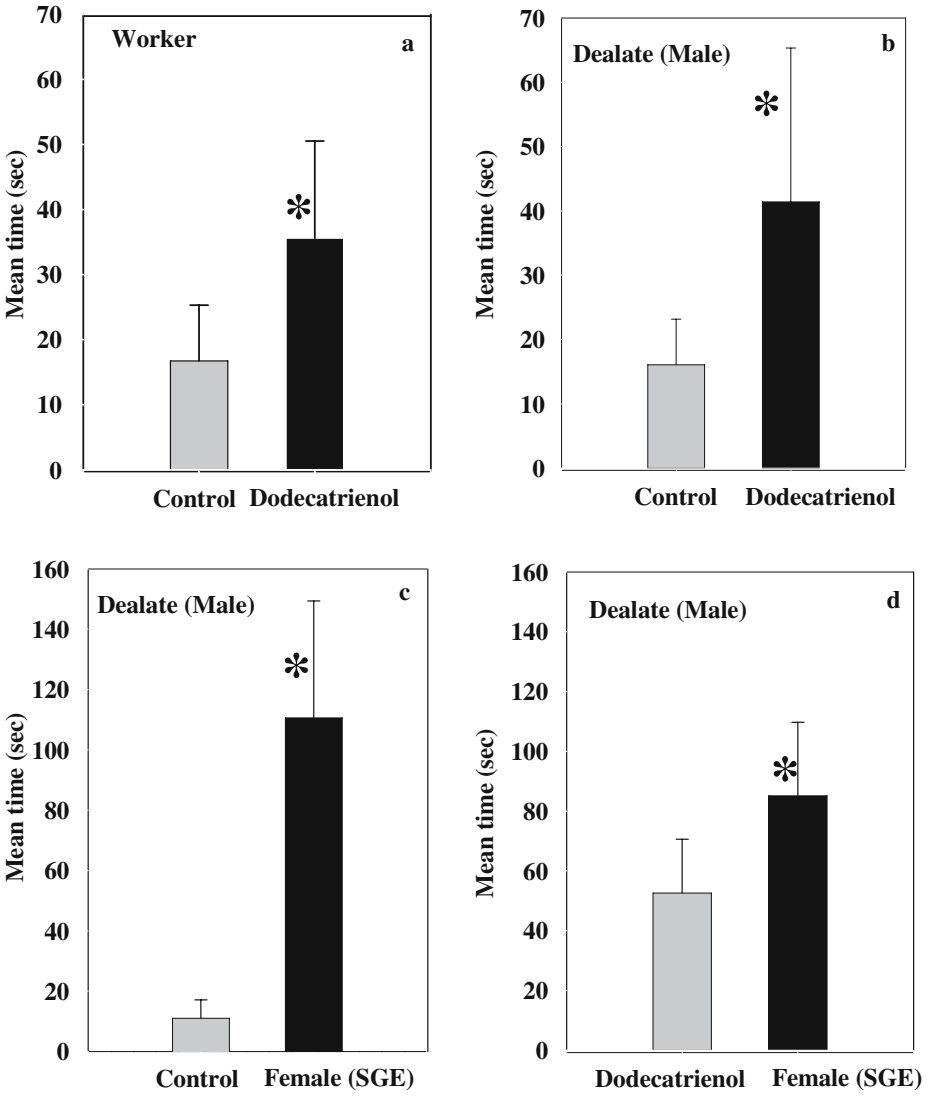

Fig. 4 Time spent (sec) on disks treated with dodecatrienol or female alate SGE by workers (**a**) and male dealates (**b**–**d**). Asterisk denotes means that are significantly different at $P<0.05$ (paired *t*-test)

Discussion

Individual termites, when allowed to walk on the Y-maze substrate, did not establish a trail that was recognized by conspecifics. Instead, it took a minimum of 28 termites walking over the same trail to establish a reliably detectable pheromone trail. This suggests that during its routine movements, a new recruit worker will prefer trails that have had considerable traffic, and these trails must be reinforced to remain effective. Grace et al. (1988) also suggested that *R. hesperus* termites are preferentially recruited to more well traveled trails.

Similar observations were made by Runcie (1987) concerning the trail-following behavior of *R. flavipes*, where trails in tubes with heavier termite traffic lasted longer than trails in tubes that were used less frequently. Single termite workers were allowed to lay trails in glass tubes and superimposed trails of as many as 50 workers remained active for only 5 min, whereas in our study trails superimposed by 28 termites remained active for 24 hr. These differences may be attributed to the properties of the substrate over which the trail was laid. In our study, the Y-maze was made of cardboard instead of a glass surface.

The concentrations of the trails did not affect the speed at which termites completed the trails. However, the concentration did affect the percentage that completed the trail bioassay. It took more than 30 termites to achieve 30 replicates in which the termite walked the entire length of the 25 cm trail because some veered off the trail before reaching the end. Termites exposed to 0.01 and 0.1 fg/cm trails walked slowly and stopped frequently, trying to sense the trail by actively waving their antennae (sampling substrate) on both sides of the trail. There was a limited range of dodecatrienol concentrations (0.1–10 fg/cm) to which the termites showed optimal trail-following behavior. The threshold concentration determined in our study for *R. hesperus* was ~60–600-fold lower than previously reported by Matsumura et al. (1972). The difference may be due to the purity of the synthetic dodecatrienol used in the two studies, or to the different substrates on which the trails were laid. In another study, the reported threshold concentration of dodecatrienol for *R. flavipes* was <0.01 pg/cm (Matsumura et al., 1968). On trails of higher concentration (>10 fg/cm), more termites failed to complete the trail or stopped occasionally and reversed direction, resulting in delays to reach the end of the treated line, than did termites on trails with between 1 and <10 fg/cm. Similar results have been reported by other researchers using different termite species (Grace, 1986; Laduguie et al., 1994b; Wobst et al., 1999; Peppuy et al., 2001; Arab et al., 2004; Robert et al., 2004). In our study, this effect manifested itself through a lower percentage of termites completing the trails at higher concentrations within the bioassay time period. Consequently, the walking speed of termites completing the trail was significantly greater for only one concentration (10 fg/cm), and there were no differences in the times taken to complete the trail among the other concentrations. As suggested by Prestwich et al. (1984), such differences may be related to the optimal response behavior of termites to the trail and have less to do with discriminatory ability.

On the Y-maze and the 25-cm long trail, significantly higher numbers of termites responded to 0.1 and 1 fg/cm treatments compared to untreated controls. The minimal threshold concentration of dodecatrienol eliciting trail following was between 0.01 and 0.1 fg/cm. The 1 fg/cm trail remained active for 48 hr. This may be because of the fact that lower concentrations volatilized from the substrate to the point where they were no longer detectable in the bioassay; higher concentrations probably still had some material "loaded" on the substrate. The natural trails and SGE trails (0.2 TE/cm) were active only for 24 hr. Thus, trails have to be reinforced by termites if they are to remain active. Runcie (1987) showed that *R. flavipes* trails leading to a food source were highly persistent compared to exploration trails. Affolter and Leuthold (2000) and Gessner and Leuthold (2001) reached a similar conclusion for trail-following behavior of *Macrotermes subhyalinus* Rambur. For another species, *Nasutitermes costalis*, extracts of 4-yr-old paves, aboveground guidelines formed by feces and debris by foragers, elicited orientation behavior (Traniello, 1982). However, *M. subhyalinus* and *N. costalis* have considerably different foraging and nesting behavior compared to *Reticulitermes* species, and observations on behavior of different species cannot be readily generalized. For example, termites starved for 120 hr were not able to discriminate between different concentrations of dodecatrienol, suggesting that *R.*

hesperus does not use concentration to differentiate between trails leading to food sources or for exploration. Under natural conditions, it seems more likely that the most highly used trails from the colony are those either leading directly to a food source, or foraging trails in a conducive soil environment.

Reticulitermes spp. rarely forage in the open, instead spending most of their time foraging underground in galleries constructed with a number of termites working on each tunnel. In nature, other factors such as tactile stimuli from workers returning from a food source, salivary secretions used to construct tunnels, moisture levels, and the age of the tunnel may provide additional signals.

Reinhard and Kaib (2001) showed that soldiers of *R. santonensis* responded only to trails of higher concentration from SGE of worker termites. In *N. costalis*, worker termites were recruited at higher concentrations compared to soldiers and third instar workers had larger sternal glands compared to soldiers, considered to be responsible for differential recruiting effects (Traniello and Busher, 1985). In our study, different castes of *R. hesperus* (worker, soldier, secondary reproductives, and male alates) responded equally well to dodecatrienol trails at 1 fg/cm. However, at 0.1 fg/cm, soldiers and male alates did not respond significantly more toward the treated arm, and 25% of workers tested failed to complete the 25-cm 0.1 fg/cm dodecatrienol trail.

Differences in threshold concentrations for various trail following chemicals have been reported in various subterranean termite genera and species (Matsumura et al., 1972; Arab et al., 2004). As suggested by other researchers (Howard et al., 1976; Kaib et al., 1982; Tokoro et al., 1994; Cornelius and Bland, 2001), termites of different genera and species may respond to dodecatrienol as a common component of a trail following signal, and there also may be other minor components involved, which may be responsible for species-specific signals.

We chose dodecatrienol concentrations of 1 fg/cm to compare with higher concentrations of dodecatrienol because >90% of the termites were able to follow 1 fg/cm trails. The fact that termites were not able to discriminate between different dodecatrienol concentrations on the two arms of the Y-maze suggests that in nature, trails contain largely qualitative information. Dodecatrienol appeared to act as a repellent at higher concentrations (≥0.01 ng/cm, Table 3). However, when the 0.01-ng/cm concentration was offered simultaneously with 1 fg/cm in a choice assay, termites did not discriminate between either concentration. Furthermore, when offered a choice between dodecatrienol (1 fg/cm) and SGE (1 TE/cm), termites were not able to discriminate between them. This suggests that dodecatrienol is a key component of the SGE signal.

Grace et al. (1988) reported that *R. hesperus* showed a differential response to a concentration gradient of SGE. In contrast, our studies indicated that *R. hesperus* did not respond to a concentration gradient and simply followed the trail. The concentrations selected for our gradient trails were based upon those used in the preliminary straight-line bioassays. Grace (1986) reported that to discriminate between increasing and decreasing gradients the difference on the treated sections must be a little over 10 times. The results suggested that termites showed optimal trail-following behavior at concentrations of between 1 and 10 fg/cm. This range seems more realistic and closer to the concentrations of trails laid by termites in nature. The ability of individual termites to either increase the production of trail pheromone or make it more concentrated so as to provide ≥100-fold differences in deposition on trails in nature seems to be unlikely. In insects such as pharaoh ants, *Monomorium pharaonis*, where trail pheromone is used for trail following, it has been demonstrated that trail geometry rather than a concentration gradient provides polarity to

ant foraging networks (Duncan et al., 2004). Their results showed that bifurcation angles similar to those found in natural networks (~60°) give the best reorientation ratios.

Termites were able to detect the dodecatrienol trails only when their antennae were very close to the trail (about 1–2 mm). The mouthparts apparently did not play a role in detecting the trail and initiating trail following. During normal trail following in termites, maxillary palpi are closer to the substrate than the antennae. When termites were allowed to walk on trail deposits as high as 1 ng/cm of dodecatrienol, they were repelled. In contrast, concentrations as high as 1 ng/cm were not repellent to termites in the bilevel Y-maze in which the antennae and palpi were not directly touching the treated surface. Together, these results suggest that the maxillary palpi may be involved in detecting repellent concentrations of dodecatrienol or perhaps the absence of repellency in the bilevel maze is just because of the additional distance of the antennae from the odor source.

In contrast, arrestant assays showed that male dealates were not repelled by dodecatrienol at relatively high concentrations, with dealates spending more time on treated disks than on controls. In other studies (Laduguie et al., 1994a, b; Robert et al., 2004), it has been suggested that at higher concentrations, dodecatrienol may have another role as a sex pheromone. However, male dealates spent more time on disks treated with extracts of female sternal glands than on disks treated with dodecatrienol, suggesting that other components are probably involved, which may act as synergists with dodecatrienol. On the basis of chemical analysis of extracts of *R. santonensis* (Laduguie et al., 1994a, b), female alates produced 10 to 100 pg of dodecatrienol, approximately 10 times more than the worker termites. Thus, dodecatrienol may be present as one of the components in female sex pheromone, serving to attract male alates for mating at higher concentrations, whereas at lower concentrations, it may act as a trail-following signal, helping in forming tandem pairs during mating.

Earlier studies (Matsumura et al., 1968; Esenther and Beal, 1979; Rust et al., 1996) suggested that wood degraded by *G. trabeum* was attractive to *Reticulitermes* spp., and dodecatrienol was isolated from fungus-degraded wood. Extracts of fungus-degraded wood can be used as arrestants in termite baits and have potential to increase bait station fidelity (Rust et al., 1996). In our feeding studies, we did not observe any phagostimulant or attractant properties of dodecatrienol applied to brown paper towel disks. When termites were transferred to petri dishes in which one half of the disk had been treated with dodecatrienol, they showed greater excitement and movement than termites in untreated controls, and it took longer for them to settle down. Thus, the attractive properties and increased feeding on wood degraded by *G. trabeum* may be due more to the effect of the degradation process on the wood composition or to other as yet unidentified compounds rather than the production of dodecatrienol.

Overall, our studies indicated that the context in which dodecatrienol was presented was critically important. When worker termites were offered a paper disk treated with a spot of dodecatrienol much larger than a termite rather than as a thin line, workers became excited and showed random movements, retouched the spot, and remained in contact with and around the treated disk. Workers perceived the stimulus, but they were not completely arrested by the stimulus. Termites exhibited normal trail-following behavior only when dodecatrienol was presented to them in its normal context, as a thin line. Concentration did not seem to play an important role in routine trail following but may have a role in mating behavior of alates.

Acknowledgments We thank the Carl/Strom Western Exterminator Scholarships for partially funding this research.

Abstract Volatiles from hosts, non-hosts, interspecifics, and conspecifics of the Asian larch bark beetle, *Ips subelongatus* Motsch., were analyzed using both gas chromatographic-electroantennographic detection (GC-EAD) and gas chromatography/mass spectrometry (GC-MS) techniques, and field trapping bioassays in Inner Mongolia, China. GC-EAD experiments indicated that *I. subelongatus* antennae (both sexes) strongly responded not only to the major male-produced conspecific components, ipsenol, and ipsdienol, but also to other bark beetle compounds (*cis*-verbenol and verbenone), host monoterpenes (α-pinene, β-pinene, and para-cymene) from *Larix* sp. logs, and non-host leaf (green leaf volatiles and geranyl acetone) and bark (C_8-alcohols and *trans*-conophthorin) volatiles. Repeatable EAD responses were also found to two compounds from hindgut extracts that are undetectable by GC. One of these minor compounds was identified as amitinol. Field trapping experiments showed that the EAD-active, major male-hindgut component, racemic ipsenol, is the only individual compound that significantly attracted both sexes of *I. subelongatus*, whereas all other compounds, including previously reported pheromone components of European *Ips cembrae*, ipsdienol and 3-methyl-3-buten-1-ol, were unattractive. Ipsdienol, 3-methyl-3-buten-1-ol, or their binary blend had no synergistic or antagonistic effects on *I. subelongatus* attraction when combined with ipsenol, whereas *cis*-

verbenol (a synomone) and verbenone (the antiaggregation semiochemical) inhibited its attraction to the ipsenol-containing attractive blend. A mixture of three EAD-active host monoterpenes, α-pinene, β-pinene, and para-cymene, was unattractive, but interrupted the pheromone response of *I. subelongatus*. Geranyl acetone, one of the strong EAD-active non-host volatiles also significantly reduced the number of *I. subelongatus* captured in traps baited with ipsenol-containing attractive blend. Our results add support to the recent phylogenetic finding that European and Asian larch bark beetles should be regarded as two distinct species: *I. cembrae* infecting larch in Europe and *I. subelongatus* infesting larch in Asia.

Introduction

The Asian larch bark beetle, *Ips subelongatus* Motsch. 1860, is one of the most serious pest insects in plantations and natural stands of larch (Pinaceae), *Larix sibirica* Ledebour, *Larix gmelinii* (Rupr.) Rupr., *Larixprincipis-rupprechtii* Mayr., *Larix kaempferi* (Lam.) Carr., and *Larix olgensis* Henry in Asia (Zhang et al., 1992). This bark beetle infests weakened, wind-thrown, and burned trees and at high population densities, attacks healthy larch trees (Zhang et al., 1989, 1992). The Asian larch bark beetle has long been considered as *I. subelongatus* by Russian and Chinese entomologists, whereas European colleagues consider this species name a synonym of the European larch bark beetle, *Ips cembrae* Heer 1836 (Postner 1974). However, a recent phylogenetic study by Stauffer et al. (2001) on different populations of the larch bark beetle from Europe and Asia indicated a 4.3% difference in mtDNA sequences between samples from these two regions and suggested that the larch bark beetle complex included at least two taxa: *I. cembrae* infesting larch in Europe and *I. subelongatus* infesting larch in Asia (Stauffer et al., 2001). Therefore, *I. subelongatus* is considered here as a valid species designation for the Asian larch bark beetle.

The aggregation pheromone system of *I. cembrae* was intensively studied in Europe during 1970s to 1980s. A three-component pheromone blend consisting of ipsenol, ipsdienol, and 3-methyl-3-buten-1-ol was first reported by (Stoakley et al., 1978). In the field, the combination of all three components was reported as synergistically attractive (Stoakley et al., 1978). In a later gas chromatography-mass spectrometry (GC-MS) study on aeration samples of *I. cembrae* infested larch logs, another monoterpene alcohol, amitinol, was identified, which significantly enhanced field response to the previously reported aggregation pheromone blend (Kohnle et al., 1988). A commercial lure, Cemprax from Shell Agrar Ltd (Cyanamid GmbH), consisted of ipsenol, ipsdienol, and 3-methyl-3-buten-1-ol has been used to monitor the population dynamics of *I. cembrae* in Germany for some years, but has not shown significant promise for mass-trapping (Zhang and Niemeyer, 1995). Further experiments on field responses to different ratios of the first three components indicated that decrease of 3-methyl-3-buten-1-ol or increase of ipsenol and ipsdienol ratios increased the trap catches (Zhang and Niemeyer, 1995). Unlike the European *I. cembrae*, little is known about the aggregation pheromone system of the Asian *I. subelongatus.* The pheromone biology and colonization behavior of the Asian *I. subelongatus* were studied using natural materials by several Chinese authors in the late 1980s (Fu et al., 1988; Yu and Zhang, 1988; Zhang et al., 1991, 1992). However, it was not until recently that Zhang and coworkers identified several potential pheromone components

from the hindgut samples of the Asian *I. subelongatus* males (still called *I. cembrae* in that paper) by GC-MS analysis, with ipsenol and ipsdienol being the major components and 3-methyl-3-buten-1-ol and several other bark beetle-related compounds as minor components (Zhang et al., 2000). Amitinol, which had been reported as one of the major pheromone components of *I. cembrae* (Kohnle et al., 1988), was not detected in the hindgut samples of *I. subelongatus* males (Zhang et al., 2000). No data are yet available on the electrophysiological and behavioral functions of these male-specific hindgut compounds of Asian larch bark beetles.

Our objectives were to (1) determine electrophysiological responses of the Asian larch bark beetle, *I. subelongatus*, to conspecifically produced compounds (potential pheromone components), interspecific synomones, host volatiles from larch logs, and non-host volatiles from angiosperm trees using GC-electroantennographic detection (EAD)/GC-MS technique and (2) test behavioral activities of the EAD-active compounds in the field in Inner Mongolia, China.

Methods and Materials

Insects Newly emerged *I. subelongatus* adults were collected from naturally attacked *Larix principis-rupprechtii* Mayr. trees in mid-September 2001, at Huamugou Forest Farm (E 117°36′–42′; N 42°24′–52′; 1,500 m a.s.l), Keshiketeng Qi, Inner Mongolia, China. The sexes were separated based on second and third elytral spine differences (Zhang and Niemeyer, 1992). Live beetles (for antennal recordings and solvent extraction of male hindguts) were maintained on newly cut larch logs (*Larix* sp.) and in collection cups with tissue papers in a refrigerator at SLU, Alnarp, Sweden. Ten unfed virgin males were allowed to colonize a 10-cm diameter *Larix* bolt with predrilled holes (25°C, 70% r. h., 20:4 L:D). After feeding for 24 hr, the males were excised from their nuptial chambers, and their hindguts were extracted in 300 μl of hexane.

Headspace Sampling of Fresh Larix Log A freshly cut larch log (10-cm diameter; 30-cm long) was placed into a polyester cooking bag (Meny Toppits, Terinex Ltd, England, 35× 45 cm) equipped with a charcoal filter tube. The headspace volatiles of the log were collected on 30 mg Porapak Q (50–80 mesh, Supelco) in a 3-mm ID Teflon tube via a portable aeration system for 2 hr as described in Zhang et al. (1999) and were extracted with 300 μl of diethyl ether. Both hindgut extracts and aeration samples were kept at −20°C until GC-EAD and GC-MS analyses.

GC-EAD and EAG Responses Two μl of the male hindgut extract and of the *Larix* log aeration sample or 1 μl of synthetic mixtures (ca 100 ng/ul each compound) of host (monoterpenes), non-host (green leaf volatiles and angiosperm bark volatiles) and conspecific compounds were injected splitless into a HP-6890 GC equipped with a HP-INNOWAX column (30 m×0.25 mm×0.25 μm) and a 1:1 effluent splitter that allowed simultaneous flame ionization detection (FID) and EAD of the separated volatile compounds. Hydrogen was used as the carrier gas. The column temperature was 40°C for the first 2 min, rising to 200°C at 10°C/min, and held for 2 min. The outlet for the EAD was inserted into a humidified airstream (0.5 m/s) over an *I. subelongatus* antennal preparation. A glass capillary indifferent electrode filled with Beadle-Ephrussi Ringer, and grounded via a silver wire, was inserted into the severed beetle's, head with antennae while the recording electrode (connected to a high-impedance DC amplifier with automatic

baseline drift compensation) was placed in contact with the distal end of the antennal club. The signal was stored and analyzed on a PC equipped with an IDAC-card and the program EAD ver. 2.3 from Synthech, Hilversum, The Netherlands.

Using the same electrophysiological recording setup and the same antennal preparation technique, EAG dose–responses of *I. subelongtus* to the synthetic 3-methyl-3-buten-1-ol were recorded. This compound was reported as one of three aggregation pheromone components for *I. cembrae* in Europe and was EAD-inactive at the normal dosages from hindgut extracts. Stimuli were prepared by applying 3-methyl-3-buten-1-ol (10^0 to 10^6 ng) in 2 μl of hexane onto a piece of filter paper (7×15 mm) in a Pasteur pipette; the seven concentrations were tested from the lowest to the highest. A solvent blank (2 μl of hexane solvent per filter paper) and an active standard control (100 ng ipsenol per filter paper) stimuli were interspersed between the highest and the lowest dosages of 3-methyl-3-buten-1-ol. Each stimulation was followed by a minimum of 60-sec purge period of filtered air to ensure recovery of antennal receptors. The EAG responses were normalized to the relative response (%) of the active standard control, i.e., 100 ng of ipsenol.

GC-MS Analysis The male hindgut extract and the larch log headspace sample were analyzed with an HP 6890 GC series coupled to an HP 5973 Mass Selective Detector using a DB-WaxETR column (0.25 μm film thickness, 60 m×0.25 mm ID; J and W Scientific, Folsom, CA), programmed from 50°C for the first 2 min, rising to 230°C at 15°C/min, then held for 15 min with helium as carrier gas. Antennally active volatiles were identified by comparison of the retention times and mass spectra with those of the available authentic synthetic compounds and with the computerized data library (Wiley7n.l).

Field Trapping Four field trapping experiments were conducted during the summers of 2002 and 2003 at the same larch plantation stand (ca 26 yr old, 10–11 m high and diameter at breast height=12–14 cm) from where the live *I. subelongatus* adults for EAD recordings and hindgut extraction were collected in 2001. Black flight barrier traps (Theyson, Germany) were used in all four experiments, deployed in lines with 10 m between traps and 30 m between trap lines (experiments). To minimize positional effects, traps together with dispensers within each experiment, were rotated after each replicate (when ≥20 beetles were caught in the best trap) in a randomized Latin-square design (Byers, 1991).

Experiment 1 (20 June–14 July 2002) tested a "natural volatile blend" identified from the hindgut of males (mostly EAD-active) including ipsenol, ipsdienol, 3-methyl-3-buten-1-ol, amitinol, (−)-myrtenol, and 2-phenylethanol, and their one-step deletion blends (subtractive approach), plus the reported pheromone blend for the European larch bark beetle, *I. cembrae*, 3-methyl-3-buten-1-ol, ipsenol, and ipsdienol. Experiment 2 was carried out from 20 June to 14 July 2002 to determine the behavioral activity of the three reported pheromone components, 3-methyl-3-buten-1-ol, ipsenol, or ipsdienol, and all their possible binary and ternary blends. Experiment 3, conducted at the same location and time period as the previous two, focused on potential effects of EAD-active compounds from conspecifics, hosts, and non-hosts on bark beetle attraction to the ternary blend of 3-methyl-3-buten-1-ol, ipsenol, and ipsdienol. A mixture of three EAD-active host monoterpenes was also included in the experiment because these had not been previously tested. Experiment 4 was carried out from 30 May to 5 July 2003, when all the treatments in experiment 2 were repeated, plus three additional treatments, including 2-phenylethanol alone, the combination of ipsenol and 2-phenylethanol, and a blank control. All chemicals, sources, release devices, and release rates are listed in Table 1.

Table 1 Chemicals, release rates, and dispensers used in field trapping experiments

Chemical	Source	Purity (%)	Release Rate (mg/24 hr)[a]	Loading (μl/vial)	Dispensers[b]
(±)-Ipsenol (Ie)	Borregaard , Norway	>98	1.4	20	Two open #730 PE vials
(±)-Ipsdienol (Id)	ICN Biomedicals, USA	95	0.6	20	One open #730 PE vial
3-Methyl-3-buten-1-ol (MB)	Aldrich Chemical Co.	>97	15	500	One open #730 PE vial
Amitinol (At)	W. Francke, Hamburg Univ., Germany	98	1	20	One open #730 PE vial
(−)-Myrtenol (Mt)	Acros Organics	97	0.5	50	One open #730 PE vial
2-Phenylethanol (PE)	Aldrich Chemical Co.	99	0.5	50	One open #730 PE vial
cis-Verbenol (cV)	J. Vrkoè, IOBC, Prague, Czechia	98	0.5	30	Two open #730 PE vials

[b] PE-vial with 6-mm diameter opening, 29-mm inner length

Statistical Analysis Trap catch data were transformed by log $(x+1)$ to fit the assumption of homogeneity of variance for analysis of variance (ANOVA). The means were compared by ANOVA followed by the Ryan–Einot–Gabriel–Welsh (REGW) multiple Q test (SPSS 8.0 for Windows) at $\alpha=0.05$. The sex ratios of beetles captured for the treatments within each experiments were compared with 95% binomial confidence intervals (Byers and Wood, 1980).

Results

GC-EAD Recordings and EAG Dose–Responses GC-EAD/MS analyses on the hindgut extract of males indicated that ipsenol and ipsdienol are the major components (ca 3:1 ratio of ipsenol to ipsdienol) eliciting very strong EAD responses by both sexes (Fig. 1a). No antennal responses were detected to the minor components, 3-methyl-3-buten-1-ol, geraniol and 2-phenylethanol at the natural dosage from the extract; however, repeatable EAD responses to two FID undetected compounds (amounts under GC-FID/MS detectable levels) were recorded. Based on the retention time and a further EAD analysis on a synthetic mixture (Fig. 1a), one of the FID undetected, antennally active compounds was

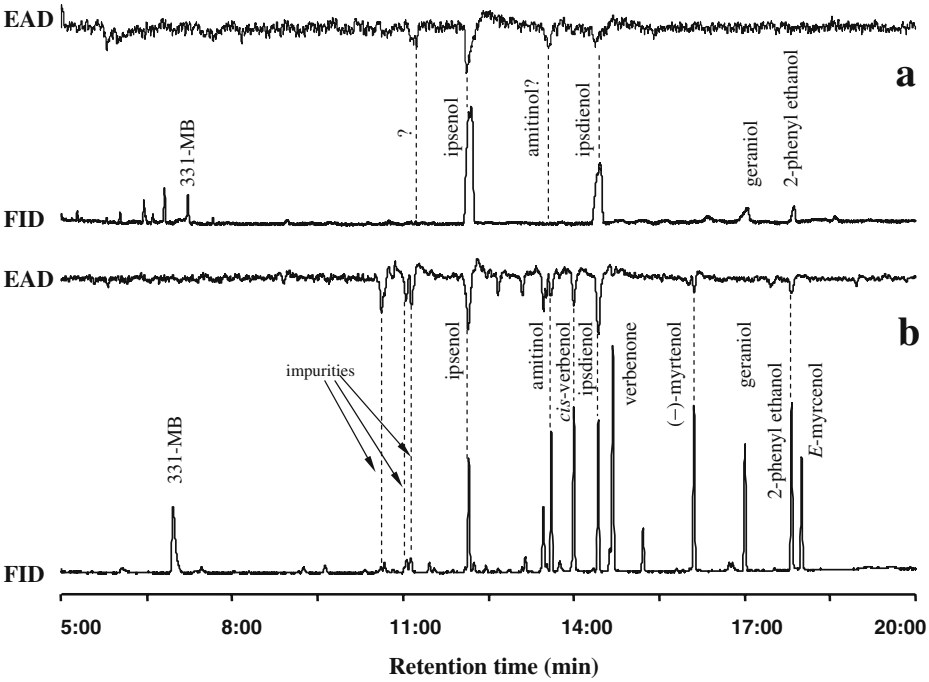

Fig. 1 GC-EAD responses of *Ips subelongatus* antennae to (**a**) hindgut extract of males feeding for 24 hr under the bark of *Larix* logs; ipsenol was ca 20 ng; (**b**) synthetic mixture including 10 major bark beetle related semiochemicals (ca 50 ng/compound); EAD active impurities (probably from ipsenol) were not identified. *Vertical lines* (- - - -) connect FID peaks with repeatable EAD peaks

tentatively identified as amitinol, whereas the other active compound remains unknown. EAD analysis on a synthetic mixture of bark beetle related compounds not only confirmed the strong antennal activities to ipsenol, ipsdienol, and amitinol from the hindgut extract of males, but also showed a significant EAD response to *cis*-verbenol, one of the major aggregation pheromone components of *Ips typographus* L. and several other *Ips* bark beetles (Byers 2004) (Fig. 1b). At the dosage tested (50 ng exposed to the antennal preparation after FID and EAD split), *I. subelongatus* antennae also responded to the minor or trace components of the hindgut extract, (−)-myrtenol and 2-phenylethanol (Fig. 1b), whereas verbenone, an antiaggregation semiochemical for many *Ips* bark beetles, was only weakly active. 3-Methyl-3-buten-1-ol and geraniol, the minor components from the male hindgut extracts and one of the major pheromone components of *I. duplicatus* (Sahlb.), *E*-myrcenol, were antennally inactive (Fig. 1b). In addition, there were some repeatable EAD responses to several unidentified impurities of the synthetic mixture (Fig. 1b). EAD analyses on the headspace sample of the fresh larch log showed strong antennal responses to two major monoterpene hydrocarbons, α-pinene and β-pinene; repeatable responses were also recorded to two minor components, para-cymene and 1-hexanol (Fig. 2). The identities of these EAD active compounds were identified by GC-MS and confirmed by GC-EAD of synthetic mixtures (results not shown). Further GC-EAD analyses on synthetic mixtures of non-host leaf and bark volatiles showed significant antennal responses to green leaf alcohols (C_6-alcohols), linalool, and geranyl acetone from angiosperm leaves, and *E*-conophthorin, C_8-alcohols and benzyl alcohol from the non-host bark (Fig. 3, 4). Other

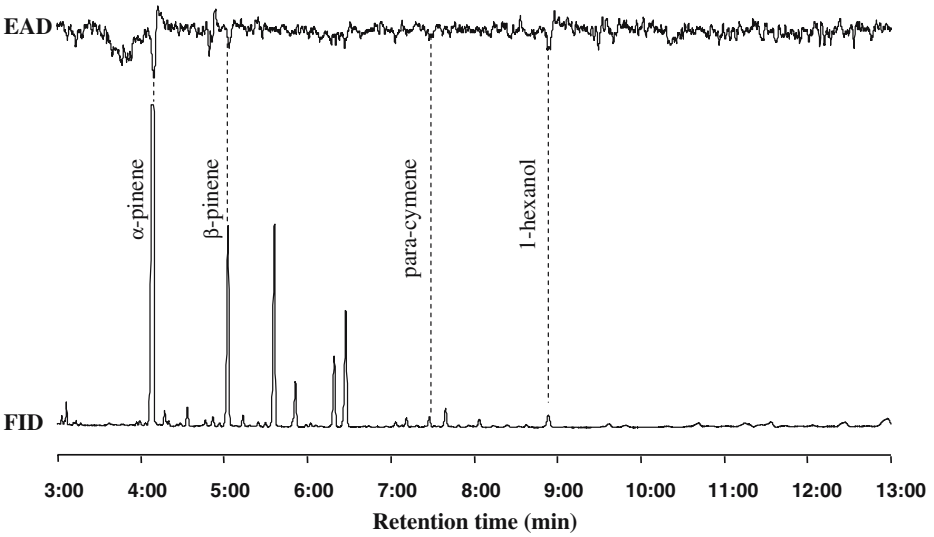

Fig. 2 GC-EAD responses of *Ips subelongatus* antennae to aeration sample of fresh *Larix* sp. host log (α-pinene was ca 140 ng)

common volatiles from angiosperm trees, such as C_6-aldehydes, benzyaldehyde, salicylaldehyde, and *Z*-3-hexenyl acetate were inactive at the dosage tested (Fig. 3, 4). Geranyl acetone and *E*-conophthorin seemed to elicit larger EAD responses than did the other non-host volatiles. No differences in antennal responses between males and females were observed. Results from EAG dose–responses to 3-methyl-3-buten-1-ol indicated that this compound is simply inactive at loading dosages of 10 μg or lower. A weak EAG response was recorded to 100 μg of 3-methyl-3-buten-1-ol, whereas significant antennal reaction was

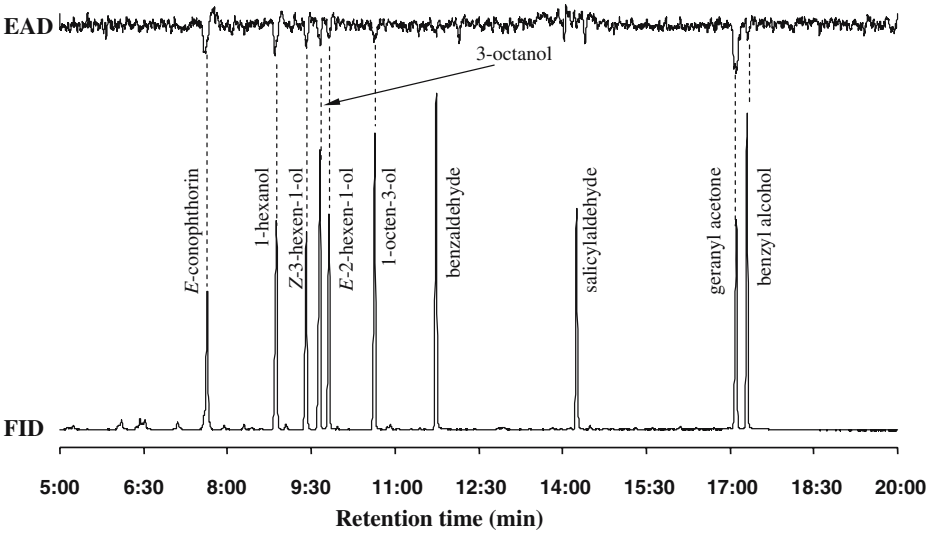

Fig. 3 GC-EAD responses of *Ips subelongatus* antennae to a synthetic mixture of ten non-host leaf and bark volatiles (50 ng/compound). *Vertical lines* (- - - -) connect FID peaks with repeatable EAD peaks

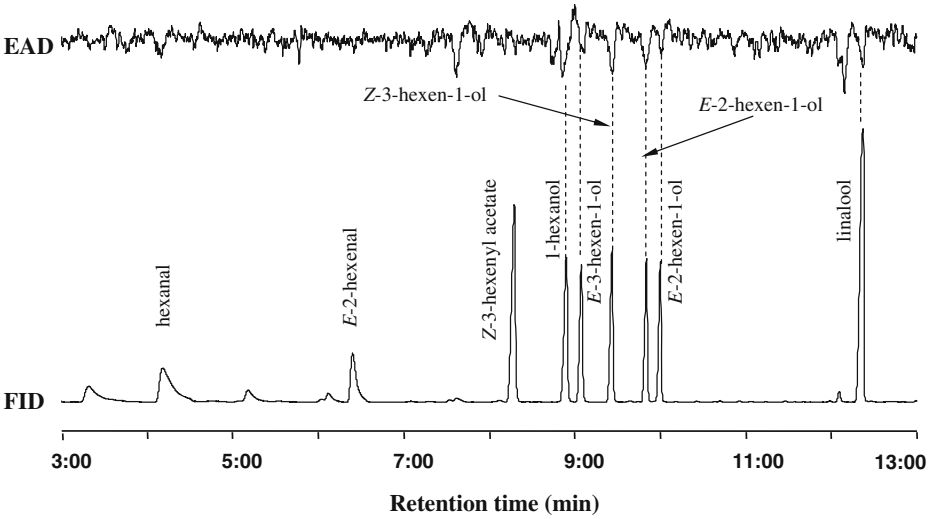

Fig. 4 GC-EAD responses of *Ips subelongatus* antennae to a synthetic mixture of several green leaf volatiles plus linalool (50 ng/compound). *Vertical lines* (- - - -) connect FID peaks with repeatable EAD peaks

observed only at 1 mg (Fig. 5). The EAG response threshold to 3-methyl-3-buten-1-ol seemed to be at least 10,000 times higher than the active standard ipsenol.

Field Trapping In experiment 1, carried out in 2002, a total of 1,153 beetles were caught during 8 replicates. The "natural volatile blend" containing five EAD-active compounds

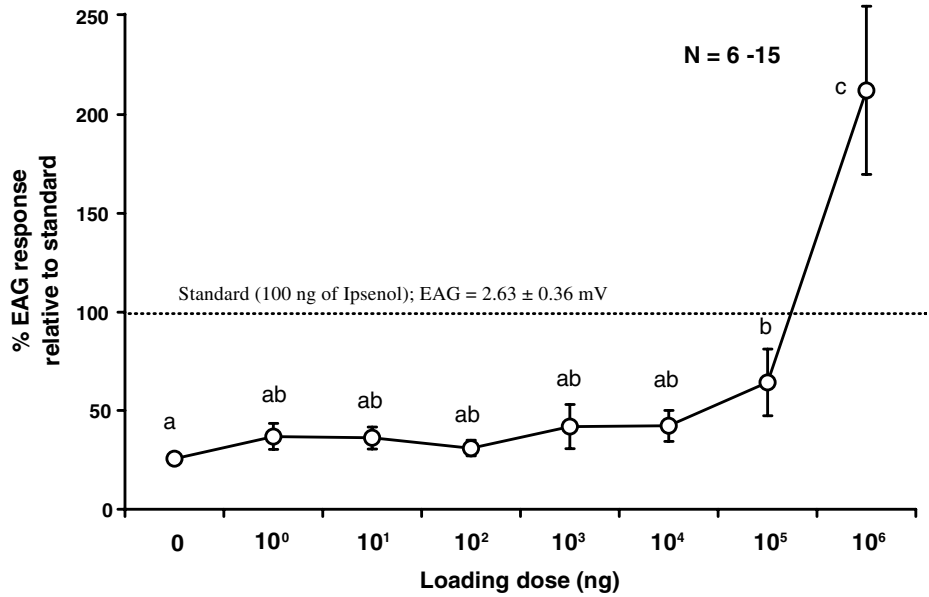

Fig. 5 EAG dose–responses of *Ips subelongatus* antennae to 3-methyl-3-buten-1-ol, one of the reported aggregation pheromone components for this species

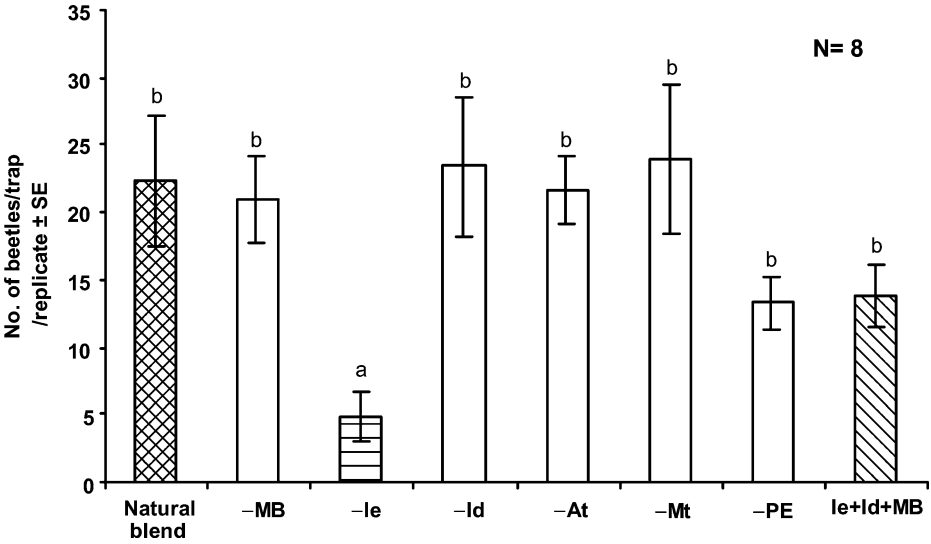

Fig. 6 Subtractive field assay of *Ips subelongatus* in traps baited with a full natural blend [3-methyl-3-buten-1-ol (*MB*), ipsenol (*Ie*), ipsdienol (*Id*), amitinol (*At*), (−)-myrtenol (*Mt*) and 2-phenylethanol (*PE*); mostly EAD-active] and partial blends; Keshiketeng Qi, Inner Mongolia, China, June 20–July 14, 2002. Means followed by the same letter are not significantly different (ANOVA on Log(x+1), REGW multiple Q-test, P>0.05)

plus 3-methyl-3-buten-1-ol identified from the male hindgut extracts was not significantly different from the mixture of the three reported pheromone components for the European *I. cembrae*, ipsenol, ipsdienol, and 3-methyl-3-buten-1-ol. Subtraction of the major component, ipsenol, from the "full blend" significantly reduced the trap catches by 78%, whereas removal of other components had no effect (Fig. 6). There were no significant differences in sex ratios (♀:♂=2.99±0.31:1) among treatments. In experiment 2, a total of 328 beetles were captured during 7 replicates with a mean sex ratio (♀:♂) of ca 2.91± 0.32:1 (no differences among treatments; 95% binomial CI). 3-Methyl-3-buten-1-ol, ipsdienol, or their combination was unattractive at the dosage tested, whereas ipsenol alone was significantly attractive to both sexes of *I. subelongatus*. Ipsenol-containing binary and ternary blends were also attractive, but were not different from the ipsenol (Fig. 7). In experiment 3, 154 beetles were recorded in 7 replicates with a mean sex ratio (♀:♂) of ca 3.12±0.59:1 (no differences among treatments; 95% binomial CI). A mixture of three EAD-active host monoterpenes, α-pinene, β-pinene, and para-cymene was not active at the dosage tested, whereas the mixture of three reported aggregation pheromone components, ipsenol, ipsdienol, and 3-methyl-3-buten-1-ol was attractive (Fig. 8). Addition of amitinol (EAD-active, FID undetected male hindgut extracts) slightly increased the trap catch, but was not statistically significant. Interestingly, addition of either the host monoterpene mixture, *cis*-verbenol, verbenone, or the non-host volatile, geranyl acetone to the active mixture significantly reduced the numbers of *I. subelongatus* captured (Fig. 8). The inhibitory effect by *cis*-verbenol was stronger than that of the other compounds. In experiment 4 carried out in 2003, a total of 1,489 beetles were trapped in 10 replicates with a mean sex ratio (♀:♂) of ca 2.1±0.42:1 (no differences among treatments; 95% binomial CI). Similar to experiment 2, 3-methyl-3-buten-1-ol, ipsdienol, or their combination was

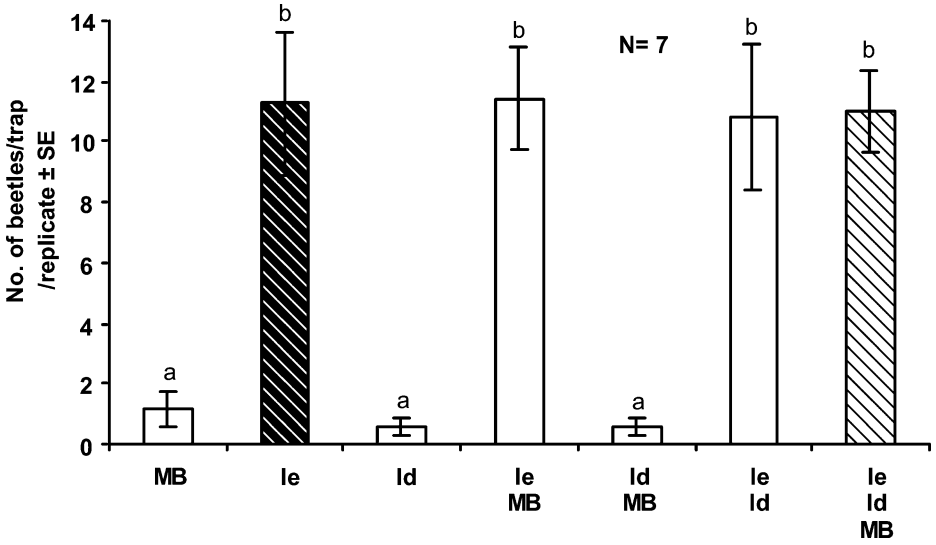

Fig. 7 Full factorial field assay of *Ips subelongatus* in traps baited with reported pheromone components of *I. cembrae*; 3-methyl-3-buten-1-ol (*MB*), ipsenol (*Ie*), or ipsdienol (*Id*) and their binary and ternary blends, Keshiketeng Qi, Inner Mongolia, China, June 20–July 14, 2002. Means followed by the same letter are not significantly different (ANOVA on Log(x+1), REGW multiple Q-test, P>0.05)

simply inactive, whereas ipsenol alone was strongly attractive (Fig. 9). Addition of 3-methyl-3-buten-1-ol, or ipsenol, or both to ipsenol did not increase trap catches. 2-Phenylethanol alone was unattractive and showed no effects on attraction of *I. subelongatus* when added to ipsenol (Fig. 9).

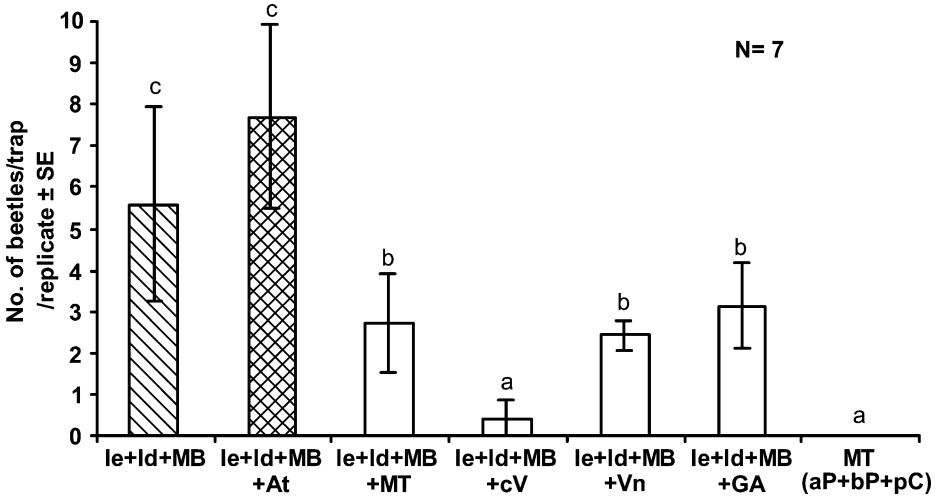

Fig. 8 Additive field assay of five EAD active compounds found from conspecifics, host and non-hosts of *Ips subelongatus* in traps baited with a mixture of three major male-produced compounds: 3-methyl-3-buten-1-ol (*MB*), ipsenol (*Ie*), and ipsdienol (*Id*), and a mixture of three monoterpenes (MT): α-pinene (aP), β-pinene (bP), and para-cymene (pC) was also tested, Keshiketeng Qi, Inner Mongolia, China, June 20–July 14, 2002. Means followed by the same letter are not significantly different (ANOVA on Log(x+1), REGW multiple Q-test, P>0.05)

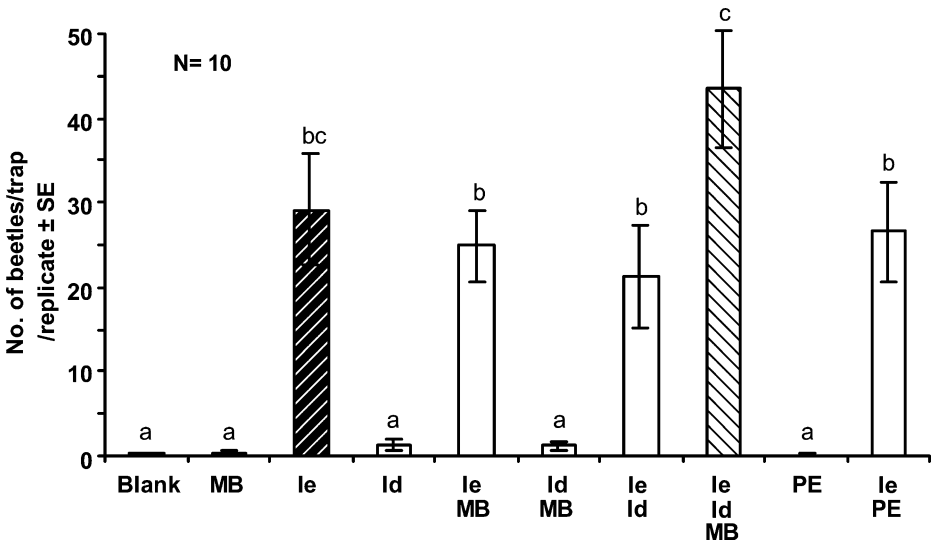

Fig. 9 Full factorial field assay of *Ips subelongatus* in traps baited with the reported pheromone components of *I. cembrae* and their binary and ternary blends, plus 2-phenylethanol (PE) and its combination with ipsenol, Keshiketeng Qi, Inner Mongolia, China, May 30–July 5, 2003. Means followed by the same letter are not significantly different (ANOVA on Log (x+1), REGW multiple Q-test, P>0.05)

Discussion

This is the first detailed electrophysiological study on semiochemicals of the Asian larch bark beetle, *I. subelongatus.* Previously, however, we did report on the enantiospecific antennal responses of several *Ips* bark beetles including *I. subelongatus* (EAD dose–response) to (5*S*,7*S*)-conophthorin, one of the major non-host volatiles from angiosperm trees (Zhang et al., 2002). Present GC-EAD analyses revealed that *I. subelongatus* antennae strongly responded to the male-produced conspecific components, ipsenol, ipsdienol, and two FID undetected compounds from male hindgut extracts, aggregation pheromone components of other *Ips* bark beetles (e.g., *cis*-verbenol), monoterpenes (α-pinene, β-pinene, and para-cymene) and 1-hexanol from host logs (*Larix* sp.), and non-host leaf (i.e., GLVs and geranyl acetone), and non-host bark (i.e., C_8-alcohols and *trans*-conophthorin) volatiles. One of the EAD-active, FID-undetected compounds was tentatively identified as amitinol, whereas the other one remains unknown. Amitinol is a pheromone component of *Ips aminitus* (Eichhoff) (Francke et al., 1980), *Ips tridens* Mannerheim (Poland and Borden, 1997), and *I. cembrae* (Kohnle et al., 1988). Similarly, amitinol was not detected by GC-FID/MSD from *Ips duplicatus* (male hindgut extracts and aeration samples of male-colonized spruce logs), but was identified with the aid of GC-EAD technique, and shown to be a potential aggregation pheromone component for this bark beetle at low release rate (Zhang et al., 2007).

Our field tests showed that ipsenol is the only individual compound that significantly attracts both sexes of *I. subelongatus*, while all other compounds (individuals or in combinations) were unattractive. These results indicate that ipsenol is the key, if not the sole, aggregation pheromone component for the Asian larch bark beetle.

For the European *I. cembrae*, ipsdienol and 3-methyl-3-buten-1-ol were reported as parts of a synergistic mixture together with ipsenol, forming a three-component aggregation

pheromone system (Stoakley et al., 1978; Renwick and Dickens, 1979). It should be noted, however, that the published data in support of the synergistic activity of 3-methyl-3-buten-1-ol is weak. On the other hand, when ipsdienol was left out of the ternary blend, the attraction of *I. cembrae* was totally eliminated (Stoakley et al., 1978). In the current study, the functionality of these two compounds as pheromone components of *I. subelongatus* is not supported. Addition of amitinol at relatively high release to the ternary blend of ipsenol, ipsdienol, and 3-methyl-3-buten-1-ol increased trap catches but not significantly. A weak increase in *I. cembrae* trap catches was also observed in Germany (Zhang and Niemeyer, 1995), whereas Kohnle et al. (1988) indicated a significant enhancement of trap catches with the addition of amitinol at high release to the ternary pheromone blend. The disparate results between these two studies might be due to different amitinol release rates used. In a recent study, addition of a small amount of amitinol to a blend of ipsdienol and (*E*)-myrcenol significantly increased the trap catches of *I. duplicatus* by 47%, whereas addition of amitinol at the high release had no positive or negative effects on the trap catches (Zhang et al., 2007). Another EAD-active and FID undetected compound from the hindgut extracts of *I. subelongatus* males remains unidentified; therefore, its functionality as a potential synergistic aggregation pheromone component cannot be excluded. The natural enantiomeric compositions of ipsenol and ipsdienol from Asian larch bark beetles (*I. subelongatus*) were 100% (*S*)-(−)-ipsenol and 96% (*S*)-(+)-ipsdienol (Zhang et al., 2000), similar to those found from the European *I. cembrae* (Francke and Vite, 1983). The inactivity of racemic ipsdienol in the current study might be due to an inhibitory effect of the unnatural antipode in the synthetic samples. However, no such inhibitory effect was indicated in the synergistic attraction of *I. cembrae* by racemic ipsdienol (Stoakley et al., 1978). On the other hand, we do not know if pure (*S*)-(−)-ipsenol would attract significantly more *I. subelongatus* than did the racemic ipsenol. To fully understand the aggregation pheromone system of Asian *I. subelongatus*, more work is needed to (1) identify the new FID-undetected/EAD-active compound, and (2) field test all the EAD-active compounds including the enantiomerically pure samples of ipsenol and ipsdienol.

cis-Verbenol is one of the two major aggregation pheromone components of the spruce bark beetle, *I. typographus* (Bakke 1976; Schlyter et al., 1987), and this compound virtually blocked the attraction of *I. subelongatus* to the ipsenol-containing attractive blend. Such an inhibitory effect was also reported for the European *I. cembrae* by Kohnle et al. (1988), which might function as an interspecific synomone between these sympatric and closely related species. Verbenone has been shown to inhibit response in over 10 species of conifer bark beetles to attractant-baited traps and trees and to deter attack in the treated conifer stands (see Borden 1997 for details). It also showed a significant inhibitory effect on attraction of *I. subelongatus* to the ipsenol-containing attractive blend. A mixture of the three EAD-active host monoterpenes, α-pinene, β-pinene, and para-cymene, was unattractive to *I. subelongatus*, but instead, the mixture inhibited the attraction to the ipsenol-containing attractive blend at the dose tested. This result suggests no long-range primary attraction to these host volatiles and no positive effect of these host volatiles to the aggregation pheromone in *I. subelongatus*. Addition of α-pinene (Stoakley et al., 1978) and larch logs (Zhang and Niemeyer, 1995) to the aggregation pheromone mixture also did not increase trap catches for *I. cembrae*. Our data and earlier reports support the hypothesis that primary attraction to host volatiles is absent (or very weak) in aggressive bark beetle species, especially *Ips* spp with strong aggregation pheromones (Schlyter and Birgersson, 1999). The inhibitory effect observed in our study might be due to a high release rate of the monoterpenes, which in nature, may be indicative of a vigorous and healthy tree unsuitable

for the bark beetle attack. Geranyl acetone, one of EAD-active non-host volatiles, significantly reduced the numbers of *I. subelongatus* captured when added to the ipsenol-containing attractive blend. Other EAD-active non-host volatiles were not tested in the current study, but their strong inhibitory effect on many other conifer bark beetles (see Zhang and Schlyter, 2004 for details) might suggest a similar function on *I. subelongatus* as well.

In summary, the most striking result of the present investigation was the discovery that *I. cembrae* and *I. subelongatus* respond differently to ipsdienol and 3-methyl-3-buten-1-ol. This result adds new support to the recent phylogenetic finding (Stauffer et al., 2001) that European *I. cembrae* and Asian *I. subelongatus* larch bark beetles are best treated as two distinct species. However, reexamination of the European *I. cembrae* samples with modern techniques such as GC-EAD might provide new understanding of its aggregation pheromone system (Sullivan 2005). From the economical point of view, traps baited with racemic ipsenol alone might be adequate for the purpose of monitoring *I. subelongatus* populations, while a natural synergistic aggregation pheromone blend, including ipsenol and other unidentified (missing) components, may have a stronger potential for mass trapping.

Acknowledgements We thank Zhang, Minghua and Wei, Yanjun from Forest Pest Control Station of Keshiketeng Qi, Inner Mongolia, China for field assistance, and Prof. Wittko Francke, University of Hamburg, Germany for the synthesis of amitinol. Valuable comments by Dr. Jeff. R. Aldrich, CAIBL/USDA/ARS, Beltsville, USA are appreciated. This study was conducted while the first author was supported by grants from the Swedish Council for Forestry and Agricultural Research (SJFR: 24.0293/98), FORMAS (230-2005-1778), and an EU 4fp project ("TATRY", CT 98-0151).

Abstract In *Leucophaea maderae*, male calling behavior involves the release of a sex pheromone from the abdominal sternal glands. An extract of sternal glands attracted conspecific females over a distance. The compounds present were identified as hydroxy-3-butan-2-one, (2*R*, 3*R*)-butanediol, senecioic acid, and (*E*)-2-octenoic acid. The same components are also present in male tergal glands. The identified compounds were tested on their own and in mixtures. Their biological function is discussed.

Keywords Cockroach · Dictyoptera · Blaberidae · *Leucophaea maderae* · Hydroxy-3-butan-2-one · (2,3)-Butanediol · 3-Methyl-2-butenoic acid · Senecioic acid · (*E*)-2-Octenoic acid · Sex pheromone · Sexual behavior

Introduction

In their observations on the mating behavior of *Leucophaea maderae*, Roth and Willis (1954) and Roth and Barth (1964) noted that virgin females did not seem to produce any sex pheromones that attracted males over a distance. A few years later, Barth (1968) found that the whole extracts of males were attractive to conspecific females. Later, Sreng (1984) showed that the male adopts a characteristic calling behavior and emits a sex pheromone from the sternal abdominal glands, which attracts females over a distance. Once both sexes are in antennal contact, the male raises its wings, revealing its tergal glands, which are covered with proteinaceous secretions (Korchi et al., 1998). The female then climbs onto the male's back to feed on this secretion. As a consequence of this behavior, the female is in the proper position for copulation.

Male volatile pheromones that function as attractants for females are relatively rare among cockroaches. The Madera cockroach, *L. maderae*, and the lobster cockroach, *Nauphoeta cinerea*, belong to the Oxyhaloinae, a small subfamily in which mating behavior is initiated by the emission of a male volatile sex pheromone secreted by the sternal glands (Sreng, 1979, 1984). The composition of the pheromone of *N. cinerea* was elucidated in our laboratory (Sreng, 1990; Sirugue et al., 1992). It is a multicomponent blend with three biologically active compounds: 2-methylthiazolidine, 4-ethylguaiacol, and hydroxy-3-butan-2-one. This secretion may also function in sexual selection and mate choice by the female (Smith and Breed, 1982; Schal and Bell, 1983; Moore, 1989, 1990, 1997; Moore and Moore, 1999; Moore et al., 2001).

In this paper, we report on the identification of compounds in the male tergal and sternal glands of *L. maderae* and the behavioral role of the identified compounds. These results are compared to those obtained from *N. cinerea*.

Methods and Materials

Insect Colonies of cockroaches were reared in glass aquaria (40×25×25 cm) maintained at a constant temperature of 26±2°C and 70% relative humidity under a reversed 12:12 photoperiodic cycle. Dry dog food and water were provided ad libitum.

Adults of both sexes, used in the bioassays, were randomly isolated from stock colonies at adult ecdysis. To avoid any mechanical or olfactory stimuli between the sexes, males and females were isolated in plastic boxes (9×6×2 cm) containing food and water. Each sex was kept in a separate room under the same rearing conditions.

Preparation of Extracts Isolated males and females (20 days old) were cooled for a few minutes at −20°C before being used 2–3 h after the beginning of the dark period. This age corresponds to the sexual maturity of adult males and females, whereas the diel period for testing corresponds to peak male calling activity of this species (Sirugue, 1992).

For gas chromatographic (GC) analyses and quantification, all the abdominal sternites and tergites of each adult were dissected rapidly with microscissors and forceps. After removing the adjacent tissues (fat body, hemolymph) with a paper towel, the sternites and tergites were placed individually into vials containing 4 ml of distilled CH_2Cl_2 and 10 μg of 2-phenylethanol as an internal standard. The tissue was allowed to extract for 3 h at room temperature, after which it was removed, and 500 μl of the extract decanted into a 2-ml vial. Extracts were kept at −20°C until analyzed.

Chemical Analysis GC analyses were performed with a CP 9000 Chrompack GC fitted with a flame ionization detector. A SPB™1701 fused silica capillary column (30 m×0.25 mm ID, 0.25 μm film thickness, Supelco, Bellefonte, PA, USA) was used for analyses. After concentration of the extract to about 10 μl, by gentle nitrogen flow, 2 μl of sample was injected into an injector operating in the splitless mode. The column was held isothermally at 40°C for 2 min, then programmed at the rate of 20°C/min for 1 min, 2°C/min to 150°C, and then 10°C/min to 250°C. Hydrogen was used as carrier gas (50 cm/s velocity at ambient temperature). The injector and detector temperatures were 260 and 280°C, respectively.

The stereochemical configuration of 2,3-butanediol was determined by retention time comparisons of the authentic standards on a Beta Dex 120 fused silica capillary chiral column (30 m × 0.25 mm ID, 0.25 μm film thickness, Supelco). GC conditions were as

previously described except that the column oven was programmed from 40 to 220°C at a rate of 5°C/min.

Gas chromatography-mass spectrometry was carried out with a Nermag R 10-10 C quadrupole mass spectrometer coupled with a Hewlett-Packard 5890 GC. The GC conditions were the same as those described above. The column was connected directly to the ion source of the spectrometer through a heated transfer line maintained at 260°C. Electron impact mass spectra were obtained at 70 eV with a 0.8-s cycle, with a source temperature of 150°C.

Compounds were identified by comparing spectra to those in the EPA/NIH (Heller and Milne, 1978), NIST/EPA/MSDC (Lias and Stein, 1990), and FLAVIC laboratory (INRA, Dijon, France) libraries. Identification of all compounds was performed by analyzing the natural products and their synthetic counterparts under the same conditions on the SPB™1701 column. The detector response factor was determined for each of the identified compounds by using 0.5, 1, 5, and 10 μg of pure chemical and used in the quantitative analyses of 10 individual males and 10 individual females.

Commercial Compounds Hydroxy-3-butan-2-one (acetoin), (2*R*, 3*R*)- and (2*R*, 3*S*)-butanediol were a gift from INRA (Dijon, France); (2*S*,3*S*)-butanediol was bought from Extrasynthèse (Geray, France), 2-phenylethanol and (*E*)-2-octenoic acid from Interchim (Montluçon, France), and 3-methyl-2-butenoic acid (senecioic acid) from Ega-Chemie (Lyon, France). All chemicals used were greater than 98% purity as determined by capillary GC analysis.

Bioassays (Y-maze olfactometer) The olfactometer was a glass tube (2 cm ID.) with a 40-cm-long common arm, dividing into two 30-cm-long choice arms, A and B (70° angle between the two choice arms). Individuals were placed separately in a test box (6×9×5 cm) for at least 2 h before each test. The box had a screen door that could be raised to allow the insect to enter the common arm at the starting point. An air stream (10 ml/s) conveyed the chemical stimulus through arm A or B to the common arm and to the "starting box" containing the insect. Each insect was tested once for 5 min. If an insect did not respond within this period, the test was stopped. The olfactometer was cleaned with CH_2Cl_2 after each test. All observations were performed between the second hour and sixth hour of the scotophase under a dim red light. Which of the two test arms the insect entered was recorded, or if the insect did not enter the common arm of the olfactometer, it was recorded as a nonresponder. The data were compared by using a binomial test according to Parker (1979). Each test was replicated 30 times using different insects.

In order to prove the existence of a male sex pheromone that attracts females over a distance, various olfactory stimuli were tested on sexually mature virgin females (20 days old): one mature virgin male (20 days old)/air, one mature virgin female (20 days old)/air, and various concentrations of male sternal gland extracts (1 to 10^{-3} male equivalent)/air. A control test (2 μl CH_2Cl_2/air) was carried out in order to check that there was no bias by the insects to one of the arms when no stimulus was present. The chemical extracts were deposited on a folded filter paper (2 cm^2), the solvent was allowed to evaporate, and the filter paper was placed at the opening of one of the choice arms (alternatively, A or B). Because the tergal glands are not involved in long-range attraction (Sreng, 1984), and their chemical composition is identical to that of the sternal secretion (see results), their extract was not tested.

In a second series of experiments, we tested various concentrations of the compounds. The experiment was conducted as described above. First, each component was tested

individually at the following concentrations: hydroxy-3-butan-2-one (H3B2) (0.1, 0.5, 1, 5, 10, 100, and 500 ng, 1 μg), (2*R,* 3*R*)-butanediol [(2,3)-BUT)] (0.1, 10, 100, 150, and 400 ng, 1 μg), senecioic acid (SENE Ac) (0.1, 1, 10, and 100 ng, 1, 2.8, and 7 μg), and (*E*)-2-octenoic acid [(*E*)-2-OCT Ac] (0.1, 1, 10, 100, 200, and 100 ng). Second, various mixtures, based on the concentration of each component in 10^{-1} male equivalent (10^{-1} ME; 20 days old) were tested: H3B2/(2,3)-BUT (380/160 ng), H3B2/SENE Ac (380/2,800 ng), H3B2/(*E*)-2-OCT Ac (380/100 ng), and H3B2/(2,3)-BUT/SENE Ac/(*E*)-2-OCT Ac (380/160/2,800/100 ng).

Results

Chemical Identification A typical GC trace of the sternal gland extract of adult males revealed the presence of four major components, which represented more than 95% of the volatile portion of the extract (Fig. 1). Comparable GC traces were obtained from male tergal gland extract. None of these compounds was detected in tergal and sternal gland extracts of females although a number of minor, unidentified peaks were common to both male and female extracts. Based on their mass spectra, the four major compounds in male extracts were identified as hydroxy-3-butan-2-one (MW 88), (2, 3)-butanediol (MW 90), 3-methyl-2-butenoic acid (senecioic acid; MW 100), and (*E*)-2-octenoic acid (MW 142). (2, 3)-Butanediol consisted of more than 99% of the (2, 3) enantiomer, and only traces of the other enantiomeric forms of the molecule were found (see methods).

The amount of each compound (mean±SEM) in the extract varied with individuals and glandular origin. In the sternal glands, all compounds were abundant: hydroxy-3-butan-2-one (3,794±239 ng), (2*R*, 3*R*)-butanediol (1,626±93 ng), senecioic acid (28,209±613 ng), and (*E*)-2-octenoic acid (1,002±22 ng). In the tergal glands, the compounds were found in

lesser quantities: hydroxy-3-butan-2-one (480.2±46.9 ng), (2*R*, 3*R*)-butanediol (51.3± 11.6 ng), senecioic acid (230.8±49.9 ng), and (*E*)-2-octenoic acid (5.3±0.8 ng).

Bioassays The results are shown in Table 1. With the solvent control, about 87% of the females entered the common arm of the olfactometer and distributed randomly between the two choice arms. When the stimulus was a live male or female, all the females entered the olfactometer. Females were not attracted to a female, but were significantly attracted to a conspecific male, compared to the blank choice arm. For most concentrations of male sternite extract tested, females significantly preferred the arm of the olfactometer containing the extract over the blank arm. At concentrations of 10^{-2} to 1 ME, 73 to 81% of females that entered the common branch preferred the arm containing the male extract to the blank arm. There was no significant preference of females to male extract at a concentration of 10^{-3} ME, suggesting that this concentration is around the threshold of the female perception of the male pheromone.

The most volatile component of the male pheromone, hydroxy-3-butan-2-one, was attractive to females when tested at concentrations from 0.1 to 1 ng (Table 2); 69 to 81% of the females that reached the intersection of both choice arms preferred the arm containing hydroxy-3-butan-2-one. Although 83 to 97% of the females reached the common arm when various concentrations of (2*R*, 3*R*)-butanediol were tested, this component was not significantly attractive at any of the concentrations tested (Table 3). Ninety to 93% of the females tested entered the olfactometer when various concentrations of senecioic acid were used (Table 4); however, only the highest amount (7 μg) tested was significantly attractive.

(*E*)-2-Octenoic acid was not attractive to the females at any of the concentrations tested (Table 5).

When four mixtures of the compounds were tested, only two were significantly attractive (Table 6): the binary mixture of hydroxy-3-butan-2-one/senecioic acid and the quaternary mixture. A number of females entered the common arm of the olfactometer when (2*R*, 3*R*)-butanediol or (*E*)-2-octenoic acid was added to hydroxy-3-butan-2-one. However, when the insects arrived at the intersection of the two arms, the females preferred the air stimulus, suggesting that the mixtures were repellent at a close distance.

Discussion

Cockroaches rely on pheromones for many aspects of reproductive behavior, especially for attraction of a sexual partner over a distance (Roth and Willis, 1954; Barth, 1968). In all the species of cockroaches studied, the emission of a sex pheromone by males or females is associated with a "calling" posture of the emitter (Willis, 1970; Schal and Bell, 1985; Sreng, 1993). The existence of sex pheromones attractive over a distance has been demonstrated in about 16 species (reviewed in Gemeno and Schal, 2004). However, the chemical identity of the attractants has been elucidated only for a limited number belonging to four families: Blattidae (Persoons et al., 1990; Farine et al., 1993, 1994; Nishii et al., 1997), Blattellidae (Nishida et al., 1976, 1979; Schal et al., 1990; Charlton et al., 1993; Nojima et al., 2005), Blaberidae (Sreng, 1990; Sirugue et al., 1992), and Cryptocercidae (Le Quéré et al., 1991). Generally, it is males that are attracted to a sex pheromone emitted by conspecific females (Willis, 1970; Moore and Barth, 1976; Schal, 1982; Schal and Bell, 1985; Abed et al., 1993b,c; Liang and Schal, 1993) but, in some Blattinae (Abed et al.,

1993a), Polyzosteriinae (Farine et al., 1993, 1994), and Oxyhaloinae (Sreng, 1990; Sirugue et al., 1992), it is the male that emits the sex pheromone.

The courtship behavior of *L. maderae* is similar to that of *N. cinerea* (Roth and Barth, 1967). Male *L. maderae* possess a well-developed glandular epithelium lying under the whole area of sternites 2 to 7 (exposed during calling) and tergites 2 to 8 (exposed during the wing-raising posture) (Sreng, 1984). Additionally, the middle part of tergite 2 shows a cuticular excrescence under which several layers of glandular cells are observed (Sreng, 1984). In male *N. cinerea*, the glandular cells are found under sternites 3 to 7 and tergites 2 to 8, whereas the *L. maderae* glandular modification is absent (Sreng, 1984).

In *N. cinerea*, the pheromone is released from the sternal glands. The secretion is a mixture of hydroxy-3-butan-2-one, 2-methylthiazolidine, 4-ethylguaiacol, (2*R*, 3*R*), and (2*R*, 3*S*)-butanediol (Sreng, 1990; Sirugue et al., 1992). Sirugue et al. (1992) showed that all these components are present in lower quantities in the tergal secretion and that 4-ethylguaiacol and 2-methylthiazolidine attract females at very low dosages (0.05 and 0.01 ng, respectively). Quantities of 2-methylthiazolidine and 4-ethylguaiacol increase gradually in males, reach a maximum at 15–20 days, and then decline (Moore et al., 1995). Variation in pheromone quantity with age parallels the age-related attractiveness of males to females, male sexual competence, and male agonistic behavior (Moore and Moore, 1999; Moore et al., 1997, 2001). Hydroxy-3-butan-2-one attracts virgin females at a dosage of 100 ng but appears to repel them at a dosage of 1 μg (Sirugue et al., 1992). Moore et al. (1995) found that the amount of hydroxy-3-butan-2-one increases in males up to age 10–15 days and is then maintained at a relatively constant level, suggesting that this component might have a different role from that of the other compounds.

In *L. maderae*, hydroxy-3-butan-2-one and senecioic acid are the main components of the sex pheromone. Hydroxy-3-butan-2-one is attractive to females when used at low dosages (0.1 to 5 ng), whereas senecioic acid is only attractive at very high dosages (7 μg).

Table 6 Y-maze olfactometer: number of females of *L. maderae* (n=30) attracted to various mixtures containing hydroxy-3-butan-2-one (H3B2), (2*R*, 3*R*)-butanediol [(2, 3)-BUT], senecioic acid (SENE Ac), and (*E*)-2-octenoic acid [(*E*)-2-OCT Ac] or air

Nonresponding Insects (n)	Stimulus A				Stimulus B			P
	H3B2	(2,3)-BUT	SENE Ac	(*E*)-2-OCT Ac	Number		Number	
2	380 ng	160 ng	–	–	11	Air	17	0.172
2	380 ng	–	2.8 μg	–	23	Air	5	<0.001
3	380 ng	–	–	100 ng	10	Air	14	0.124
0	380 ng	160 ng	2.8 μg	100 ng	23	Air	7	0.003

Considering the large amount of the latter compound detected in the sternal glandular epithelium (about 30 μg per male), it is possible that it is emitted in high amounts by a calling male. (2*R*, 3*R*)-Butanediol and (*E*)-2-octenoic acid did not attract females when tested on their own and negated the attractiveness of hydroxy-3-butan-2-one when added to it in binary mixtures.

As noted for *N. cinerea*, the behavioral role of (2,3)-butanediol is unknown. One possibility is that it is a precursor of hydroxy-3-butan-2-one in the sternal glands of both species and is synthesized by partial oxidation of (2,3)-butanediol (Bauer et al., 1990). Alternatively, hydroxy-3-butan-2-one and (2,3)-butanediol could be simultaneously produced by fermentation of glucose by bacteria and fungi (Mac Faddin, 1980; Gottschalk, 1986).

In laboratory conditions, sexually excited cockroach males may court females of other species, but successful interspecific mating never occurs. Interspecific attraction of males by female sex pheromone has been reported only in the genera *Periplaneta* and *Blatta* (Simon and Barth, 1977). Structural similarity of the sex pheromones (periplanones) among *Periplaneta* species and *Blatta orientalis* has been demonstrated using bioassays of synthetic and isolated pheromones (Seelinger, 1985; Takahashi et al., 1988, 1995; Takegawa and Takahashi, 1989; Nishii et al., 1997). Colonies of *L. maderae* and *N. cinerea* can be kept together without any interspecific mating (Everaerts et al., 1997). Olfactometer tests have shown that females of either species are not attracted to males of the other (Sirugue, 1992). Hydroxy-3-butan-2-one may play a role in this lack of cross attraction. This chemical is attractive to *L. maderae* at low dosages (0.1 to 5 ng) and attractive to *N. cinerea* at higher dosages (100 ng) (Sirugue et al., 1992). Other chemicals could contribute to the specificity of the respective pheromones when the female is closer to the male (e.g., senecioic acid for *L. maderae*, 2-methylthiazolidine and 4-ethylguaiacol for *N. cinerea*).

During courtship, males of both *L. maderae* and *N. cinerea* display two successive postures: the first, a calling posture when the sex pheromone is released, and the second, after antennal contact with a conspecific female, a wing-raising posture in which the tergal glands are exposed (Roth and Willis, 1954; Sreng, 1993). The tergal secretions are complex mixtures usually considered as "aphrodisiacs" (Brossut et al., 1975). As found in other species of cockroaches, there are exocrine proteins in the cuticular waxes (Abed et al., 1995; Korchi et al., 1998), but little is known about their function (Cornette et al., 2001, 2002, 2003). In both species, the identified volatile components of the tergal glands are the same as those found in the sternal gland. These volatile chemicals could enhance the effect of the aphrodisiac secretions, eliciting the female to climb on to the male's back.

Aggressive behavior, dominant–subordinate relationships, hierarchy, and territoriality in males are well-known behaviors in various species of cockroaches (Ewing, 1972, 1973; Simon and Barth, 1977). All these behaviors have been extensively studied in male *N. cinerea* (Ewing, 1972; Ewing and Ewing, 1973; Bell et al., 1979; Breed et al., 1980; Sirugue et al., 1992). Male dominance hierarchies and territoriality are mediated by chemical signals, and these signals are also involved in female mate choice (Smith and Breed, 1982; Schal and Bell, 1983; Moore, 1989, 1990; Sreng, 1990; Moore et al., 1995; Everaerts et al., 1997). Moore et al. (1995) demonstrated that female *N. cinerea* preferred dominant males to subordinate ones and further showed that the sternal gland of dominant males contained less sex pheromone than that of subordinate males. They hypothesized that dominant males "bully" subordinates to prevent them from releasing pheromone and having access to females. Additionally, Moore and Moore (1999) showed that female choice is

based solely on the amount of hydroxy-3-butan-2-one. As stated previously, *N. cinerea* and *L. maderae* belong to the small subfamily Oxyhaloinae, and aggressive behavior between males exists in both species (Bell et al., 1979). It would be interesting to determine if hydroxy-3-butan-2-one is multifunctional in *L. maderae*, mediating pheromonal attraction, dominant/subordinate relationships between males, and mate choice by females.

Abstract The genes of the major histocompatibility complex (MHC) are highly polymorphic loci that encode cell surface proteins, class I and II molecules. They present peptide antigens to T cells and thereby control immunological self/nonself recognition. Increasing evidence indicates that MHC genes also influence odor and mating preferences; however, it is unclear how. Here we report the results of chemical analyses of male mouse urinary odors collected from a variety of mouse strains, including MHC-congenics, recombinants, mutants, and transgenics (i.e., β2 microglobulin "knockouts," which lack class I expression, and transporters associated with antigen processing (TAP) knock-outs). After the identification of volatile odor components by gas chromatography/mass spectrometry, the odor profiles of urine samples were analyzed quantitatively by using stir bar sorptive extraction and gas chromatography/atomic emission detection. Results showed that MHC genes influenced the amounts of testosterone-mediated pheromones, sulfur-containing compounds, and several carbonyl metabolites. This is the first report to quantitatively link known mouse pheromones to classical, antigen-binding MHC loci. Surprisingly, these compounds were not influenced by TAP genes, even though these loci are MHC-linked and play a role in peptide presentation. Whereas identification of MHC-determined odorants does not reveal their metabolic origin, some constituents were also present in blood serum, and their levels were not altered by antibiotics.

Introduction

Since the discovery that odor and mating preferences are influenced by the genes of the major histocompatibility complex (MHC or H-2 in mice) in house mice (*Mus musculus domesticus*) (Yamazaki et al., 1976), several additional laboratories have found evidence for these effects (reviewed in Penn and Potts, 1998a, 1999; Penn, 2002; Beauchamp and Yamazaki, 2003). Using a Y-maze olfactometer, it was found that trained mice can discriminate among the odors of urinary samples from mice that differ genetically only in the MHC region (MHC-congenic strains) (Yamaguchi et al., 1981; Yamazaki et al., 1983; Penn and Potts, 1998b). In more recent experiments, untrained mice were able to distinguish among the odors of mouse strains that differed genetically only at a single MHC locus (Penn and Potts, 1998b; Carroll et al., 2002). Several studies now suggest that the MHC-dependent mating preferences are not confined to mice because MHC effects have been implicated in mating preferences of fish, lizards, birds, and even humans (reviewed in Penn, 2002). It has been postulated that this mating preference functions to increase the resistance of an individual's offspring to infectious diseases, either by increasing (or optimizing) MHC-heterozygosity or by providing a "moving target" against rapidly evolving pathogens (Penn and Potts, 1999). Another possibility is that MHC similarity (used to recognize kin) and disassortative mating preferences function to avoid inbreeding (Brown and Eklund, 1994). Indeed, female mice are more likely to retrieve MHC-similar than dissimilar pups, which supports the kin-recognition hypothesis (Yamazaki et al., 2000). A great deal of evidence indicates that MHC genes influence urinary odor, and a number of mechanisms have been suggested to explain how this occurs (Penn and Potts, 1998a; Beauchamp and Yamazaki 2003). Using state-of-the-art analytical methodologies, the goal of our studies has been to identify and quantitatively measure the major volatile components of urine that are influenced by MHC genes.

As an extension of our previous work, we examined urinary odors of male house mice (*M. musculus domesticus*). Mice use urine to scent-mark, and their urine is a rich source of biological signals, including primer and releaser pheromones (reviewed in Novotny et al., 1999a; Novotny, 2003). Urine confers information such as gender and endocrine status, which is perceived through the main and accessory olfactory senses (Leinders-Zufall et al., 2000; Sam et al., 2001). Mouse pheromones are relatively small and hydrophobic molecules, and MHC-mediated odorants may also fall into the same category. A number of studies indicate that the MHC-dependent odors are volatile compounds (reviewed in Penn and Potts, 1998a). MHC-dependent odorants may be either (a) direct degradation products of MHC molecules and/or peptides; (b) secondary metabolites of biochemical pathways moderated by the MHC; (c) the result of MHC-specific communities of microbial flora (the so-called microflora hypothesis; Howard, 1977; Schellinck et al., 1991); or (d) some combination of these mechanisms, e.g., metabolic products from microflora degradation of MHC-molecules or peptides (Penn and Potts, 1998a).

The physiological fluids of mammals contain complex mixtures of structurally varied metabolites, and their volatile constituents can be analyzed by combined capillary gas chromatography/mass spectrometry (GC/MS). This approach was used in the first studies characterizing the urinary constituents of mice from different strains (Novotny et al., 1980; Schwende et al., 1984, 1986). These studies established that (a) mouse urine contains a number of structurally unique substances; (b) substantial quantitative differences in the volatile substance profiles can be observed among strains; and (c) if any quantitative differences are caused by MHC, they should be relatively minor in comparison to differences influenced by non-MHC (background) genes.

The first bioanalytical study to statistically evaluate the volatiles' profiles of congenic mice found a correlation between the MHC genetic relatedness and chromatographic profiles of urine (Schwende et al., 1984). It seemed that a pattern, or a ratio of several components (ubiquitous urinary metabolites), rather than single components were primarily responsible for the MHC discrimination. A later study (Eggert et al., 1996) also used GC profiling to distinguish more general (multiple gene controlled) strain- and more narrowly controlled MHC-related differences. Singer and coworkers (1997) examined acidic metabolites, arguing that the acidic products of metabolism are far more common than neutral ones and thus more likely to be involved in the MHC signaling. Whereas their profiles of acids in male mouse urine contained 32 major constituents, only seven substances were identified, with one (phenylacetic acid) deemed important. Furthermore, they only examined MHC-congenic strains, which differ at many genes in the MHC region and, therefore, it is unclear whether these acidic compounds were influenced by MHC class I and II antigen presenting loci. In a radically different technical approach, it was shown that a set of semiconductor sensors (the so-called "electronic nose") could distinguish between the odors (from urine and blood serum) of different MHC congenic mouse strains and mutants (Montag et al., 2001). Headspace analysis by GC/MS in the same study identified only a limited number of compounds, and was not supportive of the importance of organic acids. Recently, Willse and coworkers (2005) used two-dimensional GC with MS detection and chemometric analyses to investigate differences between two congenic strains (carrying *b* vs. *k* haplotypes on C57BL/6J background) and suggested that approximately 80 compounds may differ (with 23 compounds being identified). Among these identified compounds, there were two previously known volatile chemosignaling compounds with proven pheromonal activities (Novotny et al., 1999a,b; Novotny, 2003).

Whereas no investigation to date has identified an allele- or haplotype-specific compound or a set of such substances (i.e., those that would be present in one haplotype and absent in another), some previous investigations allude to the possibility of specific ratios or "patterns" of volatiles. To examine the hypothesis that variations in odor are mainly of a quantitative nature (Schwende et al., 1984), it is necessary to measure the odor profiles with sufficient precision to detect small but biologically significant differences in concentrations. Our results here provide such quantitative data for a group of known mouse chemosignaling compounds. For the study, we used an element-specific coupled GC–atomic emission detector system (GC-AED) (carbon-, sulfur-, and nitrogen-specific lines) to obtain quantitative profiles of urinary volatiles. Additionally, AED provided the necessary precision for the minute quantities of sulfur compounds, without interference from other urinary constituents. Nitrogen line signals also supported the previous identifications of the nitrogen-containing compounds by GC-MS.

Methods and Materials

Experimental Animals Male mice of seven different strains with B6 and B10 backgrounds were purchased at 5–6 weeks of age (Jackson Laboratory, JAX Research Systems, Bar Harbor, ME, USA). To identify the odors that are influenced by MHC genes and control effects from background genes, we used MHC congenic mouse strains because the only consistent genetic differences among these strains are in the MHC region. For example, strain C57BL/10J (B10 background) carries the *b* haplotype (H-2^b), whereas its congenic strain, B10.D1-H2<q>, carries the *q* haplotype (H-2^q). We also used recombinant, mutant,

and knock-out transgenic strains to examine effects from classical MHC loci. The mouse strains used in this study are summarized in Table 1. One of the B6 strains was a mutant bm1 (B6.bm1) with a small spontaneous mutation in two amino acids in the peptide-binding region encoded by a single class I locus (Carroll et al., 2002). One of the B10 strains (B10.A) was a recombinant strain differing from B10.BR by one class I locus. Additionally, two congenic BALB strains with *b* and *k* haplotypes were included to compare strains of different background with the same MHC haplotype. Finally, two mutant strains of C57BL/6J were added to compare the animals that lack MHC class I expression or the assembly of MHC class I molecules (β2 microglobulin "knockouts"). The mice were housed individually in polypropylene cages with opaque sides and fitted wire lids (cage size: 29×18×13 cm). Wood-shaving bedding (Sani-chips, P.J. Murphy Forest Products, Montville, NJ, USA) was changed once a week. Food (Lab Diet for mice, PWI Nutrition International, Brentwood, MO, USA) and water were provided *ad libitum*. The animal room was maintained at 21–22°C, 70% relative humidity, and 12-hr light/12-hr dark lighting regime, with lights on at 0600 hours.

Urine Collection Urine samples were collected at 9–10 weeks of age. Mice were placed in a polycarbonate cylindrical urine-collecting apparatus (22 cm diameter×19 cm height) from 0900 hours for 2–4 hr. The urine collection apparatus has partitions that divide the area equally into five sectors to collect urine from five different mice simultaneously without mixing the samples. The bottom of the urine-collecting apparatus was made of a wire mesh. A plastic strip was laid beneath the urine collection apparatus, and the strip was checked every 5 min, while urine (total of at least 2 ml volume) was collected using a Pasteur pipet. The collected urine was placed in an Eppendorf tube, kept frozen using dry ice, and subsequently kept at −70°C until it was chemically analyzed. The strip was

[b] B6.*Tap1* mice are mutants of B6.6J strain. They are defective in the stable assembly and intracellular transport of class I molecules, showing severely reduced levels of class I surface molecules

[c] B6.*B2m* mice are mutants of B6.6J strain. They have little if any MHC class I protein expression on the cell surface

replaced whenever a sufficient urine volume (2 ml) was collected to avoid stale urine and contamination of samples from adjacent collection sectors.

Antibiotic Treatment After the initial collection of samples was completed, the effect of antibiotic treatment on the urinary volatile profiles was investigated (two additional sample collections). After the first collection of urine, half of the animals went through antibiotic treatment (experimental group). The other half served as control mice and went through the collection of urine again at the same time as the experimental group. For the experimental group, tetracycline was added to the drinking water of each mouse (1.3 g/l). Sugar was added to the tetracycline-treated water (2.6 g/l) to mask the bitter taste. The control group received sugar water only. Urine was collected from mice (and controls) 1 week after they started to receive tetracycline-treated water. Urinary volatile constituents were compared before and after the antibiotic treatment.

Blood Collection After all urine collections were completed and after a further 4 weeks for antibiotic clearance, the animals were anesthetized using tribromoethanol. Blood was collected directly from the heart using a 25G 1/2-in needle and a 1-ml syringe. The blood collected was centrifuged at ca. 2,000 rpm for 20 min, and the serum was removed and frozen on dry ice. The frozen serum was kept at −70°C until it was analyzed. The experimental procedure and housing conditions were approved by the Bloomington Institutional Animal Care and Use Committee of Indiana University.

Reagents and Analytical Methods All compound identifications were verified through authentic standards purchased from Aldrich (Milwaukee, WI, USA) or synthesized in our laboratory according to the previously described synthetic methods (Wiesler et al., 1984; North and Pattenden, 1990; Novotny et al., 1999b). Stir bars (Twister™, 10 mm, 0.5 mm film thickness, 24 μl polydimethylsiloxane volume) used for sorptive extraction were purchased from Gerstel GmbH (Mülheim an der Ruhr, Germany). Volatile and semivolatile compounds were extracted from 0.5 ml of urine in 20-ml capped glass vials for 60 min with a Twister™ stir bar. Urine samples were first diluted with 1.5 ml water (high-purity OmniSolv® water, EM Science, Gibbstown, NJ, USA). As an internal standard, 16 ng of 7-tridecanone in 20 μl of ethanol (Aldrich) was added to each vial. Stirring speed was 800+ rpm on the Variomag Multipoint HP 15 stirplate (H+P Labortechnic, Oberschleissheim, Germany). Prior to extraction, all glassware was rinsed with acetone and dried at 80°C. After extraction, the stir bars were rinsed with a small amount of distilled water, dried gently on a paper tissue, and placed in the thermal desorption autosampler (TDSA) tube (a product of Gerstel) for GC or GC-MS quantitative analysis. GC equipment for quantitative analysis consisted of an Agilent GC Model 6890 with an AED (Model G2350A, Agilent Technologies, Wilmington, DE, USA) and a TDSA (Gerstel). The GC was fitted with an HP-5MS column (30 m×0.25 mm, ID, 0.25 μm film thickness, Agilent). Samples were thermally desorbed with a TDSA automated system, directly into cooled injection assembly (CIS-4) of the GC, operated in splitless mode. The temperature program for desorption was 20°C (0.5 min), then 60°C/min to 280°C (10 min). Temperature of the transfer line was set at 280°C. The CIS was cooled with liquid nitrogen to −60°C. After desorption and cryotrapping, the CIS was heated at 12°C/sec to 280°C, with a hold time of 10 min. The CIS inlet was operated in the solvent vent mode, with a vent pressure of 14 psi, a vent flow of 30 ml/min, and a purge flow of 50 ml/min. The GC oven was programmed from 40°C for 5 min, then 2°C/min, to 200°C hold

10 min. The carrier gas head pressure was 14 psi (flow rate, 1.2 ml/min). The GC was operated in constant flow mode. The emission lines for carbon (193 nm), sulfur (181 nm), and nitrogen (174 nm) were monitored with the AED detector.

Compounds were identified with an Agilent 6890N GC connected to 5973i MSD MS (Agilent Technologies). The GC column and temperature program were identical to those used with the GC-AED. Electron input ionization mode was used with a scan rate of 2.4 scans/sec over the mass range of 41–350 amu. The transfer line temperature was 280°C and the ion source and quadrupole temperatures were 230 and 150°C, respectively. The TDSA–CIS sample introduction setting was identical to that described above with the GC-AED system.

Volatile compounds in serum were extracted by the stir bar method after digesting proteins with a nonspecific protease enzyme. Serum (200 μl) was placed in a clean 25-ml sample vial and diluted with 10 ml HPLC grade water and 10 ml 50 mM ammonium bicarbonate buffer, pH 8.3. Then, 2 mg of protease (Sigma protease type XIV from *Streptomyces griseus*, 5.2 units/mg) was added to the vial. Enzyme digestion was carried out for 18 hr in foil-wrapped vials (protected from light) at room temperature. After digestion, 20 μl of the internal standard solution in ethanol, containing 16 ng of 7-tridecanone, was added. Stir bar extraction was performed for 2 hr, and the sample was introduced into the GC-MS system as described for the urine analysis. Digestion of serum proteins was deemed necessary for the extraction of small volatile compounds due to possible competitive binding of compounds of interest on the surfaces of intact proteins.

Quantitative Evaluations and Statistical Analyses As the basis for quantitative comparisons of urinary chromatographic profiles, the peak areas (GC-AED) were integrated for each identified component and statistically evaluated for different mouse groups. Typically, reproducibility for the compound peak area measurements in mouse urine was ±5.0% (relative standard deviation, N=4) (see also Soini et al., 2005). Comparisons to the peak areas obtained with authentic compounds at known concentrations (ng/ml) or the internal standard peak area (16 ng of 7-tridecanone) were used to estimate the actual concentration ranges. The AED detector operated well within the linear range at the submicrogram levels for the detected compounds. Typically, the measured correlation coefficients (R^2) for the analytes were >0.99.

The peak area of the internal standard was monitored as a quality control measure for reproducibility of extraction, and chromatography and was not used for statistical evaluations. ANOVA was employed for statistical comparisons, and Tukey's test was used for *post hoc* comparisons.

Results

Comparison Among Mice With the Same Background and Different MHC Through sampling two different host strains, C57BL/6J (B6.6J) and C57BL/10J (B10.10J) (Table 1), and several MHC haplotypes and mutants within these strains, we were able to quantitatively compare the profiles of mouse urinary volatiles and assess the differences in major constituents that may occur due to a variation in the MHC region. Examples of our results from compound profiling comparisons are shown in Figs. 1 and 2. The volatiles profiles were independently assessed by GC-MS (data not shown) to verify the identities of previously known chemosignals (Schwende et al., 1986; Novotny et al., 1999a), in addition to identifying some new compounds. Statistical analyses carried out for 18 major urinary components showed significant differences (marker compounds) among the different strains for most compounds (see Table 2).

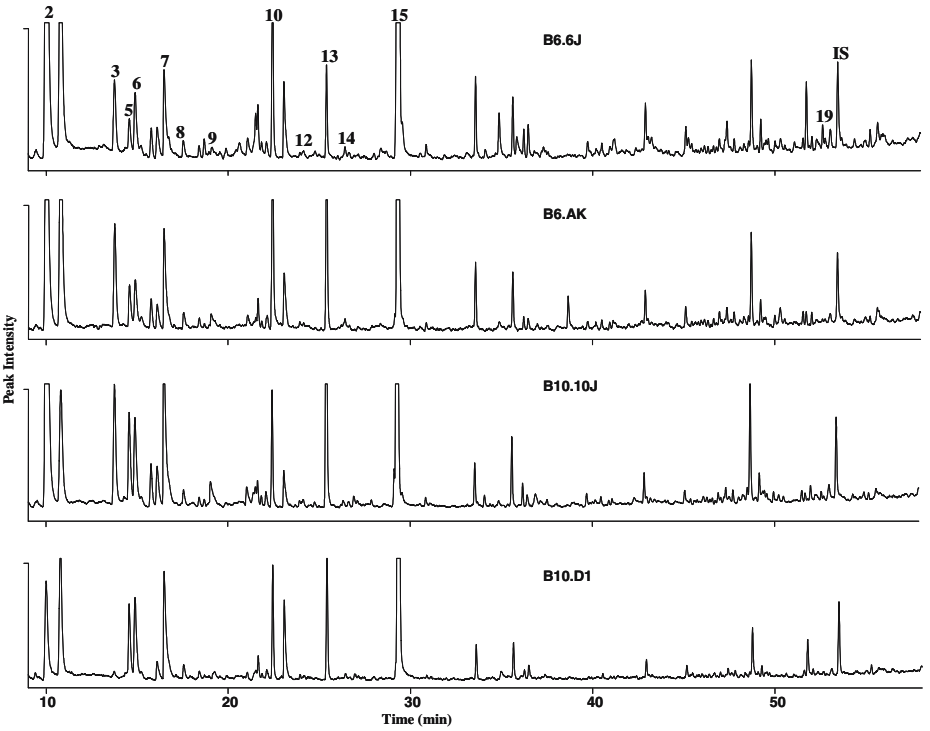

Fig. 1 A comparison of male mouse urinary profiles measured by GC-AED, using the carbon line at 193 nm, in different strains and haplotypes. Analytical conditions are described in the text. *Numbers* refer to compounds: *2*, *3*, *7*, DHF; *5*, 2-heptanone; *6*, 5-hepten-2-one; *8*, 2-ethyl-5-methyl-5,6-dihydro-(4H)pyran; *9*, 6-methyl-6-hepten-3-one; *10*, 6-methyl-5-hepten-3-one; *12*, limonene; *13*, DHB; *14*, acetophenone; and *19*, β-farnesene. *IS* internal standard

Among the marker compounds, highest concentrations were detected for dihydrofurans (DHF) (500–2,000 ng/ml), dehydro-*exo*-brevicomin (DHB) (100–400 ng/ml), and 2-*sec*-butyl-4,5-dihydrothiazole (SBT) (150–900 ng/ml). Two carbonyl compounds were found at medium concentration levels (2-heptanone: 7–150 ng/ml, 5-hepten-2-one: 12–160 ng/ml), whereas 3-hepten-2-one levels were somewhat lower (2–5 ng/ml). Sulfur compound levels (dimethyl disulfide and methyl (methylthio)methyl disulfide) were 10–40 ng/ml and 15–30 ng/ml, respectively. Another sulfur compound, bis(methylthio)methane, was found at even lower levels (1–3 ng/ml). Additional GC-MS analyses showed β-farnesene at relatively low levels (2–5 ng/ml) to be a statistically significant marker compound as well. Chemical structures of all identified components are summarized in Fig. 3.

We found significant differences in the excretion of certain components even for such a subtle genetic difference as a few amino acids in the peptide binding region of a single class I gene (B6.bm1 mutants). This is in agreement with our previous results (Schwende et al., 1984) that the differences in female mouse urinary profiles between the background strains can be greater than those caused by different MHC haplotypes among the host strain and its mutant strains. Eight representative examples of this distinction are shown in Fig. 4. For example, the measured peak areas of SBT were significantly different between B6.6J strain and its congenic strain B6.AK in SBT (Fig. 4h, Table 2). B6.bm1 differed from B6.AK in dimethyl disulfide and bis(methylthio) methane (Fig. 4b, c, Table 2). The three congenic

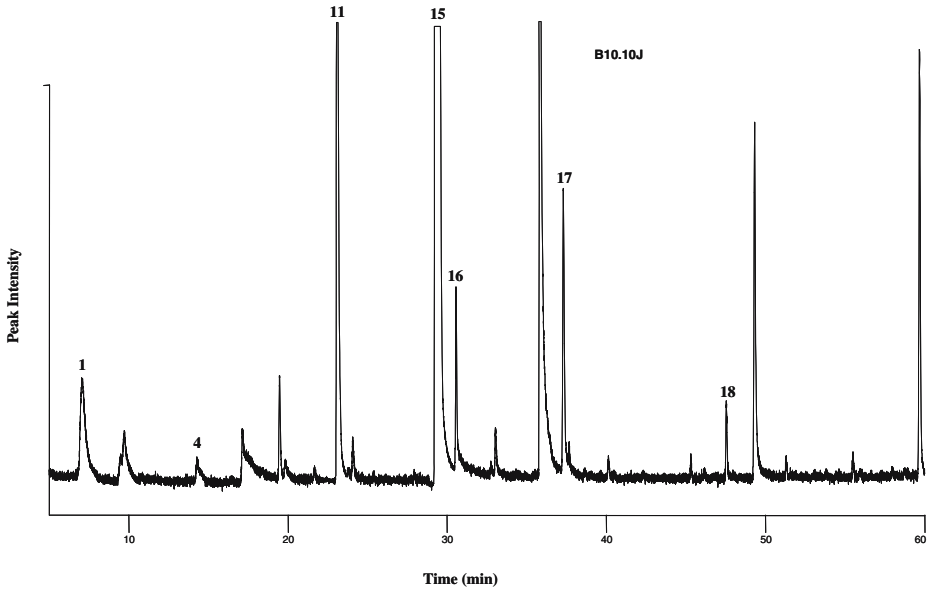

Fig. 2 A selective sulfur line measurement (181 nm) of the male mouse urinary profile by GC-AED (B10.10J strain). *Numbers* refer to compounds: *1*, dimethyl disulfide; *4*, bis(methylthio)methane; *11*, IPT; *15*, SBT; *16*, methyl (methylthio)methyl disulfide; *17*, benzothiazole; and *18*, *N*-(methylthio)methylaniline (tentative identification)

strains of B10.10J showed significantly smaller peak areas for six (B10.A, B10.BR) or seven compounds (B10.D1). The compounds that showed significantly smaller peak areas were dimethyldisulfide (in all of the three congenics of B10.10J), DHF (in B10.D1), bis (methylthio)methane (in all three congenics of B10.10J), 2-heptanone (in all three congenics of B10.10J), 6-methyl-5-hepten-3-one (in B10.A and B10.D1), isopropyl-4,5-dihydrothiazole (IPT) (B10.A and B10.BR), DHB (B10.D1 and B10.BR), and SBT (in all three congenics of B10.10J) (Fig. 4, Table 2). We also found considerable variations within each strain.

From all evaluated components, significant differences in peak areas for eight urinary components (dimethyl disulfide, DHF, bis(methylthio)methane, 2-heptanone, 6-methyl-5-hepten-3-one, IPT, DHB, and SBT) and a lack of significant differences for five other urinary components (5-hepten-2-one, 2-ethyl-5-methyl-5,6-dihydro-(4H)-pyran, methyl (methylthio)methyl disulfide, benzothiazole, and tentatively identified *N*-(methylthio) methylaniline) suggest that the levels of the former eight components reflect variations at the MHC. Figure 4 also shows the differences in peak areas according to the haplotype in the MHC region. Surprisingly, the amounts of 2-heptanone, dimethyl disulfide, and bis (methylthio)methane were larger in the B6.bm1 mutant (bm1, b, b, b) compared to the other genotypes (Fig. 4a–c). The amounts of DHB, 6-methyl-5-hepten-3-one, IPT, and DHF were larger in the haplotype *b* (b, b, b, b), especially in B6.6J, compared to the other haplotypes (Fig. 4d–g). However, even with the same haplotype *b*, there were strain differences, which suggest that regions other than MHC loci may have a role in determining the excretion of these compounds (Fig. 4d–g). When comparing SBT, the averages of the *b* and bm1 mutants were almost the same, but statistically significant differences were seen between haplotypes *b*, again especially in B6.6J and *k*, *k*+*d* (recombinant) and *q* (Fig. 4h).

[c] Peak areas of three structurally related DHF were summed in the ANOVA analyses

Comparison Among Mice With the Same MHC and Different Background Mouse strains with the same MHC haplotypes, but with large differences in the gene characteristics in other regions, were chosen to confirm that the differences in the amounts of compounds seen in the two host strains with the same MHC haplotype *b*, or the differences in the amounts of compounds seen in the two congenic strains of these host strains with the same MHC haplotype *k*, will become larger when the gene differences in the regions other than MHC are also increased. A congenic mouse strain of BALB, BALB/b, was chosen to compare with B6.6J and B10.10J because it has the same haplotype *b* in the MHC. Another congenic strain derived from the host BALB, BALB/k, was chosen to compare with B6.AK and B10.BR, which are congenic strains of B6.6J and B10.10J, with haplotype *k* in the MHC region.

The average amounts of three compounds were significantly different for BALB/b compared with B6.6J, and the total sum of peak areas was also significantly different (Table 3). Once again, the compounds that showed differences were DHF, 5-hepten-2-one, and SBT (Table 3, Fig. 4f, h) and all of them were smaller in BALB/b. There were no significant differences between BALB/b and B10.10J and between B6.6J and B10.10J. Even with the same MHC genotype, the amount of each compound thus varies, depending on the differences in the genotype in other genetic regions. When the differences in other regions become larger, the amount of compounds tends to increase, also.

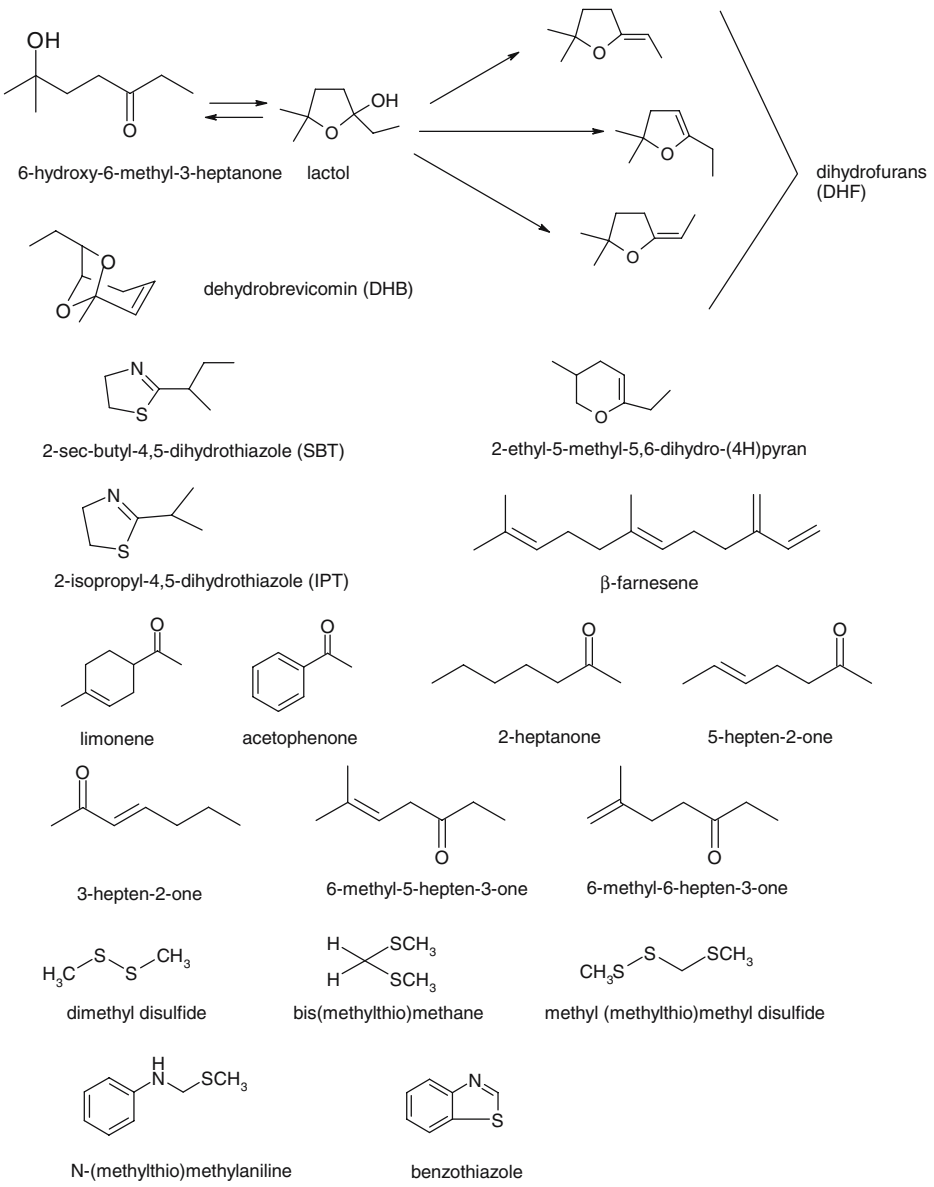

Fig. 3 Chemical structures of the identified compounds

Similar differences were found in a comparison among BALB/k, B6.AK, and B10.BR, which have the same haplotype *k* in the MHC region. There were five compounds that showed differences in peak areas (Table 3, Fig. 4a, d, e, h for compounds other than 5-hepten-2-one) with regard to a strain. *Post hoc* tests revealed that there were no differences between the B6.AK and B10.BR strains. BALB/k produced more DHB than the other two strains (Fig. 4d), but for the other four compounds, the amounts were significantly smaller in BALB/k when compared to B6.AK (2-heptanone (Fig. 4a) and 5-hepten-2-one) and B10.BR (6-methyl-5-hepten-3-one and SBT (Fig. 4e, h)). These results confirm that, even

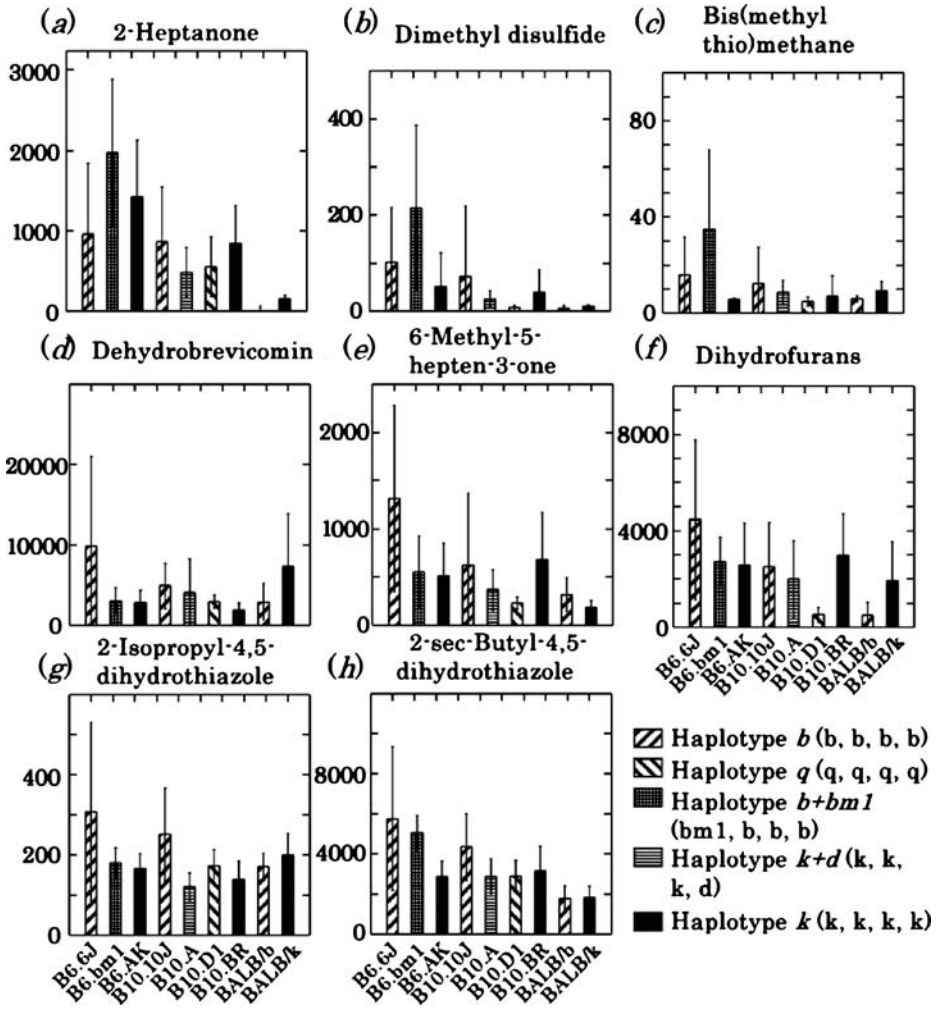

Fig. 4 Comparison of the average peak areas (±SD) according to strains and MHC haplotypes. **a** 2-heptanone, **b** dimethyl disulfide, **c** bis(methylthio)methane, **d** DHB, **e** 6-methyl-5-hepten-3-one, **f** DHF combined, **g** IPT, and **h** SBT

with the same genotype in the MHC region, these compounds vary quantitatively depending on differences in background genes, and when the differences outside the MHC gene regions become larger, the differences in urinary volatiles also increases.

Significant differences in the amounts of urinary volatiles were seen between the congenics of BALB, the B6 and B10 strains, indicating that the differences in urinary chemical profiles increased with increasing differences in background genes. Such a tendency was also seen when the relative percentages of the peak areas of all 16 measured compounds were compared. In Fig. 5, we show the relative percentages of the peak sizes for compounds in the three strains that have the same *b* haplotypes (Fig. 5a) and the three strains that have the same *k* haplotypes (Fig. 5b) in the MHC region. The two C57BL strains (B6 and B10) had quite similar relative percentage profiles when compared to the

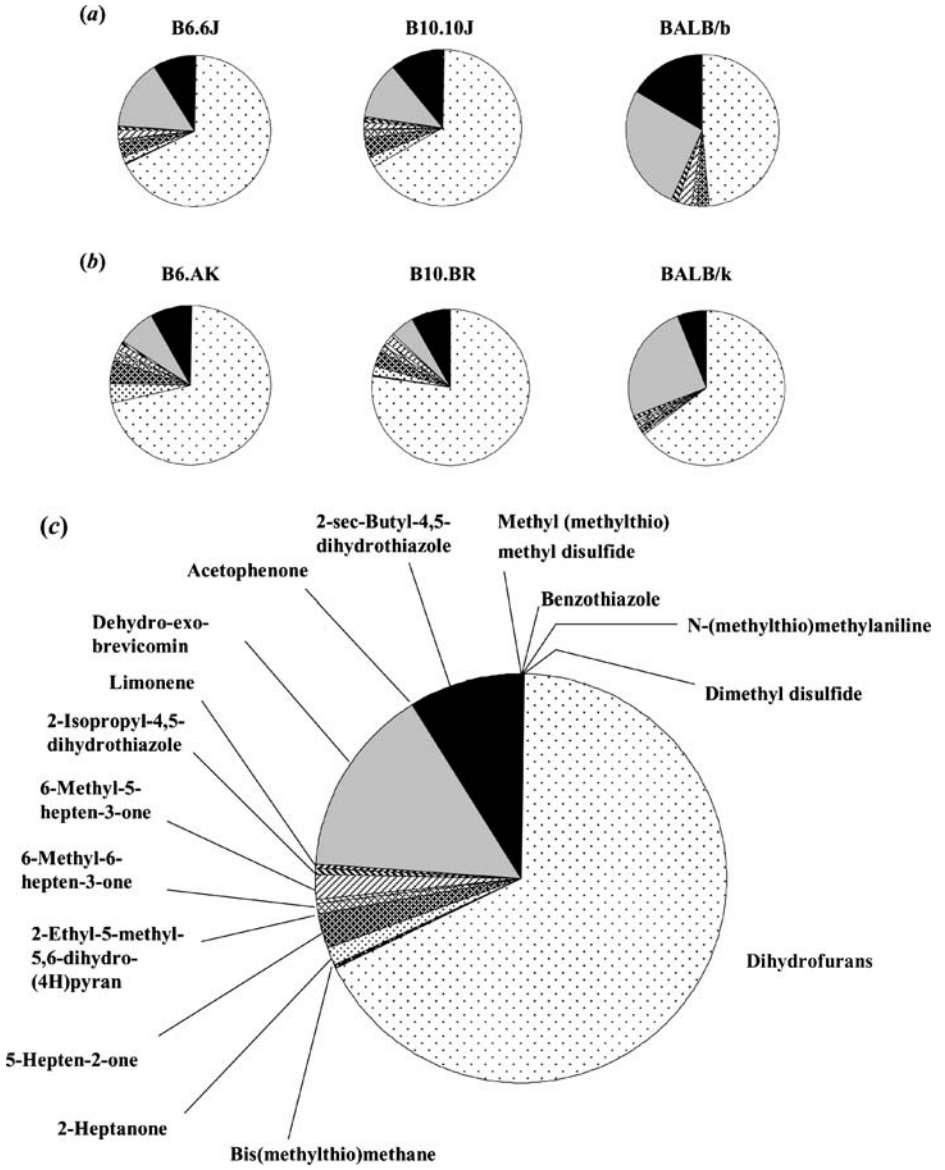

Fig. 5 Comparison of the relative percentages of components in the strains with the same MHC haplotypes H^b **(a)** or H^k **(b)**. The names of the compounds are shown in **(c)**

congenics of the BALB strain. The genetic differences in the region other than the MHC are thus suggested to influence both the amounts and relative percentages of each compound.

Comparison Between B6.6J and Its Mutant Strains In the next part of our experiments, B6.6J strain and its mutants, B6.Tap1 and B6.B2m, were compared. In the mutant B6.B2m, few, if any, MHC class I proteins are expressed on the cell surface (β2 microglobulin "knockouts"), and in the mutant B6.Tap1, the mice lack intracellular transport of peptides to

MHC class I molecules (transporters associated with antigen-processing knockouts). Here, there were significant differences in the amounts of three components: 2-heptanone ($F_{2,15}$= 6.75, P=0.008), 5-hepten-2-one ($F_{2,15}$=9.81, P=0.002), and 3-hepten-2-one ($F_{2,15}$=3.80, P=0.046). The differences in amounts between the host strain and its mutants were especially large in 2-heptanone and 5-hepten-2-one, and Tukey's *post hoc* tests revealed that there were differences between B6.B2m and its host, and between B6.B2m and the other mutant strain (2-heptanone: B6.6J vs. B6.B2m, P=0.04; B6.B2m vs. B6. Tap1, P=0.011; 5-hepten-2-one: B6.6J vs. B6.B2m, P=0.016; B6.B2m vs. B6.Tap1, P=0.002). These differences were due to the smaller amounts in B6.B2m (Fig. 6). This suggests that, even without the stable assembly and intracellular transport of MHC class I molecules, B6.Tap1 may have an odor similar to its host strain B6.6J, whereas B6.B2m mice have less 2-heptanone and 5-hepten-2-one when compared to their host strain because of the lack of MHC class I gene expression. These results, in turn, suggest that the MHC gene complex encoding class I proteins plays an important role in determining the amount of 2-heptanone and 5-hepten-2-one.

Serum Chemical Profiles and Influence of Antibiotic Treatment The serum volatiles' profiles contained some of the same compounds found in the mouse urinary profiles. A dihydrofuran (decomposition product of a pheromone 6-hydroxy-6-methyl-3-heptanone (Novotny et al., 1999b)), DHB, and SBT were observable at low levels in serum (Fig. 7). Also, after the antibiotic treatment, we did not find any significant differences in the profiles of urinary volatile compounds, such as a decrease of components that might be expected as bacterial products.

Discussion

General Considerations Our data support the hypothesis that differences in volatile compound concentrations associated with different individuals or groups can potentially be "quantified" by the vomeronasal (VN) organ or the major olfactory epithelium. Volatile profile constituents recorded in this study from the urinary specimens of adult male mice consisted of several previously identified male pheromones, which are also differentially bound by major urinary proteins (Sharrow et al., 2002), and known to provide quantitative responses of the VN neuronal mechanism for the volatiles that they transport to scent marks. The overall metabolic relationship of these volatiles to MHC genes still remains elusive. Numerous identified compounds can be traced to known metabolic sources, such as the oxidative pathways or production triggered by hormone levels. We found that some of these compounds were detectable in blood serum. However, there was no evidence that their levels in urine were affected by antibiotics, which does not support the microflora hypothesis, without necessarily ruling it out. Within the dozens of urinary volatile constituents, we found numerous compounds influenced by MHC genes, regardless of the host strain. Even with subtle and small differences in genotype (bm mutants), these changes in urinary constituents were easily discernable by our analytical procedures, as well as by the olfactory receptors of mice.

The chemical structures of the volatile urinary constituents identified in our study can be classified into different chemical groups (Fig. 3). However, the metabolic origin of these compounds is mostly unclear. Whereas it is evident from numerous biological experiments that MHC genes influence odor, there is no obvious connection between the direct gene products, class I and class II proteins, and the volatile compounds identified in this work. While the commensal microflora might be a possible source, we found no major changes in

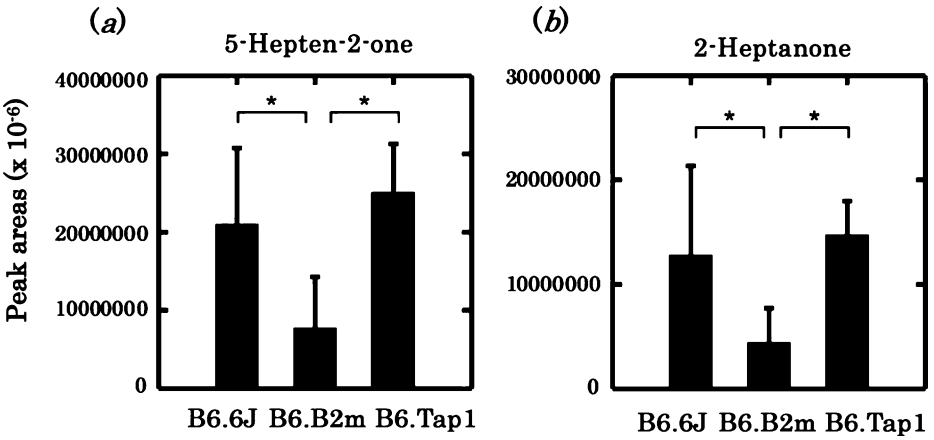

Fig. 6 Comparison of the average total peak areas (±SD) of B6.6J and its knockout mutant strains. **a** 5-hepten-2-one, **b** 2-heptanone. *Asterisks* denote $P<0.05$

the profile of urinary volatiles following treatment with a broad-spectrum antibiotic. Moreover, several major constituents implicated here in the MHC distinction were previously shown to occur in the bladder urine (Novotny et al., 1990), and, as demonstrated here, the same compounds were also detectable in blood serum.

Biochemical Attributes of Detected Volatiles It was previously observed that only urine from anestrous females provided reliable, measurable volatile signals, and the components

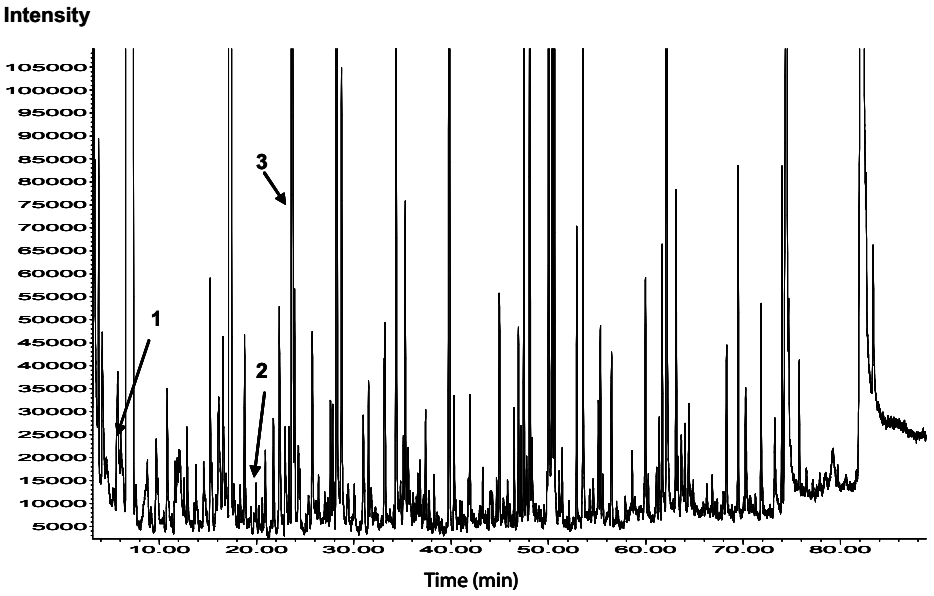

Fig. 7 Volatile compound profile of male mouse serum (B6.6J) determined by GC-MS. Analytical conditions are described in text. *Arrows* indicate the compounds found also in mouse urine: *1*, DHF; *2*, DHB; and *3*, SBT

enhanced during the estrus could "overshadow" the possible changes due to MHC (Schwende et al., 1984). The volatiles enhanced during the estrous cycle (Andreolini et al., 1987) include 2-heptanone, (*E*)-4-hepten-2-one, DHB, and DHF, with the last one implicated as the dehydration artifact (Harvey et al., 1989) of a physiologically active 6-hydroxy-6-methyl-3-heptanone (Novotny, 2003).

The results presented here indicate that several testosterone-dependent urinary volatiles are influenced by MHC, including SBT, DHB, and the above-mentioned DHF. All three major urinary constituents have been implicated as multimodal pheromones (for a review, see Novotny et al., 1999a), with SBT being a uniquely male substance and the other two detectable in large amounts in urine from male mice and only as minor components of the female urine. Most of these substances bind to the major urinary proteins with variable affinities (Sharrow et al., 2002). The metabolic origin of these "mouse-unique" biologically active compounds has not been determined, although it was postulated (Novotny et al., 1995) that the formation of SBT could involve the amino acids L-cysteine and L-isoleucine. It is interesting to note that the MHC appears to influence hormonal pathways (Klein, 1978; Ivanyi, 1978).

The remaining components implicated here as significant in MHC distinction can be divided into two chemically distinct groups: sulfur-containing compounds and carbonyl-containing metabolites. The metabolic origin (and, possibly, hormonal dependence) of IPT is likely similar to that of the male mouse pheromone, SBT, except for a different amino acid origin. Dimethyl disulfide and bis(methylthio)methane, both sulfur-containing molecules, were statistically significant in terms of MHC distinction, whereas methyl (methylthio) methyl disulfide, benzothiazole, and tentatively identified *N*-(methylthio)methylaniline were not, although they might have some other (non-MHC) chemosignaling function.

The biological carbonyl compounds, observed as MHC-correlated in this work, include most prominently 2-heptanone (known to be physiologically active; Novotny et al., 1986; Jemiolo et al., 1989), 6-methyl-5-hepten-3-one, 5-hepten-2-one, and 3-hepten-2-one. Two of these were particularly evident in the distinction between the B6.6J host strain and its two mutant variants. The metabolic origin of these ketones is most likely from oxidation of lipid or fatty acid precursors.

A previous study using a gas sensor array, the so-called "electronic nose" (Montag et al., 2001), was able to distinguish among MHC congenic and class I mutant strains, probably on the basis of very volatile odors due to the analytical procedure used. In their experiment, milliliter volumes of sample headspace (without preconcentration) were used, thus limiting detection to very volatile compounds and possibly major mixture components of the odor. This is consistent with the quantitative differences in the early-eluting components observed in our previous GC studies (Schwende et al., 1986; Novotny et al., 1999b). Moreover, the chemical nature of some of these compounds (oxygenated and sulfur-containing substances) appears favorable for the discriminatory response of gas-sensing surface reactions (Albert et al., 2000). Whereas some of the identified molecules (of both prerenal and postrenal origin) are probably detected by VN neurons (Leinders-Zufall et al., 2000), less volatile and nonvolatile molecules, such as MHC class I peptides (Leinders-Zufall et al., 2004), could also play a role in biological recognition under ecologically different circumstances (direct physical contact with sample). Whether or not there is a connection between MHC-dependent volatile odorants and MHC class I peptides is unknown.

Our study suggests that 2-heptanone and 5-hepten-2-one (products of oxidative pathways) are among the major candidates for chemosignaling that are mediated by the MHC. However, our results also indicate that concentrations of these compounds are not solely determined by MHC because there were differences seen in their amounts even in the

strains with the same MHC, but with differences in other gene regions (different background strains). Thus, it will be necessary to search for candidate genes that might be linked to genes in the MHC region, and that might work together to produce the odor profile characteristic of each individual.

Acknowledgments This work was sponsored partially by the Metabolomics and Cytomics Initiative at Indiana University, Bloomington, IN, and ARO Contract DAAD19-03-1-0215. RAPID COMMUNICATION

Solitary Foraging in the Ancestral South American Ant, *Pogonomyrmex vermiculatus*. Is it Due to Constraints in the Production or Perception of Trail Pheromones?

Hugo Torres-Contreras · Ruby Olivares-Donoso · Hermann M. Niemeyer

Received: 15 March 2006 / Revised: 30 October 2006 / Accepted: 27 November 2006 /

Abstract Several North American species of *Pogonomyrmex* harvester ants exhibit group foraging, whereas South American species are exclusively solitary foragers. The composition of the secretions of the poison and Dufour glands in the South American species, *Pogonomyrmex vermiculatus*, were analyzed, and the secretions and their components were tested as trail pheromones in laboratory bioassays. The major compounds in the poison gland were the alkylpyrazines, 2,5-dimethylpyrazine, 2,3,5-trimethylpyrazine, and 3-ethyl-2,5-dimethylpyrazine. The Dufour gland contained five alkanes, from tridecane to heptadecane, with pentadecane being most abundant. In behavioral bioassays, poison gland extracts and the mixture of pyrazines produced a trail pheromone effect, whereas the Dufour gland extracts and the alkanes had no effect on ant locomotion. We conclude that group foraging in *P. vermiculatus* does not arise from the inability to produce or detect possible pheromones, but rather, from physiological and/or ecological factors.

Keywords Harvester ants · Trail pheromones · Alkylpyrazines · Trimethylpyrazine · Pentadecane · Behavioral bioassays

Introduction

Harvester ants of the genus *Pogonomyrmex* are common in arid and semiarid habitats from southern Canada to the southern extreme of Tierra del Fuego (Taber, 1998). Phylogenetic reconstructions of the genus *Pogonomyrmex* based on morphological, chromosomal, ecological, and behavioral characters show the ancestral nature of the South American species (Taber, 1998). They are exclusively solitary foragers, in contrast to the North American species, some of which exhibit group foraging (a derived character) and generate and use trails for the exploitation of food patches (Johnson, 2001). In this latter group, group

foraging behavior with recruitment of individuals is mediated by semiochemicals emitted from the poison and Dufour glands (Hölldobler et al., 2001). The major compounds secreted by the poison gland of species from North America are alkylpyrazines (Hölldobler et al., 2001), whereas the Dufour gland contains many types of compounds such as alkanes, alkenes, esters, terpenes, ketones, and aldehydes (Hölldobler et al., 2004). In this work, we tested whether the solitary foraging behavior of an ancestral species is due to its inability to produce or to detect chemical signals involved in group foraging. In the South American species, *Pogonomyrmex vermiculatus*, we identified the chemicals produced by the poison and Dufour glands and evaluated the effect of extracts of both glands and the chemicals contained therein on the locomotion behavior of the ants in laboratory bioassays.

Methods and Materials

Sample Collection Forager workers from five colonies were collected during January 2005 in Las Chinchillas National Reserve (31°30′ S, 71°06′ W). The ants were held in acrylic boxes and transported to the laboratory, where they were maintained according to standard rearing conditions (Hölldobler and Wilson, 1990).

Thirty worker ants of *P. vermiculatus* were killed by freezing (−18°C for 5 min). The poison and Dufour glands were separately dissected from each individual under distilled water by using a stereomicroscope. The individual glands were sealed in soft glass capillaries, which were introduced directly into the injector port of a gas chromatograph by using a solid sample injector as described by Morgan (1990).

GC-MS Analysis of Samples The analyses of compounds contained in the glands were carried out on an HP-5890 gas chromatograph coupled to an HP-5972 mass selective detector with an integrated data system. Ionization by electron impact (70 eV) was carried out at 280°C. The GC was equipped with a SPB-5 capillary column (30 m×0.25 mm ID, Supelco, Deerfield IL, USA). Helium was used as carrier gas at 2 ml/min. The capillaries containing the glands were heated in the injector port to 180°C for 3 min before crushing them in the solid sample injector. The oven temperature was held at 30°C for 2 min, then increased to 250°C at 7°C/min, then held at 250°C for 5 min. The presence or absence of a given compound in the chromatographic profile of each individual gland was determined by comparison of mass spectra with a library database and was confirmed by injection of authentic standards and comparison of Kovats indexes. This procedure was followed for alkanes, 2-tetradecanol, 2,5-dimethylpyrazine (DMP), and 2,3,5-trimethylpyrazine (TMP) (Aldrich Chem. Co.), and for 3-ethyl-2,5-dimethylpyrazine (EDMP) (Carlos Cramer Productos Aromáticos S.A.C.I., see below for details). When standards were not available (heptadecene), tentative identification was based on comparison of the mass spectrum with a library mass spectrum and reported Kovats index values. Identifications were considered positive if the similarity index between experimental and library mass spectra was higher than 90% and if Kovats indexes did not differ by more than 5 U (differences were typically less than 3 U). In the case of ethyldimethylpyrazine, where mass spectra are similar between isomers, an authentic standard that contained 3-ethyl-2,5-dimethylpyrazine and 2-ethyl-3,5-dimethylpyrazine was analyzed. These two compounds produced well-separated peaks, and the peak with the lower Kovats index, which was identified as 3-ethyl-2,5-dimethylpyrazine (E.D. Morgan, personal communication), coincided with the peak in the

samples analyzed. To quantify the pyrazines and alkanes present in single glands, calibration lines were generated with serial dilutions of authentic standards.

Bioassays with Gland Extracts Poison and Dufour glands were dissected from 40 worker ants. All glands of the same type were deposited in a sample vial containing 1.0 ml hexane, crushed, and filtered to produce extracts. Behavioral tests were performed in a Y-shaped Plexiglass olfactometer with 5×5 cm cross-section, 40-cm long stem, and 15-cm long branches at an angle of 30°. The floor of the olfactometer was lined with filter paper. Chemical trails extending from the base of the stem to the end of the branches were produced with 25 μl of gland extract (one-gland equivalent, treatment trail) and 25 μl of solvent (hexane, control trail). In the stem, chemical trails were drawn along imaginary lines 1.25 cm distant from the walls; in the branches, chemical trails were drawn along the center of the floor. Twenty-five seconds after application of the extracts and solvent, a test ant was liberated at the base of the stem. The first choice of arm was recorded, and the time allocated to this first preference was determined for each test ant. Twenty-four replicates for the poison gland treatment and 26 replicates for the Dufour gland treatment were performed. Additional bioassays were performed with one-gland equivalent of mixtures of the three pyrazine standards (45 ng, 40 replicates) and the five alkane standards (675 ng, 34 replicates), in the same proportions as those found in the glands. The arena was thoroughly cleaned with ethanol between replicates, and the filter paper liner was replaced. Data on the first choice of arm of the Y-olfactometer were analyzed by using a Chi-square test with one degree of freedom and Yates' correction factor; values for residence time in the first arm chosen by the ants were compared with *t*-tests for independent samples (Statistica 6.0 software). For both statistical tests, $\alpha=0.05$.

Results

The poison glands of *P. vermiculatus* contained a mixture of three alkylpyrazines: 2,5-dimethylpyrazine (DMP), 2,3,5-trimethylpyrazine (TMP), and tentatively identified 3-ethyl-2,5-dimethylpyrazine (EDMP). TMP was most abundant (67.7±3.1%, mean ± standard error), followed by DMP (20.1±4.2%), and EDMP (12.2±2.6%). The Dufour glands contained mainly five alkanes (96.9±0.6%: tridecane, tetradecane, pentadecane, hexadecane, and heptadecane), traces of 2-tetradecanol (0.1±0.01%), and a heptadecene (0.1±0.01%). Pentadecane was by far the major component (95.2±0.6%), followed by heptadecane (2.3±0.3%), tetradecane (1.4±0.2%), tridecane (0.9±0.2%), and hexadecane (0.2±0.02%).

In choice bioassays, significantly more worker ants went into the olfactometer arm containing the poison gland extract than the solvent control ($\chi^2=4.26$, $N=15$, $P<0.05$; Fig. 1a), and foragers spent more time in the arm with the poison gland extract than in the arm with the hexane control ($t=2.62$, $df=28$, $P<0.05$; Fig. 1c). This pattern was confirmed in tests that used authentic pyrazine standards, with ants preferring the treatment over the control arm ($\chi^2=4.32$, $N=28$, $P<0.05$; Fig. 1b). Ants also spent more time in the treatment than in the control arm ($t=2.93$, $df=54$, $P<0.05$; Fig. 1d). In contrast, ants showed no preference for the arm with Dufour gland extract (treatment=10, control=5, nonresponders=11; $\chi^2=1.06$, $P=0.30$), and spent equivalent amounts of time in the Dufour gland extract and hexane control arms (252±62 vs. 210±72 sec in the arm containing Dufour gland extract and solvent, respectively; $t=0.44$, $df=28$, $P=0.66$). Experiments with alkane standards confirmed these results. Thus, ants showed no preference for the arm with the alkane mixture vs. solvent

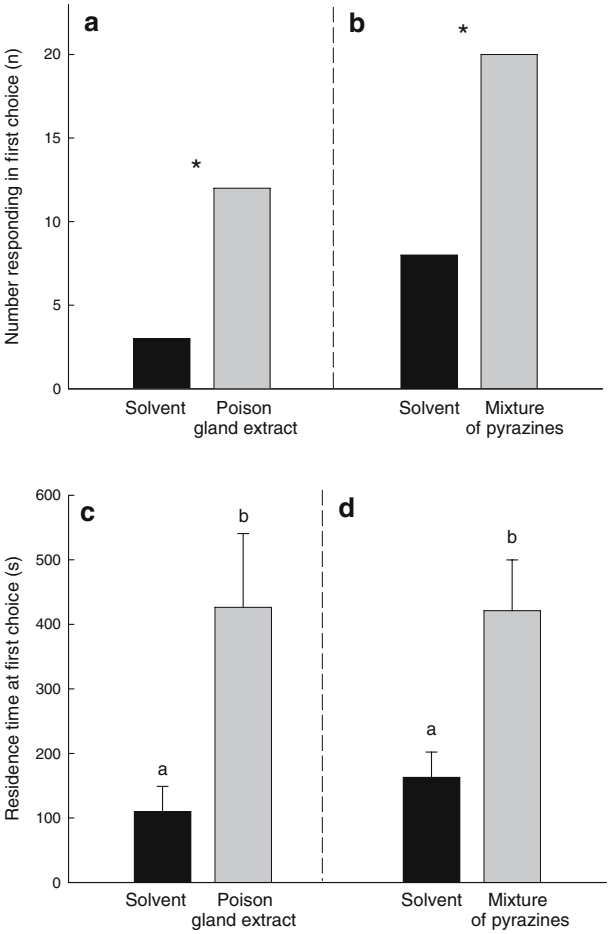

Fig. 1 **a**,**b** First arm choice of *Pogonomyrmex vermiculatus* workers exposed in a Y-olfactometer to different treatments vs. hexane solvent controls (*$P<$ 0.05, Chi-square test). **c**,**d** Time allocated to the arm of the first choice (values are means ± standard error; different letters above bars indicate significant differences in a *t*-test for independent samples)

(treatment=14, control=8, nonresponders=12; $\chi^2=1.14$, $P=0.28$) and spent similar amounts of time in the treatment and control arms (283±38 vs. 290±46 sec in the arm containing the mixture of alkanes and solvent, respectively; $t=0.13$, $df=42$, $P=0.89$).

Discussion

In group-foraging North American species of *Pogonomyrmex*, poison gland secretions constitute short-lived signals (20 to 30 min) allowing ants to recruit nestmates and move long distances towards food patches along trunk trails (see references in Hölldobler et al., 2001). These secretions contain pyrazines, which have been identified as trail pheromone components in several genera of the subfamily Myrmicinae (*Aphaenogaster*, *Atta*, *Eutetramorium*, *Manica*, *Messor*, *Myrmica*, *Pheidole*, *Pogonomyrmex*, and *Tetramorium*) (Hölldobler et al., 2001, and references therein). The poison gland of *P. vermiculatus* contained ca 45 ng pyrazines per gland, which is within the range reported for other

Pogonomyrmex species (30–200 ng per gland) (Hölldobler et al., 2001). Furthermore, our bioassays (Fig. 1 a–d) suggest that compounds present in the poison gland of *P. vermiculatus* can function as trail pheromones. Finally, the preference of treatment (poison gland extract or mixture of pyrazines) over control was ca 3:1 in the first choice of arm and also in the residence time. These proportions are comparable with the strength of recruitment behaviors elicited by pyrazines in group foraging *Pogonomyrmex barbatus* (ratio ca 4:1 for treatment vs. control; Hölldobler et al., 2001).

The secretions from the Dufour gland of group-foraging North American *Pogonomyrmex* serve as long-lasting orientation signals (on the order of hours) and allow continuous reinforcement of the trail leading to the foraging site with chemical signals specific for each colony (Hölldobler et al., 2004, and references therein). Hydrocarbons have been reported as the principal compounds secreted by the Dufour gland in the genus *Pogonomyrmex* (Hölldobler et al., 2004). Pentadecane, the major compound present in *P. vermiculatus*, has also been reported as the major compound in the Dufour glands of *Pogonomyrmex occidentalis* and *Pogonomyrmex salinus* (Billen et al., 1987, do Nascimento et al., 1993), two group-foraging species. However, neither the Dufour gland extract nor the reconstructed hydrocarbon mixture contained therein elicited changes in the locomotion of *P. vermiculatus* in relation to controls. This lack of effect may be due to the fact that *P. vermiculatus* only uses food patches situated near the nest (at distances <5 m, H. Torres-Contreras, personal observation), and hence, the reinforcement of trails with chemical signals would be superfluous. However, olfactometry tests do not allow us to exclude the possibility that in the field, these compounds may function as homing signals (see references in Hölldobler et al., 2004).

In this study, we demonstrated that *P. vermiculatus*, a solitary foraging harvester ant, produces and perceives compounds that function as trail pheromones in congeneric species. Given the ancestral nature of *P. vermiculatus*, this suggests that the character "production of semiochemicals" was fixed early in the evolutionary history of the group. If *P. vermiculatus* is able to perceive chemicals that in other *Pogonomyrmex* species are involved in group foraging behavior, then why does not this species (or, in general, the species of South America) exhibit group foraging? Several explanations are possible. First, it is probably not a question of the amount of compounds deposited by foragers because the total content in the glands of *P. vermiculatus* was similar to that of group foraging *Pogonomyrmex* species, and the content of one poison gland was shown to affect the locomotion patterns of test ants. Second, the absence of group foraging may be related to the number of foraging individuals. If the number of foragers is low, then, their efficiency in distributing the trail pheromones in the substratum would also be low, thus, constituting a limitation to the amplification of the signal (e.g., Beekman et al., 2001). In support of this proposal, the nests of the South American *Pogonomyrmex* species have fewer workers than the nests of North American species (Taber, 1998), and therefore, fewer individuals are assigned to foraging tasks (H. Torres-Contreras, personal observation). Third, because the number of ant species that forage and compete for seeds in arid habitats of Northern Chile is low (Medel, 1995) in comparison with the number of species present in the deserts of North America (Johnson, 2001, and references therein), group foraging may not be necessary in the South American species. Fourth, the proportion at which the three pyrazines were found in *P. vermiculatus* was similar to that found in *Pogonomyrmex maricopa*, a species documented as a solitary forager but which when confronted with a high abundance of resources exhibits recruitment of individuals and group foraging (Johnson, 2001). Thus, the pyrazines present in the poison gland of *P. vermiculatus* could play a role as a trail

pheromone and allow nestmate recruitment when there is a high availability and a patchy distribution of seeds in the habitat. The testing of these hypotheses is currently underway.

Acknowledgments We thank E. D. Morgan for advice during the implementation of the solid sample injection technique and for sharing unpublished results on the analysis of pyrazines and J. G. Millar for suggestions during the editing of the original manuscript. We also thank Claudia Cabrillana for assistance in the laboratory. Financial support by FONDECYT (grant 3060064 to H.T.-C.) and International Program in the Chemical Sciences at Uppsala University (H.M.N.) is gratefully acknowledged.

RAPID COMMUNICATION

Flower Scent of Floral Oil-Producing *Lysimachia punctata* as Attractant for the Oil-Bee *Macropis fulvipes*

Abstract Most flowers offer nectar and/or pollen as a reward for pollinators. However, some plants are known to produce mostly fatty oil in the flowers, instead of nectar. This oil is exclusively collected by specialized oil-bees, the pollinators of the oil-plants. Little is known about chemical communication in this pollination system, especially how the bees find their hosts. We collected the floral and vegetative scent emitted by oil-producing *Lysimachia punctata* by dynamic headspace, and identified the compounds by gas chromatography coupled to mass spectrometry. Thirty-six compounds were detected in the scent samples, several of which were flower-specific. Pentane extracts of flowers and floral oil were tested on *Macropis fulvipes* in a biotest. Flower and oil extracts attracted the bees, and some of the compounds identified are seldom found in the floral scent of other plants; these may have been responsible for the attraction of the bees.

Keywords Floral and vegetative scent · Dynamic headspace · GC-MS · Oil-flower oil-bee pollination system · *Lysimachia punctata* · *Macropis fulvipes* · Flight cage · Biotest

Introduction

The interaction between flower-oil-producing plants and flower-oil-collecting bees is an interesting pollination system, and was first described by Vogel (1971). About 2,400 plant species in 10 different families produce flower oil by specific organs (elaiophores), mostly instead of nectar. The oil is the main floral reward, and is collected by ca. 320 species of specialized bees that pollinate the flowers (Neff and Simpson, 2005). The collected oil is used together with pollen as provision for the larvae, and some species use it also as a brood-cell lining (Cane et al., 1983). Oil-producing flowers and flower-oil-collecting bees are mostly neotropical. In Europe, only some species of *Lysimachia* (Myrsinaceae) produce floral oil, which is collected only by *Macropis* bees (Mellitinae) (Vogel, 1986). *Macropis* collects oil and pollen only from *Lysimachia* spp. as food for their larvae. Little is known

S. Dötterl (✉) · I. Schäffler

e-mail: stefan.doetterl@uni-bayreuth.de

about how the bees find their host plants, but floral scents are assumed to be responsible for the attraction of *Macropis* to *Lysimachia* (Vogel, 1986). From other pollination systems, it is known that floral scent is important in attracting the pollinators (e.g., Dötterl et al., 2005, 2006).

The purpose of this study was to collect and identify the scent emitted by the green parts, flowers, and pure oil of *Lysimachia punctata* L. by dynamic headspace and gas chromatography coupled to mass spectrometry (GC-MS) methods. Further, solvent extracts of flowers were tested for their attractivity to *Macropis fulvipes* (Fab.) in a biotest conducted in a flight cage.

Methods and Materials

Plant Material and Volatile Collection Floral scent was collected from plants growing in the Ecological–Botanical Garden of the University of Bayreuth. Scent was collected from flowering inflorescences (3 samples, 1–3 stems, 15–35 flowers), from pure oil (3 samples from 50 flowers each), and from nonflowering stems (3 samples, 3–5 stems). Oil for scent analyses was collected on filter paper. To trap scent, the oil-containing filter paper and the flowering, and nonflowering stems were enclosed for 10 min (flowering stems) or 60 min (nonflowering stems and oil) within polyester oven bags (31×20 cm for flowering and nonflowering stems; 10×10 cm for pure oil, Toppits®, Germany), and the emitted volatiles were trapped for 2–4 min in an adsorbent tube by using a membrane pump (G12/01 EB ASF Rietschle-Thomas Inc., Puchheim, Germany), adjusted to a flow rate of 200 ml/min. ChromatoProbe quartz microvials from Varian Inc. (length 15 mm, inner diam. 2 mm) were used as adsorbent tubes after cutting the closed end, and filling them with a mixture (1:1) of 3 mg Tenax-TA (mesh 60–80, Supelco) and Carbotrap (mesh 20–40, Supelco). The adsorbents were held in the tubes with glass wool.

To obtain samples for biotests, 50 flowers (two samples, each flower was extracted for 1 min) were extracted in pentane p.a. (Merck KgaA, Germany). Furthermore, floral oil was collected with filter paper from 50 flowers and dissolved in pentane p.a. (one sample).

Chemical Analysis The dynamic headspace samples were analyzed on a Varian Saturn 2000 mass spectrometer coupled to a Varian 3800 gas chromatograph equipped with a 1079 injector fitted with the ChromatoProbe kit, using the same method as described by Dötterl and Jürgens (2005). The GC-MS data were processed by using the Saturn software package 5.2.1. Component identification was carried out with the NIST 02 mass spectral database, or MassFinder 3, and confirmed by comparison of retention times with published data (Adams, 1995). Identification of individual components was confirmed by comparison of both mass spectrum and GC retention data with those of authentic standards. For quantification, known amounts of different terpenoids, fatty acid derivatives, and benzenoids were injected, and the mean response of these compounds was used.

Biotests Pentane extracts of flowers and pure oil were used in biotests conducted in a flight cage (7.2×3.6×2.2 m) in which ca. 20 female bees built nests and collected oil and pollen as food for their larvae. All bees in the flight cage were individually marked, and before the tests, all *Lysimachia* plants were removed. Two setups were used for the tests. First, a dual choice test in which a pentane extract of 50 flowers of *L. punctata* (corresponding to flowers of 3–4 flowering stems) and pure pentane (control) were offered to the bees on yellow paper flowers. Second, a three-choice test in which a pentane extract of 50 flowers,

a pentane extract of oil collected from 50 flowers, and pure pentane were offered to the bees on a horizontal glass surface (diam. 2.5 cm). The responses of bees were observed for 1 hr, and bees landing on the artificial "flowers" were recorded. The responses of bees were classified into two categories: (1) landing, when the bees landed on the artificial flowers; and (2) collection of oil, if the bees collected oil for at least 2 sec from the artificial "flowers." The oil collection behavior of *Macropis* was previously described in detail by Vogel (1986).

Results and Discussion

The chemical composition of scent emitted by flowering and nonflowering stems and from pure floral oil of *L. punctata* is summarized in Table 1. In total, 36 compounds were found—among them fatty acid derivatives, aromatics, mono- and sesquiterpenoids. The total amount and the number of compounds varied greatly between flowering and nonflowering stems. The vegetative parts of the plants emitted 14 compounds, especially several fatty acid derivatives and terpenoids—among them (*E,E*)-α-farnesene, (*Z*)-3-hexenyl acetate, D-limonene, and the benzenoid benzaldehyde. Most compounds were emitted by the flowering stems (32). Twenty-two of these compounds were not found in the samples collected from the nonflowering stems, and these were emitted only by the flowers. Most of the flower-specific compounds were found only in small percentages, and only four compounds occurred with amounts of at least 5%, i.e., 1-phenyl-1,2-propanedione, linalool, (*E*)-citral, and (*Z*)-β-ocimene. Some compounds, which were found in nonflowering and flowering stems, were emitted in small amounts from vegetative parts, but with high total and percentage amounts from flowering stems [e.g., (*E*)-β-ocimene (*Z*)-3-hexenyl acetate]. The oil samples emitted nine compounds (four of them were not emitted from nonflowering stems) with high percentage amounts of aromatics 1-phenyl-1,2-propanedione and 1-hydroxy-1-phenyl-2-propanone. These aromatic compounds are uncommon floral scent compounds, and are described in the floral scent of only few species (see Knudsen et al., 2006).

The biotests revealed that the compounds emitted by the flower and oil extracts were responsible for attraction of *M. fulvipes* (Table 2). In the two-choice test, 12 of the ca. 20 nest-provisioning females were attracted to the paper flower impregnated with a pentane extract of *L. punctata* flowers from a distance of several meters. No bees were attracted to the control flower. In the three-choice test, 11 of the ca. 20 nest-provisioning individuals landed on the glass surfaces containing either the pentane extract of whole flowers or the pentane extract of pure oil. None was attracted to the control glass surface. Eight of the 11 attracted individuals landed on the glass surface containing the whole flower extract, and 2 of them collected oil (1 of these specimens for several minutes). Three individuals were attracted to the "oil flower," and one of these collected oil from the surface (for several minutes). In this three-choice test, oil bees were attracted by the flower (floral oil) scent without any visual cues (flower shape or color). Dynamic headspace analyses from the artificial flowers revealed that they released nearly the same spectrum of compounds emitted from flowers and pure oil of *L. punctata* (Schäffler and Dötterl, unpublished data).

The results reveal that vegetative parts and flowers of *L. punctata* emit several scent compounds, and that some of them are also emitted from pure oil. Because these oil compounds were emitted in much higher total amounts from whole flowers compared to pure oil (Table 1), it is suggested that the scents that are released by floral tissues are taken up by the oil (because they are soluble in it) and are revaporized (compare with Raguso,

[b] Identification based on authentic standards

Table 2 Number of females of *M. fulvipes* landing in a dual choice test on paper flowers impregnated with pentane (control) or with a pentane extract of flowers of *L. punctata*, and in a three-choice test on glass surfaces containing a pentane extract of flowers/pure oil of *L. punctata* or pentane only

	Control	Flower Extract	Oil Extract
Dual choice test (paper flowers)	0	12 (0)[a]	nt[b]
Three-choice test (glass surfaces)	0	8 (2)	3 (1)

[a] Values in parentheses are the number of bees collecting oil.

[b] nt = not tested

2004). Furthermore, female bees were attracted to pentane extracts of whole flowers and pure floral oil, and the uncommon floral scent compounds characteristic for *L. punctata* were possibly responsible for this attraction. It is interesting to note that bees only collected oil from the glass surface, and oil-collection behavior was not elicited at the paper flowers. Therefore, it seems that bees have chemoreceptors on their legs for detection of oil, and that oil-collection behavior is triggered when oil, available on a surface, comes in contact with the receptors. Free-standing oil was not available on the paper flowers because it was taken up by the paper.

Acknowledgements We are grateful to Gregor Aas for permission to build the flight cage in a green house at the Ecological–Botanical Garden (EBG), and to use *L. punctata* plants growing in the EBG for this study. Peter Hartmann helped collect bees for the flight cage. Karlheinz Seifert and Thomas Gedig provided a standard 1-hydroxy-1-phenyl-2-propanone. Joseph Woodring, Gregor Aas, and two anonymous reviewers improved earlier versions of this manuscript.

Allelochemical Induction of Cytochrome P450 Monooxygenases and Amelioration of Xenobiotic Toxicity in *Helicoverpa zea*

Ren Sen Zeng · Zhimou Wen · Guodong Niu · Mary A. Schuler · May R. Berenbaum

Received: 14 July 2006 / Accepted: 4 December 2006 /

Abstract Polyphagous herbivores encounter allelochemicals as complex mixtures in their host plants, and the toxicity of an individual compound may be influenced by the chemical matrix in which it is encountered. Certain plant constituents may reduce toxicity of cooccurring compounds by inducing detoxification systems, including cytochrome P450s, which can metabolize a broad range of substances. The polyphagous corn earworm *Helicoverpa zea* encounters a diversity of plant allelochemicals in its many host plants and, as well, can encounter aflatoxins, mycotoxins produced by *Aspergillus flavus* and *Aspergillus parasiticus* that infect damaged grains. Dietary supplementation of each of three plant allelochemicals that are frequently (coumarin, COU), occasionally (indole-3-carbinol, I3C), or rarely (xanthotoxin, XAN) encountered by *H. zea* larvae substantially reduced the toxicity of aflatoxin B1 (AFB1) to *H. zea*. Compared to fourth instars on diets containing 1 μg/g AFB1 that failed to develop and pupate, fourth instars on diets containing I3C and XAN increased in mass by 216.1 and 700% after 6 days, and pupated at rates of 40 and 88%, respectively. Diets containing COU or XAN also significantly reduced the mortality rates of caterpillars exposed to the insecticides, diazinon and carbaryl. Diets containing COU and XAN increased *CYP6B8* transcripts 2.6-fold; *CYP321A1* transcripts increased 20.7, 8.3, and 10.6-fold in response to COU, I3C, and XAN, respectively. These results indicate that consumption of plant allelochemicals can ameliorate toxicity of natural and synthetic toxins encountered by insects, and they suggest that P450s induced by these allelochemicals contribute to detoxification of these chemicals in *H. zea*.

I3C	Indole-3-carbinol
XAN	Xanthotoxin
COU	Coumarin
SDS	Sodium dodecyl sulfate

Introduction

Polyphagous herbivores encounter allelochemicals as complex mixtures in their host plants, and the toxicity of an individual compound may be influenced by the chemical matrix in which it is encountered (Berenbaum, 1985). In some synergistic interactions, cooccurring plant constituents interfere with or disable insect detoxification systems to enhance toxicity. In the polyphagous corn earworm *Helicoverpa zea*, for example, the toxicity of the phototoxic plant furanocoumarin xanthotoxin is enhanced in the presence of myristicin, a phenylpropene essential oil component that inhibits the cytochrome P450 monooxygenases that detoxify furanocoumarins in this species (Berenbaum and Neal, 1987). Whereas certain allelochemical interactions are beneficial to the plant in enhancing its defense against herbivores, other interactions among allelochemicals may be beneficial to the herbivore. In some cases, cooccurring chemicals reduce the toxic consequences of allelochemical ingestion in that some herbivores selectively sequester host plant carotenoids and xanthophylls, which reduce oxidative stress produced by ingestion of cooccurring plant phototoxins (Aucoin et al., 1990; Fields et al., 1990; Carroll et al., 1997). Other interactions that benefit the herbivore result from activation or potentiation of detoxification systems that include P450s. A tremendous diversity of plant allelochemicals, including furanocoumarins, coumarin, phenylpropenes, alkaloids, triterpenes, tetraterpenes, flavonoids, and cardenolides are capable of inducing P450 activities in herbivorous insects (Yu, 1982, 1983, 1987; Cohen et al., 1989; Capua et al., 1991; Snyder et al., 1993; Hung et al., 1995; Li et al., 2002a), but the toxicological benefits of such induction have been documented only rarely. In some cases, these benefits are mediated by the plant signaling substances, jasmonic acid and salicylic acid, which activate biosynthetic defense responses in plants damaged by herbivores or pathogens. Ingestion of jasmonic acid or salicylic acid leads to the up-regulation of CYP6B8 and other detoxification enzymes in *H. zea* (Li et al., 2002b). Induction of these broadly substrate-specific enzymes in response to plant signals allows this insect to gear up its capacity to detoxify allelochemicals in advance of their biosynthesis by the plant (Li et al., 2002b).

Because of the broad substrate-specificity of at least some P450s in the polyphagous *H. zea*, the potential exists for interactions between plant allelochemicals and other cooccurring toxins. Whether these interactions benefit the herbivore depends on the substrate specificities and catalytic activities of the induced P450s. Because herbivorous insects are exposed to a variety of toxic xenobiotics other than host plant constituents, Cleveland et al. (2003) have suggested that the ability of insect herbivores to detoxify plant allelochemicals may equip them for resistance against toxins produced by pathogens that infect their host plants. For *H. zea*, one such toxin is aflatoxin B1, a metabolite produced by

Aspergillus flavus and *Aspergillus parasiticus*, two closely related fungal species that can infect multiple host plants of *H. zea* (Diener et al., 1987; Wilson and Payne, 1994), particularly during infestation by this insect (Dowd, 1998). Aflatoxins are dihydrofurocyclopentenones or dihydrofurolactones that owe their toxicity to their ability to form irreversible adducts to nucleic acids with the concomitant inhibition of DNA replication and DNA-dependent transcription (Murray et al., 1982). Unlike most P450-mediated detoxification reactions in which toxins are inactivated, P450-mediated reactions are capable of transforming aflatoxin B1 (AFB1) to more toxic metabolites, including AFB1-8,9-epoxide, by the epoxidation of the terminal furan ring (Murray et al., 1982). Such bioactivation of AFB1 is mediated by CYP6A2 in the Hikone-R strain of *Drosophila melanogaster* (Saner et al., 1996) and several P450s in humans. In *H. zea*, the toxicity of AFB1 is ameliorated by piperonyl butoxide inhibition of P450s (Zeng et al., 2006) but the identity of the P450(s) responsible for this bioactivation has not yet been defined.

In addition to mycotoxins, herbivorous insects can encounter insecticides in combination with allelochemicals. Whether insecticides are detoxified or bioactivated by insect P450s depends both on the insecticide structure and the specific P450 isoforms present. Whereas pyrethroids are detoxified by CYP6D1 in the house fly *Musca domestica* (Scott, 1999; Scott and Wen, 2001) and by CYP6B8 (Li et al., 2004) and CYP321A1 in *H. zea* (Sasabe et al., 2004), bioactivation of the organophosphorothioate pesticide diazinon is mediated by CYP6A1 in the house fly (Sabourault et al., 2001). In some species, the ability to metabolize plant allelochemicals cross-protects them against synthetic insecticides (Kennedy, 1984; Li et al., 2000). The major mechanism for this cross-resistance is the ability of some P450s to detoxify both plant allelochemicals and synthetic insecticides (Li et al., 2004; Sasabe et al., 2004). Some of these P450s are differentially induced by a wide range of host plant allelochemicals, including those that are nontoxic themselves (Prapaipong et al., 1994; Hung et al., 1995; Li et al., 2002a, 2004; Sasabe et al., 2004), thereby influencing the ability of insects to detoxify or bioactivate compounds ingested in their diet.

The broad diet of *H. zea* leads to exposure to a wide range of allelochemicals, which are processed in part by P450s with broad substrate ranges (Li et al., 2004). At the same time, the susceptibility of several of its host plants to *Aspergillus* infection makes this species likely to encounter mycotoxins, and its economic status virtually assures exposure to multiple insecticides throughout its range. Thus, *H. zea* is an ideal subject for investigating the toxicological significance of allelochemical induction of P450s in the presence of exogenous toxins. Specifically, we examined the toxicity of two insecticides, diazinon and carbaryl, and one mycotoxin, AFB1, in the presence of three plant allelochemicals known to induce P450s that are encountered with varying frequency by this species: coumarin (COU), which is frequently encountered, indole-3-carbinol (I3C), which is occasionally encountered, and xanthotoxin (XAN), which is rarely encountered throughout the host plant range of *H. zea* larvae. We also determined the effects of these plant allelochemicals on transcription of the *H. zeaCYP6B8*, *CYP6B9*, *CYP6B27*, and *CYP321A1* genes encoding P450s known to detoxify allelochemicals and insecticides.

Methods and Materials

Chemicals and Enzymes

Aflatoxin B1, indole-3-carbinol, coumarin, and xanthotoxin (8-methoxypsoralen; 99.6% purity) were obtained from Sigma (St. Louis, MO, USA). Analytical grade dimethyl

sulfoxide (DMSO) was purchased from Fisher Scientific. RQ1 DNase, RNasin and AMV reverse transcriptase were from Promega (Madison, WI, USA), Taq polymerase and deoxynucleotide triphosphates (dNTPs) were from Invitrogen (Carlsbad, CA, USA) and the TRIzol reagent was from Gibco-BRL (Cleveland, OH, USA). Diazinon and carbaryl were from Chem Service (West Chester, PA, USA).

Insects

An insecticide-susceptible laboratory strain of *H. zea*, provided by B. Ria Barrido of Abbott Laboratories (Chicago, IL, USA) was used for all experiments. *H. zea* larvae were individually reared on a semisynthetic control diet containing wheat germ (Waldbauer et al., 1984) and maintained in an insectary kept at 23–26°C with a photoperiod of 16-hr light to 8-hr dark. For each experiment, caterpillars that had molted within 12 hr were selected for all treatments to insure homogeneity in developmental age.

AFB1 Bioassays

Stock solutions of AFB1 were prepared in DMSO at a concentration of 1 μg/μl. Caterpillars within 12 hr of molting to either fourth or fifth instar, depending on experiment, were assigned to four different treatments: (1) control diet containing 200 μl DMSO per 100 g; (2) AFB1 diet containing 100 μl of AFB1 stock solution in DMSO and 100 μl DMSO per 100 g diet (i.e., 1 μg AFB1 per gram diet); (3) allelochemical diets containing 100 mg indole-3-carbinol, 100 mg coumarin or 50 mg xanthotoxin dissolved in 100 μl DMSO and additional 100 μl DMSO per 100 g diet (corresponding to 1 mg COU or I3C per gram diet or 0.5 mg XAN per gram diet); (4) allelochemical + AFB1 diets, containing 100 mg indole-3-carbinol or coumarin, 50 mg xanthotoxin (fifth instars) or 25 mg xanthotoxin (fourth instars) dissolved in 100 μl DMSO and 100 μl AFB1 stock solution in DMSO per 100 g diet (corresponding to the combination of 1 μg AFB1 and 1 mg COU or I3C or 0.25–0.5 mg XAN per g diet).

Caterpillars feeding on these different diets were individually reared in 30-ml plastic cups in an insectary at 23–26°C with a photoperiod of 16-hr light to 8-hr dark. Weight gain was measured after 3 d in experiments with fifth instars and 6 d in experiments with fourth instars. Larval developmental stage and mortality were monitored daily until pupation, at which point pupal weights were measured within 48 hr of the final larval molt. Each set of bioassays was replicated three times, and 20 larvae were tested in each bioassay.

Insecticide Bioassays

Diazinon was used in our insecticide bioassays because this insecticide is bioactivated by P450s in some species (Feyereisen, 1999). Fifth instars were reared in an insectary at 23–26°C with a photoperiod of 16-hr light to 8-hr dark for 48 hr on diets containing either COU at 1 mg/g diet, I3C at 1 mg/g diet or XAN at 0.5 mg/g diet, after which time 3 μl of 100 μg/μl diazinon in acetone (300 μg total) and 3 μl of 33.3 μg/μl carbaryl in acetone (100 μg total) were topically applied to each caterpillar. These insecticides were not delivered in the diet because their fast-acting neurotoxic effects would likely interfere with allelochemical ingestion. Control bioassays were conducted with topical applications of 3 μl of acetone. Treated insects were kept in an incubator at 28°C with a photoperiod of 16-hr light to 8-hr dark, and mortality was assessed 5 hr after insecticide application. Insects were considered dead if they were on their backs and unable to right themselves when

disturbed. Bioassays were replicated at least three times and 20 larvae were tested in each bioassay.

RNA Isolations

Fifth instar *H. zea* within 12 hr of molting and within a weight range of 170–270 mg were randomly assigned to treatment groups. Twenty larvae in each treatment group were placed on diets containing COU at 1 mg/g diet, I3C at 1 mg/g diet or XAN at 0.5 mg/g diet. There were two control treatments, one with unamended diet and another with artificial diet containing 0.2% DMSO to control for solvent effects. After 48 hr of feeding, larvae were sacrificed and midguts excised and cleaned in 0.1 M sodium phosphate buffer (pH 7.8). Total RNA was extracted from each group of 20 pooled larvae with TRIzol reagent, treated with 5 U RQ1 DNase for 30 min at 37°C, cleaned up using a Qiagen RNeasy kit (Valencia, CA, USA), quantified by A_{260} and stored at −80°C.

RT-PCR Southern Analyses

RT-PCR Southern analyses were used to quantify the levels of the *CYP6B8*, *CYP6B9*, *CYP6B27*, and *CYP321A1* transcripts. To keep RT-PCR amplifications within their linear ranges, 50 μl RT-PCR reactions contained 100 ng total RNA, 0.5 μl RNasin (40 U/μl), 0.5 μl AMV reverse transcriptase (10 U/μl), 0.25 μl Taq polymerase (5 U/μl), 25 μl 2× RT buffer containing dNTPs, and 1 μl forward and reverse primer (10 μM) each. Gene-specific forward/reverse primer sets used in these reactions were (5′-TCTTGTGGACAGCATTAT TAGC-3′/5′-CAAGTCCGAATGGTAAGTACGC-3′) for CYP6B8, (5′-GATCTTT TATTTTCCGGCAGTG-3′/5′-CTTTCTCAATGACCACGTCTGTTC-3′) for CYP6B9, (5′-ATTTTTCCAACGGCGGTAAAG-3′/5′-CGGGAATTTTGTAATCTCTAGT-3′) for CYP6B27, (5′-TAGTGTGGAGGGTGACCAACTG-3′/5′-CGGACAACAAGCCAGTCG TAGGC-3′) for CYP321A1, and (5′-TGGGAYGAYATGGAGAAGATCTGG-3′/5′-TAGATGGGBACBGTGTGBGAGACA-3′ with Y (C/T), B (C/G/T)) for actin, which was used as a reference. RT-PCR reactions were initiated with first strand cDNA synthesis at 42°C for 50 min. After denaturation of the RNA-cDNA hybrid at 94°C for 5 min, 18 PCR amplification cycles (94°C for 1 min, 60°C for 1 min, and 72°C for 2 min) were run and followed by a final extension for 5 min. Ten μl of concentrated (6×) loading dye were added to each reaction, and 20 μl of each sample were run on 1.0% agarose gel in 1×TBE buffer. After gel-blotting, the Hybond-N membranes (Amersham-Pharmacia Biosciences, Uppsala, Sweden) were prehybridized and then hybridized with P^{32}-labeled gene-specific probes at 42°C overnight in hybridization buffer containing 5× SSC, 5× Denhardt's solution, 50% formamide, 50 mM sodium phosphate (pH 7.0), and 0.5% SDS. Membranes were washed twice at low stringency in buffer containing 2×SSC, 0.1% SDS at 42°C each for 15 min and once at high stringency in buffer containing 0.2×SSC, 0.1% SDS at 62°C for 15 min. Membranes were autoradiographed and quantified by phosphoimager analysis using a Typhoon 8600 variable model imager (Amersham-Pharmacia Biotech). RT-PCR Southern analyses were repeated three times with RNA samples prepared from midguts of larvae in three independent biological replicates.

Statistical Analyses Data were evaluated by one-way analysis of variance (ANOVA) with treatment differences among means tested at $P=0.05$ using the Tukey *post hoc* test. All data for pupation rates are means from three replicates with 20 caterpillars/treatment. Because significant differences were found among replicates in pupal weights, this parameter was

analyzed independently for each replicate, and representative values from one replicate are reported.

Results

Indole-3-carbinol Dietary exposure of fourth and fifth *H. zea* instars to 1 mg/g I3C significantly reduced toxicity of 1 μg/g AFB1 to *H. zea*. The average weight gain, pupation rate and pupal weight of fifth instars on diets containing 1 mg/g I3C + 1 μg/g AFB1 increased by 108.0% ($P<0.001$), 69% ($P=0.002$), and 26.9% ($P<0.001$), respectively, compared with caterpillars on diets containing only 1 μg/g AFB1 (Fig. 1a–c). Pupation rates on diets containing 1 mg/g I3C + 1 μg/g AFB1 did not differ from rates on control diets (Fig. 1b).

Fourth instars on diets containing 1 mg/g I3C + 1 μg/g AFB1 gained 71.5% more weight ($P=0.036$) after 6 d of feeding compared with caterpillars on diets containing only 1 μg/g AFB1 (Fig. 1a). Whereas no fourth instars on diets containing 1 μg/g AFB1 succeeded in pupating, addition of 1 mg/g I3C to the diet increased pupation rates to 40% and pupal weights to 261.3 mg ($P<0.001$) (Fig. 1b, c).

Coumarin Fifth instars consuming diets containing 1 mg/g COU + 1 μg/g AFB1 displayed weight gain, pupation rate, and pupal weight increases of 139.1% ($P<0.001$), 40.5% ($P=0.035$), and 23.6% ($P=0.002$), respectively, compared with caterpillars receiving only 1 μg/g AFB1 (Fig. 2a–c). Pupation rates and weight gain on diet containing 1 mg/g COU + 1 μg/g AFB1 were equivalent to those on control diet (Fig. 2a, b). Pupation rate (63.3%) ($P<0.001$) and pupal weights (265.1 mg) ($P<0.001$) of fourth instars on diets containing 1 mg/g COU + 1 μg/g AFB1 were significantly higher than those of *H. zea* on diets containing AFB1 alone (5.0% pupation rates and 164 mg pupal weight) (Fig. 2b, c). Caterpillars on diet containing COU + AFB1 increased in size by 216.1% after 6 d of treatments ($P<0.001$) (Fig. 2a).

Xanthotoxin Caterpillars simultaneously treated with XAN and AFB1 displayed substantially greater tolerance to AFB1 compared with those exposed only to AFB1. Weight gain of fifth instars on diets containing 0.5 mg/g XAN + 1 μg/g AFB1 after 3 d of treatment increased by 135.2% ($P=0.0017$) (Fig. 3a), and pupal weights increased by 29.3% ($P<0.001$) (Fig. 3c) compared to *H. zea* on diets containing AFB1 alone. Even more strikingly, the weight gain of fourth instars after 6 d on a diet containing 0.5 mg/g XAN + 1 μg/g AFB1 increased by 700% ($P<0.001$) (Fig. 3a) compared to caterpillars on diets containing only AFB1. Whereas no fourth instars on diets containing 1 μg/g AFB1 succeeded in pupating, addition of 0.25 mg/g XAN to the diet increased pupation rates to 88.3% and pupal weights to 279 mg ($P<0.001$) (Fig. 3b, c). Pupation rates in the presence of XAN were, in fact, not significantly different from pupation rates of larvae on control diets ($P=0.057$).

Insecticides Five hours after exposure to diazinon, fifth instars consuming control diets experienced 68.8% mortality. In contrast, caterpillars fed for 48 hr on diets containing COU, I3C, or XAN experienced mortality rates of 18.8% ($P<0.001$), 31.3% ($P=0.005$), and 36.3% ($P=0.013$), respectively, after diazinon treatment (Fig. 4). Similarly, where fifth instars consuming control diets experienced 68.7% mortality 5 hr after carbaryl exposure,

H. zea consuming diets containing COU, I3C, and XAN experienced mortality rates of 25.0% (P=0.004), 38.8% (P=0.048), and 37.5% (P=0.038), respectively, after carbaryl exposure (Fig. 4).

Induction of P450 Transcripts To determine whether COU, I3C, and XAN enhance the detoxification of AFB1 by inducing transcription of P450 genes in *H. zea*, RNA samples were analyzed from fifth instars fed for 48 hr on diets supplemented with each of the three plant allelochemicals. All three chemicals induced accumulation of *CYP321A1* transcripts over basal levels present in fifth instar control midguts (Fig. 5). *CYP321A1* transcripts accumulated approximately to 10.6-fold higher levels in response to 0.5 mg/g XAN, 8.3-fold higher levels in response to 1 mg/g I3C, and 20.7-fold higher levels in response to

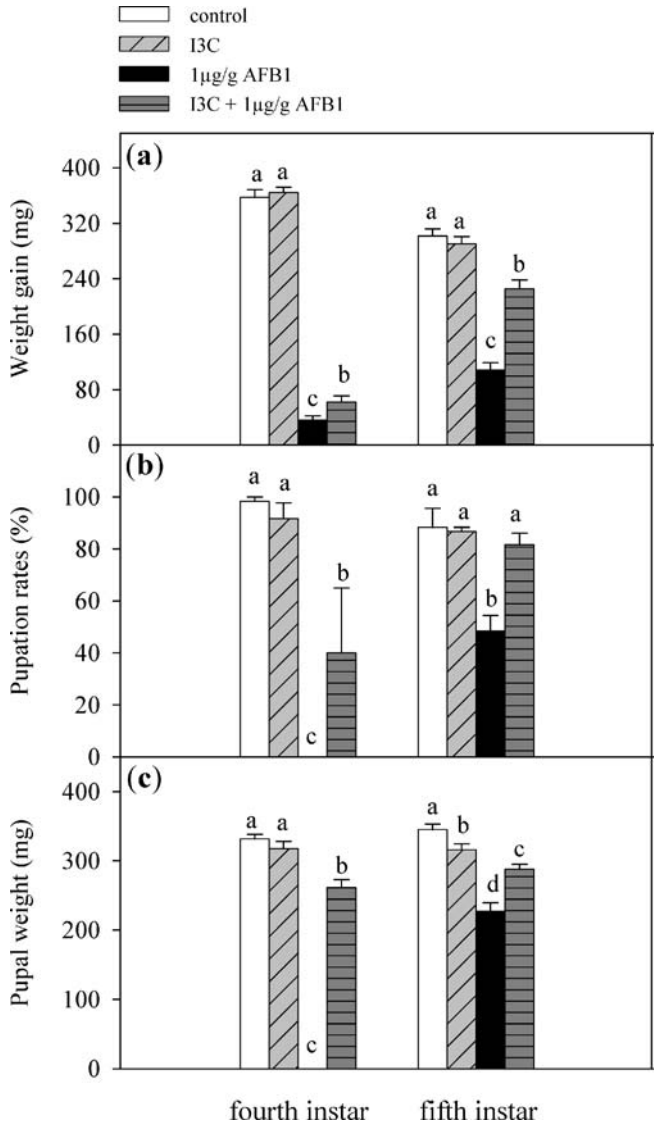

Fig. 1 Effects of I3C on growth and pupation of *H. zea* fourth and fifth instars exposed to 1 μg/g AFB1. Values shown for pupation rate are means+standard error from three replicates with 20 caterpillars/treatment. Values for weight gain and pupal weight are representative of one of the three series of replicates. Significant differences (P<0.05 using Tukey *post hoc* test) among treatments in a group are indicated by different letters above the bars

1 mg/g COU. Comparison among transcripts indicated that the induction responses were gene-specific. *CYP6B8* transcripts were induced approximately 2.6-fold by 1 mg/g COU, 2.6-fold by 0.5 mg/g XAN, and not at all by I3C (Fig. 5). Neither *CYP6B8* nor *CYP321A1* was upregulated in the presence of AFB1 alone. The other two P450 transcripts analyzed, *CYP6B9* and *CYP6B27*, were not induced significantly by any of these compounds.

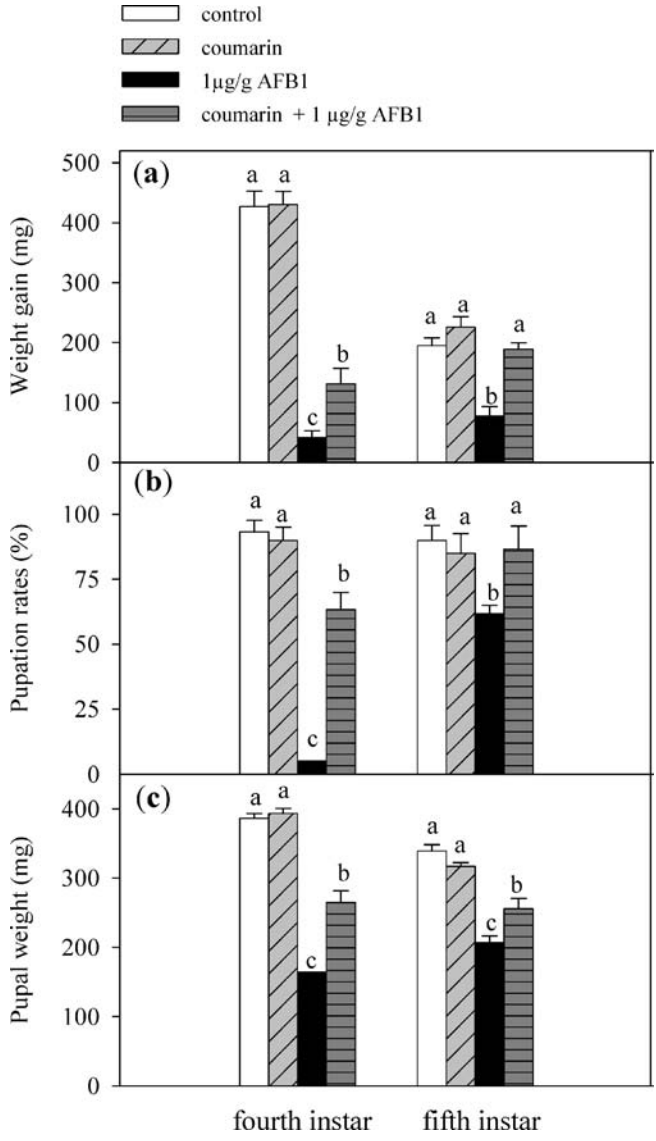

Fig. 2 Effects of COU on growth and pupation of *H. zea* fourth and fifth instars exposed to 1 μg/g AFB1. Values shown for pupation rate are means+standard error from three replicates with 20 caterpillars/treatment. Values for weight gain and pupal weight are representative of one of the three series of replicates. Significant differences ($P<0.05$ using Tukey *post hoc* test) among treatments in a group are indicated by different letters above the bars

Discussion

Plant allelochemicals have been demonstrated or implicated in chemoprotection in many vertebrate systems (Bailey et al., 1987; Grubbs et al., 1995; Takahashi et al., 1995a,b; Goeger et al., 1998, 1999; Manson et al., 1998; Xu et al., 2001; Stoner et al., 2002). These effects are generally attributed to the ability of these compounds to induce detoxification enzymes, mainly P450s. While a large body of evidence has shown that plant allelochemicals induce P450s in insects, rarely have the experiments been carried out to demonstrate a correlation between the induction of P450s and the enhancement of an insect's tolerance to toxins. Feeding on a broad range of plant species, including many of

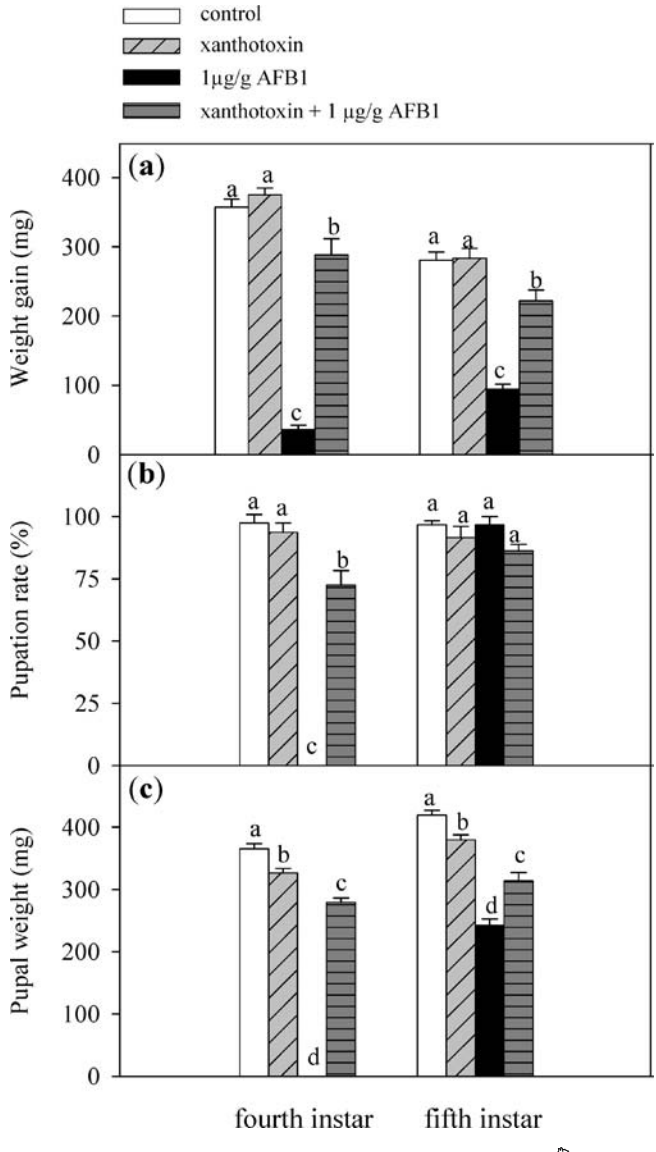

Fig. 3 Effects of XAN on growth and pupation of *H. zea* fourth and fifth instars exposed to 1 μg/g AFB1. Values shown for pupation rate are means+standard error from three replicates with 20 caterpillars/treatment. Values for weight gain and pupal weight are representative of one of the three series of replicates. agricultural importance that are susceptible to infection by *Aspergillus*, assures that corn earworms are exposed to mycotoxins and/or insecticides concurrent with the many allelochemicals in their host plants. The corn earworm, therefore, represents a good model to determine whether there is a correlation between P450 induction by plant allelochemicals and the effects of these chemicals on the toxicity of mycotoxins and insecticides to insects.

The frequency with which herbivorous insects encounter a specific allelochemical depends on many factors including the distribution of allelochemicals throughout the host range and the frequency with which a host plant is used. Of the three allelochemicals examined, COU is widely distributed in host plants and frequently encountered by *H. zea*, I3C is derived from glucosinolates in cruciferous plants and occasionally encountered (Chevolleau et al., 1997), and XAN is found in several plant families including Apiaceae and Rutaceae (Berenbaum, 1991) and rarely encountered. Our data show that all three allelochemicals substantially reduced the toxicity of AFB1, diazinon, and carbaryl to *H. zea*. In parallel with their effects in reducing toxicity of AFB1, diazinon, and carbaryl to *H. zea*, these allelochemicals selectively induced the transcription of midgut P450s in *H. zea* larvae. Of the four P450s examined, CYP6B8 transcripts were induced 2.6-fold by both COU and XAN, and CYP321A1 transcripts were induced at a much higher level by all three allelochemicals (20.7-fold by COU, 8.3-fold by I3C, and 10.6-fold by XAN). Both P450s have been shown to metabolize many different types of toxins including insecticides in vitro (Li et al., 2004; Sasabe et al., 2004). These results indicate that induction of toxin-

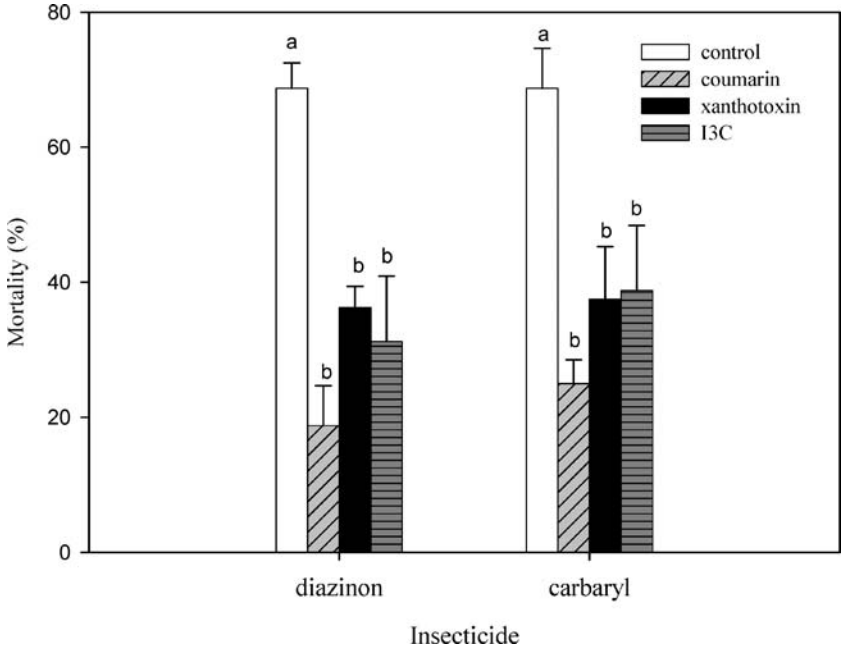

Fig. 4 Allelochemical-induced insecticide resistance. After exposure of newly molted fifth instars to diets containing 0.2% DMSO (control) plus 1 mg/g COU, 1 mg/g I3C or 0.5 mg/g XAN for 48 hr, the mortality rates of *H. zea* were monitored after 5 hr of treatment with 300 μg diazinon/caterpillar or 100 μg carbaryl/caterpillar. Values are means+standard errors from four replicates with 20 caterpillars/replicate. Significant differences ($P<0.05$ using Tukey *post hoc* test) among treatments in a group are indicated by different letters above the bars

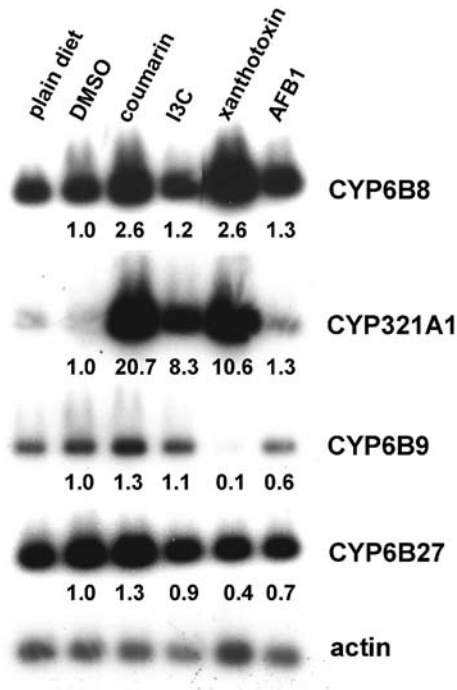

Fig. 5 P450 transcript induction by plant allelochemicals. Total RNA pooled from 20 midguts of newly molted fifth instar *H. zea* feeding for 48 hr on diet containing plant allelochemicals. Control, unamended diet; DMSO, diet containing 0.2% DMSO (used as a solvent to dissolve the tested allelochemicals); coumarin, diet containing 1 mg/g COU; I3C, diet containing 1 mg/g I3C; xanthotoxin, diet containing 0.5 mg/g XAN; AFB1, diet containing 1 μg/g AFB1. The induction level for each was calculated by normalizing the signal of each gene against actin and then using the DMSO control as a reference point

detoxifying P450s in insects significantly enhances this insect's tolerance to toxins. The responses to XAN are especially interesting. Despite the fact that only slightly higher concentrations of XAN than tested here are toxic to *H. zea* (Berenbaum and Neal, 1985) and that this furanocoumarin is only rarely encountered by this species, it is extremely effective at reducing the toxicity of AFB1 and insecticides to *H. zea* and inducing *CYP6B8* and *CYP321A1* transcript accumulation.

Synergistic interactions arising from inhibition of detoxification enzymes by cooccurring plant allelochemicals have been exploited in the development of commercial synergists for pesticides designed to circumvent metabolic resistance. Indeed, sesamin, a methylenedioxyphenyl compound found in *Chrysanthemum* (=*Tanacetum*) *cinerariaefolium*, the pyrethrum plant, is among the oldest of commercial pyrethroid synergists (Whittaker and Feeny, 1971). By the same token, understanding the sort of antagonistic interactions among plant constituents demonstrated here, according to which inducers of detoxification enzymes reduce toxicity of cooccurring allelochemicals, can provide insights into optimizing chemically based pest management programs, potentially providing mechanistic explanations for the differential efficacy of insecticides on different crop species or varieties (e.g., Alverson and Gorsuch, 1982; Kennedy, 1984; Abro and Wright, 1989).

Abstract Temperature directly affects the growth, survival, and development rates of poikilothermic insect herbivores; it may also have an important indirect impact, via the activities of plant defensive enzymes. The effects of wounding birch leaves and temperature on the growth and development rates of a Lepidopteran moth, *Epirrita autumnata*, were studied. We also examined the activities of a mountain birch (*Betula pubescesns* spp. *czerepanovii*) defensive enzymes, specifically the polyphenoloxidases (PPOs), in relation to temperature and wounding. The optimal temperature for early instars in terms of survival and developmental rates was between +15 and 20°C. Wounding treatment had different effects on birch PPO activity depending on the temperature: at +12°C, wounding decreased the activity, suggesting induced amelioration at that temperature, whereas at +25°C, wounding increased the activity, suggesting induced resistance. However, larval growth was retarded slightly, but significantly, on the leaves of wounded twigs at both temperatures. Both PPO activity and larval growth rates were affected within 12 h, indicating the existence of a transcription- and translation-independent defense system in birch leaves. We suggest that underlying the increase in PPO activity and the decrease in larval growth rate may be H_2O_2, which has been shown to accumulate in response to wounding. Our results also provide a possible biological mechanism for the hypothesis that low temperatures promote the success of *E. autumnata* and other Lepidopteran larvae via decreased defensive enzyme activities of host plants at lower temperatures.

Introduction

Temperature is one of the fundamental abiotic factors that lay down the boundaries for the ranges of animals and plants. Temperature affects enzyme activities, growth, development rates, and further population dynamics of plant-eating animals. Food quality is a bottom-up factor that varies spatially and temporally; it is affected by abiotic factors, such as ambient temperature, and by biotic factors, such as wounding by herbivores (Scriber and Slansky, 1981). Plants are not silent victims; they are defended against herbivores by multiple strategies, and an herbivore attack triggers complex and delicate signaling pathways that lead to an activated defense (Lamb and Dixon, 1997).

A number of studies have shown that foliar phenoloxidase activities have a negative impact on the performance of several species of insect herbivores (e.g., Felton et al., 1989; Bi and Felton, 1995; Tscharntke et al., 2001). Polyphenol oxidases (PPOs) are ubiquitous enzymes found in both plants and animals. PPOs are located in plastids (Vaughn and Duke, 1984), apart from their vacuolar phenolic substrates, but the rupture of cell compartments brings the enzymes together with their substrates. PPOs use several plant phenolics as substrates, converting them to highly reactive quinones that attach covalently to the electron-rich moieties of multiple compounds, including amino acids and proteins (Felton et al., 1989). Precipitation of amino acids, especially electron-rich essential amino acids, is suggested to decrease the nutritive value of plant tissues for herbivores, reducing, in turn, the growth rate of juvenile insects (Felton et al., 1989).

Wounding and herbivory also trigger production of reactive oxygen species such as H_2O_2 (Bi and Felton, 1995; Orozco-Cárdenas et al., 2001; Ruuhola and Yang, 2006), which have direct defensive roles: for instance, acting as a feeding deterrent (Lamb and Dixon, 1997) or causing oxidative damage in the insect midgut (Bi and Felton, 1995). In addition, H_2O_2 is also a substrate of peroxidases (PODs) and mediates distress signaling in plants (Lamb and Dixon, 1997; Alvarez et al., 1998). Like PPOs, PODs use plant phenolics as substrates, converting them to quinones, but they have multiple other roles in addition to defense, including lignification, suberization, and the cross-linking of cell walls proteins (Hiraga et al., 2001). Overall, the role of defensive enzymes has largely been ignored in ecological studies focusing on the roles of secondary compounds in plant–herbivory interactions.

Cool springtime temperatures have often been associated with the outbreaks of several species of forest Lepidoptera in the northern hemisphere (Myers, 1998), including *Epirrita autumnata* (Lepidoptera: Geometridae) (Niemelä, 1980; see also Haukioja et al., 1988). Weather conditions have been suggested to act as a Moran effect, synchronizing the fluctuation of Lepidopteran species over wide geographic areas (Myers, 1998). However, the biological mechanisms that explain the link between cool temperature and Lepidopteran outbreaks are not known.

Some insect species, such as *E. autumnata*, are adapted to a wide temperature range. The geometrid *E. autumnata* is common throughout most of the Holoarctic region and shows regular large-scale outbreaks in mountain birch forests of the northernmost mountainous area (Tenow, 1972). As temperature is a critical determinant for enzyme activities, we predicted that mountain birch foliar oxidase activities might be considerably hindered at low temperatures. We undertook a study to examine the effect of temperature on foliar enzyme activities and on the growth of young instar *E. autumnata* and their interaction.

Methods and Materials

Experimental Organisms Experiments were conducted in the laboratory of the Kevo Subarctic Research Institute of the University of Turku (69°45′ N, 27°00′ E) in summer 2003. Mountain birch [*Betula pubescens* spp. czerepanovii (Orlova) Hämet-Ahti] forms uniform stands at the arctic tree line in northern Fennoscandia. Mountain birch harbors over 50 species of folivorous insects (Koponen, 1973), *Epirrita autumnata* Borkhausen (Lepidoptera: Geometridae) being the most deleterious species (Tenow, 1972, 1975; Kallio and Lehtonen, 1973).

E. autumnata larvae are highly polyphagous, but in the subarctic area the main host is the mountain birch, due apparently to its abundance. Larvae hatch in spring at the time of mountain birch leaf-flush (Haukioja et al., 1988; Kaitaniemi and Ruohomäki, 1999); the successful synchronization of hatching with bud burst is essential for larval development (Ayres and MacLean, 1987a; Tammaru, 1998). Low-altitude sites, such as river valleys, regularly experience low winter temperatures, killing the eggs. Outbreaks usually occur at high-altitude sites (Tenow, 1972, 1975; Kallio and Lehtonen, 1973; Virtanen et al., 1998), but cannot occur after a cold winter (Ruohomäki et al., 2000).

Experimental Design We used two temperatures: a constant +12°C, corresponding to the mean temperature of *E. autumnata* larval period, which has been used regularly in the bioassay of *E. autumnata* and other birch herbivores (e.g., Kause et al., 1999; Riipi et al., 2002; Lempa et al., 2004; Ruusila et al., 2005; Kapari et al., 2006), and +25°C, corresponding to the temperature of a warm summer day. These two temperatures were originally selected to test methodological aspects: how do regularly used rearing temperatures of *E. autumnata* (+12 and +25°C) affect the results of bioassays? In other words, we did not want to test only direct effects of rearing temperatures, but also indirect effects via temperature-modified changes in leaf enzyme activities. In addition, this study helps in the evaluation of ecological aspects of temperature in nature, as a high variation between night and day temperatures is characteristic for subarctic climate, but warm summer days occur regularly. For example, at end of June 2003, Kevo was the warmest region in Finland.

We selected, haphazardly, 10 mountain birches growing on the upper part of the Puksala fell. In early June, four branches were cut from each tree and brought to the laboratory. Isolated plant organs are used routinely in physiological studies, and isolation does not normally prevent local enzyme induction (e.g., Constabel and Ryan, 1998). Four twigs (length ca 1 m) from each tree were randomly allocated to four temperature–treatment combinations: +25 control, +25°C larval treatment, +12°C control, and +12°C larval treatment (Table 1). All the twigs were placed into holders, and the freshly cut ends were put into water. The experiment was started by releasing 10 larvae onto the larval twigs (10 larvae per treated twig). The larvae were allowed to feed freely on the larval twigs for 12 h, after which sampling for the enzyme analyses and for the RGR-experiment was conducted (Table 1).

Bioassay with Larvae *E. autumnata* larvae originating from the crossing of previous-season moths collected both from the Kevo area and an outbreak area in Norway, were reared individually in plastic 48-ml vials under a natural temperature regime until they molted to the third instar. Larvae were fed with mountain birch leaves every second or third day; thus, they had fresh food and did not suffer from a shortage of food. After molting to the third instar, larvae were placed at +1°C without food. When all had molted, new fresh leaves were provided to larvae for pre-feeding 12 h before the experiment (+12°C).

Table 1 The scheme of experimental procedure of a short-term temperature trial

Ten mountain birch trees, four twigs from each tree, pre-incubation 12 h[a]					
Two twigs at +12°C			Two twigs at +25°C		
A control twig	A larval twig		A control twig	A larval twig[a]	
Twenty-four-hour bioassay with third instars					
+12°C (150 larvae; 50 larvae/treatment)			+25°C (150 larvae; 50 larvae/treatment)		
Unwounded shoot from the control twig	Unwounded[b] shoot from the larval twig	Wounded[b] shoot from the larval twig	Unwounded shoot from the control twig	Unwounded[b] shoot from the larval twig	Wounded[b] shoot from the larval twig
Enzymatic assays[c]					
+12°C			+25°C		
Unwounded shoots from the control twig	Unwounded shoots from the larval twig		Unwounded shoots from the control twig	Unwounded shoots from the larval twig	

[a] Ten *E. autumnata* larvae were released on each larval twig and were allowed to feed freely for 12 h. Larvae were at their third instar and reared in lab conditions.

[b] This data (temperatures were kept separately) was combined in the statistical procedure.

[c] Enzyme samples were collected at the same time when the growth trial was started.

We used 10 broods and 30 larvae per brood, divided between 2 temperatures and 3 treatments per temperature (50 larvae per treatment, total 300 larvae; Table 1). For the bioassay, 5 short shoots from each control twig were cut randomly for 5 larvae, and 5 wounded and 5 unwounded short shoots from the larval twigs were selected for 10 larvae (each control twig was repeated 5 times; larval twigs 10 times). The cut ends of the short shoots were placed into a small cup of water to prevent the leaves from drying out during the experiment. Shoots and larvae were placed individually into a 100-ml jar after determination of the initial larval weight. Larvae on short shoots collected from twigs incubated at +12°C were reared at this temperature, whereas larvae on short shoots incubated at +25°C were correspondingly reared at that temperature (see Table 1). Larvae were reared at both temperatures for 24 h, after which final weights were determined.

Protein Extraction and Enzymatic Assays Twelve hours after release of larvae onto the larval twigs, leaf samples were collected for enzyme analyses (Table 1). Undamaged leaves from both control and larval twigs were collected and immediately frozen in liquid nitrogen, and stored at −80°C before the analyses. Enzyme extractions were conducted as described in Ruuhola and Yang (2006). We used the 1-mM serine protease inhibitor phenylmethanesulfonyl fluoride (PMSF; Sigma) in the extraction buffer to prevent proteolysis and activation of latent PPO during the isolation process.

Enzyme activities were measured with a spectrophotometer coupled to an external water bath to control the reaction temperature, using methods described in more detail in Ruuhola and Yang (2006). Enzyme activities were measured at the corresponding experimental temperatures: +12 and +25°C. Catechol oxidase activity of PPOs (EC 1.10.2.2) was measured at pH 5.8, with 80 mM catechol as a substrate at wavelength of 420 nm; combined PPO/POD activity was measured similarly, but with 6.5 nM H_2O_2 as a co-substrate. The protein assay method of BioRad was used to measure protein contents of enzyme samples. All measurements were conducted in triplicate.

Temperature Optima for Birch Oxidases Temperature optima for foliar oxidase activities were tested by measuring enzyme activities at temperatures raging from +6 to +72°C for PPO and from +6 to +58°C for combined PPO/POD, which was measured in the presence of exogenous H_2O_2. Three enzyme samples were haphazardly chosen from both the control and larval treatments for determination of temperature optima. The enzymes themselves were kept on ice; substrates and buffers were kept at measurement temperature, and a circulating water bath was set to the same temperature. All measurements were conducted in triplicate; the reaction time was 3 min.

Temperature Optima for Development Rate of Moth Larvae For the range finding of optimal temperature for the development rate of early instars, *E. autumnata* larvae (50 larvae per temperature) were reared on an artificial diet at five different temperatures ranging from +5 to +25°C. The diet was based on the recipe of Goujet and Guilbort (in Singh, 1985), modified as in Ruuhola et al. (2001). This time, however, we used powdered mountain birch leaves instead of powdered *Salix phylicifolia* leaves. Newly hatched first instars were transferred individually onto a piece of the artificial diet in sterile petri dishes, diameter 6 cm. Dishes were enclosed with parafilm to prevent the escape of small insects. The piece of food was changed every other day.

Statistical Analyses We analyzed data with generalized mixed linear models (procedure MIXED in the SAS statistical software, release 8.2). The dependent variable was the growth of *E. autumnata* (final weight−initial weight within 24 h). As initial weight is the major determinant for the final weight, it was set as a covariate in the analysis. Fixed effects in the analyses were temperature (+12 and +25°C), defoliation treatment (control or damaged twigs), initial weight (as a covariate), and treatment×initial weight interactions. To simplify the model, we calculated the mean for two larvae grown on damaged and adjacent undamaged leaves (the mean for larvae belonging to same brood grown on the same twig; one on the undamaged adjacent leaf, the other on the damaged leaf). These two treatments did not differ statistically in larval growth rates. Experimental tree was handled as a subject and larval brood as a random effect. To compute the denominator degrees of freedom for the tests of fixed effects, we applied the method of *Satterthwaite*. The effect of temperature on the duration of first and second *E. autumnata* instars (that were reared on the artificial diet at five different temperatures) were tested with a nonparametric *Kruskal–Wallis's* test (procedure *NPAR1WAY* in the SAS statistical software, release 8.2)

Enzyme activities were also tested with generalized mixed linear models (procedure MIXED in the SAS statistical software, release 8.2). Fixed effects were temperature and defoliation treatment and their interaction; tree was assigned as a subject and a random effect. We used contrasts to clarify the relationship between temperature and treatment in the PPO activities that showed a significant treatment×temperature interaction.

Results

Larval Growth in Relation to Temperature and Foliar Wounding The growth rates of *E. autumnata* third instars were markedly affected by growth temperature: the growth rate was over twice as fast at +25°C as at +12°C (Fig. 1). In addition, growth was slightly, but significantly, slower on leaves of larval twigs than on those of control twigs (Table 2,

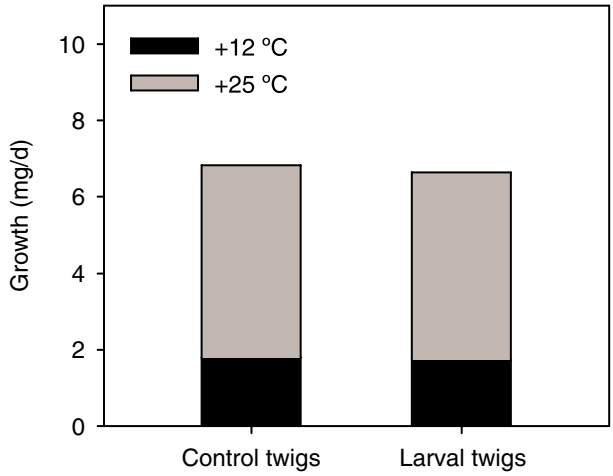

Fig. 1 Growth rate (final weight−initial weight within 24 h) of third instar *Epirrita autumnata* at two temperatures on the leaves of control and wounded twigs of mountain birch

Fig. 1). Although larvae were randomly allocated to treatments, the treatment×initial weight interaction was also significant (Table 2). Larvae with different initial weight probably responded differentially to the treatments.

Temperature affected development time of larvae (duration of the first instar *Chi-square*=147.8, $P<0.001$; duration of the second instar *Chi-square*=101.7, $P<0.001$). The optimum temperature for larval growth was +25°C; at this temperature, development from first to third instar lasted an average of 6.4 days (Fig. 2). At +20°C, development time was 1 day longer; at +15°C, development was 3.5 days longer than at +25°C. After that, development time increased rapidly; at +10°C, it was twice as long as at +15°C. At +5°C, the duration of first instar lasted as long as 25 days; we did not measure the development time to the third instar. At temperatures from +15 to +25°C, the duration of the second instar was shorter than that of the first instar, while at +10°C, the duration of the first instar was shorter than that of the second.

Although, the development rate of *E. autumnata* larvae was fastest at +25°C, larval mortality also increased markedly at this temperature (Fig. 2). Larval mortality was also high at the other end of the temperature range, i.e., at +5°C. Mortality rate was lowest between +10 and 20°C. According to survival and development rates, the optimum temperature for young instars was between +15 and 20°C.

Foliar Enzyme Activity in Relation to Temperature and Wounding We found significant temperature×wounding interaction in the activity of foliar PPOs (Table 3, Fig. 3A and B). Wounded twigs at +25°C had higher enzyme activities than wounded twigs at +12°C (contrast between wounding treatments at +12 and +25°C: specific PPO activity: $F_{1,27}$= 12.67, P=0.001 and PPO activity per gram leaf material (FW): $F_{1,27}$=15.25, P=0.001), whereas control treatments did not differ (contrast between control treatments in +12 and +25°C: specific PPO activity: $F_{1,27}$=0.54, P=0.467 and PPO activity g leaf fw^{-1}: $F_{1,27}$= 0.54, P=0.469). Interestingly, at +12°C, leaf damage decreased PPO activities, whereas at +25°C, leaf damage increased PPO activities in the adjacent undamaged leaves (Fig. 3A and B). Temperature also markedly affected the activity of foliar PPOs; both specific activity and activity per gram leaf material (FW) were significantly higher at +25°C than at +12°C (Table 3, Fig. 3A and B). The wounding treatment as such had no effect on activity (Table 3). Temperature, but not wounding, affected combined PPO/POD activities (Table 3, Fig. 3C and D).

POD activities were not affected by temperature or wounding treatment (Table 3, Fig. 3E and F). Interestingly, POD activities showed an opposite tendency (but nonsignificant) than PPO activities; activity was higher in leaves of larval branches than control leaves at +12°C, but lower at +25°C. In contrast, the activity of antioxidative catalase was affected by temperature; the activity being higher at +25°C than at +12°C, and the wounding treatment had a marginally increasing effect on catalase activity (Table 3, Fig. 3G and H).

Foliar PPO showed a surprisingly high temperature optimum: activity increased until +55°C, after which it collapsed (Fig. 4A). Our preliminary results suggest that birch PPOs are actually heat-labile enzymes, as activity declined rapidly when the enzyme itself was incubated at +55°C (data not shown). The range finding of temperature optima for combined PPO/POD activity was measured independently, using catechol and H_2O_2 as substrate and co-substrate respectively. This combined activity was also surprisingly high at cold temperatures, but started to decline after +25°C (Fig. 4B).

Discussion

Growth rate of third-instar *E. autumnata* was greatly affected by growth temperature; at +25°C, larvae grew twice as fast as at +12°C. Larvae also grew more slowly on leaves of larval than of control twigs. Both rapidly induced resistance (e.g., Haukioja and Hanhimäki, 1985; Kaitaniemi and Ruohomäki, 2001) and delayed induced resistance (e.g., Haukioja et al., 1985; Ruohomäki et al., 1992, 1996) are well-established phenomena in mountain birch, although induced amelioration has also been reported in mountain birch as a response to herbivory (Lempa et al., 2004). Our study, however, is the first to find induced resistance of mountain birch as an immediate reaction occurring within 12 h, suggesting the existence of a rapid transcription- and translation-independent defense mechanism.

In the range-finding experiment for the temperature optimum, we found that development rate from first to third instar was also fastest at +25°C, although larval survival rate was poor at that temperature. The optimal growth and survival rates of early instars were between +15 and +20°C. Larvae, however, were able to develop at temperatures as low as +5°C, even though development from first to second instar took almost a month. The development rate of autumnal moth larvae is known to be highly temperature-dependent; the length of *E. autumnata* larval stage depends on the ambient

temperature, varying from 2 weeks to almost 2 months (Ruohomäki et al., 2000). In other words, warm summer temperatures seem to be advantageous for the autumnal moth, enabling a rapid development rate and a short larval stage. At temperatures above or below the optimum, insect performance is expected to decrease (Scriber and Slansky, 1981); in

other words, insect growth rate is not usually linear in relation to temperature. Ayres and MacLean (1987b) found that low temperatures retarded the development of molting larvae more than growing larvae; thus, ambient temperature is apparently critical for larval molting from one instar to another, and may partly explain the nonlinearity of development rates in relation to temperature.

Warm early season temperatures may also have adverse consequences, in spite of their evident growth-promoting effects. Virtanen and Neuvonen (1999) reported that *E. autumnata* larval survival and females' fecundity were lower and larval parasitism higher at warmer than at lower temperatures. The 3-week delay in larval hatching, when the weather was cold and leaf development slow, had no significant effect on the survival of the first instar or on larval weight gain (in Haukioja, 1980). In addition, larvae that had hatched too early also remained active longer at cool temperatures, giving them a better chance to find food and survive (Haukioja et al., 1988). In our study too, the mortality of young instars increased at +25°C; the first instars, on the other hand, were able to survive at +5°C, feeding minimally, for almost a month—some larvae even succeeded in molting to the second instar.

Temperature and food quality interact to determine the suitability of plants for herbivores. For example, the effects of allelochemicals from Solanaceae species on the relative growth rates of *Manducta sexta*, *Helicorpa zea*, and *Spodoptera exigua* depended greatly on thermal regime, from a growth-promoting effect to a negative, growth-retarding one (Stamp and Yang, 1996). Also, temperature interacts with food quality in the interaction between mountain birch and autumnal moth: the growth rate of fifth instars was more affected by leaf age at +24°C than at +6°C (Ayres and MacLean, 1987a).

The birch defensive enzyme PPO showed interesting features. At +12°C, foliar PPO activity was reduced in leaves of larval twigs. At +25°C, in contrast, wounding increased PPO activity, suggesting an induced susceptibility of birches at low temperatures and an induced resistance at higher temperatures. Moth larvae used in the wounding treatment did not feed more than 12 h on the branches at both treatment temperatures, indicating that PPO activity responds very quickly to the presence of feeding larvae. In our earlier study (Ruuhola and Yang, 2006), PPO activity was induced systemically within 24 h in branches distinct from the wounded sites, confirming the quick induction of birch PPOs.

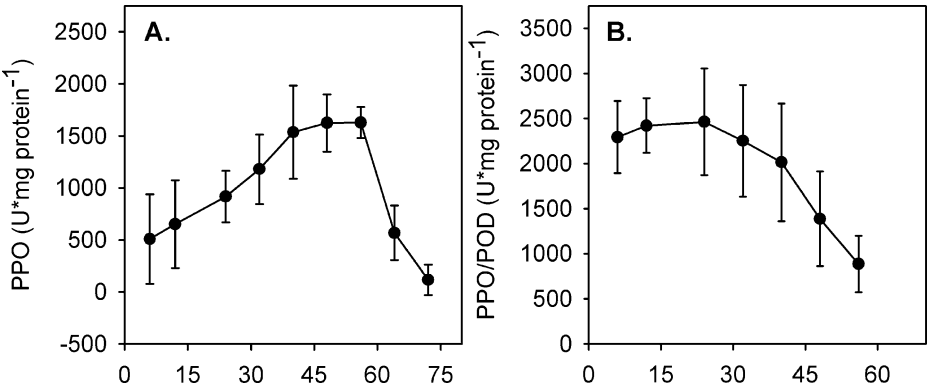

Fig. 4 Optimal temperatures for PPO (**A**) and PPO/POD (**B**) activities. Pure PPO activity was measured with catechol as a substrate and combined PPO/POD activity with catechol as a substrate and H_2O_2 as a co-substrate. *Bars* represent SE; $N=6$

The second intriguing feature of birch PPO was the high temperature optimum: the highest activities were found between +25 and 55°C. Heat-shock induction of PPOs has been reported for other plant species (Mathew and Parpia, 1971; Lee et al., 1991; Doğan et al., 2005) and could be due to the release of latent PPO (Lee et al., 1991) or a conformational change in a polypeptide (Mathew and Parpia, 1971). Doan et al. (2004) found that PPO activity correlated with levels of solar radiation, and PPO activity was suggested to act as a defense against photochemical oxidation and co-occurring high populations of insect herbivores. The high temperature optimum for birch PPO may reflect a possible role of enzymes in the defense of photochemical oxidation, as in direct sunlight, the temperature of a leaf may rise surprisingly high.

The unusually fast response of birch PPOs suggests transcription- and translation-independent induction. PPOs have been reported to exist as a latent form in many plant species, and they seem to be stable proteins (Söderhäll, 1995; Thipyapong et al., 1995). We do not yet know whether birch has a latent PPO reserve, which could be induced by herbivory and high temperature. However, we used PMSF to inhibit protease activity, and the increase in activity was probably not a consequence of the release of latent PPOs. Moreover, we measured PPO activity in the absence of exogenous catalase, which can be used to remove endogenous H_2O_2. The increased PPO activity in leaves of larval twigs at +25°C may thus be a consequence of the increased endogenous level of H_2O_2, which PODs need as a co-substrate and which is known to accumulate as a response to wounding (Bi and Felton, 1995; Orozco-Cárdenas et al.,2001; Gould et al., 2002; Musetti et al., 2005; Ruuhola and Yang, 2006).

Our results may contest the use of one even temperature in bioassays. More reliable results would be obtained by using varying temperatures following the natural temperature variation. First, temperature variation between nights and days may be considerable in subarctic climate. Second, rearing temperature affects not only the growth of animals, but also the activities of defensive enzymes and may change the effects of allelochemicals on the performance of herbivores.

Our results, also, may offer a possible mechanism for the hypothesis that low spring temperature promotes the success of *E. autumnata* by providing better food via decreased defensive enzyme activities, as PPO activity was highly temperature-dependent. Moreover, both larval growth rate and PPO activity were affected after the 12-h wounding treatment, suggesting a transcription- and translation-independent induced mechanism in both cases. At +12°C, PPO activity was decreased by the wounding treatment as was the growth of larvae that contradicts that PPOs act as defensive enzymes against *E. autumnata* larvae at this temperature. However, POD activity increased slightly (albeit nonsignificantly) at this temperature and may explain the retarded growth of larvae. At +25°C, PPO activity was increased by wounding and larval growth was retarded. In another study, we found that growth, consumption, and food conversion efficiencies of the last and the most voracious fifth instar were negatively related to foliar PPO and PPO/POD activities in damaged trees, but not in control trees (Ruuhola et al. unpublished results).

Our results suggest biological mechanisms behind the interactive relations between biotic and abiotic factors in determining the resistance and suitability of plants for herbivores. However, further studies need to be conducted with different instars (and species) and different temperatures before we can get closer to an answer for the key question: can cool spring temperatures affect the population dynamics of Lepidopteran species outbreaks via improved food quality due to decreased activities of defensive enzymes? We should neither forget the effects of temperature on the third level of tritrophic

interaction, namely, diseases, parasites (see also Kapari et al., 2006), and predators; these may be more strongly affected by low temperatures than their hosts (Nuorteva and Jussila, 1967; Virtanen and Neuvonen, 1999).

Acknowledgements We thank the staff of the Kevo Subarctic Research Institute and the Department of Animal Physiology for providing facilities. We also thank Seppo Neuvonen, Irma Saloniemi and Erkki Haukioja, who offered constructive comments on the manuscript. In addition, we thank our hardworking field assistants, Netta Tolvanen, Tanja Kyykkä, Fia Haavisto, Pauliina Wäli, and Jenny Koivisto. Ellen Valle kindly checked the English language. Abstract Scots pine populations contain individuals with widely differing amounts and composition of monoterpenes and exist as one of two chemotypes: with or without Δ^3-carene. We investigated the significance for ecological studies of two types of variation in monoterpenes: (1) the inherent variability in the concentration of monoterpenes or their relative amounts in needles of seedlings, saplings, and mature trees; and (2) phenological variation in developing needles. The relative composition of needle monoterpenes in 5-year-old saplings changed during the needle development period until the final composition was reached upon needle maturity. Changes in composition depended on chemotype. Needles of the "no-Δ^3-carene" chemotype had higher absolute concentrations of α-pinene, β-pinene, camphene, and total monoterpenes than "Δ^3-carene" chemotype. For the "Δ^3-carene" chemotype, the relative concentration of Δ^3-carene during the needle growing season and immediately after emergence of seedlings was higher compared to that reached at needle maturity. Repeated removal of single needles (at weekly intervals during growth) from 5-year-old saplings did not influence the composition of monoterpenes. Within a natural Scots pine dominated woodland, 18% of mature Scots pines (N=574) belonged to

the "no-Δ^3-carene" chemotype. Chemotypic variation within populations means that the statistical power with which differences in monoterpene concentrations can be detected is lower when sampling from the whole population compared to sampling within chemotypes. Reduction of this background variation and accounting for chiral variation if present, would significantly aid efficiency, interpretation, and understanding of processes in chemical and ecological research. One method for achieving this is the screening of plants for chemotypes before the establishment of experiments or field sampling regimes. We present a summary of suitable analytical methods for needle tissue that facilitates this prior screening.

Introduction

Monoterpenes have multiple ecological functions (Langenheim, 1994; Huber et al., 2004). For example, they can act as allelopathic agents inhibiting seed germination (Vokou et al., 2003), affect soil microbial processes including nitrification (Paavolainen et al., 1998) and nutrient cycling (White, 1994), and act as chemical defenses against insect and mammalian herbivory (Duncan et al., 1994; Linhart and Thompson, 1999). Scots pine (*Pinus sylvestris* L.) contains a large pool of monoterpenes in the resin that comprise about 1% of the dry weight of needles (Heyworth et al., 1998; Kainulainen et al., 2000a). As monoterpenes are volatile, they are continually released into the airspace surrounding the plant (Janson, 1992). Within this chemical landscape, specific enantiomers can elicit specific responses such as neuronal responses in the antenna receptor cell of several insect species including a specialist pine weevil (Wibe et al., 1998) and bark beetles (Pureswaran et al., 2004a) where they are used for host recognition (Wallin and Raffa, 2001). The defensive function of monoterpenes is thought to derive predominantly from their lipophilicity and ability to disrupt cell membrane processes (Wink, 2003), as they have limited water solubility (Weidenhamer et al., 1993). Because of this general and specific "bioactivity" and their heritability (Hiltunen, 1976), monoterpenes mediate ecological and evolutionary interactions across multiple scales (Theis and Lerdau, 2003, Iason et al., 2005).

Monoterpene composition in conifers is diverse, varying widely between (Hatcher, 1994) and within (Forrest, 1980; Latta et al., 2003; Pureswaran, et al., 2004b) species. Within populations of Scots pines, there are large concentration variations among individual trees (Forrest, 1980); analysis of isozymes showed 93% of the variation to be within and only 7% between populations (Kinloch et al., 1986). Analysis of chloroplast microsatellites attributes 89% of the genetic variation within and 11% between populations (Naydenov et al., 2005). Monoterpenes in Scots pine consist of four major and at least eight minor compounds (Sjödin et al., 2000) that vary in composition between different tissues in individual trees (Sjödin et al., 1996). There are two different chemotypes for Scots pine that refer to Δ^3-carene being either present or absent (Chalchat et al., 1985; Weissmann and Lange 1990). Constitutive variation in monoterpenes within and between Scots pine populations is genetically determined to some degree (Bohlmann et al., 1998; Phillips et al., 2003; Theis and Lerdau, 2003; Martin et al., 2004, Huber et al., 2004). However, monoterpenes in *Pinus* can also be induced by environmental factors such as herbivory (Litvak and Monson, 1998), adding to the source of variability to natural populations.

Quantification of environmental influences on the composition and concentration of monoterpenes against this background variability is fraught with methodological and statistical problems. We suggest that prior screening of experimental material or wild populations for monoterpenes can reduce background variability and increase the probability of detection of responses of concentrations of specific compounds to factors of interest. In contrast, most studies that have used monoterpenes to infer genetic variation (Hiltunen, 1976) use the relative proportions of monoterpenes (Forrest, 1980) and consider these to be constant for individual trees.

In this work, we investigated monoterpene variability in Scots pine. Specifically, we asked: (1) whether proportions of needle monoterpenes in 5-year-old saplings vary phenologically during the period of needle development; (2) how monoterpene concentrations vary with age of seedlings during their early growth; and (3) how production of individual monoterpenes is affected by chemotype in Scots pine. Based on the results, we illustrate chemical difference between the two chemotypes and advocate taking these into account for experimental designs that investigate either the effects of monoterpenes on ecological processes or environmental influences on monoterpene production. To enable preexperimental screening, we describe a technique that uses small amounts of plant material, one Scots pine needle, and we show that the sampling does not impact future monoterpene composition.

Methods and Materials

Sampling and Extraction of Monoterpenes from Needles Monoterpenes are stored in Scots pine needles within resin canals. Whole needle extraction yields only a quarter of the absolute concentration compared to cut needles; hence, needles need to be cut into sections approximately 5 mm in length to assure access to all resin canals (Lin et al., 2001). Exhaustive extraction with hexane is reached after 90 min for cut needles and 15 d for whole needles. Kieselgel 60 (Merck, Darmstadt, Germany) was used to adsorb co-extracted polar compounds and water from hexane extracts. Samples thus prepared may be stored for up to 3 mo at −20°C.

For determination of absolute concentrations, isobutylbenzene was used as internal standard. The dry weight of needles was determined after evaporation of the liquid phase at room temperature followed by drying the sample for 48 hr at 50°C.

Gas Chromatography—Determination of Low Concentrations of Monoterpenes by Using GC-MS-SIM A gas chromatography-mass spectroscopy (GC-MS) consisting of a Trace GC 2000 (ver. 1.3) and Trace DSQ mass spectrometer (ver. 1.3.0 SP4) was used. A Sol Gel 10-25 column (30 m×0.25 mm id from SGE, UK) was used for separations. Xcalibur™ (ver. 1.3). software was used for data capture and analysis. The temperature program started at 50°C (held for 1 min), followed by a temperature gradient of 3°C min^{-1} up to 75°C, followed by a gradient of 30°C min^{-1} up to 200°C (held for 2 min) to clean the column. The injection volume was 2 μl, and injections were conducted in the splitless mode. The mass spectrometer was used in single ion monitoring (SIM) mode for the 93 mass fragment only. Data were captured between 2.5 and 10 min.

The monoterpenes of Scots pine extracted and quantified with retention times and response factors for the 93 mass fragment are given in Table 1. The lowest amount of α-pinene detected with this method was 20 pg, which corresponded to 0.001 μg $(g\ DM)^{-1}$.

Table 1 Retention times and response factors for the 93 mass fragment for monoterpenes of Scots pine

Compounds	Retention Time (min)	Response Factor
α-Pinene	3.35	17.3
Camphene	3.65	9.4
β-Pinene	4.07	13.9
Myrcene	4.49	5.4
Isobutylbenzene[a,b]	4.60	1
Δ^3-Carene	4.89	16.3
α-Terpinene	5.02	7.2
Limonene[c]	5.34	7.7
γ-Terpinene	6.15	10.3
Terpinolene	7.01	6.7

[a] Internal standard

[c] Bornyl acetate co-eluting

Gas Chromatography—Determination of High Concentrations of Monoterpenes and Their Enantiomers by Using GC-FID A Carlo Erba MFC 500 GC with flame ionization detector (FID) (T=250°C) equipped with a WCOT fused silica 25 m×0.25 mm i.d. column coated with CP WAX 52 CB (Varian, UK) was used. Injection volumes were 1 μl, and the splitting ratio was 1 to 50. Initial temperature was 70°C followed by a temperature gradient of 3°C min^{-1} up to 160°C. The following monoterpenes in order of retention were separated and identified: tricyclene, α-pinene, camphene, β-pinene, sabinene, Δ^3-carene, myrcene and α-phellandrene (co-eluting), α-terpinene, limonene, β-phellandrene, γ-terpinene, and terpinolene. A ChromQuest (ver. 2.53) chromatography workstation was used for data capture and processing. The response factor for the FID was taken as one for all monoterpenes (Raffa and Steffeck, 1988). The lowest concentration of α-pinene detected with this method was 2 ng, which corresponded to 100 μg (g DM)$^{-1}$.

For the determination of enantiomers, column coupling was used. Individual monoterpene peaks were transferred onto a CP chiralsol-Dex CB column (25 m by 0.25 mm) using a switching valve. Identification of enantiomers was based on commercial standards.

Phenological Variation in Needle Monoterpenes Ten 5-year-old Scots pine trees were sampled every week to fortnight from February to December 2004 by removing one needle of the last growing seasons cohort (referred to as "old needles"), and after late May when new needles emerged, one needle from the current seasons growth (referred to as "young needles"). Scots pines grow by forming new branches each year from buds set during the previous growing season. In this context, a branch describes the section of wood formed during the last growing season at the onset of sampling (9 February 2004). Needles were taken from different branches, and once a needle was removed, the branch was marked with polytetrafluoroethylene (PTFE) tape to prevent resampling from that branch (to avoid possible changes due to induction). During consecutive sampling occasions, branches were chosen on alternate whorls. One needle was used for extraction on each sampling occasion. The extracts were analyzed by using the GC-FID method.

Variation in Absolute Monoterpene Concentrations During Early Growth in Seedlings (3 and 8 wk Old) The absolute concentration of individual monoterpenes was determined in 3- (N=351) and 8-wk-old seedlings (N=1,076), which were grown from seed collected from the same population. Seeds were germinated in damp paper towels and transplanted into potting soil in cellular seedlings trays (3×3×5 cm). The growing medium consisted of Levingtons 2Ca compost (intermediate nutrient level, coarse, acidic) with 10% grit and a slow release fertilizer (Ficote 180) added at a rate of 4.5 kg m^{-3} (Levingtons, Ipswich,

Suffolk, UK). From each seedling, one needle was removed and used for extraction. Absolute concentrations were determined by using the GC-MS-SIM method.

Consequences of Chemotypic Differentiation: Monoterpene Concentrations in Needles of Scots Pine Saplings (3 to 12 Yr of Age) Two populations of saplings were sampled at two different locations. Population 1 was situated at latitude 57°0′ N and longitude 3°30′ E. Population 2 was located at latitude 57°3′ N and longitude 3°16′ E. Samples were collected in March and April 2003. From each sapling, ten needles were removed and extracted on-site. Samples were taken in duplicate. Monoterpenes were quantified with the GC-FID method.

Consequences of Chemotypic Differentiation: Monoterpene Concentrations in Needles of Mature Scots Pines The study site consisted of a natural Scots pine dominated woodland covering about 4 km^2 that is located at latitude 57°3′ N and longitude 3°16′ E. Needle samples were obtained between January and March 2002 and January and April 2003, by cutting off at least ten branch ends (including all the needles from the latest growth period) from at least two different main branches located on the southern side, low crown level of each of 574 mature trees. Samples were placed into ziplock plastic bags and most of the air removed before sealing. Needles were frozen on-site by placing the plastic bag between two aluminum plates kept in an ice box containing dry ice and stored at −20° C. From each Scots pine, at least 20 needles were cut and extracted (in duplicate). Monoterpenes were determined with the GC-FID method.

Statistical Analyses Mean monoterpene concentrations in the needles of the "no-Δ^3-carene" and "Δ^3-carene" chemotypes were compared in the sample of 574 mature trees, and separately, in the samples of saplings collected from "population 1" and "population 2". Distributions of these data and their residuals following analysis of variance (ANOVA) were skewed. Therefore, the descriptive statistics presented are medians and upper and lower quartiles. The *F*-statistics presented were from ANOVAs that used normalizing cube-root transformed data.

The statistical power associated with sampling needles from the whole population of trees or from only the "Δ^3-carene" or "no-Δ^3-carene" chemotypes was investigated for the population of 574 mature trees. The probability of detecting an increase in mean of 20% in α-pinene concentration, at $P<0.05$ with a *t*-test, was calculated from a simulation that involved drawing two groups with sample sizes increasing in number from 2 up to 80 per group, at random either from within the "Δ^3-carene" or "no-Δ^3-carene" chemotypes, or from the population as a whole. The simulations were run 1,000 times for each sample size. These tests were performed on cube-root transformed data, and they compared the power of detecting a difference between means on the cube-root scale that was equivalent to a 20% difference on the original untransformed scale. The rationale for comparing the effect of Δ^3-carene chemotype on needle α-pinene concentration was that intercorrelations among the monoterpenes mean that almost all monoterpenes covary with Δ^3-carene chemotypes, and α-pinene is the most abundant monoterpene.

Results

Phenological Variation in Needle Monoterpenes within Season Figure 1 shows the relative proportion of α-pinene and Δ^3-carene sampled from Scots pine trees of the "Δ^3-carene"

chemotype only, over an extended period of time. For the "old" needles, the relative concentration of α-pinene and Δ^3-carene did not change significantly during the sampling period. The relative concentrations in newly emerged needles differed from "old" needles with α-pinene being initially produced at lower relative concentration and Δ^3-carene being produced initially at higher relative concentration compared to "old" needles. For "young" needles, the relative concentrations changed until those of "old" needles were obtained late during the growing season.

By chance, eight of the ten experimental trees belonged to the "Δ^3-carene" chemotype (Figs. 1 and 2). The "no-Δ^3-carene" chemotype produced α-pinene initially in higher proportions in "young" compared to "old" needles. The relative proportion of camphene and β-pinene, the next most abundant monoterpenes, also gradually increased in newly emerging needles reaching a stable relative concentration.

Note that although the combined dataset containing both chemotypes contained a larger number of samples (Fig. 2), the relative concentrations of monoterpenes had higher standard errors of estimate, showed a less clear temporal trend in composition, and had a lower mean relative concentration of Δ^3-carene. This pattern of errors of estimate being greater in the whole population despite its larger sample size, compared with those in the restricted sample of the Δ^3-carene chemotype, is also seen by comparing the interquartile ranges of α-pinene and Δ^3-carene concentrations in Tables 3 and 4. The consequences of the greater variance (in this case α-pinene) in the overall population compared to the two constituent chemotypes are illustrated in the analysis of the statistical power associated with sampling different group sizes from the monoterpene analyses of needles from 574 mature trees (Fig. 3). The analysis shows that the probability of detecting a difference in 20% between the means of two samples is lower for any given group size, when the comparison

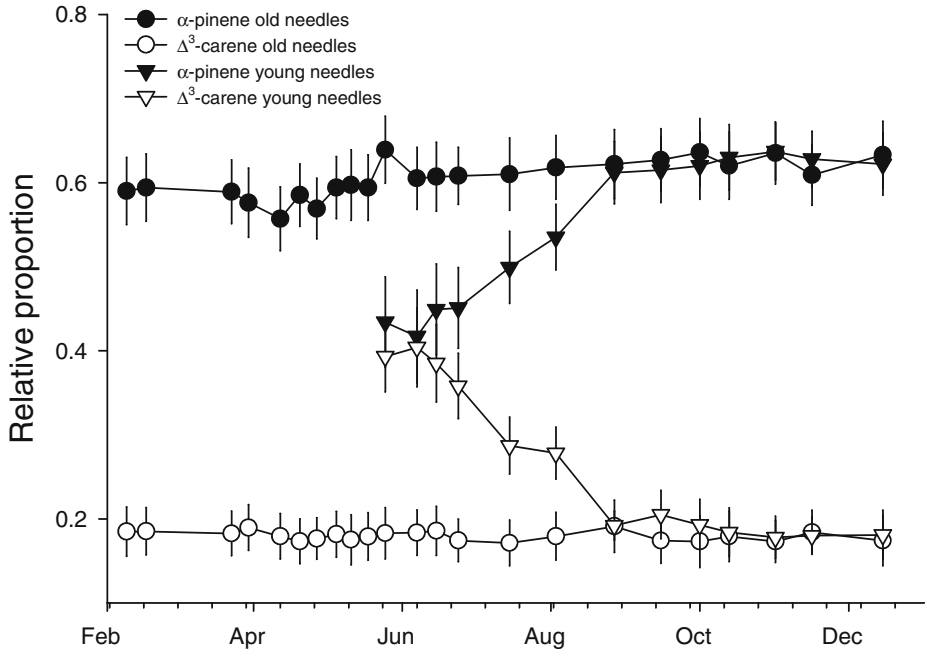

Fig. 1 Relative proportion of α-pinene and Δ^3-carene in old and young needles of Scots pine for the chemotype containing Δ^3-carene. *Bars* are one standard error (N=8)

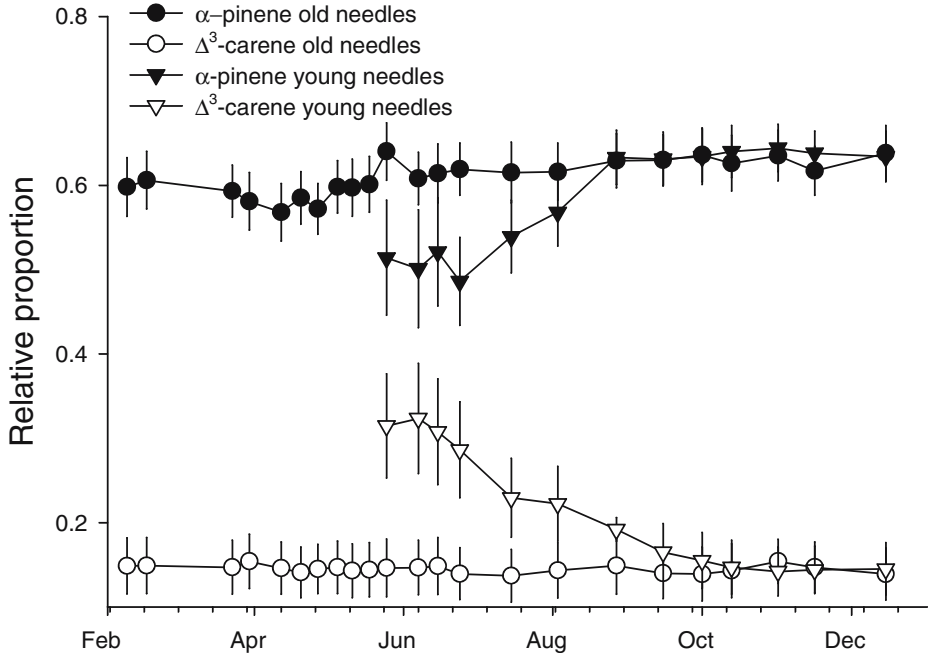

Fig. 2 Relative proportion of α-pinene and Δ^3-carene in old and young needles of Scots pine. *Bars* are one standard error (N=10)

is being made within the overall population, compared to the groups being drawn from within either of the two chemotypes (Fig. 3). The sample size required to maximize statistical power is larger in the case of the whole population.

Screening of Seedlings The maximum and mean concentrations of monoterpenes measured for 3- and 8-wk-old seedlings, respectively, is given in Table 2. The mean and maximum absolute concentrations of individual and total monoterpenes determined in the seedlings increased by a factor of 4 between wk 3 and 8. For the two major monoterpenes, the mean relative concentration for α-pinene was with about 30%, considerably lower than 54% obtained for mature Scots pine. For Δ^3-carene, the relative concentration for seedlings was about 45%, which was considerably higher than the mean of 25% obtained for mature Scots pines.

Characteristics of Chemotypes in Saplings and Mature Scots Pines For the 574 mature Scots pines, α-pinene and Δ^3-carene contributed 75.9% of the total needle monoterpenes with 49.9% for α-pinene and 26.0% for Δ^3-carene (median values). β-Pinene and camphene were the third and fourth most abundant monoterpenes with relative concentrations of 5.2 and 4.3%, respectively. However, as the whole population consists of two chemical subpopulations, these relative concentrations depend on the chemotype (Table 3). The "no-Δ^3-carene" chemotype contains 76.8% α-pinene, 0% Δ^3-carene, 10.1% β-pinene, and 4.7± 0.2% camphene as relative concentrations. This contrasts with the "'Δ^3-carene" chemotype, which contained 45.0% α-pinene, 29.8% Δ^3-carene, 4.5% β-pinene, and 4.1% camphene. The "no-Δ^3-carene" chemotype comprised 11.5 and 14.4% of the saplings sampled in

populations 1 and 2, respectively (Table 4), whereas for the mature Scots pine population, its proportion was 17.6% (Table 3).

There were notable differences in absolute amounts of almost all the individual and the total monoterpenes between the chemotypes, and these differences drove the observed differences in the relative proportions of the monoterpenes reported above. Separation of populations by chemotype (Tables 3 and 4) showed that the "no-Δ^3-carene" chemotype had consistently higher concentrations of α-pinene, β-pinene, and camphene in all three populations (Tables 3 and 4; ANOVA: $P<0.001$). These greater concentrations of the most abundant monoterpenes mean that the concentrations of total monoterpenes in the "no-Δ3-

Concentrations are in mg (g DM)$^{-1}$.

carene" chemotype were actually higher than those of the "Δ^3-carene" chemotype (Tables 3 and 4). Although the greater concentration in total monoterpenes in the "no-Δ3-carene" chemotype was not significant in mature trees (ANOVA: *NS*, Table 3), the effect was statistically significant in saplings from population 1 (ANOVA $P<0.001$, Table 4) and population 2 (ANOVA: $P<0.05$, Table 4).

In the needles from the 574 mature trees, there were significant ($P<0.001$) and near linear correlations between tricylene and camphene ($r=0.980$) and Δ^3-carene and terpinolene ($r=0.978$). α-Pinene was correlated with limonene ($r=0.725$, $P<0.001$) and was the best predictor of total monoterpenes ($r=0.820$, $P<0.001$). α-, γ-terpinene, and sabinene were correlated with Δ^3-carene ($r=0.756$, $r=0.793$, $r=0.722$), respectively, with $P<0.001$ for all. These correlations were confirmed by using the two populations of saplings even though the correlation coefficients differed slightly.

Enantiomeric Composition The enantiomeric composition of individual monoterpenes also showed variability. In the needles of a subset of the mature Scots pine population (N=143), chiral analysis showed that only four were enantiomeric. The mean percentage composition was, in three cases, dominated by a single enantiomer; α-pinene, the most abundant monoterpene, existed predominantly in the form of (+)-α-pinene [74.4±1.4% (mean± SEM), Fig. 4]. β-Pinene and camphene were dominated by (−)-β-pinene (84.7±0.8%), and (−)-camphene (84.4±0.5%), respectively. The enantiomers of limonene occurred in approximately equal proportions (53.6±0.8% (+)-limonene).

Discussion

This study uses five independent datasets to illustrate the variability of monoterpene concentration and composition depending on phenology and chemotype in populations of Scots pine. In particular, we found consistent trends of higher relative concentration of Δ^3-carene in growing needles for the "Δ^3-carene" chemotype and higher total monoterpene concentration in the "no-Δ^3-carene" chemotype in mature needles. The effects exerted by pine monoterpenes on associated organisms depend on the monoterpene proportionate

[a] As whole needles were extracted, absolute concentrations are only about a quarter of those using cut needles.

composition (Iason et al., 2005; Pakeman et al., 2006; Thoss and Byers, 2006), which we show to be dependent on the chemotype.

The inheritance of monoterpene synthesis (Hiltunen, 1976), with the "no-Δ^3-carene" chemotype being considered the double recessive genotype (Kinloch et al., 1986), is expressed through monoterpene synthases (Huber et al., 2004; Martin et al., 2004). The significant correlations between individual monoterpenes within different Scots pine populations supports the existence of fewer monoterpene synthases than individual monoterpenes produced (Davis and Croteau, 2000; Schwab, 2003). Camphene co-occurred with tricyclene and Δ^3-carene co-occurred with terpinolene, α- and γ-terpinene, and sabinene. These correlations mostly agree with the monoterpene biosynthesis in Scots pine as described by Juvonen (1966, quoted in Hiltunen, 1976), apart from sabinene that seems to co-occur with Δ^3-carene rather than with β-phellandrene. Two different biosynthetic pathways have been described for β-pinene and might underlie the reason for the weaker correlations between β-pinene and all other monoterpenes. The enantiomeric composition of needles from mature Scots pines showed a disproportionately high production of (+)-α-pinene, (−)-β-pinene, and (−)-camphene, while limonene was racemic (Sjödin et al., 1996, 2000). On the basis of the biosynthetic pathways, determination of the concentrations of α- and β-pinene, camphene, and Δ^3-carene should suffice for preexperimental screening for Scots pine because: (1) they had significant correlations

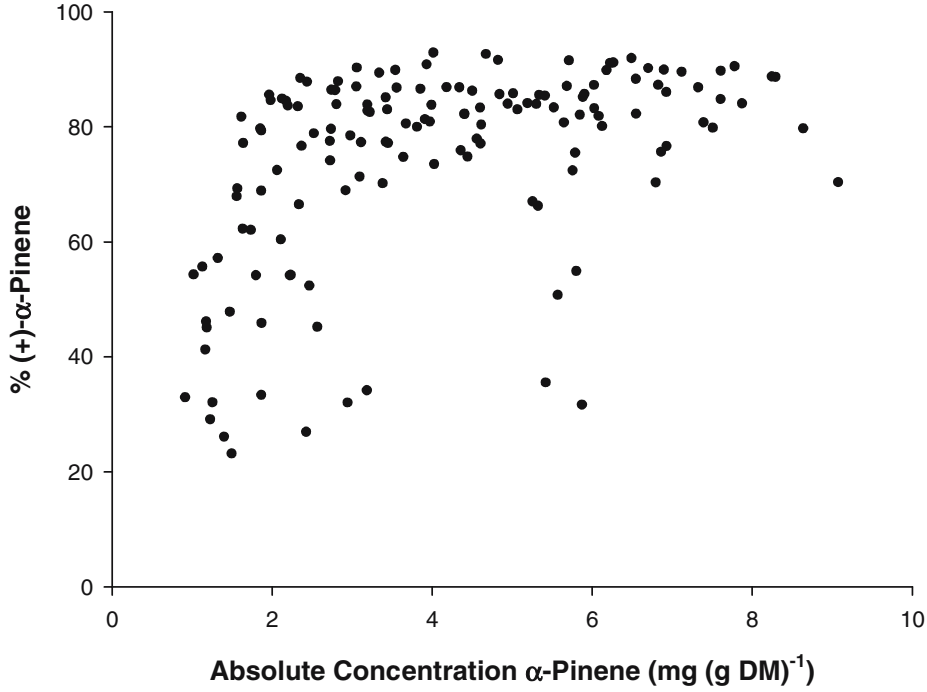

Fig. 4 The percentage of the (+)-α-pinene enantiomer vs the absolute total concentration of α-pinene, in needles of 143 mature Scots pine trees

with those monoterpenes that occurred in minor relative proportions, and (2) their sum comprised 79 to 94% of total monoterpenes.

For Scots pine, one mature needle can be used for preexperimental screening, as its content represents predominantly constitutive monoterpene production. No variation in the composition of monoterpenes occurred between different year-classes of mature needles or time of sampling. Even if the most relevant tissue for a future experimental investigation differs from needles, we advocate the usage of needles for preexperimental screening, as it allows determination of the chemotype that applies to other aboveground tissues of Scots pine (Thoss, unpublished data).

The "no-Δ3-carene" chemotype did not have lower concentrations of total monoterpenes than the "Δ^3-carene" chemotype. In fact, in the plants where Δ^3-carene was absent, the concentration of total monoterpenes was higher, suggesting that the absence of Δ^3-carene was compensated for by other monoterpene synthases. With regard to the chemical characteristics of the two chemotypes, it was surprising to note in the "Δ^3-carene" chemotype that the particular compound had been produced in higher relative concentrations in seedlings and during needle development compared to the composition at needle maturity. We speculate that there may be evolutionary reasons for this allocation of resources to a relatively high proportion of Δ^3-carene in very young developing pine needles; it may be associated with a higher biological activity and protective function (Ikeda et al., 1977). α-Pinene and Δ^3-carene differ in their chemical reactivity with autoxidation and polymerization occurring at lower temperature and at higher yields for Δ^3-carene compared to α-pinene (Rothenberg et al., 1998). These differences in reactivity

could explain the lack of occurrence of chemotypes consisting predominantly of Δ^3-carene, as the oleoresin could polymerize within the resin canal system and negatively impact the defensive function of oleoresin that relies on its fluidity.

Relative proportions of monoterpenes in plants have been used to define species characteristics (von Rudloff, 1975; Sjödin et al., 1996, 2000; Latta et al., 2000, 2003) and population genetics (Forrest, 1980; Naydenov et al., 2005). They also have been utilized in ecological studies (Delorme and Lieutier, 1990; Sadof and Grant, 1997; Tiberi et al., 1999; Barre et al., 2003; Nerg et al., 2004). Absolute concentrations are the preferred measure where either some form of dose-dependency is thought to underlie the processes being studied (Duncan et al., 1994; Iason et al., 1996; Litvak and Monson, 1998) or where an ecophysiological response of pines to an environmental manipulation is investigated (Kainulainen et al., 1996, 2000a,b; Heyworth et al., 1998; Lamontagne et al., 2000, 2002; Sallas et al., 2003). Quantification of monoterpene enantiomers appears to be important in the study of specific interactions with specialist insects (Wibe et al., 1998; Pureswaran et al., 2004a). Nonetheless, the role of monoterpenes in Scots pine resistance to specialist insects (Sadof and Grant, 1997, Barre et al., 2003, Nerg et al., 2004) and in other broader ecological functions (see Introduction) has also been identified without recourse to analysis of enantiomers. We know of few, if any, studies in which the intra- and interpopulation variation of monoterpenes, satisfactorily takes into account chirality of compounds based on large sample sizes, and we advocate that this deficiency should be corrected. It is clear that either or both the measurement of relative proportions and absolute concentrations of monoterpenes, with and without chiral separations, are of utility, but the most suitable analysis, of course, depends on the aims of the study in question.

A random selection of Scots pine trees is likely to result in a mixture of two chemotypes: the "no-Δ^3-carene" chemotype, which occurs in about every fifth tree of mature Scots pines, and the "Δ^3-carene" chemotype. It is possible that the reason that a few studies that investigate the causal relationship of environmental manipulations on absolute monoterpene production (Kainulainen et al., 1996, 2000a,b; Heyworth et al., 1998; Lamontagne et al., 2000, 2002; Sallas et al., 2003) have found any significant responses for monoterpenes is because the existence of the two chemotypes was not accounted for in the experimental designs. The effects of chemotypic variation on the concentrations of Δ^3-carene itself are likely to be profound, as its values are zero for about 20% of the population. In addition, this study demonstrates the consequences for statistical sampling of the variation in the concentrations or proportions of other monoterpenes, which also vary between the Δ^3-carene chemotypes. Although our statistical treatment did not specifically include chiral differences, the predominance of particular enantiomers means that our conclusions regarding the statistical consequences of variability, e.g., for selection of samples, are also likely to hold when the different enantiomers are taken into account.

Based on these observations, we suggest that the effects of different chemotypes should be incorporated into experimental designs and sampling programs for chemical ecology studies, and we describe a suite of rapid sampling and analysis techniques that will enable this preexperimental screening. The effects of contrasting enantiomers should also be considered in studies in which compounds exist as enantiomers in varying proportions and in which their specific effects may be important. Furthermore, unless contrasting treatments can be applied within individuals or by controlling for genetically based variation by other means, such as cloning, then a statistically rigorous sampling regime, with adequate replication, should be applied to studies of chemically variable systems such as monoterpenes.

Acknowledgements We thank the Scottish Executive Environment and Rural Affairs Department for funding this study; Joan Beaton and Diane Smith for raising the seedlings and other assistance; David Elston of Biomathematics and Statistics Scotland for advice; and Bob Mayes, Simon Thirgood, and anonymous referees for critically reviewing the manuscript. We thank the Balmoral Estate and the National Trust for Scotland, Mar Lodge Estate for access to the study sites. Abstract In the Temecula Valley of California the proximity of citrus groves to vineyards influences the incidence and severity of Pierce's disease (PD) in grapes, a disease caused by the gram-negative bacterium, *Xylella fastidiosa*. Although the glassy-winged sharpshooter (GWSS), the major insect vector of the bacterium, feeds on and moves back and forth between citrus groves and vineyards, there are no visible symptoms of disease caused by *X. fastidiosa* in citrus. Previous evidences suggested that while grapevines are susceptible to the PD strain of *X. fastidiosa*, citrus trees are resistant or tolerant but could be a reservoir to harbor the pathogen for the GWSS acquisition. We investigated the mechanisms of host plant resistance/susceptibility by examining the *in vitro* effect of xylem fluid from grapefruit, orange, lemon, and grape on the growth, aggregation, and attachment of a *X. fastidiosa* strain isolated from grape. Our results revealed that xylem fluid from grapefruit, orange, and lemon trees caused the bacterial cells to form aggregations of large whitish clumps, whereas the xylem fluid from grape vines created a visible thick biofilm. The densities of *X. fastidiosa* cells in grapefruit xylem fluid treatment were significantly higher at 6, 8, and 9 d postinoculation compared with those in grape xylem fluid treatment. The cell densities of *X. fastidiosa* cultures in orange or lemon xylem fluid were generally lower than those in grape xylem fluid treatment, whereas citrus xylem fluid significantly inhibited *X. fastidiosa* biofilm formation compared to grape xylem fluid.

Introduction

Xylella fastidiosa is a plant pathogenic bacterium that reproduces in the xylem and plugs the water-conducting tissue of grape wines, leading to Pierce's disease (PD) (Davis and Thomson, 1977; Purcell 1981). The losses because of PD in California are severe and in Temecula Valley alone growers have lost about 30% of their vineyards. In Southern California, *X. fastidiosa* is mainly vectored by the glassy-winged sharpshooter (GWSS) *Homalodisca coagulata*. The GWSS is native to the southeastern United States and northern Mexico and was first detected in California in 1989 (Sorensen and Gill, 1996). Although the insect has a broad host range, comprising many plant species in 35 families (Turner and Pollard, 1959), the major crop hosts in Temecula Valley are citrus and grapes. Previous studies in California had identified 94 plant species in more than 28 plant families as hosts of *X. fastidiosa* (Freitg 1951; Turner and Pollard, 1959; Raju et al., 1980, 1983; Sorensen and Gill, 1996; Costa et al., 2004). Most of them are asymptomatic but serve as inoculum sources of *X. fastidiosa* for vector acquisition (Purcell and Saunders, 1999).

Studies in the Temecula Valley revealed that proximity of citrus groves to vineyards has a positive effect on the incidence and severity of PD in grapes (Perring et al., 2001). The disease incidence and severity are greatest in grapevines adjacent to citrus, and decline with increasing distance from citrus (Perring et al., 2001). Several PD strains of *X. fastidiosa* were previously isolated from sweet orange trees in Florida (Hopkins et al., 1978) and by the use of insect vectors, the bacterium was transmitted from these trees to grapevines (Hopkins et al., 1978). This indicates that the PD strain of *X. fastidiosa* could survive and colonize in citrus plants and could be transmitted from citrus plants to grapevines. Although the GWSS feeds on and moves back and forth between citrus and grape plants in the Temecula Valley, there are no apparent *X. fastidiosa* disease symptoms in citrus. This suggests that citrus plants are resistant or tolerant to the PD strain of *X. fastidiosa* but may serve as a reservoir to harbor the pathogen for GWSS acquisition. Because little is known about the mechanisms involved in host plant resistance/susceptibility to *X. fastidiosa* in the system, additional information is required to determine if citrus can be a suitable reservoir for the PD strain of *X. fastidiosa*.

Biofilm is a form of microbial growth in which the cells embedded in an adhesive polysaccharide matrix aggregate and attach to a surface usually in a wet environment (Costerton et al., 1995). Biofilm is common in nature in which many important microbial processes take place. For example, biofilm formation is required for pathogenesis in many microbial species such as *Pseudomonas aeruginosa* in cystic fibrosis and oral bacteria in gingivitis (Parsek and Singh, 2003; Crossman and Dow, 2004; Scheie and Petersen, 2004). *Xylella fastidiosa* aggregates to form biofilm inside its host plants and vectors (Marques et al., 2002), and this phenomenon was implicated in *X. fastidiosa* pathogenesis (Newman et al., 2004). Recently, a defined medium was developed for *X. fastidiosa* based on the chemistry of xylem fluid of the susceptible grape cultivar Chardonnay (Leite et al., 2004). This reported medium supported better *X. fastidiosa* growth and stimulated bacterial aggregation and biofilm formation *in vitro* (Leite et al., 2004). However, the effect of xylem fluid of citrus on *X. fastidiosa* growth, aggregation, and biofilm formation remains unknown. The objective of this study was to determine the effect of host plant xylem fluid on *X. fastidiosa* growth, aggregation, and attachment to abiotic surfaces.

Methods and Materials

Experimental Plots and Collection of Xylem Fluid Commercial citrus (grapefruit, lemon, and orange) groves in proximity to vineyards were selected in the Temecula Valley, California. Three blocks of 30 citrus and 30 grape plants were used. Fifteen plants of each species were randomly selected from each block for xylem fluid extraction. Collection of xylem fluid was done between 6:00 and 10:00 A.M. in October of 2003 by using a pressure chamber apparatus as described previously (Anderson et al., 1989, 1992). Five terminal shoots from each plant were used for xylem extraction, as these are the preferred feeding sites for GWSS on plants (Mizell and French, 1987; Bi et al., 2005). Upon collection, the xylem fluid in microcentrifuge tubes was immediately placed on dry ice before final storage in a −80°C freezer until final use.

Bacterial Growth, Aggregation, and Attachment Assays A *X. fastidiosa* strain A05 (isolated from infected grape vines in the Temecula Valley) was used in this study (Costa et al., 2004). The bacterial growth was measured at an optical density of 600 nm with a spectrophotometer (Beckman Coulter DU 640). A fresh *X. fastidiosa* strain A05 culture was inoculated into PD3 medium (Davis et al., 1980), supplemented with xylem fluid (xylem fluid/medium=1:1) in borosilicate glass culture tubes on a rotary shaker at room temperature (around 24°C). At 4, 5, 6, 7, 8, 9, and 10 d after inoculation, the tubes were vortexed for 1 min to homogenize the cell suspension. Silwet-L-77 (given by OSI Specialties of GE Silicones) was added to each tube (with a final concentration of 0.001%) to disperse the bacterial cells just before homogenization. The absorbance was then measured at 600 nm. At 10 d after inoculation, the culture was photographed to record aggregation.

The effect of xylem fluid on *X. fastidiosa* attachment was evaluated by measuring biofilm formation of the bacterial cells grown *in vitro*. Formation of biofilm on the abiotic surfaces was assayed as described by Espinosa-Urgel et al. (2000). Briefly, cells of *X. fastidiosa* strain A05 were inoculated at an initial A_{600} of about 0.1 into PD3 medium supplemented with xylem fluid at 25 and 50% (v/v). The inoculum was then dispensed into polystyrene microtiter plates and incubated at 24°C. At 2, 4, and 6 d after incubation, one of the plates was taken out for processing. Each well was gently washed with deionized water, and stained with 1% (wt/vol) crystal violet. After 15 min at room temperature, the wells were washed thoroughly until there was no more residual stain in the well except that absorbed by the attached bacteria. After drying, the stain was solubilized in ethanol. The absorbance of the resulting solution was measured at 600 nm.

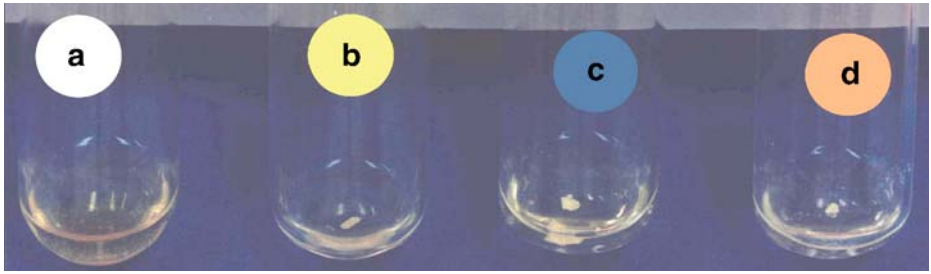

Fig. 1 Effect of host plant xylem fluid on *X. fastidiosa* aggregation. PD3 medium was supplemented with host plant xylem fluid. Tubes a, b, c, and d were each supplemented with xylem fluid from grape, grapefruit, orange, and lemon, respectively. Note the white clumps of *X. fastidiosa* aggregates formed in the grape fruit, orange, and lemon xylem fluid treatments

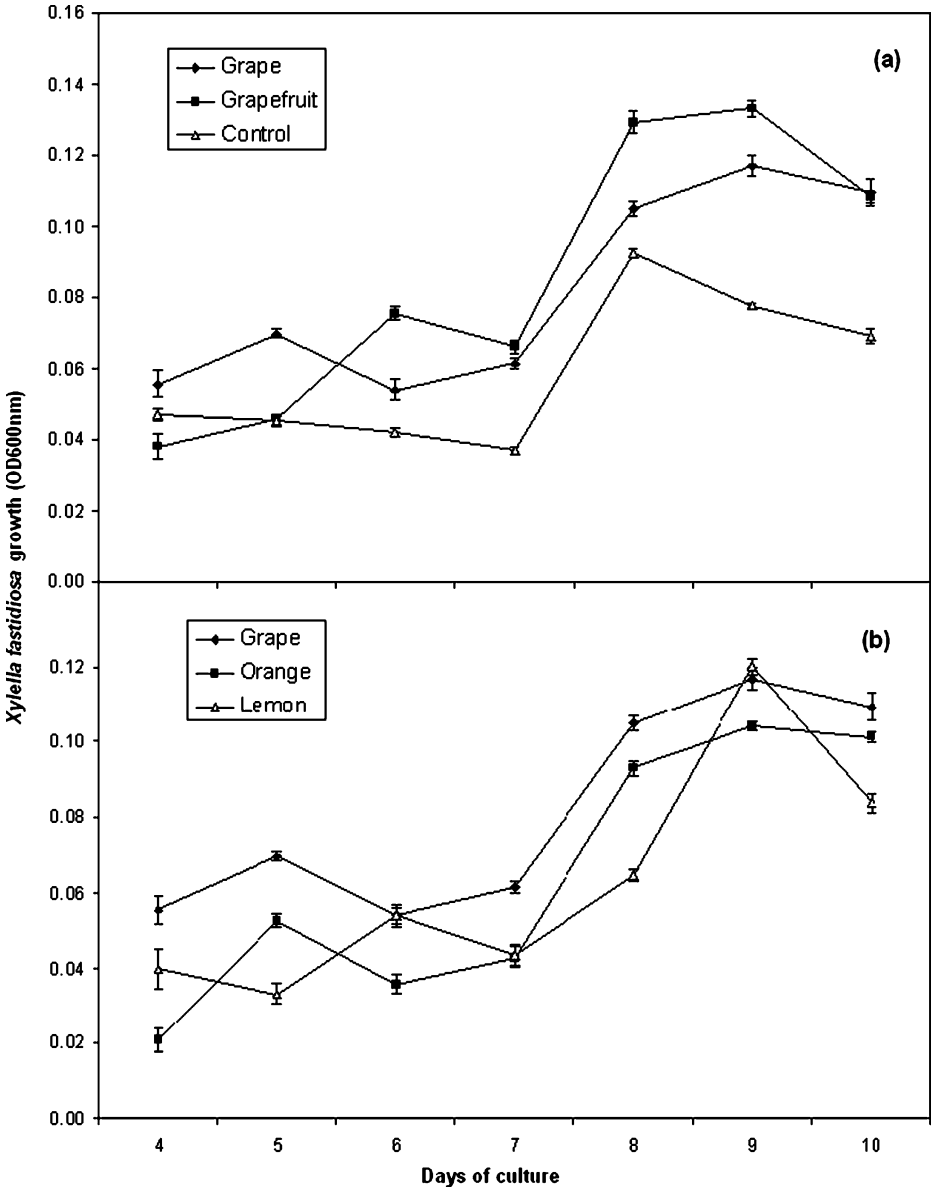

Fig. 2 Effect of host plant xylem fluid on *X. fastidiosa* growth. *X. fastidiosa* was inoculated into PD3 medium supplemented with xylem fluid from the indicated host plants. Control was *X. fastidiosa* growth in PD3 medium alone. The growth of the cultures was recorded by uniformly suspending the cells in the culture and measuring the absorbance at 600 nm

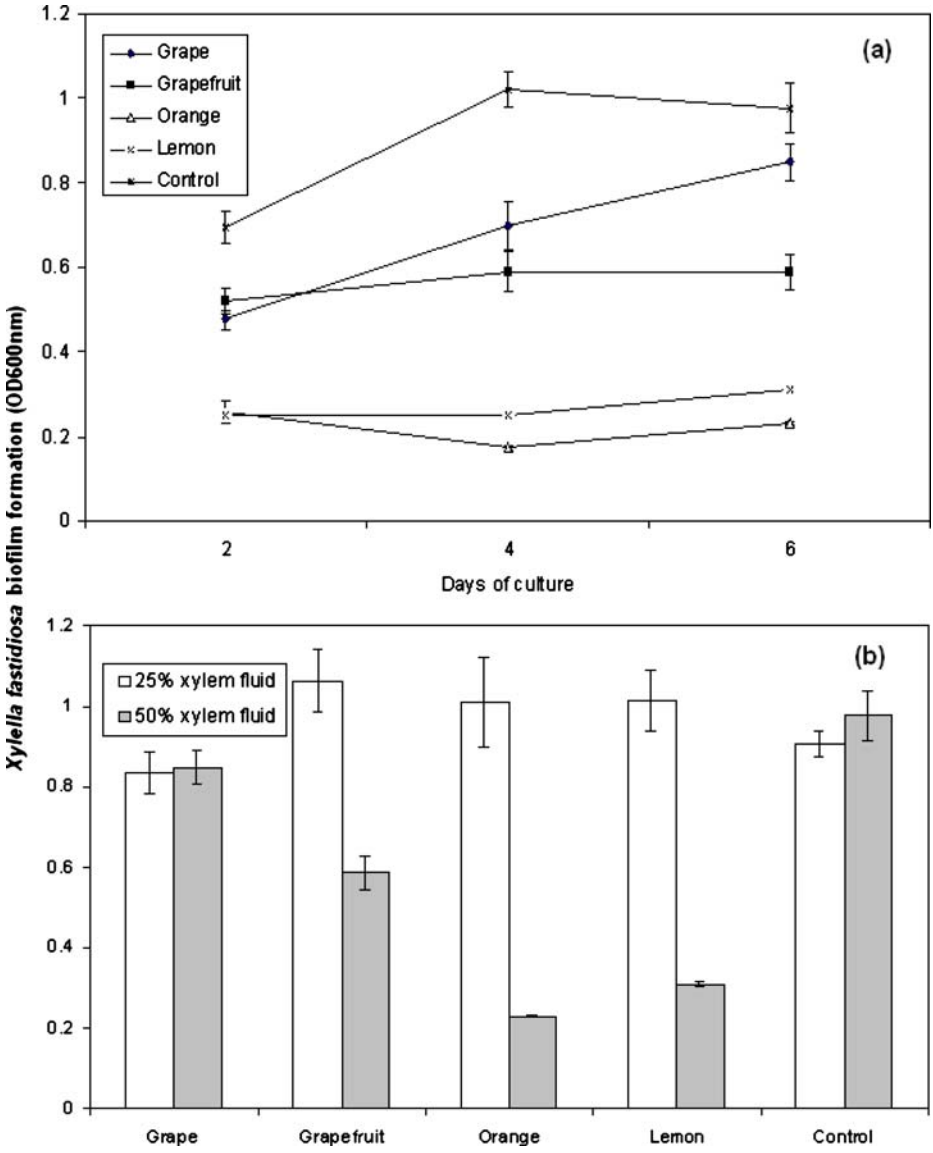

Fig. 3 Effect of host plant xylem fluid on *X. fastidiosa* biofilm formation. Biofilm formation was measured in microtiter plates as described in the "Materials and Methods" section. Biofilm cells were stained with crystal violet, the amount of stain absorbed was dissolved in ethanol, and the resulting absorbance was measured. **(a)** PD3 medium supplemented with xylem fluid at 50% (v/v). **(b)** Optic density was measured at d 6 after the culture

Statistical Analyses Analysis of variance (ANOVA) and the least significant difference test in one-way completely randomized ANOVA in SAS (SAS Institute Inc. 1999–2001) were used to analyze the resulting data and separate the means.

Results

In xylem fluid of grapefruit, orange, and lemon, *X. fastidiosa* A05 cells aggregated to form large whitish clumps suspended in the culture, leaving the culture medium clear with no observable turbidity (Fig. 1b–d); in contrast, grape xylem fluid inoculated with the same *X. fastidiosa* culture did not cause visible clumping, but rather a visibly thick biofilm was formed on the surface of glass tube and the culture was turbid (Fig. 1a). After dispersion of the clumps with Silwet-L-77, we found that the absorbance of *X. fastidiosa* culture in the grapefruit xylem fluid treatment was 14–40% higher after 6, 8, and 9 d of culture ($F_{4,35}$= 48.98, 122.41, and 105.25, respectively, $P<0.001$) compared with that in the grape xylem fluid treatment (Fig. 2a). The absorbance of *X. fastidiosa* culture in orange xylem fluid treatment was 8–168% less at all culture test periods (from d 4 to 10) ($F_{4,35}$=12.67, 55.43, 48.98, 18.49, 122.41, 105.25, and 53.21, respectively, $P<0.001$), whereas the absorbance of *X. fastidiosa* culture in lemon xylem fluid treatment was 31–110% less after 4, 5, 7, 8, and 10 d of culture ($P<0.001$) in comparison with the absorbance of *X. fastidiosa* culture in grape xylem fluid treatment (Fig. 2b).

Xylem fluid of the citrus species generally inhibited biofilm formation by *X. fastidiosa* A05 compared to that of grape (Fig. 3a). In 2-d-old cultures, lemon and orange xylem fluid treatments suppressed the amount of *X. fastidiosa* biofilm by nearly twofold ($F_{4,35}$=48.51, $P<0.001$). In 4-d-old cultures, xylem fluid of lemon and orange reduced *X. fastidiosa* biofilm formation by 2.8- and 4.0-fold ($F_{4,35}$=80.38, $P<0.001$), respectively. In 6-d-old cultures, xylem fluid of grapefruit, lemon, and orange decreased the *X. fastidiosa* biofilm formation by 1.4-, 2.7- and 3.7-fold ($F_{4,35}$=75.01, $P<0.001$), respectively. Compared with the 25% xylem fluid cultures at 6 d after inoculation, 50% xylem fluid of grapefruit, orange, and lemon decreased *X. fastidiosa* biofilm formation by 1.8- to 4.4-fold ($F_{4,35}$=28.65, 48.39, and 84.78, respectively, $P<0.001$) whereas 50% grape xylem fluid had no significant effect ($F_{4,35}$=0.05, P=0.83) (Fig. 3b).

Discussion

Xylem fluid of grapefruit, lemon, and orange can support *X. fastidiosa* growth, suggesting that these citrus species are suitable hosts for *X. fastidiosa* and may serve as a reservoir of the pathogen for GWSS acquisition in Temecula Valley. Citrus species were shown to be favorable hosts of GWSS in southern California, although they remain asymptomatic for *X. fastidiosa* infection (Bi et al., 2005; Castle et al., 2005). It is possible that GWSS transmits *X. fastidiosa* between citrus and grape plants in the course of feeding on and moving back and forth between these crops. With respect to citrus in the Temecula Valley, grapefruit constitutes the largest acreage, and its xylem fluid is most conducive to growth of *X. fastidiosa*. The severe PD incidences in grapevines close to citrus may be caused by multiplication of the pathogen in citrus and further transmission to grapevines.

Our observation of biofilm inhibition by citrus xylem fluid and stimulation by grape xylem fluid is consistent with PD strains of the bacterium not causing disease in citrus whereas remaining virulent in grapes. The results of this study appear to provide a link

between pathogenesis and biofilm formation, whereas at the same time explaining (at least partly) why the local PD strain is not pathogenic to citrus species. The formation of biofilm is considered a major virulence factor in many bacterial pathogens of plants, including *X. fastidiosa* (Marques et al., 2002).

Our results suggest that the growth, aggregation, and biofilm formation of the *X. fastidiosa* in the xylem fluid of citrus and grape were mediated by the xylem fluid chemistry. *X. fastidiosa* is a nutritionally fastidious bacterium (Wells et al., 1987). It was found that in defined medium certain amino acids such as asparagines, cysteine, glutamine, glycine, serine, and threonine are essential for *X. fastidiosa* growth; glucose stimulates the growth, whereas fructose and sucrose have an inhibiting effect (Wells et al., 1987; Chang and Donaldson, 2000). Amino acid profiles and sugar contents in xylem fluid of grape and citrus are different (Anderson et al., 1989; Bi et al., 2005). It is unknown whether differences in amino acid profiles and the sugars in the xylem fluid may differentially affect growth, aggregation, and biofilm formation of the *X. fastidiosa*. Redox status also affects the tendency for *X. fastidiosa* aggregation and biofilm formation. Adding reducing agents such as glutathione to artificial medium promotes *X. fastidiosa* aggregation and biofilm formation (Leite et al., 2004). It was reported that thiols mediate the aggregation and adhesion of *X. fastidiosa* (Leite et al., 2002). Thiol-containing compounds in xylem fluid include cysteine, methionine, and glutathione. The redox status in citrus and grape xylem fluid and its role in *X. fastidiosa* aggregation and biofilm formation, and host plant resistance/susceptibility to PD need to be further investigated.

Our findings that the xylem fluid of grape, a symptomatic host, and citrus species, asymptomatic hosts, of *X. fastidiosa*, have different effects on *in vitro* activities of the bacterium have ramifications for the control of PD. New avenues are now open for the exploitation of plant xylem fluid chemistry in the studies of *X. fastidiosa*/plant and *X. fastidiosa*/insect interactions to develop host plant resistance as component of PD management strategies. Experimentation is underway to identify the specific chemical constituents of the xylem fluid, as well as the differences in their concentrations, among the various plants species that are hosts to *X. fastidiosa*, and their roles in host plant resistance to PD.

Abstract Adult beetles of *Diabrotica virgifera virgifera* LeConte (western corn rootworm) feed on pollen of *Zea mays* L. (corn) and other plant species. To identify *D. virgifera* feeding stimulants, beetle responses to mixtures of known and novel phagostimulants, presented at their naturally occurring concentrations in maize pollen, were compared to individual component responses applying the amount occurring in 0.2 mg of pollen per cellulose feeding disk. On a molar basis, three major sugars (fructose, glucose, and sucrose) were more prevalent in corn pollen buffer extract (CPE) than free amino acids. Western corn rootworm feeding was stimulated by the three sugars (28% disk consumption) and, to an even greater extent, by a mixture of 21 free amino acids (41% disk consumption). However, the combination of three sugars and 21 amino acids elicited a level of *D. virgifera* feeding (41% disk consumption) similar to that of the 21 amino acids alone. A novel maize pollen phagostimulant was purified from CPE by using solid-phase extraction followed by RP-HPLC. Based on its mass fragment pattern, two UV maxima (254 and 359 nm), and previous isolation from maize pollen, this phagostimulant is tentatively identified as isorhamnetin 3-*O*-neohesperidoside. This compound interacted additively with the mixture of three sugars and 21 amino acids, to produce 77% of the phagostimulation level of CPE. Therefore, a possible stimulatory mechanism for *D. virgifera* feeding on corn pollen has been elucidated.

Introduction

Pollen feeding by beetles is thought to be a primitive insect–plant association. Feeding on gymnosperm pollen by beetles predates the advent of angiosperms (Samuelson 1994), and angiosperm radiation has been associated with increase in beetle diversity (Farrell 1998). More than 184 angiosperm species are pollinated almost exclusively by beetles (Bernhardt 2000), but the pollen-feeding behavior of Coleoptera has been overshadowed by the greater incidence of this trait in the Hymenoptera.

There is quantitative and qualitative variability in the nutrients, including protein, amino acids, sugars, sterols, vitamins, and lipids, found in the pollen of different plant species (Stanley and Linskens, 1974). Chemical components of *Zea mays* L. (corn) pollen have been studied extensively. Sucrose is the predominant sugar and comprises 98% of the soluble carbohydrates and 5% of the pollen fresh weight (Hoekstra et al., 1989). The amount of fructose and glucose is inversely proportional to sucrose content and depends on the pollen storage conditions (Speranza et al., 1997). In sweet corn pollen, proline was the most abundant free amino acid, followed by serine and alanine (Stanley and Linskens, 1974; Hollister and Mullin, 1999). Flavones are absent from maize pollen, but ten flavonol glycosides, derived from kaempferol, quercetin, and isorhamnetin, have been reported (Ceska and Styles, 1984). Among these, quercetin 3,3′-*O*-diglucoside is the most abundant. Pollen is the corn tissue with the greatest concentration of sterols, with a profile dominated by 24(28)-methylene-sterols (Guo et al., 1995) and small amounts of castasterone and other brassinosteroids (Suzuki et al., 1986). Other biochemical components in *Zea mays* pollen have also been identified (Bianchi et al., 1990; Anaya et al., 1992; Radlowski et al., 1996; Bih et al., 1999).

Few studies have investigated the effects of host pollen chemical components on beetle feeding behavior. As one example, the Mexican beetle *Zygogramma bicolorata* Pallister (Chrysomelidae) feeds selectively on pollen of the weed *Parthenium hysterophorus* L. (Compositae), which contains parthenin, a sesquiterpene lactone feeding stimulant for this species (Jayanth et al., 1993). Phagostimulants for adult western corn rootworms (WCR), *Diabrotica virgifera virgifera* LeConte, from several pollen hosts have been investigated by using a thin-layer chromatography (TLC)-based feeding bioassay (Hollister and Mullin, 1999; Lin and Mullin, 1999). L-Alanine and L-serine are the most phagostimulatory amino acids for adult WCR (Hollister and Mullin, 1998; Kim and Mullin, 1998). Some lipids and midpolarity compounds from sunflower (*Helianthus annuus* L.) pollen that potentiate amino acid phagostimulation have also been identified (Lin and Mullin, 1999).

Adult WCR feed on pollen and other nutritious floral parts of host plants. Sweet corn and winter squash (*Cucurbita maxima* Duchesne) pollens are preferred. The essential role of pollen feeding in the reproductive and developmental success of many arthropods may be explained by the relatively high nutrient content, absence of harmful deterrents, and lack of fitness-reducing phytochemicals in this food compared to other plant tissues (Roulston and Cane, 2000). Elliot et al. (1990) demonstrated that the fecundity of maize pollen-fed female WCR was greater than that of beetles excluded from pollen. Maize pollen also enhanced development of other insect species (Ye-Ebiyo et al., 2000).

A structure–activity relationship study that used amino acids and derivatives suggested that multiple amino acid sites on beetle taste receptors interact to produce the net phagostimulatory input to the central nervous system (Kim and Mullin, 1998; Mullin and Kim, 2001). However, the feeding behavior of adult WCR on maize pollen was not explained by free amino acids and/or sugars only, suggesting that other phagostimulatory components are present. The objective of this study was to identify novel feeding stimulants in maize pollen and to examine the effects of phagostimulant combinations on WCR feeding responses.

Methods and Materials

Insects A nondiapausing laboratory strain of western corn rootworm (WCR) was purchased from French Agricultural Research, (Lamberton, MN, USA). Adult beetles were fed sliced store-bought acorn squash fruit and water *ad libitum* and were maintained at 25±1°C and a 16L:8D photoperiod in an M-31 Environmental Growth Chamber (Chagrin Falls, OH, USA).

Corn Pollen Extraction Corn pollen (sweet corn, *Zea mays* L. var. Bodacious) was extracted with 30 mM tripotassium citrate (pH 6.0) buffer as previously reported (Kim and Mullin, 2003).

Free Amino Acid Analysis Free amino acid (AA) analysis was carried out as described (Hollister and Mullin, 1999). The fraction containing AA after Dowex 50X8 cation-exchange chromatography (H^+ form) of CPE was derivatized with phenylisothiocyanate (PITC) and then analyzed by HPLC (Cohen and Strydom, 1988) with a Waters Novapak C_{18} reverse-phase column (4 μm, 3.9×150 mm, 60 Å) and a Waters 600E Multisolvent Delivery System with a 2487 Dual λ Absorbance Detector. The HPLC mobile phase consisted of: (A) 140 mM sodium acetate, with 0.5 ml triethylamine/liter, titrated to pH 6.35 with glacial acetic acid; and (B) 60% acetonitrile with a linear gradient of 2 to 50% eluent B in A over 35 min at 1.5 ml/min. The absorbance was measured at 254 nm.

Sugar Analysis The pollen buffer extract (CPE, 2 ml) was applied to a solid-phase extraction (SPE) tube (6 ml, Discovery DSC-18, Supelco), which was equilibrated with water before loading the sample. Nonbinding materials were eluted with water (6 ml) and then 10, 40, and 100% methanol (4 ml each) were used subsequently to wash off bound compounds. A water fraction containing sugars and free amino acids was evaporated to dryness with a Savant SC110 SpeedVac, whereas the three methanol fractions were dried using a Büchi Rotovapor (Brinkmann, Westbury, NY, USA) and later used for isolation of flavonoids. The dried water fraction was redissolved in 0.5 ml H_2O and applied to a Dowex 50X8 cation-exchange chromatography column (Hollister and Mullin, 1999) to separate sugars from free amino acids. Three sugar standards, fructose, glucose, and sucrose were processed in the same manner to evaluate their recovery rates. Isocratic separation of fructose, glucose, and sucrose by HPLC was achieved on a Cyclobond II (γ-cyclodextrin, 5 μm, 4.6×250 mm) column (Astec, Whippany, NJ, USA). The eluent was 90% acetonitrile at a flow rate of 2 ml/min and UV detection at 195 nm.

TLC Analysis The water fraction (SPE Water) containing sugars and amino acids after solid-phase extraction (SPE) as well as the corn pollen extract were also analyzed by TLC (LK5DF, 20×20 cm plate, 19 channels, Whatman) using standard sugars (fructose, glucose, and sucrose) and AA. For sugar analysis, the TLC plate was developed with ethyl acetate–MeOH–water (5:1.5:0.5) and the same developing solvent system with a different ratio (5:4:2) was used to separate free amino acids. After being air-dried, the plate was sprayed with naphthoresorcinol or ninhydrin and then heated for 5–10 min at 100°C to maximize sugar (Walters and Mullin, 1988) or amino acid (Hollister and Mullin, 1999) visualization, respectively.

Identification of Phagostimulants in the Corn Pollen Extract All phagostimulatory components bound by reverse-phase SPE of the corn pollen extract were eluted with 40% methanol (Fig. 1). This methanol-wash fraction (SPE MeOH) was analyzed by using reverse-phase HPLC (Novapak C_{18} column, 4 μm, 3.9×150 mm, 60 Å). The eluent system

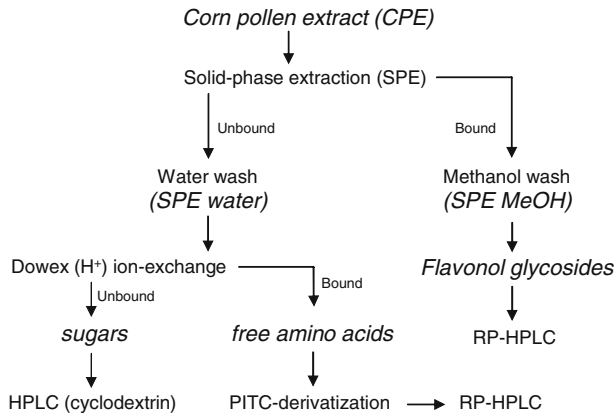

Fig. 1 Scheme for isolation of phagostimulants for adult western corn rootworm from corn pollen

consisted of (A) 75% methanol and (B) H_2O; going from 40 to 100% of eluent A in 15 min at 1.0 ml/min with a linear gradient. Absorbance was measured at both 254 and 359 nm to guide collection of peak fractions, which were then dried with a Rotavapor. Each fraction was dissolved in 20 mM sodium citrate buffer (pH 5.5) or 40% methanol for use in feeding bioassays. The UV–visible spectra of a purified bioactive sample were measured in methanol with a Waters 2487 Dual λ Absorbance Detector. One fraction out of 6 SPE MeOH fractions collected from HPLC showed a mild phagostimulatory effect on beetle feeding, and the phagostimulatory compound was identified with a Waters 2695 HPLC and detected with a Waters 2996 photodiode array detector and a Micromass Platform LC mass spectrometer (Waters, Bedford, MA, USA). A C_{18} HPLC column (LiChrospher RP-18, 250×4 mm, 5 μm endcapped, Varian, Lake Forest, CA, USA) was connected through a microsplitter valve (Upchurch Scientific, Apple Valley, MN, USA) to maintain a flow rate (200 μl/min) to ESI-MS. LC/ESI mass spectra were acquired by scanning the mass range from 100 to 700, and data acquisition and processing were controlled by using MassLynx v.3.5 software (Micromass, Manchester, UK). The eluent system consisted of (A) 90% acetonitrile with 0.05% formic acid and (B) H_2O with 0.05% formic acid. Column linear gradients for samples were: 0–5 min 40% A, 5–6 min 40–100% A, 6–7 min 100–40% A, and 7–8 min 40% A.

Feeding Bioassay Studies on phagostimulants were performed by using a no-choice bioassay (Hollister and Mullin, 1998). All feeding bioassays were performed by using postmated females and males aged between postemergence days 8 and 35 because mating occurred maximally between postemergence days 5 and 7 under our lab conditions. This reduced the possible interaction in a bioassay arena between randomly selected beetles. Beetles were usually used in consecutive bioassays with a 3- to 5-d interval (36- to 84-hr squash fruit feeding followed by 12-hr starvation, then 24-hr feeding bioassay). Beetles were deprived of food, but not water, for 12 hr before the bioassay. After starvation, two beetles (sex undetermined) were randomly placed into a 100×20-mm Petri dish containing one regenerated cellulose disk (26.5 mm^2, 1.0 μm pore size; Schleicher and Schuell, Daytona Beach, FL, USA) suspended in the middle of the dish on a minuten pin 2 mm above a paraffin layer covered with a moistened filter paper. Chemicals dissolved in an appropriate organic solvent, buffer or water (4 μl—this volume completely saturated a disk) were applied with a Hamilton repeating dispenser (Reno, NV, USA) to the disk. After a 24-hr feeding period, dry disk areas were determined

to the nearest 0.1 mm^2 with an Optomax V image analyzer (Analytical Measuring Systems, Saffron Walden, UK) and then subtracted from the mean disk area (26.5 mm^2) of 10 disks not offered to beetles, to give the area consumed. Consumption data are presented as a mean percentage of the disk area consumed per two beetles ± standard error of the mean (SEM) after 24 hr (water control=4.3±3.4%, N=24). At least eight replicates of each treatment were run for each of at least six independent feeding bioassays. Combined data were square-root transformed to improve normality and homogeneity of variance, and a one-way ANOVA was used to test for treatment effects followed by the Tukey–Kramer test using JMP 6 (SAS Institute, Cary, NC, USA).

Sample concentrations used in all feeding bioassays were approximated from that found in a 0.2-mg pollen equivalent. For example, the 21 amino acid sample contained proline (8.1), serine (2.8), alanine (1.2), γ-aminobutyric acid (GABA, 0.9), glutamine (0.8), aspartic acid (0.4), glutamic acid (0.4), arginine (0.2), threonine (0.2), and valine (0.2 nmol/disk) + 11 amino acids (asparagine, cysteine, glycine, histidine, isoleucine, leucine, lysine, methione, phenylalanine, tryptophan, and tyrosine, 0.08 nmol/disk each), and the three sugar samples consisted of fructose, glucose, and sucrose, at 37.7, 31.7, and 17.1 nmol/disk, respectively. All standard amino acids and sugars were purchased from Sigma–Aldrich (St. Louis, MO, USA).

Results

Three major sugars, fructose, glucose, and sucrose, were more prevalent in the corn pollen buffer extract (CPE) than free amino acids (AA) on a molar basis (Table 1). Fructose and glucose were about twice as abundant as sucrose, and were the only monosaccharides and disaccharides detected. Proline dominated the AA, followed by serine, alanine, and GABA, which is consistent with previous findings by Hollister and Mullin (1999). The only significant difference in AA content of corn pollen between the present study and one by

Table 1 Sugar and free amino acid contents of the corn pollen buffer extract

Chemical	Content (nmol ± SEM/mg pollen equivalent)
SUGARS[a]	
Fructose	188.4±3.67
Glucose	158.5±2.91
Sucrose	85.6±0.71

[a] Sugar (N=7) or free amino acid (N=5) analyses were performed on three independent extracts, and the seven dominant amino acids are shown.

Hollister and Mullin (1999) was that glutamine replaced asparagine as a major amino acid. To measure phagostimulatory activity, concentrations of standard chemicals or pollen extract fractions were fixed at approximately 0.2-mg pollen-equivalent per disk. This amount was dramatically lower than those used in two previous studies with adult WCR [3.6- and 5-mg pollen equivalent for Hollister and Mullin (1999) and Lin and Mullin (1999), respectively], but stimulated two beetles to consume 50–100% of a regenerated cellulose disk in 24 hr (J. Kim, personal observation). The isolation scheme to discover and analyze phagostimulatory compounds found in the corn pollen extract is depicted (Fig. 1).

The mixture of two known phagostimulatory amino acids [serine (2.8 nmol/disk) and alanine (1.2 nmol/disk), Hollister and Mullin, 1998; Kim and Mullin, 1998] or the 19-AA mixture lacking serine and alanine (12.18 nmol total/disk) stimulated 25 and 31% of disk consumption, respectively (Fig. 2). Because feeding responses were usually highly variable among individual bioassays, data from independent experiments were combined. Feeding response to the combined mixture of 21 AA (41%) was significantly greater than to the two-AA mixture (25%), but not to the 19-AA mixture (31%). Although the total molar concentration of the three sugars was much higher (86.5 nmol/disk) than that of the 21 AA (16.18 nmol/disk total), feeding response to the sugars (28%) was lower and similar to responses produced by the 2- or 19-AA mixtures. It is interesting to note that feeding response to the mixture of three sugars and 21 AA was not significantly different from either the 21 AA combination or the three-sugar mixture, alone. Moreover, the combined AA and sugars (39% disk consumption) only attained 57% of the phagostimulatory level (69% disk consumption) of the CPE (Fig. 3).

The free amino acids and sugars were present in the water fraction (SPE Water) after SPE, whereas the methanol fraction (SPE MeOH) contained weakly hydrophobic compounds such as flavonoids and other phenolics (Fig. 1), many of which absorb at 359 nm. Feeding bioassays on fractions collected from HPLC of SPE MeOH showed that only the sixth peak

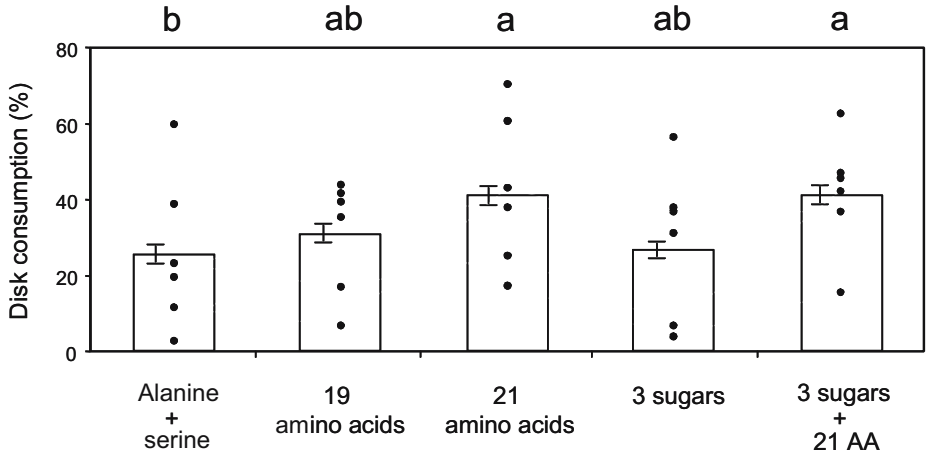

Fig. 2 Feeding responses (% disk consumption ± SEM) to amino acids, sugars and a mixture of the two. Twenty-one amino acids (AA) and three sugars were at approximately 0.2-mg pollen equivalent/disk. Each point indicates the mean values of six independent runs (eight replicates each) while the bars represent the mean of the combined data. Different letters represent significant differences by the Tukey–Kramer test ($P<0.05$) after a square-root transformation of values

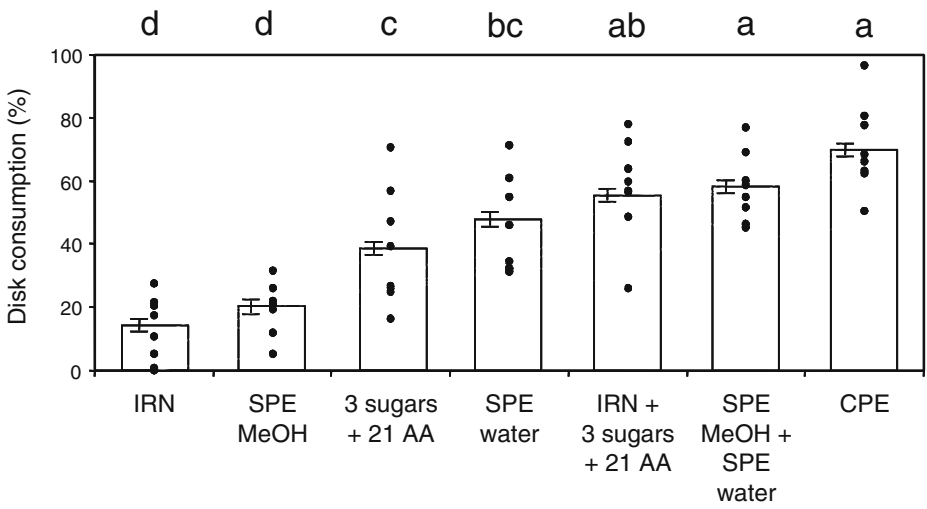

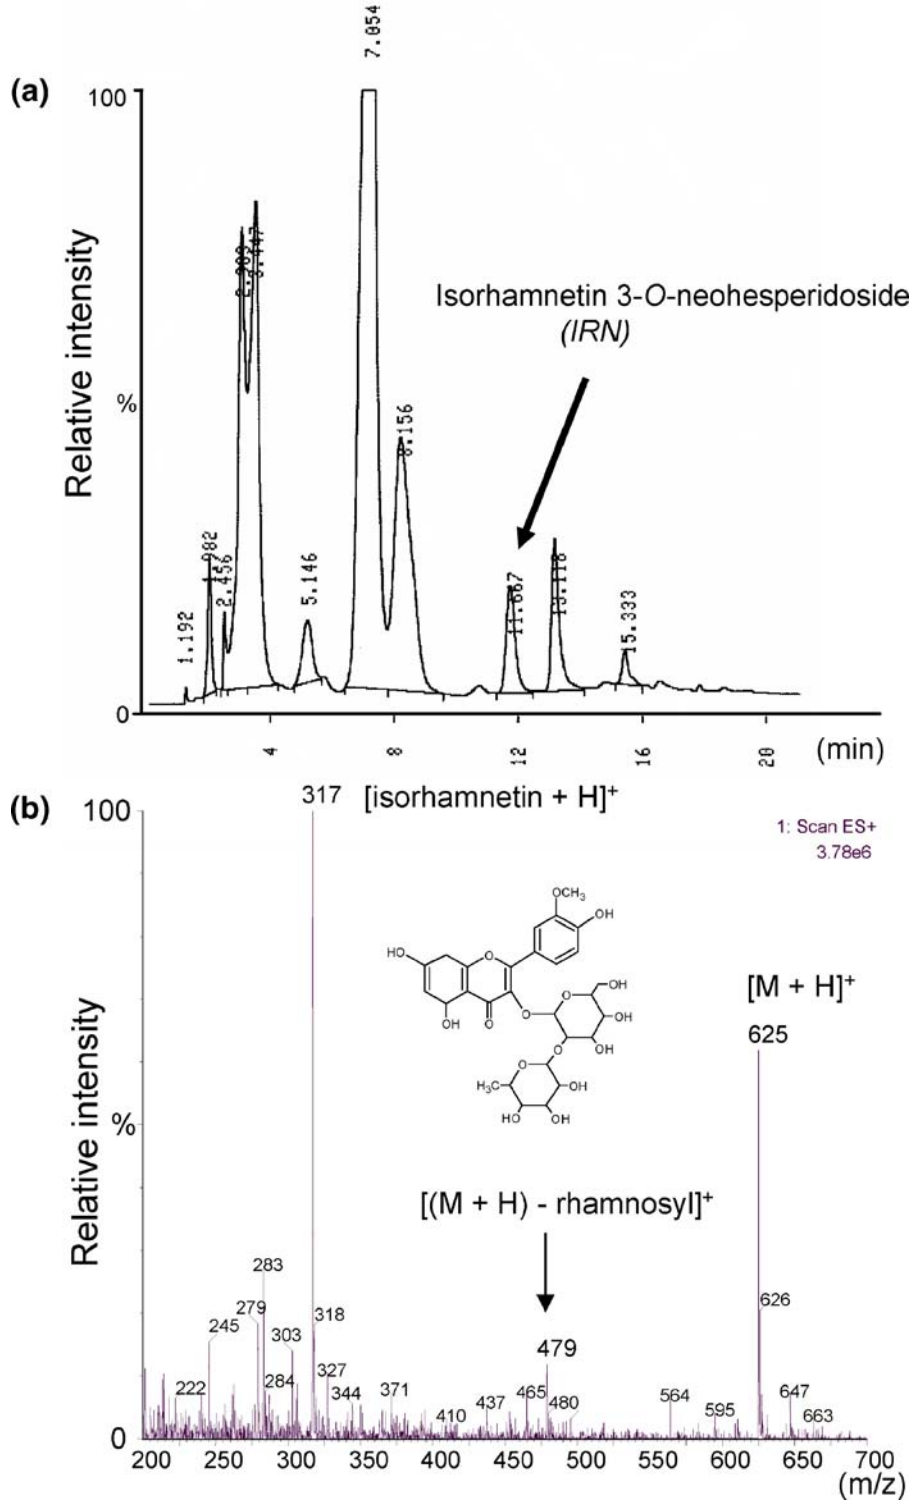

Fig. 3 Feeding responses (% disk consumption ± SEM) to phagostimulatory components in the corn pollen extract (CPE). The methanol (SPE MeOH) or water (SPE Water) fractions after solid-phase processing of CPE contained a flavonol diglycoside (IRN, see Fig. 4) or 21 amino acids and three sugars, respectively. All samples used in feeding bioassays were approximately at a 0.2 mg-corn pollen equivalent/disk. Each point indicates the mean values of eight independent runs (at least eight replicates each) while the bars represent the mean of the combined data. Different letters represent significant differences by the Tukey–Kramer test ($P<0.05$) after a square-root transformation of values

by area and in order of decreasing polarity at retention time 11.7 min (Fig. 4a) was slightly phagostimulatory (15% disk consumption), whereas other peaks did not stimulate beetle feeding (data not shown). This fraction also additively enhanced phagostimulation elicited by the mixture of three sugars and 21 AA (Fig. 3). The UV–visible spectrum of this purified fraction in methanol showed two major absorbance peaks at 254 and 359 nm (Mabry et al., 1970; Markham, 1982), and mass fragments were observed at *m*/*z* 479 $[(M + H)\text{-rhamnosyl}]^+$ and 317 $[\text{isorhamnetin} + H]^+$ (Fig. 4b). The absence of a *m*/*z* 463 $[(M + H)\text{-glucosyl}]^+$ fragment for a diglycosyl–isorhamnetin indicates the unknown is a monosubstituted rhamno-glucoside. Based on this UV, MS, and HPLC data in comparison with literature on known corn pollen and other floral flavonol glycosides (Ceska and Styles, 1984; Chaurasia and Wichtl, 1987; Nørbaek and Kondo, 1999), we tentatively identify this phagostimulant as isorhamnetin 3-*O*-neohesperidoside (IRN).

There was no significant difference in feeding responses between SPE MeOH and IRN, suggesting that IRN accounts for most of the phagostimulation elicited by the SPE MeOH fraction (Fig. 3). Likewise, feeding responses to the mixture of three sugars and 21 amino acids were not significantly different from SPE Water, which contained the free AA and sugars, suggesting that AA and sugars are responsible for most of the phagostimulation elicited by the SPE water fraction. Feeding response to the mixture of SPE MeOH and SPE water was significantly different from either SPE MeOH or SPE water, and beetle feeding was enhanced additively, which was not significantly different from feeding responses to CPE (Fig. 3). This additive feeding response was also observed in the case of IRN and 3 sugars + 21 AA. Feeding response to the mixture of IRN and three sugars + 21 AA was significantly different from either IRN or the three sugars + 21 AA individually.

TLC was used to compare the amounts of sugars or amino acids in SPE or CPE after derivatization with standard spray reagents. Visual intensities of color reactions for sugars with naphthoresorcinol or AA with ninhydrin in SPE water or CPE on the TLC plate were similar to those of equivalent amounts of standard sugars or AA (J. Kim, personal observation).

Effects of phagostimulant mixtures on feeding responses were studied by comparing the observed feeding response (% disk consumption elicited by a mixture) with the expected feeding response (the sum of % disk consumption elicited by each component). Beetle feeding was enhanced additively in response to the combination of SPE MeOH with SPE Water (89% of the sum of feeding responses to each component) or the combination of IRN with the three sugars and 21 amino acids (98%) (Fig. 3). On the other hand, the observed feeding response to the mixture of 2 and 19 AA was much lower (73%) than the expected value. In addition, the mixture of three sugars and 21 AA was less than the expected value (59% of the sum of each component response) (Fig. 2).

Discussion

The molecular weight and fragment patterns (Fig. 4) of the unknown compound from SPE MeOH fraction of the corn pollen extract and its two UV maxima (Mabry et al., 1970; Bacon et al., 1975; Markham, 1982) suggest a monosubstituted flavonol diglycoside. Only isorhamnetin among the possible *O*-methylethers of quercetin has been reported in maize pollen, and no rutinosides (6-*O*-rhamnopyranosyl-β-D-glucopyranoside) or other rhamnosides have been detected in this maize organ (Ceska and Styles, 1984). This 3-*O*-substituted neohesperidoside (2-*O*-rhamnopyranosyl-β-D-glucopyranoside) of isorhamnetin has been found in flowers and pollens of other plants (Chaurasia and Wichtl, 1987; Nørbaek and Kondo, 1999), and is one of the active flavonol glycosides in cardioprotective typhae (cattail) pollen, the Chinese medicine pu huang (Zhou, 2004). Although ^{13}C-NMR would be required to rigorously distinguish this neohesperidoside from the respective rutinoside, we conclude that isorhamnetin 3-*O*-neohesperidoside (CAS# 55033-90-4), the fifth or sixth major flavonol glycoside, previously reported from maize pollen (Ceska and Styles, 1984), is the likely candidate for this rootworm phagostimulant.

Simmonds (2003) reviewed the dynamic roles of flavonoids as feeding and oviposition stimulants or deterrents in insect–plant interactions, particularly in reference to Lepidoptera. In Coleoptera, several flavonoids are known phagostimulants and antifeedants for various chrysomelid beetles (Matsuda, 1978; Nielsen et al., 1979). Lin and Mullin (1999) demonstrated that quercetin 3-*O*-β-glucoside extracted from sunflower pollen was mildly phagostimulatory to adult WCR. In the field situation, however, insects taste a complex mixture of both primary and secondary phytochemicals, which can act as feeding stimulants, deterrents, or neutral compounds. Nonetheless, few insect studies have investigated the feeding effects of phagostimulant mixtures, especially both nutrients and

◀**Fig. 4** (**a**) Reverse-phase HPLC analysis of a methanol-wash fraction after processing through a solid-phase extract (SPE MeOH) from the corn pollen buffer extract. Only one fraction (IRN) stimulated beetle feeding in an additive manner over that of a mixture of three sugars and 21 amino acids (see Fig. 3). Absorbance was measured at 359 nm. plant secondary metabolites, in comparison to the individual component responses at their naturally occurring concentrations.

All of the free amino acids present in maize pollen should be considered when evaluating their role in eliciting pollen feeding. Phagostimulation elicited by the 21 AA combination was significantly greater than for the binary blend of the primary phagostimulatory amino acids, serine, and alanine. Surprisingly, the remaining 19 AA had phagostimulatory activity similar to these latter two AA at corn pollen concentrations (Fig. 2). It is unclear how this 19 AA mixture elicited a moderate level of beetle feeding without containing a strong stimulatory amino acid (Kim and Mullin, 1998), although proline is mildly phagostimulatory (Hollister and Mullin, 1998).

Phagostimulatory interactions between three sugars and 21 free amino acids on beetle consumption were less than additive (Fig. 2), indicating the probability of a competitive interaction at common taste receptor sites. By contrast, IRN enhanced reference-feeding responses in an additive manner when combined with the phagostimulatory mixture of three sugars and 21 AA (Fig. 3). It is interesting to note that a high concentration (up to 1-mg pollen equivalent) of IRN did not further enhance beetle feeding (data not shown). This indicates that IRN is not a strong phagostimulant by itself, but appears to modulate beetle feeding response when combined with other phagostimulatory compounds. For example, a combination of flavonol glucosides and sinigrin elicited a significant feeding preference in diamondback moth, *Plutella xylostella* L., for the mixture over the glucosinolate alone (van Loon et al., 2002). Flavonoids are known to be "biting" and "swallowing" factors for *Bombyx mori* (Hamamura, 1970), and their potential role in these mechanisms for interactions of phagostimulants at beetle taste receptors or their postingestive effects on beetle fitness for WCR need further evaluation.

The opposite relative amounts of glutamine and asparagine between the present study where glutamine is higher and Hollister and Mullin (1999) may reflect differences in extraction efficacy (buffer in the present study vs. aqueous methanol), or changes in pollen composition or extractability of free amino acids due to storage periods up to 6 years at −80°C. Sucrose has been reported as the dominant sugar in corn pollen (Hoekstra et al., 1989), but fructose and glucose were more prevalent than sucrose in the CPE used in this study. Degradation during buffer extraction or pollen storage may account for these discrepancies. Nevertheless, a buffer extract from recently collected corn pollen (e.g., var. 'Jackpot' in 2001) elicited the same level of phagostimulation as did the CPE used in this study (data not shown), although its contents of sugars and AA were not examined.

Whereas lipophilic compounds in corn pollen failed to stimulate or deter beetle feeding (J. Kim, personal observation), hydrophilic components, especially free amino acids and sugars, explained about 57% of total phagostimulation elicited by CPE (Fig. 3). Isorhamnetin 3-*O*-neohesperidoside, in addition, served as a costimulant for the combined three sugars and 21 AA explaining about 77% of the CPE consumption (Fig. 3). However, unknown compounds interacting with known phagostimulants may account for phagostimulatory factors yet to be discovered in maize pollen. Future studies are needed to address the mechanisms by which primary chemical stimuli for pollen feeding interact, and how these key behavioral factors for beetle feeding may be used in design of control tactics for adult WCR.

Abstract Sawfly larvae of the tribe Phymatocerini (Hymenoptera: Tenthredinidae), which are specialized on toxic plants in the orders Liliales and Ranunculales, exude a droplet of deterrent hemolymph upon attack by a predator. We investigated whether secondary plant metabolites from Ranunculaceae leaves are sequestered by phymatocerine *Monophadnus* species, i.e., *Monophadnus alpicola* feeding upon *Pulsatilla alpina* and *Monophadnus monticola* feeding upon *Ranunculus lanuginosus.* Moreover, two undescribed *Monophadnus* species were studied: species A collected from *Helleborus foetidus* and species B collected from *Helleborus viridis*. Comparative high-performance liquid chromatographic–photodiode array detection–electrospray ionization–mass spectrometric analyses of plant leaf and insect hemolymph extracts revealed the presence of furostanol saponins in all samples. Larvae of species A and B actively sequestered (25*R*)-26-[(α-L-rhamnopyranosyl) oxy]-22α-methoxyfurost-5-en-3β-yl *O*-β-D-glucopyranosyl-(1→3)-*O*-[6-acetyl-β-D-glucopyranosyl-(1→3)]-*O*-β-D-glucopyranoside (compound **1**). This compound occurred at a 65- to 200-fold higher concentration in the hemolymph of the two species (1.6 and 17.5 μmol/g FW, respectively) than in their host plant (0.008 and 0.268 μmol/g FW, respectively). In *M. monticola*, compound **1** was found at a concentration (1.2 μmol/g FW) similar to that in the host plant (1.36 μmol/g FW). The compound could not be detected consistently in *M. alpicola* larvae where, however, a related saponin may be present. Additional furostanol saponins were found in *H. foetidus* and *H. viridis*, but not in the two *Monophadnus* species

feeding on them, indicating that sequestration of compound **1** is a highly specific process. In laboratory bioassays, crude hemolymph of three *Monophadnus* species showed a significant feeding deterrent activity against a potential predator, *Myrmica rubra* ant workers. Isolated furostanol saponins were also active against the ants, at a concentration range similar to that found in the hemolymph. Thus, these compounds seem to play a major role for chemical defense of *Monophadnus* larvae, although other plant secondary metabolites (glycosylated ecdysteroids) were also detected in their hemolymph. Physiological and ecological implications of the sequestered furostanol saponins are discussed.

Introduction

Specialization on plant species containing secondary metabolites with broad-range toxicity offers herbivores the opportunity to sequester these metabolites and to use them for their own defense (Duffey 1980). Sequestration of plant-derived secondary metabolites has been repeatedly described from Lepidoptera and Coleoptera species, and in a few cases from other insect orders such as the Orthoptera and Hymenoptera (Laurent et al., 2005).

Tenthredinid sawfly (Hymenoptera) species of different subfamilies are able to sequester plant secondary metabolites in larval hemolymph (Bowers et al. 1993; Schaffner et al., 1994; Müller et al. 2001). Laboratory and field experiments indicate that larval hemolymph from these sawfly species is highly deterrent to different groups of predators (Schaffner et al., 1994; Müller and Brakefield, 2003). Boevé and Schaffner (2003) observed that larvae with high hemolymph deterrence activity towards *Myrmica rubra* L. exhibit "easy bleeding", i.e., they possess an integument with such a low resistance that even slight mechanical damage provokes release of hemolymph. Sawflies that do not possess a deterrent larval hemolymph have an integument that is significantly more resistant to mechanical damage. Based on these observations, Boevé and Schaffner (2003) hypothesized that there is a functional link between larval integument resistance and hemolymph deterrence, jointly acting as a chemical defense strategy.

Sawflies of the closely related genera *Rhadinoceraea*, *Phymatocera*, and *Monophadnus* (Tenthredinidae, Phymatocerini) display a particularly low larval integumental resistance (Boevé and Schaffner, 2003). This implies that many if not all phymatocerine sawflies are able either to sequester harmful secondary plant metabolites from their host plant or to synthesize deterrents de novo, and to store them in their hemolymph. So far, sequestration of plant secondary metabolites has been found in *Rhadinoceraea nodicornis*, which takes up and stores steroid alkaloids from *Veratrum album* in the larval hemolymph (Schaffner et al., 1994). Sawflies of the genera *Rhadinoceraea* and *Phymatocera* feed on Liliales and Asparagales, while species of the genus *Monophadnus* live on Ranunculaceae (Liston 1995). The corresponding order of Ranunculales is distantly related to Liliales and Asparagales, belonging to the Di- and Monocotyledones, respectively. We suppose the diverging host specialization is linked to chemical similarities between the two plant taxa. Our hypothesis is that sawflies of the taxon Phymatocerini, which share the ability to bleed easily, also share the ability to sequester plant compounds.

Here, we investigated whether the sawflies *Monophadnus* species A (field host plant: *Helleborus foetidus* L.), species B (*Helleborus viridis* L.), *M. monticola* (Hartig) (*Ranunculus lanuginosus* L.), and *M. alpicola* Benson (*Pulsatilla alpina* L.) sequester plant secondary metabolites in their defensive hemolymph. The work was primarily devoted to furostanol saponins, since: (1) such steroid saponins occur in Ranunculaceae as well as in Liliales and Asparagales (Wissner and Kating, 1974; Hardman and Benjamin, 1976; Tschesche et al., 1984); (2) the closely related steroid alkaloids occur in Liliales and are sequestered by at least one Phymatocerini species (see above); (3) steroidal compounds possess well-known deleterious effects on animals (Teuscher and Lindequist, 1987; Harmatha 2000).

Material and Methods

Insect and Plant Samples

Sawfly larvae and leaves of their host plants were collected in different regions of Switzerland: *Monophadnus* species A on *H. foetidus* from the Jura mountains (Kantons Jura and Baselland), *Monophadnus* species B on *H. viridis* from south of the Alps (Kanton Ticino), *M. alpicola* on *Pulsatilla alpina* from the Bernese Oberland (Kt. Bern) and alpine regions of Kanton Wallis, and *M. monticola* on *Ranunculus lanuginosus* from the Jura mountains (Kt. Solothurn), the Bernese Oberland (Kt. Bern), and Kanton Wallis. Reference specimens of all species have been deposited in the collections of the Deutsches Entomologisches Institut, ZALF e.V. (Müncheberg, Germany).

Sawfly larvae were maintained in the laboratory on leaves of their host plants. Hemolymph droplets were collected in glass capillaries after gently piercing the larval integument with forceps. The hemolymph was accumulated in ethanol and stored at −20°C in the dark. Each ethanolic extract was sonicated in an ice bath for 15 min and then vortexed for 1 min. After centrifugation (5 min, 4,000 rpm), the supernatant was transferred to a new vial, and the precipitate was reextracted twice with methanol under the same conditions. The combined supernatants were dried under N_2, and redissolved in methanol up to a concentration of 1 to 3 mg/ml.

For quantitative analyses, hemolymph was obtained from 23 larvae of *Monophadnus* species B, five species A, six *M. alpicola*, and 10 *M. monticola*. A total of 203, 39, 103, and 69 μl of hemolymph was collected from these species, respectively. These four samples of hemolymph yielded 9.6 mg of dry extract (from which 4.8 mg were soluble in methanol), 3.5 (2.7), 9.9 (5.5), and 14.8 (5.4), respectively.

Full-grown leaves of *H. viridis*, *H. foetidus*, *P. alpina*, and *R. lanuginosus* were collected in the same areas as the larvae (see above). The fresh plant material was chopped and directly extracted in methanol at room temperature. After concentration under reduced pressure ($T<$ 40°C), the crude extract was partitioned with *n*-hexane, chloroform, *n*-butanol, and distilled water to obtain four corresponding fractions. After removing the solvent in a rotavapor ($T<40$°C), each fraction was freeze-dried, and the residue was dissolved in methanol, centrifuged, and the clear supernatant used for analyses (see Qualitative and Quantitative Analyses section).

Chemicals

By preliminary comparative LC-UV-MS analyses of each hemolymph sample and of several plant extracts, saponins were detected regularly in the hemolymph as well as in the

butanolic plant fraction. The isolation of sufficient quantities of purified saponins allowed us to run further analyses in specific conditions.

A standard of (25*R*)-26-[(α-L-rhamnopyranosyl)oxy]-22α-methoxyfurost-5-en-3β-yl *O*-β-D-glucopyranosyl-(1→3)-*O*-β-D-glucopyranosyl-(1→3)-*O*-β-D-glucopyranoside (compound **2**; Fig. 1) was obtained as described in Braca et al. (2004).

Isolation of Compound **1**

Fresh leaves of *H. viridis* (180 g) were extracted until exhaustion with methanol at room temperature. The extract was evaporated to give a residue (9 g) that was subsequently partitioned between *n*-hexane, chloroform, *n*-butanol, and water, yielding fractions in the proportions of 21, 1, 20, and 58%, respectively. A portion of the *n*-butanol fraction (1.8 g) was chromatographed on Sephadex LH-20 column (100×5 cm) using methanol as eluent. Fractions of 8 ml were collected and grouped into 13 major fractions according to their features on thin layer chromatography (TLC) performed on silica 60 F_{254} gel-coated glass sheets with *n*-butanol–acetic acid–water (60:15:25) and chloroform–methanol–water (40:9:1). Fractions 19–21 of the Sephadex LH-20 column were further purified by preparative HPLC (flow rate 2.0 ml min^{-1}) with methanol–H_2O (6.5:3.5) to give compound **1** (t_R=15 min, 5 mg). The preparative HPLC system consisted of a Shimadzu LC-8A series pumping system equipped with a Shimadzu injector, a semipreparative Waters μ-Bondapak C_{18} column (30 cm×7.8 mm i.d.), and a Waters R401 refractive index detector. ^1H and ^{13}C NMR experiments, recorded in CD_3OD, were performed on a Bruker DRX-600 NMR spectrometer using the UXNMR software package. The spectra obtained were in accordance with those described by Braca et al. (2004) for (25*R*)-26-[(α-L-rhamnopyranosyl)oxy]-22α-methoxyfurost-5-en-3β-yl *O*-β-D-glucopyranosyl-(1→3)-*O*-

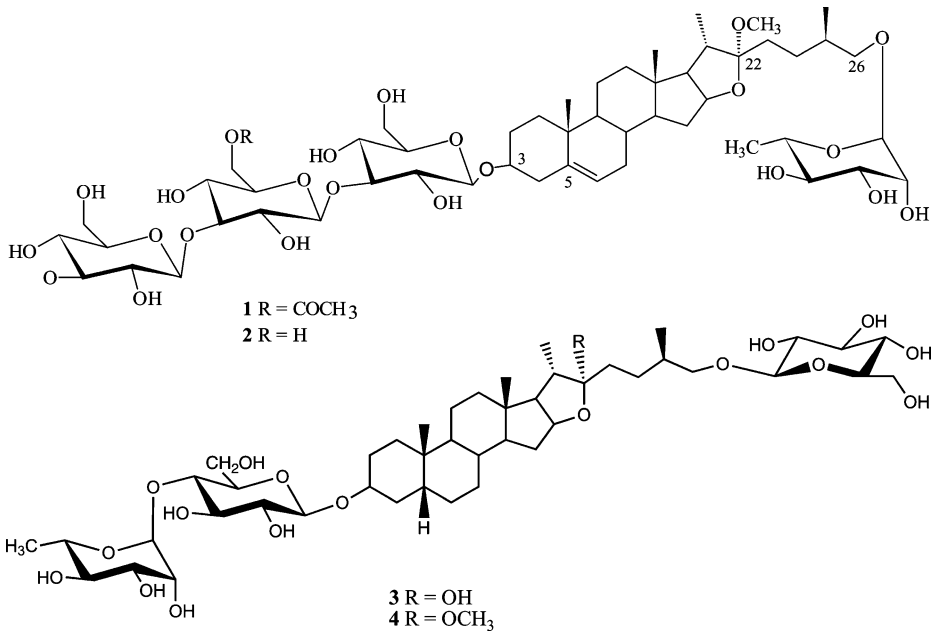

Fig. 1 Structures of furostanol saponins isolated from *Helleborus* species

[6-acetyl-β-D-glucopyranosyl-(1→3)]-*O*-β-D-glucopyranoside (Fig. 1), isolated from *H. viridis* collected at Alpe del Vicerè (Como Province, Italy).

Isolation of Compounds **3** and **4**

H. foetidus leaves (173 g FW) were extracted until exhaustion with methanol at room temperature and concentrated under vacuum ($T<40°C$). The residue (9 g) was redissolved in water and subsequently partitioned between *n*-hexane, chloroform, *n*-butanol, and water, yielding fractions in the proportions of 11, 0.5, 59, and 33%, respectively. The *n*-butanolic fraction (1.69 g) was chromatographed on a Sephadex LH-20 column (100×5 cm) using methanol as eluent. Fractions of 8 ml were collected and grouped into 13 major fractions by their TLC features as described above. The fourth (75 mg) of these fractions was further purified by preparative HPLC (see above) eluting with methanol–water (6.5:3.5, flow rate 2 ml min^{-1}), and the peak at $t_R=20$ min was collected (7.5 mg). The MS spectrum was in agreement with (25*R*)-26-[(β-D-glucopyranosyl)oxy]-22α-hydroxy-5β-furostan-3-β-yl *O*-α-L-rhamnopyranosyl-(1→4)-β-D-glucopyranoside, as described by Liang et al. (2002). This compound (i.e., compound **3** that contains a C-22 hydroxy group) was mixed with the C-22 methoxyl form (compound **4**; see Fig. 1).

Qualitative and Quantitative Analyses

High-performance liquid chromatographic–photodiode array detection–electrospray ionization–mass spectrometric (HPLC–UV/PDA–ESI/MS) analyses were performed by using a Surveyor LC pump, a Surveyor Autosampler, coupled to a Surveyor PDA detector and LCQ Advantage ion trap mass spectrometer equipped with Xcalibur 3.1 software (Thermo Finnigan, San Jose, CA, USA). Analyses were performed with a μ-Bondapak C_{18} column, 30 cm×3.9 mm i.d. (Waters Corporation, Milford, MD, USA). We followed the step gradient described by de Combarieu et al. (2002) using as solvents 0.01% aqueous formic acid (A) and acetonitrile (B): 0–20 min, 85–75% A, 15–25% B; 20–40 min, 75–55% A, 25–45% B; 40–55 min, 55–20% A, 45–80% B; 55–65 min, isocratic 20% A, 80% B. Flow rate was 1.0 ml/min. The column was at 23°C. UV channels were set at 246 and 200 nm.

ESI–mass spectrometer conditions were optimized to achieve maximum sensitivity for compounds **1** and **3**: positive ion mode, source voltage 4.5 kV, sheath gas (N_2) at flow rate 60 au, curtain gas (N_2) at 9.00 au, source current 80 A, capillary voltage 3 V, and capillary temperature 280°C. Full scan spectra were obtained in the positive ion mode, with a scan time of 1 sec, and from *m*/*z* 250 to 1,400. Ion trap conditions: acquisition in automatic gain control with a max-inject time of 200 ms. For the MS^2 analyses the most intense molecular ions were isolated with a width of 1 *m*/*z* unit and fragmented by using an activation amplitude of 25%.

To assess saponin concentration in plant and hemolymph samples, aliquots of four appropriate concentrations of the isolated saponin **1** and of the saponin mixture consisting of compounds **3** and **4** were injected onto the analytical system, eluted, and monitored with the ESI/MS detector under the conditions detailed above. Injections were performed in triplicates for plant samples and in duplicates for hemolymph samples, and peak areas were integrated and related to the amount of injected external standard. Linear regressions, interpolations, and Student–Newman–Keuls tests were done with the GraphPad Prism v.3 software (San Diego, CA, USA). Calibration curves and quantitative analyses of saponins in plant and hemolymph samples were replicated at three different days.

Feeding Deterrent Effect on Ants

Crude hemolymph was extracted in ethanol, filtered on celite powder, the solvent evaporated under a stream of N_2, and the dried extract then redissolved in sucrose 0.1 M. Two samples of purified saponins were also used. A sample of compound **1** (95% purity by HPLC–ESI/MS) contained a small amount of compound **2**, while a sample of compound **3** was inevitably in equilibrium with compound **4** (see above) in a ratio 2 to 1. The saponin samples were dissolved first in ethanol, then in sucrose 0.1 M (in volumes of 5 and 95%, respectively) to ensure good saponin dissolution. Preliminary tests comparing sucrose 0.1 M with ethanol in sucrose 0.1 M (1:19) gave no difference in feeding by *M. rubra* (see below).

The deterrent activity of the sawfly hemolymph and the purified steroidal saponins was assessed by the following bioassay. Forty *M. rubra* workers were placed in a Petri dish (9.5 cm diameter), in which they were offered a choice between 50 µl control solution (sucrose 0.1 M) and 50 µl of a test solution (12 replications). The number of ants feeding on each solution was recorded after 5 min. The test solution was sucrose 0.1 M containing 8 mg dry hemolymph or 0.8 mg purified plant secondary metabolite per milliliter solution. Eight-milligram dry hemolymph per milliliter solution was used as start concentration in previous works (Schaffner et al., 1994; Boevé and Schaffner, 2003; Boevé and Müller, 2005). Tenfold dilutions were then tested in the same way. The results were analyzed with the Wilcoxon matched-pairs signed-ranks test.

Results

Comparative analyses of sawfly hemolymph and fractions of their host plant leaves revealed that compound **1** was consistently detected in the following sawfly larvae: *Monophadnus* species A, species B, and *M. monticola*. Furthermore, the butanolic fraction of the plant *H. viridis* (Figs. 2 and 3) contained compound **1**. Compound **2**, that is the deacetylated form of compound **1**, was only detected in *H. viridis*, and compounds **3** and **4** were only present in extracts from *H. foetidus* (Fig. 3).

Compound **1** was also detected, but inconsistently, in *M. alpicola* and *P. alpina*. Furthermore, a peak (compound **5**) was detected in *M. alpicola* and *P. alpina* that showed a mass spectrum with a pseudomolecular peak at *m*/*z* 1,268 yielding a fragment at *m*/*z* 1,105.5 (loss of 162 Da) in a MS^2 experiment (see Table 1). This suggests that the structure of this compound (**5**) may correspond to compound **1** with an additional hexose moiety.

The response of the ESI/MS detector to different concentrations of compound **1** was linear in the range 0.01 to 0.25 mg/ml (r=0.999), and to those of compounds **3** and **4** (in a ratio 2:1) in the range 0.5 to 0.125 mg/ml (r=0.999). The resulting concentrations of the compounds in the hemolymph of *Monophadnus* species A, species B, and *M. monticola* as well as in their host plants are given in Table 2. Compound **1** was approximately 60- to 200-fold more concentrated in the hemolymph of *Monophadnus* species A and species B than in their respective host plants, indicating a particularly efficient mode of sequestration of compound **1** by these two sawfly species.

The larval hemolymph of *Monophadnus* species A, species B, and *M. monticola* was highly deterrent to ants at 8 mg DW per milliliter of solution (Table 3). At this concentration, no or almost no ants were feeding on the test solution. For these three species, a significant difference in the distribution of ants on test and control solutions was

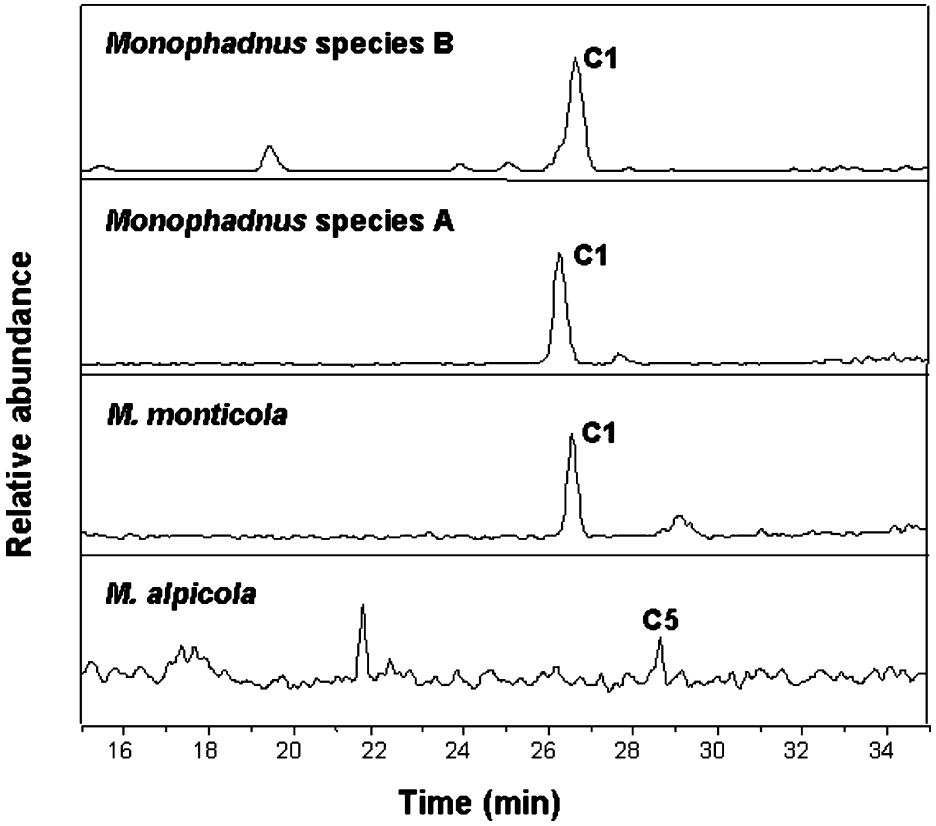

Fig. 2 HPLC–ESI/MS base peak chromatograms of hemolymph extracts from *Monophadnus* larvae, showing the occurrence of the furostanol saponins, compounds **1** and **5** (C1, C5)

lost at a concentration of 0.08 mg hemolymph DW per milliliter of solution. The tested furostanol saponins proved to be deterrent as well, up to this concentration, and compounds **3** and **4** showed a slightly higher deterrence than compounds **1** and **2** (Table 3).

Discussion

Among the furostanol saponins detected, compound **1** was the dominant one stored in the hemolymph of three *Monophadnus* species: *Monophadnus* species A, species B, and *M. monticola*. Among the host plants, *H. viridis* was the only one where compound **1** was a major steroidal saponin, while *H. foetidus* had mostly compounds **3** and **4**. Thus, it is likely that compound **1** is selectively sequestered by *Monophadnus* species A. It remains to be shown how furostanol saponins pass through the gut wall and how they are stored in the hemolymph, but it is likely that their uptake relies on an active transport and/or an efficient storage system, as proposed by several authors in other cases of sequestration (Duffey 1980; Bowers 1992).

In the plant material, compounds **1** and **4** are supposed to possess originally a hydroxyl group at C-22. This position is easily methoxylated under exposure to methanol (Liang

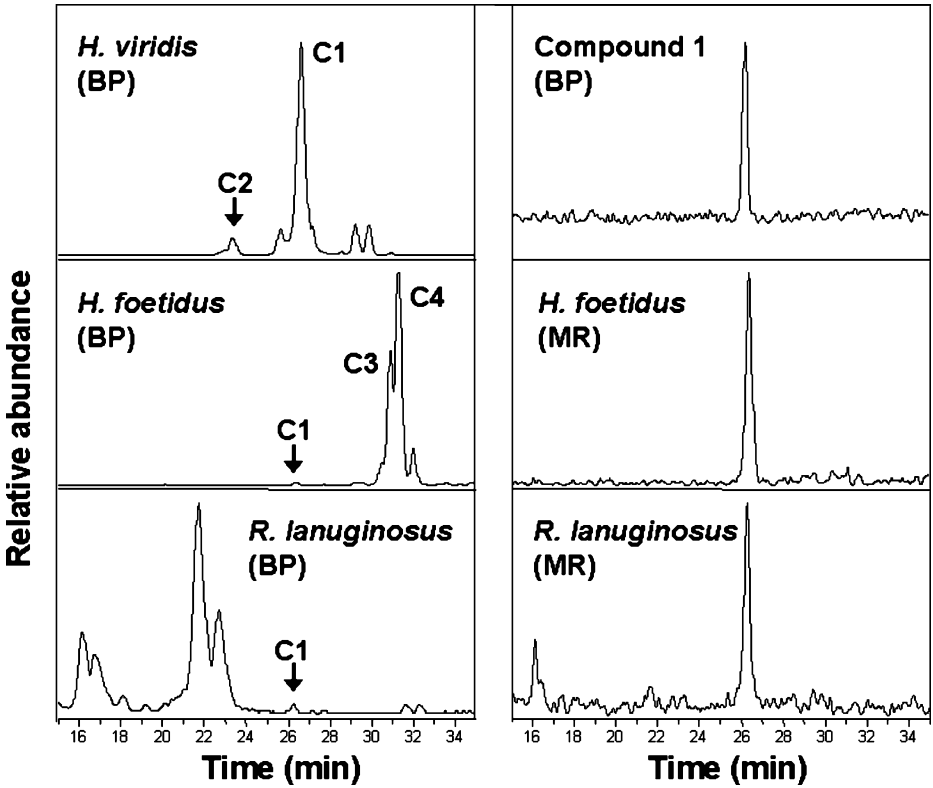

Fig. 3 HPLC–ESI/MS chromatograms of *n*-butanolic extracts from Ranunculaceae leaves, showing the occurrence of several furostanol saponins, compounds **1** to **4** (C1, C2, C3, and C4), and of isolated compound **1**. Base peak (BP) and mass range (MR; with m/z=1,105.5) chromatograms are shown

et al., 2002). Thus, different times of exposition to this solvent, during the extraction and subsequent isolation procedures, may have caused different methoxylation levels of the saponins present in the samples of *H. viridis* and *H. foetidus*. The same applies for the insect samples, which were also extracted in methanol, and for samples subjected HPLC–ESI/MS where methanol was used as well.

Triterpenoid saponins are part of the chemical defense in a number of leaf beetles (Termonia et al., 2002; Gillespie et al., 2003), but, to our knowledge, the results presented here provide the first evidence for sequestration of steroidal saponins into the larval body of insect herbivores. Criocerine leaf beetles incorporate steroidal saponins in fecal shields to enhance their defense (Morton and Vencl, 1998; Vencl et al., 1999). It is interesting to note that steroidal alkaloids, which are sequestered by the sawfly *Rhadinoceraea nodicornis* (Schaffner et al., 1994), have also been found in these criocerine fecal shields (Vencl et al., 1999). This suggests that the criocerine leaf beetles and Phymatocerini sawflies have evolved different ways to exploit the same group of plant secondary metabolites for their own defense.

Steroidal saponins are known to have deterrent and toxic effects on a broad range of invertebrates (Applebaum and Birk, 1979; Harmatha 2000). They act by forming an insoluble complex with sterols, such as cholesterol, which results in the breakdown of

sterol-based physiological processes such as molt or growth. In contrast to the criocerines, *Monophadnus* larvae must take up the steroidal saponins through the gut wall to accumulate them in their body, where it may directly interfere with these processes. It remains to be shown how *Monophadnus* larvae prevent autotoxicity by the sequestered steroidal saponins.

Sequestration of steroidal saponins appears to protect the larvae of all *Monophadnus* species studied from attack by ants. Predatory insects with biting–chewing mandibles constitute the type of predators that are most effectively deterred by the hemolymph released through woundings of the easily damaged integument of some sawfly larvae, including the *Monophadnus* species (Boevé and Schaffner, 2003; Müller and Brakefield, 2003; Boevé and Müller, 2005). In the field, workers of the ant *Lasius niger* L. retreated immediately after biting into a larva of *Monophadnus* species B in which they made contact with its hemolymph; the ants were then observed cleaning their mandibles for several minutes (Barker, personal observation). In our bioassays, the sequestered steroidal saponins tested as isolated, purified compounds proved to be highly deterrent to *M. rubra* ants (Table 3). The saponins were still active at a concentration of 0.08 mg saponins per milliliter solution (i.e., 0.07 μmol compound **1** per gram of FW solution), which is less than

Table 2 Concentration of furostanol saponins in larval hemolymph of *Monophadnus* species and leaves of their host plants

Negative sign (−) Not detected

the concentrations of compound **1** (at least 1.2 μmol/g FW) found in the hemolymph. Thus, it is likely that the chemical defense of the studied sawfly larvae is primarily based on the sequestration of steroidal saponins into the hemolymph. Besides the furostanol saponins, however, glycosylated ecdysteroids were detected in the hemolymph of *Monophadnus* species B. The hemolymph contained polypodine B glycoside and 20-hydroxyecdysone glycoside, whereas leaves of its host plant, *H. viridis*, contained their aglycones, polypodine B and 20-hydroxyecdysone (Prieto, unpublished data). Ongoing research aims to quantify their concentrations in larvae and host plant, and to determine their activity as feeding deterrents.

Steroidal saponins have been found in a variety of monocotyledonous plant families (Evans 1989). In contrast, Ranunculaceae constitute one of the few dicotyledonous families from which steroidal saponins have been described (Wissner and Kating, 1974; Petricic

Table 3 Feeding deterrent activity of *Monophadnus* larval hemolymph and of saponins against *M. rubra* ant workers

1974; Tschesche et al., 1984). Because a large majority of Phymatocerini sawflies are specialists on members of Liliales, Asparagales, or Ranunculaceae, it is likely that the steroidal saponins and alkaloids played an essential role in the evolution and radiation of the Phymatocerini. Moreover, larvae and females of *Rhadinoceraea nodicornis* are able to perceive steroidal alkaloids (Barker et al., 2002; Barker and Schaffner, unpublished data), indicating that the sequestered plant secondary metabolites also play a role in host plant selection. There are, however, a few apparent exceptions to this pattern within the Phymatocerini. For example, *Rhadinoceraea micans* and *R. reitteri* feed on *Iris*, a plant genus from which no steroidal saponins or steroidal alkaloids have been described so far. This encourages us to further investigate the influence of chemoecological parameters on radiation of Phymatocerini sawflies.

Acknowledgement We thank Prof. N. de Tommasi (Dipartimento di Scienze Farmaceutiche, Università di Salerno, Italy) for advice and registering the NMR spectra available for our studies; Dr A. Taeger for advice on sawfly identification; and Prof. M. Hilker and two anonymous referees for their constructive reviews. The authors acknowledge the financial support provided by the European Community's Improving Human Potential Programme under contract HPRN-CT-1999-00054 (INCHECO) and the Swiss Bundesamt für Bildung und Wissenschaft.

Abstract Several previous studies have addressed pheromone communication in various flour beetles (Coleoptera: Tenebrionidae), including the confused flour beetle, *Tribolium confusum* (du Val). Different stereoisomers of 4,8-dimethyldecanal (DMD) were reported as the only components of an aggregation pheromone, but the behavioral activity of DMD is low. In the present study, additional previously reported secondary metabolites (benzoquinones and hydrocarbons) were tested for electrophysiological activity (EAG) with both sexes of *T. confusum*. Two benzoquinones and three monoenic hydrocarbons elicited significant EAG activity from both male and female antennae. There was an elevated male EAG response (vs. the females) to two out of the three hydrocarbons and for both quinones. The EAG-active compounds were subsequently investigated for behavioral activity in a walking bioassay. Benzoquinones are considered toxic and have been assigned a function as alarm substances in flour beetles, but we found that methyl-1, 4-benzoquinone in intermediate concentrations was attractive to both male and female beetles and could therefore act as an aggregation pheromone component. Males were also attracted to ethyl-1,4-benzoquinone. The corresponding hydroquinones, presumed precursors of the benzoquinones, did not elicit any electrophysiological response and were not tested for behavioral activity. The unsaturated hydrocarbons (1-tetradecene, 1-pentadecene, and

1-hexadecene) elicited significant EAG responses from both male and female antennae and were also attractive in the behavioral assay. Our results show that several beetle-produced compounds, in addition to 4,8-dimethyldecanal, may be part of a complex pheromone system in flour beetles and play a role in mediating aggregation in *T. confusum*.

Introduction

Beetles of the genus *Tribolium* (Coleoptera: Tenebrionidae) are cosmopolitan and common pests in grain stores and flour mills. Numerous studies have investigated beetle-produced volatiles and their behavioral activity in several species of this genus, including *Tribolium confusum* (e.g., Ryan and O'Ceallachain, 1976), *Tribolium castaneum* (Herbst) (e.g., Loconti and Roth, 1953), and *Tribolium destructor* (Uyttenboogast) (e.g., Howard, 1987).

Aggregation behavior is elicited by 4,8-dimethyldecanal (DMD) in several *Tribolium* species (Suzuki, 1980; Suzuki and Sugawara, 1979; Suzuki et al., 1984, 1987; Arnaud et al., 2002). Theoretically, there are four different stereoisomers of DMD, and it has been hypothesized that the isomeric composition may differ among species. Response rates of both males and females of the confused flour beetle *T. confusum* were highest to the 4*R*,8*R* isomer both electrophysiologically and behaviorally (Levinson and Mori, 1983), whereas an 8:2 mixture of 4*R*,8*R*- and 4*R*,8*S*-DMD has been reported to mimic the aggregation pheromone of *T. castaneum* (Suzuki et al., 1984). The behavioral response to DMD is, however, low and seems to leave room for additional compounds to be identified as components of an efficient pheromone communication system (Olsson et al., 2006). Furthermore, traps baited with DMD have so far had limited success for applied purposes, which underlines the need for development of new attractants for this important group of insect pests.

Several previously identified beetle-produced volatiles may be pheromone component candidates. In addition to DMD, adults of the confused flour beetle, *T. confusum* produce benzoquinones (Engelhardt et al., 1965; von Endt and Wheeler, 1971; Suzuki et al., 1988) and volatile hydrocarbons (von Endt and Wheeler, 1971; Keville and Kannowski, 1975; Suzuki et al., 1975; Howard, 1987) (Table 1). The behavioral activity of benzoquinones has been examined for both *T. castaneum* and *T. confusum* (Loconti and Roth, 1953; Mondal and Port, 1984; Faustini and Burkholder, 1987). Most studies agree that these are defensive compounds with a repellent effect on conspecific larvae and adults (Mondal, 1985). They have also been suggested to counteract the aggregation effect of DMD (Faustini and Burkholder, 1987). The most studied unsaturated hydrocarbon produced by *Tribolium* flour beetles, 1-pentadecene, has been examined in the context of cuticular lipids and defensive secretions of flour beetles (Keville and Kannowski, 1975; Tschinkel, 1975; Suzuki et al., 1975, 1988; Lockey, 1978; Markarian et al., 1978). Different functions of 1-pentadecene have been proposed, e.g., bio-solvent for benzoquinones facilitating their absorption in the cuticle (von Endt and Wheeler, 1971; Markarian et al., 1978), repellent (Suzuki et al., 1975), or copulation pheromone (Keville and Kannowski, 1975).

We hypothesized that the *T. confusum* aggregation pheromone is more complex than what has been reported and that the previously identified quinones and unsaturated

hydrocarbons are potential attractive pheromone components. The activity of these compounds to male and female beetles was examined by using electroantennography (EAG) and an open-arena walking bioassay and compared to the activity of DMD under the same conditions.

Methods and Materials

Insects T. confusum beetles were reared in 2.5 dm^3 jars half-filled with a 4:1 (wt:wt) mix of whole-wheat flour and Brewer's yeast, in a climate chamber at 23°C, 60% RH, and with a photoperiod of L17:D7. They were separated into males and females as adults (Ho, 1969) at least 2 wk before the bioassays were performed and were between 6 mo and 1 yr old when tested.

Chemicals Two stereoisomers of 4,8-dimethyldecanal, the (4*R*,8*R*)- and the (4*R*,8*S*)-isomers [(4*R*,8*R*)-DMD and (4*R*,8*S*)-DMD, respectively, Fig. 1] were prepared (Suzuki, 1981; Suzuki et al., 1983, Fig. 1). Thus, (4*R*,8*R*)-DMD was obtained starting from the (*R*)-enantiomer of 2-methylbutanol [(*R*)-**1**] and commercially available (*S*)-citronellal [(*S*)-**2**]. The alcohol (*R*)-**1** (not commercially available) was obtained by using a lipase-catalyzed resolution (Nordin et al., 2000) of readily available racemic 2-methylbutanol (*rac*-**1**, Fluka, Sigma-Aldrich Sweden AB, Stockholm, Sweden). A twofold molar excess of vinyl acetate and *rac*-**1** (100 g) were allowed to react in pentane (1 L), catalyzed (E=2.56) by powdered lipase PS "Amano" [10 g (Amano Enzyme Inc., Nagoya, Japan)]. The reaction was stirred at room temperature until 92% conversion was reached. The enzyme powder was filtered off, and the clear filtrate was poured onto a chromatography column (Silica gel 60, 230–400 mesh, Fluka, Sigma-Aldrich Sweden AB, Stockholm, Sweden). After elution with an ether/pentane gradient (1 to >5% ether), the remaining ester reagent and the produced ester (vinyl acetate and 2-methyl-1-butyl acetate, respectively) were collected. Gradient elution using ether (5 to 75%) in pentane gave the remaining unreacted (*R*)-2-methylbutanol. Re-

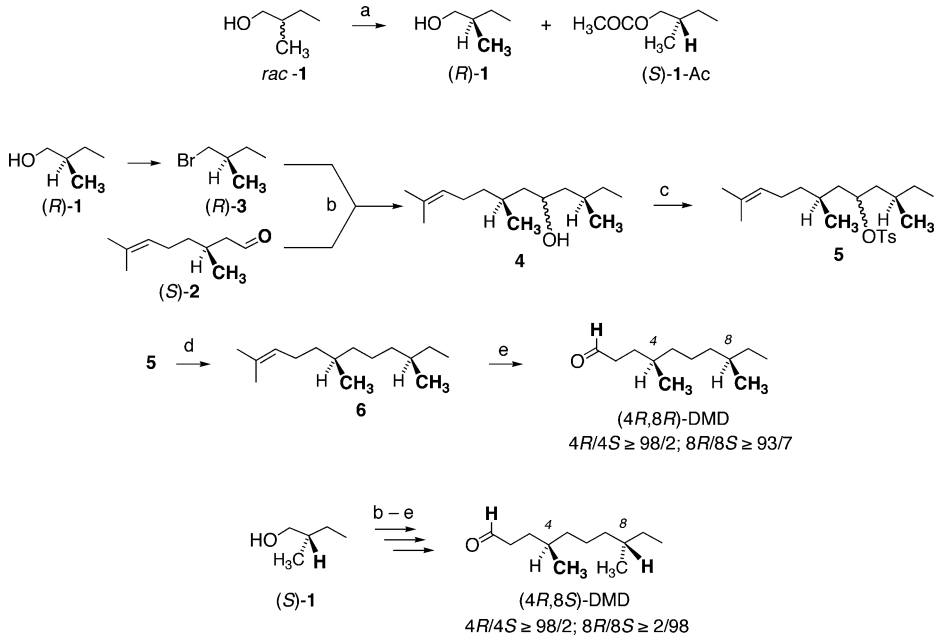

Fig. 1 Synthesis of various isomers of 4,8-dimethyldecanal. Reaction conditions: (a) Vinyl acetate, Amano PS lipase, pentane, room temperature, 2–4 d. (b)*1* (*R*)-1-Bromo-2-methylbutane [(R)-**3**], Mg, diethylether; *2* Add (*S*)-**2** in diethylether; *3* H_3O^+/H_2O, 60%. (c) TsCl/pyridine. (d) $LiAlH_4$, diethylether, 40% over two steps. chromatography of the alcohol fraction furnished (*R*)-**1**, 7 g [86% ee by GC, β−DEX™ 325 (Supelco, Sigma-Aldrich Sweden AB, Stockholm, Sweden), 30 m×0.25 mm i.d., d_f = 0.25 μm; carrier gas He 15 psi, split ratio 30:1, 40°C/20 min, 0.5°C/min, 50°C]. Retention time (min): 33.5 (*R*)-**1** and 34.9 (*S*)-**1**. The resolution experiment was repeated, but the reaction was interrupted at 72% conversion to give a sample of (*R*)-**1** of lower enantiomeric purity (20 g, 60% ee). The alcohol (*R*)-**1** was converted to the corresponding bromide (*R*)-**3**, which was transformed into the Grignard reagent, and reacted (Suzuki, 1981; Suzuki et al., 1983) with commercially available (*S*)-citronellal, [(*S*)-**2**] (Sigma-Aldrich Sweden AB, Stockholm, Sweden), approximately 97.5% ee by GC, [β-DEX™ 225 [(Supelco, Sigma-Aldrich Sweden AB, Stockholm, Sweden), 30 m×0.25 mm i.d., d_f=0.25 μm; carrier gas He 15 psi, split ratio 30:1, 90°C/20 min, 1°C/min, 120°C. Retention time (min): 37.4 (*S*)-**2** and 37.9 (*R*)-**2**]. This reaction sequence furnished the alcohol **4** as a mixture of diastereomers, which was converted to the tosylate **5**. This was reduced with lithium aluminum hydride to furnish the alkene **6**, which was subjected to epoxidation followed by periodate mediated oxidative cleavage to yield (4*R*,8*R*)-DMD. Thus, (*R*)-**1** (86% ee) gave (4*R*,8*R*)-DMD as a stereoisomeric mixture (>99% chemical purity by GC) with a calculated (4*R*,8*R*)/(4*R*,8*S*)/(4*S*,8*R*)/(4*S*,8*S*) ratio of 91/7/2/0 (based on the stereoisomeric purities of the starting materials), below called 4*R*,8*R*-DMD. Similarly, (*R*)-**1** (60% ee) furnished (4*R*,8*R*)-DMD as a mixture with a (4*R*,8*R*)/(4*R*,8*S*)/(4*S*,8*R*)/(4*S*,8*S*) ratio of 78/20/2/0.3 (>98% chemical purity by GC), below called an 8:2 mixture of 4*R*,8*R*-DMD/4*R*,8*S*-DMD. We prepared the other naturally occurring stereoisomer of tribolure [(4*R*,8*S*)-DMD] from (*S*)-**2** and (*S*)-2-methylbutanol [(*S*)-**1**] (both compounds from Sigma-Aldrich Sweden AB,

Stockholm, Sweden, and both approximately 96% ee by GC), by using the same reaction sequence, but excluding the first reaction, the resolution step (step a, Fig. 1). This resulted in a mixture of stereoisomers (>97% chemical purity by GC) with an approximate (4*R*,8*R*)/(4*R*,8*S*)/(4*S*,8*R*)/(4*S*,8*S*) ratio of 2/96/0/2 (based on the stereoisomeric purities of the starting materials), below called 4*R*,8*S*-DMD. The physical properties of our samples were identical to those described earlier (Mori et al., 1983, 1985).

Methyl-1,4-benzoquinone (MBQ) and methylhydroquinone (MHQ) were commercially available (Sigma-Aldrich Sweden AB, Stockholm, Sweden) and were used as received. Ethylhydroquinone, EHQ, and ethyl-1,4-benzoquinone, EBQ, were obtained (Fig. 2) from 2,5-dihydroxyacetophenone, **7** (Sigma-Aldrich Sweden, AB, Stockholm, Sweden). Thus, when subjected to Clemmensen reduction, compound **7** gave ethylhydroquinone, EHQ. After recrystallization from toluene, colorless crystals were obtained (approximately 99% chemical purity by GC). M.p. 104–6°C (Alberola et al., 1980: m.p. 110°C). EHQ was oxidized by chromium trioxide in acetic acid/water to give crude ethyl-1,4-benzoquinone, EBQ, as a deep orange oily crystal mass. Sublimation to a cold finger in vacuo (approximately 100 mmHg) yielded bright yellow needles (>99% purity). M.p. 34°C (Harman and Cason, 1952: m.p. 37°C).

Four synthetic monounsaturated hydrocarbons were obtained commercially: 1-Tetradecene (C14:1) (Sigma-Aldrich Germany GmbH, Germany), 1-pentadecene (C15:1) (Acros Organics, Geel, Belgium), 1-hexadecene (C16:1) (Fluka Chemika, Sigma-Aldrich Chemie Gmbh, Steinheim, Germany), and 1-heptadecene (C17:1) (Sigma-Aldrich Chemie Gmbh, Steinheim, Germany) (chemical purity >97% by GC).

The DMD samples and the hydrocarbons were dissolved in redistilled *n*-hexane, whereas quinones and hydroquinones were dissolved in methanol (Table 2). The purities and concentrations of the synthetic compounds were determined by coupled gas chromatography-mass spectrometry. The gas chromatograph, HP 5890 series II was equipped with an HP1 nonpolar cross-linked polydimethylsiloxane column [(Hewlett Packard Sverige AB, Kista, Sweden), 30 m×0.25 mm i.d.×0.25 μm film thickness] and interfaced with an HP 5792A mass spectrometer working in scan mode. Helium was used as carrier gas. The initial temperature was maintained at 50°C for 2 min and then increased by 10°C/min to the final temperature of 250°C.

Electrophysiology (EAG) The *T. confusum* antenna was carefully excised from the head, so that all the segments and the basal nerve were still attached to the antenna. The antenna was mounted between two glass capillary electrodes (1.5 mm o.d., 1.2 mm i.d.) filled with Ringer solution, in contact with a silver wire. The base of the antenna was first inserted into the ground glass electrode. The tip of the recording electrode was bowl-shaped, and half of the last distal antennal segment was immersed into the saline solution. The DC potential was recorded on a computer using a custom-built amplifier (Hanson B-102), and an IDAC A/D converter and software (Auto Spike v. 3.0) purchased from Syntech, Hilversum, The

Ethylhydroquinone	10^0–10^5	Not tested
Unsaturated hydrocarbons	10^1–10^7	10^{-1}–10^4

Netherlands. Filtered and humidified air was continuously flowing over the mounted antenna (approximately 0.5 m/s). A Pasteur pipette, containing a 0.5-cm^2 piece of filter paper impregnated with a 10-µl solution of the test chemical in a defined amount, was used to deliver the stimulus in a 2.5-ml puff during 0.5 s by means of a stimulus controller (CS-02, Syntech, Hilversum, The Netherlands). The solvents used for the stimuli were tested alone and elicited minimal EAG responses, indistinguishable from responses to air. Ten micrograms of two DMD isomers, 4*R*,8*R*- and 4*R*,8*S*-DMD, and also an 8:2 mixture of 4*R*,8*R*-DMD to 4*R*,8*S*-DMD were tested initially. The EAG responses were recorded every 3 min after the excision to test the longevity of the antennal preparation. This experiment was followed by an EAG study of the response to different doses of the most active isomer.

In the following experiments, an active control consisting of 10 µg of 4*R*,8*R*-DMD was applied before each test stimulus. Five seconds separated the DMD control puff and the tested substance puff, and 10 sec separated two tested doses. Every EAG response will, therefore, be presented as a normalized response that corresponds to the ratio between the EAG response induced by the tested solution of benzoquinones/hydrocarbons and the response induced by 10 µg 4*R*,8*R*-DMD. Each experiment was conducted in five replicates for both sexes.

Behavioral Assay The open-arena olfactometer was a modified version of a walking bioassay previously used for investigations of beetle behavior (Lanne et al., 1987; Olsson et al., 2006). The olfactometer was 0.8 m long and 0.2 m wide. A source of compressed air provided a laminar airflow of 0.2 m/s over the arena and an air exhaust evacuated contaminated air to the outside of the building. The floor of the arena was made of a glass plate on which a sheet of paper was placed. This paper was replaced between tests of different compounds. The test compound was released from a 1-µl glass capillary (32 mm long, 0.1 mm i.d.) (Drummond, MICROCAPS®, Drummond Scientific Co., Broomall, PA, USA), which was suspended over, but not touching, the paper at the upwind end of the arena. Two capillaries were used when testing the benzoquinones. Whereas all the methanol solvent had evaporated from the capillary within 10 min, evaporation of the *n*-hexane required only 5 min. Actual release rates of the test compounds are not known. The laboratory temperature and relative humidity were controlled at 22.5±0.5°C and 60±5%, respectively.

Ten beetles of the same sex were put in a vial. Ten vials, five for each sex, were used to test one dose of a chemical. The vial was placed in the center of the olfactometer and was left for 30 sec for beetles to acclimate. The capillary was filled with the solution and beetles were released and allowed to respond during 5 min. At the end of the test, beetles collected upwind from the release point were counted as responding/attracted (beetles approaching the capillary within the 5 min were withdrawn before they could touch the odor source and

then counted as responding). New beetles were used in each test, so that one beetle was not tested more than once a day. The measured response in each test was calculated as the number of beetles attracted out of the ten tested. Solvent was used as a control (methanol for benzoquinones, *n*-hexane for the other compounds). An active control consisting of 1 μg of 4*R*,8*R*-DMD was tested each day to check that the beetles were behaving similarly each experimental day.

Statistical Analyses Statistical tests were performed with the statistical software Minitab® 14.0 for Windows. Analyses of variance (ANOVA) were carried out for both the electrophysiological and behavioral experiments. Three factors were tested initially (antenna, sex, and dose of tested chemical) for the electrophysiological trials, whereas two factors (sex and dose of tested chemical) were tested in the behavioral trials. General linear model (GLM) (Wolfinger and Chang, 1995) was used instead of ANOVA when unbalanced datasets were analyzed. Differences between means were tested for significance with Dunnett's (comparison with a control) or Newman and Keuls' (comparison by groups of means) tests.

Results

DMD, Choice of the Active Control for Subsequent Experiments Antennal activity decreased significantly with time after the excision of the antenna in both sexes (females, $F_{4,60}$=167.14, P<0.001; males, $F_{4,60}$=208.49, P<0.001) (Fig. 3). There were differences in both female ($F_{2,60}$=2.48, P=0.022) and male ($F_{2,60}$=43.65, P<0.001) EAG activities among the three stimuli. Due to their EAG activities, the two isomers and the blend were tested behaviorally (Fig. 4). There was no difference in walking behavior between the

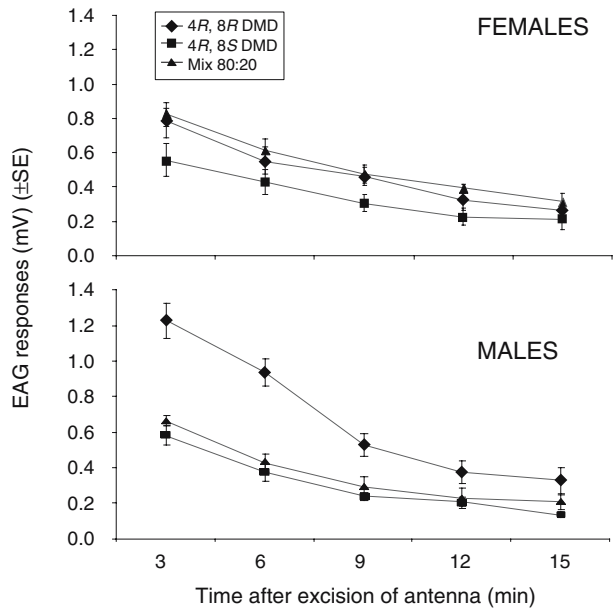

Fig. 3 Effect of time on mean EAG responses (±SE) of female and male *Tribolium confusum* antennae (N=5) to 10 μg of 4*R*,8*R*-DMD, 4*R*,8*S*-DMD, or an 80/20 blend of the two isomers

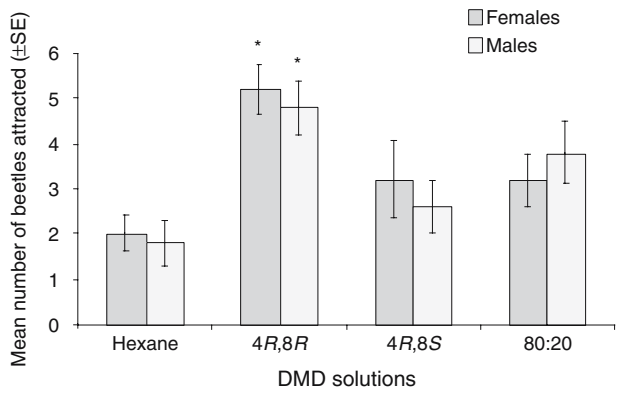

Fig. 4 Mean behavioral responses (±SE) of *Tribolium confusum* (N=5) to 1 μg of 4*R*,8*R*-DMD, 4*R*,8*S*-DMD, or an 80/20 blend of the two isomers. *n*-Hexane was used as control. * indicates significant difference from the control within each sex (Dunnett's test, P<0.001)

sexes, but the responses to the two isomers and the blend were different ($F_{4,40}$=7.42, P< 0.001), and 4*R*,8*R*-DMD was more attractive than the *n*-hexane control (Dunnet's test, P<0.001).

EAD and Behavioral Dose–response to 4R,8R-DMD 4*R*,8*R*-DMD was the most active and attractive isomer, so it was tested in different concentrations in both EAG and behavioral assays. There was a positive dose–response relationship in EAG for both females ($F_{5,80}$= 105.8, P<0.001) and males ($F_{5,80}$=30.7, P<0.001). The two highest doses (1 and 10 μg) elicited higher EAG responses than the *n*-hexane control in both females (Dunnet's test, P< 0.001) and males (Dunnet's test, P<0.001) (Fig. 5). The highest dose (1 μg) induced a higher walking response in both females and males (Dunnet's test, P<0.001), whereas 0.1 μg induced a higher response than the control (Dunnet's test, P<0.05) for females only (Fig. 6). There were no differences between male and female responses.

Benzoquinones Both MBQ and EBQ elicited higher EAG responses than the control (Fig. 7) ($F_{6,52}$=20.97, P<0.001 and $F_{5,44}$=13.25, P<0.001, respectively). There were also significant differences in EAG responses between the sexes for both MBQ ($F_{1,52}$=4.58, P= 0.037) and EBQ ($F_{1,44}$=10.25, P=0.003); males were more sensitive. In the walking assay, MBQ attracted both sexes (GLM, $F_{5,68}$=8.42, P<0.001) compared to methanol (Fig. 8).

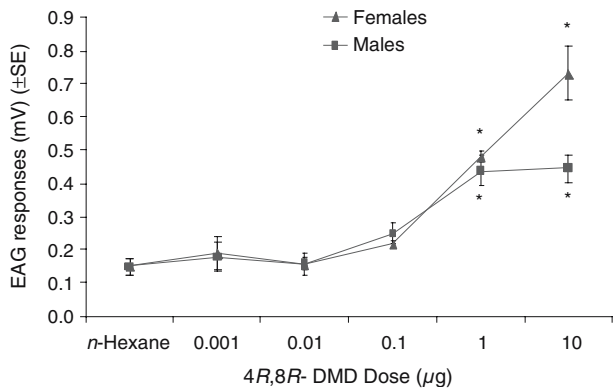

Fig. 5 Effect of 4*R*,8*R*-DMD dose on the antennal responses (±SE) of female and male *Tribolium confusum* (N=5). * indicates significant difference from the *n*-hexane control within each sex (Dunnett's test, P<0.001)

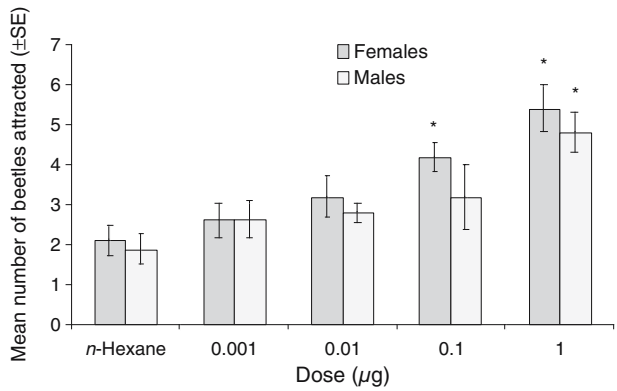

Fig. 6 Mean behavioral responses (±SE) of *Tribolium confusum* (N=5) to increasing doses of 4*R*,8*R*-DMD. *n*-Hexane was used as control. * indicates significant difference from the *n*-hexane control within each sex (Dunnett's test, P<0.05)

There was no difference in behavior between males and females in response to MBQ ($F_{1,68}$=1.61, P=0.209), whereas there was an interaction between dose and sex with EBQ ($F_{6,76}$=4.69, P<0.001). Female and male attraction were found to be dose-dependent for EBQ ($F_{6,38}$=4.05, P=0.003 and $F_{6,38}$=6.03, P<0.001, respectively). The EAG experi-

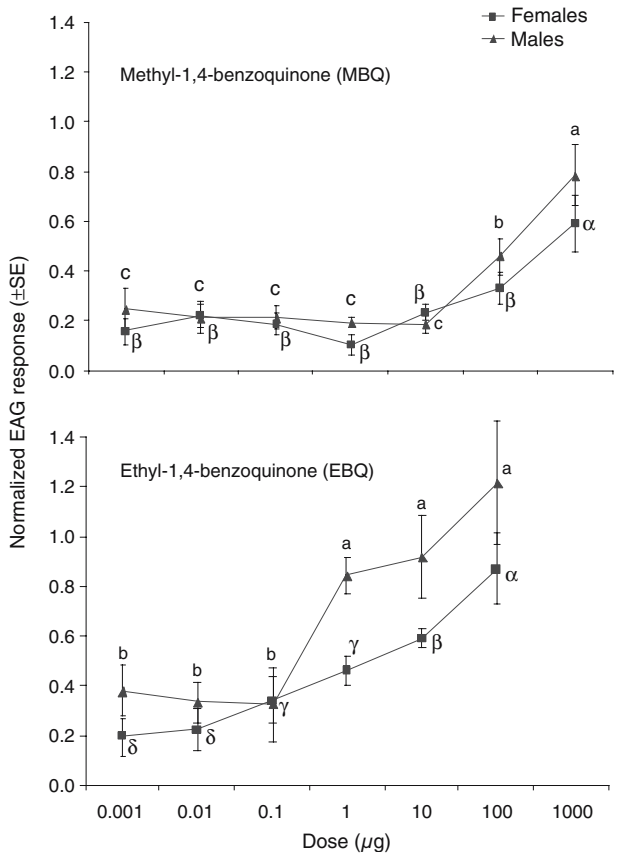

Fig. 7 Effect of doses of methyl-1,4-benzoquinone and ethyl-1,4-benzoquinone on antennal responses (±SE) of female and male *Tribolium confusum* (N=5). EAG responses to benzoquinones have been normalized to the 10 μg 4*R*,8*R*-DMD responses. Means with the same letter within each sex are not significantly different (Newman and Keuls test; α=0.05, N=5, df=24)

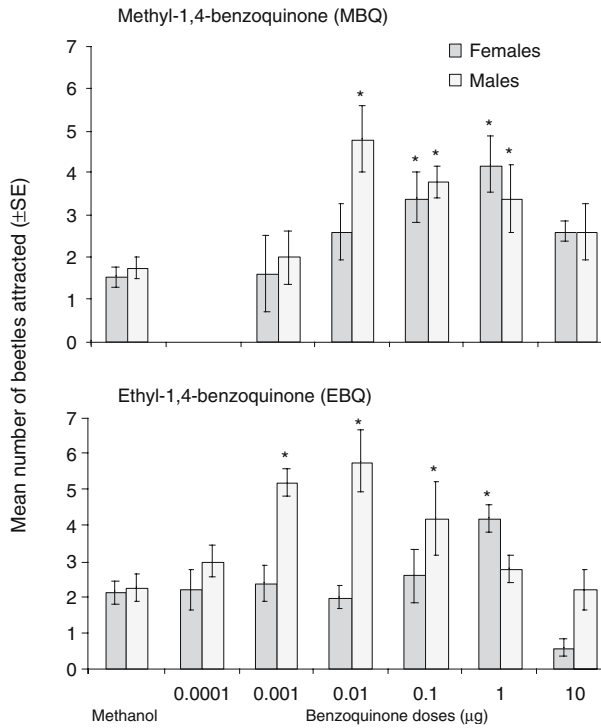

Fig. 8 Mean behavioral responses (±SE) of *Tribolium confusum* (N= 5) to increasing doses of methyl-1,4-benzoquinone and ethyl-1,4-benzoquinone. Methanol (1 µl) was used as control. * indicates means that are significantly different from the methanol control (Dunnett's test, P<0.05)

ment with the benzoquinone precursors, the hydroquinones, revealed no activity for any of the doses of MHQ or EHQ. These substances were, therefore, not tested behaviorally.

1-Tetradecene Female and male antennal responses were dependent on the dose of C14:1 ($F_{6,24}$=13.99, P<0.001 and $F_{6,24}$=21.93, P<0.001, respectively) (Fig. 9). The male response was higher than the female response at the higher doses. In the behavioral assay, the beetles displayed a positive dose–response to C14:1 ($F_{6,76}$=7.84, P<0.001), and there was no difference between the sexes (Fig. 10).

1-Pentadecene Female and male antennae responded differently, generally with higher male responses, to different doses of C15:1 in the EAG experiment ($F_{6,24}$=56.03, P<0.001 and $F_{6,24}$=16.86, P<0.001, respectively) (Fig. 9). In the walking assay, both sexes displayed a dose-dependent attraction to C15:1 ($F_{6,76}$=5.02, P<0.001), but no difference between the sexes was observed (Fig. 10).

1-Hexadecene Males and females responded similarly in the EAG experiment to C16:1 (Fig. 9). The dose had an effect on the antennal responses of both sexes ($F_{6,52}$=10.93, P< 0.001). The longer homolog C17:1 elicited no significant EAG response (data not shown). Both males and females were attracted to C16:1 in the walking bioassay (GLM, $F_{6,76}$=4.29, P<0.001) (Fig. 10).

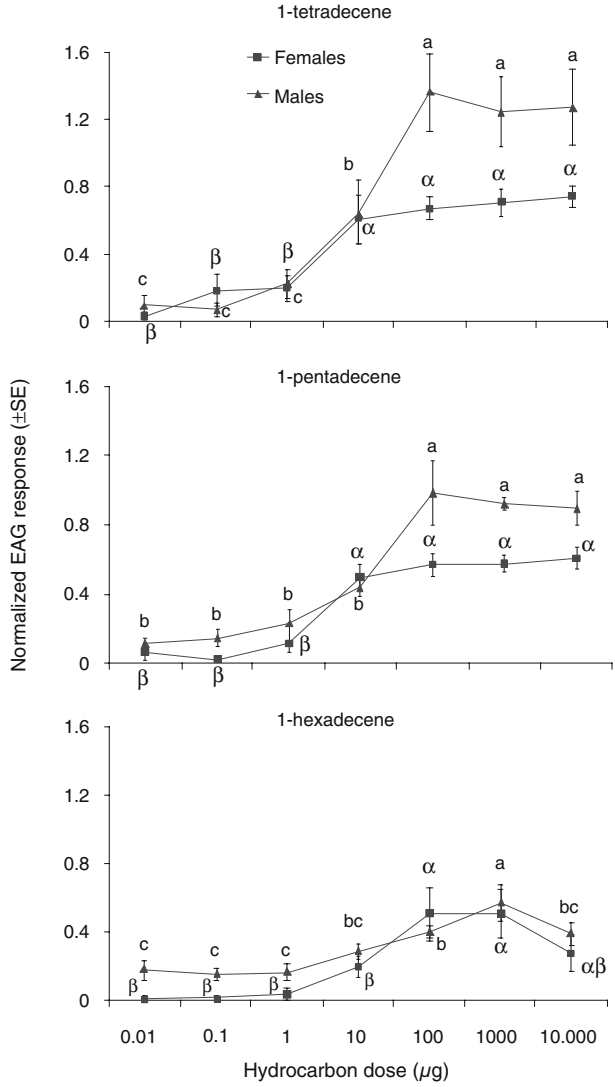

Fig. 9 Effect of doses of 1-tetradecene, 1-pentadecene, or 1-hexadecene on antennal responses (±SE) of female and male *Tribolium confusum* (N=5). EAG responses to hydrocarbons have been normalized to the 10 μg 4*R*,8*R*-DMD responses. Means with the same letter within each sex are not significantly different (Newman and Keuls test; α=0.05, N=5, df=24)

Discussion

This study of secondary metabolites from the confused flour beetle *T. confusum* shows that several semiochemicals, in addition to the previously identified aggregation pheromone DMD, elicit antennal and behavioral responses in both sexes and may comprise a more complex pheromone system. Both electrophysiological and behavioral responses of male and female *T. confusum* were highest to the 4*R*,8*R* isomer of DMD, in agreement with the work of Levinson and Mori (1983). However, benzoquinones, commonly referred to as defensive secretions or inhibitors of microbial growth in the flour beetles (Engelhardt et al., 1965; Faustini and Burkholder, 1987; Mondal, 1990), were also found to be EAG-active

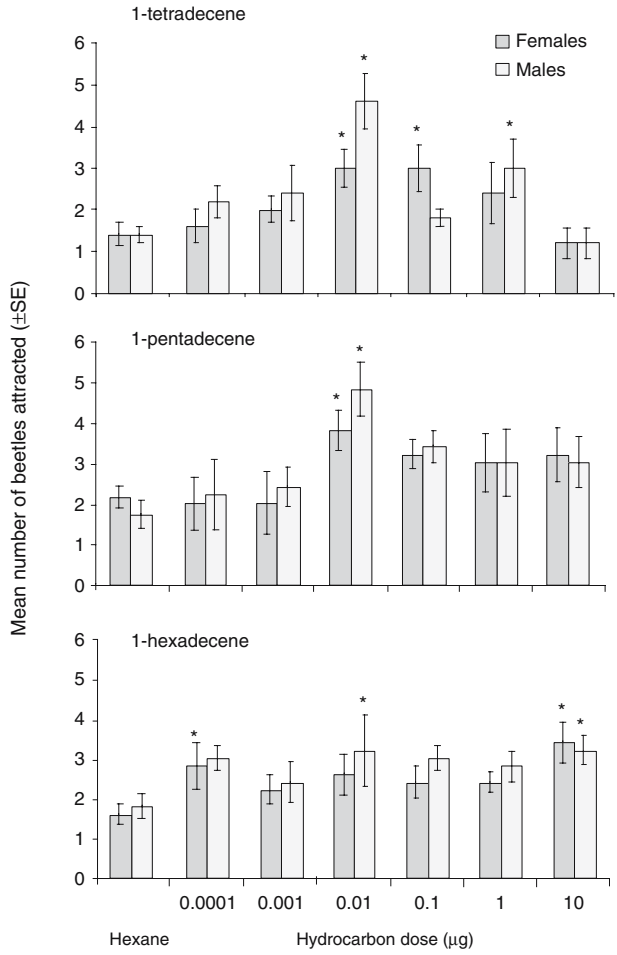

Fig. 10 Mean behavioral responses (±SE) of *Tribolium confusum* (N=5) to increasing doses of 1-tetradecene, 1-pentadecene, or 1-hexadecene. *n*-Hexane (1 µl) was used as a control. * indicates means significantly different from the *n*-hexane control (Dunnett's test, $P<0.05$)

and as attractive as 4*R*,8*R* DMD, especially to males. Furthermore, two unsaturated hydrocarbons elicited antennal responses and attraction of both female and male beetles.

A dense population of flour beetles could potentially produce substantial amounts of the benzoquinones. Engelhardt et al. (1965) estimated that when subjected to stress, e.g., extreme temperature, the amounts of these compounds released by *T. confusum* were around 1 µg/beetle/3 hr. Our results suggest that lower concentrations attract both males and females, whereas higher concentrations reduce attraction. The reduced attraction to the high concentrations is in agreement with Faustini and Burkholder (1987), who reported that higher concentrations can cause the beetles to disperse. It seems adaptive that the beetles have evolved different behavioral responses to different concentrations of benzoquinones, and these compounds may serve as a spacing pheromone at higher concentrations, similar to what has been reported for other compounds in aphid chemical ecology (e.g., Quiroz et al., 1997; Gonzales et al., 1999).

Antennal receptors in *T. confusum* responded to the three unsaturated hydrocarbons (C14:1, C15:1, C16:1). Male antennae had stronger responses to the highest doses of the

C14:1 and C15:1 than female antennae. Both EAG and behavioral responses decreased with increasing chain length, and the attraction to C16:1 is low in both sexes, which could partly be explained by the corresponding decrease in volatility of the stimuli. The attraction of males (and females) to the hydrocarbons agrees with the male response to pentadecene and heptadecene reported by Keville and Kannowski (1975). They found that males mounted other males and females upon stimulation with these volatiles. In contrast, they did not find any female response to the hydrocarbons, whereas in our study, females responded both electrophysiologically and behaviorally. Suzuki et al. (1975) reported that the hydrocarbons in question were repulsive when 10 μg were deposited on a filter paper. Our results do not explicitly support this claim, but the maximal dose used in our experiments (10 μg) did, at least, not elicit any significant attraction. Comparisons between tests using different dispensers are difficult to make as application of similar doses does not necessarily imply the same actual emission. We conclude that, similarly to the benzoquinones, the three hydrocarbons (C14:1, C15:1, and C16:1) were as attractive as the previously reported aggregation pheromone DMD in the behavioral assay. Unsaturated hydrocarbons could thus play an aggregative role when released at low doses complementary to the benzoquinones.

Gas chromatography in combination with electroantennographic detection (GC-EAD) should have been a suitable method to test the relative activity of precisely quantified amounts of various pheromone candidates and also to examine insect extracts for potential pheromone component candidates. However, we could not use GC-EAD for measuring the activity of different compounds at different concentrations as the lifetime of antennal preparations was short and variable. Regular use of this approach would have allowed the introduction of a better-defined amount of the stimulus, but would at the same time have introduced new problems when it came to the recording of the actual response. GC-EAD analyses of natural samples were also not productive. GC-EAD recordings from *T. confusum* will require major improvements of the antennal preparation.

The likely mixed function of semiochemicals produced by flour beetles is similar to what has been reported for secretions of sternal glands in caddisflies (Trichoptera). Several compounds produced in these glands show high fumigant activity and have been assigned a function in chemical defense (Ansteeg and Dettner, 1991). Compounds produced in the same glands, and in some cases, even the same compounds as those reported by Ansteeg and Dettner (1991) have been confirmed as components of sex and aggregation pheromones, respectively, in *Rhyacophila fasciata* and *Hydropsyche angustipennis* (Löfstedt et al., 1994).

The chemical communication of the *Tribolium* flour beetles appears complex, and several classes of chemicals are involved in their behavior. The present study shows that DMD is not the only compound produced and attractive for *T. confusum*. This raises the question of the natural composition of the aggregation pheromone of these beetles. Indeed, *T. confusum* aggregation pheromone seems to be composed of a blend of chemicals, which depending on emitted amounts, are able to attract the beetles as efficiently as DMD. Further studies should focus on experiments involving several of the active chemicals to highlight increased attraction or even possible synergy.

Position Around A Tree: Consequences For Pheromone Detection

Abstract The air flow pattern expected around a cylindrical object such as a tree in slow wind, is predicted from fluid mechanics to have areas of faster flow (upwind) and slower recirculating flow with eddies (downwind). An organism located on the surface of a tree would experience different flow depending on its circumferential position. If that organism was searching for a chemical signal, such as a pheromone plume, it might maximize its probability of chemodetection by placing itself in areas of greatest flow speed (the upwind surface of the cylinder, i.e., in front of the separation points). We tested whether wood cockroaches in the genus *Parcoblatta* exhibit such upwind positioning; they live in forests, and males actively fly from tree to tree, while searching for females releasing sex pheromone. In contrast to an expectation of upwind preference, male cockroaches were evenly distributed around trees relative to upwind (measured with a novel "feather boa" flow visualization technique), even though the wind direction was relatively steady. We investigated whether sex pheromone could be detected at any location around a cylindrical surface in a laboratory flow chamber by using *Bombyx mori* wing fanning as a bioassay. Although upwind moths arrayed on the surface detected pheromone more rapidly, pheromone detection occurred at least a third of the time at any position, which could explain the even distribution of *Parcoblatta* males around trees.

Introduction

Many forest insects localize potential mates by the use of volatile, airborne pheromones (Elkinton et al., 1987; Brady et al., 1989; Wyatt et al., 1993, 1997). Wind is the primary

pathway for communication via the olfactory channel; as such, it determines where pheromones will be carried. Although the pheromone molecules and the air currents that bear them are invisible, we can visualize their movements by using smoke, bubbles, and other physical markers. These visualization techniques have been vital in developing our understanding of natural airflow patterns in forests and grasslands (David et al., 1982, 1983; Elkinton et al., 1987; Willis et al., 1994; Murlis et al., 2000). Air flow patterns dictate the shape and behavior of pheromone plumes and the challenges faced by insects tracking such complex and intermittent signals. It is well-established that pheromone released by an insect travels downwind in a meandering sinuous plume as a result of wind shifts (David et al., 1982, 1983; Murlis et al., 1992, 2000). Despite the slow (<1 m/sec) and shifting air movements in a forest (Smith et al., 1972; Oliver, 1975), insects are able to track pheromone or host-odor plumes and locate odor-emitting individuals (Brady et al., 1989, 1990; Willis et al., 1994).

An animal located on a tree or other obstacle, around which pheromone-laden air is swirling, may have opportunities to intercept or miss a pheromone plume, depending on its location around the tree. Downwind of a cylindrical obstacle, the air is moving especially slowly and recirculating in eddies (Fig. 1) (Brady et al., 1989; Vogel, 1994). It follows from this flow pattern that for individuals on a surface: (1) upwind individuals should intercept pheromone first, whereas individuals further downwind on the same tree would receive a delayed and possibly diluted chemical sample; (2) as a result of these velocity differences between upwind and downwind areas, individuals can potentially change the amount of air they sample by changing their position around the cylinder. Therefore, insects on the upwind surface would be sampling a larger volume of air per unit time, which would allow an individual to increase its likelihood of encountering pheromone molecules.

To evaluate whether potential advantages of upwind positioning are utilized by a forest insect that uses volatile sex pheromones to locate a mate, we measured circumferential positions of native wood cockroaches in the genus *Parcoblatta* in a forest. These cockroaches actively court in early summer during the evenings (Hebard, 1931; Helfer, 1953; Lawson, 1967; Horn and Hanula, 2002). The short-winged (nonflying) females are found primarily on the ground and release sex pheromone (Gorton, 1980; Gemeno et al., 2003). Males are long-winged and fly from tree to tree, presumably while searching for a pheromone-releasing female (Gorton, 1981; Miller, personal observation).

In the laboratory, complementary investigations were performed to evaluate how the timing and probability of interception of pheromone plumes varied with location around a

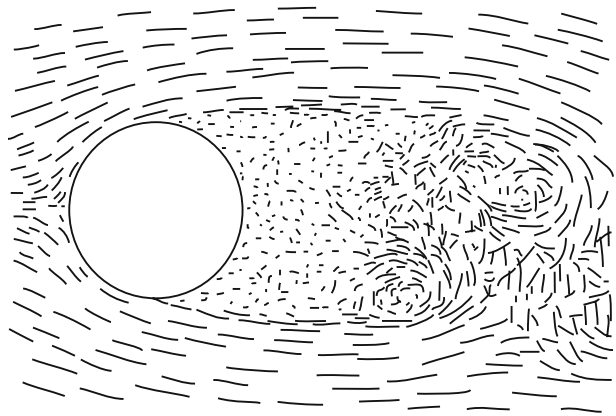

Fig. 1 The pattern of flow around a cylinder. This is visualized by using *pathlines*; a *pathline* shows the path followed by a parcel of air during a set time interval (Vogel, 1994). Flow approaches the cylinder from the left, and *longer pathlines* indicate faster flow. Flow near the downwind surface of the cylinder is much slower and contains swirling eddies. The cylinder and flow are viewed in cross-section. (*Pathlines* were drawn based on a photograph in Van Dyke, 1982, p. 31, of flow at Re=2000)

cylinder. For these measurements, we used a wing fanning assay to visualize pheromone interception by moths arrayed around a cylinder in controlled flows. Adult male *Bombyx mori* show a clear visual response (wing fanning) to detection of the sex pheromone released by the females (Loudon and Koehl, 2000).

If wind direction is shifting substantially, an organism on a tree surface would need to relocate to stay upwind. To measure the rate at which the upwind direction on a tree changed over a biologically relevant time scale (on the order of minutes or hours), we made multiple measurements of upwind direction both in a natural forest and on solitary trees in a field.

Methods and Materials

Distribution of Parcoblatta Relative to Wind Direction Orientation behavior of males from two species of *Parcoblatta* cockroaches (*Parcoblatta pennsylvanica* and *Parcoblatta uhleriana*) was observed during their mating season in June of two successive years. [Note that authorities differ on the spelling for *P. pennsylvanica*; Hebard (1917) uses *P. pensylvanica*.] The field site was a deciduous forest within the Rockefeller Experimental Tract, Lawrence, KS (Kansas Biological Survey). Male cockroaches became active (were flying around) as darkness fell. After landing on tree trunks, males often touched the tree surface briefly with their antennae before taking off or staying in place, but did not often walk far on the tree surface. Activity of these flying males declined about 4 hr after dark (males were sometimes observed to move under bark). After sighting a male on a tree surface, its circumferential position was measured with a compass, and its height above the ground was measured to the nearest centimeter (cm) with a meter stick. Upwind direction was recorded at each tree at the time the cockroach was sighted by using a novel marabou "feather boa" visualization method (marabou feathers are easily displaced, being fine and light). The boa (marabou feather boa, Hobby Lobby) was wrapped around the tree at the time and height at which the male was located, generating a circumferential wind indicator. The down-like feathers splayed apart in response to the wind, indicating upwind direction at the tree surface, which was recorded with a compass. In addition to upwind direction, the boa visualization method enabled us to determine whether the air speed was below the slow threshold air speed, indicating extremely still air. Thus, this boa method allowed measurement of wind direction, but only a qualitative (or threshold) estimate of wind speed. This method differs from the method of Baker and Cardé (1979) that used the calibrated displacement of a single feather to estimate air speed at a single location.

The response threshold of the marabou boa (minimum air speed required for a detectable response) was determined by placing it around a cylinder (9-cm diameter) placed inside a large slow-flow chamber (cross-sectional area=1,089 cm^2). The air moving through the chamber passed through a flowmeter (King Instrument Company) that was used to measure the volume flow rate, from which the average cross-sectional velocity was calculated. The response threshold of the boa, denoted by noticeable parting of feathers showing wind direction, corresponded to an average ambient flow of approximately 2.5 cm/sec (imperceptible by humans).

Variability in Upwind Direction at Tree Surfaces for Solitary Trees Wind direction variability was estimated at tree surfaces during the months of June and early July. Measurements of upwind direction were taken once every minute for solitary trees. Each of the six "solitary" trees was a minimum of 7.5 m from any neighboring tree. The variability

in wind direction over time for individual trees was estimated from multiple measurements; the upwind direction was recorded to the nearest degree at the surface of individual trees by using a compass and boa (as described above) for 10 successive measurements at 1-min intervals for each tree. Three sets of 10 successive measurements were taken at each of three different times: in the morning, midday, and evening for each tree ("morning" times were between 8 and 10:40 A.M., "afternoon" times between 12 and 2:40 P.M., and "evening" times between 8 and 10:40 P.M.). The variability in wind direction was calculated as the circular standard deviation of the 10 successive minute-by-minute measurements at a tree; the circular standard deviations were averaged for the three (or two) sets for each time of day and tree. During one morning, measurements were not taken due to rain. The circumferences of these six trees ranged from 0.17 to 1.45 m.

Variability in Upwind Direction at Tree Surfaces for Forest Trees We also determined whether upwind direction was the same for multiple trees in a group, both in the forest and at its edge, to look at the effect of neighboring trees during the month of June. We selected 10 trees along the edge of the forest and 10 trees within the forest for repeated measurements of wind direction over a 10-d period, recording upwind directions once early in the evening (8–9 P.M.) and once 1/2 to 2 1/2 hr later (weather permitting). We also compared the frequency with which the wind exceeded a slow threshold (proportion of times that wind direction was detectable using the feather boa method) between "edge" and "within forest" trees.

Experimental Animals for Pheromone Detection in Laboratory Measurements *B. mori* were reared on mulberry leaves under a natural light cycle. Once caterpillars had pupated, they were sexed, placed in individual cups, and checked daily for emergence. All males used were at least 1 d old and unmated; some males were used repeatedly by random selection from the available males. Unmated females were used as a sex pheromone source.

Experimental Setup for Controlled Flow in Laboratory Measurements Tethered male moths were arrayed around a vertical cylinder (27 cm tall and 16.6 cm diameter) centered in a flow chamber (60×84×27 cm). The moths were located halfway up the cylinder, spaced 45° apart (eight males total at a time). Moths were secured to wooden supports that passed through slits in the otherwise solid cylinder, allowing them to be positioned at the cylinder surface ("0 cm") or 5 cm out from the surface. Moths were positioned with their anterior–posterior axes oriented vertically, so that their wing fanning would drive air downwards (Loudon and Koehl, 2000) rather than around the cylinder. The flow chamber was located in a laboratory hood, which generated the air flow and exhausted the pheromone-laden air to the outside. The flow chamber was either centered within the hood opening or positioned against a side to generate different types of flow: symmetrical or asymmetrical (left/right), respectively. These different flows generated pheromone plumes of different shapes (Fig. 2). Cloth mesh covered the front of the flow chamber to slow and smooth the flow. Trials were videotaped by a camera (Sony Digital Handycam DCR-PC101) mounted above the flow chamber.

The cylinder with the array of eight moths was placed in the center of the flow chamber with one male placed directly upwind. Lights were turned on, and the moths were given time to acclimate to the flow (~20 min), because males would wing fan when they were disturbed by movement or changes in lighting. Once most males had ceased fanning, the pheromone was released into the air stream as described below. Any males that were already fanning at the beginning of the trial were not included in the analysis. The response

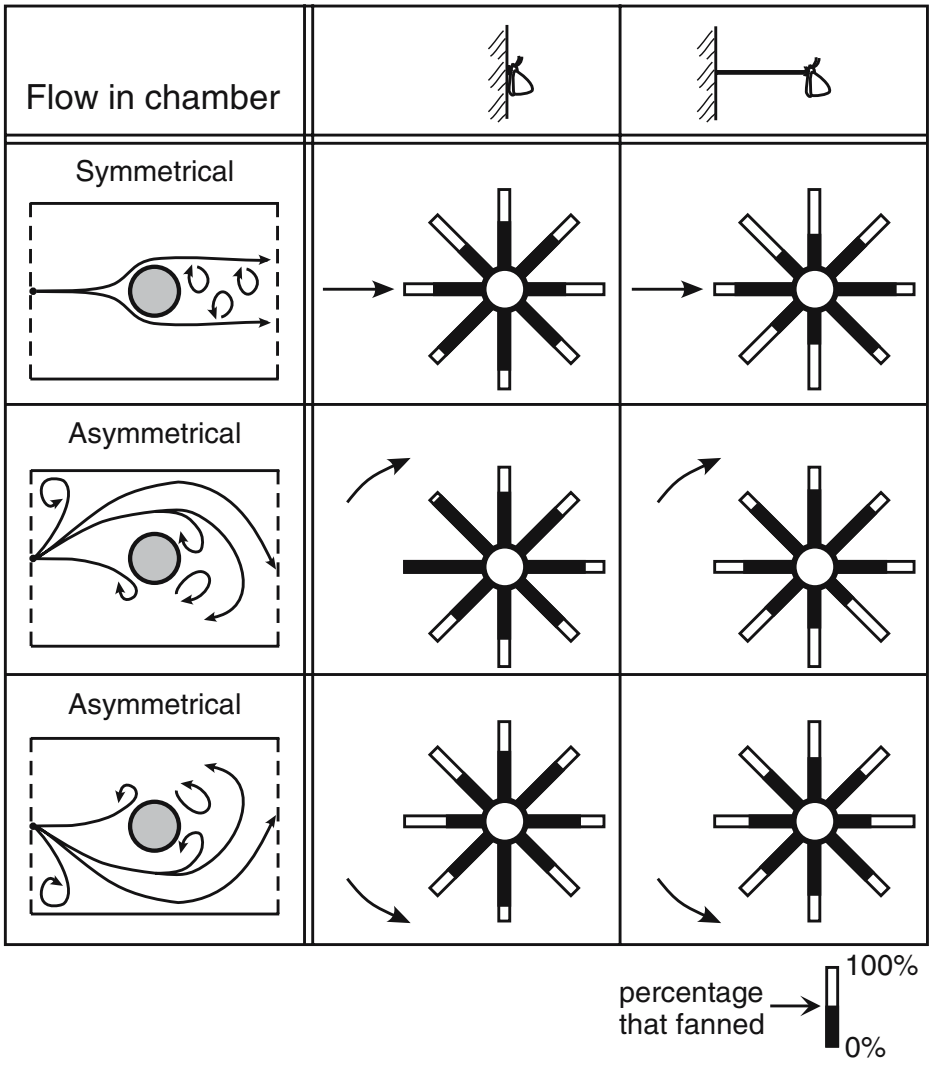

Fig. 2 Male detection of pheromone from all positions around the cylinder. On average, this detection occurred 62% of the time, as indicated by wing fanning, across all flow types and moth positions. The percentage of males that fanned is indicated by the *black fill in the bar*. A *diagrammatic representation* of the flow treatment appears in the left column as viewed from above, with the pheromone plume generated from a point source as shown. The distance of the moth from the surface of the cylinder (0 or 5 cm) is indicated in the *top row*; the moths on supports are shown as viewed from the *side*

times (onset of wing fanning) of the males were recorded for 30 sec starting with the pheromone release. The cylinder was then rotated so that a different male was now in the upwind position (order randomly assigned), the males were given at least 5 min to acclimate to new positions, and the wing fanning response times to the next pheromone plume were recorded. The cylinder was turned repeatedly until each of the eight males had been in each position once (eight rotations). These eight rotations, with eight male responses at each of the eight positions, were considered one "trial." A pool of 51 male moths was used in the 23 trials.

One to three live females visibly extruding their pheromone glands were placed into a 30-ml syringe centered at the upwind edge of the flow chamber (34 cm upwind). The amount of pheromone released by the females was unknown and presumably variable, which was not a concern because the responses at different positions around the cylinder were compared to each other, thus, providing an internal control. To generate a pheromone plume, air was passed through the syringe slowly and joined the air moving through the flow chamber. The air passed through the syringe at a volume flow rate of 9.9 ml/sec for 8 sec time interval; therefore, approximately twice the volume of the syringe was exchanged during the stimulus. The air flow through the syringe was controlled with an aquarium pump, a solenoid valve, and a custom-built timing circuit (Instrumentation Design Laboratory, University of Kansas) and was calibrated by collecting air in an underwater graduated cylinder with the same setup. A light-emitting diode (LED) light (in view of the video camera but not the moths) was illuminated for the 8 sec that air was passing through the syringe, to record the timing of the pheromone release on the videotape. For the controls (N=3 sets of eight males), air was passed through a clean syringe without a female, and the males were observed for 30 sec. The inner surface of the chamber was cleaned daily (wiped with ethanol and air-dried).

Controlled Flow in Chamber We generated slow flows within a flow chamber that contained small, ephemeral eddies to mimic those characteristics of air flow that we would expect in a natural forest (Fig. 2). We generated a symmetrical flow (Fig. 2, top) and asymmetrical flows (Fig. 2, middle and bottom) that contained a large circulating gyre in addition to the flow that separated and moved around both sides of the cylinder. These gyres were either clockwise or counterclockwise when viewed from above, depending on whether the flow chamber was placed against the right or left side of the hood opening, respectively. The large-scale gyration had the effect that the "upwind" area on the cylinder was displaced slightly to one side. Flow visualization by using smoke indicated that small-scale eddies formed and dissipated at a variety of different locations within the chamber at different times leading to a complex and slightly unpredictable flow. The temperature within the chamber ranged between 23 and 24°C.

The flow chamber was illuminated by lamps on both sides; however, lighting was nonuniform due to additional natural lighting from windows. The difference in light levels appeared to change the behavior of the males slightly, with those in brighter lighting fanning more readily. In symmetrical flow, males would be expected to fan at the same time as those opposite them. However, we found that those on the side with brighter lighting fanned earlier than males in dimmer lighting at both 0 and 5 cm from the cylinder (Wilcoxon rank sums; 0 cm, $P_{2\text{-sided}}<0.001$; 5 cm, $P_{2\text{-sided}}=0.003$; time difference was 2 sec or less). To compensate for the difference in speed of fanning as a result of differential lighting, we applied a light correction factor. Adjustments of ±0.5 or 1 sec were applied to each position (except directly upwind or downwind) and distance from the cylinder surface in all flow conditions.

Burning incense sticks were used as a smoke source to visualize air flow patterns and speeds around the cylinder and within the flow chamber. Although incense smoke is not neutrally buoyant, the horizontal component of movement is independent of its upward component. Smoke was illuminated from both sides and filmed from above. Motion analysis software (Motus 8, Vicon/Peak Performance, Englewood, CO, USA) was used to digitize smoke paths across multiple frames of video to determine how long it took smoke to travel from the syringe to the cylinder to the nearest 1/60 of a second. Note that the distance smoke traveled to reach the cylinder is not the same for symmetrical flow as it is

for asymmetrical flow, because in symmetrical flow, smoke traveled directly to the point on the cylinder closest to the syringe. Flow visualization demonstrated that there was no significant difference in the time for smoke to reach analogous points on the left vs. the right sides of the cylinder in symmetrical flow (two-way analysis of variance (ANOVA) with side and position as classes, $N=38$, $P=0.186$ for side comparison).

Flow speeds from the syringe to the cylinder estimated by smoke movements (as described above) are as follows: symmetrical 0.5 m/sec (±0.04 SD, $N=3$), asymmetrical clockwise 0.2 m/sec (±0.04 SD, $N=18$), and asymmetrical counterclockwise 0.3 m/sec (±0.6 SD, $N=18$). Therefore, it took approximately 0.5–2 sec for the pheromone to be carried from the syringe to an upwind moth, depending on the flow. For symmetrical flow, it would take approximately 2 sec for the front of a pheromone patch to leave the syringe, diverge, and be carried completely past the two sides of the cylinder. Pheromone that has passed downwind of the cylinder may be caught up in a recirculating eddy and brought back to the surface more slowly (Fig. 2). For asymmetrical flows, it would take approximately 10–20 sec for a pheromone patch to leave the syringe and swirl completely around the cylinder.

Statistical Analysis Circular statistics were performed in Oriana 2.01b (Kovach Computing Systems; Anglesey, Wales). Other statistical analyses were done by using SAS (version 8.2, Cary, NC, USA).

Results

Natural Wind Conditions and Parcoblatta Positions Male *Parcoblatta* cockroaches of both species were found in approximately equal numbers on the upwind and downwind halves of trees: *P. pennsylvanica* ($N=14$ upwind, $N=13$ downwind) and *P. uhleriana* ($N=19$ upwind and $N=24$ downwind). The distribution around the circumferences of trees with respect to the upwind direction was not different from a uniform distribution for either species (Fig. 3; Rayleigh's uniformity test for circular statistics $P>0.05$). We also tested whether *Parcoblatta* males were positioning themselves on the tree by compass direction; there was no difference from a uniform distribution for either species (Fig. 3; Rayleigh's uniformity test for circular statistics $P>0.05$). Although males from both species were found at a variety of different heights above the ground (range 0.1 to 2.3 m), the species were found at different heights on average, as has been shown earlier (same species,

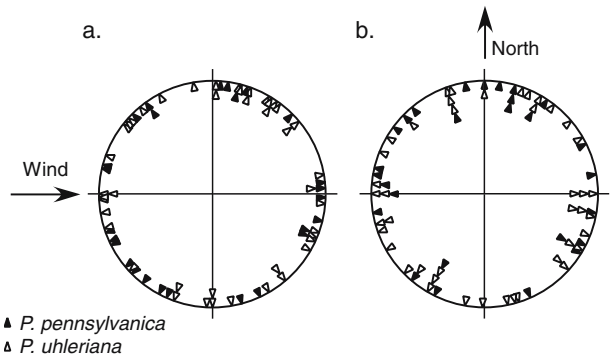

Fig. 3 Distribution of cockroaches of both species around tree circumferences. Each triangle corresponds to the position of an individual adult male. Positions are displayed in two different frames of reference (*a* and *b*). *a* Positions relative to the upwind direction. *b* Positions relative to magnetic north

Gorton, 1980; different species and genera, Schal, 1982). *P. pennsylvanica* males were significantly higher up than *P. uhleriana* males (1.1 vs. 0.6 m averages; one-way *ANOVA*, $P<0.001$ for species).

Variability of Flow Direction at Tree Surfaces for Solitary Trees Variability in wind direction on a time scale of minutes is significantly affected by time of day, with evening wind direction being the least variable (Fig. 4). Note that our evening measurements were made during the courtship time of *Parcoblatta*. The standard deviation (circular) of wind direction of the minute-by-minute measurements over the 10-min intervals in the mornings averaged 17° ($N=4$ sets), in the afternoon, averaged 24° ($N=6$ sets), and in the evening, averaged 10° ($N=6$ sets) (ANOVA of wind variability with time of day, $P<0.01$, $N=16$).

Variability of Flow Direction at Tree Surfaces for Forest Trees Variability in wind direction in the forest was estimated by comparing upwind direction at the surface of trees early in the evening (8–9 P.M.) and later (between 1/2 and 2 1/2 hr later) at the same trees (10 trees at the forest edge and 10 more interior). The upwind direction at these surfaces typically did not change much during an evening: the average difference in upwind direction for individual forest trees was 23° for trees at the edge of the forest ($N=58$; averages of absolute differences) and 31° for the more interior trees ($N=36$; averages of absolute differences).

The variability of upwind direction at the surfaces of trees for a group of 10 trees was not affected by its location (edge vs. within forest) (Wilcoxon sign-rank test, $N=8$ sets of 20 trees, $P>0.05$). However, there was a small but significant difference in upwind direction at the surface of trees depending on whether the tree was at the edge of the forest or more interior: the average difference was 15° (Wilcoxon sign-rank test, $N=8$ sets of 20 trees, $P<0.027$), suggesting that the wind direction is shifted by the resistance of the vegetation as the air passes through the forest.

Wind speed was also affected by tree location (edge vs. within forest). The number of times during which flow was too slow to displace the boa feathers was significantly higher within the forest (wind not detectable in 44% of trials) compared to trees at the forest edge (wind not detectable in 17% of trials) (Wilcoxon sign-rank test, $N=17$ sets of 20 trees, $P<0.005$).

Detection of Pheromone Around a Cylinder in Controlled Flows Within our experimental conditions, sex pheromone was detected by at least some of the male moths, for any flow type, at any position or distance from the cylinder (Fig. 2). Across all trials, an average of 62% of the moths were able to detect pheromone (noted by wing fanning behavior; range

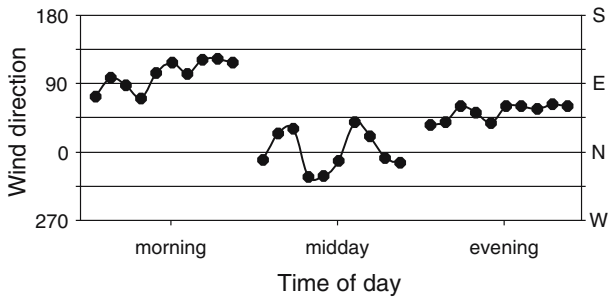

Fig. 4 Variability in upwind direction at a tree surface as a function of time of day. Shown is a representative set of measurements taken every min for 10 successive min at 3 different times during the day (starting at 8 A.M., 12 P.M., and 8 P.M.). Wind striking the tree surface at its northern-most point has a wind direction of "0" (east is 90, south is 180, west is 270)

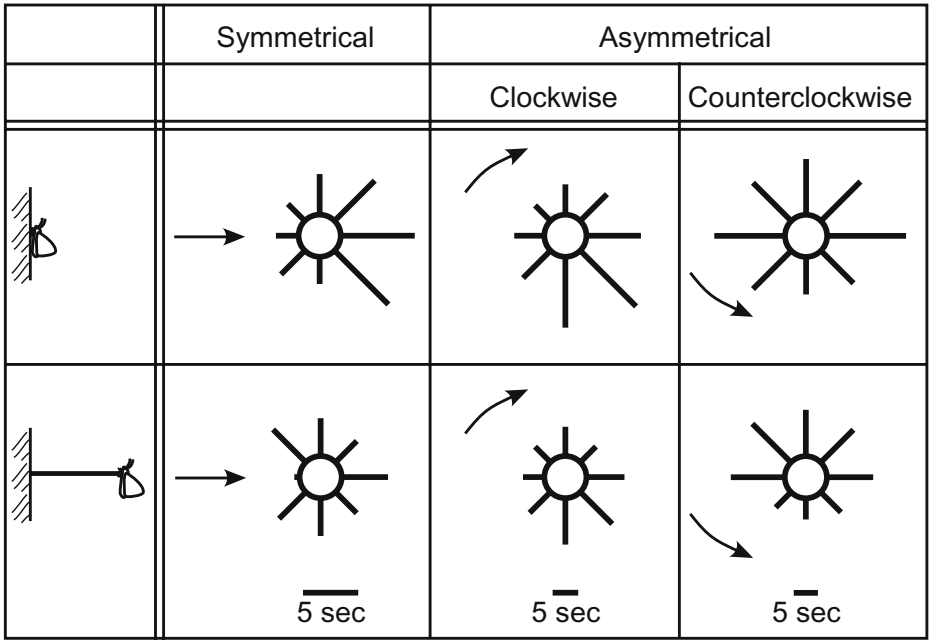

Fig. 5 Male moths at different positions around the cylinder wing at different times. Moths fanned whether the moths were located at the surface (*top row*) or 5 cm from the surface (*bottom row*). The *left column* illustrates the orientation of the moths when viewed from the side. Moths on the upwind areas tended to wing fan before moths on the downwind areas, for all flow types. The *lengths of the lines* represent the median of the wing fan onset times for all moths at that location (during the 30-sec observation period, the light correction factor has been applied as explained in the text; each column is drawn to a different time scale as indicated)

35–100% at any position for any flow/distance from cylinder combination). Male moths at the surface of the cylinder (0 cm) showed a slightly higher tendency to wing fan than males 5 cm from the surface (67 vs. 60%; chi-square $P=0.006$). There was a difference in the probability of pheromone detection at different positions around the cylinder in symmetrical flow for males positioned 5 cm from the cylindrical surface but not for males at the surface (0 cm) (chi-square $P<0.001$ for frequency of wing fanning by position for the symmetrical flow when 5 cm from surface, $P=0.5$ for 0 cm). Position around the cylinder did not affect the probability of pheromone detection in asymmetrical flow (chi-square $P>0.05$ for all four cases).

In almost all cases, males upwind on the cylinder fanned earlier than males downwind. For males in asymmetrical flow at both distances (0 and 5 cm) from the surface and males in symmetrical flow on the surface (0 cm), individuals on the upwind half of the cylinder fanned earlier than those on the downwind half (Mann–Whitney, $P_{Z,\ 2\text{-tailed}}<0.001$; Fig. 5). In symmetrical flow, the narrow pheromone plume closely followed the contour of the cylinder, so for moths 5 cm from the surface, only those directly upwind intercepted the plume as it approached the cylinder, whereas all others experienced a delay as the plume reached them by a combination of eddies and molecular diffusion. These eddies are sufficiently rapid that in this case (symmetrical flow, moths 5 cm from the surface), there was a marginally significant difference in fanning time between the front and back halves of the cylinder with males on the back half fanning slightly earlier on average than males on the front half (Mann–Whitney, $P_{Z,\ 2\text{-tailed}}<0.054$), although males at the single position

most upwind fanned the earliest (Fig. 5). Positions perpendicular to the flow were not included in the analysis for symmetrical flow because they are neither upwind nor downwind.

The median response time for moths in symmetrical flow was the same whether the moths were 0 or 5 cm from the surface (paired *t*-test by position $P=0.554$; Fig. 5). In the more erratic asymmetrical flows, moths positioned 5 cm from the surface responded more rapidly than moths positioned at the surface (paired *t*-test by position $P<0.032$ and $P<0.005$ for clockwise and counterclockwise flows, respectively). Pheromone detection, as denoted by the onset of wing fanning, occurred throughout the 30-sec observation period. No male moths fanned during the three controls. In addition, there was no evidence that a wing fanning male influenced the response of its neighbors by its wing fanning (by changing the probability or timing of their responses), similar to observations on wing fanning in gypsy moths by Elkinton et al. (1984).

Discussion

There are potential advantages of being on the upwind surface of a tree for an organism chemically sampling its environment. An organism there will usually intercept an airborne chemical signal earlier than an organism on the downwind surface, as we have shown here. In addition, an organism on the upwind surface will sample a chemical plume before it has undergone the additional mixing and dilution that usually occurs in the eddies downwind of the object. However, in practice, it may be difficult, if not impossible, for an organism already on the surface to locate the upwind side. Although air strikes the upwind surface, it also strikes the downwind surface as it swirls behind the object (Fig. 2), and therefore, an organism has ambiguous information about the ambient wind direction if it is walking along the surface (Brady et al., 1989, 1990). In contrast, a flying insect approaching a tree could land on either the downwind or the upwind surface, depending on whether it was flying upwind or downwind before landing. The effect of wind direction on landing patterns of flying insects has been investigated by Broce et al. (1991), who found that both stable flies, *Stomoxys calcitrans*, and house flies, *Musca domestica*, were more likely to land on the downwind side of cylinders. Landing in these areas offers increased protection from the wind, and the downwind landing preference was strengthened with increased wind speed (Broce et al., 1991).

We have measured the time delay in pheromone interception experienced by males on the downwind surface of cylinders for a range of slow flow types (Fig. 5). The magnitude of time delay will be a function of the air speed and the size of the tree. For slow air speeds typical of a forest, males on the upwind surface detected pheromone seconds to tens of seconds before the downwind males on the same cylinder. Particularly long delays are a result of the pheromone being returned to the surface after recirculating in an eddy. Whether seconds of difference confer an advantage to an organism on an upwind surface (compared to a downwind surface) may depend on the mating system of that species. For example, for competing organisms tracking a sex pheromone, the first to locate the pheromone-emitting individual could have a mating advantage. In addition, for blood-feeding insects such as tsetse flies, a delay in detection may cause difficulties in locating a host before that host moves away. Note that frequent wind shifting found in some habitats would diminish this prospective small upwind advantage. Willemse and Takken (1994)

have discussed the general difficulty of locating an upwind host by tsetse flies when the wind direction is shifting.

In addition to the velocity differences that exist between the upwind and downwind areas of an object, air moves more slowly next to an object's surface and diminishes to a velocity of zero at the surface (the "no-slip condition"). This slow flow near a surface can impact the behavior of organisms; for example, minute scale insects need to rear up on their hind legs to reach faster air flow farther from a leaf surface to take off in dispersal (Washburn and Washburn, 1984). Because of slowed air adjacent to a tree surface, an insect on a tree could project its antennae out into faster air flow to sample a larger volume of air per unit time and more rapidly detect pheromone. Using *B. mori* as pheromone detectors, we found that moths positioned 5 cm from the surface responded more rapidly on average than moths positioned at the surface, but pheromone was detectable at both of those distances. *Parcoblatta* cockroaches have long antennae (~2–3 cm), whereas *B. mori* moths' antennae are a tenth as long (~2–3 mm). By positioning the *Bombyx* moths both 0 and 5 cm from the surface, we encompassed a range potentially sampled by cockroaches and other forest insects. The flow pattern around a cylinder (Fig. 1) is an approximation for a flow pattern around a fairly cylindrical tree; the flow will also be affected by the roughness of the surface of the tree (e.g., bark texture).

The flow behavior depicted in Fig. 1 (eddies moving downwind or shed vortices) will be relevant for a broad range of tree sizes and wind speeds and can be predicted by the magnitude of a dimensionless number, the Reynolds number, $Re=uL/\nu$ (u=velocity of the air, L=tree diameter, ν=kinematic viscosity of the air; Brady et al., 1989; Vogel, 1994). Eddies that move downwind are predicted for the combination of tree sizes and wind speeds that result in $Re>40$ (Fig. 6), which includes the majority of natural conditions in a forest (Brady et al., 1989). The degree to which this predicted air flow pattern is relevant around trees in a forest depends, in part, on the wind variability. Note that if the wind is shifting direction frequently, the flow pattern will resemble Fig. 1 less closely, and there is less advantage and more difficulty for an organism to position itself upwind.

Our minute-by-minute measurements of wind direction at tree surfaces were significantly less variable in the evening than during the morning and midday (Fig. 4). The circular standard deviation was 10° in the evening, so about 65% of successive minute-by-

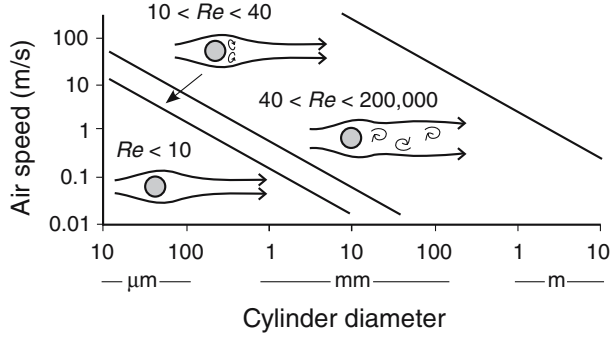

Fig. 6 Air flow patterns around a cylinder as predicted from fluid mechanics. The *air patterns* shown (for air approaching from the left) are expected for a cylinder in cross-flow for a wide range of air speeds and cylinder diameters (Vogel, 1994). The air flow conditions in this study were within the large interval represented by Reynolds numbers (Re) in the range $40<Re<200{,}000$, within which downwind eddies are expected. The kinematic viscosity of air is assumed to be 15×10^{-6} m^2/sec in the calculation of Re. See text for the equation to calculate Re. (Figure modified from Fig. 21.4 in Loudon, 2003)

minute measurements of upwind direction are within 10° (normal distribution approximation). Upwind direction measured at tree surfaces in the forest over longer intervals (at least 1/2 hr) during evenings differed only by an average of 26° (between the earlier and later measurements). Under these conditions, a stationary individual on the upwind half of a tree is likely to remain there for at least several minutes. Because of the lower variability in wind direction during evening hours, evening is the most advantageous time for pheromone-detecting individuals to position themselves on the upwind surfaces of trees, but this was not observed in the field for *Parcoblatta* males.

It is difficult to make direct comparisons of wind variability with other studies because the reported variability in wind direction will be strongly influenced by the sampling frequency (Brady et al., 1989) and whether the direction is measured against a tree surface or in the space between trees. However, the wind variability that we documented is similar to that reported by Elkinton et al. (1987) between trees in a coniferous forest, and much less than reported by Brady et al. (1989) adjacent to tree surfaces in a "mopane" woodland. Wind speed also has been reported to be slower and less variable in the evening than in morning or midday (Zöllner et al., 2004).

Our results indicate that pheromone interception occurs from all locations around a cylindrical object such as a tree, which may partially explain the even distribution of *Parcoblatta* males around trees during courtship periods, despite the relatively consistent upwind direction. It is unknown whether a detection advantage of seconds would affect the mating success of a *Parcoblatta* male. It is also possible that not all observed males were actively courting and that individuals on upwind and downwind surfaces were engaged in different activities (e.g., tracking females vs. resting), as is assumed for tsetse flies selecting upwind and downwind resting sites (Brady et al., 1989). The population density is sufficiently low that the observed distribution of cockroaches is unlikely to result from avoidance; usually only one cockroach was seen on a single tree, although two or three were found on occasion, and many trees had none.

The presence of neighboring trees is expected to impact the flow around a tree, in both magnitude and direction (Smith et al., 1972). The physical influence of trees on downwind flow has been considered for the orientation of diurnal forest insects, and in some cases, is more important than the visual stimulus provided by the tree (Wyatt et al., 1993, 1997; Foster and Ayers, 1995). We found that the magnitude of the wind speed was lower within the forest than at its edge. As a result of the slow wind speed in a forest, the flow pattern will be controlled largely by the spatial pattern of tree trunks, branches, and leaves, instead of by large-scale atmospheric processes (Smith et al., 1972). For example, air may move more rapidly through a natural channel offering less resistance to the wind than within adjacent denser areas of the forest. A difference in air flow speeds between channels and denser areas may induce slow areas of circulation and weak ephemeral eddies that we attempted to mimic in our experimental flow chamber ("asymmetrical" flows; Fig. 2 middle and bottom). Even in these complex asymmetrical flows, we found earlier wing fanning response times for individuals positioned on the upwind halves of the cylinders.

The use of wing fanning to infer pheromone detection has been an influential and useful technique for understanding the behavior of pheromone plumes traveling through the environment (Elkinton et al., 1984; Sanders, 1986; Charlton and Cardé 1990). The use of wing fanning as a proxy for pheromone interception requires appropriate experimental design to control for other factors that influence fanning. We observed that wing fanning may be initiated by environmental stimuli in addition to the presence of sex pheromone, such as a sudden increase in light intensity or air movement, so we avoided supplying such stimuli as much as possible. No males wing fanned during the controls. In addition, the

small light gradient in our experimental flow chamber resulted in a small but consistent difference in fanning response; we corrected for this difference as described above, and used both clockwise and counterclockwise gyres for our asymmetrical flow patterns (Fig. 2). Wing fanning may be affected by other factors, such as temperature (Elkinton et al., 1984).

The microhabitat selected by an organism will influence both the type and amount of information available to that organism because the characteristics of the environment will affect stimulus transmission (Dusenbery, 1992). Transmission of a chemical stimulus will be particularly dependent on air flow (or water flow for aquatic organisms) in the microhabitat (Atema, 1988; Murlis et al., 1992; Koehl, 2006). Organisms at different locations around the surface of an object will experience differences in flow, with upwind organisms usually intercepting a chemical signal earlier. Although the potential advantages of earlier interception from an upwind surface do not appear to be utilized by male *Parcoblatta* wood cockroaches in a forest, we have demonstrated that pheromone detection can occur at any position around a cylindrical object in a flow chamber, which could explain the even distribution of *Parcoblatta* males around trees.

Acknowledgments Custom-built solenoid valve controller for pheromone delivery was built by the Instrumentation Design Laboratory, University of Kansas. Grant support was provided to CL by the National Science Foundation IBN 9984475 and EPS-0236913 with matching support from the State of Kansas through Kansas Technology Enterprise Corporation. Support was provided to SF through NSF REU grant DBI-0353911 and to GLM through the KSR Small Grant program from the Kansas Biological Survey and the Entomology program at the University of Kansas. Derek Kellogg, Chelsea Johnson, and Eric Siegfried assisted with field observations, and Norm Slade with statistical analyses. The manuscript was improved by insightful comments from Derek Kellogg and two anonymous reviewers.

Abstract The sex pheromone of *Lonomia obliqua* Walker (Lepidoptera: Saturniidae) was studied in the laboratory. All female calling occurred during the scotophase. Most females (70.6%) called first within 24 hr of eclosion. Calling varied with age of female, with older (5- to 6-day-old) females calling earlier in the scotophase and for longer durations than younger (0- to 1-day-old) females. The sex pheromone gland of 1- to 3-day-old virgin females was extracted during the calling peak. A Y-olfactometer bioassay showed significant attraction of males to a filter paper containing the female gland extract. Gas chromatographic-electroantennogram detection (GC-EAD) analysis of the extract indicated the presence of at least two possible pheromone components. Gas chromatographic-mass spectrometric analysis of the major GC-EAD-active peak indicated a hexadecenyl acetate; chemical derivatization indicated $\Delta 11$ unsaturation. Synthetic samples of (*E*)- and (*Z*)-11-hexadecenyl acetate were obtained by coupling 10-bromo-1-decanol and 1-hexyne, utilizing lithium chemistry. The comparison of the retention time of dimethyl disulfide derivatives of the natural compound, to those of synthetic chemicals, confirmed the natural compound as (*E*)-11-hexadecenyl acetate. The minor component was identified as the related alcohol, (*E*)-11-hexadecenol. The ratio of the two components in female extract was 100:35. Preliminary tests of males in a Y-olfactometer showed that their response to a mixture of the two compounds was not significantly different from that to gland extract.

Introduction

Lonomia obliqua Walker (Lepidoptera: Saturniidae) is one of the most important urban insects in Brazil due to the urticating spines on the larva. Contact with the toxin present in the spines can cause burns, bleeding, and, in worst cases, acute renal failure, hemorrhagic disorder, and death (Duarte et al., 1990). In Brazil, the distribution of the insect is concentrated in the southern states. Aspects of the biology and morphology of *L. obliqua* have been reported (Lorini, 1999, 2004; Lorini and Corseuil, 2001).

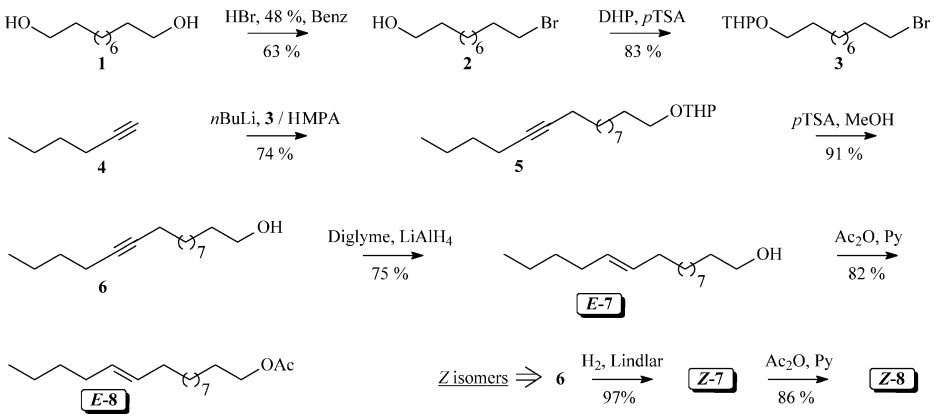
Compared to some families of Lepidoptera, there are relatively few studies on the identification of sex pheromones of Saturniidae. The sex pheromones of *Antheraea polyphemus* (Kochansky et al., 1975), *Nudaurelia cytherea* (Henderson et al., 1973), *Antheraea pernyi* and *Samia cynthia ricini* (Bestmann et al., 1989), and some species in the genera *Hemileuca* and *Saturnia* (McElfresh and Millar, 1999a,b,c; McElfresh et al., 2001a, b) are known.

The aim of the present study was to determine the effect of age on the calling behavior of *L. obliqua* females and to identify the sex pheromone of the species. Additionally, the behavioral responses of males to gland extract and to a blend of synthetic chemicals were also evaluated.

Methods and Materials

Insect Rearing Adults used in the experiments were obtained from caterpillars collected in the field in the northern region of the state of Rio Grande do Sul, Brazil. Insects were maintained in a controlled-environment room, with a mean temperature of 25±0.5°C, RH 65±15%, and a 13:11 (L to D) photoperiod. Larvae were allowed to feed on the leaves of *Platanus acerifolia* until pupation. Pupae were transferred into plastic containers (8×3 cm) lined with filter paper and maintained in an environmental chamber under the same conditions as for the larvae. The filter papers in the pupal containers were moistened daily. At the beginning of each scotophase, adults were collected and sexed according to the method of Lorini (1999).

Calling Behavior of Females After emergence, virgin females were transferred to a room at the same conditions as used for pupae. Females were placed in individual cages made of plastic tubes (PVC), measuring 15×10 cm, sealed on one side with transparent glass and on the other with nylon net. They were observed during the scotophase of each day until death. A tungsten lamp, covered with three layers of red cellophane paper and positioned approximately 80 cm from the cage, was used during observations of behavior. To determine the effect of age on calling, 65 virgin females were observed from the first to the sixth day after emergence, at 10-min intervals during each scotophase. From these observations, we obtained information about the time of onset of calling, the time spent calling, and the number of calling bouts.



Extraction of Sex Pheromone from Glands Light pressure was applied to the terminal part of the abdomen of a female to expose the last abdominal segments on which the sex pheromone gland is located. The gland was dissected and extracted for 30 min in a 2-ml glass vial containing 0.5 ml of hexane. The extract was transferred to a clean vial, concentrated under a flow of argon, and stored at −20°C until use.

Analytical Procedures Coupled gas chromatographic-electroantenographic detector (GC-EAD) analysis was performed on male antennae with a system based on that of Leal et al. (1992, 1994). A Varian 3800 gas chromatograph, equipped with a DB-5 column (30 m× 0.25 mm×0.25 μm; Agilent Technologies, Santa Clara, CA, USA) and a splitless injector, was used in these analyses. The oven was programmed from 70°C (1 min hold) to 250°C at 7°C/min and kept at this temperature for 5 min. Gas chromatography-mass spectrometry (GC-MS) analyses were performed with a Varian 3800–Saturn 2000 GC-MS-MS ion trap detector, fitted with a DB-5 capillary column, under the same conditions as described above.

Synthesis High-grade reagents and solvents were used in the syntheses. Chromatographic purifications were carried out on silica gel 60, Merck, 230–400 mesh. Dimethyl disulfide (DMDS) derivatization was carried out according to the method of Vincenti et al. (1987). ^{1}H and ^{13}C NMR spectra were recorded on a Bruker DRX-400 (400 and 100 MHz, respectively).

The starting material, 1,10-decanediol (**1**), was subjected to monobromination to yield 10-bromodecan-1-ol (**2**), which was subsequently protected with DHP to give ether **3**. The anion generated with *n*-BuLi from 1-hexyne (**4**) was alkylated with bromide **3**, affording compound **5**, which was directly deprotected to yield alcohol **6**, the direct precursor of the pheromones, because it possesses a triple bond at C-11 and functionality at C-1. The isomer (*E*)-11-hexadecenol (**7**) was obtained by reacting alcohol **6** with $LiAlH_4$, under reflux of diglyme, while the isomer (*Z*)-11-hexadecenol (**7**) was prepared by catalytic hydrogenation of the same compound **6**. The ^{1}H NMR analysis of the vinyl protons of the resulting compounds indicated an isomeric purity >97%. The isomers (*E*)- and (*Z*)-11-hexadecenyl acetate (**8**) were obtained by acetic anhydride acetylation of the corresponding alcohols (*E*)-**7** and (*Z*)-**7**, respectively (Scheme 1).

10-Bromodecan-1-ol (2) To a stirred solution of 1,10-decanediol (**1**) (5.2 g; 30.4 mmol) in benzene (100 ml), 48% aqueous HBr (5.0 ml) was added at room temperature. The reaction was refluxed for 24 hr, trapping water with a Dean-Stark apparatus. The mixture was successively washed with 1 M NaOH, 10% HCl, and brine. The organic layer was separated, dried over anhydrous Na_2SO_4, and concentrated *in vacuo*. The crude oil obtained

Scheme 1 Synthesis of the components of the sex pheromone of *L. obliqua* and their (*Z*)-isomers

was distilled to give compound **2** in 63% yield (4.4 g). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.28–1.46 (m, 12H); 1.56 (quint, J=6.8 Hz, 2H); 1.65 (bs, 1H); 1.85 (quint, J=6.8 Hz, 2H); 3.41 (t, J=6.8 Hz, 2H); 3.63 (t, J=6.8 Hz, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 25.72, 28.15, 28.74, 29.37 (2C), 29.47, 32.75, 32.81, 34.00, 62.98. GC-MS *m/z* (%): 220/218 (M-18, 0.14), 190/192 (7.7), 162/164 (10.8), 148/150 (54), 97 (39.8), 83 (53.4), 69 (93.4), 55 (96.6), 43 (43.7), 41 (100).

1-(Tetrahydro-2'-pyranyloxy)-10-bromodecane (3) To a stirred solution of **2** (3.5 g; 15.25 mmol) in dry THF (15 ml), some crystals of *p*TSA and dihydropyran (1.65 ml; 18 mmol) were added. The reaction was stirred at room temperature for 4 hr and then washed with brine. The organic layer was separated, dried over anhydrous Na_2SO_4, and concentrated *in vacuo*. Crude product **3** (83%, 3.9 g) was employed in the next step without further purification. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.28–1.46 (m, 12H); 1.50–1.62 (m, 6H); 1.68–1.75 (m, 1H); 1.81–1.89 (m, 3H); 3.35–3.42 (m, 1H); 3.43 (t, J=6.8 Hz, 2H); 3.48–3.53 (m, 1H); 3.73 (dt, J=6.8 and 9.6 Hz, 1H); 3.84–3.90 (m, 1H); 4.56-4.58 (m, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 19.72, 25.52, 26.22, 28.17, 28.75, 29.37, 29.43 (2C), 29.75, 30.80, 32.83, 34.02, 62.35, 67.66, 98.85. GC-MS *m/z* (%): 320/322 (M, 0.38), 109 (0.9), 101 (8.61), 85 (100), 69 (8.40), 55 (16.5), 41 (23.1).

1-(Tetrahydro-2'-pyranyloxy)-11-hexadecyne (5) To a stirred solution of 1-hexyne (**4**) (2.34 ml; 20.2 mmol) in dry THF (10 ml), under argon, *n*-BuLi (6.0 ml, 2.0 M in hexane) was added dropwise at −78°C. The solution was slowly warmed to 0°C and stirred at this temperature for 40 min. The reaction was cooled again to −78°C, and compound **3** (3.0 g, 10 mmol) in dry HMPA (2.0 ml) was added and left for 1 hr. The mixture was warmed to 0°C and stirred for 50 min. The reaction was extracted with ethyl ether and washed with brine. The organic layer was separated, dried (Na_2SO_4), and concentrated *in vacuo*. The crude product was purified by column chromatography (silica gel, hexane to ethyl acetate 9:1), affording **4** in 74% yield (2.2 g). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.91 (t, J=6.8 Hz, 3H); 1.45–1.52 (m, 24H); 1.53–1.58 (m, 2H); 2.11–2.16 (m, 4H); 3.35–3.41 (m, 1H); 3.47–3.53 (m, 1H); 3.73 (dt, J=6.8 and 9.6 Hz, 1H); 3.84–3.90 (m, 1H); 4.56–4.58 (m, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.65, 18.46, 18.77, 19.72, 21.95, 25.54, 26.27, 28.87, 29.19 (2C), 29.51 (2C), 29.57, 29.78, 30.81, 31.30, 62.32, 67.69, 80.19 (2C), 98.83. GC-MS *m/z* (%): 322 (M, 0.44), 280 (0.33), 265 (1.26), 207 (1.1), 165 (1.84), 121 (4.07), 101 (27.9), 85 (100), 81 (35.4), 67 (41.2), 55 (48.7), 41 (71.1).

11-Hexadecyn-1-ol (6) To a stirred solution of **5** (2.0 g, 6.2 mmol) in MeOH (10 ml), some crystals of *p*TSA were added. The mixture was stirred at room temperature for 4 hr. Methanol was removed, and the residue was diluted in ethyl ether and washed with saturated solutions of $NaHCO_3$ and brine. The organic layer was separated, dried over anhydrous Na_2SO_4, and concentrated *in vacuo*. Crude product **6** (91%, 1.34 g) was employed in the next step without further purification. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.90 (t, J=6.8 Hz, 3H); 1.25–1.51 (m, 21H); 2.12–2.16 (m, 4H); 3.63 (t, J=6.8, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.64, 18.46, 18.77, 21.94, 25.76, 28.86, 29.18 (2C), 29.44, 29.48, 29.57, 31.29, 32.82, 63.05, 80.19 (2C). GC-MS *m/z* (%): 164 (1.48), 149 (2.06), 135 (4.23), 121 (10.1), 110 (19.4), 96 (88.6), 81 (100), 67 (76.8), 55 (69.7), 41 (99).

(E)-11-Hexadecen-1-ol (7) A solution of compound **6** (1.5 g, 6.30 mmol) in diglyme (10 ml) was added dropwise to a suspension of $LiAlH_4$ (0.23 g, 6.30 mmol) in diglyme (10 ml) at room temperature. The resulting mixture was stirred at 130°C, under argon, for

5 hr. The reaction was quenched by the addition of aqueous NaOH, 0.1 mol/l (10 ml), followed by the addition of ether (50 ml). The organic layer was separated, dried over anhydrous Na_2SO_4, and concentrated *in vacuo*. The crude product was purified by column chromatography (silica gel, hexane to ethyl acetate 9:1), affording (*E*)-**7** in 75% yield (1.1 g). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.88 (t, J=6.8 Hz, 3H); 1.25–1.40 (m, 19H); 1.53–1.61 (m, 2H); 1.94–1.99 (m, 4H); 3.65 (t, J=6.8, 2H); 5.37–5.40 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.97, 22.20, 25.75, 29.16, 29.44, 29.50, 29.56 (2C), 29.60, 29.66, 31.85, 32.29, 32.61, 32.83, 63.11, 130.32 (2C). GC-MS *m/z* (%): 240 (M, 0.09), 222 (5.23), 194 (1.87), 180 (0.92), 152 (3.0), 138 (7.23), 123 (14.0), 109 (24.4), 96 (64.5), 82 (92.3), 67 (55.4), 55 (100), 41 (75.0).

(Z)-11-Hexadecen-1-ol (7) To a stirred solution of **6** (0.5 g, 2.1 mmol) in MeOH (5 ml), 5% $Pd/BaSO_4$ (20 mg) and quinoline (two drops) were added. The mixture was stirred under hydrogen atmosphere (25 psi) in a Parr® apparatus for 4 hr and filtered on Celite®. The solvent was evaporated *in vacuo*, and the residue was extracted with ether and washed with 10% HCl, water, and brine. The organic layer was separated, dried over anhydrous Na_2SO_4, and concentrated *in vacuo*. The product was purified by column chromatography (silica gel, hexane to ethyl acetate 9:1), affording (*Z*)-**7** in 97% yield (0.48 g). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.90 (t, J=6.8 Hz, 3H); 1.24–1.39 (m, 19H); 1.53–1.60 (m, 2H); 1.97–2.04 (m, 4H); 3.64 (t, J=6.8, 2H); 5.33–5.36 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.97, 22.20, 25.75, 29.16, 29.44, 29.50,29.56 (2C), 29.60, 29.66, 31.85, 32.29, 32.61, 32.83, 63.11, 130.32 (2C). The MS data are the same as described for the (*E*)-isomer **7**. The retention times of compounds (*Z*)- and (*E*)-**7** were identical to that of the minor component of the natural pheromone.

(E)-11-Hexadecenyl acetate (8) To a stirred solution of pyridine (0.5 ml) and compound (*E*)-**7** (0.5 g, 2.1 mmol), acetic anhydride (0.4 ml, 4.0 mmol) was added, and the resulting mixture was stirred overnight at room temperature. The reaction was diluted in ethyl ether (20 ml) and washed with saturated $NaHCO_3$ solution, 10% HCl, and brine. The organic layer was separated, dried over anhydrous Na_2SO_4, and concentrated *in vacuo*. The product was purified by column chromatography (silica gel, hexane to ethyl acetate 9:1), affording (*E*)-**8** in 82% yield (0.47 g). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.89 (t, J=6.8 Hz, 3H); 1.22–1.40 (m, 18H); 1.55–1.65 (m, 2H); 1.96–2.02 (m, 4H); 2.05 (s, 3H); 4.05 (t, J=6.8, 2H); 5.37–5.40 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 21.02, 22.20, 25.93, 28.62, 29.15, 29.27, 29.50 (2C), 29.52 (2C), 29.66, 31.85, 32.29, 32.61, 64.67, 130.33 (2C), 171.22. GC-MS *m/z* (%): 282 (M, 0.09), 222 (15.2), 194 (2.90), 180 (1.82), 166 (5.30), 152 (5.44), 138 (13.45), 124 (23.8), 110 (33.7), 96 (82.9), 82 (100), 67 (56.4), 55 (78.8), 43 (81.8), 41 (61.2).

(Z)-11-Hexadecenyl acetate (8) In the same manner as for the (*E*)-isomer, the alcohol (*Z*)-**7** (0.2 g, 0.83 mmol) afforded the acetate (*Z*)-**8** in 86% yield (0.2 g). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.90 (t, J=6.8 Hz, 3H); 1.25–1.38 (m, 18H); 1.58–1.65 (m, 2H); 1.98–2.03 (m, 4H); 2.05 (s, 3H); 4.05 (t, J=6.8, 2H); 5.33–5.36 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.00, 21.02, 22.36, 25.92, 26.93, 27.20, 28.61, 29.28 (2C), 29.52 (3C), 29.77, 31.98, 64.67, 129.87 (2C), 171.24. The MS data are the same as described for (*E*)-**8**. The retention times of compounds (*Z*)- and (*E*)-**8** were identical to that of the major component of the natural pheromone.

Olfactometer Tests The behavior of males in the presence of the natural female pheromone was observed in a Y-olfactometer. In the first test, a glass olfactometer, with arms 10×

40 cm, was used. The bioassay was conducted during the scotophase at 25±1.0°C and 65±15% RH. The airflow, produced by a vacuum pump, was 2.5 l/min. A piece of filter paper, 2 cm^2, loaded with 5 μl (one female equivalent) of female gland extract, was placed at the extremity of one arm, and a filter paper with solvent applied (and left to evaporate) was placed in the other arm as a control. A virgin male was placed in the olfactometer, and which of the two arms he moved into was recorded; if he did not move into either arm, he was recorded as a nonresponder. Twelve replicates were performed. For the second test, 0.1 μg of a 1:0.35 mixture (on filter paper) of synthetic (*E*)-11-hexadecenyl acetate:(*E*)-11-hexadecenol was tested against a solvent blank. In the third test, the same synthetic blend as in the second test was tested against one female equivalent of extract. Ten replicates (each a single male) were performed for the last two tests.

Statistical Analyses Comparisons of the calling behavior on different days were made by ANOVA, followed by a Tukey highest significant difference test (Statistica and Stat Soft, Inc., 1999). The olfactometer responses were analyzed by using the R Statistical System (R Development Core Team, 2005). The choice experiment (gland extract vs. hexane) was tested with a GLM for Quasibinomial data using the logit link function (Crawley, 2005). Proportions were calculated by dividing the numbers of insects that chose a particular arm by the total insects tested. The analysis was carried out as follows. A full model was fitted, and significance was assessed by testing the change in deviance after the removal of a term from the model. After fitting the full model, the data were examined for overdispersion by dividing the residual deviance by the residual degrees of freedom to give the dispersion parameter; relatively large values of residual deviance suggest overdispersion and risk potential overestimation of the significance level (Crawley, 2002). To account for this, the residual deviance was rescaled by the dispersion parameter, and an *F* test was used to evaluate whether the removal of a term caused a significant increase in deviance. In addition, model fit was checked by examining the distribution of residuals. The validity of each analysis was verified with residuals analysis (Crawley, 2005). All significant differences are reported at $P<0.05$.

Results and Discussion

Virgin *L. obliqua* females exhibited calling behavior only during the scotophase. The behavior consisted of a female positioning with the wings totally opened, showing the end part of the abdomen, and exposing the ovipositor and pheromone gland. This compares to the work by Fornés and Hernández (2000) on *Hylesia metabus* (Lepidoptera: Saturniidae), who showed that females are active during crepuscular–nocturnal hours but not active during the photophase.

The mean age of females calling for the first time was 13.9±12.6 hr after emergence, with the range being 1.2–51.5 hr. The percentage of females that first called on the first day after emergence was 70.6%, on the second day, 27.8%, and on the third day, 1.6%. Among the females, 92.3% were observed to call once a day, 6.2% twice a day, and only 1.6% three times during the same day. Because not all female callings happened at the same chronological age, comparisons were made by "calling age" (Turgeon and McNeil, 1982).

Age-related data for onset and duration of calling are reported in Table 1. In general, females began calling earlier in the scotophase as they aged, with the mean onset of calling being significantly different between 1-day-old and 5- and 6-day-old females. Furthermore, older females tended to call for a longer duration than younger females. These age-related

Table 1 Mean onset time (hours into the scotophase) and mean time spent calling during the scotophase for different-age virgin females of *L. obliqua* (±SEM), (*N*=65)

Days	Mean Onset Time of Calling[1]	Time Spent Calling (hr)
1	6.0±0.2 a	3.20±0.21
2	5.35±0.2 ab	3.81±0.27
3	5.2±0.2 ab	4.26±0.30
4	5.25±0.2 ab	4.00±0.35
5	4.85±0.4 b	4.17±0.50
6	4.84±0.4 b	4.37±0.51

[1] Means in the column followed by the same letter are not significantly different (Tukey HSD test, $P<0.05$).

effects on calling probably ensure that older, unmated females will mate by attracting males earlier in the scotophase than younger females are capable of doing (Swier et al., 1977).

Sex pheromone glands from virgin females, 1- to 3-day-old, were extracted at peak calling (sixth–seventh hour into scotophase), and the extracts were tested in the olfactometer. A significantly greater percentage ($F_{1,10}=5.82$, $P=0.016$) of males were attracted to the arm containing the pheromone extract than to the control arm (Fig. 1). Responses of males in the olfactometer were similar to those observed for *Phyllocnistis citrella* (Gracillariidae) (Parra et al., 2002; Parra-Pedrazzoli et al., 2006) and suggested that the gland extracts elicit sexual attraction of males.

GC-EAD analysis of extract by using male antennae showed antennal responses to two components present in the gland extract (Fig. 2). The major EAD-active peak was at 25.31 min, whereas the minor one was at 23.51 min. The flame ionization detector showed the two compounds to be present in the extract at a ratio of 100:35. GC-MS analysis of the major EAD-active peak gave identifying features for a monounsaturated C16-acetate: a strong peak at *m/z* 43 and a peak at *m/z* 222, resulting from loss of acetic acid from the molecular ion *m/z* 282 (confirmed by chemical ionization measurement). The minor constituent was presumed to be the related alcohol because the mass spectrum showed a *m/z* of 222, suggesting loss of water from the molecular ion. The molecular weight was confirmed as 240 by chemical ionization.

Double-bond positions in the two components of the *L. obliqua* pheromone extract were determined by reaction with DMDS. GC-MS analysis of the resulting mixture showed the

presence of the DMDS adduct of a Δ11-hexadecenyl acetate [*m/z* 376 (M^+) and major fragments at *m/z* 259 and 117] and of a Δ11-hexadecenol [*m/z* 334 (M+), *m/z* 217, and *m/z* 117] (Fig. 3).

To determine the geometry of the double bond of the compounds and to provide samples for laboratory and future field bioassays, we carried out a six-step synthesis of (*E*)- and (*Z*)-

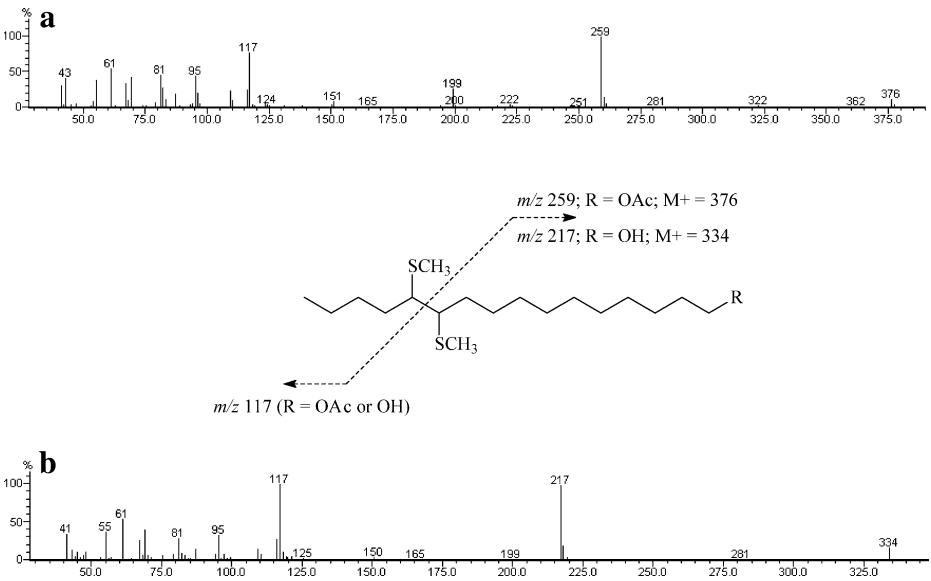

Fig. 3 Mass spectra of derivatives obtained by DMDS reaction with the two components of the pheromone gland extract of *L. obliqua*. The major product (A) and the minor (B) gave a fragmentation pattern that confirmed the location of the double bond at position 11

isomers of 11-hexadecenyl acetate (**8**) and 11-hexadecen-1-ol (**7**) based on the work of Kang and Park (1988) (see Scheme 1).

The mass spectra of synthetic alcohols **7** and acetates **8** were indistinguishable from those of the minor and major components of the natural pheromone, respectively. However, retention time data alone did not establish the geometry of the double bond because the isomers were poorly resolved on the DB-5 column. Therefore, all the synthetic isomers of **7** and **8** were converted to DMDS adducts, and the retention times of the synthetic adducts compared with those of the DMDS adducts of compounds in the pheromone extract. The addition of DMDS to double bonds for monounsaturated compounds is a stereospecific process, with the (*Z*)-isomer affording the *threo*-adduct and the (*E*)-isomer giving the *erythro*-adduct (Caserio et al., 1985). Even though adducts of regio-isomers show nearly identical EI-mass spectra, they typically have different retention times on capillary gas chromatography (Attygalle, 1998).

Almost baseline separation of (*Z*)- and (*E*)-11-hexadecenyl acetate–DMDS derivatives (34.7 and 35.1 min) was achieved by using the DB-5 column. The corresponding DMDS derivative in the pheromone extract had the same retention time as the (*E*)-isomer. DMDS adducts of (*Z*)- and (*E*)-hexadecenol were also easily resolved (32.4 and 32.8 min, respectively). The corresponding adduct in the pheromone extract had the same retention time as that of the (*E*)-isomer (Fig. 4). Based on these results, the two compounds were identified as (*E*)-11-hexadecenyl acetate (major component) and (*E*)-11-hexadecenol (minor component).

In the preliminary olfactometer trial that tested the synthetic blend of the two compounds versus a solvent blank, 60% of the males moved into the arm with the synthetic blend, whereas only 10% moved into the solvent blank arm (the remainder were nonresponders). A further preliminary olfactometer trial that tested the synthetic blend against female extract showed that 40% of the males moved into the arm with the synthetic blend and 30% into the arm with the extract. Although preliminary in nature, these experiments suggest that the two-component synthetic blend does attract male *L. obliqua*. Together, our data indicate that a mixture of (*E*)-11-hexadecenyl acetate and (*E*)-11-hexadecenol forms the sex pheromone of *L. obliqua*. This is the first report of these compounds as sex pheromone components of a saturniid moth.

In summary, we have described the periodicity of the calling behavior of *L. obliqua* females and identified their sex pheromone. Field experiments are now in progress, which aim to try to develop a program to monitor populations and prevent problems caused by this pest.

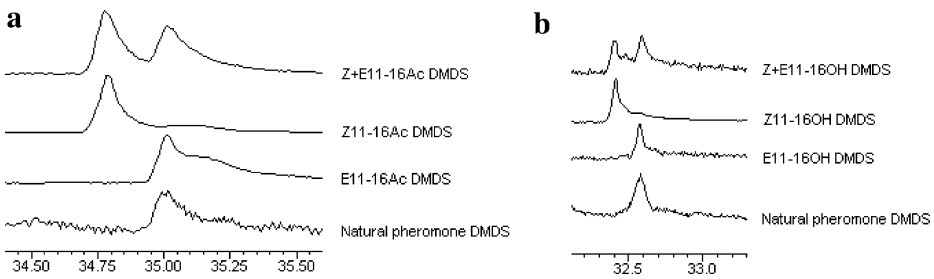

Fig. 4 Determination of the double-bond geometry of (A) 11-hexadecenyl acetate (Z+E11-16Ac) and (B) 11-hexadecenol (Z+E11-16OH) of the two sex pheromone components of *L. obliqua* using DMDS derivatization

Abstract Semifield experiments were conducted to study the oviposition of gravid *Culex quinquefasciatus* females in response to one or 10 egg rafts, or 3.0 μg of synthetic oviposition pheromone, (-)-(*5R,6S*)-6-acetoxy-5-hexadecanolide, a dose equivalent to 10 egg rafts. These treatments were added to the small bowls filled with either hay infusion or water in a small (0.3-m spacing) or a large-square design (3.4-m spacing). Oviposition choice was more pronounced in the "small square" assays. Mean number of egg rafts laid in response to a single egg raft in an oviposition jar filled with hay infusion was significantly greater than with all other treatments. When the oviposition pheromone dose was increased from one to 10 rafts or when 3.0 μg synthetic oviposition pheromone were dispensed on a floating receptacle, synergistic effects were observed between the oviposition pheromone and the hay infusion at both distances. This study is the first demonstration that the amount in a single raft induces oviposition of gravid *Cx. quinquefasciatus* females under semi-natural conditions.

with the egg rafts can influence the propensity of gravid female *Culex* mosquitoes to oviposit (for review, see McCall, 2002). After the original experiments with natural egg rafts (Osgood, 1971; Osgood and Kempster, 1971; Bruno and Laurence, 1979), the pheromone was identified as (-)-(*5R,6S*)-6-acetoxy-5-hexadecanolide (Laurence and Pickett, 1982). Several synthesis routes have been developed, usually resulting in a mixture of two (Laurence and Pickett, 1982) or four stereoisomers (Dawson et al., 1990; Olagbemiro et al., 1999; Michaelakis et al., 2005).

The egg aggregation activity of the synthetic pheromone has been confirmed in laboratory assays (Laurence and Pickett, 1982, 1985; Laurence et al., 1985; Hwang et al., 1987; Otieno et al., 1988a; Dawson et al., 1990; Mordue et al., 1992; Blackwell et al., 1993; Millar et al., 1994; Olagbemiro et al., 2004) and in field trials (Otieno et al., 1988b; Mboera et al., 2000a,b; Olagbemiro et al., 2004). The antipode does not induce *Culex quinquefasciatus* (Say) oviposition (Laurence and Pickett, 1985; Hwang et al., 1987) and, presumably, does not hinder the activity of the synthetic pheromone (Laurence and Pickett, 1982; Dawson et al., 1990; Olagbemiro et al., 1999, 2004). However, no studies have directly compared the synthetic racemic mixture with pure pheromone compound (or raft), which is needed to validate the latter suggestion.

Oviposition bioassays with *Culex* species traditionally have been performed in small screened cages. In such a setup, the placement of a single egg raft in one of two oviposition bowls led to a significant tendency for the females to oviposit in that bowl (Bruno and Laurence, 1979), and the threshold quantity of synthetic oviposition pheromone dispensed from a floating receptacle was determined to be 0.02 μg (Laurence and Pickett, 1985), which is about 1/15 the amount of pheromone present in a single egg raft (Laurence and Pickett, 1982). Hwang et al. (1987) reported a 50-fold reduction of the threshold quantity of pheromone needed when the pheromone was applied directly on the water surface. A dose of 100 μg of pheromone on a floating receptacle reduced egg raft deposition (Blackwell et al., 1993).

No dose-response experiments in the field have been reported for the oviposition pheromone; without exception, field trials have been carried out by treating oviposition sites with effervescent tablets laced with 5 mg of the active pheromone (Otieno et al., 1988b; Mboera et al., 2000a,b; Olagbemiro et al., 2004), an equivalent of over 16,000 egg rafts. Previous studies demonstrated that the oviposition pheromone, (-)-(*5R,6S*)-6-acetoxy-5-hexadecanolide induces oviposition in gravid *Cx. quinquefasciatus* females under particular conditions in the laboratory (small cages) and field (high doses of pheromone), but do not establish whether a oviposition response is induced by the pheromone under more natural conditions.

In the present study, gravid *Cx. quinquefasciatus* females were provided oviposition sites with natural doses of oviposition pheromone (one raft, 10 rafts, or equivalent doses of synthetic oviposition pheromone, (-)-(*5R,6S*)-6-acetoxy-5-hexadecanolide) at two different distances in outdoor large screened cages. Additional four-choice assays were performed to validate the inactivity of the pheromone's antipode (+)-(*5S,6R*)-6-acetoxy-5-hexadecanolide by testing it against the solvent or in a direct comparison with the synthetic oviposition pheromone. In two-choice bioassays, the preference of females for laying eggs in an oviposition site containing 10 rafts or an equivalent dose of the synthetic oviposition pheromone in a racemic mixture with the antipode was determined. We hypothesized that a female's choice of where to deposit her eggs will be more pronounced in the assays where the stimuli were placed near each other than at a distance. Two-choice bioassays, a common experimental design, often provide increased discrimination over the same treatments presented singly, because in the former case responders can simultaneously sample two alternatives. Such simple choices may not present themselves in nature, however, where responders are more likely to have to make "take it or leave" it choices (Wagner, 1998; Cardé, 2005). The latter comparisons may provide a more realistic measure of the selective forces dictating selection of an oviposition site in nature.

Methods and Materials

Mosquitoes *Culex quinquefasciatus* originated from Riverside County, CA, USA and were maintained in a climate room (27±2°C, 70±3% RH) with a 16:8 L/D cycle including a 1-hr dusk-and-dawn period provided with one 25-W incandescent light bulb. Larvae were reared on an artificial diet (3:1, rat chow/yeast mixture) in plastic trays (4 L). Each day, pupae were collected and allowed to emerge in 30×30×30 cm screen cages (Bioquip®, Rancho Dominguez, CA, USA) and provided with a 10% sucrose solution. A week to 10 d after emergence, mosquitoes were offered the opportunity to feed overnight on live 1- to 5-d-old white leghorn chicks, *Gallus gallus domesticus* L., (UCR animal use protocol #A-0404016-2). The following morning, the mosquito cage was transferred to a greenhouse with a natural photoperiod. The greenhouse was temperature controlled (23±4°C, 56±15% RH). Six to eight d after blood feeding, gravid females were collected in 400-ml cardboard containers (20 per container) and used in the experiments.

General Experimental Conditions Bioassays were conducted outdoors in tent-shaped screen cages ($h \times w \times l$, 2×4×4 m, COS-1313S Quest), consisting of a roof and four screened sides with flaps at the bottom. Long plastic pipes (5 cm i.d.) filled with sand for ballast were placed on the flaps to prevent released mosquitoes from escaping. Cages were arranged in a square (20×20 m) in the shade of trees (Chinese wingnut, *Pterocarya stenoptera*) at Agricultural Operations of the University of California at Riverside, from August 5 to November 28, 2005. Each cage contained either four (Experiments 1–5) or two (Experiment 6) oviposition jars. An oviposition jar consisted of a plastic container (175 ml, sidewall 5.5 cm, top diameter 9.5, bottom diameter 5.8 cm), in which a small glass "shell" vial (12×50 mm) was placed. The bottom of the glass vial was secured to the bottom of the containers with putty (QuakeHold, Trevco, CA, USA). The outer surface of the container was spray-painted black (NOW spray paint, Sherwin-Williams Co., OH, USA).

The oviposition jar (black container and glass vial) was filled with 100 ml of either hay infusion or water (details below). The glass vial of the oviposition jar received one of the oviposition pheromone related stimuli (OPRS) or a control treatment (see below). In the four-choice bioassays (Table 1: Experiments 1–5), the oviposition jars were arranged in either a small square (0.3×0.3 m) at the center of the cage ("near") or in a large square (3.4×3.4 m) at 0.3 m from the corners of the cage ("distant"). In the two-choice bioassay (Table 1: Experiment 6), the two oviposition jars were placed in opposite corners of either the small or large square. In each experiment, bioassays were replicated twice each night for four nights (N=8), with 20 gravid females per replicate at both distances. Experiments commenced an hour before sunset and ended approximately at 09:00 the next morning, when the number of egg rafts laid in each jars were counted and the females were recollected and removed from the cages. Different groups of mosquitoes and fresh stimuli were used in all tests.

Stimuli Hay infusion was prepared with the formula used by the Mosquito Control Research Laboratory in Parlier, CA, USA (University of California, Davis) as an oviposition medium in gravid traps: 5.6 g of dried and shredded Bermuda grass and 0.34 g of bakers yeast per 2.5 L water. The hay infusion in a 3.8-L glass jar was placed in a hood in the laboratory. After 7 d, the infusion was filtered through a cloth to remove the grass fragments and used in the experiments.

Synthetic samples of the mosquito oviposition pheromone (MOP), (5*R*,6*S*)-6-acetoxy-5-hexadecanolide and its antipode, (5*S*,6*R*)- 6-acetoxy-5-hexadecanolide, were provided by

[a] All experiments were replicated with oviposition jars arranged in a small square at the center of the tent ('near') and in a large square ('distant') $N=8$.

[b] Oviposition jars contained either 100 ml of hay infusion or water.

[c] OP=1,000 ppm oviposition pheromone (−)-(*5R,6S*)-6-acetoxy-5-hexadecanolide.

[d] AP=1,000 ppm antipode, (+)-(*5S,6R*)-6-acetoxy-5-hexadecanolide.

[e] AP=1,000 ppm racemic mixture of oviposition pheromone and antipode.

Bedoukian Research Inc. Samples were analyzed by gas chromatography (6890 Series GC, Agilent Technologies, Palo Alto, CA, USA) to determine chemical purity. Hexane solutions (see below) were injected in splitless mode with the inlet and FID at 250°C and separated on a HP-5 column (25 m×0.32 mm; 0.25 μm). The oven was operated at 100°C for 1 min, increased to 250°C at a rate of 10°C/min, and held at the final temperature for 5 min. Under these conditions, both pheromone and antipode appeared at 18.14 min. Each sample gave a single peak in addition to the solvent front. Next, we determined the enantiomeric purity of the two stereoisomers by gas chromatography equipped with a chiral column, Chiraldex GTA (25 m×0.25 mm; 0.125 μm; Astec, Whippany, NJ, USA), which was operated at constant temperature, 175°C. MOP appeared at 92.78 min, whereas the retention time of the antipode was 91.62 min. The enantiomeric excess of (5*R*,6*S*)- and (5*S*6*R*)- 6-acetoxy-5-hexadecanolide were estimated as >99.5% and >99%, respectively, thus indicating a high enantiomeric purity.

The chemical analysis above indicated that samples prepared with the same nominal concentrations gave peaks with different areas, possibly because of residual organic solvents in the synthetic samples and/or experimental error in sample preparations. To generate samples with exactly the same concentrations, we prepared 10 μg/μl hexane solutions (10,000 ppm) of MOP and its antipode and dilute them with distilled hexane into 5, 1, and 0.1 μg/μl. These samples (1 μl of each concentration) were injected in three replicates, and the mean area for each concentration was plotted vs. concentrations to generated linear curves ($R^2>0.99$), with different slopes. The highest concentration of the samples generating large FID areas were adjusted, the adjusted sample was diluted, and the procedure was repeated until the slope of the MOP and antipode samples were identical. After confirming that the 1 μg/μl (1,000 ppm) samples of the two semiochemicals gave

nearly the same FID responses, the samples were used for behavioral studies. Racemic samples were prepared by adding equal volumes of the two stereoisomers.

The following oviposition pheromone-related stimuli (OPRS) were used: i. one egg raft, ii. 10 egg rafts, iii. 3.0 μg (-)-(*5R,6S*)-6-acetoxy-5-hexadecanolide (oviposition pheromone), iv. 3.0 μg (+)-(*5S,6R*)-6-acetoxy-5-hexadecanolide (antipode), v. 0.6 μg racemic mixture (3.0 μg oviposition pheromone and 3.0 μg antipode). Egg rafts, laid by gravid *Cx. quinquefasciatus* females the night preceding the experiment, were transferred onto the glass vials of the oviposition jars, already filled with hay infusion or water, just before the start of the experiment. To control for visual cues of the rafts used in Experiments 1 and 2, equivalent numbers and sized artificial rafts, made of pieces of black closed cell foam rubber (Tight Fit Foam Weather Strip, W.J. Dennis, IL, USA), were used in the control oviposition jars. Doses of 3.0 μl of oviposition pheromone or the antipode in hexane (1,000 ppm) or 6.0 μl of a racemic mixture of the two compounds in hexane (1,000 ppm) were applied onto a microscope cover glass (12 mm diameter) cut in half. After the solvent had evaporated, the cover glasses were wrapped individually in aluminum foil, transported to the field site, and transferred with the treated side upward onto the glass vials of the oviposition jars, already filled with hay infusion or water, just before the start of the experiment. Similarly treated cover glasses with equivalent doses of hexane served as controls. Each stimulus was tested twice at each corner of the squares and each stimulus combination was tested twice in each of the four cages.

Experiments The study consisted of six experiments (Table 1). In Experiment 1, gravid females were introduced into cages containing two oviposition jars with 100 ml of hay infusion and two with 100 ml of water. Two jars (one with hay infusion and one with water) received a single egg raft, and two jars received an artificial egg raft (see above). Experiments 2–4 were set up similarly, except for using 10 rafts, 3.0 μg of oviposition pheromone or 3.0 μg of the antipode (or their appropriate controls), respectively, instead of one raft as the OPRS. In Experiment 5, gravid females were introduced into cages containing four oviposition jars with 100 ml of hay infusion each. Jars received either 3.0 μg of oviposition pheromone, 3.0 μg of the antipode, 6.0 μg of the racemic mixture, or an equivalent amount of hexane. In Experiment 6, gravid females were introduced into cages containing two oviposition jars, each with 100 ml of hay infusion. Jars received either 10 egg rafts or 6.0 μg of the racemic mixture of the oviposition pheromone and antipode. In Experiment 6, there were no controls for the visual cues presented by the rafts or cover glasses.

Statistical Analyses Under the assumption that a gravid female deposits her eggs in a single raft (Clements 1992), egg raft counts correspond with the numbers of females ovipositing. Because in some cases data were not normally distributed, data were analyzed by nonparametric tests. Within jar arrangement (distant or near), factorial experiments (Experiments 1–5) were each subjected to Friedman's method for randomized blocks, followed by Wilcoxon signed ranks test to compare differences between treatment means (N=8) (Sokal and Rohlf, 2005). The results of the two-choice bioassay (Experiment 6) were analyzed by using the Wilcoxon signed ranks test (N=8). The results of all experiments together were subjected to Wilcoxon signed ranks test to determine significant differences between the numbers of egg rafts laid in the replicates with the jars arranged near each other with the distant ones; for each night, the numbers of egg rafts laid in the two replicates of the former were summed and paired with the total of rafts laid in the two replicates of the latter (N=24, Experiments 1–6 replicated for four nights).

Results

For all four-choice bioassays (Experiments 1–5), Friedman's method for randomized blocks indicated highly significant ($P<0.005$) effects of the treatments on the numbers of rafts laid in the oviposition jars. Results of the follow-up test (two-tailed Wilcoxon signed ranks test) to compare differences between treatment means are shown in Figs. 1 and 2. Experiment 1 revealed that the mean number of egg rafts laid by gravid *Cx. quinquefasciatus* females in response to a single raft floating in an oviposition jar filled with hay infusion was significantly greater than the mean numbers laid in any of the three other oviposition jars present when the jars were placed near each other, but not when they were placed 3.4 m apart. In the latter case, the mean numbers of rafts in the two jars filled with hay infusion containing either a floating single egg raft or an artificial raft were not significantly different ($Z=1.439$, $P=0.150$, two-tailed Wilcoxon signed ranks test). In Experiment 2, the mean number of egg rafts laid in response to 10 rafts floating in an oviposition jar filled with hay infusion (Fig. 1) was greater than the mean number laid in response to 10 artificial rafts floating on hay infusion when the oviposition jars were placed near each other ($Z=2.521$, $P=0.012$) and when placed at a

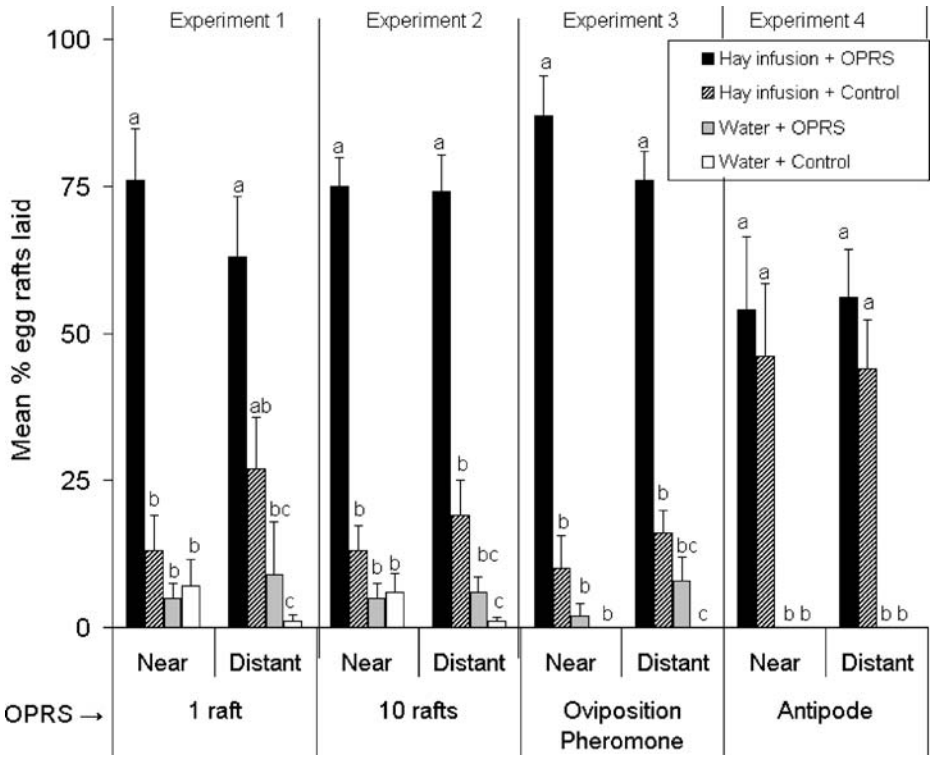

Fig. 1 Oviposition of gravid females of *Culex quinquefasciatus* in eight four-choice bioassays in outdoor tents (Experiments 1–4). Stimuli were presented either near (0.3 m) or distant (3.4 m) from each other within a tent. Vertical bars represent standard errors ($N=8$). Within each bioassay, statistical analysis was carried out using Friedman's method for randomized blocks, followed by Wilcoxon signed ranks tests (different letters denote significant differences at $P<0.05$, two-tailed). OPRS=Oviposition Pheromone Related Stimulus, Control=appropriate control for the OPRS used (see Table 1), Oviposition Pheromone=3.0 μl 1,000 ppm oviposition pheromone, Antipode=3.0 μl 1,000 ppm antipode, Racemic=6.0 μl 1,000 ppm racemic mixture of oviposition pheromone and antipode

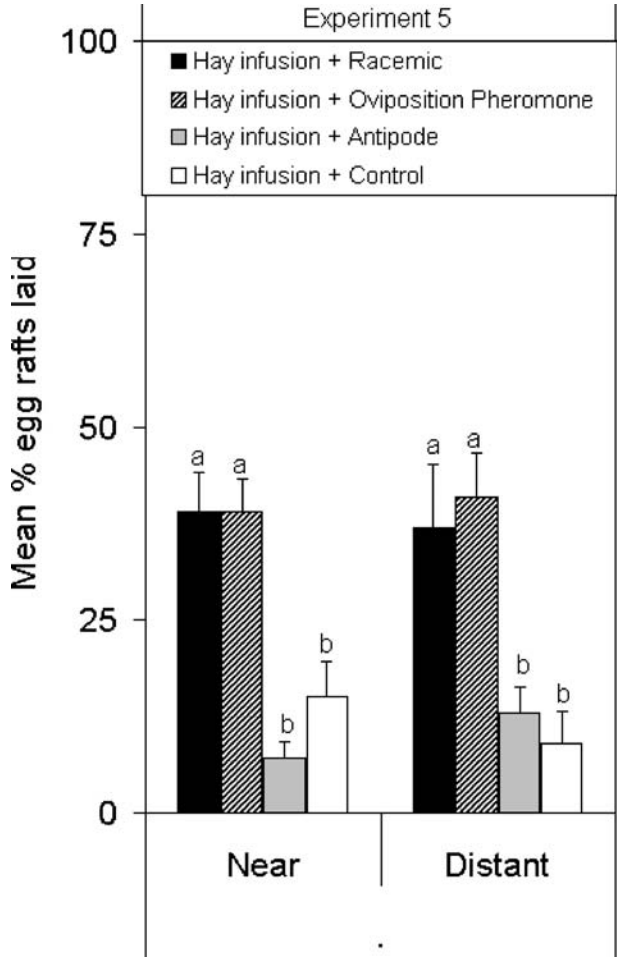

Fig. 2 Oviposition of gravid females of *Culex quinquefasciatus* in two four-choice bioassays (Experiment 5) in outdoor tents. Stimuli were presented either near (0.3 m) or distant (3.4 m) from each other within a tent. Vertical bars represent standard errors (N=8). Within each bioassay, statistical analysis was carried out using Friedman's method for randomized blocks, followed by Wilcoxon signed ranks tests (different letters denote significant differences at $P<0.05$, two-tailed). Racemic=6.0 μl 1,000 ppm racemic mixture of oviposition pheromone and antipode, Oviposition Pheromone=3.0 μl 1,000 ppm oviposition pheromone, Antipode=3.0 μl 1,000 ppm antipode, Control=6.0 μl hexane

distance (Z=2.527, P=0.012). Similar results were found when using 3.0 μg of oviposition pheromone (Experiment 3: Z=2.527, P=0.012; Z=2.533, P=0.011), but not when using 3.0 μg of the antipode (Experiment 4: Z=0.680, P=0.496; Z=0.681, P=0.496) as the OPRS. In all four preceding experiments (Experiments 1–4), the mean numbers of rafts laid in response to OPRS on water was not significantly different ($P>0.05$) from its control on water, at either distance. For both distances in Experiment 5 in which all oviposition jars were filled with hay infusion (Fig. 2), no significant differences in mean number of rafts were found between oviposition jars containing 6.0 μg of racemic mixture of the oviposition pheromone and the antipode, and an equivalent amount of pure oviposition pheromone (near: Z=0.213, P=0.872; distant: Z=0.845, P=0.012) or between 3.0 μg of the antipode and the control with only the solvent (near: Z=0.816, P=0.414; distant: Z=1.005, P=0.315). In the two-choice bioassays of Experiment 6 (Fig. 3), the mean number of rafts laid in response to 6.0 μl of racemic mixture was not significantly different, from the mean number laid in response to 10 rafts in hay infusion (near: Z=1.693, P=0.090; distant: Z=1.160, P=0.246) at either distance.

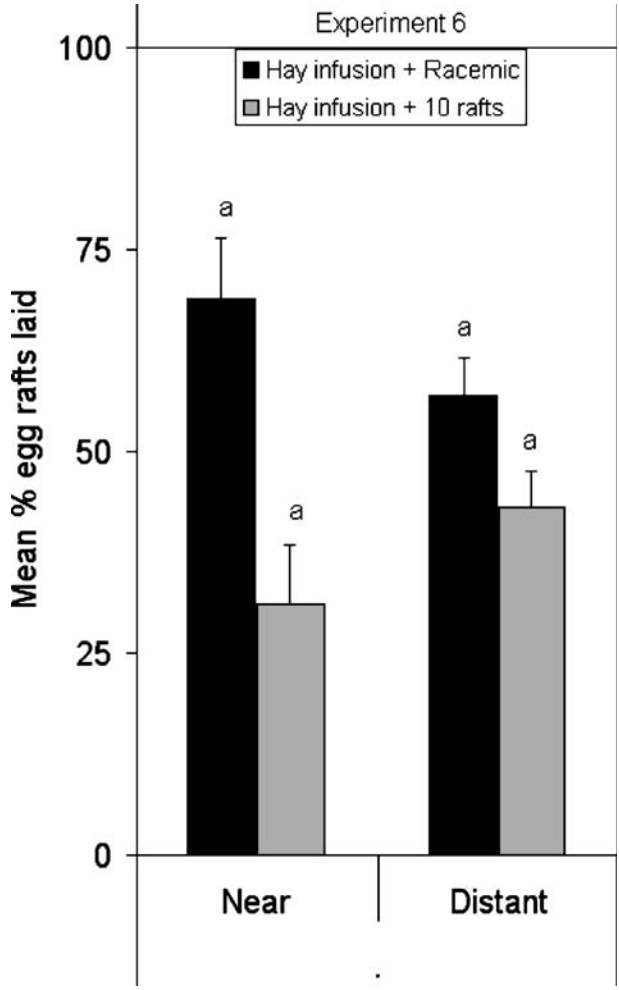

Fig. 3 Oviposition of gravid females of *Culex quinquefasciatus* in two two-choice bioassays (Experiment 6) in outdoor tents. Stimuli were presented either near (0.3 m) of distant (3.4 m) from each other within a tent. Vertical bars represent standard errors (N=8). Within each bioassay, statistical analysis was carried out using Wilcoxon signed ranks tests (different letters denote significant differences at $P<0.05$, two-tailed). Racemic=6.0 µl 1,000 ppm racemic mixture of oviposition pheromone and antipode

The mean numbers of rafts laid per night in the replicates with the jars placed near each other were lower than in those when they were placed distant from each other (Table 1, $Z=3.987$, $P<0.001$, two-tailed Wilcoxon signed ranks test).

Discussion

These oviposition studies were conducted outdoors under natural photoperiod and weather conditions, and with a moderately large experimental space to permit natural orientation behavior of the mosquitoes to occur. Our results confirmed laboratory studies (Bruno and Laurence, 1979) in that female *Cx. quinquefasciatus* differentiated between suitable oviposition sites with a single raft and nearby sites without an egg raft, and showed that this trend, although not significant, persisted when the distances between the oviposition sites were increased from 0.3 to 3.4 m. For an odor cue from an egg raft to evolve into an aggregation/oviposition pheromone, the presence of multiple egg rafts should improve

survival/reproduction of larvae from both the first and subsequently laid rafts. Presumably, such aggregation generally lessens the rate of predation on larvae, and this benefit outweighs the cost of pheromone production on female fecundity (McCall, 2002). Our study is the first demonstration of an effect of a single raft on the oviposition of gravid *Cx. quinquefasciatus* females under seminatural conditions. The priming effect of the first egg raft was enhanced by others subsequently laid in that bowl (Clements, 1999), but that is also expected to occur in the field (Reiskind and Wilson, 2004). When the stimulus was increased from one to 10 egg rafts, females showed a distinct preference for the hay infusion jars with the rafts at both distances tested.

The results of the bioassays with 3.0 μg pure synthetic oviposition pheromone were comparable with those of its natural equivalent (10 rafts); aggregation of egg rafts in the oviposition sites containing the oviposition-related stimulus. No significant differences were found between the numbers of rafts in the jars containing hay infusion with or without the antipode (Experiments 4 and 5, Figs. 1 and 2) or those with the pure oviposition pheromone or the racemic mixture (Experiment 5, Fig. 2), which confirmed that the antipode is not active in inducing or reducing oviposition by *Cx. quinquefasciatus* females (Laurence and Pickett, 1982, 1985; Hwang et al., 1987; Dawson et al., 1990; Olagbemiro et al., 1999, 2004). The direct comparison of day-old natural rafts with equivalent doses of synthetic oviposition pheromone in a racemic blend on a floating glass slide (Experiment 6, Fig. 3) revealed that despite differences in the mode of pheromone presentation, their effects on oviposition of *Cx. quinquefasciatus* were comparable. When oviposition sites were placed near each other, the synthetic pheromone tended to receive greater number of rafts than the natural pheromone source, but this difference was not significant.

This is the first report comparing the effect of the synthetic oviposition pheromone emanating from an artificial source with its natural counterpart. Aggregation of egg rafts was obtained with low doses (3.0 μg) of synthetic oviposition pheromone (pure or in racemic mixture) on a floating receptacle in our semifield trials. In previous field trials, high doses (5 mg) of active oviposition pheromone were applied onto the water surface by means of effervescent tablets (Otieno et al., 1988b; Mboera et al., 2000a,b; Olagbemiro et al., 2004). Increased oviposition activity was observed in the oviposition sites several days after the high initial dose of the synthetic oviposition pheromone (Otieno et al., 1988b; Mboera et al., 1999). Although the residual activity was not determined in our study, the results are promising for using low pheromone in field trials in less developed countries where the cost of the synthetic pheromone is an issue.

Oviposition jars containing water, irrespective of the presence of a floating oviposition pheromone-related stimulus (Experiments 1–4), received low numbers of rafts. This suggests that the role of the pheromone may be secondary to that of site-derived odors (Millar et al., 1994), although pheromone and kairomones act synergistically in our study and others (Otieno et al., 1988a; Mordue et al., 1992; Mboera et al., 2000a,b). Alternatively, contact components present in the oviposition medium used might play an important role in the acceptance or rejection of an oviposition site by the female. In our study, as in many other oviposition bioassays (Blackwell et al., 1993; Isoe and Millar, 1995; Olagbemiro et al., 1999, 2004; Mboera et al., 2000a; Michaelakis et al., 2005), only the overall effect of the pheromone and the hay infusion on oviposition was scored (egg raft count) without an analysis of the behavioral segments leading to this endpoint. Other bioassays, such as two-choice olfactometers (Osgood and Kempster, 1971), video recordings (Pile et al., 1991), sticky-screen assays (Isoe and Millar, 1995), and gravid traps (Mboera et al., 2000b) have been used in an attempt to distinguish the behavioral events leading to oviposition. However, in many cases the behavior of mosquitoes is affected by the bioassay design. We

scored egg rafts deposited on a known suitable oviposition substrate (Gjullin et al., 1965) or in water to compare the effects of various pheromone-related stimuli floating in a seminatural setting.

In Experiments 1–3, the number of egg rafts in the hay infusion jar with the OPRS was significantly greater than all three other nearby jars, which in turn were not significantly different. The latter was not the case in the replicates with the distant jars. Although this and the result of Experiment 6 support our hypothesis that the female's choices were more pronounced in the replicates with the oviposition sites near each other than those at a distance, the difference was more subtle than anticipated.

The total number of egg rafts deposited varied widely between the experiments that were conducted between August 5 and November 24 (Table 2). This large variation in oviposition activity was expected to be at least partly caused by the changing weather conditions over the 4-mo experimental period (the maximum daily temperature ranged from 18 to 35°C and the minimum relative humidity ranged from 7 to 67%). Unexpectedly, the total number of egg rafts deposited in a bioassay depended largely on the proximity of the oviposition jars. In all but one experimental night (Table 1, night 5), more rafts were laid in the replicates with the jars distant from each other than those nearby (Table 1). This phenomenon was probably an artifact of the experimental setup and may have been caused by differences in the average distance between the females and the jars rather than in the distance between the jars themselves. Most females rested on the screened sites of the cages

immediately after release from the center of the cage and were recovered from between the folds of the flaps at the bottom corners of the cage on the following morning. Thus, females may have had a higher probability of encountering suitable jars in the treatments with the jars at the corners of the cages than those with the jars arranged in a small square at the center of the cage.

Three possible explanations are suggested for the number of females ovipositing being clearly affected by distance, whereas their choice for an oviposition site seemed only marginally influenced. Females may fly along the edge of the cage in search of a suitable oviposition site without selecting the one first encountered, suggesting that females make a distinction between hay infusion sites based on the oviposition pheromone detected at a distance of a meter or so. Alternatively, females may fly along the edges of the cage and, upon encountering the pheromone at close range, land and/or oviposit. Another possibility is that females visit and land at several oviposition sites before deciding where to oviposit.

The oviposition pheromone thus could function as an attractant (Osgood and Kempster, 1971; Pile et al., 1993) in the former, and as an arrestant (Pile et al., 1991, 1993) and/or stimulant of oviposition in the second situation, or potentially a combination of both in the latter. Although organic infusions appear to function both as an attractant and oviposition stimulant for *Cx. quinquefasciatus* females (Ikeshoji, 1966a, b), further research is necessary to elucidate the modes of action of the oviposition pheromone for it to be effectively utilized in gravid traps. In particular, it will be useful to determine if these odors induce upwind anemotaxis or some form of chemotaxis in still air (collectively termed "attraction"), changes in velocity (orthokinesis), landing, or oviposition. Endpoint measurements such as egg deposition do not establish how orientation maneuvers influence oviposition.

Acknowledgment We thank Prof. W. Walton for providing the *Cx. quinquefasicatus* colony, S. Cockerham facilitating use of the field site at Agricultural Operations, UCR, Prof. J. Millar for the use of his greenhouse for maintaining mosquito colonies, and S. Raoufian for assistance in maintaining the mosquito colony. Dr. S. McElfresh is thanked for his advice on numerous occasions and Dr. M. Cooperband for her comments on an earlier version of the manuscript. We are grateful to Bedoukian Research Inc., Danbury, CT, USA for providing synthetic samples of the mosquito oviposition pheromone and its antipode. This research was supported by a grant from National Institutes of Health (# 1-UO1-A10058267).

Abstract The sex pheromone of the red banded mango caterpillar, *Deanolis sublimbalis* (Lepidoptera: Crambidae), a serious pest of the mango *Mangifera indica* (Anacardiaceae) in India and Southeast Asia and a recent invader into northern Australia, has been identified. Three candidate compounds were identified from pheromone gland extracts of female moths, using gas chromatography (GC), GC-electroantennographic detection and GC-mass spectrometric analyses, in conjunction with dimethyldisulfide derivatization. Field bioassays established that both (*Z*)-11-hexadecenal (*Z*11-16:Ald) and (3*Z*,6*Z*,9*Z*)-tricosatriene (3*Z*,6*Z*,9*Z*-23:Hy) were required for attraction of male *D. sublimbalis* moths, and 1,000 μg of a 1:1 mix of *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy was more attractive to male moths than

caged virgin females. However, the binary blend was only attractive when the isomeric purity of the monounsaturated aldehyde was >99%, suggesting that the (*E*)-isomer was inhibitory. Although (*Z*)-11-hexadecen-1-ol (*Z*11-16:OH) was tentatively identified in gland extracts, the addition of this compound to the binary blend did not increase the numbers of moths captured. The pheromone can now be used in integrated pest management strategies.

Introduction

The red banded mango caterpillar *Deanolis sublimbalis* Snellen (Lepidoptera: Crambidae) is a serious pest of mango *Mangifera indica* (Anacardiaceae) in India and many regions of Southeast Asia (Golez, 1991; Waterhouse, 1998; Sujatha and Zaheruddeen, 2002). Damage is caused by the distinctively marked larvae boring into the flesh and kernel of mango fruitlets, allowing secondary infection to develop, which renders the fruit unsuitable for market or consumption (Golez, 1991; Waterhouse, 1998). Infestation levels of *D. sublimbalis* can exceed 40% in commercial mango crops (Tipon 1979 cited by Golez, 1991). Krull (2004) reported infestation levels of ca 4–23% at four sites in the Central Province of Papua New Guinea (PNG) with infestation on some trees being as high as 77%.

The range of *D. sublimbalis* extends from India east into Burma, China, Taiwan, and south into Thailand, the Philippines, Brunei, Indonesia, and PNG (Waterhouse, 1993; Li-Ying et al., 1997). Recently, this moth has been found on the tip of Cape York Peninsula in far north Queensland, Australia on isolated feral and noncommercial street and domestic mango trees (Foulis, 2000). Although the incursion of *D. sublimbalis* into Australia has so far been contained using strict quarantine measures (Foulis, 2000), the possibility of spread into the southern commercial growing areas threatening the Australian $100 million mango industry (AMIA, 2006) cannot be ruled out. Consequently, there has been an urgent need to develop sensitive monitoring methods to detect any southern spread.

Our objective was to identify the sex pheromone of *D. sublimbalis.* We report, here, the conclusive identification of one compound and tentative identification of two further compounds in pheromone gland extracts of *D. sublimbalis* and the evaluation of their biological activities in field bioassays in PNG.

Methods and Materials

Insects Infested mango fruitlets were collected from a mango orchard at Tahira (09.5157° S, 147.2876° E), Central Province, PNG, and kept in plastic containers until pupation of larvae. Larvae exited the fruit to pupate in a layer of sawdust in the bottom of the containers. Pupal cocoons were placed in sealed plastic containers (Lily® 35-ml portion cups with lids; Huhtamaki Henderson Ltd., Auckland, NZ) for shipment by air freight to HortResearch, Lincoln, New Zealand. Adult moths were allowed to emerge in a secure room in the Landcare Research quarantine facilities at Lincoln, and each sex was kept separately in 40 cm^3 humidified polycarbonate plastic boxes, at 25°C and 75% RH, under a 12:12 hr light:dark reverse photoperiod. Moths were provided with 10% sucrose solution.

Females had their pheromone glands excised and extracted, whereas males were used for coupled gas chromatography-electroantennographic detection (GC-EAD) analyses. Male *D. sublimbalis* have pronounced black tufts on their mid-tarsi, and an abdomen that extends beyond the hind wings, characters which aided sex determination.

Pheromone Gland Extracts All pheromone gland extracts were taken from 24- to 72-hr-old actively calling females, 2–3 hr into the scotophase. Excised pheromone glands were placed in 50 µl *n*-hexane in a liquid-nitrogen-cooled 0.5-ml conical vial. After all glands had been excised, the vial and its contents were brought to room temperature and left for 5 min before the supernatant was transferred to a 1.1-ml conical glass vial. Extracts were stored at −80°C until analysis. To quantify pheromone titer per female, the pheromone glands of 11, 15, and 17 females were extracted in 50 µl aliquots of *n*-hexane containing 50 ng of (*Z*)-10-pentadecenal (*Z*10-15:Ald) internal standard, as described above. The supernatant from each of these extracts was then concentrated under a stream of argon to 10 µl, and a 1-µl aliquot was analyzed by GC-mass spectrometry (GC-MS).

Chemicals *Z*10-15:Ald, (*Z*)-11-hexadecenal (*Z*11-16:Ald), (*E*)-11-hexadecenal (*E*11-16:Ald), (*Z*)-11-hexadecen-1-ol (*Z*11-16:OH), and (*E*)-11-hexadecen-1-ol (*E*11-16:OH), were purchased from Pherobank, Wageningen, The Netherlands (all ≥97% isomerically pure by GC analysis). *Z*11-16:Ald of high isomeric purity (>99%) was also obtained from Pherobank for use in field bioassays. (3*Z*,6*Z*,9*Z*)-Tricosatriene (3*Z*,6*Z*,9*Z*-23:Hy; ca 95% isomerically pure) used for comparative chromatographic and spectrometric analyses was synthesized at HortResearch, Palmerston North. In addition, 3*Z*,6*Z*,9*Z*-23:Hy (>99% isomerically pure) was supplied by J. M. Chong (University of Waterloo, Ontario, Canada) for additional comparative analyses and for field bioassays.

Synthesis of (3Z,6Z,9Z)-tricosatriene Synthesis of (3*Z*,6*Z*,9*Z*)-tricosatriene is described in the online supplement at (see electronic supplementary material).

Gas Chromatography-Electroantennographic Detection Pheromone gland extracts of *D. sublimbalis* were analyzed by GC-EAD using a Varian 3800 gas chromatograph, equipped with both polar and nonpolar columns, coupled to an EAD Recording Unit (Syntech Research and Equipment, Hilversum, The Netherlands). For details of the preparation of moth antennae and the setup of associated equipment for GC-EAD analyses, see Gibb et al. (2006). Extracts were analyzed on DB-5 (30 m×0.25 mm i.d.×0.5 µm film; Agilent Technologies, Palo Alto, CA, USA) and BPX-70 (30 m×0.25 mm i.d.×0.25 µm film; SGE, Victoria, AU) columns, with 1:1 split outlets. Helium was used as carrier gas (1 ml min^{-1}), and injections were splitless for 0.6 min. Injector and detector temperatures were 220 and 300°C, respectively, and the GC temperature program was 80°C for 1 min, 10°C min^{-1} to 240°C, hold for 30 min. Kováts retention indexes (KIs) (Kováts 1965; Marques et al., 2000) were calculated for the compounds that elicited antennal responses.

Gas Chromatography-Mass spectrometry Pheromone gland extracts of *D. sublimbalis* and *Z*11-16:Ald, *E*11-16:Ald, *Z*11-16:OH, *E*11-16:OH, and 3*Z*,6*Z*,9*Z*-23:Hy standards were analyzed by GC-MS on VF-5 ms (30 m×0.25 mm i.d.×0.25 µm film; Varian Inc., Walnut Creek, CA, USA) and BPX-70 (30 m×0.25 mm i.d.×0.25 µm film; SGE) columns, using a Varian 3800 gas chromatograph, with a 0.6-min splitless injection (injector 220°C), coupled to a Varian 2200 MS. The helium flow was 1 ml min^{-1} with the transfer line at 250°C, and the ion

trap temperature at 200°C. The GC temperature programs were 1 min at 80°C, 10°C min^{-1} to 240°C, and hold for 15 min (VF-5 ms column), or 1 min at 80°C, 10°C min^{-1} to 130°C, hold 3 min, 5°C min^{-1} to 190°C, and hold for 20 min (BPX-70 column).

Dimethyldisulfide Derivatizations For dimethyl disulfide (DMDS) derivatizations of *Z*11-16:Ald, *E*11-16:Ald, *Z*11-16:OH, and *E*11-16:OH standards (10 ng in 20 μl of *n*-hexane) and a 10-female *D. sublimbalis* gland extract, we followed the procedure described by Buser et al. (1983) and Leonhardt and DeVilbiss (1985). Approximately 50 μl of DMDS and 5 μl of iodine solution (60 mg of I_2 in 1 ml of Et_2O) were added to the solution of interest in a 1.8-ml glass vial sealed with a Teflon-lined cap and were reacted at 40°C for 15 hr. The reaction was quenched with 50 μl of a 5% aqueous solution of $Na_2S_2O_3$, and the organic layer was dried with anhydrous Na_2SO_4, transferred to a clean conical vial, and concentrated with a stream of argon to less then 5 μl. A 1-μl aliquot was analyzed by GC-MS on the VF-5 ms column with the temperature program described previously (injector 250°C; 8 min solvent delay). The adducts from the (*E*) and (*Z*)-hexadecenals and the hexadecen-1-ols, although having identical spectra, were easily separated.

Field Bioassays Field bioassays were carried out in PNG during the 2005 mango season, in street trees in Port Moresby (trial A) and in mature orchards at Tahira (trials B and C; "Kensington Pride" mango) and the Pacific Adventist University (PAU), Port Moresby (09.4073° S, 147.2781° E) (trial D; main mango cultivars were "Kensington Pride", "Glenn" and "Irwin"). Green delta traps (Clare et al., 2000) were attached to trees at a height of ca 2.5 m, with at least 20-m spacings between traps and at least 20-m spacings between replicates in all trials. Trap positions within each replicate were re-randomized, and sticky inserts were replaced each time traps were checked. Test compounds, in ratios established from GC-MS analysis of *D. sublimbalis* gland extracts, were loaded onto red rubber septa (Thomas Scientific Inc., Philadelphia, PA, USA).

In trial A (July 19 to August 4), the attraction of *D. sublimbalis* males to various combinations of the three candidate compounds was tested. Traps were checked three times at intervals of 4–8 d. Treatments were (1) blank control, (2) 1000:0:0, (3) 0:1000:0, (4) 0:0:1000, (5) 500:500:0, (6) 1000:0:50, and (7) 500:500:50 μg loadings of *Z*11-16:Ald, 3*Z*,6*Z*,9*Z*-23:Hy, and *Z*11-16:OH (*N*=3).

Trial B (August 16 to September 27) was a repeat of trial A, but included caged virgin females as an additional treatment (treatment 8). Traps were checked 14 times at intervals of 1–5 d. Female moths were replaced every 3–5 d and supplied with 10% sugar solution applied to cotton dental rolls. There were three replicates.

Trial C was a dose response trial based on treatment 5 from trials A and B and was set up from September 27 to December 21. Traps were checked 18 times at intervals of 2–6 d, except for the last occasion when traps were left for 13 d because of low catches during that period. Treatments were (1) blank control, (2) 10, (3) 100, (4) 1000, and (5) 3000 μg doses of a 1:1 mix of *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy (*N*=6).

In trial D (September 29 to November 6), the attraction of *D. sublimbalis* males to a 1000 μg dose of the 1:1 mix of *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy was compared, in which *Z*11-16:Ald was either >99% (treatment 1) or ca 97% (treatment 2) isomerically pure (*N*=6). Traps were checked five times at intervals of 7–10 d.

Statistical Analyses Only treatments that trapped moths were included in the statistical analyses. Because there was some variation in the number of days between trap checks, the

response variate used in the analyses was the average number of moths caught per day. For trials A and B, a mixed model was fitted to the response variate, with treatment as the fixed effect, and date as the random effect.

For trial C, a mixed model was fitted to the response variate, with lure dose, assessment date and its interactions as fixed effects, and assessment date within replicates as random effects. Assessment date was included as both random and fixed effects to ascertain any systematic effects of assessment date with changes in lure dose (fixed effects) over and above the variability in the response variate due to assessment date (random effects).

Both models assumed that the error terms were normally and independently distributed, with zero mean and constant variance. The response variate was transformed, before analysis, using the square root transformation, to ensure that the model assumptions were met. Data were analyzed by analysis of variance (ANOVA) using GenStat Release 8.1 (VSN International Ltd., UK). Means separation tests for trials A and B were carried out using Fisher's protected least significant difference (LSD) at the 5% significance level. For trial C, means were separated with Tukey's honest significant difference (HSD) at the 5% significance level, to adjust for any false differences. Model adequacy checks were performed by examining histograms, normal probability plots, and scatter plots of the residuals.

Results

Identification of Pheromone Components In GC-EAD assays, male *D. sublimbalis* antennae responded repeatedly to three compounds in female moth pheromone extracts (Peaks 1–3; Fig. 1).

These compounds were identified as *Z*11-16:Ald, 3*Z*,6*Z*,9*Z*-23:Hy, and *Z*11-16:OH, as follows. The calculated KIs of compound 1 (1809 and 2373 on the DB-5 and BPX-70 columns, respectively) suggested the presence of a C_{16} monounsaturated aldehyde (Marques et al., 2000), and the retention times were identical to those of the *Z*11-16:Ald standard. Analysis by GC-MS provided further proof that compound 1 was *Z*11-16:Ald, with good retention time and mass spectral matches with the standard. Furthermore, GC-MS analysis of the DMDS-derivatized extract showed an adduct with a molecular ion at *m*/*z* 332 (11%) and diagnostic ions at *m*/*z* 117 (52%, $[C_5H_{10}SCH_3]^+$) and 215 (100%, $[OC_{11}H_{20}SCH_3]^+$), indicating the addition of DMDS to a double bond at position 11. We also noted that male *D. sublimbalis* antennae responded equally well to the *E*11-16:Ald standard (Peak b, Fig. 1; KIs of 1809 and 2348 on the DB5 and BPX-70 columns, respectively), even though this stereoisomer was not detected in gland extracts.

The mass spectrum of compound 2 [*m*/*z* 318 (2%, M^+), 262 (3%), 135 (14%), 121 (14%), 108 (28%), 93 (37%), 79 (100%), 67 (52%), 55 (22%) and 41 (41%)] and its elution order before tricosane on the VF5-ms column (KI 2272), suggested the nonconjugated C_{23} triunsaturated hydrocarbon, 3*Z*,6*Z*,9*Z*-23:Hy (Underhill et al., 1983; Millar, 2000). This was confirmed by matching retention times on the DB-5 and BPX-70 columns with those of a standard (KIs of 2270 and 2431, respectively) and by matching the mass spectrum to that of a standard. In addition, male *D. sublimbalis* antennae responded similarly to compound 2 and to the 3*Z*,6*Z*,9*Z*-23:Hy standard (Fig. 1), although the antennal response to the compound was relatively small compared with the response to the other pheromone components. We also observed that antennae of males responded to impurities in the synthetic 3*Z*,6*Z*,9*Z*-23:Hy including an unknown compound, and to isomers of 3*Z*,6*Z*,9*Z*-23:Hy (Peaks a, c, and d; Fig. 1). While it was not possible as part of this study to verify

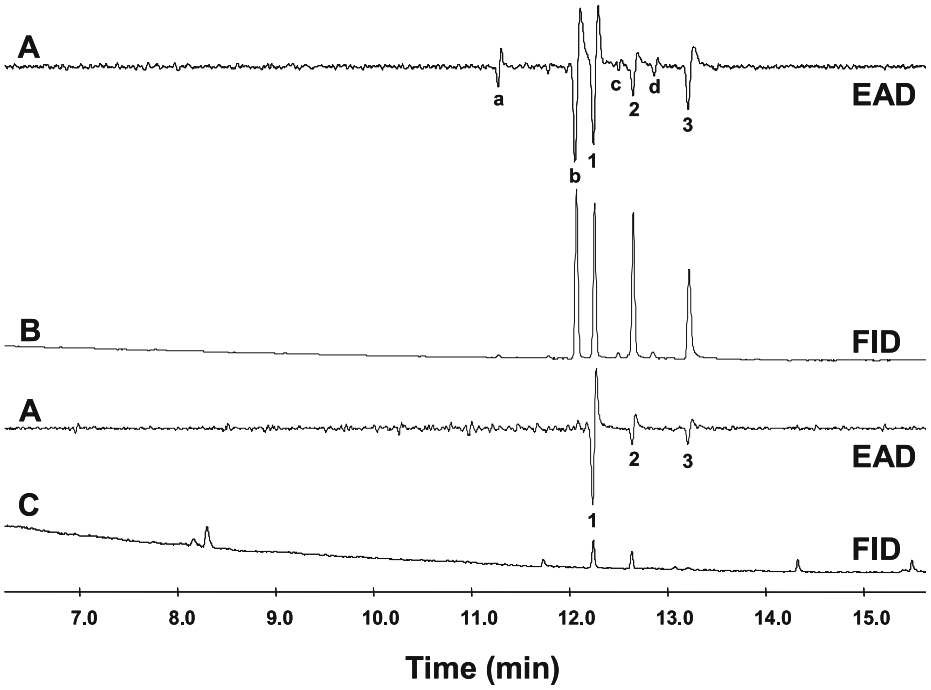

Fig. 1 Coupled gas chromatogram-electroantennograms of (**A**) *Deanolis sublimbalis* male antennae responding to (**B**) synthetic compounds (5 ng), and (**C**) insect-produced compounds in a *D. sublimbalis* female pheromone gland extract, eluting from a BPX-70 column. **1**=(*Z*)-11-hexadecenal, **2**=(3*Z*,6*Z*,9*Z*)-tricosatriene, and **3**=(*Z*)-11-hexadecen-1-ol. Spikes **a**, **c**, and **d** are antennal responses to an unknown compound and two unknown isomers of the C_{23} triunsaturated hydrocarbon respectively, in the synthetic (3*Z*,6*Z*,9*Z*)-tricosatriene. Spike **b** is the antennal response to synthetic (*E*)-11-hexadecenal

that all the double bonds of the natural tricosatriene have a *Z* configuration due to the small amount of material available, the results of the comparative analyses by GC and GC-MS and the biological activity of 3*Z*,6*Z*,9*Z*-23:Hy in GC-EAD and field bioassays strongly suggest the *Z*,*Z*,*Z* isomer. Therefore, we have tentatively identified compound 2 as 3*Z*,6*Z*,9*Z*-23:Hy.

We confirmed the double bond position and geometry of compound 3 to be *Z*11-16:OH by matching its retention times on the DB-5 and BPX-70 columns (KIs of 1865 and 2518, respectively) with those of the *Z*11-16:OH standard (Marques et al., 2000). Male *D. sublimbalis* antennae also responded well to *Z*11-16:OH (Fig. 1). Although compound 3 was a relatively minor component in extracts and not always detectable by GC-MS, we were nevertheless able to obtain an adequate spectrum from a composite extract of 36 female *D. sublimbalis* glands, which matched that of the standard. However, we were not able to verify the structure of compound 3 using DMDS derivatization because of co-elution and the small amount of material in the derivatized gland extract.

Analyses of three replicates of *D. sublimbalis* gland extract by GC-MS on the VF5-MS column revealed that *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy were present at a ca 1:1 ratio. The amount of *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy per *D. sublimbalis* pheromone gland was calculated to be 237±37 and 247±97 pg (mean ± SEM), respectively. The proportion of

*Z*11-16:OH in *D. sublimbalis* pheromone gland extracts, compared with *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy, was ca 5% (*N*=3) by GC-EAD analysis.

Field Bioassays The results of the field bioassays established that both *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy were necessary and sufficient to attract male *D. sublimbalis* moths (Fig. 2). Analysis of the data from blend trials A and B indicated significant effects for treatment ($P<0.018$ and <0.001, respectively). In both trials, the blank controls or the lures loaded with the individual compounds were not attractive to male *D. sublimbalis*. Although the binary blend of *Z*11-16:Ald and *Z*11-16:OH (treatment 6) attracted a few male moths (*N*=4) in trial A, this same mix was not attractive at the Tahira mango orchard (trial B). However, at both sites, the binary blend of *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy (treatment 5), and the ternary blend of *Z*11-16:Ald, 3*Z*,6*Z*,9*Z*-23:Hy, and *Z*11-16:OH (treatment 7) attracted moths (Fig. 2). In addition, at the mango orchard where we compared the synthetic compounds with caged virgin females, both treatments 5 and 7 were more attractive to male moths than were females. Although treatments 5 and 7 attracted similar numbers of moths in trial A, at the Tahira mango orchard (trial B), treatment 5 was more attractive to male moths than treatment 7.

In trial C, we tested a range of doses of the 1:1 blend of *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy. Effects of lure dose ($P<0.001$), assessment date ($P<0.001$), and interaction between assessment date and lure dose ($P=0.002$) were observed. Although one moth was captured in the blank trap of replicate 4 (Fig. 3), this point was not included in the statistical analysis because the moth was captured during a period of peak male flight activity, and its capture was probably a random event. No moths were captured with the 10-μg lure and only a few (*N*=13) with the 100 μg loading.

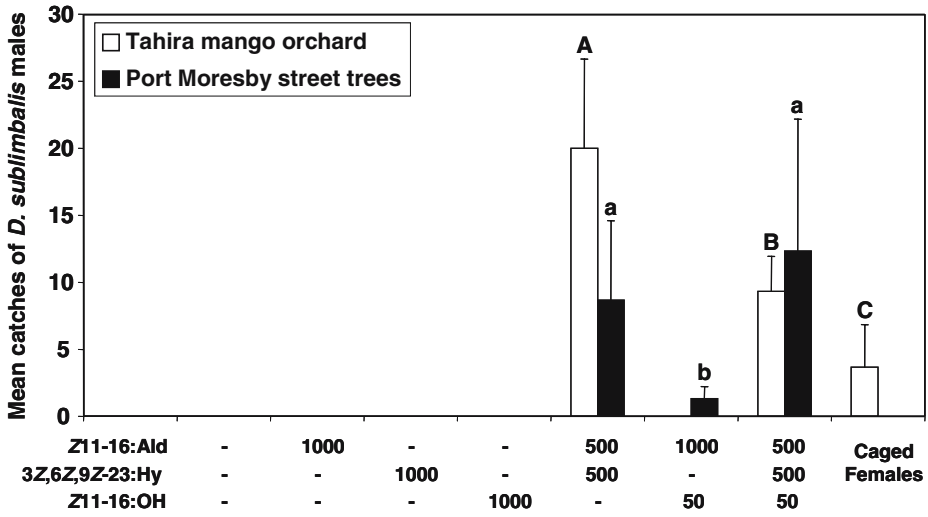

Fig. 2 Mean (+SEM) total catches of *Deanolis sublimbalis* male moths in green delta traps baited with either various combinations of the three compounds that elicited EAD responses or caged female *D. sublimbalis*, in street trees in Port Moresby, and at a mango orchard at Tahira, Central Province, Papua New Guinea (trials A and B). The caged females treatment was not included in the Port Moresby street trees bioassay. Amounts on the *x*-axis are micrograms per lure, and treatments labeled with the same letter are not significantly different ($P>0.05$)

A total of 533 moths were captured in trial C, with similar numbers recorded from traps baited with either the 1000- or 3000-μg lures (235 and 284 male moths, respectively; Fig. 3). Traps baited with the 1000-μg lure and the 3000-μg lure were still capturing male *D. sublimbalis* in similar numbers after 13 weeks. These results suggest that a 1000-μg loading would be an appropriate dose of the binary blend for detection and routine monitoring of male *D. sublimbalis*.

Toward the end of 2004, we carried out a blend trial at the Tahira and PAU sites, using less isomerically pure forms of *Z*11-16:Ald (ca 97% isomerically pure) and 3*Z*,6*Z*,9*Z*-23:Hy (ca 95% isomerically pure), but we only captured moths in traps baited with the caged females (Gibb, unpublished data). These results and the responses of male moths' antennae to *E*11-16:Ald and to isomers of 3*Z*,6*Z*,9*Z*-23:Hy (Fig. 1) suggested the likelihood of an inhibitory effect from one or more of the stereoisomers. Therefore, after obtaining high purity *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy (both >99% isomerically pure), we partially tested this hypothesis in trial D at PAU. A total of 161 moths were trapped in trial D but only with treatment 1, in which the *Z*11-16:Ald was >99% isomerically pure, thus, providing a possible explanation for the initial negative results.

Discussion

We identified *Z*11-16:Ald, and tentatively identified 3*Z*,6*Z*,9*Z*-23:Hy and *Z*11-16:OH, from extracts of the sex pheromone glands of female *D. sublimbalis* moths. None of the

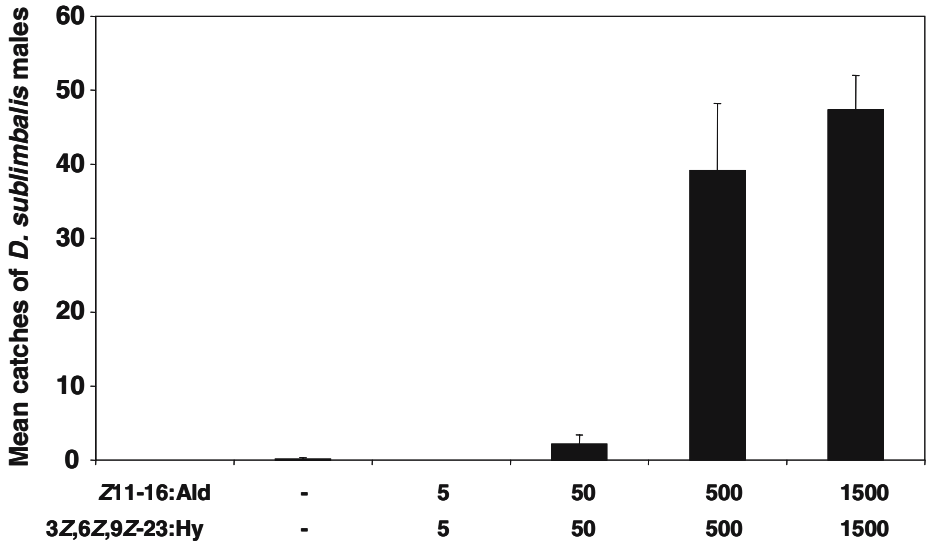

Fig. 3 Mean (+SEM) total catches of *Deanolis sublimbalis* male moths in green delta traps baited with various doses of the two-component blend of (*Z*)-11-hexadecenal and (3*Z*,6*Z*,9*Z*)-tricosatriene, in a mango orchard at Tahira, Central Province, Port Moresby, Papua New Guinea (trial C). Amounts on the *x*-axis are micrograms per lure

individual compounds were attractive and the two-component blend of *Z*11-16:Ald and *Z*11-16:OH was only weakly attractive to male moths. In contrast, the two-component blend of *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy was highly attractive, and the ternary blend was no more attractive than the binary blend of *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy at the ratios tested. A 1000-μg loading of this binary blend captured ca six times more moths than caged female *D. sublimbalis* (Trial C, Fig. 2). Effective attraction of *D. sublimbalis* male moths required *Z*11-16:Ald of high isomeric purity (trial D), indicating that the (*E*)-isomer is antagonistic. This result suggests that a sympatric species might utilize *E*11-16:Ald as a component of its sex pheromone, presumably in the India–Burma region from where both *M. indica* and *D. sublimbalis* are believed to originate (Waterhouse, 1998).

*Z*11-16:Ald is one of the most frequently identified compounds from lepidopteran sex pheromone glands, with more than 80 species producing it either singly or in combination with other compounds (El-Sayed, 2006). Conversely, the triunsaturated hydrocarbon, 3*Z*,6*Z*,9*Z*-23:Hy, has only been identified twice before in the sex pheromone glands of Lepidoptera, first, as a minor component in two arctiid species (Bell and Meinwald, 1986), and second, as a component in the sex pheromone of a South American crambid (Cabrera et al., 2001). The latter sex pheromone, consisting of *E*11-16:OH and the triene, is similar to the two-component blend identified here from *D. sublimbalis*. These blends of a comparatively short-chain monounsaturated alcohol or aldehyde and a longer-chain polyene were considered to be unusual in lepidopterans (Cabrera et al., 2001; Ando et al., 2004; Jurenka, 2004). However, this type of combination has also recently been reported in three pyralid species (Leal et al., 2005; Millar et al., 2005). Our study is the fifth such example in the superfamily Pyraloidea of a lepidopteran sex pheromone that comprises both a type I and a type II compound, adding additional weight to the suggestion by Millar et al. (2005) that such blends are likely to be relatively common.

The pheromone can now be used for detection and monitoring of this invasive pest in the quarantine area of Cape York Peninsula and the Torres Strait islands. In addition, the pheromone has the potential to be used for control of *D. sublimbalis* in commercial mango plantings using mating disruption or mass trapping (Suckling, 2000). However, trapping systems other than the delta traps used in our trials should be evaluated to avoid trap saturation, as a prerequisite to any mass trapping trials (e.g., bucket traps; see Gibb et al., 2006). Similarly, dispersal and mating behavior of *D. sublimbalis* needs further study before any such direct control attempts. For example, Sujatha and Zaheruddeen (2002) reported that adult *D. sublimbalis* moths are "very sluggish", and therefore, probably not capable of flying long distances, but no empirical data were provided. Limited dispersal would be a distinct advantage for control using mass trapping or lure and kill tactics.

Our data (this study, Trial C) suggest that a 1000-μg loading of the binary mix of *Z*11-16:Ald and 3*Z*,6*Z*,9*Z*-23:Hy on a red rubber septum is an effective attractant for male *D. sublimbalis* moths under tropical field conditions in PNG. However, further development of the pheromone as a management tool will also require its field longevity to be established unequivocally, ideally, in conjunction with a study to compare red rubber septa with alternative lure matrixes.

Acknowledgement We thank Sine Gelua for technical assistance with rearing insects and field bioassays and Adam Matich and Andréa Stephens for commenting on an earlier version of the manuscript. Funding was provided by the Australian Center for International Agriculture Research (ACIAR), Horticulture Australia Ltd (HAL), Growcom (formerly Queensland Fruit and Vegetable Growers Association), and the New Zealand Foundation for Research, Science and Technology (FRST), under "Better Border Biosecurity" and previous programmes, to develop scientific capability to respond to biosecurity incursions.

Abstract Two Melittini species, *Macroscelesia japona* and *M. longipes* (Lepidoptera: Sesiidae), are native to Japan, but occupy different localities as their host plants seldom grow together. The contents of the sex pheromone gland of adult females of both species, obtained after rearing larvae collected from the field, were investigated by gas chromatograph-electroantennogram detection (GC-EAD) and gas chromatograph-mass spectrometry (GC-MS) analyses. Two GC-EAD-active components were found in a crude extract of *M. japona* female pheromone gland, and identified as (2*E*,13*Z*)-2,13-octadecadien-1-ol (E2,Z13-18:OH) and (2*E*,13*Z*)-2,13-octadecadienal (E2,Z13-18:Ald). The average ratio of these two components was about 1:10. In the field, *M. japona* males were attracted to traps baited with E2,Z13-18:Ald alone, but the strongest attraction was observed with a 1:100 mixture of E2,Z13-18:OH and E2,Z13-18:Ald. The same two components were found in extracts of *M. longipes* females, but in a markedly different ratio. Male *M. longipes* were attracted most strongly to lures containing a 20:1 mixture of

E2,Z13-18:OH and E2,Z13-18:Ald, although some males were also attracted to lures with E2,Z13-18:OH alone. Although the two species do not generally occur in sympatry, our data indicate that, in the event of overlap, cross attraction of the two species is unlikely.

Keywords (2*E*,13*Z*)-2,13-octadecadien-1-ol · (2*E*,13*Z*)-2,13-octadecadienal · Clearwing moth · Melittini · Reproductive isolation · Lepidopteran pheromones

Introduction

The Sesiidae is a family that includes over 1,000 diurnal species worldwide (Pühringer and Kallies, 2004). Adults of most species have wasp-mimic stripes (yellow or red bands with a black body), in a species-specific pattern that may be involved in mate recognition. In addition to visual cues, sesiids use female sex pheromones in mating (Bûda and Karalius, 1985; Karalius and Bûda, 1993). Since the original study on *Synanthedon pictipes* and *S. exitiosa* by Tumlinson et al. (1974), the sex pheromones of 15 species of Sesiidae have been identified (Ando, 2006). These identifications, however, have been mainly conducted in Europe and the United States, and information about Asian species is limited. About 30 yr ago, sex attractants for two agricultural pests, *S. hector* and *S. tenuis*, were discovered by a field screening test in Japan by using a synthetic pheromone of *S. pictipes* and related compounds (Yaginuma et al., 1976; Tamaki et al., 1977). However, no actual pheromone identifications were published on the Japanese species in this family until our recent study on *Nokona pernix* (Naka et al., 2006).

The Sesiidae are divided into two subfamilies, Sesiinae and Tintiinae, with the former subdivided into six tribes: Synanthedonini, Paranthrenini, Melittini, Sesiini, Osminini, and Cissuvorini. Pheromone studies worldwide have been carried out mainly with species in the tribes Synanthedonini and Paranthrenini. Species in each of the six tribes occur in Asia, but no species in the tribe Osminini are found in Japan (Arita and Ikeda, 2000; Pühringer and Kallies, 2004). The tribe Melittini is one of the largest tribes of Sesiinae, comprising six genera and 150 species in Asia, Africa, and the New World (Pühringer and Kallies, 2004). However, pheromones have been reported only for one species, *M. cucurbitae* (Klun et al., 1990). In Japan, six species in the tribe Melittini, two *Macroscelesia* species and four *Melittia* species, are known (Arita and Ikeda, 2000). Both *Macroscelesia* species are monophagous, feeding on different host plants in different habitats. Larvae of *M. japona* burrow into the stems of *Gynostemma pentaphyllum*, whereas larvae of *M. longipes* bore into the stems of *Actinostemma lobatum* (Arita and Ikeda, 2000). *G. pentaphyllum* grows commonly in Japanese coppices, whereas *A. lobatum* is an endangered species, growing in riverbeds. In Japan, almost all rivers are now enclosed between protective walls, virtually removing all habitats for *A. lobatum*. *M. longipes*, which feeds exclusively on *A. lobatum*, and has shown a consequent reduction in numbers.

Although *G. pentaphyllum* and *A. lobatum* seldom grow together, it is possible that adults of the two moths might coincide as they have similar flight periods and their distributions may be in close proximity. With this in mind, we set about to determine whether the two closely related clearwing moths have different pheromone systems, as well as to increase the information on pheromone components used by Asian sessiid species. This report deals with the identification and field evaluation of the first pheromones from clearwing moths in the tribes Melittini.

Methods and Materials

Insects and Pheromone Extraction About 40 overwintering larvae of *M. japona* were collected in Maihara City, Shiga Prefecture, in November 2003 and vernalized in a refrigerator at 8±1°C without light for 2 mo. After vernalization, insects were kept in a plastic cage at 25±1°C under a 15L: 9D photoperiod until they emerged as adults. Adults were sexed based on their antennae (Arita and Ikeda, 2000). Under laboratory conditions, females exhibited the calling position irregularly during the photophase. Therefore, we observed the behavior of 1- or 2-d-old virgin females and excised their abdominal tips when a calling position was observed. Abdominal tips were placed individually in hexane (250 μl/female) for 5 min to extract the pheromone, before analysis by gas chromatography- electroantennographic detection (GC-EAD; Struble and Arn, 1984) and gas chromatography-mass spectrometry (GC-MS).

For the study on *M. longipes*, about 20 galls containing larvae were collected from a riverbed near Lake Sanaru in Hamamatsu City, Shizuoka Prefecture, in August 2003. The galls were kept at 25±1°C under a 15L-9D photoperiod until the adults emerged after 15–20 days. As *M. longipes* females showed a calling position 1–4 hr after the beginning of the photophase, their abdominal tips were excised 4 hr after the beginning of the photophase. Extracts were made and analyzed as for *M. japona*.

Chromatography and Derivatization of the M. japona Pheromone The crude extract of pheromone glands [10 female equivalents (FE)] was adsorbed on a microcolumn packed with Florisil® (100–200 mesh, Floridin Co., 200 mg). The column was successively eluted with 1 ml each of hexane and 5, 10, 20, and 50% diethyl ether in hexane. Each fraction was concentrated by a gentle nitrogen stream and an aliquot (1 FE) analyzed by GC-EAD. The 5% diethyl ether fraction (9 FE), which included an electroantennogram (EAG)-active aldehyde component, was treated with $NaBH_4$ (0.5 mg) in 2-propanol (0.1 ml) for 3 hr at room temperature. After mixing with water (1 ml), the crude products were extracted with hexane (0.5 ml) and analyzed by GC-MS.

Chemicals (2*E*,13*Z*)-2,13-octadecadienyl acetate (E2,Z13-18:OAc) was supplied by Shin-Etsu Chemical Co., Ltd. (Tokyo, Japan). The sample included traces (<2%) of some unknown impurities, but not the corresponding alcohol. (2*E*,13*Z*)-2,13-octadecadien-1-ol (E2,Z13-18:OH) was prepared by the hydrolysis of E2,Z13-18:OAc with methanolic NaOH. Other geometric isomers of (2,13)-octadecadien-1-ol were synthesized from 1,9-nonanediol. Their synthesis and structure confirmation by NMR analysis have been reported in a previous paper (Naka et al., 2006). (2*E*,13*Z*)-2,13-octadecadienal (E2,Z13-18:Ald), was obtained by oxidation of E2,Z13-18:OH with pyridinium chlorochromate in CH_2Cl_2. ^{1}H NMR: δ (ppm) 0.90 (t, 3H, *J*=7.3 Hz), 1.2–1.4 (broad s, 16H), 1.50 (m, 2H), 2.02 (m, 4H), 2.33 (dt, 2H, J=7 and 7 Hz), 5.35 (m, 2H), 6.12 (dd, 1H, *J*=7.9 and 15.6 Hz), 6.85 (dt, 1H, *J*=6.8, and 15.6 Hz), 9.50 (d, 1H, *J*=7.9 Hz). ^{13}C NMR: δ (ppm) 14.0, 22.4, 26.9, 27.2, 27.9, 29.2, 29.3, 29.4, 29.5 (× 2), 29.8, 32.0, 32.8, 129.8, 129.9, 133.0, 159.1, 194.2.

Analytical Instruments The GC-EAD apparatus and conditions have been reported (Naka et al., 2006). Briefly, an HP-5890 Series II gas chromatograph, (Hewlett-Packard, Wilmington, DE, USA) with a DB-23 capillary column (0.25 mm×30 m, J&W Scientific, Folsom, CA, USA) was used for the analyses. The oven temperature was maintained at

100°C for 2 min, programmed at a rate of 20°C/min to 175°C, then at 6°C/min to 220°C, and held at this temperature for 15 min. The effluent from the column was split at a ratio of 1:1 into two lines, one of which led to a flame ionization detector (FID) and the other to the EAD. GC-MS analyses were conducted in electron impact ionization mode (EI, 70 eV) using an HP-5973 mass spectrometer interfaced to an HP-6890 gas chromatograph, using the same column and conditions as for the GC-EAD analyses. The ion source temperature was 230°C. ^{1}H and ^{13}C NMR spectra were recorded using a JEOL Alpha 500 Fourier transform spectrometer at 500.2 and 125.7 MHz, respectively, for $CDCl_3$ solutions containing TMS as an internal standard.

Field Tests Attraction of *M. japona* males to synthetic lures was examined at coppices in Ibaraki Prefecture. Test I was conducted in Chikusei and Tsukuba cities from June 30 to July 12, 2003; test II was conducted in Tsukuba City from June 25 to July 10, 2003; and tests III and IV were performed in Tsukuba City from June 17 to July 16, 2004. Test chemicals were absorbed onto a white rubber septum (Sigma-Aldrich Co., St. Louis, MO, USA), which was placed in the center of a sticky board trap (Takeda Chem. Co. Ltd., Tokyo, Japan). Traps were placed 1.5 m above the ground and at least 10 m from each other. Numbers of captured males in each trap were counted every few days. After counting, the traps were rotated to eliminate any positional effect (Latin square design; Perry et al., 1980).

Trials testing *M. longipes* synthetic pheromone were conducted over 4 d in mid-August, 2004 at the riverbed of an oxbow in Fujimi City, Saitama Prefecture. As *M. longipes* is an endangered species, we did not capture males with a sticky trap but recorded their behavior around rubber septa baited with synthetic chemicals. Each septum was fixed to a riverside plant with a safety pin, 50 cm above the ground.

Statistical Analyses The EAG data that used 1 ng of synthetic pheromone compounds (see Fig. 3a and c) were analyzed by one-way ANOVA. Means that were significantly different were separated by Tukey–Kramer's HSD test (Sokal and Rohlf, 1995). For the EAG-dose data, using synthetic E2,Z13-18 compounds and for the field trials, the data were log-transformed before analysis by one-way ANOVA. Means that were significantly different were separated by Tukey–Kramer's HSD test. The level of significance in all tests was set at 5%.

Results

Identification of Pheromone Components of M. japona Male *M. japona* antennae were stimulated by two components, I and II (Fig. 1a). Component I eluted from a Florisil® column with 10% ether in hexane, indicating an alcohol, whereas component II eluted with 5% ether in hexane, indicating an acetate or aldehyde. The mass spectrum of component I (Fig. 1b, c) showed M^+ at m/z 266 (relative intensity: 1.4%), $[M\text{-}H_2O]^+$ at m/z 248 (10.1%), and a series of fragment ions derived from straight-chain compounds, indicating octadecadien-1-ol. The spectrum is similar to that of synthetic E2,Z13-18:OH, which is easily distinguished from spectra of 3,13-octadecadien-1-ol by the relative intensity of M^+ and $[M\text{-}H_2O]^+$ (Naka et al., 2006). The retention time (R_t) of Component I was the same as that of authentic E2,Z13-18:OH, but different from those of the three other geometric isomers [(2*E*,13*E*)-isomer, R_t 11.30 min; (2*Z*,13*E*)-isomer, R_t 11.46 min; (2*Z*,13*Z*)-isomer,

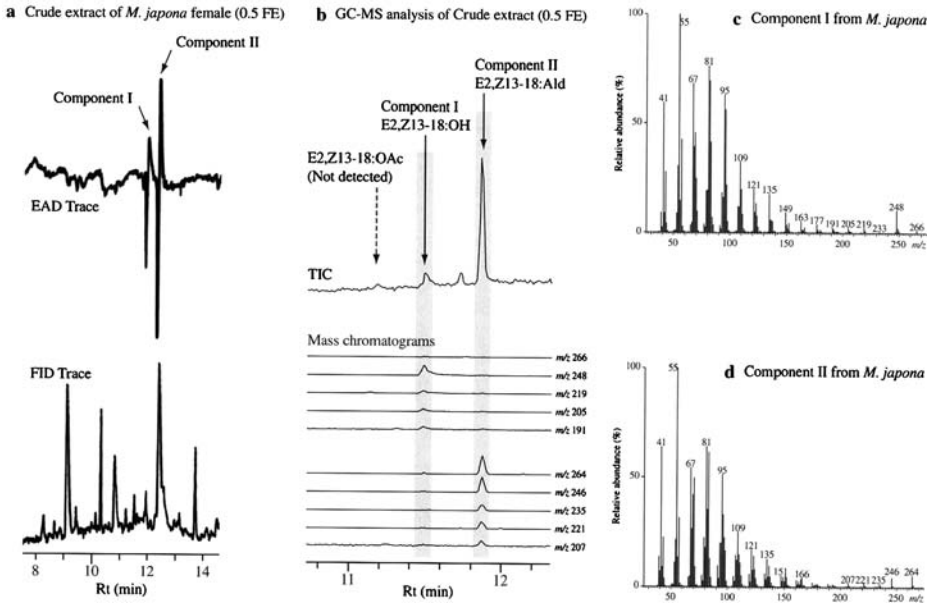

Fig. 1 Analysis of the sex pheromone components of *Macroscelesia* japona by GC-EAD and GC-MS. (a) GC-EAD analysis of pheromone extract (0.5 FE). (b) GC-MS analysis of extract (0.5 FE); total ion chromatogram (TIC) and mass chromatograms monitoring diagnostic ions at *m/z* 266 (M^+ of E2,Z13-18:OH), *m/z* 248 ($[M-18]^+$ of alcohol and $[M-60]^+$ of acetate), 219, 205, and 191 of E2,Z13-18:OH and E2,Z13-18:OAc, and *m/z* 264 (M^+), 246 ($[M-18]^+$), 235, 221, and 207 of E2,Z13-18:Ald. E2,Z13-18:OAc was not detected in the crude extract. (c) Mass spectrum of Component I (E2,Z13-18:OH). (d) Mass spectrum of Component II (E2,Z13-18:Ald)

R_t 11.67 min]. The mass spectrum of component II showed M^+ at m/z 264 (4.4%) and $[M-H_2O]^+$ at m/z 246 (4.4%), indicating an octadecadienal (Fig. 1c, d). This spectrum corresponded closely to that of synthetic E2,Z13-18:Ald. Furthermore, $NaBH_4$ reduction of the 5% ether fraction produced E2,Z13-18:OH, indicating that Component II was E2,Z13-18:Ald. Ten GC-MS injections (1 FE each) of different extracts allowed determination of the mean amounts of the two components: 0.3±1.2 ng/female for E2,Z13-18:OH and 4.2±5.4 ng/female for E2,Z13-18:Ald. The two components were in a ratio of roughly 1:10, although there was considerable variation among samples. No other candidate pheromone chemicals, such as E2,Z13-18:OAc, could be detected (Fig. 1b).

Identification of Pheromone Components of M. longipes Antennae of *M. longipes* males exhibited consistent EAG responses to two compounds with the same retention times as components I and II of *M. japona* (Fig. 2a). GC-MS analysis of the pheromone extract (Fig. 2a–d) confirmed that extract of *M. longipes* pheromone gland contained E2,Z13-18:OH and E2,Z13-18:Ald. Three GC-MS injections (1 FE each) of *M. longipes* extract gave a mean titer of E2,Z13-18:OH of 16.8±8.0 ng/female. E2,Z13-18:Ald was detected in one sample (0.4 ng/female), but not in the other two.

EAG Activities of Synthetic Compounds EAG responses of male antennae to synthetic compounds known to be pheromone components of Sesiidae were determined for the two

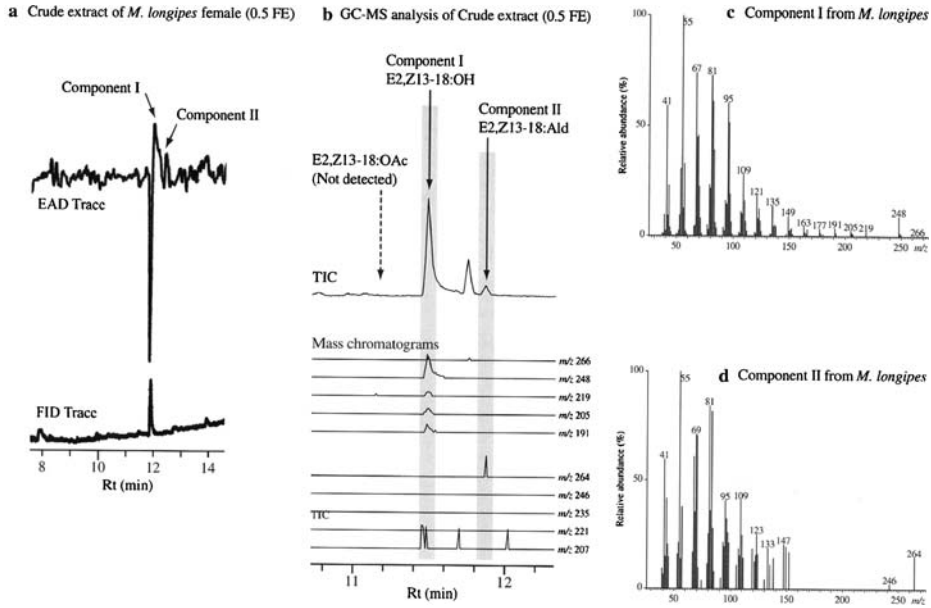

Fig. 2 Analysis of the sex pheromone components of *Macroscelesia* longipes by GC-EAD and GC-MS. (a) GC-EAD analysis of pheromone extract (0.5 FE). (b) GC-MS analysis of extract (0.5 FE); total ion chromatogram (TIC) and mass chromatograms monitoring diagnostic ions at *m/z* 266 (M^+ of E2,Z13-18:OH), *m/z* 248 ($[M-18]^+$ of alcohol and $[M-60]^+$ of acetate), 219, 205, and 191 of E2,Z13-18:OH and E2,Z13-18:OAc, and *m/z* 264 (M^+), 246 ($[M-18]^+$), 235, 221, and 207 of E2,Z13-18:Ald. E2,Z13-18:OAc was not detected in the crude extract. (c) Mass spectrum of Component I (E2,Z13-18:OH). (d) Mass spectrum of Component II (E2,Z13-18:Ald)

Macroscelesia species (Fig. 3). *M. japona* antennae showed the greatest response to E2, Z13-18:Ald, the more abundant component in the pheromone gland of females, and a moderate response to E2,Z13-18:OH, the less abundant compound (Fig. 3a). Responses to both compounds were greater than responses to all other compounds tested (ANOVA, $df=6$, $F=21.50$, $P<0.01$). There were no significant differences in response of antennae with respect to dose of three 2,13-dienyl compounds. However, the relative response to the three different compounds was the same at all doses (E2Z13-18:Ald> E2Z13-18:OH> E2Z13-18:OAc) (Fig. 3b). *M. longipes* antennae showed the greatest EAG response (greater than to all other compounds tested; ANOVA, $df=6$, $F=9.90$, $P<0.01$) to E2,Z13-18:OH, the most abundant compound in the female pheromone gland extract (Fig. 3c). Again, there were no significant differences in response to antennae with respect to dose of the three 2,13-dienyl compounds. However, EAG responses to E2,Z13-18:OH were greater than responses to the other two compounds at all three doses tested (Fig. 3d).

Field Attraction of M. japona Males Of the single-component lures baited with one of the 2,13-dienyl compounds, only traps baited with E2,Z13-18:Ald caught male *M. japona* (Test I, Table 1). When different amounts of E2,Z13-18:OH or E2,Z13-18:OAc were added to E2,Z13-18:Ald, surprisingly, only traps baited with both E2,Z13-18:OAc and E2,Z13-18:Ald caught males (Test II, Table 1). As treatments with E2,Z13-18:OAc appeared to shut down trap capture to all other blends (including to that of E2,Z13-18:Ald alone), further tests were conducted in which the effect of the alcohol component was evaluated in a field

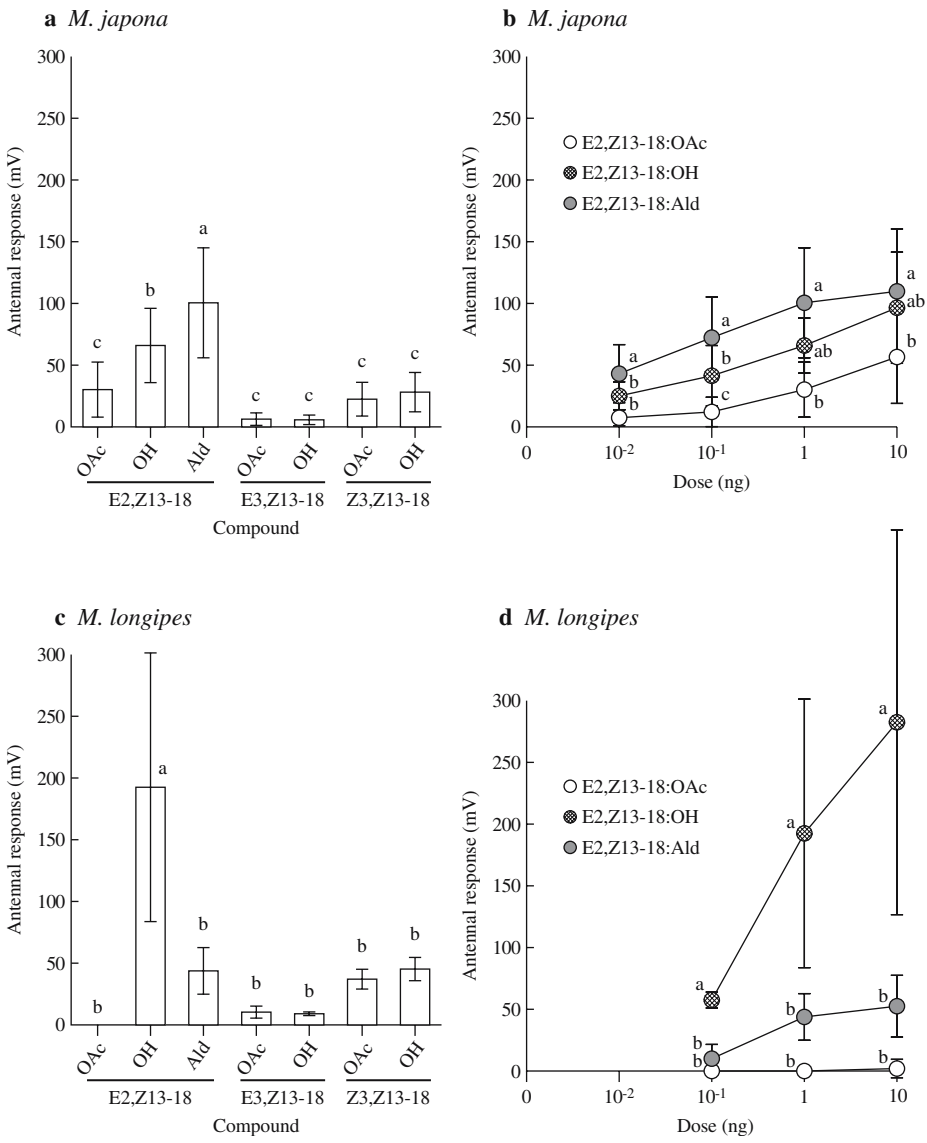

Fig. 3 EAG responses of *Macroscelesia japona* and *M. longipes* males. (a) EAG responses of antennae of *M. japona* males to synthetic standards (1 ng). (b) Responses of antennae of the *M. japona* males to various doses of (2*E*,13*Z*)-2,13-octadecadienyl compounds. (c) EAG responses of antennae of *M. longipes* males to synthetic standards (1 ng). (d) Responses of antennae of the *M. longipes* males to various doses of (2*E*,13*Z*)-2,13-octadecadienyl compounds. Responses are the means of at least ten antennae of *M. japona* and four antennae of *M. longipes*. Values followed by a different letter are significantly different at $P<0.05$ (Tukey–Kramer's HSD test) in (a)–(c). In (d), values followed by a different letter are significantly different at $P<0.05$ (Tukey–Kramer's HSD test) for a given dose of the different compounds

about 4 km from the field testing mixtures of the aldehyde and acetate. Traps baited with lures containing both E2,Z13-18:Ald and E2,Z13-18:OH caught significant numbers of males (Test III, Table 1), with the greatest numbers (significantly greater than for all other treatments) being caught in the 1:100 (E2,Z13-18:OH: E2,Z13-18:Ald) blend. Again binary

[a] Test I was performed in two fields (N=3); Chikusei City (a private coppice under Kokai-Ohashi Bridge) and Tsukuba City (coppices in NIAES) from June 30 to July 12, 2003. Test II was performed in Tsukuba City (N=4); coppices in NIAES, NIES and Yukari-no-Mori from June 25 to July 10, 2003. Tests III and IV were performed in the same fields as Test II (N=3) from June 17 to July 16, 2004.

[b] Values followed by a different letter are significantly different at the 5% level by Tukey-Kramer test.

blends of E2,Z13-18:Ald and E2,Z13-18:OAc caught significant numbers of male *M. japona* (Test IV, Table 1).

Field Attraction of M. longipes Males Because *M. longipes* males fly slowly, their behavior around synthetic lures could readily be observed in the field. Two behaviors were observed: approaching the lure and touching the lure with forelegs. Males only approached lures containing E2,Z13-18:OH (Table 2). About half of the approaching males touched the lures. The greatest numbers of males that approached lures did so to binary blends of E2,Z13-18:OH and E2,Z13-18:Ald; the numbers that approached the 1,000:50 and 1,000:300 lures were significantly greater than the number that approached the lure containing only E2,Z13-18:OH. Greater numbers of males touched the 1,000:50 lure (E2,Z13-18:OH: E2,Z13-18:Ald) than touched any of the other lures. The numbers of males that approached or touched the binary blend of E2,Z13-18:OH and E2,Z13-18:OAc were not significantly

different from the numbers that approached or touched the lure containing only E2,Z13-18:OH (Table 2).

Discussion

GC-EAD, GC-MS analyses of pheromone extracts, combined with field studies, revealed E2,Z13-18:OH and E2,Z13-18:Ald as common pheromone components of two *Macroscelesia* species, *M. japona*, and *M. longipes*. The major component of the former species was aldehyde and that of the latter was alcohol. These compounds were identified by comparison with chemical data of known compounds, not by direct chemical reaction, because of the limited number of available insects. All the dienyl compounds known as Sesiidae pheromones or attractants have a C_{18}-chain skeleton unsaturated at the 3- and 13-positions or the 2- and 13-positions (Ando, 2006). The GC-MS data of the alcohol component of both *Macroscelesia* species strongly indicated a 2,13-dienyl structure (Naka et al., 2006). Configurations of the two double bonds were determined by comparing R_t values of the natural component and the four geometric isomers. The second component was indicated as an aldehyde by its elution time on the DB-23 column. The double-bond positions and configurations of the aldehyde component from *M. japona* females were determined by reduction by $NaBH_4$ to produce the same dienyl alcohol as the other pheromone component. To assist in pheromone identifications of other sessiid moths, we intend to synthesize the four geometric isomers of 2,13-18:Ald.

Compounds with the C_{18} 2,13-dienyl skeleton have been reported as sex pheromones in several species in the lepidopteran families of Sesiidae, Cossidae, and Tineidae. All these compounds have a (2*E*,13*Z*)-configuration; no 2,13-dienes with other configurations have been found in pheromone gland extracts of female moths. (Ando, 2006; El-Sayed, 2006). In the Sesiidae, E2,Z13-18:OH and E2,Z13-18:Ald have been identified only from *Melittia cucurbitae* (Klun et al., 1990) and *Sesia apiformis* (Francke et al., 2004), respectively,

whereas E2,Z13-18:OAc has been identified in a number of species. Interestingly, *Melittia cucurbitae* is taxonomically close to *Macroscelesia* spp.

The reproductive isolation of sibling species, through use of different blends of common sex pheromone components, has been reported in many species of moths (Löfstedt et al., 1991; Ishikawa et al., 1999). Our study revealed that two *Macroscelesia* species produce the same two pheromone components, E2,Z13-18:OH and E2,Z13-18:Ald, but apparently in a different ratio. In accord with this, males of the two species appear to respond optimally to blends similar to those produced by their respective females: 1:100 for *M. japona* males and 20:1 for *M. longipes* males (Tables 1 and 2). Although single-component blends that are attractive to the other species were tested in the respective habitats of the two species, no *M. japona* males approached lures in the habitat of *M. longipes*, and no *M. longipes* males were captured in traps in the test for *M. japona* males. This result suggests that geographical overlap of the species is not common (at least in the areas tested), and precludes any possible hybridization of the two species. However, if there were any geographical overlap, our data suggest that there would be little, if any, cross attraction between the species.

Although E2,Z13-18:OAc was not detected in the pheromone glands of the two *Macroscelesia* species, we were interested in its activity with respect to males of the two species. The acetate appeared to have little effect on *M. longipes* males. However, in the case of male *M. japona*, addition of this compound to E2,Z13-18:Ald gave increased trap captures relative to the latter compound alone. Field Tests II and IV indicated that E2,Z13-18:OAc may have acted as a substitute for E2,Z13-18:OH, the minor pheromone component of *M. japona*. Substitution of a minor component by other analogs has been observed in other lepidopteran species (Linn et al., 1984; Sugie et al., 2003; Inomata et al., 2005). However, in field Test II, the blends of the aldehyde and acetate caught significantly greater numbers of moths than the natural blends of the aldehyde and alcohol, with trap catches to the latter blends being completely suppressed. This preferential response to an unnatural blend over a natural one is perplexing, and suggests that *M. japona* males could be attracted to another species that produces a blend of E2,Z13-18:Ald and E2,Z13-18:OAc. To date, no species using this mixture as a sex pheromone has been identified, and the mixture in our field trials attracted no other species. However, considering the diversity of Sesiidae, and the apparent limited variety of chemicals used by this family as pheromone components, it is possible that some species secrete such a mixture. Further studies on a greater number of species of Sessiidae are necessary to identify such species.

Acknowledgments We are grateful to Mr. R. Wakasugi, D. Wakatsuki, S. Onodera, and students of the Laboratory of Zoology at Meijo University, and Mr. T. Takamura in Nagoya City for collecting galls of *Macroscelesia* spp., Dr. F. Mochizuki of Shin-Etsu Chemical Co., Ltd. for supplying dienyl acetate. We also thank Drs. A. Mochizuki and K. Ito at NIAES, T. Nakazawa at BASE, and Mr. K. Fukuzumi in Nagoya City for advice and information. This work was supported in part by a research fund from Heart Co. Ltd. (Tokyo, Japan).

Mice Respond Differently to Urine and Its Major Volatile Constituents from Male and Female Ferrets

Abstract Our previous chemical investigation showed that the concentrations of urinary volatiles from males were much higher than those from females in the ferret (*Mustela furo*). The current study was designed to examine the behavioral significance and ecological relevance of this difference for one of the main prey of the ferret, the house mouse (*Mus musculus*). Our data showed that male mice displayed no difference in their response to raw male and female ferret urine. However, they showed significantly less response to female mouse urine mixed with ferret urine than to pure female mouse urine, and to female mouse urine mixed with male ferret urine than to female mouse urine mixed with female ferret urine. Furthermore, high levels of the three major volatiles (quinoline, 2,5-dimethylpyrazine, and 4-hepatanone) in male ferret urine were as effective as raw male ferret urine was in inhibiting the response of male mice. We discuss the ecological and behavioral significance of these findings in terms of chemical mimicry and cognitive feature extraction of predator odors in mice.

Introduction

Numerous studies have shown that predator odor can modify rodents' behavior and physiology. Further investigation has revealed that some key volatiles from carnivore feces, specialized skin gland secretions, and urine play crucial roles in the process, although they are usually not as effective as the natural scent sources in their entirety (Mason et al., 1994; Müller-Schwarze, 1995; Apfelbach et al., 2005). Few attempts have been made to investigate whether male and female predator' odors can elicit differential responses from their prey (Apfelbach et al., 2005). One exception is the study by Stoddart (1980), although he failed to find any difference in the response of rodents to male and female cat odors. Our recent chemical analysis of ferret (*Mustela furo*) urine revealed that the total amount of volatiles in male urine was 10 times that in female urine. This dramatic difference may provide a source for rodent prey to respond differentially so as to exploit the behavioral difference between male and female ferrets (Zhang et al., 2005).

Although sympatric predators possibly exert a stronger effect than allopatric predators do on their rodent prey (Mappes et al., 1998), the prey's response to the odors of predators is generally considered to be innate due largely to sulfur compounds common in carnivores (Mason et al., 1994). For this reason, search for carnivore scent-based rodent repellents has mainly focused on sulfur-containing compounds (Vernet-Maury et al., 1984; Sullivan et al., 1988a,b; Epple et al., 1995; Burwash et al., 1998; Bramley and Joseph, 2001). However, chemical investigation has revealed that sulfur compounds in secretions or excretions from some carnivores are often minor components or even absent (Preti et al., 1976; Brinck et al., 1983; Schildknecht and Birkner, 1983; Raymer, 1984; Raymer et al., 1985; Service et al., 2001; Buesching et al., 2002a,b). This suggests that nonsulfur compounds may be important in the response of rodents to their predators. Indeed, Nolte et al (1993) reported that several nonsulfur-containing compounds repel mice. One such compound is o-aminoacetophenone, a volatile chemical commonly found in the anal gland secretions of several *Mustela* species (Brinck et al., 1983; Zhang et al., 2003, 2005).

Ferret urinary volatiles are nonsulfur compounds, with quinoline, 2,5-dimethylpyrazine (2,5-DMP), and 4-heptanone as the major constituents (Zhang et al., 2005). The proportions of these three compounds in total urinary volatiles are 39.0%, 25.0%, and 22.4% in males, and 41.9%, 9.2%, and 6.8% in females, respectively (Zhang et al., 2005). Previous work showed that sulfur compounds from the anal glands of ferrets can elicit aversive response from rodents (e.g., Sullivan et al 1988a,b; Mason et al., 1994; Epple et al., 1995). However, some findings suggest that urine (without sulfur compounds) from *Mustela* species, such as American minks (*M. vison*) and ferrets, can also alter the behavior of rodents (Epple et al., 1993; Roberts et al., 2001; Cloe et al., 2004).

Interestingly, both 2,5-DMP and 4-heptanone are also found in urine from female house mice. The former is a female-specific pheromonal compound, whereas the latter is associated with pregnancy and lactation (Novotny et al., 1986; Jemiolo et al., 1987). This coincidence of chemical compounds between predator and prey raises the question of how male mice respond to potentially conflicting information from female conspecifics and their main predator. Our present work, therefore, is aimed at answering the questions of whether ferret male and female urine can elicit differential responses and whether the synthetic analogues of the three major volatile constituents can inhibit the response of house mice. Regarding the first question, because the major urinary volatiles are different between male and female ferrets, we hypothesize that mice can differentiate between male and female ferret urine. For the second question, since the presence of a major predator poses a high risk to mice, the potential attraction of male to female mice could be overcome by the presence of a life-

threatening predator. For this reason, we hypothesize that the responses of mice will be more strongly affected by chemicals unique to predator urine than by chemicals common to the urine of both mice and predator.

Methods and Materials

Experimental Animals

Mice We used 23 naïve male and 12 female ICR/Albino house mice, age 9–10 mo. They were purchased from Harlan Sprague–Dawley, Inc., Indianapolis, IN, USA, and were kept individually in polypropylene cages (27×12×17 cm) in Indiana University Animal Facility. The mice were housed at 21±0.2°C and 50–70% RH. A 12L:12D reverse light cycle regime was used with light on at 2200 hours. Purina Mouse Chow and water were supplied *ad libitum*. The bedding material (sawdust) was changed weekly. Test males used as odor recipients were randomly assigned to two groups for experiment series 1 (12 males) and experiment series 2 (11 males), respectively. The subjects were used in random order. Four estrous females were selected as urine donors.

Ferrets Four adult male and five adult female ferrets in breeding condition (about 1 yr of age) were purchased from Marshall Farms (North Rose, NY, USA). Upon arrival at the Boston University Animal Facility, they were individually housed in modified rabbit cages under a long-day (16L:8D) photoperiod. Ferrets were fed with moistened Purina Ferret Chow once a day, whereas water was available *ad libitum*. The handling procedure for mice and ferrets complied with the institutional guidelines for animal use and care for both Indiana University and Boston University.

Sample Preparation and Experimental Procedure

Quinoline, 2,5-DMP, and 4-heptanone were purchased from Aldrich Chemical Company. They were each diluted to 0.5% in deionized water for the behavioral test. We roughly estimated the concentrations of quinoline, 2,5-DMP, and 4-heptanone to be 0.96, 0.64, and 0.54 ppm, respectively, in male ferret urine by comparing their gas chromatographic peak areas with those of concentration-known internal standards (Zhang et al., 2005). Various odor samples of the synthetic chemicals were created by adding the synthetic compounds to either estrous female mouse urine or female ferret urine, and tested using male mice.

Experiment series 1 To characterize the responses of mice to male and female ferret odor, responses of male mice to a binary choice of raw male or female ferret urine were measured over 4 consecutive days. Next, we tested the responses of male mice to a binary choice of female mouse urine (FMU) with added male or female ferret urine at concentrations of 50%, 20%, and 10%. After finding that all concentrations were effective, we tested the responses of male mice to a binary choice of 10% raw ferret urine (either male or female) in FMU against FMU alone.

Experiment series 2 To investigate the roles of the three major volatile constituents in ferret urine on the responses of male mice to male and female ferret urine odor, we first tested FMU with only one of the synthetic chemicals, at about 40 times its natural level in male

ferret urine, against FMU. Next, we tested the permutations of FMU spiked with one of the three compounds (at about 40 times its level in male ferret urine) against each other in binary choices. Then, we tested all three chemicals (at 40 times their levels in male ferret urine) added to FMU against either FMU or FMU with quinoline (at 40 times the level in male ferret urine). Finally, we tested combinations of FMU contaminated by 10% (v/v) one of the following: (A) spiked female ferret urine (FFU) by the three synthetic chemosignals at 40 times their natural levels in male ferrets; (B) spiked FFU by them at the natural levels in males; (C) 10% raw FFU; and (D) 10% raw male ferret urine.

Urine Collection

Female mouse urine collection We determined female estrus by examining the vaginal smear. Four estrous females, out of 12, were randomly selected and each kept in a metabolic cage for urine collection for 6 hr. Urine was fed to a vial immersed in dry ice. Urine samples were stored at −20°C until used in a behavioral test.

Ferret urine collection As described by Zhang et al. (2005), ferrets were placed individually in a clean cage with a grid floor and a clean collecting pan underneath to collect urine. Fresh urine from each of four males and three females was collected and immediately stored on ice. Urine that was deposited with or next to feces was not collected. All urine samples were stored at −20°C until use. Pooled urine samples of either sex were used.

Behavioral Test

The preference of male mice to two aqueous scent samples was tested in the dark. Immediately before each trial, a test mouse in its home cage was transferred to the test room under dim light. Scent samples were presented to the mouse by a disposable glass capillary (i.d. 1.1–1.2 mm; o.d. 1.3–1.4; 15 cm length; Drummond Scientific Co., Broomall, PA, USA), similar to the methods used by Lai et al. (1996) and Zhang et al. (2001). Each capillary contained a 10-μl sample aliquot. The opening of the capillary was sealed by Tube Sealing Compound N:O 510 (Chase Instruments Corp., Rockwood, TN, USA) so as to suspend the aqueous sample inside the capillary 1 cm from the sample-containing end. The sample-containing end of the capillary was presented to a mouse, whereas the other end was held by an observer wearing disposable plastic gloves. Two aqueous samples were presented simultaneously to the test subject for 3 min after it first showed a sniffing response. The two capillaries were lowered through the wire lid and kept approximately 2 cm apart. The time that the mouse spent sniffing within 1 cm from the tip and licking the end of the capillary was recorded for both treatments. A mouse was used only once a day. Subjects whose investigating time was less than 1 s on a day were excluded for that day.

Statistical Analysis

Wilcoxon matched-pairs signed-rank test was used for behavioral response using the program SPSS (Version 10.0). The level of significance was set at $\alpha=0.05$ for all tests.

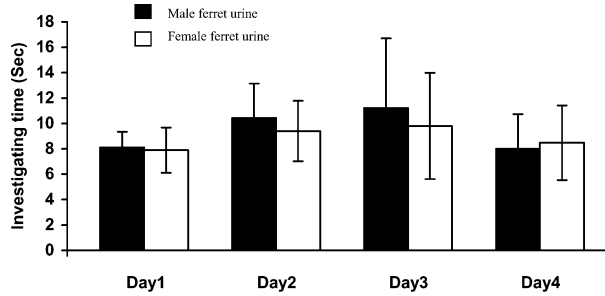

Fig. 1 Responses (mean ± SE) of male mice to male (black) and female (white) ferret urine over four consecutive days

Results

Experiment Series 1. Effects of Male and Female Ferret Urine on Responses of Male Mice

Male mice did not show a differential response to male and female ferret urine in the 3-min daily test on each of 4 successive days (Day 1: N=12, Z=0.079, P=0.938; day 2: N=12, Z=1.177, P=0.239; day 3: N=12, Z=1.098, P=0.272; day 4: N=12, Z=0.314, P=0.754) (Fig. 1). However, when 50%, 20%, or 10% of ferret urine was added to FMU, male mice spent less time investigating FMU mixed with male ferret urine than that mixed with female ferret urine (N=12, Z=2.824, P=0.005; N=11, Z=2.667, P=0.008; N=11, Z=2.756, P=0.005) (Fig. 2). Compared with FMU, adding either 10% male or female ferret urine to FMU reduced the responses of male mice (N=12, Z=3.060, P=0.002 and N=11, Z=2.667, P=0.008, respectively, Fig. 2).

Experiment Series 2: Roles of Three Major Constituents in Eliciting Responses of Mice

Effects of Single Major Components

Male mice reduced investigating time to FMU with quinoline (N=12, Z=2.667, P=0.008), 2,5-DMP (N=10, Z=2.497, P=0.013), or 4-heptanone (N=11, Z=2.134, P=0.033) compared with pure FMU (Fig. 2). Furthermore, male mice spent less time investigating FMU with quinoline compared with FMU with either 2,5-DMP (N=12, Z=2.667, P=0.008) or 4-heptanone (N=10, Z=2.293, P=0.022). They did not respond differently between FMU containing 2,5-DMP and that containing 4-heptanone (N=10, Z=0.968, P=0.330) (Fig. 3).

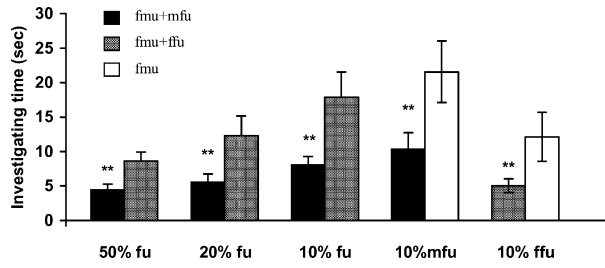

Fig. 2 Responses (mean ± SE) of male mice comparing binary choices between female mouse urine (fmu) mixed with various concentrations of ferret urine (fu), either male (mfu) or female (ffu). Additionally, binary choices between fmu and fmu plus 10% mfu or 10% ffu were compared. **P<0.01; *P<0.05

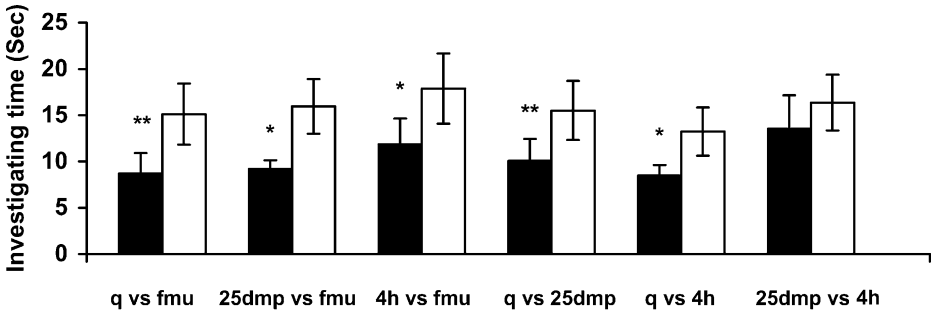

Fig. 3 Responses (mean ± SE) of male mice to female mouse urine (fmu) spiked with quinoline (q), 2,5-dimethylpyrazine (25dmp), or 4-heptanone (4h) in various binary choices. $^{**}P<0.01$; $^{*}P<0.05$

Combined Effect of the Three Major Components

FMU with quinoline, 2,5-DMP, and 4-heptanone together, reduced the investigative response of male mice compared to pure FMU ($N=10$, $Z=2.803$, $P=0.005$) or FMU with quinoline ($N=12$, $Z=2.432$, $P=0.015$) (Fig. 4).

Effect of Mimicking Male Ferret Urine by Spiking Female Ferret Urine with the Three Compounds

Male mice showed less response to FMU scented by 10% female ferret urine containing the three synthetic compounds at about 40 times their natural levels in male ferret urine, than to the same treatment with the three synthetic compounds at roughly the natural levels of male ferrets ($N=10$, $Z=2.089$, $P=0.037$). The response of mice to FMU mixed with 10% female ferret urine, with the three compounds at roughly their natural levels in male ferret urine, was also reduced compared to their response to FMU mixed with 10% raw female ferret urine ($N=10$, $Z=2.497$, $P=0.013$). There was no difference in response to FMU plus the

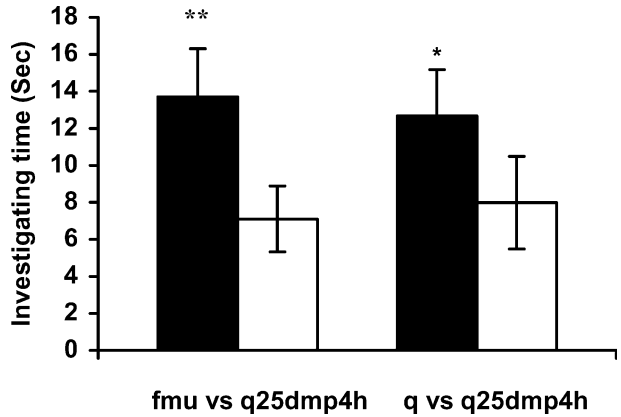

Fig. 4 Responses (mean ± SE) of male mice to female mouse urine (fmu) spiked with quinoline (q), 2,5-dimethylpyrazine (25dmp), and 4-heptanone (4h) together, versus either fmu alone or fmu with *q* only. $^{**}P<0.01$; $^{*}P<0.05$

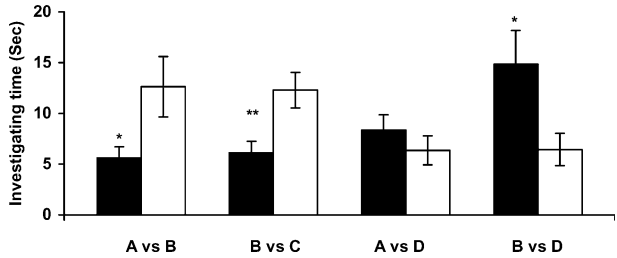

Fig. 5 Binary choices testing the responses (mean ± SE) of male mice to female mouse urine (fmu), mixed with 10% of the following: A= female ferret urine (ffu) plus quinoline (q), 2,5-dimethylpyrazine (25dmp), and 4-hepatanone (4h), all at concentrations 40 times that found in natural male ferret urine (mfu); B= ffu plus *q*, 25 dmp, and 4h, all at natural concentrations found in male ferret urine (mfu); C= ffu; D= mfu. $^{**}P<0.01$; $^{*}P<0.05$

treated female ferret urine with three synthetic compounds, at about 40 times their natural levels in male ferret urine, compared to FMU plus 10% male ferret urine ($N=10$, $Z=1.274$, $P=0.226$). In contrast, mice showed a greater response to FMU plus the three synthetic compounds, at about their natural levels in male ferret urine, compared to FMU plus 10% male ferret urine ($N=10$, $Z=2.089$, $P=0.037$) (Fig. 5).

Discussion

In experiment series 1, we found that mice did not show a difference in response to pure male and female predator odor, consistent with previous work (Stoddart, 1980). However, when female mouse urine was used as a background odor, male mice showed a differential response between sexually dimorphic male and female ferret urine (Zhang et al., 2005). Hence, our hypothesis that mice are able to discriminate between male and female ferret urinary odors is supported. A reason for the apparent discrepancy between the results may be that the response of mice to ferret odor is context-dependent. Urine of male and female ferrets by itself might represent an equal level of threat to mice. However, when mixed with female mice urine, a situation was created for male mice to leverage between a potential benefit (female mouse as a mate) and a cost (the presence of a ferret), and male mice showed behavioral differentiation between the male and female ferret urine.

In experiment series 2, our results suggest that adding any of the synthetic versions of the three compounds to the urine of estrous female mice reduced investigation by male mice. In particular, quinoline, present in ferrets but absent in mice, exhibited a stronger inhibitory effect than the other two chemicals (which are present in both ferrets and female mice) (Andreolini et al., 1987; Jemiolo et al., 1987; Zhang et al., 2005). Thus, our second hypothesis is also supported. Researchers have shown that titers of 2,5-DMP and 4-heptanone in female mice are related to the nonreceptive condition (Novotny et al., 1986; Andreolini et al., 1987; Jemiolo et al., 1987). The compound 2,5-DMP is a mouse pheromone component, which is excreted at a high level by crowded female mice, with the vital behavioral function of the Lee-Boot effect. Its level goes up during diestrous days and down on the estrous day (Novotny et al., 1986; Andreolini et al., 1987; Jemiolo and Novotny, 1993). 4-Heptanone is found in the urine of female mice, and attains a high level in pregnant and lactating females (Jemiolo et al., 1987). That is, these compounds exist in ferrets [both males and females, albeit in different quantities, see Zhang et al. (2005)] and also characterize nonreceptivity of

female mice. This may be the reason why their increases in the urine of estrous females reduced the investigative response of males. Furthermore, the coincidence in the timing of the increase of 2,5-DMP and 4-Heptanone in the urine of female mice and when male mice are unwanted supports the contention that females might chemically deceive males by mimicking the presence of ferrets. This deception could cause an opposing selection pressure for males to evolve an anti-deceptive response. Indeed, our study shows that males exhibited a stronger response to quinoline, which is present in ferrets but not female mice, than to either 2,5-DMP or 4-heptanone. In other words, quinoline may convey unambiguous information about the presence of ferrets. This presumed chemical mimicry, in terms of the function served for the mimicker, would be fundamentally different from other known mimicry systems (e.g., Pasteur, 1982; Dettner and Liepert, 1994). Further studies are needed to substantiate this as well as to investigate how such a system might evolve.

Of the three major volatile compounds in ferret urine, quinoline had the strongest deterring effect. This result demonstrates an evolutionary convergence in the response of a variety of prey animals because quinoline is also an effective repellent for ants, spiders, cockroaches, and frogs (Eisner et al., 1997). Interestingly, apart from ferret urine, quinoline is found mainly in the thoracic glands of phasmid insects (*Oreophoetes peruana*) as a defensive substance (Schildnecht et al., 1986; Zhang et al., 2005).

Our study supports the general rule that for prey recognition, individual components of an odor are less effective than the whole (Müller-Schwarze, 1995; Mason et al., 1994; Schulte et al., 1994; Apfelbach et al., 2005). This is shown by the combination of the three components being more effective than the most effective single compound (quinoline), and by the three compounds together, at their natural concentrations, being less effective than male ferret urine. With regard to the latter point, the three component blend was only as effective as male ferret urine when presented at levels much higher than their natural levels. This suggests that other minor constituents in ferret urine may also play a role in eliciting the aversive response. One possible compound is *o*-aminoacetophenone, which is a repellent for birds and mice (Nolte et al., 1993).

Acknowledgments We are grateful to Dr. Janne Sundell for valuable comments on our earlier draft. We are grateful to Drs. Sarah K. Woodley and Michael J. Baum who provided us with ferret urine. This research was supported by grants [No. DC 24180 to M.V. N] from the National Institute of Deafness and Other Communication Disorders, National Institute of Health (NIH), and US Department of Health and Human Services. The manuscript preparation and data processing were partially supported by the CAS Innovative Research International Partnership Project (CXTDS2005-4).

Abstract Urine from the house mouse, *Mus musculus domesticus*, contains a high concentration of major urinary proteins (MUPs), which convey olfactory information between conspecifics. In wild populations, each individual expresses a different pattern of around 8 to 14 electrophoretically separable MUP isoforms. To examine whether other *Mus* species express MUPs and exhibit a similar level of individual heterogeneity, we characterized urinary proteins in urine samples from an aboriginal species, *Mus macedonicus*, captured from different sites in Turkey. Anion exchange chromatography and electrospray ionization mass spectrometry demonstrated that *M. macedonicus* urine contained a single major peak of mass 18,742 Da, and in contrast to *M. m. domesticus*, all individuals were the same. The *M. macedonicus* masses were not predicted from any known MUP gene sequence. Endoproteinase Lys-C (Lys-C) digestion of the purified *M. macedonicus* urinary protein followed by matrix assisted laser desorption time of flight (MALDI-TOF) mass spectrometry demonstrated that it shared considerable, but not complete, sequence homogeneity with *M. m. domesticus* MUPs. Three *M. macedonicus* Lys-C peptides differed in mass from their *M. m. domesticus* counterparts. These three peptides were further characterized by tandem mass spectrometry. The complete sequences

of two were determined, and in conjunction with methyl esterification, the amino acid composition of the third was inferred, and the sequence narrowed down to three permutations. The complete *M. macedonicus* sequence contained a maximum of seven amino acid substitutions, discernible by tandem mass spectrometry, relative to a reference *M. m. domesticus* sequence. Six of these were on the surface of the molecule. Molecular modeling of the *M. macedonicus* sequence demonstrated that the amino acid substitutions had little effect on the tertiary structure. The differences in the level of heterogeneity between the two species are discussed in relation to their environment and behavior. In addition, the differences in protein structure allow speculation into molecular mechanisms of MUP function.

Introduction

House mice, *Mus musculus domesticus*, have evolved intricate and sophisticated methods of chemical communication (Hurst, 1987; Hurst and Beynon, 2004). The major urinary proteins (MUPs) are key components of this signaling system (Beynon and Hurst, 2004). MUPs are eight stranded beta-barrel pheromone binding proteins (Adams and Sawyer, 1990; Flower et al., 1993), encoded by a multigene family, expressed in the liver, and secreted into the urine via the kidneys (Finlayson et al., 1965). A number of small, volatile molecules have been identified as endogenous MUP ligands, most of which are reproductive priming pheromones (Bacchini et al., 1992; Robertson et al., 1993; Novotny et al., 1999) that also influence behavior (Malone et al., 2001). MUPs prolong the release of the volatile ligands from scent marks and may also protect them from oxidation (Hurst et al., 1998). However, this does not explain the extreme polymorphism that is a feature of these proteins in *M. m. domesticus*. Each individual expresses around 8 to 14 electrophoretically separable MUP isoforms, with only very closely related individuals (Hurst et al., 2001) or inbred laboratory mice (Robertson et al., 1996) expressing the same pattern. We have demonstrated that this extreme polymorphism provides a genetically stable method of communicating the individual ownership of scent marks (Hurst et al., 2001, 2005).

Knowledge of the structure and function of MUPs has mostly been derived from *M. m. domesticus*. These mice are thought to have become commensal some 10,000 yrs ago in the Fertile Crescent, utilizing some of the earliest human settlements there (Cucchi et al., 2005). Therefore, the history of *M. m. domesticus* has become inextricably intertwined with that of humans. Their innate agility and flexibility has proved ideal for the continued exploitation of human populations as a ready source of food and other resources, which has facilitated their spread from the Fertile Crescent to all parts of the world (Silver, 1995). Where food resources are abundant (for example around grain stores and livestock housing), population densities typically reach high levels (Berry, 1981; Bronson, 1979), and mice live in territorial social groups in which the ranges of many individuals overlap (Hurst, 1987; Barnard et al., 1991). *Mus m. domesticus* is one of at least three subspecies of house mice that have parapatric distributions and that interbreed where they make contact (Boursot et al., 1993). There are also three other *Mus* species (*Mus macedonicus*, *Mus spretus*, and *Mus spicilegus*) that are closely related to and occur sympatrically with *M. musculus* in Europe

and the Middle East (Boursot et al., 1993; Suzuki et al., 2004). These species are termed aboriginal mice as, unlike the commensal *M. musculus*, they live independently of humans. Commensal mouse populations differ in a number of aspects of their behavior compared to free living aboriginal species (Patris and Baudoin, 1998; Ivantcheva and Cassaing, 1999). Here, we studied the aboriginal mouse, *M. macedonicus*, a short-tailed species that is found in Greece, Turkey, and elsewhere in the Middle East. The aim of this study was to characterize MUPs from *M. macedonicus* and compare them to the well-characterized MUPs from *M. m. domesticus*.

Methods and Materials

Animals and Sampling

Adult male *M. macedonicus* and *M. m. domesticus* urine donors were caught during May–July 2001 in Sherman traps from four locations dispersed around Turkey (Fig. 1). Urine voided by the animals in response to handling (typically 20–50 μl) was collected into 1.5 ml capped polypropylene test tubes and frozen within 5 min. All samples were subsequently stored at −20°C before analysis. Reference MUPs were obtained from pooled urine samples from adult male C57BL/6 mice. These were obtained by bladder massage, frozen immediately, and stored at −20°C.

Urine Sample Preparation

Urine samples were desalted before further analysis with Vivaspin 5,000 Da molecular weight cutoff centrifugal concentrators (Sartorius, Epsom, UK). Typically, a 50 μl urine sample was placed in a prerinsed concentrator and made up to a final volume of 500 μl with distilled water. The sample was then centrifuged at 10,500×*g* for 15 min, which was sufficient to reduce it to 50 μl. This was then expanded to 500 μl with distilled water, and the

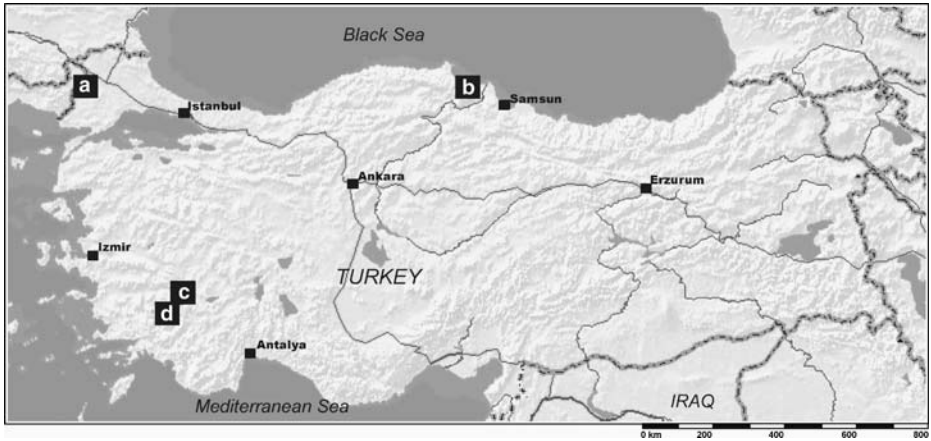

Fig. 1 Map of *Mus macedonicus and M. musculus domesticus* collection sites. Wild specimens of *M. macedonicus* and *M. m. domesticus* were collected for urine samples from four locations in Turkey, labeled (a–d). *Mus macedonicus* were caught in sites: (a), Eskiköy, Uzunkoprü, Edirne, 41°20′ N 26°37′ E (sample 123) and (c), Korucuk, Denizli, 37°49′ N 29°09′ E (samples 129 and 131), whereas *M. m. domesticus* were from (b), Kozköy, Yakakent, Samsun, 41°38′ N 35°31′ E (sample 171) and (d), Denizli, 37°47′ N 28°59′ E (samples 141 and 145)

process was repeated. The sample was then removed from the apparatus and stored at −20°C until required. An identical process was used to desalt fractions collected from anion exchange chromatography before analysis by electrospray ionization mass spectrometry (ESI-MS)

Ion Exchange Chromatography

Anion exchange chromatography was performed on a Dionex Bio-LC platform fitted with a Dionex ProPac SAX column (2×250 mm) and a ProPac SAX guard column (2×50 mm). In all cases, the column flow rate was 0.2 ml/min. After equilibration with 20 mM Tris, pH 8.5, desalted urine samples, (typically 1–5 μl) were loaded onto the column. Samples were eluted from the column with a linear NaCl gradient of 0–500 mM in 30 min. The eluent from the column was monitored at 214 nm in a flow cell of 9 mm path length. Where applicable, fractions were collected by hand directly after passage through the flow cell. All aspects of data acquisition and processing were controlled through the Dionex Chromeleon software.

Proteolysis of MUPs

Anion exchange purified MUPs were proteolyzed by endoproteinase Lys-C (Lys-C), endoproteinase Glu-C (Glu-C), or trypsin (Roche Diagnostics, Lewes, UK). An aliquot (typically 100 μl) of the MUP fraction was reduced with 10 mM 2-mercaptoethanol for 1 hr at room temperature (RT) or with 10 mM dithiothreitol (DTT) at 55°C for 1 hr. In some instances, cysteine residues were carbamidomethylated by incubating the reduced protein preparation with a 55-mM final concentration of iodoacetamide for 1 hr at RT. Removal of reduction and carbamylation reagents was achieved by protein precipitation or centrifugal filtration in a Vivaspin apparatus as described previously. Protein precipitation was achieved by the addition of an equal volume of 20% (w/v) tricarboxylic acid (TCA). After centrifugation at 14,000×*g* for 10 min, the supernatant was discarded, and the precipitate was washed twice with diethyl ether. Residual ether was removed from the sample by incubation at 40°C for 10 min, and the precipitate was resuspended in its starting volume of either 100 mM Tris, pH 8.5 (Lys-C and Glu-C) or 100 mM Tris/2 mM $CaCl_2$, pH 8.5 (trypsin). Protease solution (2 μl of 0.1 mg/ml) was added to the resuspended precipitate, which was then incubated overnight at 37°C. The reaction was subsequently stopped by addition of a 5-μl aliquot of formic acid. Samples prepared by Vivaspin desalting were digested under identical conditions.

Esterification of MUP Lys-C Peptides

Esterification of carboxyl groups within MUP Lys-C peptides was achieved according to Shevchenko et al. (2003). Lys-C peptides from digests of *M. macedonicus* and *M. m. domesticus* MUPs were initially desalted into a solution of 0.1% (v/v) trifluoro-acetic acid (TFA)/50% (v/v) acetonitrile with Zip-Tips (Millipore, Billerica, MA, USA). This solution was subsequently reduced to dryness in a vacuum centrifuge. A 1 ml aliquot of ethanol was placed in a 1.5-ml test tube and placed at −20°C for 15 min, after which, a 150 μl aliquot of acetyl chloride was added, and the mixture was incubated at room temperature for 10 min. The dried peptides were immediately treated with 15 μl of this mixture and incubated at room temperature for 45 min before drying in a vacuum centrifuge. The dried, esterified peptides were finally dissolved in MALDI matrix solution (see below) before matrix assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectrometry.

Matrix Assisted Laser Desorption Ionization-Time of Flight (MALDI-TOF) Mass Spectrometry

MALDI-TOF mass spectrometry of MUP digests was performed on a Waters-Micromass M@LDI instrument. Peptide mixtures from proteolytic digests of MUPs were mixed in a 1:1 ratio with a matrix solution consisting of saturated α-cyano-4-hydroxy-cinnaminic acid (Sigma Chemical, Poole, UK) in 50% (v/v) acetonitrile/0.2% (v/v) TFA. A 1 μl aliquot of this preparation was deposited on the MALDI target and allowed to dry at RT. Spectra were subsequently acquired between 1,000 and 4,000 Th with the laser energy optimized to give the best signal to noise ratio for each sample. The laser firing rate was 5 Hz and 10 spectra (collected over 2 sec) were combined. The final mass spectrum was a combination of 10–15 such combined data sets, representing 100–150 individual laser shots. All aspects of data acquisition, processing, and machine management were controlled through the MassLynx software suite (versions 3.5 and 4.0).

Electrospray Ionization (ESI) Mass Spectrometry

Electrospray ionization mass spectrometry (ESI-MS) and tandem mass spectrometry (ESI-MSMS) were performed on a Micromass Q-ToF Micro instrument, fitted with a nanospray source. The electrospray was created from a silver-coated glass capillary with a 10-μm orifice (New Objective, Woburn, MA, USA), held at a potential of +2,000 V relative to the sample cone. For measurement of the mass of intact MUPs, a desalted sample was introduced into the mass spectrometer by syringe pump infusion (Harvard Instruments Ltd, Edenbridge, UK) at a rate of 0.5 μl/min. In this case, the instrument was operated in TOF only mode, with the quadrupole analyzer operating in R_f only mode to allow transmission of all ions. Raw data were gathered between 700 and 1,400 Th at a scan/interscan speed of 2.4/0.1 sec. These raw data were subsequently de-convoluted using the MaxEnt 1 module contained within the MassLynx 3.5 software. To create the MaxEnt damage model, peak width and resolution parameters of 0.75 and 1 Da/channel were used, respectively, and data were processed over the mass range 18,400–19,000 Da.

De novo Sequencing

For tandem mass spectrometry on peptides derived from MUP proteolytic digests, samples were introduced into the mass spectrometer at 0.2 μl/min following reversed phase high pressure liquid chromatography (RP-HPLC) (see below). In this case, the initial quadrupole analyser was set to allow passage only of selected precursor ions to a gas cell, where they were fragmented by collision with argon. The mass of the resulting fragment ions was then measured by the TOF analyzer. Selection of precursors and fragmentation energy were controlled automatically by using the data dependent acquisition facility within the MassLynx software. Precursor spectra were acquired between m/z 400 and 1,500 at a scan/interscan speed of 2.4/0.1 sec. Product ion spectra were acquired between m/z 100 and 2,000 at a scan/interscan speed of 1.0/0.1 sec. Raw product ion spectra were de-convoluted using the MaxEnt 3 algorithm within the MassLynx software. The charge state of the parent peptide was determined from the isotope envelope in the precursor spectrum. Interpretation of product ion spectra and the determination of peptide sequences were facilitated by the PepSeq module within MassLynx.

Reverse Phase-HPLC

Before ESI-MSMS, MUP peptides were separated by RP-HPLC on a Dionex Ultimate system. The system was fitted with a PepMap C18 column (LC Packings, Camberley, UK), 15 cm×75 μm, bead size 3 μm and pore size 100 Å. Before separation, aliquots (2–5 μl) of MUP peptides were desalted in-line using a Dionex Switchos apparatus, fitted with a 1 mm×300 μm, C18 precolumn. The precolumn was initially equilibrated in 0.2% (v/v) formic acid at 30 μl/min. Peptides were then loaded and washed for 3 min at the same flow rate and then eluted with 90% acetonitrile/0.2% formic acid, introduced as a linear gradient of 0–50% in 30 min at 0.2 μl/min. The column eluent was monitored by UV absorbance at 214 nm, before delivery to the mass spectrometer.

Molecular Modeling

Protein sequences derived from the *M. macedonicus* MUPs were used to direct homology models. Briefly, protein structures were modeled in the structure of MUP1 1I04.PDB (Timm et al., 2001). After alignment of the two sequences (no insertions or deletions were necessary), the models were built to the highest quality possible using the Modeler package of the Discovery Studio package (Accelrys, Cambridge, UK, ver 1.5). Because the four C-terminal most residues of MUP1 cannot be defined because of main chain flexibility (Krizova et al., 2004), these residues were not modeled.

Results and Discussion

We analyzed urine from three samples each of *M. macedonicus* and *M. m. domesticus*, obtained from mice caught from geographically distinct locations (Fig. 1). The two species demonstrated different patterns of MUP expression. When the urinary proteins were resolved by ion exchange chromatography, the elution profile of *M. macedonicus* urine consisted of a single major peak and two barely detectable smaller peaks (Fig. 2a). The retention time of the major peak expressed by each individual was similar, (maximum absorbance at 21.69, 21.83, and 21.86 min), suggesting little difference in their MUP profiles. By contrast, the *M. m. domesticus* samples were noticeably more complex and varied among individuals in the number of major and minor peaks (Fig. 2b). Furthermore, the retention times of the major peaks differed by more than 0.25 min among samples, contrasting strongly with the invariable elution times of the major peak in the *M. macedonicus* samples. It is probable that such differences in elution time reflect different proteins (Robertson et al., 1996). Each of the three *M. m. domesticus* samples also differed in the relative proportions of the peaks, which added to the overall level of heterogeneity. For *M. m. domesticus*, such heterogeneity is not surprising and is similar to that observed previously in wild *M. m. domesticus* populations (Robertson et al., 1997; Pes et al., 1999; Veggerby et al., 2002; Beynon and Hurst, 2004). Of greater interest was the relative simplicity and the lack of comparable heterogeneity in the *M. macedonicus* urine samples, which we have never observed in *M. m. domesticus* samples caught from many different locations.

We previously demonstrated the utility of mass spectrometric analysis of intact urinary MUPs (Evershed et al., 1993; Robertson et al., 1996, 1997; Beynon et al., 2002). All six samples generated complex and overlapping mass spectra corresponding to multiple charged protein variants that were readily transformed into true mass spectra (Fig. 3). The

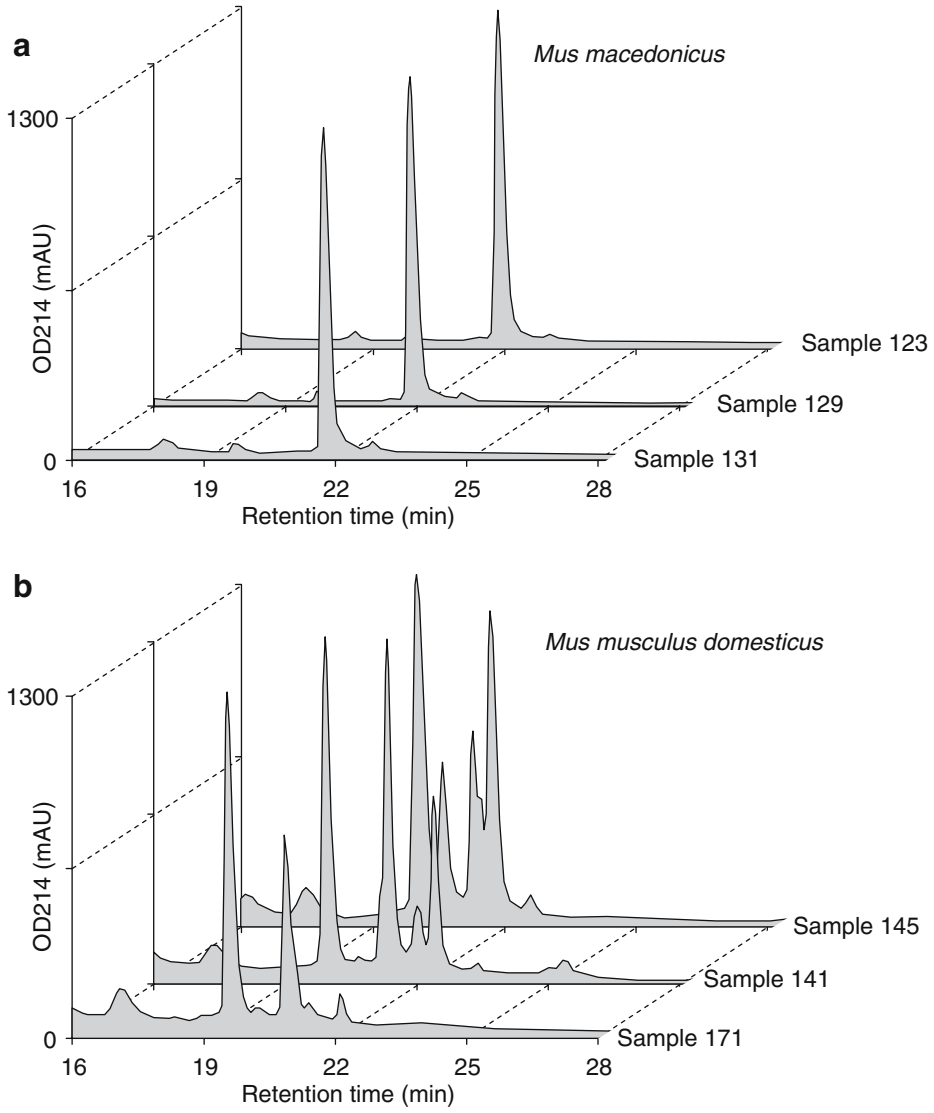

Fig. 2 Anion exchange chromatography profiles of MUPs from three urine samples of (a) *Mus macedonicus* (123, 129, and 131) and (b) *M. m. domesticus* (141, 145, and 171). MUPs were desalted with a centrifugal concentrator (see Methods and Materials section for details). Anion exchange chromatography was performed on a 2×250 mm Propac SAX anion exchange column mounted on a Bio LC chromatography platform (Dionex, Camberly, UK). The column was equilibrated with 20 mM Tris buffer, pH 8.5 at 0.2 ml/min, before loading aliquots (5 μl) of desalted MUPs from the same *M. macedonicus* and *M. m. domesticus* samples as described previously. After loading, each sample was washed for 5 min, after which, the sample was eluted with a linear NaCl gradient of 0–500 mM in 30 min. Proteins eluting from the column were detected by monitoring the absorbance at 214 nm of the column eluate, in a flow cell of 1 cm path length

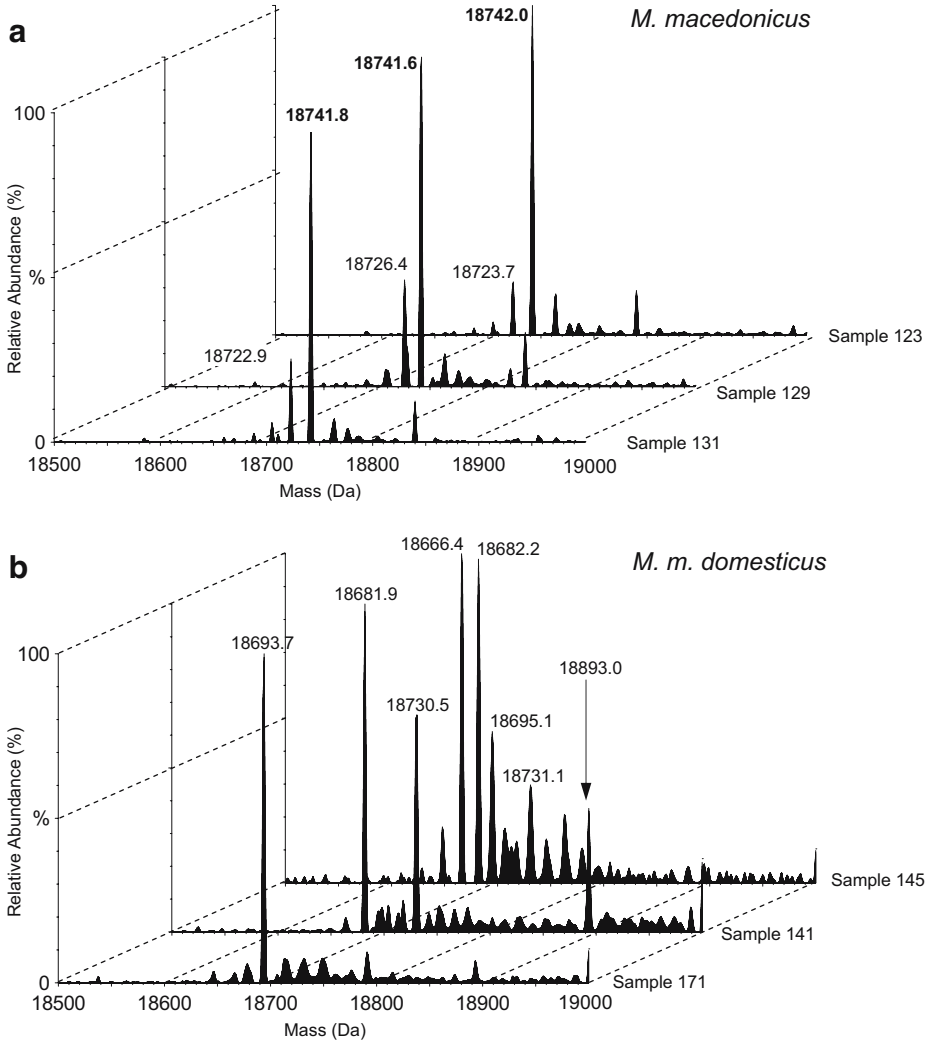
three *M. macedonicus* samples were characterized by a dominant mass peak at 18,742 Da (Fig. 3a). The close agreement between these three masses (0.4 Da) is within the expected instrument error (approximately ± 2 Da) and is consistent with all three samples containing the same, single protein species. The spectra all contained a second smaller peak at 18,723,



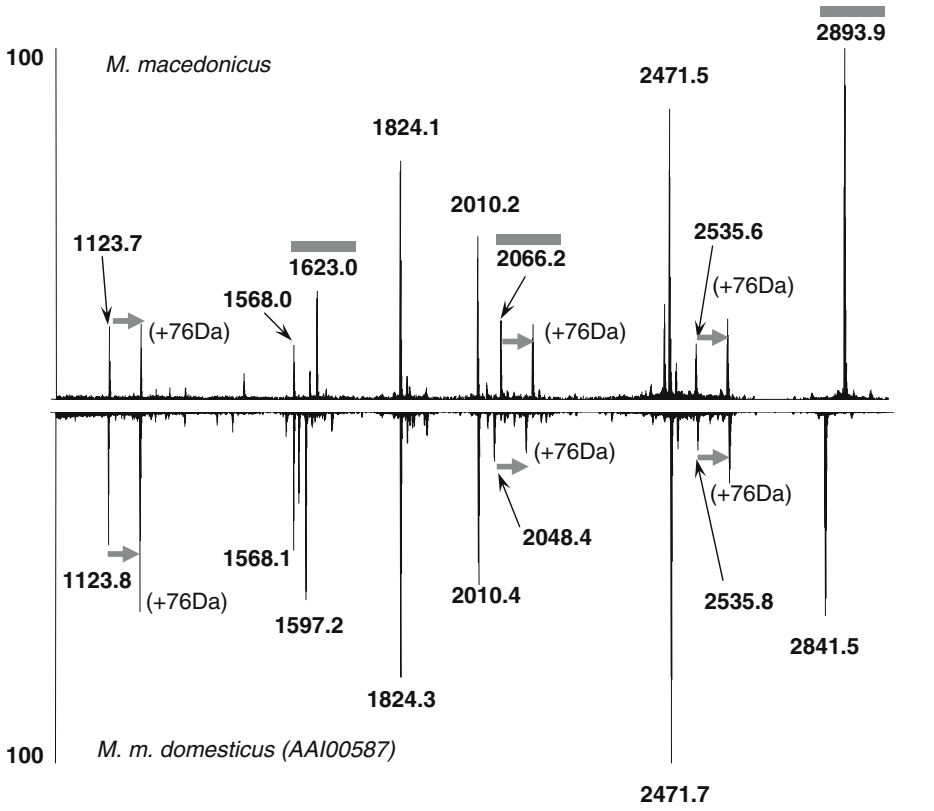


Fig. 3 ESI Mass Spectra of Unfractionated MUPs from three urine samples of (a) *Mus macedonicus* (123, 129, and 131) and (b) *M. m.domesticus* (141, 145, and 171). MUPs were separated (Fig. 2) and diluted 1:50 with a solution of 50% (v/v) acetonitrile/0.2% formic acid. This was introduced into a Q-tof Micro mass spectrometer (Micromass plc, Manchester UK) at 0.5 μl/min from a syringe infuser (Harvard Instruments, Holliston, MA, USA). The mass spectrometer was operated in TOF only mode, and raw data were gathered between m/z 700 and 1,400 with a scan/interscan time of 2.4/0.1 sec, respectively. Finally, raw data were deconvoluted and transformed to a true mass scale using MaxEnt 1 software

18,726, and 18,724 Da that probably also corresponds to a single protein. Two other features were also common to these mass spectra; a small peak at 18,763 Da and a slightly more abundant peak at 18,840 Da. The former, 21 Da higher than the base peak, is consistent with formation of a sodium adduct, whereas the latter is 98 Da higher than the base peak, consistent with the formation of a phosphate or sulfate adduct. We have commonly observed these artifacts in previous analyses, and it is unlikely that these reflect additional proteins.

The mass spectra obtained from urine samples of *M. m. domesticus* were more complex and heterogenous among individuals (Fig. 3b) than found for *M. macedonicus*, even though the two species were both collected from the same geographical region (Fig. 1). The number of major peaks (>20% base peak intensity) differed greatly. Sample 171 was the simplest, and unusually, expressed a single major peak at 18,694 Da, whereas sample 141 contained three peaks at 18,682, 18,730, and 18,893 Da. Sample 145 was most complex with peaks at 18,666, 18,682, 18,695, and 18,731 Da. Some of these masses have previously been observed in other wild mice or in inbred mouse strains, notably the protein at 18,694 Da, in C57BL/6, BALB/c, and wild mice (Robertson et al., 1996, 1997); 18,682 Da in wild mouse populations (Robertson et al., 1997), and 18,893 Da in inbred C57BL/6 mice (Armstrong et al., 2005).

Urine samples from *M. macedonicus* exhibited a single peak on anion exchange chromatography comprising a protein of mass 18,742 Da. To confirm that this protein was a MUP, and to investigate its relationship to known *M. m. domesticus* MUPs, the primary structure of the protein was analyzed by mass spectrometry. The protein was digested by endopeptidase Lys-C (Lys-C) in parallel with a MUP from urine of the inbred strain C57BL/6. Lys-C was selected over other proteases for this analysis as it was known from previous work to produce a small number of large peptides that were readily analyzed by MALDI-TOF mass spectrometry. This has previously allowed confirmation of >95% of the amino acid sequence from *M. m. domesticus* MUPs (Robertson et al., 1996). The amino acid sequence of the C57BL/6 reference MUP (GenBank accession number AAI00587, molecular mass 18,644 Da) had previously been inferred by comparison of intact protein molecular mass to the theoretical mass predicted by the cDNA sequence (Robertson et al., 1996) and comparison of Lys-C peptide masses to those predicted by the cDNA sequence (unpublished observation). This particular MUP was chosen on experimental grounds, as it was readily purified from C57BL/6 urine. The resultant peptides were surveyed by MALDI-TOF mass spectrometry. The mass spectrum of C57BL/6 MUP Lys-C peptides (Fig. 4), displayed nine masses corresponding to those predicted by the cDNA sequence (AAI00587). This analysis confirmed the identity of 156 of the 162 amino acids in the sequence (>96% coverage). The remaining unassigned amino acids were two tripeptides, the masses of which were too low for MALDI-TOF analysis. Three peptides (1123.8, 2048.4, and 2535.8 Th) were associated with additional "shadow" peaks at +76 Da. The predicted sequence for each of these peptides contains a cysteine residue that was maintained in the reduced state during proteolytic digestion by the addition of 2-mercaptoethanol. The 76-Da mass increase is consistent in mass with the formation of a β-mercaptoethanol adduct with those cysteine residues, providing good confirmation of the presence of cysteine residues in these peptides.

The corresponding mass spectrum of *M. macedonicus* Lys-C peptides revealed six peaks which shared masses with peptides in the C57BL/6 reference spectrum (Fig. 4). This was presumptive evidence for the identity of 100 amino acid residues and that the 18,742-Da *M. macedonicus* protein was indeed a MUP. The amino acid coverage in this instance was 61% (assuming a total of 162 residues). Three of the Lys-C peptides predicted from the cDNA sequence and present in the *M. m. domesticus* sample were absent from the *M. macedonicus* MUP (LysC peptides L2, L4, and L5), whereas the *M. macedonicus* sample contained three different peptides (m/z 1,623.0, 2,066.2, and 2,893.9). These peptides, likely to be the equivalent peptides to L2, L4, and L5, were selected for further MS analysis. The presence of a +76-Da adjacent peak (putatively a 2-mercaptoethanol adduct) to the peptide at m/z 2,066.2, suggested that in common with the equivalent *M. m. domesticus* peptide L5, it contained a cysteine residue.

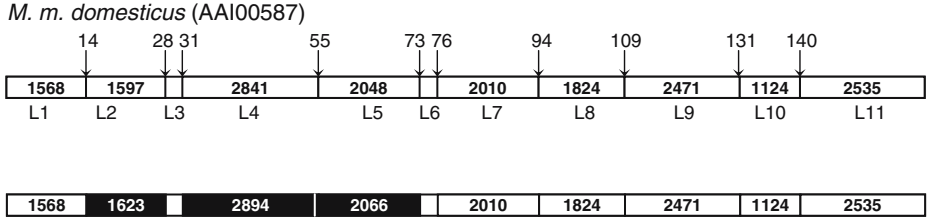

Fig. 4 MALDI-TOF peptide mapping of endoproteinase Lys-C peptides from a *Mus macedonicus* and *M. musculus domesticus* (C57BL/6) MUP. Anion exchange purified MUPs were digested with endoproteinase Lys-C (see Methods and Materials section for details). The mass of the resulting peptides was determined using MALDI-TOF mass spectrometry. Peptides were identified in the *M. m. domesticus* sample by comparison of the MALDI masses to a set of predicted masses (*L1–L11*) generated from a theoretical digest of a translated cDNA sequence (accession number AAI00587). Comparison of *M. macedonicus* peptide masses to those of *M. m. domesticus* allowed identification of both identical peptides and those where amino acid substitutions had occurred. Peptides thought to contain amino acid substitutions in the *M. macedonicus* sample are *labeled with a horizontal bar*. Additional ions, attributed to reaction of cysteine residues with β-mercaptoethanol, were observed 76 Da higher than certain peptides. Such peaks are labeled (+76 Da)

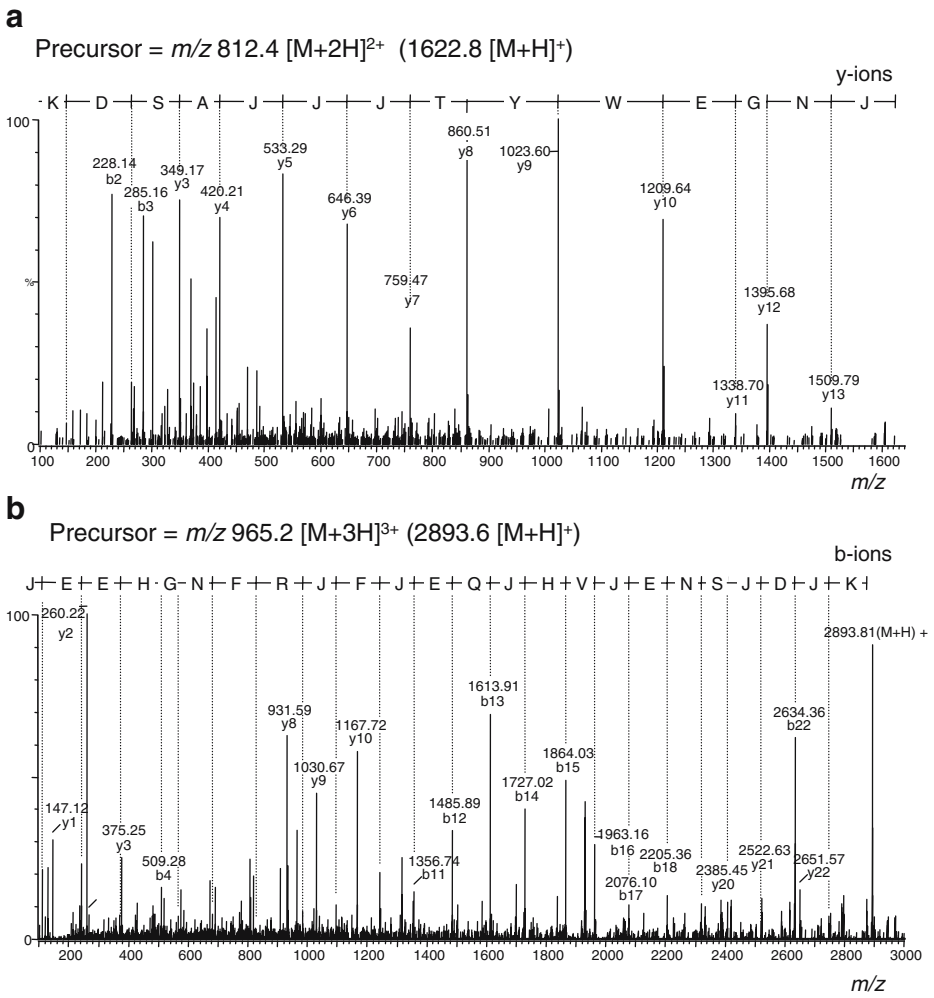

Fig. 5 Product ion mass spectra of (a) m/z 812.4 ($[M+2H]^{2+}$, 1,623.0 Da) and (b) m/z 965.2 ($[M+3H]^{3+}$, 2,893.9 Da) *Mus macedonicus* peptides. Tandem LC-MSMS experiments were performed on a Micromass Q-tof Micro mass spectrometer and a Dionex Ultimate RP-HPLC system (see Methods and Materials section for details). A Lys-C digestion of an anion exchange purified *M. macedonicus* MUP (18,742 Da) was introduced into the system, and ions of interest (m/z 812.4, 2+ and 965.2, 3+) were selected for tandem mass spectrometry using the data dependent switching feature within the MassLynx software. Fragmentation energy was similarly automatically selected using this feature. Product ion spectra were combined and de-convoluted using MaxEnt 3 software, with the charge state parameter determined from the isotope envelope of the precursor ion scan. De-convoluted spectra were interpreted with the MassSeq software included in the MassLynx package. Sequence information for the m/z 812.4 peptide was gained from a y-ion series, whereas that of the m/z 965.2 peptide was determined from a b-ion series. In this latter case, the identity of the 8 C-terminal residues was confirmed by a similar experiment on a trypsin digest (data not shown)

The three novel *M. macedonicus* peptides were sequenced by electrospray ionization tandem mass spectrometry. The first of the three unique *M. macedonicus* peptides (1,623.0 Th, $[M+H]^+$) was observed as a doubly charged ion at m/z 812.4 under electrospray ionization conditions. This fragmented readily to yield an abundant series of y ions (Fig. 5a). From these data, the amino acid sequence of the peptide was determined to be

*J*NGEWYT*JJJ*ASDK, where *J* is used to represent either leucine or isoleucine, which are isobaric and unable to be differentiated. This sequence is virtually identical to peptide L2 from *M. m. domesticus* AAI00587, ($_{15}$INGEWHTIILASDK$_{28}$), assuming correspondence of the leucine and isoleucine residues. The only difference between these peptides was the substitution of a tyrosine for a histidine residue in the *M. macedonicus* peptide. The mass difference of a His/Tyr substitution is +26 Da. The difference between the measured m/z values of the AAI00587 L2 peptide and the 1,623.0 *M. macedonicus* peptide is +25.8 Da, which confirms this as the sole change. In addition to characterizing this substitution, this experiment confirmed the identities of 14 additional amino acids in the *M. macedonicus* MUP, with the caveat of the residual ambiguity due to the isobaric pair of leucine and isoleucine.

The second unique *M. macedonicus* peptide (m/z 2,893.9 Th, $[M+H]^+$) was observed as a triply charged ion of m/z 965.2 in the precursor spectrum, implying an internal basic residue. During tandem mass spectrometry, this peptide did not generate a full series of y ions but fragmented to produce a complete set of b ions (Fig. 5b), from which the sequence of the peptide was determined as JEEHGNFRJFJEQJHVJENSJDJK. The sequence of the N-terminal eight residues of this peptide (JEEHGNFR) was confirmed by tandem mass spectrometry of a tryptic digest of the same preparation (data not shown). Although this sequence shared significant homology with peptide L4 from AAI00587, ($_{31}$IEDNGNFRLFLEQIHVLENSLVLK$_{55}$), it differed at three positions. The observed differences (from *M. m. domesticus* to *M. macedonicus*) were $D_{33}E$, $N_{34}H$, and $V_{53}D$. The arginine residue at position 40 was consistent with the triply charged precursor ion. Thus, an additional 24 residues of the *M. macedonicus* MUP were identified, and again, the interpretation was confirmed from the mass difference between the *M. m. domesticus* L4 peptide (52.4 Da) and the proposed *M. macedonicus* sequence (53 Da).

The final *M. macedonicus* peptide identified as a target for tandem mass spectrometry sequencing (2,066.2 Th, $[M+H]^+$) was also observed as a triply charged ion of m/z 689.4 under electrospray ionization conditions, consistent with an internal basic residue. Although this peptide did not generate a complete set of y or b ions (Fig. 6), the analysis yielded partial sequences from both y and b ion series that overlapped. The y ion series yielded the partial sequence of FHJ.....JSMVADK. The b ions gave a sequence of ...ECSEJSMV. Amalgamating these two sequences gave an overall amino acid sequence of FHJ...ECSEJSMVADK. When aligned to peptide L5 from AAI00587 ($_{56}$VHTVRDEECSELSMVADK$_{73}$), a high level of similarity was apparent. Two amino acid substitutions were observed in the *M. macedonicus* peptide; these were $V_{56}F$ and $T_{58}L$. The substitution of F/V at position 56 has been previously observed in other MUPs, and the V_{56} residue in the C57BL/6 sequence used in this study (AAI00587) is only observed in a minority of cases. This residue is located within the central, ligand-binding calyx and modulates the ability to bind specific ligands (Darwish Marie et al., 2001).

Four residues in the middle of the peptide remained unassigned. To establish the identity of these residues in L5, a Lys-C digest of the *M. macedonicus* protein was treated with an ethanolic solution of acetyl chloride to convert free carboxyl groups within the peptides to the corresponding methyl esters. Peptides, thus modified, increase in mass by 14 Da for each methyl group added, quantifying the number of acidic residues within the peptide. MALDI-TOF mass spectrometry of a reduced, carbamidomethylated and esterified Lys-C digestion of the *M. macedonicus* MUP (Fig. 7) yielded ions of masses consistent with the predicted number of carboxyl groups from previous assignments. For peptide L5, the mass difference between the carbamido peptide and the methylated carbamido peptide was 84 Da (6×14), which identified five acidic residues plus the C terminus. Previous tandem mass

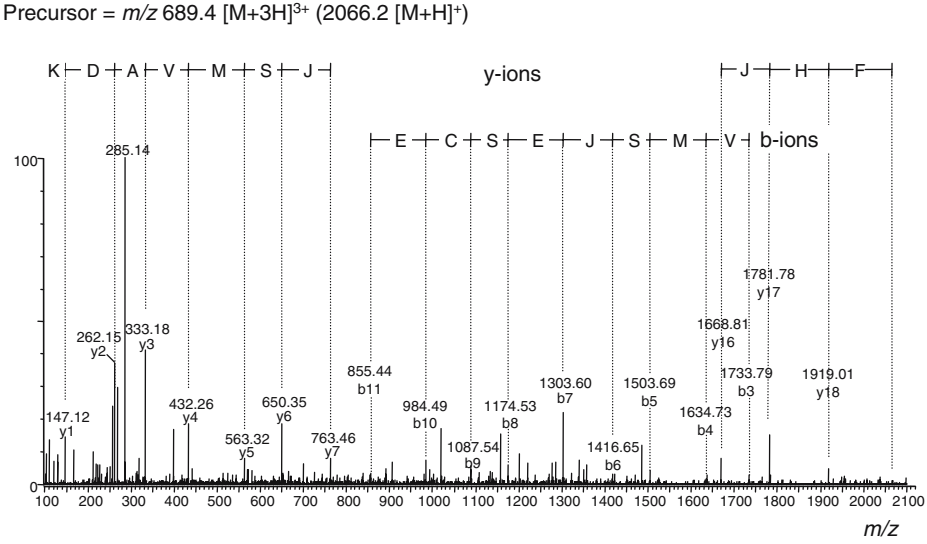

Fig. 6 Product ion mass spectrum of m/z 689.4 ($M+H^+$ 2,066.2 Da) *Mus macedonicus* peptide. A tandem LC-MSMS experiment was performed on a *M. macedonicus* Lys-C peptide of m/z 689.4, under identical conditions to those described in the Fig. 5 legend. Once again, this peptide was isolated from a *M. macedonicus* MUP Lys-C digest, using data dependent switching. The MaxEnt 3 de-convoluted product ion spectrum was interpreted using PepSeq software. In this instance, a composite partial sequence was inferred from both b and y ions

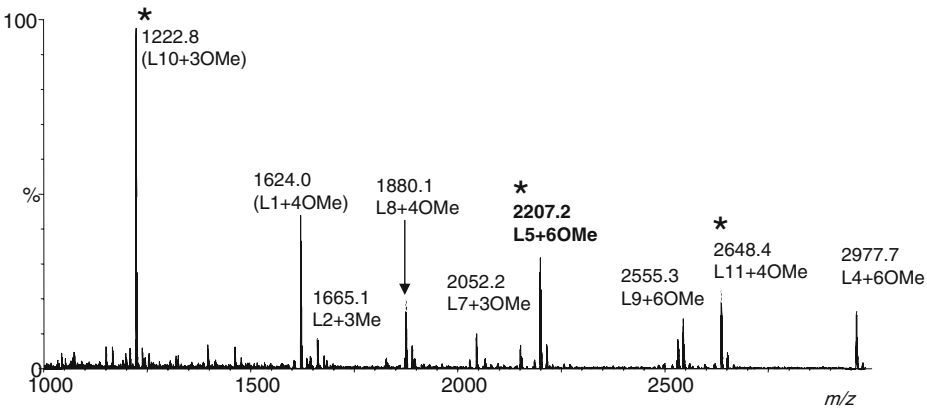

Fig. 7 MALDI-TOF mass spectrum of a methyl esterified Lys-C digest of a carbamidomethylated *M. macedonicus* MUP. Quantification of acidic residues within Lys-C peptides from a *M. macedonicus* MUP was achieved by methyl esterification. Before digestion, an anion exchange purified *M. macedonicus* MUP preparation was reduced, carbamidomethylated, and digested with Lys-C (see Methods and Materials). Peptides were then extracted from the solution using reverse phase chromatography media (Zip Tips), washed with 0.1% (v/v) trifluoroacetic acid (TFA), and finally desorbed and collected in a solution of 50% (v/v) acetonitrile/0.1% (v/v) TFA. Solvents and TFA were then removed from this preparation using a vacuum centrifuge. A 1-ml aliquot of methanol was incubated at −20°C for 15 min before addition of acetyl chloride (150 µl). A 20-µl aliquot of this solution was then added to the dried Lys-C peptides and incubated at RT for 45 min. Esterified Lys-C peptides unique to *M. macedonicus* are marked with an asterisk (*)

spectrometric analysis of this peptide identified the positions of three of these residues, leading to the conclusion that two of the four unidentified residues were also acidic, namely, aspartate (D) or glutamate (E).

The identification of two acidic residues in the unassigned portion of L5 allows inferences to be drawn as to the identities of the remaining two unassigned residues. On ESI-MS, peptide L5 is triply charged, implying that it contains an internal basic residue. Although the histidine residue at position 57 is weakly basic, a more likely explanation of this charge state is that the arginine residue at position 60 in the *M. m. domesticus* sequence is conserved, as observed in all the urinary MUPs previously characterized in our laboratories (Robertson et al., 1996). The L5 peptide from *M. m. domesticus* is 42 Da heavier than the equivalent peptide from *M. macedonicus* (allowing for residues assigned by tandem mass spectrometry). The assumption that R_{60} is conserved and the knowledge that two of the residues are acidic allows for only two possibilities for the final assignment of the sequence. In the first scenario, the two acidic residues at positions 61 and 62 are identical to the *M. m. domesticus* sequence, in which case a V/G substitution at position 59 in the *M. macedonicus* sequence would account for the mass difference. The second scenario allows for the possibility of a D/E substitution at position 61 and a V/A substitution at position 59 to give a net loss of 42 Da in the *M. macedonicus* peptide. On the basis of this analysis, the remaining four amino acid residues in L5 are assigned either as [GR(DE)] or [AR(DD)]. The order of these amino acids is not apparent from the above analysis and has been assigned on the basis of the overall level of conservation observed between the two MUPs (Fig. 8).

Endopeptidase Lys-C digestion of AAI00587 creates two tripeptides (L3 and L6), each of which has a predicted mass of less than 400 Da. Such peptides are difficult to analyze with MALDI-TOF mass spectrometry because of background signal from ions in the chemical matrix. We have, however, observed in previous experiments that Lys-C has a

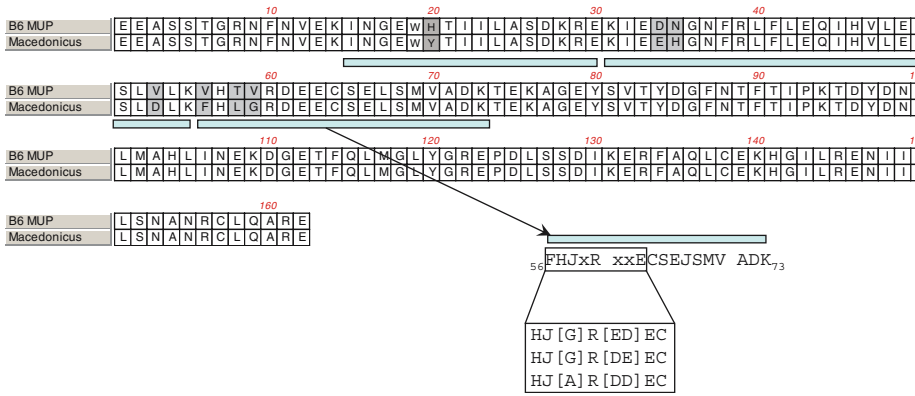

Fig. 8 Comparison of *M. macedonicus* and *M. m. domesticus* MUP sequences. Inferred data about the sequence of the *M. macedonicus* MUP from MALDI-TOF, LC-MS, and LC-MSMS analysis were amalgamated into a single composite sequence and compared to the known sequence of a *M. m. domesticus* MUP (accession number AAI00587, labeled "B6 MUP"). Positions of amino acid substitutions in the two sequences are shaded. Full sequence identification was not achieved between residues 59 and 62, but was narrowed down to three permutations following methyl esterification (see Fig. 7). An expanded view of this area is inset and the three possible permutations included. Amino acid identities within the three permutation sequences inferred from methyl esterification are shown in brackets. The arginine residue at position 60 is assigned provisionally, pending further proof, on the basis of overall peptide charge state (3+) and conservation between known MUP sequences

tendency to omit cleavages in the peptide chain in areas where lysine residues are in close proximity. To assess whether the two tripeptides in *M. macedonicus* possessed the same sequence as those in AAI00587, an additional LC-MS experiment was run on the Lys-C peptides. In this instance, the m/z values for L2+L3 (1,018.54, $[M+2H]^{2+}$) and L5+L6 (820.70, $[M+3H]^{3+}$ with an oxidized methionine residue) were readily observed in extracted ion chromatograms (data not shown). The two tripeptides were therefore assigned to the *M. macedonicus* sequence as identical to the *M. m. domesticus* sequence.

The assembled *M. macedonicus* sequence was aligned to that of AAI00587 (Fig. 8). Of the 162 amino acids in the *M. macedonicus* sequence, 152 are identical to AAI00587, seven residues are known to differ, and the identity of a further three is unclear, although their chemical class has been determined. This has allowed the modeling of the variant residues into the three dimensional structure using the Modeler facility within the Discovery software package and crystallographic coordinates (Kuser et al., 2001) (Fig. 9), lodged in the National Centre for Biotechnology Information (NCBI) structural database (http://www.ncbi.nlm.nih.gov).

In constructing the model *M. macedonicus* MUP structure, we had to consider two types of uncertainty in the sequences derived from proteomics experiments. First, the amino acids between residues 58 and 61 could not be unambiguously determined by tandem mass spectrometry, and the three possibilities that existed (GRED, GRDE, ARDD) were modeled. Secondly, it is not possible to discriminate between the isobaric residues leucine and isoleucine. To assess the importance of these residues, we constructed two artificial sequences based on AAI00587, in which all Ile/Leu residues were converted to either Leu or Ile. Models built on the parent 1I04 structure were compared, and the RMSD of the alpha carbon atoms of the two structures was 0.14 Å. The overall main chain trajectories were virtually identical. We conclude that Leu/Ile substitution would not have a major effect on the model structures. Accordingly, we built *M. macedonicus* models assuming that the identity of Leu/Ile residues were the same as for AAI00587. For the six variant structures based on the unresolved pentapeptide (see above), all yielded high quality models with alpha carbon RMSD of less than 0.25 Å and similar main chain trajectories (Fig. 9). All proteins passed the Protein Health checks built into the Modeler package. Other than

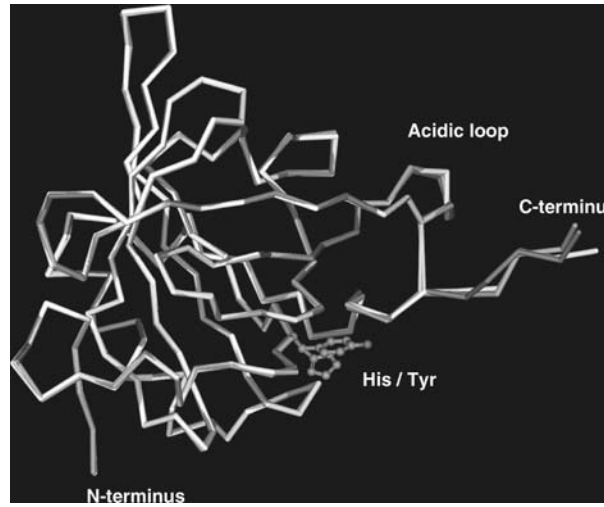

Fig. 9 Homology model building of *M. macedonicus* sequences. The three variants of the possible *M. macedonicus* sequence, varying at the acidic loop (GRED, GRDE, and ARDD) were used to construct homology models based on the MUP structure 1I04.PDB. All three models were aligned structurally to the 1I04 structure, with an RMSD in each instance of less than 0.16 Å. The uncertain acidic loop is highlighted, as is the His/Tyr substitution that is in close proximity to the GxW lipocalin motif. Because the structures are so similar, no labels have been included to identify them individually

the ambiguous acidic loop region of the *M. macedonicus* protein sequences, there are a number of amino acid substitutions relative to MUPs from *M. m. domesticus*. These changes ($H_{20}Y$, $D_{34}E$, $N_{35}H$, $V_{53}D$, $T_{58}L$, $V_{59}G$) do not influence the ligand binding cavity and are solvent exposed.

To assess the level of similarity between the *M. macedonicus* sequence and those from *M. m. domesticus*, we compared it to all the known *M. m domesticus* sequences in the NCBI database. The amino acid sequence of the *M. macedonicus* MUP shares most similarity with a group of MUPs for which only incomplete sequences are available. These, in turn, are most similar to the male-specific 18,893 Da MUP discovered in C57BL/6 mouse, but also widely present in wild caught *M. m. domesticus*. This protein has a high capacity for binding of the male specific ligand 2-*sec*-butyl-4,5-dihydrothiazole (thiazole) that accords with a function in male-specific signaling (Armstrong et al., 2005).

The simple MUP pattern in *M. macedonicus*, together with the lack of individual variability, suggests that MUPs do not have sufficient polymorphism to provide an individual ownership signal in scent marks in this species, in contrast to *M. m. domesticus*. This may reflect the difference in the population ecology of this aboriginal grassland species compared to the commensal house mice and possibly reflects the more ancestral form. While the field ecology of *M. macedonicus* is not well known, in line with the other aboriginal species of *Mus* in Europe and the Middle East, *M. macedonicus* in Turkey can be presumed to have large territories, and individuals are highly agonistic to each other (reviewed by Frynta et al., 2005). Both male and female *M. macedonicus* are much more aggressive than *M. m. domesticus* (Frynta and Čiháková, 1996), and individuals may be largely nonoverlapping. By contrast, in commensal *M. m. domesticus* populations, multiple males and females live within territorial social groups, and there may be extensive spatial overlap between neighbors when borders are not easily defended (Hurst, 1987; Barnard et al., 1991). This results in an unusually high level of aggregation and contact between individuals in this species. As male *M. m. domesticus* advertise their territorial dominance through scent marks (Hurst and Beynon, 2004), it is possible that this may have been a strong driver for the evolution of individual-specific MUP patterns in *M. m. domesticus* but not in the aboriginal species. Given their dispersed distribution, there is likely to be much less requirement for advertising individual scent ownership in *M. macedonicus* and other widely dispersed rodent species. This suggests the intriguing hypothesis that the extreme polymorphism and individual variability in MUP patterns seen in *M. m. domesticus* is a species-specific adaptation for signaling individuality in a complex social system where individuals vary in social status. *M. macedonicus* is one of a number of aboriginal mouse species that have evolved independently of *M. m. domesticus*, inhabit different environments, and display different forms of behavior. Information about the MUPs and MUP genes in these animals remains scarce (Sampsell and Held, 1985), yet they provide a valuable opportunity to investigate the function of both MUPs and their ligands and the evolution of a family of proteins used for scent signaling. To this end, a wider survey of MUPs from aboriginal mice of both sexes, which includes both primary structure and ligand status, has the possibility to produce greater insights into the wider context of MUP polymorphism and function.

Acknowledgments We are grateful for the assistance of Coskun Tez and support from the Genetics Society toward the fieldwork. The work was carried out under research grants from the Biotechnology and Biological Sciences Research Council, UK to J.L.H. and R.J.B.

Abstract Red imported fire ants, *Solenopsis invicta* Buren, build nests by excavating soil. Incorporation of ant-derived chemicals in nesting material has long been known; however, only a few chemicals have been identified. This paucity of identified ant-derived chemicals may be due to the interference from soil-borne compounds in chemical analysis. In the laboratory, red imported fire ants were able to build their nest using moistened silica gel as the only building material. This provided an opportunity to establish a profile of ant-derived chemicals in nest material without the presence of any soil-borne artifacts. A new method for profiling ant-derived chemicals in nest material by using GC-MS was developed. All nests contained cuticular hydrocarbons and venom alkaloids. Phosphoric acid, glycerol, lactic acid, and malonic acid also were identified from samples collected from the silica gel nest.

Keywords *Solenopsis invicta* Buren · Nest · Cuticular hydrocarbons · Venom alkaloids · Organic acids · Amino acids · Phosphoric acid · Glycerol

Introduction

The red imported fire ant, *Solenopsis invicta* Buren, is a nest-building ant species that builds its nests by excavating soil. An ant nest not only protects the colony from intruders, but also provides a system for microclimate regulation, which is essential for ant colony survival (Hölldobler and Wilson, 1990). Nest construction by *S. invicta* not only alters the physical properties of the soil, such as infiltration and leaching (Green et al., 1998, 1999), but also the chemical properties, such as element enrichment (Herzog et al., 1976; Lockaby and Adams, 1985; Green et al., 1998, 1999). The ant nest is a central site for many ant activities, and chemicals in the nest may influence colony activities. There is evidence

J. Chen (✉)

that red imported fire ants incorporate ant-derived organic compounds into the nest soil. For example, cuticular hydrocarbons were found in the nest soil (Vander Meer, unpublished data, cited in Vander Meer and Lofgren, 1988). Red imported fire ants also have been reported to disperse venom alkaloids on the brood surface and mound soil as disinfectants (Obin and Vander Meer, 1985; Storey et al., 1991).

Ants have been reported to be able to differentiate their own nests from others. For example, Florida harvest ants, *Pogonomyrmex badius* (Latreille), showed a strong preference towards their own nest material when presented a choice between their own nest material and that of another colony (Hangartner et al., 1970). Hubbard (1974) found fire ants preferentially dug in nest materials from their own colony when offered a choice of soil from their own mound and fresh soil or nest material from another colony. Singer and Espelie (1998) found that workers of fungus-growing ants, *Apterostigma collare* Emery, differentiated their own nest from other nests, and suggested that chemicals incorporated into the nest soil might be the basis for nest recognition.

An ant nest should be an ideal place for the growth of microorganisms, considering the regulated moisture and temperature conditions, and a mechanism to suppress the growth of pathogenic microorganisms inside the nest may be critical to colony fitness. Incorporating antimicrobial agents into nesting material may serve this purpose. Indeed, venom alkaloids of fire ants are known antimicrobial agents (Blum, 1988; Storey et al., 1991).

Soil is the most complex biomaterial on earth (Young and Crawford, 2004), and chemical analysis of organic components in soil is often problematic. In a preliminary study, I found that red imported fire ants would build their nests using moistened silica gel as the only building material under laboratory conditions (Chen, unpublished data). This provided an opportunity to analyze the chemicals incorporated in the nest material by red imported fire ants without interference from any soil-borne chemicals. The objective of this study was to establish a detailed profile of ant-derived chemicals in the nesting material by extraction and analysis of nests constructed from silica gel.

Methods and Materials

Collection and Maintenance of Colonies Ant colonies were collected from Washington County, Mississippi, USA, and the water drip method was used to separate ants from mound soil (Banks et al., 1981). Ants were maintained in a 44.5×60.0×13.0-cm plastic tray. Fluon® (Ag Fluoropolymers, Chadds Ford, PA, USA) was coated on the inside wall of the tray to prevent ants from escaping. Distilled water, 10% sugar solution, and adult crickets were provided to colonies *ad libitum*. A 14×2.0-cm Petri dish with 1.0 cm of hardened dental plaster (Castone®, Dentsply International Inc. York, PA, USA) on the bottom was used as an artificial nest, placed in the center of each tray. There was a 5-cm diam brood chamber in the bottom of the Petri dish. Above the dental plaster were two 8-mm access holes. The Petri dish lid was painted black (1302 Gloss Black Spray Enamel, Louisville, KY, USA) to block light. All colonies were maintained at 21–27°C and RH between 70 and 85%. The social form of *S. invicta* colonies was determined using PCR. Primers described in Valles and Porter (2003) were used to amplify *Gp-9* alleles indicating monogyne or polygyne colony status. Specimen collection, DNA extraction, and PCR methods were as described by Chen and Allen (2006).

Nesting Devices and Procedures Fire ant workers exhibited nest building behavior even when the queen was absent. Two nest-building scenarios, queenless subset colonies and queenright intact colonies, were established in the laboratory by using silica gel (35–60 mesh, Sigma-Aldrich, St Louis, MO, USA) as the only nest building substrate. The device for a queenright intact colony scenario consisted of one plastic tray (20×6 cm) with a 500-ml square bottle right underneath it. There were five 3-mm access holes between the tray and the bottle, and the inside wall of the tray was coated with Fluon®. The bottle was filled with moistened silica gel (50% water, *w*/*w*), which had been washed with acetone and distilled water and dried at 350°C for at least 12 hr. The nesting device for the queenless scenario was similar except smaller in size. A petri dish (8.6×2.2 cm) and a capped Wheaton liquid scintillation vial (20 ml) were used. The inside wall of the Petri dish was coated with Fluon®. There was a 3-mm access hole between the Petri dish and the vial.

Mature colonies were used in this experiment as demonstrated by the presence of brood and alates. Four colonies (three polygyne and one monogyne) were used for the queenright colony scenario and seven colonies (five polygyne and two monogyne) for the queenless scenario. The entire colony was used for each queenright scenario (21 to 45 g), whereas in the queenless scenario, 1.25–1.50 g ants [12.2–18.2% brood and 8.2–10.0% alates (male + female)] were used for each nesting device. Ants were released in the nesting device. All experiments were conducted at 21–27°C and RH between 70 and 85%. Controls were established in the same manner as described except no ants were released into the devices. No food was provided in nesting devices for either treatments or controls.

Collection of Silica Gel Samples Ants removed silica gel from the bottle and vials when they built their nests. While ants were making their nest, the silica gel removed was accumulated in the plastic tray of the queenright scenario or the Petri dish in the queenless scenario. After 2 wk, these silica gel samples were collected by directly transferring silica gel from the nest devices into glass beakers. No further separation of ants from silica gel was necessary because at that time only a few ants were usually present, which were removed with forceps.

Silica gel samples in the nest (inside the bottles or vials) were collected in a different way. Because most ants were inside the nest, they needed to be separated from the silica gel. The nest sand was collected by first disassembling the nest device and transferring the silica gel and ants into an aluminum pan (33.5×6.5 cm) with its inside wall coated with Fluon®. The silica gel was then spread on the bottom of the pan. A Petri dish (8.6×2.2 cm) with a 0.5-cm entrance hole on the side was placed upside down in the pan and served as an artificial nest. Ants moved into the Petri dish with all their brood avoiding the open space. The silica gel in the pan was collected after workers with all the brood had moved into the artificial nest. Samples were stored at −15°C in a glass beaker, which was sealed with Teflon tape. Only fresh samples, stored in the refrigerator for less than 2 d, were used for chemical analysis.

Extraction Some silica gel particles in the plastic tray and Petri dish were colored either brown or brownish–yellow, which was attributed to ant excretion. The colored silica gel samples (each consisted of 10–15 silica gel particles) were directly derivatized with 50 µl *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (BSTFA) in 150 µl pyridine at 60°C for 6 hr. Uncolored silica gel from outside the nest and silica gel inside the nesting device (each sample consisted of 2.5–3.0 g silica gel) were analyzed separately, and all these silica gel samples were subjected to three different solvent extractions: pentane, pyridine, and water

(6×3 ml). Pentane and pyridine extractions were concentrated to 200 μl and no derivatization was conducted. The water extract was freeze-dried and then derivatized by using 50 μl BSTFA in 150-μl pyridine at 60°C for 6 hr.

Chemical Identification The presence of cuticular hydrocarbons and venom alkaloids in nesting material was confirmed by comparing chromatograms and mass spectra of silica gel samples to those of worker pentane extractions. Both cuticular hydrocarbon and venom alkaloids have been extensively analyzed by using gas chromatography. Because the amounts of cuticular hydrocarbons and venom alkaloids were both in the microgram range, the profiles were well established (Nelson et al., 1980; Obin, 1986; Ross et al., 1987). Five signature cuticular hydrocarbon peaks and four of the most significant venom alkaloid peaks were used in this study because the patterns of these peaks had been previously identified (Vander Meer and Lofgren, 1988). Cuticular hydrocarbons included n-heptacosane, 13-methylheptacosane, 13, 15-dimethylheptacosane, 3-methylheptacosane, and 3,9-dimethylheptacosane (Obin, 1986), and four venom alkaloids included *trans*-2-methyl-6-(*cis*-4-tridecenyl)piperidine, and *trans*-2-methyl-6-n-tridecylpiperidine, *trans*-2-methyl-6-(*cis*-6-pentadecenyl)piperidine, and *trans*-2-methyl-6-n-pentadecylpiperidine (Vander Meer, 1986; Ross et al., 1987). Cuticular hydrocarbons and venom alkaloids in worker pentane extraction were separated with a silica gel column consisting of a 14.6× 0.6 cm disposable pasteur pipette filled with 5 cm 35–60 mesh silica gel with the tip blocked with a plug of glass wool. One gram of workers was extracted in 5-ml hexane for 5 hr and the extraction was concentrated to 200 μl under N_2 flow and then loaded onto the silica gel column. Cuticular hydrocarbons were eluted with the first 8-ml hexane, and venom alkaloids were then eluted with 4-ml pyridine. Identification of all other chemicals was achieved by comparing the GC retention time and mass spectrum of targeted compound to those of chemical standards.

Gas Chromatography–Mass Spectrometry A Varian GC-MS system was used consisting of a CP-3800 gas chromatograph with a DB-1 capillary column (30 m×0.25 mm i.d., 0.25 μm film thickness) and a Saturn 2000 mass selective detector. The GC temperature was programmed as follows: initial temperature 50°C, held for 1 min, increased to 240°C at 20°C/min, and held for 29.5 min. The split ratio was 1:10, injection temperature was 250°C, and transfer line temperature was 270°C. The mass spectrometer was operated at 70 eV in the electron impact mode.

Results

Ants removed silica gel from the bottles or vials until the space in the bottle or vial could accommodate the whole colony. Workers moved all brood into the bottles or vials within 2 d. Workers preferred depositing their excreta along the edge of the nesting device. Some silica gel particles turned either brownish or yellow, most likely due to excretion. After ants built their nest in the nesting devices, only a few workers were seen outside the nest. Cuticular hydrocarbons were found in pentane and pyridine extracts of all samples, and the retention times and mass spectra of cuticular hydrocarbons matched those of worker body extractions (Fig. 1). Venom alkaloids were found in pyridine extracts of all samples collected inside the nest; however, in only one sample (queenless), four venom alkaloids were all detected. No venom alkaloids were

found in silica gel, which was removed from the nest by ants while they were building their nest. The retention times and mass spectra of venom alkaloids matched those of worker body extractions (Fig. 2). The water extract of silica gel collected inside the nests contained lactic, malonic, and phosphoric acids as well as glycerol (Fig. 3).

Uric acid, urea, glycerol, phosphoric acid, amino acids, and organic acids were found in silica gel particles with ant excretion (Fig. 4). Thirteen organic acids were identified from all excreta samples, including lactic, malonic, benzoic, succinic, methylmaleic, 3-methylglutaric, malic, suberic, azelaic, hexadecanoic, 2-quinolinecarboxylic, gluconic, and stearic acids. Nine amino acids were identified in excreta samples, including alanine, glycine, *N*-acetylglycine, serine, threonine, aspartic acid, glutamine, phenylalanine, and tyrosine. The profile of amino acids in excreta was not consistent among

Discussion

Cuticular hydrocarbons and venom alkaloids were found in the nest materials, in agreement with the literature (Obin and Vander Meer, 1985; Vander Meer, unpublished data, cited Vander Meer and Lofgren, 1988; Storey et al., 1991). However, the results of this study show that red imported fire ants also deposited other compounds on nest materials.

Excreta were believed to be a source of element enrichment in mound soil of red imported fire ants (Herzog et al., 1976; Green et al., 1998, 1999), and organic compounds found in the excreta would possibly be accumulated in the mound. Although *S. invicta* is one of the most well-studied ant species in the United States, there is surprisingly little information on its excreta. Petralia et al. (1982) reported that larvae of *S. invicta* produced two forms of excretory products: a white precipitate composed of uric acid and a clear liquid of water and salts. Chen (2005) reported *S. invicta* excreted phosphoric acid. The chemistry of fire ant excreta has not been more fully examined until now.

Uric acid and urea were found in all brown or yellow silica gel samples, which suggested that the discoloration of the silica gel was due to the ant excreta. Urea excretion is not unusual in insects (Cochran, 1985), but it has never been reported as a nitrogenous excretory product of red imported fire ants. Many other nitrogenous compounds were also found in the colored silica gel, such as amino acids and 2-quinolinecarboxylic acid, raising interesting questions about the nitrogenous excretory mechanism of red imported fire ants, such as whether the amino acids and 2-quinolinecarboxylic acid also function as nitrogenous excretory products of *S. invicta*.

It was known that red imported fire ants excrete phosphoric acid (Chen, 2005). The results of this study show that fire ants also incorporate phosphoric acid into their nesting material because phosphoric acid was present in the water extractions of all samples collected inside the nests. Phosphoric acid and urea are well-known plant growth promoters. Thus, phosphoric acid and the nitrogen-containing excretory compounds may contribute to the abundant vegetation commonly found around fire ant mounds.

Glycerol was also found in the nesting materials and is known to be a humectant that promotes retention of moisture. Incorporation of glycerol into the nest material would influence the moisture balance inside the nest, and may contribute to microclimate regulation within the nest. This may be important when the environmental humidity is low, such as during a dry season.

Although all compounds identified inside the nest, such as lactic acid, malonic acid, phosphoric acid, and glycerol, also were found in excreta, the possibility of a secretory origin of these compounds cannot be excluded. Organic acids have been found as exocrine gland components of numerous ant species. A well-known example is formic acid, a component of poison gland secretions of formicine species (Hölldobler and Wilson, 1990). In addition to formic acid, acetic acid, butyric acid, isovalerianic acid, (D) 3-hydroxydecanoic acid, indoleacetic acid, and phenylacetic acid have been associated with ants of different species (Hölldobler and Wilson, 1990). Furthermore, Mikheyev (2003) reported four fatty acids and benzoic acid in the *S. invicta* male accessory glands, where they were believed to have a role in the formation of a mating plug. Benzoic acid was also found in the excreta of red imported fire ants. Because alates were present in all experiments, the possibility that benzoic acid might have come from the male accessory glands cannot be ruled out.

Incorporation of organic acids into nest material by red imported fire ants has not been reported. Organic acids are commonly recognized antimicrobial agents (Cherrington et al., 1991). For example, lactic acid, benzoic acid, and malic acid are used as food preservatives

for human consumption (http://www.lactose.co.uk/milkallergy/foodadditives200.html). The presence of these organic acids in the nesting materials may significantly affect the microorganism communities inside the nests, which in turn may influence colony fitness.

Knowledge of nest chemistry may contribute to our understanding of the behavior and chemical ecology of a nest-building ant species. The technique described herein may be useful in establishing profiles of ant-derived chemicals in the nests for other mound-building ant species.

Abstract Ascidians (sea squirts) may defend themselves from predators, biofouling competitors, and bacterial infection by producing secondary metabolites or sequestering acid, but many species also accumulate heavy metals, most notably vanadium. The defensive functions of heavy metals in ascidians remain unclear, and to this end, the solitary Caribbean tunicate, *Phallusia nigra*, was studied to localize vanadium in its tissues and to assess the defensive properties of vanadium-containing compounds. As determined by flame atomic absorption spectroscopy, the internal tissues and blood contained the highest vanadium concentrations (mean values of 2,280 and 1,886 ppm dry mass, respectively), followed by the tunic surface (871 ppm dry mass). Results of laboratory feeding assays with the bluehead wrasse, *Thalassoma bifasciatum*, confirmed outcomes of past studies that demonstrated that vanadyl sulfate ($VOSO_4 \cdot 6H_2O$) and sodium vanadate (Na_3VO_4) were unpalatable to fish, although these salts do not accurately reflect the chelation environment or oxidation state of vanadium in living tunicates. Fresh preparations of whole tunic, internal tissues, and blood were unpalatable to fish, but freezing and thawing of internal tissues and blood rendered them palatable. Crude organic extracts of whole tunic and internal tissues contained vanadium metabolites (225 and 750 ppm dry mass, respectively) and were palatable to *T. bifasciatum*; crude extracts also exhibited no antimicrobial effects against a panel of four marine bacteria known to be pathogens of marine invertebrates (*Vibrio parahaemolyticus*, *Vibrio harveyi*, *Leucothrix mucor*, and *Deleya marina*). Nonacidic vanadium (+3) complexes neither deterred predation nor inhibited microbial growth, whereas acidic aqua vanadium (+3 and +4) complexes were unpalatable to *T. bifasciatum* and exhibited antimicrobial activity. Difficulties in decoupling low pH from oxidation state and chelation environment of vanadium prevent definitive conclusions about the importance of some vanadium metabolites, but low pH appears to be the principal agent of chemical defense for *P. nigra*.

Introduction

Ascidians are soft bodied, sessile fouling invertebrates that are common in benthic marine environments and are widely distributed from the tropics (Hernández-Zanuy and Carballo, 2001) to the poles (Sahade et al., 1998). They secrete a body covering, the tunic, which consists predominantly of polysaccharides and proteins. Calcareous spicules are also found in the tunic of some species (e.g., Lambert and Lambert, 1987). Spicules were once thought to provide a physical defense against predation; however, fish-feeding assays performed with calcareous spicules of tunicates (Lindquist et al., 1992; López-Legentil et al., 2006) have demonstrated that mineralized inclusions have no deterrent effect. Tissue toughness of the tunic and an overall low nutritional value of ascidians have also been thought to deter predation. Tarjuelo et al. (2002) found a positive correlation between palatability and energy content in six ascidian species, but other studies have failed to support this hypothesis (Lindquist et al., 1992).

Putative chemical defenses of tunicates include secondary metabolites and inorganic acids (Pawlik, 1993; Pisut and Pawlik, 2002; Tarjuelo et al., 2002; López-Legentil et al., 2006), but may also include heavy metals, most notably vanadium (Webb, 1939; Ciereszko et al., 1963; Swinehart et al., 1974; Stoecker, 1978, 1980b). Some marine organisms use low pH as a form of chemical defense, ascidians among them (Thompson, 1960). Some ascidians accumulate sulfuric acid (pH≤2.0) in bladder cells located within the tunic (Webb, 1939; Swinehart et al., 1974). Pisut and Pawlik (2002) demonstrated that food pellets with pH≤3.0 were deterrent in feeding assays with the bluehead wrasse, *Thalassoma bifasciatum*.

It has long been recognized that ascidians actively accumulate heavy metals, including manganese, magnesium, iron, molybdenum, niobium, tantalum, chromium, and titanium, but most commonly vanadium (Webb, 1939; Ciereszko et al., 1963). Elemental vanadium does not exist in nature, but rather in anionic and cationic form with oxidized states ranging from −1 to +5. The most common oxidation states of vanadium under physiological conditions occur as +3, +4, and +5 (Rehder, 1999). Vanadium has been identified in trace amounts in bacteria, plants, and animals, where it acts to facilitate oxidative and reductive pathways. The vanadium center is necessary for nitrogen-fixing bacteria as part of the vanadium–nitrogenase enzyme complex involved in the reduction of gaseous N_2 to NH_4^+.

The black sea squirt *Phallusia nigra* (= *Ascidia nigra*) is a large solitary phlebobranch ascidian that ranges from Florida to Texas and throughout the West Indies on pilings and sea walls. In the field, *P. nigra* does not show signs of predation, and the tunic is free of fouling organisms (Goodbody, 1962; Hirose et al., 2001). In comparison to other ascidians, *P. nigra* has some of the highest recorded vanadium concentrations and is one of the best studied with respect to vanadium chemistry. In *P. nigra*, vanadium is stored primarily as vanadium (+3)(~70%), but vanadium (+4) is also present (~30%; Webb, 1939; Swinehart et al., 1974; Kustin et al., 1976; Frank et al., 2003). The coordination chemistry of the metal has yet to be completely clarified (Dingley et al., 1982; Bruening et al., 1985). X-ray absorption spectroscopic (XAS) investigations of the blood cells of this tunicate suggest that vanadium resides in more than one ligand environment and includes both V (+3) and V (+4) complexed with water molecules and V (+3) chelated to

proteins containing catechol and pyrogallol moieties. These ligand environments include low molecular weight proteins derived from the amino acids 3,4-dihydroxyphenylalanine (DOPA) or 3,4,5-trihydroxyphenylalanine (TOPA) (Bruening et al., 1985; Frank et al., 2003).

The concentration of vanadium in seawater is between 0.0003 and 0.003 parts per million (ppm). Most marine organisms contain vanadium concentrations of 1 to 3 ppm dry mass, but some ascidians have been shown to accumulate vanadium to 3,000 ppm (Ciereszko et al., 1963; Swinehart et al., 1974). In seawater, vanadium exists as vanadate ($H_2VO_4^- / HVO_4^{-2}$), vanadium (+5). In *P. nigra*, vanadium (+5) is accumulated from seawater, reduced to V (+4) and then stored as V (+3) (Dingley et al., 1982; Brand et al., 1989; Michibata et al., 2003). Vanadium is sequestered primarily in blood cells called vanadocytes (Kustin et al., 1976; Brand et al., 1989; Hirose, 1999; Hirose et al., 2001; Frank et al., 2003), but can also be found in high concentrations in a thin layer located near the exterior tunic surface (Stoecker, 1978). The oxidation state of vanadium is influenced by both the pH of the localized environment and the chelating ligands (Rehder, 1999). The mechanism of vanadium uptake, reduction, transfer, and accumulation has yet to be clarified (Michibata et al., 2003).

Stoecker (1978, 1980a,b) proposed that heavy metals, particularly vanadium, provide ascidians with antipredatory and antifouling defenses. The importance of vanadium as an antipredatory chemical defense was examined by using feeding assays with fish and crabs incorporating the vanadium salts, vanadyl sulfate ($VOSO_4 \cdot 6H_2O$) and sodium vanadate ($NaVO_3$). These compounds had a minimum deterrent concentration of 1,250–3,333 ppm dry mass (~100 ppm wet tissue mass). However, vanadium in ascidian tissues occurs in biochemical complexes that differ from those found in salts used for feeding assays (e.g., Bruening et al., 1985; Frank et al., 2003).

Low pH is coupled with heavy metal accumulation and storage in adult ascidians. In an attempt to decouple the relationship between inorganic acids and vanadium, we compared two nonacidic vanadium (+3) complexes to two acidic aqua vanadium (+3 and +4) complexes in laboratory assays by testing for antipredatory and antimicrobial activity. For comparison, components of the vanadium complexes and vanadium salts were tested for antipredatory and antimicrobial activity. In addition, *P. nigra* tissues and blood samples, both fresh and previously frozen, and crude organic extracts of *P. nigra* whole tunic and internal tissues were also assayed. In this study, we addressed the following questions: (1) Does vanadium act as a chemical defense of *P. nigra*? (2) Are the deterrent properties of vanadium affected by complexation environment and associated pH?

Methods and Materials

Whole individuals of *P. nigra* were collected with substrate intact along sea walls and pilings in the Port Largo Canal, Key Largo, FL, USA, in October 2002 and January 2003. Individuals were collected by self-contained underwater breathing apparatus (SCUBA) at depths between 3 and 7 m. Substrate attached to the basal portion of tunicates was carefully removed and each individual was immediately weighed and a volume determined by submerging the animal in a graduated cylinder and recording the amount of seawater displaced.

Blood of *P. nigra* was isolated as described in Brand et al. (1989). In brief, blood was extracted by heart puncture with a sterile 3-ml syringe and an 18.5-gauge wide bore hypodermic needle. The blood collected from each individual was placed in a sterile 2-ml cryogenic vial. Extracted blood was flash frozen in an ethanol and dry ice slurry (~−70°C) to limit oxidative effects. The tunic of each individual was then dissected from the internal

tissues, and the volume and mass of each were determined. After dissection, both the tunic and internal tissues were rinsed with distilled water and frozen in separate containers. Specimens of *P. nigra* were collected for the purpose of obtaining samples of the tunic bladder cell layer. This layer was separated from the rest of the tunic by using a sterile scalpel (Stoecker, 1978; Hirose, 1999; Hirose et al., 2001). The volume and mass of the tunic bladder cell layer were recorded. After dissection, the bladder cells were flash frozen and stored as previously stated.

Tunic and internal tissues were chopped into small pieces and exhaustively extracted in a mixture of 1:1 dichloromethane is to methanol (DCM:MeOH) followed by 100% MeOH using previously described methods (Pawlik et al., 1995). Frozen samples of tunic, tunic bladder cells, internal tissues, and blood were freeze dried until a constant mass was attained. Subsamples of whole tunic, internal tissues, tunic bladder cell layer, blood samples, and crude extracts of tunic and internal tissues were digested in hot concentrated 2:1 nitric acid is to sulfuric acid (HNO_3:H_2SO_4) (Sigma-Aldrich, trace metal grade) in a 25-ml Teflon digestion vessel. The concentration of vanadium from each sample was measured with flame AAS by using the standard curve method with a Perkin Elmer 3110 AAS and nitrous oxide (N_2O_2) (Kustin et al., 1976; Stoecker, 1978).

A solution of vanadium chloride (VCl_3, Fisher Scientific) in 1 M HCl was used to simulate the hexaaqua V (+3) component of *P. nigra* blood cell chemistry. The V (+3) fraction of the blood chelated by DOPA or TOPA-like ligand was simulated by V (acetylacetonate)$_3$ (Strem Chemicals Inc.) and K_3[V(catecholate)$_3$]·1.5 H_20 (Cooper et al., 1982), which was prepared as needed. The V (+4) fraction of the blood cells was reproduced as $VOSO_4$·6 H_2O in 1 M HCl (Frank et al., 2003). The vanadium (+3) tris (catecholate) complex, K_3[V(catecholate)$_3$] (molecular weight=519.55), was synthesized by using the methods described by Cooper et al. (1982). All operations were carried out with standard Schlenk techniques under nitrogen (N_2) atmosphere. Vanadium (+4) catecholate and vanadium (+3) catecholate complexes can be distinguished from one another by the presence of a V=O stretch at 977 cm^{-1} within the infrared (IR) spectra of V (+4) tris(catecholate) and the absence of this band in corresponding V (+3) tris(catecholate) complexes (Selbin, 1966). The techniques of infrared spectroscopy with a potassium bromide pellet (KBr) and ultraviolet (UV) spectroscopy were used to confirm the presence and coordination of vanadium in all synthesized vanadium compounds. Reaction products were purified by recrystallization.

Stock solutions of each vanadium-containing compound were prepared on the basis of the molecular weight of the vanadium fraction in proportion to the molecular weight of the entire vanadium complex. Three stock solutions of each vanadium complex with vanadium concentrations of 1,000, 2,000, and 4,000 μg/ml were prepared relative to known vanadium concentrations in tissues of *P. nigra*. The pH of each stock solution, and of ascidian blood, was determined by pipetting 30 μl of solution onto analytical pH strips (EM-reagents 9580, 9581, and 9590). The pH of fresh and frozen tissues was also determined by using analytical pH strips by pressing the test strip to the surface of the tissue with light pressure. Each stock solution and tissue type was measured three times to determine a mean pH value; the pH values were consistent and did not vary with each reading.

Fish feeding assays were performed with the bluehead wrasse, *T. bifasciatum*, a generalist Caribbean reef predator, as described in Pawlik et al. (1995). Vanadium complexes, reaction precursors, tissue and blood extracts were incorporated into a food matrix composed of freeze-dried squid mantle (5 g), alginic acid (Sigma-Aldrich, Na-salt form) (3 g), and distilled water (100 ml) (see Pisut and Pawlik, 2002 for discussion of food value of ascidian tissues). The mixture was stirred until homogenous and then packed into a

3.0-ml syringe and extruded into a 0.25-M calcium chloride ($CaCl_2$) solution, which caused the squid matrix to harden. After a few minutes, the spaghetti-like strand was removed from the $CaCl_2$ solution and rinsed with deionized water. The resulting string was cut with a razor blade into 4.0-mm long pellets. Control pellets were made in the same manner with the addition of the same solvent as used to dissolve the metabolite or extract for the corresponding treatment. Some highly basic compounds reacted with the squid and alginic acid matrix and caused it to harden before being extruded into the $CaCl_2$ solution. These compounds were instead incorporated into a food matrix composed of freeze-dried squid mantle (5 g), carageenan (3 g) (Sigma-Aldrich, type 1 commercial grade), and distilled water (100 ml). The mixture was stirred until homogenous and heated in a microwave until boiling. The mixture was then quickly remixed and poured onto a clean bench top and allowed to harden. Once the carageenan mixture had cooled, the resulting gel was cut with a razor blade into 4 mm long pellets. Control pellets were made in the same manner with the addition of the same solvent as used to dissolve the metabolite or extract for the corresponding treatment.

Five 30 gallon aquaria were divided into 24 cells, and groups of two to four yellow-phase *T. bifasciatum* were placed in each cell. Groups of fish were randomly chosen during feeding assays and offered a control food pellet, followed by a treatment pellet. If the fish rejected the treatment pellet, another control pellet was offered to determine whether the fish had stopped feeding; groups of fish that would not eat control pellets were not used in assays. A pellet was considered rejected if not eaten after a minimum of three attempts by one or more fish to take it into their mouth cavity or if the pellet was approached and ignored after one such attempt. Fish were fed 10–30 min before assays to limit effects due to extreme hunger. Uneaten pellets were removed from tanks after each assay. By using the Fisher exact test, a significant difference in the number of treated and control pellets eaten was determined for an individual 10-replicate assay if 4 or more pellets were rejected ($P \leq 0.043$, one-tailed test). Therefore, treatments were considered deterrent if the mean number of pellets eaten was ≤ 6 (Pawlik et al., 1995).

To assess the effect of basic (high) pH on palatability, food pellets were made as before with carageenan and the addition of 1 N sodium hydroxide (NaOH) that provided the desired pH, as indicated by pressing pellets against analytical test strips. Control pellets were made in the same manner, but did not include the addition of base. The mixture was stirred and microwaved for 30 sec. The heated mixture was poured onto a clean bench top and allowed to harden. Food pellets were cut from the hardened gel. Feeding assays were performed as before; however, the pH of food pellets was determined with analytical test strips both before assay and after pellets were rejected to assure consistency in pellet pH values. The pH of successive assays was increased within a range starting at pH 7.0 to 14.0. Control pellets had a pH of 7.0.

Antimicrobial activity was assessed for vanadium-containing compounds and reaction precursors and crude organic extracts of *P. nigra* tunic and internal tissues. Each compound and tissue extract was tested against an assembly of four marine bacteria that included: *Vibrio harveyi* (Microbial Identification, Inc., MIDI, Newark, DE, USA), *Deleya marina* (American Type Culture Collection (ATCC) 35142), *Vibrio parahaemolyticus* (ATCC 27969), and *Leucothrix mucor* (ATCC 25906). The bacterium *V. harveyi* was isolated and identified as part of a previous study by Kelly et al. (2003) and has been recognized as an opportunistic pathogen of certain fish and marine invertebrates. The marine microbe *D. marina* is a common surface fouling bacterium, and both *V. parahaemolyticus* and *L. mucor* are known marine pathogens that can cause disease in marine invertebrates (Kelly et al., 2003). Standard disc-diffusion antimicrobial assays were performed by inoculating each

bacterial test strain onto the surface of a YP agar medium plate: peptone (1.0 g l^{-1}) and yeast extract (1.0 g l^{-1}) in filtered seawater (32–36‰) with the addition of agar (15 g l^{-1}) (Newbold et al., 1999). Culture concentrations were measured before each antimicrobial bioassay by using a Milton Roy Spectronic 20 D at 500 nm. Only cultures that had an absorbance between 0.2 and 0.5 were used to inoculate bioassay media plates. A 100-µl aliquot of inoculated broth was spread with a sterile glass rod over the entire agar surface to form an evenly distributed film. Compounds were dissolved in solvent and tested by pipetting 30 µl onto a sterile circular paper disc (Becton Dickinson, 6×0.9 mm, disc volume=30 µl) and allowing the solvent to evaporate. Crude organic extracts were dissolved in methanol before transfer to paper disc. All solvents used to dissolve air-sensitive materials were degassed of oxygen before use, and all stock solutions were stored under inert atmosphere with purified nitrogen. After pipetting the stock solution onto a paper disc, the solvent was evaporated under nitrogen. Stock solutions were monitored for color change that would indicate oxidation events. If oxidation occurred, the solutions were remade before use in the assay. The discs were placed on the surface of the inoculated agar (up to nine per plate). By pressing lightly on the disc with an analytical pH strip, the pH of each disc was checked once the discs had rehydrated after being placed on the agar plate. All strains were incubated at room temperature (22°C), and a confluent film developed over the entire agar surface after 24 hr. Clear halos (zones) surrounding the discs denoted areas of inhibited microbial growth. The computer-imaging program Image J (National Institutes of Health, USA, http://rsb.info.nih.gov/ij/) was used to calculate area of inhibition zones by subtracting the area of the disc (28.27 mm^2) from the total area of clear zone. Compounds that exhibited inhibition zones (total area of clear zone minus the area of the disc) of greater than or equal to 50 mm^2 were considered to possess acute antimicrobial activity. Statistical analyses were not used to assign significance of differences between treatments because the disc diffusion assay is used as a qualitative measure of antibacterial activity (Newbold et al., 1999).

Results

Mean vanadium concentrations in tissues, blood samples, and crude organic extracts of *P. nigra* ranged from 2,280 ppm dry mass (63 ppm wet mass) in internal tissues to 225 ppm dry mass (7 ppm wet mass) in crude organic extracts of the ascidian tunic (Table 1). Assay foods prepared from tissue and blood of *P. nigra* were variable in their palatability to the

Table 1 Flame atomic absorbance spectroscopy results of the vanadium content (ppm ± SD) of freeze dried *P. nigra* tissues, blood samples, and crude organic extracts of whole tunic and internal tissues

Sample	*N*	Vanadium Content (ppm)	
		Dry Mass	Wet Mass
Whole tunic	6	259±157[a]	5±3
Tunic bladder cell layer	7	871±390[b]	18±8
Internal tissues	5	2,280±822[c]	63±23
Blood	7	1,886±567[c]	38±12
Crude extract, internal tissues	4	750±289	31±12
Crude extract, tunic	4	225±126	7±4

Wet mass concentrations were converted from dry mass. Significant differences in concentrations for tissues and blood are shown as different superscript letters (one-way ANOVA, N=3, F=41.02; Ryans–Einot–Gabriel–Welsch Multiple Range Test, homogeneous subsets at P=0.05).

generalist consumer fish, *T. bifasciatum*, with fresh material highly deterrent, while frozen material was readily eaten (Fig. 1). Both freshly dissected whole tunic tissue (pH ~ 2.0) and previously frozen tunic (pH=7) were unpalatable to *T. bifasciatum*. Freezing and thawing neutralized low pH of tissues but did not affect the vanadium content. In all cases, fishes

Treatment	Vanadium Concentration µg/ml	Food Pellet pH
Whole Tunic (fresh)	5 ± 3	2.0

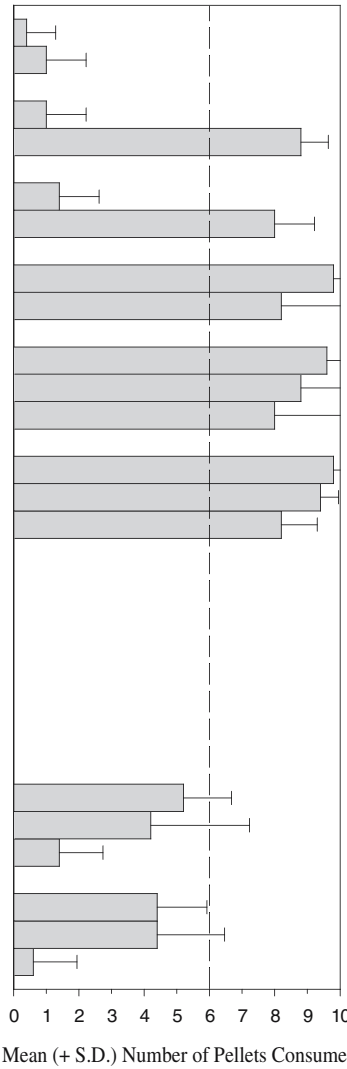

Fig. 1 Consumption by the bluehead wrasse, *T. bifasciatum*, of food pellets treated with tissue and blood of *P. nigra*, vanadium complexes, and vanadium salts. Compounds were considered deterrent if the mean number of pellets eaten for any individual assay were less than or equal to 6 ($P \leq 0.043$, Fisher exact test, one-tailed), as indicated by the *dotted line* on the graph. Mean + SD shown for five replicate assays of each treatment. Vanadium concentration and pH of food pellet are shown for each treatment

approached and mouthed the pieces of the tunic but did not eat them. Food pellets made with finely chopped tunic tissue, fresh and frozen, were also mouthed and the squid matrix consumed; however, the bulk of the tunic tissue was rejected. Freshly dissected soft body internal tissues (pH=7) were unpalatable to *T. bifasciatum*, whereas frozen and thawed tissues were consumed, but in this case, there was no change in pH after freezing and thawing. Fishes rejected freshly collected *P. nigra* blood (pH ~ 2) incorporated into food pellets, whereas frozen and thawed blood (pH=7) was palatable.

In the same feeding assays with *T. bifasciatum*, crude organic extracts of ascidian tissues, vanadium complexes, and vanadium salts were also variably deterrent, with the greatest level of unpalatability associated with low pH (Fig. 1). Crude organic extracts of internal tissues contained high vanadium concentrations (750 ppm dry mass=31 ppm wet mass, Table 1), but were palatable to *T. bifasciatum* (Fig. 1). The nonacidic vanadium (+3) compounds bound to DOPA/TOPA-like chelation environments were also tested, and V (acetylacetonate)$_3$ and K_3[V(catecholate)$_3$] were palatable to *T. bifasciatum* at all of the concentrations assayed. Food pellets with vanadyl sulfate were unpalatable to *T. bifasciatum*, but at the highest pH assayed (pH=2.2), a mean of five pellets were eaten, with decreasing palatability as the vanadium content was increased and the pH decreased. Food pellets made with the vanadium salt sodium vanadate at all concentrations (pH=11) were unpalatable to *T. bifasciatum* (Fig. 1). This effect was not attributable to high pH because food pellets treated with NaOH to generate high pH were only unpalatable to *T. bifasciatum* at pH≥13.0 (Fig. 2). The pH of food pellets treated with NaOH was tested after rejection by assay fishes and had not changed.

By using a standard disc-diffusion assay, crude organic extracts of tunic and internal tissues, vanadium complexes, and vanadium salts were assessed for antimicrobial activity against a panel of four marine bacteria known to infect marine invertebrates. Crude organic extracts of dissected tunic and internal tissues (N=3 for each tissue type vs. each bacteria) of four individual tunicates did not exhibit any antimicrobial activity against the panel of marine bacterial lines tested (data not shown). The nonacidic vanadium (+3) complexes, V (acetylacetonate)$_3$, and K_3[V(catecholate)$_3$] did not exhibit any antimicrobial activity against the entire panel of marine bacteria; however, the acidic aqua vanadium (+3 and +4) complexes inhibited microbial growth (Table 2). Although assayed at equivalent vanadium concentrations, the two vanadium salts had different effects on the panel of bacteria.

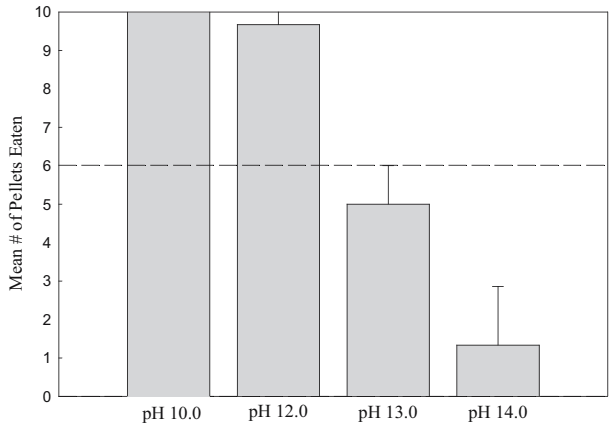

Fig. 2 Consumption by *Thalassoma bifasciatum* of food pellets treated with sodium hydroxide. Fish consumed ten control pellets in all cases. Treatments were considered deterrent if the number of pellets eaten was less than or equal to 6 (P≤0.043, Fisher exact test, one-tailed), as indicated by the dotted line on the graph. Mean + SD shown for three replicate assays of each treatment

Sodium vanadate at all concentrations (pH=11) did not inhibit microbial growth, whereas vanadyl sulfate (pH 1.9 to 3.6) did produce clear zones of inhibition (Table 2)

Discussion

The presence of low pH and heavy metals in the tissues of ascidians has long been recognized. Stoecker (1978) first hypothesized that inorganic acids and heavy metals, most notably vanadium, provided ascidians with effective antipredatory and antifouling defenses. Parry (1984) disputed Stoecker's results, but arguments by Parry (1984) were correlative and based on the existence of other tunicate species in similar habitats that contained neither vanadium nor acid, yet remained uneaten or fouled. Parry (1984) did not consider the presence of secondary metabolites as defenses that might function in the absence of vanadium and sulfuric acid. Stoecker (1980a) conducted feeding assays with fish and crabs with the salts vanadyl sulfate and sodium vanadate. These salts putatively represented the oxidation state of vanadium when it was released from the ascidian during a predation event. The results of the feeding assays reported herein that used the bluehead wrasse, *T. bifasciatum*,

corroborate those of Stoecker (1980a) that used the fishes *Fundulus heteroclitus* (common killifish), *Abudefduf saxatilis* (sergeant major), and *Haemulon sciurus* (blue striped grunt). However, salts of vanadium do not accurately reflect vanadium as it is found in the tissues and blood of *P. nigra*. Furthermore, pH and vanadium accumulation and storage in adult ascidians are coupled, making it difficult to determine the chemical deterrence of the individual components.

This study is the first to attempt to decouple the chemical deterrence of vanadium from low pH in assessing the chemical defense of an ascidian. The presence of vanadium did not always deter predation or inhibit microbial growth (Fig. 1, Table 2), whereas low pH consistently did both. Whole tunic deterred feeding despite having a low concentration of vanadium, regardless of whether it was assayed at pH 2 or 7 (Fig. 1), suggesting a physical defense of the outer body covering. Crude extracts of tunic and internal tissues that contained vanadium but were not acidic neither deterred predation nor inhibited microbial growth. Vanadium species decoupled from acidity by chelation to DOPA/TOPA-type ligands did not deter predation or inhibit microbial growth; however, acidic aqua vanadium (+3 and +4) complexes were deterrent in both assay systems.

Localization of chemical defenses to specific regions of an organism is exhibited in terrestrial plants and marine organisms (Zangerl and Rutledge, 1996; Dworjanyn et al., 1999; Van Alstyne et al., 1999) and has also been suggested in tunicates (Pisut and Pawlik, 2002; Tarjuelo et al., 2002). Surface associated defenses may enhance the survival of an organism by providing a mechanism to protect against predation, deter fouling organisms, and control epibiont populations (Wahl et al., 1994). Acidity is important in deterring potential predators and is probably effective against most grazers and browsers (Thompson, 1960; Stoecker, 1980a). Davis and Wright (1989) hypothesized that surface acidity would be neutralized by the buffering capacity of seawater, but Pisut and Pawlik (2002) demonstrated that low pH persists in tissues for some time. Brief localized exposure to low pH may be enough to deter a potential predator (Hirose et al., 2001). Pisut and Pawlik (2002) demonstrated that pieces of the acidic tunic of *Ascidia interrupta* were unpalatable to *T. bifasciatum* in feeding assays, whereas crude organic extracts of the tunic were palatable. Moreover, epibionts are rare on species that have acidic tunics (Stoecker, 1980a).

In the solitary tunicate *P. nigra*, low pH and vanadium are associated with the tunic exterior. Acidic fluid is released from bladder cells localized near the exterior surface when the tunic is bruised or damaged (Hirose et al., 2001; Pisut and Pawlik, 2002). Vanadium is not evenly distributed throughout *P. nigra* tissues (Table 1), corroborating the previous work of Stoecker (1978) and Ciereszko et al. (1963). Vanadium is stored mainly in blood cells called vanadocytes, but is also accumulated at the tunic surface (Kustin et al., 1976; Brand et al., 1989; Hirose, 1999; Hirose et al., 2001; Frank et al., 2003). Interestingly, vanadocytes are able to migrate from blood vessels located in the tunic and accumulate in the pigmented layer located at the tunic surface. However, the coordination environment of vanadium at the tunic surface has yet to be fully clarified.

Acidic tissues are repellant to most fish (Thompson, 1960) and may primarily explain why *P. nigra* is unpalatable to fish predators. Tissues associated with low pH were unpalatable to *T. bifasciatum*; however, these same tissues that were frozen and then thawed exhibited higher pH values and were more palatable, perhaps, because of the buffering capacity of spicules or salts in the tunic. Although this process would not affect the presence of vanadium in these tissues, the oxidation state and ligand coordination associated with vanadium could be affected due to changes in the storage environment and oxidative effects of cell lysis. Non-chelated vanadium (+3) ions are unstable in air or moisture and are rapidly oxidized at pH≥2 (see review in Rehder, 1999). Interestingly, tunic

tissue pieces from both fresh and frozen *P. nigra* were both unpalatable to *T. bifasciatum* despite differences in pH, a result that cannot be readily explained.

In standard disc diffusion assays, crude organic extracts of the tunic and internal tissues of *P. nigra* did not inhibit the growth of any of the bacteria assayed. Nonacidic vanadium (+3) compounds also did not inhibit microbial growth, whereas low pH and acidic aqua vanadium (+3 and +4) complexes did. Although assayed at equivalent vanadium concentrations, the two vanadium salts had different effects on the panel of bacteria. Sodium vanadate (pH=11) did not inhibit microbial growth, whereas vanadyl sulfate (pH 1.9 to 3.6) did produce clear zones of inhibition. Acidic fluids that are released from ruptured bladder cells may be able to kill or inactivate bacteria or other microorganisms that would otherwise gain access to tunic tissues. Difficulties in decoupling low pH from oxidation state and chelation environment of vanadium prevent definitive conclusions about the defensive properties of some vanadium metabolites, but low pH appears to be the principal agent of chemical defense for *P. nigra*.

Jasmonic Acid-Induced Changes in *Brassica oleracea* Affect Oviposition Preference of Two Specialist Herbivores

Maaike Bruinsma · Nicole M. Van Dam · Joop J. A. Van Loon · Marcel Dicke

Abstract Jasmonic acid (JA) is a key hormone involved in plant defense responses. The effect of JA treatment of cabbage plants on their acceptability for oviposition by two species of cabbage white butterflies, *Pieris rapae* and *P. brassicae*, was investigated. Both butterfly species laid fewer eggs on leaves of JA-treated plants compared to control plants. We show that this is due to processes in the plant after JA treatment rather than an effect of JA itself. The oviposition preference for control plants is adaptive, as development time from larval hatch until pupation of *P. rapae* caterpillars was longer on JA-treated plants. Total glucosinolate content in leaf surface extracts was similar for control and treated plants; however, two of the five glucosinolates were present in lower amounts in leaf surface extracts of JA-treated plants. When the butterflies were offered a choice between the purified glucosinolate fraction isolated from leaf surface extracts of JA-treated plants and that from control plants, they did not discriminate. Changes in leaf surface glucosinolate profile, therefore, do not seem to explain the change in oviposition preference of the butterflies after JA treatment, suggesting that as yet unknown infochemicals are involved.

Introduction

Plants can be attacked by many herbivorous insects and have evolved a variety of defense strategies, including morphological barriers, synthesis of toxic or repellent secondary metabolites, and the release of synomones that attract natural enemies of the herbivores.

These defenses can be constitutive, i.e., expressed independent of the presence of an attacker, or inducible, in which case defense compounds accumulate in response to attack (Karban and Baldwin, 1997). Herbivores can detect induced defensive compounds and respond by avoiding these plants, which signal lower suitability as a host plant (Landolt, 1993; De Moraes et al., 2001; Kessler and Baldwin, 2001; Meiners et al., 2005). Induced plant defense can affect herbivorous insects directly through the production of toxic compounds or indirectly through the production of cues that indicate intra- or interspecific competition for the herbivores (Schoonhoven et al., 2005). Moreover, induced plant defense signals can reduce the enemy-free space for the herbivores. For parasitoids and predators, induced infochemicals may indicate the presence of their host or prey on the plant (Turlings et al., 1990; Dicke and Vet, 1999). Phenotypic changes in individual plants may therefore affect insects at different trophic levels, and thus, the composition of the insect community and food web associated with the plant (Price et al., 1980; Van Zandt and Agrawal, 2004; Takabayashi et al., 2006).

Already in the 19th century, Kirby and Spence (1863) observed that *Pieris brassicae* females preferred to lay their eggs on plants devoid of eggs. Later, this was confirmed under more controlled conditions by Rothschild and Schoonhoven (1977) for both *P. brassicae* and *Pieris rapae*. This avoidance of infested plants is caused by a physiological response of the plant to oviposition, rather than by compounds excreted by the butterflies themselves (Blaakmeer et al., 1994). The butterflies also avoid egg deposition on leaves with feeding larvae (Rothschild and Schoonhoven, 1977). It was postulated that butterflies avoid laying eggs on herbivore-infested plants because herbivore attack induces defense compounds in plants that can influence the performance of their offspring and to reduce the risk of inter- or intraspecific competition and parasitism (Thompson and Pellmyr, 1991; Shiojiri et al., 2002). Egg-induced chemical changes in *Brassica* plants are also known to arrest *Trichogramma* parasitoids that parasitize *Pieris* eggs (Fatouros et al., 2005).

Oviposition-site selection involves an important behavioral decision in the life cycle of an herbivorous insect because hatching larvae have limited dispersal capacity (Renwick and Chew, 1994). *P. rapae* is a solitary butterfly that lays one egg at a time, whereas *P. brassicae* is gregarious and lays batches of about 20–100 eggs. *P. rapae* appears to spread the risk of larval mortality, laying few eggs within any patch. This has the advantage of being able to exploit isolated plants (Davies and Gilbert, 1985). *P. brassicae*, however, needs patches of plants because one large egg batch will require more than one plant for all caterpillars to develop into adults. Oviposition-site selection is performed in consecutive phases of searching and contact evaluation. *P. rapae* butterflies use visual, olfactory and tactile cues during these phases (Rothschild and Schoonhoven, 1977; Renwick and Radke, 1988). Acceptance of a site may be determined by the balance of positive and negative factors (Renwick and Radke, 1988). Renwick and Radke (1988) suggest that olfaction does not play a role in attraction to a host plant, but may be involved in avoidance of non-host plants. *P. rapae* and *P. brassicae* are crucifer specialists and are known to use glucosinolates, toxic secondary metabolites characteristic for Brassicaceae, as oviposition stimulants. Glucobrassicin and sinigrin are effective oviposition stimulants for *P. brassicae* and *P. rapae* (Renwick et al., 1992; Van Loon et al., 1992a).

A major signal-transduction pathway involved in induced plant defense is the octadecanoid pathway (Arimura et al., 2005). A central compound in the pathway is jasmonic acid (JA), which has an important role in direct and indirect defense in many plant species. In response to JA or methyl jasmonate (MeJA) treatment, increased concentrations of several compounds have been documented in a range of plant species, e.g., proteinase inhibitors (Moura and Ryan, 2001), polyphenol oxidases (Thaler et al., 1996), nicotine

(Baldwin et al., 1996), trypsin inhibitors (Cipollini and Sipe, 2001), glucosinolates (Cipollini and Sipe, 2001; Van Dam et al., 2004; Mewis et al., 2005), and increased volatile emission (Boland et al., 1995; Dicke et al., 1999; Koch et al., 1999).

Herbivores are reported to be affected by JA treatment of plants. Several studies have focused on the larval stage of the herbivores and have shown reduced relative growth rates and leaf consumption (Van Dam et al., 2000; Gols et al., 2003; Van Dam et al., 2004). In field experiments, spraying of JA decreased the abundance of caterpillars, flea beetles, aphids, and thrips (Thaler et al., 2001). Other studies addressed the influence of JA application to plants on oviposition-site selection behavior of adult herbivores. These studies showed that JA application can result in induced resistance as well as induced susceptibility (Stanjek et al., 1997; Kessler and Baldwin, 2001; Lu et al., 2004).

Here, we studied how JA application affects oviposition of two specialist herbivores on cabbage, *Pieris rapae* L. and *P. brassicae* L. (Lepidoptera: Pieridae) that are closely related, yet differ drastically in the amount of eggs they put on one plant. Our study is the first to compare closely related herbivores with a different oviposition strategy, which might affect the consequences of JA-induced responses. JA is known to mediate the induction of chemical defense responses in plants to feeding damage and deposition of eggs (Dicke and Van Poecke, 2002; Hilker and Meiners, 2006; Mumm and Hilker, 2006). By using JA, we were able to examine the effects of induced defense responses in cabbage. Moreover, JA application has the advantage that visually detectable damage and the presence of herbivores or eggs are avoided. Finally, JA allows control over the strength of induction through controlled dosages. We hypothesized that JA treatment would inhibit the oviposition of the butterflies. We made solvent extracts to address the identity of the active plant compounds that influenced butterfly behavior. Rather than testing whole-leaf extracts, however, we extracted the glucosinolates from the surface of both control and JA-treated plants and tested the oviposition preference of the butterflies for these glucosinolate fractions on a neutral substrate. Furthermore, we included a control experiment to exclude a potential direct effect of JA on oviposition behavior. We addressed the following questions: (1) does JA treatment of cabbage plants affect host plant selection of the two *Pieris* butterfly species; (2) are there differences between solitary and gregarious butterflies; (3) does JA treatment affect glucosinolate levels in leaf surface extracts; and (4) do changes in glucosinolate levels determine the changes in oviposition preference?

Methods and Materials

Plants and Insects Brussels sprouts plants, *Brassica oleracea* var. *gemmifera* L. (Brassicaceae) cultivar Cyrus were grown from seed in a greenhouse in plastic pots (11×11×11 cm) at 20–28°C, 40–80% RH and a 16-hr light/8-hr dark photoperiod. All experiments were conducted with 6- to 7-wk-old plants. Stock colonies of the large cabbage white *P. brassicae* and the small cabbage white *P. rapae* were maintained on Brussels sprouts in a climatized room at 20–22°C, 50–70% RH and a 16-hr light/8-hr dark photoperiod.

Chemical Analysis Brussels sprouts plants were sprayed with 0.1 mM JA or control solution. JA ((±) jasmonic acid, purity >97%; Sigma-Aldrich, St Louis, MO, USA) was applied to the surface of the leaves, i.e., plants were sprayed with a JA solution with 0.1% Tween 20 until run-off or just with 0.1% Tween 20 for the control. The next day, glucosinolates (GLS) were extracted from the surface of the intact Brussels sprouts leaves. Each sample consisted of four leaves (between the third to sixth leaf from the base of a

plant) that were cut at the base of the petiole. Directly after cutting, the lamina was dipped for 5 sec in 300 ml of dichloromethane, and after a 5-sec interval, it was dipped for 5 sec in 150 ml of methanol (Städler and Roessingh, 1990; Van Loon et al., 1992a; Griffiths et al., 2001). The methanol was evaporated from the crude methanol dip-volume with a rotary evaporator (IKA-Werke GmbH, Staufen, Germany). For each treatment, 11 plants were sampled. The extract was redissolved in methanol, desulphatased on a DEAE-Sephadex A25 column, and separated on a reverse phase C-18 column by using high performance liquid chromatography (HPLC) as described in Van Dam et al. (2004). Glucosinolate detection was performed with a photodiode array (PDA) detector (200–350 nm) with 229 nm as the integration wavelength. Sinigrin (sinigrin monohydrate, ACROS, NJ, USA) was used as an external standard. We used the correction factors at 229 nm from Buchner (1987) and the EC (EC, 1990) to calculate the concentrations of the glucosinolates. Desulfoglucosinolate peaks were identified by comparison of HPLC retention times and UV spectra with standards kindly provided by M. Reichelt, MPI Chemical Ecology and a certified rape seed standard (Community Bureau of Reference, Brussels, code BCR-367R). The surface area was measured directly after dipping, and the dry mass of the leaves was measured after drying at 50°C for 72 hr. The GLS content was calculated in pmol per cm^2 leaf material.

Herbivore Oviposition Preference Test Pieris adults emerged from pupae in a large oviposition cage (67×100×75 cm) in a greenhouse compartment at 22–24°C and 50–70% RH. Apart from natural daylight, cages were illuminated by sodium vapor lamps (type SON-T, 500 W, Philips, The Netherlands) from 8:00 A.M. until 2:00 P.M. In this cage, they were provided with a 10% sucrose solution and an oviposition substrate; depending on the experiment, a plant or an artificial leaf made of green cardboard paper sprayed with sinigrin. For the experiments, one male and one female butterfly were introduced per oviposition cage (67×50×75 cm) in the same greenhouse compartment, on the day before the experiment. In these cages, the butterflies were also provided with sucrose solution. At 8:30 A.M., the treated leaves or papers and respective controls were introduced into the cages, and the butterflies were allowed to oviposit until the beginning of the afternoon. At 2:00 P.M., the leaves were removed, and the number of eggs was counted. The experiments were carried out in several cages per day and 3–4 d per treatment with new pairs of butterflies each day, adding up to a total of 24–36 independent replicates.

Surface Application of JA The effect of JA-induced changes in Brussels sprouts plants on butterfly behavior was tested in oviposition experiments with *P. brassicae* and *P. rapae*. Three concentrations of JA solution, 0.01, 0.1, and 1 mM, corresponding to approximately 1.25, 12.5, and 125 μg JA/g fresh weight (or 0.25, 2.5, and 25 nmol JA/cm^2) respectively, were sprayed on the plants and tested against a control (plants treated with 0.1% Tween 20). The next morning, just before the start of the experiment, the fourth, fifth, and sixth leaves from the base of the plants were cut, and their petioles were placed directly into a vial with tap water and introduced into the cages with butterflies.

Systemic Uptake of JA For *P. rapae*, two application methods were used to assess the effect of JA-induced changes in Brussels sprouts on oviposition preference. For the second application method, the fourth, fifth, and sixth leaves were cut from untreated plants and placed in a 0.1-mM aqueous JA solution 22 hr before the start of the experiment. Total uptake of the solution was on average 6.3±1.5 ml per control leaf and 6.0±1.6 ml for JA-treated leaves (corresponding to approximately 20 μg JA/g fresh weight or 5 nmol JA/cm^2, assuming homogeneous distribution over the leaf tissue after uptake).

Effect of Pure JA on Oviposition Preference In the next experiment, green cardboard paper sprayed with an oviposition stimulant was used to test the effect of pure JA on the oviposition behavior of *P. rapae* on an inert substrate. Sinigrin has been shown to be a suitable oviposition stimulant for *Pieris* butterflies (Van Loon et al., 1992a) and was therefore used to stimulate oviposition on the artificial substrate in this experiment. The paper (8×11.5 cm) was treated with 1 ml of a 5-mM sinigrin solution (Janssen Pharmaceutica, Tilburg, The Netherlands) by spraying it with a Desaga chromatographic sprayer (Heidelberg, Germany). Subsequently, after drying, papers were sprayed with either 1 ml of a 1-mM JA solution or water (control substrates) just before the test (210 μg JA/carton or 11 nmol JA/cm^2).

Bioassays with Purified Glucosinolate (GLS) Fractions GLS were extracted from the leaf surface as described for the chemical analysis. For each treatment, control and 0.1 mM JA, 60 plants were used for the extraction, of which four to five leaves per plant were dipped. Subsequently, the extracts were fractionated following the protocol of Sørensen (Sørensen, 1990). The GLS fractions were stored in the freezer until analysis. The GLS were dissolved in methanol to make two concentrations, one corresponding to the amount of GLS extracted from the material of two plants in 0.8 ml and one concentration corresponding to the amount of GLS from one leaf in 0.8 ml. Hereafter, we will express these concentrations in gram leaf equivalents (gle). One gle corresponds to the amount of GLS extracted from 1 g fresh and intact leaf. With an average weight of 6 g per leaf, the highest concentration corresponds to 48 gle and the lower concentration to 6 gle. With a sprayer, a volume of 0.8 ml of one of the solutions was sprayed on green paper following the same method as described above for the test of pure JA. *P. rapae* butterflies were offered a two-choice situation, with one paper sprayed with GLS extracted from control plants and one paper with GLS from JA-treated plants.

Performance of P. rapae Caterpillars The development of first instar caterpillars to pupae was observed on control and JA-treated plants. Control plants were sprayed with a 0.1% Tween 20 solution and JA-treated plants with a solution of 0.5 mM JA with 0.1% Tween 20. Thirty newly hatched *P. rapae* caterpillars were evenly distributed over two plants per treatment, 24 hr after treatment, and were placed in cages (67×50×75 cm) in a greenhouse compartment at 22–24°C and 50–70% RH. The plants were replaced with new plants twice a week, so that the maximum time between induction and larval feeding never exceeded 5 d. The number of days until pupation and pupal weight were recorded.

Statistical Analyses Each individual butterfly female was subjected to a two-choice situation, in which most individuals oviposited on both control and JA-treated leaves. As the egg load differed between individuals, the number of eggs on each treatment per individual was treated as a paired sample. The oviposition data for *P. rapae* were normally distributed; therefore, they were analyzed with a paired *t*-test. The oviposition data for *P. brassicae* were not normally distributed, and therefore, analyzed with the nonparametric equivalent of the paired *t*-test, the Wilcoxon matched-pair signed-ranks test. The data on the developmental time of the caterpillars in the performance test were not normally distributed and were analyzed with a Mann–Whitney *U* test for differences between the treatments. Pupal weight was normally distributed and analyzed with an analysis of variance (ANOVA). Changes in GLS content were analyzed with a Mann–Whitney *U* test. Statistical analyses were performed with SPSS 11.0.

Table 1 Glucosinolate content in surface extracts of *Brassica oleracea* leaves in pmol/cm^2 for control and JA-treated plants

Compound	Control Treatment Median (range)[a,b]	JA Treatment Median (range)[a,c]	*Z*	*P*
Glucoiberin	10.7 (6.3–21.7)	0 (0–6.0)	−2.713	0.007
Sinigrin	9.3 (0–23.5)	4.2 (0–6.8)	−1.774	0.076
4-Hydroxyglucobrassicin	0.7 (0–6.1)	0 (0–0)	−2.207	0.027
Glucobrassicin	34.9 (18.4–98.2)	88.6 (38.6–132.5)	−1.479	0.139
4-Methoxyglucobrassicin	0.5 (0–2.5)	0 (0–1.3)	−1.370	0.171
Total amount of glucosinolates	64.1 (27.0–155.7)	90.0 (42.9–138.8)	−0.563	0.573

[a] Interquartile range from first to third quartile

[b] $N=10$

[c] $N=11$

Results

Chemical Analysis Five GLS were detected in *B. oleracea* leaf surface samples: glucoiberin, sinigrin, 4-hydroxyglucobrassicin, glucobrassicin, and 4-methoxyglucobrassicin (Table 1). No significant difference was detected between JA-treated and control leaves for the total amount of GLS per cm^2. The amounts of glucobrassicin, the most abundant glucosinolate in these samples, 4-methoxyglucobrassicin, and sinigrin, did not significantly differ between control and JA-treated leaves. The amounts of glucoiberin and 4-hydroxyglucobrassicin collected in the leaf surface extracts were significantly lower for JA-treated leaves compared to control leaves (Table 1). The same results were obtained when calculated for the GLS content expressed as nmol per mg dry weight (not shown).

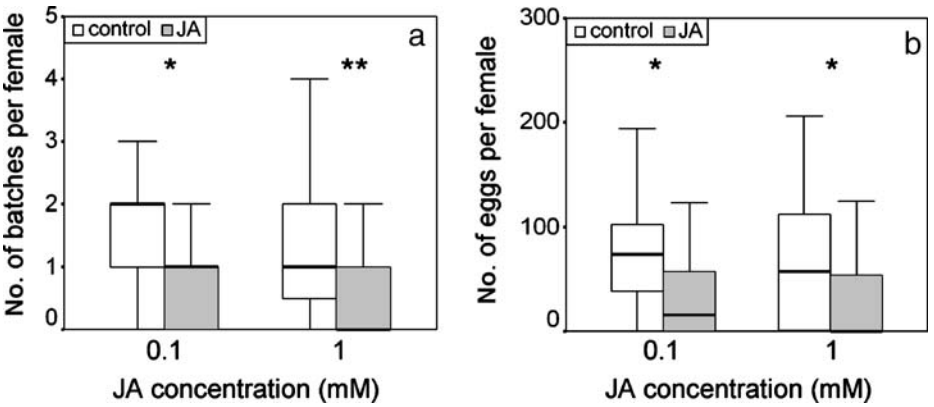

Fig. 1 *Pieris brassicae* oviposition on control and JA-treated plants. Two concentrations of JA were tested against a control. The box represents the interquartile range from first to third quartile, the line across the box indicates the median; *asterisks* indicate statistical differences between the preference for control and JA-treated plants (*$P<0.05$, **$P<0.01$, Wilcoxon matched-pair signed-ranks test). **a** Egg batches per female per leaf. **b** Eggs per female per leaf

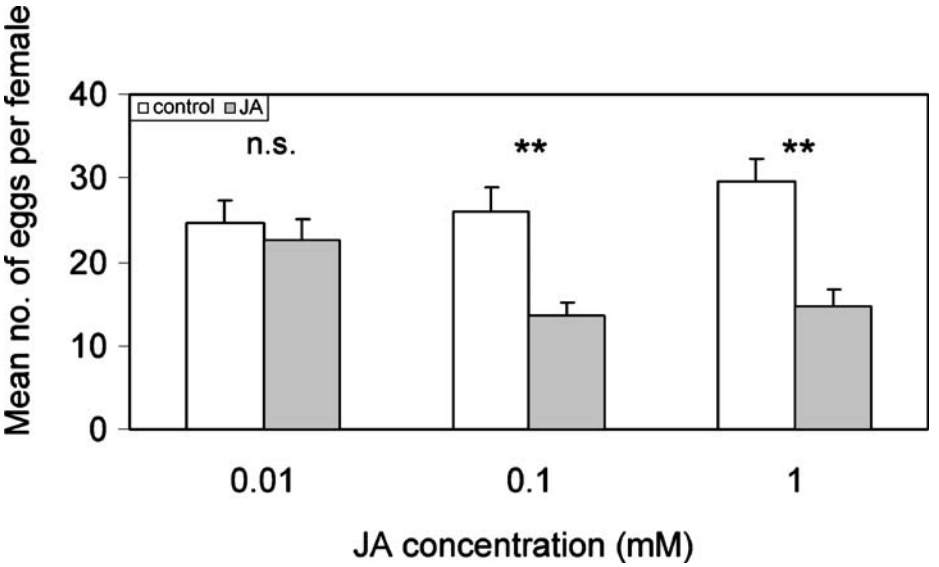

Fig. 2 *Pieris rapae* oviposition preference (measured as the number of eggs per female per leaf) between control and JA-treated *B. oleracea*. Three concentrations of JA were tested against a control in 24 replicated experiments for each concentration. Mean numbers of eggs per female + SEM are given; *asterisks* indicate statistical differences between the preference for control and JA-treated plants (n.s. $P>0.05$, $^{**}P<0.01$, paired *t*-test)

Herbivore Oviposition Preference: Surface Application of JA As *P. brassicae* lays its eggs in batches, both the number of egg batches and the number of eggs per leaf were counted. For the 1 mM JA treatment, the number of batches was significantly lower on JA-treated leaves than on control leaves ($N=36$, $Z=-2.628$, $P=0.009$, Wilcoxon matched-pair signed-ranks test), and the total number of eggs was significantly lower as well ($N=36$, $Z=-2.035$,

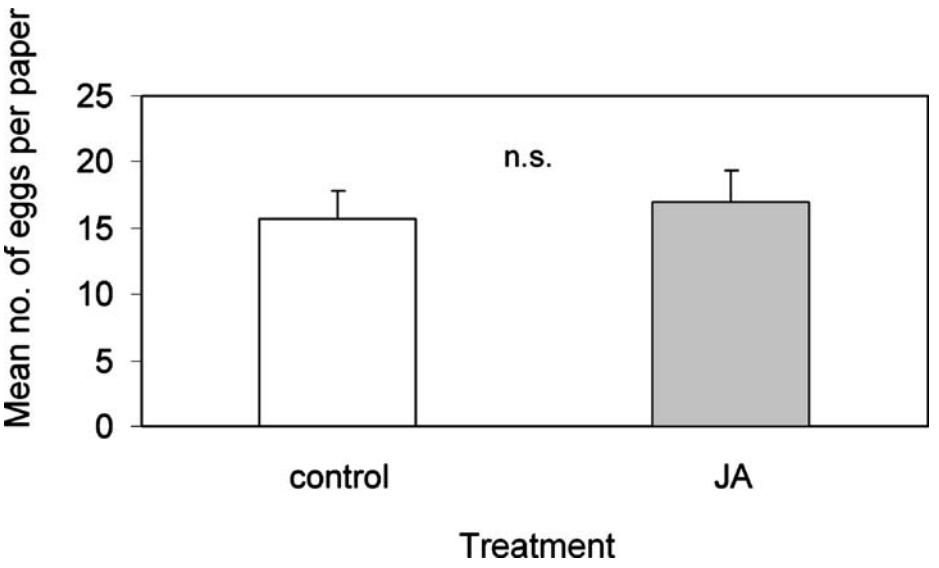

Fig. 3 Oviposition of *P. rapae* on green paper sprayed with sinigrin plus JA and green paper with sinigrin only. Mean number of eggs per female per paper leaf + SEM (n.s. $P>0.05$, paired *t*-test, $N=27$)

Table 2 Glucosinolate (GLS) content in fractions from leaf surface extracts from control and JA-treated plants in pmol/cm^2, *Z* and *P*-values of Mann–Whitney *U* test

Glucosinolate	GLS from control plant	GLS from JA-treated plant
Glucoiberin	4.9	3.9
Sinigrin	3.1	5.1
4-Hydroxyglucobrassicin	Not detected	Not detected
Glucobrassicin	16.0	81.0
4-Methoxyglucobrassicin	Not detected	0.8

P=0.042, Wilcoxon matched-pair signed-ranks test). For the 0.1-mM JA treatment, the result was similar (*N*=27, batches: *Z*=−2.223, *P*=0.026; eggs: *Z*=−2.138, *P*=0.032, Wilcoxon matched-pair signed-ranks test) (Fig. 1). Experiments with 0.01 mM JA application did not show discrimination by the butterflies between the treated and control leaves (results not shown). Also, *P. rapae* butterflies significantly preferred to oviposit on control leaves compared to JA-treated leaves (Fig. 2). The leaves treated with the two highest concentrations of JA tested, 1 and 0.1 mM, were avoided in favor of the control leaves (paired *t*-test, respectively, *t*=3.805, *df*=23, *P*=0.001 and *t*=3.681, *df*=23, *P*=0.001). The lowest concentration of JA tested, i.e., 0.01 mM, did not affect the distribution of eggs over the leaves (*t*=−0.662, *df*=23, *P*=0.52, paired *t*-test).

Systemic Uptake of JA In the experiment with *P. rapae* that employed systemic uptake of JA through the petiole, the same result was obtained: the number of eggs on the JA-treated leaves (10.0±1.57) was lower than on the control (19.12±2.82) leaves (*t*=3.976, *df*=31, *P*<0.001, paired *t*-test).

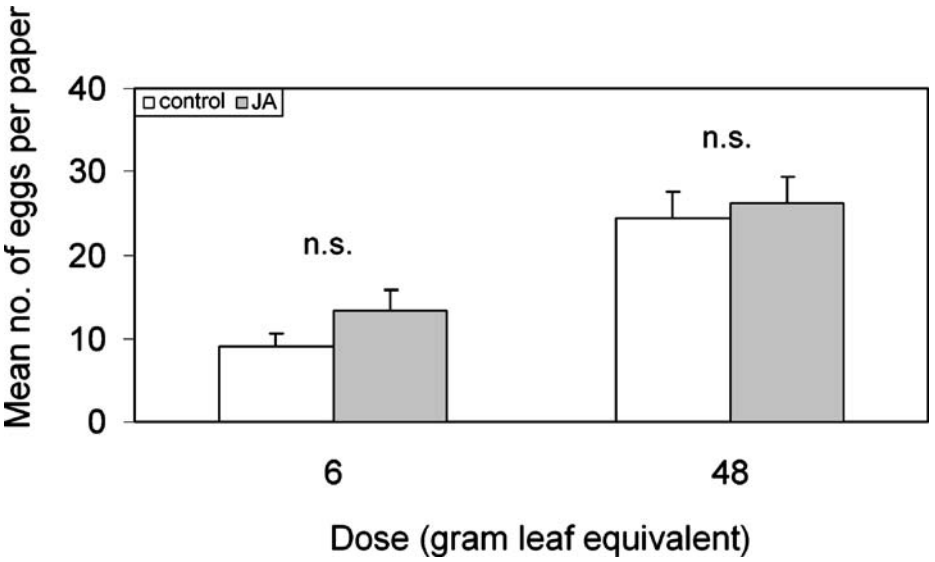

Fig. 4 Oviposition of *P. rapae* on green paper sprayed with purified GLS-fractions from leaf surface extracts of control and JA-treated plants. Mean number of eggs per female per paper leaf + SEM (n.s. *P*>0.05, paired *t*-test, *N*=20)

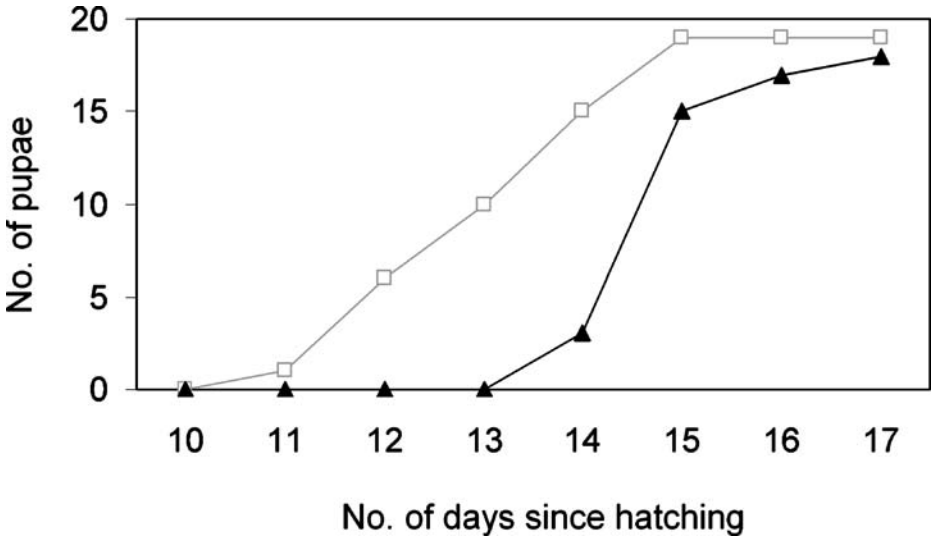

Fig. 5 Development time of *P. rapae* caterpillars from hatching until pupation on control [*open squares* (□)] and JA-treated [closed triangles (▲)] plants. Cumulative number of pupae per treatment

Effect of Pure JA on Oviposition Preference When paper treated with sinigrin and JA was compared to paper with only sinigrin, there was no difference in the number of eggs the butterflies deposited on the two substrates (t=−0.438, df=26, P=0.67, paired t-test) (Fig. 3). These results show that the observed effect of the JA treatment on herbivore oviposition behavior was due to induced changes in leaf tissue rather than to a direct repellent or deterrent effect of JA itself.

Bioassays with Purified Glucosinolate Fractions The butterflies did not discriminate between the two GLS fractions (Table 2), the number of eggs on paper with the GLS from control plants, and the number of eggs on paper with GLS from JA-treated plants was not different for either concentration (concentration 6 gle: Z=−1.514, N=20, P=0.130, Wilcoxon matched-pair signed-ranks test; 48 gle: t=−0.523, df=19, P=0.607, paired t-test) (Fig. 4).

Performance of P. rapae *Caterpillars* About two-thirds of the caterpillars survived until pupation, and a similar number of caterpillars reached the pupal stage on both treatments, 19 on control and 18 on JA-treated plants (Fig. 5). The caterpillars on JA-treated plants pupated on average after 15 d, while the caterpillars on the control plants pupated significantly sooner, on average after 13 d (Mann–Whitney U, Z=−4.071, P<0.001). The average pupal weight on the control plants, 165±3.4 mg, was similar to that on the JA-treated plants, 158±3.3 mg (ANOVA, F=2.665, df=1, P=0.112).

Discussion

Our data show that JA treatment of Brussels sprouts leaves reduces the acceptance of leaves for oviposition by *P. rapae* and *P. brassicae* in a similar way. Treatment of leaves with 0.1 or

1 mM JA reduced the proportion of eggs the butterflies laid on these leaves. A concentration of 0.01 mM JA did not change oviposition preference. The former concentrations are comparable to the concentrations of JA or MeJA that were applied to several plant species in other studies and that reduced development of *Spodoptera exigua*, *Trichoplusia ni*, *Manduca sexta*, thrips, and aphids (Thaler et al., 1996; Avdiushko et al., 1997; Van Dam et al., 2000; Omer et al., 2001), and abundance of *Manduca quinquemaculata*, *S. exigua*, thrips, and flea beetles in the field (Kessler and Baldwin, 2001; Thaler et al., 2001). For cabbage plants, Lu et al. (2004) found inducible resistance in a susceptible *Brassica* species (Chinese cabbage, *Brassica campestris* L.) and induced susceptibility in a resistant *Brassica* species (common cabbage, *B. oleracea*) for *Plutella xylostella* L.

To exclude that JA itself caused the above effect, we tested the phytohormone on an inert substrate and studied two different application methods to the leaf material. We considered this an essential control that is lacking in other studies. The results of these experiments show that it was not JA itself that caused the difference in oviposition preference between control and JA-treated leaves, thus providing proof that processes in the plant induced by the JA treatment changed the acceptability of the leaves. It has also been reported previously that development of cabbage looper or tobacco hornworm larvae is not affected when MeJA is added to an artificial diet, but it is retarded when MeJA was applied to cabbage or tobacco plants (Avdiushko et al., 1997).

In leaf surface extracts of JA-treated and untreated Brussels sprouts, we found five glucosinolates. After JA application, glucobrassicin, the major glucosinolate in the *B. oleracea* cultivar we used, occurred at a level twice as high as in control plants, and glucoiberin and 4-hydroxyglucobrassicin concentrations decreased. The total glucosinolate content did not change significantly. However, most other studies on glucosinolate content in Brassicaceous plants after induction by JA- or MeJA-treatment or insect attack have reported an increase in glucosinolates, although there is substantial variation among different species, or even genotypes, and type of induction (Bodnaryk, 1994; Cipollini and Sipe, 2001; Mikkelsen et al., 2003; Mewis et al., 2005). Moreover, glucosinolates may not be evenly distributed throughout the leaf. We measured glucosinolate content in a surface extract after 24 hr, whereas most studies have measured glucosinolate content in whole leaf extracts and after a longer induction time. Recently, Reifenrath et al. (2005) postulated that the wax layer does not contain glucosinolates, and the polar glucosinolates that are found by using the solvent extraction method are washed from the inner leaf to the outside through the stomata. Nevertheless, we chose a surface extraction method because the butterflies retrieve chemosensory information from the leaf surface, as they do not damage the leaf before ovipositing. Surface extracts are thus likely to give a better reflection of the chemosensory information used than whole leaf extracts.

Both butterfly species distinguish between induced and non-induced leaves, most likely based on chemical differences, as JA-induced leaves do not display herbivore presence or damage. The different levels of two out of five glucosinolates in the surface extracts may provide a chemosensory basis for the oviposition preference observed, although the isolated GLS from the two treatments yielded no differences in acceptance of the paper for oviposition. While the isolated GLS on paper stimulated oviposition behavior, they appear not to be the main cue to discriminate between the JA-induced and non-induced cabbage plants.

We did not quantify other chemicals, stimulants, deterrents, or precursors that might mediate preference behavior, such as isothiocyanates, terpenoids, other glycosides, or amino acids (Huang et al., 1993; Renwick and Chew, 1994; Soldaat et al., 1996; Agrawal and Kurashige, 2003). Both *P. rapae* and *P. brassicae* can perceive a broad range of chemicals (Van Loon et al., 1992b; Hern et al., 1996). Electroantennogram responses to a

range of plant volatiles are similar for both species (Van Loon et al., 1992b), although host plant selection by *Pieris* butterflies appears largely based on contact chemoreception rather than olfaction (Renwick and Chew, 1994). Host plant selection is suggested to depend on a balance of stimulants and deterrents and not just on the detection of presence or absence of particular compounds (Huang et al., 1993; Bruce et al., 2005). Therefore, glucosinolates, in combination with other stimulants or deterrents, may determine the acceptance of a host plant by the butterflies.

The octadecanoid pathway, in which JA is a key molecule, is involved in induction of synomones in response to oviposition and to herbivore damage (Meiners and Hilker, 2000; Dicke and Van Poecke, 2002; Hilker and Meiners, 2006; Mumm and Hilker, 2006). JA treatment of plants results in emission of synomones that attract natural enemies like predatory mites and parasitoids (Dicke et al., 1999; Hilker and Meiners, 2002; Van Poecke and Dicke, 2002; Hilker and Meiners, 2006). This attraction results in a higher natural enemy density around damaged plants, and therefore, it is advantageous for the herbivores to avoid oviposition on induced plants. Moreover, intact plants lack competitors, either intra- or interspecific. Herbivores may use induced plant cues to detect the presence or absence of other herbivores, especially because plant cues are, although less reliable, often easier to detect than cues from the herbivores themselves (Vet and Dicke, 1992).

Furthermore, induced plants may affect herbivores directly by influencing the performance of their offspring. For *P. rapae*, the development time differed between caterpillars feeding on JA-induced and caterpillars feeding on non-induced plants. Development of the caterpillars to pupae took longer on the induced plants, which exposes them to natural enemies for a longer time and gives them a disadvantage in the competition for resources with other herbivores. These results comply with those of Agrawal and Kurashige (2003), who showed that growth of *P. rapae* larvae was reduced on herbivore-induced Brassicaceae.

In summary: (1) JA treatment of *B. oleracea* results in avoidance of host plants by the two *Pieris* butterflies; (2) the related gregarious and solitary butterfly species tested responded in a similar fashion to JA-treated plants; (3) JA treatment reduced the contents of two out of five glucosinolates in leaf surface extracts of Brussels sprouts; and (4) the purified GLS fractions could not explain the observed avoidance behavior. The results indicate that JA-induced infochemicals play an important role in host plant selection behavior of these butterflies; however, the phytochemicals involved still have to be elucidated.

Acknowledgments We thank Niels Agerbirk for advice on GLS isolation; Ciska Raaijmakers for technical assistance with the chemical analysis; Leo Koopman, Frans van Aggelen, André Gidding, and PPW for the supply of insects and plants; Erik Poelman, Tjeerd Snoeren, and Adriana Alvarez for comments and discussion; and the undergraduate students who participated in some of the experiments: Paul Egan, Eloy Erro, Olivia Garcia Gonzales, and Pascal van der Sandt. This work was supported by a VICI grant from the Netherlands Organization for Scientific Research, NWO (865.03.002).

Abstract The prevailing reaction of plants to pest attack is the activation of various defense mechanisms. In tomato, several studies indicate that an 18 amino acid (aa) peptide, called systemin, is a primary signal for the systemic induction of direct resistance against plant-chewing pests, and that the transgenic expression of the *prosystemin* gene (encoding the 200 aa systemin precursor) activates genes involved in the plant response to herbivores. By using a combination of behavioral, chemical, and gene expression analyses, we report that systemin enhances the production of bioactive volatile compounds, increases plant attractivity towards parasitiod wasps, and activates genes involved in volatile production. Our data imply that systemin is involved in the systemic activation of indirect defense in tomato, and we conclude that a single gene controls the systemic activation of coordinated and associated responses against pests.

Introduction

A large number of the plant defenses against pests are inducible and avoid an unnecessary use of metabolic resources in the absence of recurring and frequent attack (Walling, 2000; Heil and Baldwin, 2002). The activation of defense mechanisms following insect attack leads to the production of several toxins and antifeedant proteins, which reduce the fitness of the invader (direct defense), and volatile organic compounds (VOCs), used by natural enemies of phytophagous insects as semiochemicals to locate their victims (indirect defense) (Stout et al., 2006). Interestingly, some direct defense strategies, particularly those that slow herbivore growth by reducing their digestive efficiency, may not increase the fitness of the plants under attack without a third trophic level because slow-growing insects will eat more plant material while completing their development (Kessler and Baldwin, 2002).

Tomato plants and other Solanaceae respond to chewing insects and mechanical wounding by releasing a highly mobile peptide called systemin (Bergey et al., 1996; Schilmiller and Howe, 2005). In tomato, this 18-amino acid (aa) molecule is synthesized as a 200-aa precursor protein named prosystemin (McGurl and Ryan, 1992). After its proteolytic cleavage, the peptide binds a plasma membrane-bound receptor kinase (Scheer and Ryan, 2002). Subsequently, it is assumed that the signaling pathway proceeds via the activation of a phospholipase activity, with the release of linolenic acid and the formation of jasmonic acid (JA) and its derivative, methyl jasmonate (Bergey et al., 1996). Eventually, the transcriptional activation of a number of genes, yet to be fully identified, leads to an increase of compounds (i.e., proteinase inhibitors and polyphenoloxidase) that are directly toxic to phytophagous insects (Bergey et al., 1996). Currently, mutational evidence implies that long-distance defense signaling is transmitted mainly by JA as a wave travelling via a positive amplification loop that involves systemin release (Schilmiller and Howe, 2005).

While it is widely accepted that systemin activates the wound response in undamaged parts of the plant (Ryan and Pearce, 2003), unexpectedly, its possible role in modulating ecological interactions has not been elucidated. In infested plants, it is necessary that a signal be transmitted from the site of damage to distal unwounded leaves to trigger synthesis and the release of VOCs because volatile compounds are synthesized *de novo* at the site of release (Paré and Tumlinson, 1998). However, it is not clear whether there is a signal specific for volatile production (Degenhardt et al., 2003). It has been proposed that at least some plant elicitors of defense genes are likely to boost effects broader than expected, possibly having the role to activate shared resistance responses (Walling, 2000), because for a plant, challenged by different invaders, it is less expensive to have signal transduction pathways that are involved in the coordinated response to pests (Walling, 2000; Kessler and Baldwin, 2002).

Most of the knowledge about plant indirect defenses and the emission of volatiles attractive to parasitoids has been based on plant treatment with chemical elicitors such as JA (Thaler, 1999; Birkett et al., 2000; Howe, 2004; Cooper and Goggin, 2005). Although considerable progress has been made by using exogenously applied compounds, it has been pointed out that artificial chemical treatments rarely mimic natural responses in quantitative terms (Heil and Baldwin, 2002), and they elicit many physiological and morphological changes that are not related to resistance (Heil, 2002). Recently, the roles of some genes in

plant indirect defense mechanisms have been elucidated by direct genetic manipulation. Several studies have focused on the downregulation of gene expression, which results in the lowering of both volatile production and attractiveness towards predators and parasitoids (Vancanneyt et al., 2001; Kessler et al., 2004; Sanchez-Hernadez et al., 2006). Nonetheless, studies that aim at the identification of mechanisms that enhance direct and indirect plant defense are of greatest interest for plant biotechnology and integrated pest management (Degenhardt et al., 2003).

Our aim was to investigate if the plant hormone systemin can increase indirect defense mechanisms via the transcriptional activation of genes involved in the production of volatile compounds. We report that the overexpression of the systemin precursor influences volatile signaling in tomato, indicating that a single plant hormone leads to the systemic activation of coordinated responses. These results support the model that the elicitation of multiple yet associated defensive pathways is likely to be advantageous and may be necessary if plants need to defend themselves adaptively from diverse insect species.

Methods and Material

Plants and Insects Transgenic tomato overexpressing the *prosystemin* cDNA under the control of the 35S RNA CaMV promoter (BBS) and control plants BB (*Solanum lycopersicum* cv. Better Boy) were as described (McGurl et al., 1994). Plants were grown in sterilized soil and maintained in controlled environmental chambers for 3 weeks from sowing at 26+1°C with a photoperiod of 16:8 hr light/dark. The aphid parasitoid *Aphidius ervi* Haliday was reared on one of its natural hosts, the pea aphid *Acyrthosiphon pisum* (Harris), maintained on potted broad bean (*Vicia faba* L.) cv. Aquadulce as described (Guerrieri et al., 2002). Aphid and parasitoid cultures were kept in separate environmental chambers at 20±1°C, 65±5% relative humidity, 18:6-hr light/dark photoperiod. Insect parasitoids for the flight behavior bioassays were reared as synchronized cohorts as reported (Guerrieri et al., 2002).

Flight Behavior Bioassay Towards Plants Flight behavior of *A. ervi* towards tomato plants was measured as relative attractiveness in a single-choice wind tunnel bioassay. Behavioral observations were carried out as described previously (Guerrieri et al., 2002), modified by using a larger experimental glass box (100×50×50 cm). One hundred and fifty parasitoid females were tested for each target by releasing them individually in the odor plume 35 cm downwind from the target. Each female was only used once. Parasitoids were observed for a maximum time of 10 min, and flight behavior data were recorded and analyzed with the aid of event-recording software (the Observer, Noldus Information Technology, Wageningen, the Netherlands). Behavioral experiments were conducted on several days, and targets were presented in a random order to reduce the effect of temporal variability on the results. In a wind tunnel bioassay, 10 uninfested plants of each BB and BBS were tested. The percentage of response (oriented flights, landings on the target) to each target was calculated. The number of parasitoids responding to each target in any experiment was compared by a G test for independence with William's correction (Sokal and Rohlf, 1995). The resulting values of G were compared with the critical values of x^2 (Rohlf and Sokal, 1995).

Volatile Collection and Identification All glassware, silicon, and Teflon connections were scrupulously clean and heated at 100°C overnight before use. Volatiles from BB and BBS plants were collected by an airtight entrainment system immediately after the wind-tunnel

bioassay. Single plants were placed into bell jars (20 l) sealed with Parafilm and connected to a circulation pump whose flow was adjusted at 200 ml/min. Before reentering the pump, the air passed through an adsorbent trap made of Tenax (Cat. no. 226-336, SKC, Eighty Four, PA, USA) connected to the system by a Teflon-capped glass plug. In order to reduce any stress to the plant in the system, each collection lasted 3 hr. Air entrainment volatiles were separated by an integrated system including thermal desorber (Tekmar TD-800), gas chromatograph (column: RTX-200, 60 m, 0.25 mmID, 0.25 μm, carrier gas: He), and mass spectrometer. The resulting peaks were compared with 36 available standards (Appendix) and compound's database (National Institute of Standards and Technology). The mean quantities of these compound collected from 10 plants of each BB and BBS were analyzed by ANOVA, and the resulting values of P were compared with the critical values of x^2 (Rohlf and Sokal, 1995).

Flight Behavior Bioassay Towards Compounds After identification, commercial standards of the individual compounds that were overproduced by BBS plants were diluted in redistilled hexane and tested in a single choice wind tunnel bioassay. Each compound was tested at a concentration of 1 mg/ml. For each compound, a 50-μl solution was placed singly onto a small piece (3×1 cm) of filter paper (Whatman, no.1). This was inserted into an open-ended glass test tube (6×1 cm) with the end facing the parasitoid and surrounded by a green circular target to reduce any negative effect due to the absence of physical stimuli normally provided by the plant. A fresh aliquot of solution and a new piece of filter paper were used for each female parasitoid. A similar target, which was dosed with 50 μl redistilled hexane, served as control. One hundred and fifty parasitoid females were tested in a single-choice bioassay for each compound, under the same general conditions as those described above for the BB and BBS tests. Compounds were tested on different days in different sequences to eliminate any time variation. The percentage of response (oriented flights, landings on the target) to each compound was calculated and compared by a G test for independence with William's correction (Sokal and Rohlf, 1995). The resulting values of G were compared with the critical values of x^2 (Rohlf and Sokal, 1995).

RNA Isolation and Real-Time RT-PCR Total RNA was prepared from leaves as described (van Blokland et al., 1998) and subsequently treated with RNase-free DNase I (Amersham, Buckinghamshire, UK) to remove residual genomic DNA. First-strand cDNA was synthesized according to previously reported procedures (Corrado et al., 2005). Amplification of the cDNA coding for the *Elongation Factor 1-α* gene, a ubiquitously expressed gene (Shewmaker et al., 1990), served as control for cDNA synthesis and PCR efficiency in the different samples. Moreover, the sequences annealed by the two primers StEF fw and LeEF rv are localized in two contiguous exons for the detection of possible contaminant DNA in the PCR amplifications. Real-time PCRs were performed by using the ABI PRISM 7000 Sequence Detection System (Applied Biosystems, Foster City, CA, USA). Reactions (total volume of 25 μl) were prepared with 12.5 μl of the 2× SYBR Green PCR Master Kit (Applied Biosystems), 0.3 pmol of a primer pair, and 0.2 μl of cDNA template. Three independent amplifications were performed from each cDNA sample, and reactions were done in triplicates. The thermal cycling program started with a step of 2 min at 50°C and 10 min at 95°C, followed by 40 cycles of a 15 sec step at 95°C followed by 1 min at Ta indicated in Table 1. To check the specificity of the amplification products, a dissociation kinetics analysis was performed after each assay. Reaction products were also resolved onto an agarose gel to verify amplicon size. The primer pairs used and the size of the expected amplicons are shown in Table 1. Primers, designed with the aid of the Primer Express 2.0

software (Applied Biosystem) were chosen to amplify a fragment between 50 and 150 bp. Relative quantitation of gene expression was carried out using the $2^{-\Delta CT}$ method (Livak and Schmittgen, 2001), where $\Delta Ct = Ct_{\text{target gene}} - Ct_{\text{reference gene}}$. We used the housekeeping *Elongation Factor 1-α* gene (Shewmaker et al., 1990) as an endogenous reference gene for the normalization of the expression levels of the target genes. The statistical significance of the results was evaluated as already reported (Alfano et al., 2005).

Results

Effect of Prosystemin Overexpression on the Behavior of an Insect Parasitoid and VOC Production In a wind tunnel test, plants overexpressing the systemin precursor (BBS) proved to be significantly more attractive to naïve females of the aphid parasitoid *A. ervi* than untransformed control plants (BB) (Fig. 1). Nearly three times as many parasitoids oriented towards transformed plants and landed on them compared to controls. Remarkably, as parasitoids were never in contact with tomato plants before the assay, this response is innate. The GC-MS analysis of the volatiles collected from BBS and BB plants immediately after the wind-tunnel test revealed that systemin is involved in the production and/or release of biologically active VOC (Fig. 2). We recorded a significant increase in the total production of these compounds in BBS plants (92,974.1, vs. 35,633.6 ng collected from BB; P=0.03, df=1), and among them, eight were identified (the complete list of purified compounds used for identification is reported in the Appendix). Significant differences were not recorded in the production/release of (*Z*)-3-hexen-ol, 6-methyl-5-hepten-2-one, phellandrene, and *trans*-caryophyllene. In contrast, we collected significantly larger quantities of four monoterpenes from BBS plants, β-ocimene, α-pinene, β-myrcene/3-carene, and limonene (Fig. 3). To prove that these identified compounds overproduced by

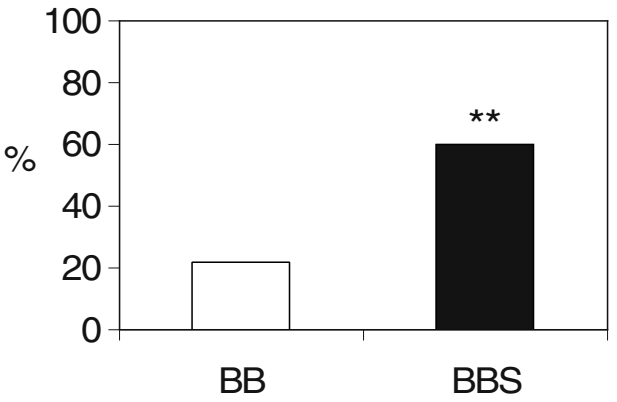

Fig. 1 Flight response (% of female showing oriented flights) of the aphid parasitoid *A. ervi* towards tomato plants in a wind tunnel bioassay (N=150, P<0.001)

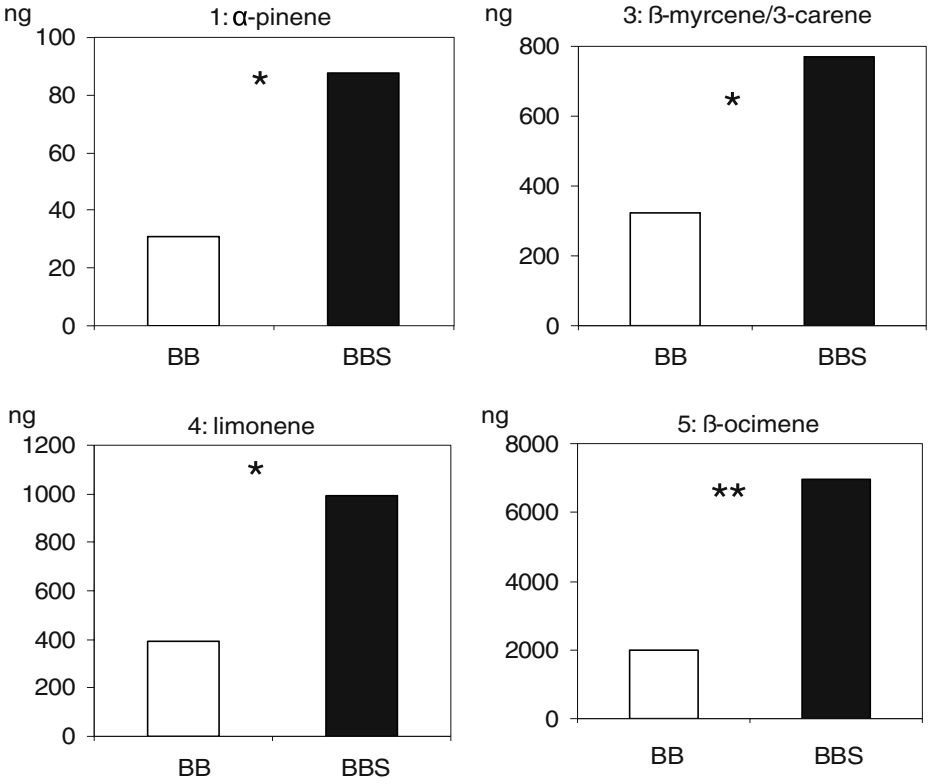

Fig. 3 Quantitative differences of the emission of identified compounds released by BB and BBS plants. Each *panel* shows the mean quantity collected from 10 plants of each BB and BBS expressed in nanograms (*single asterisks*, $P<0.05$; *double asterisks*, $P<0.01$)

BBS plants affect the foraging behavior of the parasitoid *A. ervi*, we assayed α-pinene, β-myrcene, 3-carene, and limonene in a wind tunnel test. Each of these compounds elicited a significant higher proportion of oriented flights by this parasitoid in respect to bidistilled hexane, with α-pinene being the most attractive (Fig. 4).

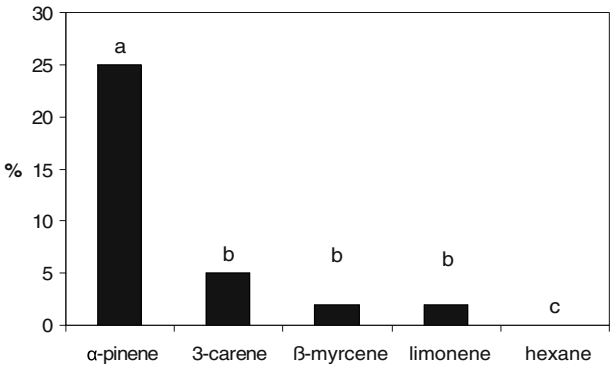

Fig. 4 Flight response of *A. ervi* towards pure volatile compounds in a wind tunnel bioassay expressed as percentage of females showing oriented flights towards the target ($N=150$, *different letters* indicate a statistical difference: *a–b*, $P<0.001$; *b–c*, $P<0.01$)

Expression Analysis Of Genes Involved In Indirect Defense And Volatile Production It has been shown that systemin overexpression increases the transcription of *Lox* genes (Bergey et al., 1996); yet, as there are at least four lipoxygenase in tomato (*TomloxA*, *B*, *C*, and *D*), their role has not been completely clarified in respect to defense mechanisms. We analyzed the expression level of *TomloxC* and *TomloxD*, as their gene products are targeted to chloroplasts, the proposed major site for fatty acid hydroperoxide metabolism. Real-time PCR experiments with gene-specific primers indicated that prosystemin overexpression associates with an increased level of expression of both *TomloxC* and *TomloxD* genes, implying that they have direct roles in plant defense and volatile production in leaves (Fig. 5). On the other hand, the transcription level of the *TomloxB*, which is not involved in the production of the known tomato flavor volatiles (Griffiths et al., 1999), was not affected (Fig. 5). Our results indicate that, in tomato, individual LOX isoforms are differentially regulated and should have distinct functions in systemin-mediated onset of direct and indirect defense mechanisms. The metabolism of linoleic and linolenic acids (the principal LOX substrates) is determined not only by the substrate and product specificities of the lipoxygenases but also by fatty acid hydroperoxide lyases (HPLs) (Matsui et al., 2001), important for the production of a vast class of VOC (Paré and Tumlinson, 1997). The analysis of the level of expression of the *HPL* indicated a moderate relative increase in the amount of transcripts in the BBS plants. Finally, as the analysis of volatile blend in transgenic plants indicated the presence of terpenoids, we also analyzed the expression of *germacrene C synthase* (*GCS*). This gene encodes one of the main enzymes responsible for the sesquiterpene synthase activity in tomato leaf (Colby et al., 1998). Our results indicated that prosystemin overexpression associates with increased levels of transcription of *GCS C*, a key gene involved in the production of terpenoid volatile compounds in tomato.

Only recently has the systemin peptide been proposed as a promoter for long-distance defense responses by supporting the jasmonate production in vascular tissues. Hence, if an important role of the *prosystemin* gene is to generate and amplify a cell-to-cell signal to increase the production of phloem-mobile JAs, *prosystemin* transcription should be subject

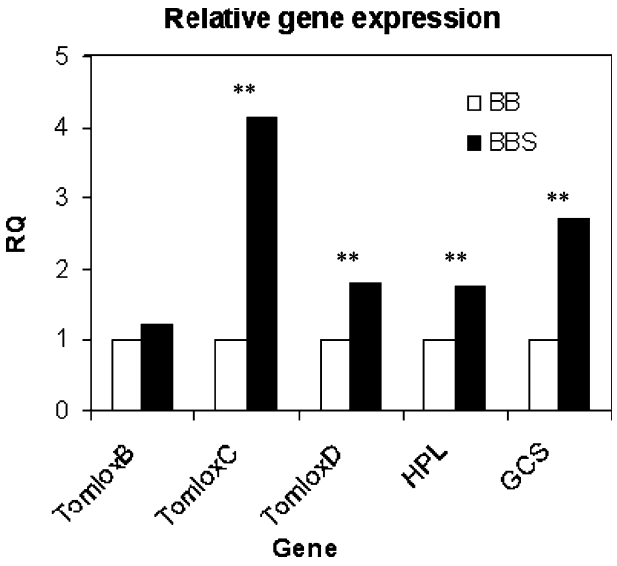

Fig. 5 Relative gene expression by real-time PCR of genes involved in indirect defense against insects. For each gene, the graph displays the relative quantity of the target in BB (*white columns*) and in BBS (*black columns*). Quantities (*RQ*) are shown relative to the calibrator BB genotype. On the *x-axis* is reported the lists of the target genes analyzed. On the *y-axis* is reported the results of the relative quantification calculations. Relative quantities are graphed on a linear scale. *Asterisks* indicate that the $2^{-\Delta Ct}$ values were significantly different ($P<0.01$; Student's *t*-test)

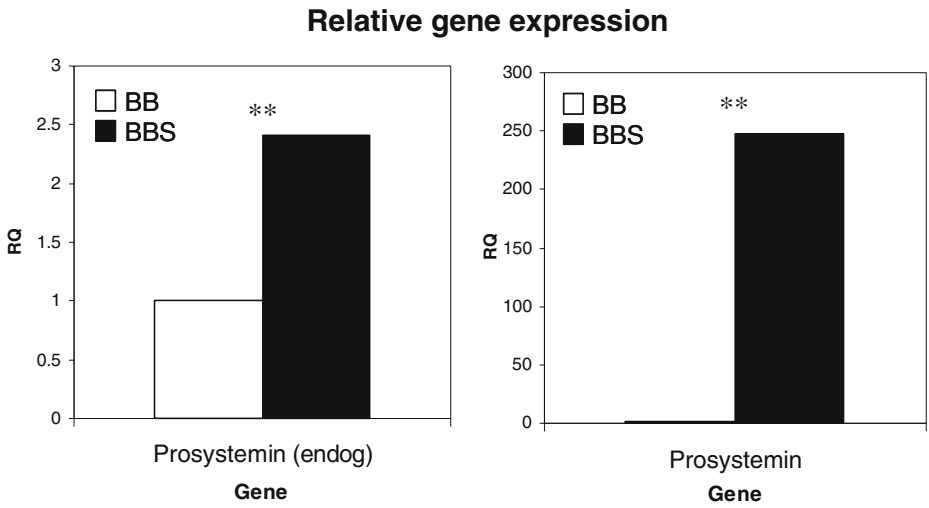

Fig. 6 Relative gene expression of *prosystemin* transcripts by real-time PCR. The graph displays the relative quantity of the target transcripts in BB (*white columns*) and in BBS (*black columns*). *Left panel*: primers were designed to amplify only the transcripts of the endogenous *prosystemin* gene. *Right panel*: primers were designed to amplify both the endogenous and the transgenic *prosystemin* transcripts. Quantity (*RQ*) is shown relative to the calibrator BB genotype. On the *y-axis* is reported the result of the relative quantification calculations on a linear scale. *Asterisks* indicate that the $2^{-\Delta Ct}$ values were significantly different ($P<0.01$; Student's *t*-test)

to a positive enhancement to generate a transmissible signal. We investigated whether the transgenic expression of *prosystemin* cDNA has some transcriptional influence on the endogenous gene. For this purpose, we used two pairs of primers. The pair BB–BBS fw and BB–BBS rv anneals in a region shared by the transgene and the endogenous genes, and hence, they are able to amplify both transcripts. A relative quantification study based on real-time PCR experiments indicated that the amount of *prosystemin* transcripts in transgenic plants is much higher than in unwounded control plants, as expected. The primer PcSISrv RT anneals in a 3′ untranslated region that is absent in the transgenic *prosystemin* cDNA. This primer, in combination with the PcSISfw RT, can amplify only transcripts of the endogenous gene. A relative quantification study indicated that the expression of the endogenous *prosystemin* gene more than doubled in the transgenic BBS (Fig. 6). These experiments indicated that, despite the high level of defensive proteins in transgenic plants constitutively accumulating the systemin precursor, the *prosystemin* overexpression associates with an increase in the expression of the endogenous gene.

Discussion

The identification of genes that can be used to increase plant indirect defenses is of interest to understand plant biology and ecological relations and holds great promise for modern agricultural practices (Degenhardt et al., 2003). While there are different chemicals that, when exogenously applied, can influence tritrophic interactions, only a relatively reduced number of mutants with an altered production of some type of VOC have been identified (Kessler and Baldwin, 2002; Schilmiller and Howe, 2005). Many have obtained down-regulating gene expression by antisense technology (Vancanneyt et al., 2001; Kessler et al.,

2004; Sanchez-Hernadez et al., 2006). A straightforward approach towards the functional characterization of plant genes that can enhance indirect defenses is probably the analysis of genes that are naturally involved in the generation of response against pests. Because both direct and indirect defense should co-operate in nature to increase the fitness of the plants under attack, we investigated the role of *prosystemin* in tritrophic interactions. Different lines of evidence indicated that *prosystemin* overexpression associates with increased indirect defenses in tomato. Although we cannot exclude that additional factors, such as oral secretions, can influence, in a more complex way, plant gene expression and VOC production in undamaged leaves (Alborn et al., 1997; Maffei et al., 2004), our work indicates that the primary signal molecule systemin controls overlapping transduction pathways for different resistance mechanisms. The presence of a plant signal that coordinates the mounting of both direct and indirect defense implies that the attraction of a third trophic level is a relevant function of nonspecifically induced plant volatiles. This is in agreement with the finding that long-lasting mechanical wounding on defined leaf areas (in absence of herbivores) is sufficient for the emission of an herbivore-like VOC blend (Mithofer et al., 2005). The broad-role of systemin here described means that even pests completely devoid of salivary secretion or producing chemicals that are not recognized by the plant response systems would eventually trigger coordinated defense mechanisms.

While it has been demonstrated previously that jasmonate-inducible plant defenses cause increased parasitism of herbivores (Thaler, 1999), our results indicate that the effects of nonspecifically induced volatiles are more complex than expected. The response of *A. ervi* to the VOC induced by *prosystemin* overexpression must be considered innate, as the parasitoids used in a wind tunnel bioassay were obtained from a different host and, thus, have never been in contact with tomato plants. It has been recently reported that tomato plants respond to biotic stresses altering the profile of VOC only in a quantitative way (Ament et al., 2004; Kant et al., 2004; Sanchez-Hernadez et al., 2006), and the effect of the systemin is consistent with those observations (see Fig. 2). All of the compounds that are overproduced/released by tomato plants that overexpress *prosystemin* seem to play a role in the attractiveness towards *A. ervi*. Apart from β-ocimene, which has been tested previously at the same concentration and that elicited a very high response (Birkett et al., 2000), among the four remaining compounds overproduced/released by BBS plants, α-pinene was the most active, followed by limonene, 3-carene, and β-myrcene (Fig. 4). The release of these compounds appears to be associated to plant responses to unspecific stresses, including aphid infestation (Sasso et al., unpublished), and this could explain the positive response recorded in an aphid parasitoid. Moreover, the lower attractiveness (expressed as percentage of oriented flights) that single compounds elicited in respect to the bioassay with plants, was expected as a consequence of the partition of the volatile bouquet. Furthermore, it is also possible that other unidentified peaks can also be involved in multitrophic interactions. As a consequence, for engineering volatile emission to make crop plants more attractive towards pests enemies, genes that code primary defensive signals may be preferred to those that control a single or a limited set of volatile compounds (Degenhardt et al., 2003).

While our data are consistent with an important role for the octadecanoid-related pathways in enhancing multiple and associated response to pests (Walling, 2000; Schilmiller and Howe, 2005), they contrast with a recent publication indicating that, despite that the *spr2* tomato mutant (impaired in the JA biosynthesis) has a reduced level of indirect defense, *prosystemin* overexpression associates with a marginal difference in VOC production (Sanchez-Hernadez et al., 2006). The authors proposed that this discrepancy may be due to the rather low concentration of JA present in the prosystemin overexpressing plants, sufficient to elicit only direct defense genes. This is supported by the finding that

two genes that encode enzymes required for the synthesis of JA (*AOC* and *OPR3*) presented similar very low expression levels (almost undetectable for *OPR3*) in the unwounded 35S::prosys and control plants (Sanchez-Hernadez et al., 2006). However, it is puzzling that such level of expression is also present in the JA-deficient mutant *spr2* (Sanchez-Hernadez et al., 2006), probably suggesting that the activity of these genes is not sensitive to the variation of JA concentration *in planta*. Additionally, in our system, volatiles were collected from the whole plant, including the pot, as bioactive VOC can be produced even from the belowground part of the plant (Rasmann et al., 2005) and for a 6-fold-longer period of time (3 hr). Finally, in agreement with our data, almost all the compounds identified by Sanchez-Hernadez et al. (2006) are present in the list of volatiles collected in this work, with one, namely, β-myrcene, being significantly higher in the plant overexpressing systemin.

Having verified the *prosystemin* overexpression in the transgenic plants and proved that also the endogenous *prosystemin* gene is more active than in control plants, we analyzed the level of expression of genes that have been experimentally linked to volatile production in tomato by using the more sensitive real-time PCR assay. Consistent with the chemical analysis of the volatile blend, some genes responsible for the production of different VOC (i.e., members of the *Lox* family, *HPL*, *GCS*) are overexpressed in the transgenic plants. Our data also indicate the presence of at least a dual regulation of the LOX isoforms in tomato, as not all *Tomlox* genes are involved in systemin-mediated response to biotic stress. For instance, we showed that *TomloxC*, a gene that has been considered important during fruit development for its contribution to aroma and flavor generation (Chen et al., 2004) and whose expression in leaves is undetectable by Northern assay (Heitz et al., 1997), may play a role in the production of volatile defense compounds in leaves. It is not surprising that the same genes perform both roles. The generation of a stronger fruit aroma and the production of VOC involved in indirect defense are two functions that, while aiding seed dispersal and attracting parasitoids, respectively, should increase plant fitness by these diverse biotic interactions.

In summary, our data indicate that systemin is an important element of the whole defensive response in tomato. Considering that some of the identified VOC could participate in plant-to-plant communication (Holopainen, 2004), it would be interesting in the future to address the role of systemin in more complex interactions.

Abstract Inducible terpenes and lipoxygenase pathway products, e.g., green-leaf volatiles (GLVs), are emitted by plants in response to herbivory. They are used by carnivorous arthropods to locate prey. These compounds are highly reactive with atmospheric pollutants. We hypothesized that elevated ozone (O_3) may affect chemical communication between plants and natural enemies of herbivores by degrading signal compounds. In this study, we have used two tritrophic systems (*Brassica oleracea–Plutella xylostella–Cotesia plutellae* and *Phaseolus lunatus–Tetranychus urticae–Phytoseiulus persimilis*) to show that exposure of plants to moderately enhanced atmospheric O_3 levels (60 and 120 nl l^{-1}) results in complete degradation of most herbivore-induced terpenes and GLVs, which is congruent with our hypothesis. However, orientation behavior of natural enemies was not disrupted by O_3 exposure in either tritrophic system. Other herbivore-induced volatiles, such as benzyl cyanide, a nitrile in cabbage, and methyl salicylate in lima bean, were not significantly reduced in reactions with O_3. We suggest that more atmospherically stable herbivore-induced volatile compounds can provide important long-distance plant-carnivore signals and may be used by natural enemies of herbivores to orientate in O_3-polluted environments.

Introduction

Isoprenoids comprise the predominant group of plant-emitted volatile organic compounds (VOCs) followed by alcohols and carbonyls (Kesselmeier and Staudt, 1999; Owen and Peñuelas, 2005). They have various ecophysiological functions in plants (Peñuelas and Llusià, 2004). They mediate plant–plant (Baldwin et al., 2006; Ton et al., 2007) and several plant–insect (see Owen and Peñuelas, 2005 for a review) interactions. Within the isoprenoids are terpenes, some of which are attractive to phytophagous insects (Ibrahim et al., 2005; Tooker et al., 2005) and evoke electrophysiological responses, including in specialist insects (see Bruce et al., 2005 for a review). They are also attractive to carnivorous arthropods. Many studies have addressed the role of *de novo*-synthesized terpenes (mono-, sesqui-, and homoterpenes) (Paré and Tumlinson, 1999) in the recruitment of herbivore natural enemies, e.g., predators and parasitoids (see Dicke, 1999 for a review; Ibrahim et al., 2005; Kappers et al., 2005; Schnee et al., 2006).

In addition to volatile terpenes, herbivore feeding induces the emission of many lipoxygenase (LOX)-pathway-derived alcohols, esters, and aldehydes from plants (Holopainen, 2004). The emission of these LOX products, commonly referred to as green-leaf volatiles (GLVs), is the result of mechanical damage caused by herbivore feeding. They seem not to be enhanced by elicitors, and, therefore, their release has been described as instantaneous "bleeding" from damage sites. However, two related herbivores can lead to the emission of distinctive ratios of GLVs in the same plant species (Turlings and Wäckers, 2004).

Terpenes and some GLVs can readily react with ozone (O_3) and lead to the formation of many products in the gas phase and the particulate phase (Yu et al., 1999; Calogirou et al., 1999; Atkinson and Arey, 2003; Holzinger et al., 2005). The current concentrations of this tropospheric oxidant show regional and seasonal variations (Calogirou et al., 1996), and they are expected to increase in the coming years (IPCC, 2001). O_3 can affect phytophagous insect performance (Coleman and Jones, 1988; Holopainen et al., 1997; Kopper and Lindroth, 2003) and behavior (Jøndrup et al., 2002; Agrell et al., 2005) due to changes in the plant physiology and chemistry. Few studies have addressed O_3 effects on olfactory cues. O_3 exposure can elicit the emission of herbivore-inducible homoterpenes (Vuorinen et al., 2004a), but terpenes may react with O_3 leading to the destruction of olfactory cues, disrupting insect chemical communication (Gate et al., 1995). This may affect the choices that insects make, thus influencing their reproductive success (Dicke, 2000).

We coupled VOC collections with behavioral tests in Y-tube olfactometers to answer two questions: (1) Can O_3 affect the VOCs in the headspace of intact and herbivore-damaged plants? and (2) Can the oxidation of plant-emitted VOCs disrupt chemical communication between plants and higher trophic levels? We studied two model tritrophic systems. The first was comprised of cabbage plants (*Brassica oleracea* ssp. *capitata*), the oligophagous herbivorous larvae of *Plutella xylostella*, and the solitary hymenopterous endoparasitoid *Cotesia plutellae*. The second was comprised of lima bean (*Phaseolus lunatus*), the polyphagous herbivorous mite *Tetranychus urticae*, and the predatory mite *Phytoseiulus persimilis*. We found that high reactivity and short atmospheric lifetime of terpenes and LOX products in near-ambient (60 nl l^{-1}) and enhanced (120 nl l^{-1}) atmospheric O_3 concentrations resulted in complete degradation of many of these compounds, but the predators and parasitoids still detected herbivore-damaged plants. These results suggest that natural enemies of herbivores might use O_3-stable inducible plant volatiles or degradation products resulting from the oxidation of terpenes that are more stable than their precursors as signals for orientation.

Methods and Materials

Living Material We used standard procedures (Vuorinen et al., 2004a, b) to cultivate cabbage (*B. oleracea* ssp. *capitata* L. cv. Lennox) and lima-bean (*P. lunatus* L.) plants and to rear the herbivores *P. xylostella* L. (Lepidoptera: Yponomeutidae) and *T. urticae* Koch (Acari: Tetranychidae) and the parasitoid *C. plutellae* Kurdjumov (Hymenoptera: Braconidae). The predatory mite *Phytoseiulus persimilis* Athias–Henriot (Acari: Phytoseidae) reared on *T. urticae* feeding on lima bean was supplied by Biotus OY (Forssa, Finland).

Setup for Oxidation of VOCs A main charcoal-filtered airflow of 1.6 l min^{-1} was introduced into an O_3 generator (Model 1008-RS, Dasibi Environmental Corp., CA, USA). The resulting O_3-enriched airflow was divided equally (0.8 l min^{-1}) and channeled into two 22.3-l glass desiccators (Schott Duran, Mainz, Germany) that contained the odor sources. Each odor source consisted of four plants, intact or herbivore-damaged, potted in semirigid polypropene pots, with Teflon covering the soil surface to avoid excess humidity inside the dessicators. The insect feeding damage was accomplished by transferring 10 third-instar *P. xylostella* larvae or 100 *T. urticae* individuals onto two leaves of each cabbage or lima-bean plant, respectively, for 48 hr. The outgoing airflow from each dessicator was branched to give two 0.4 l min^{-1} airflows regulated by airflow meters (NG-LG type, Platon Flow Control, Basingstoke, UK). One branch from each dessicator was diluted with pressurized air, and each was connected to an O_3 analyzer (Model O342M, Environment S.A., Poissy, France) allowing the constant measurement of O_3 in the headspace of each set of plants. Before the experiments, each analyzer was calibrated with the O_3 in the respective dessicator to set target O_3 enrichment levels (0, 60, and 120 nl l^{-1}). The remaining airflow branching from each dessicator was used either to collect volatiles in the headspace of intact and damaged plants or to conduct behavioral tests with the natural enemies (Fig. 1). The whole system was connected by Teflon tubing. Two lamps (PAR, approximately 350 μmol m^{-2} s^{-1}, Model Shuttle Plus, LIVAL, Sipoo, Finland) were placed over the vessels to maintain the optimal photosynthesis levels in the plants.

VOC Collection and Analyses VOCs from the headspace of both intact and damaged plants were collected into tubes containing 150-mg Tenax TA adsorbent (Mesh 60/80, Supelco, PA, USA) at an airflow of 0.215 l min^{-1} for 60 min. The same set of plants was used consecutively for collections at the various O_3 levels. Collections were repeated four times (N=4). O_3 scrubbers [copper tube 4 mm in diameter with an inner bath of potassium iodide (KI)] were placed before the adsorbent to avoid degradation of samples by O_3.

VOCs were analyzed by gas chromatography-mass spectrometry (GC-MS) (Vuorinen et al., 2004b) with a capillary column with a 0.5- and 0.33-μm film for cabbage and lima-bean samples, respectively. The quantification was achieved by comparison with commercially available reference substances or synthesized (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) (Ibrahim et al., unpublished). α-Thujene, (*E*)-β-ocimene, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) were calculated by proposing the responses to be the same as the responses of α-pinene, linalool, and DMNT, respectively. Benzyl cyanide and 2-butanone were estimated on the basis of the internal standard 1-chloro-octane. Emission rates in the absence of O_3 were calculated and expressed in nanogram per gram of DW per hour (leaves dried at 60°C for 48 hr). The quantities of chemical compounds in the headspace of plants were calculated in nanogram per liter.

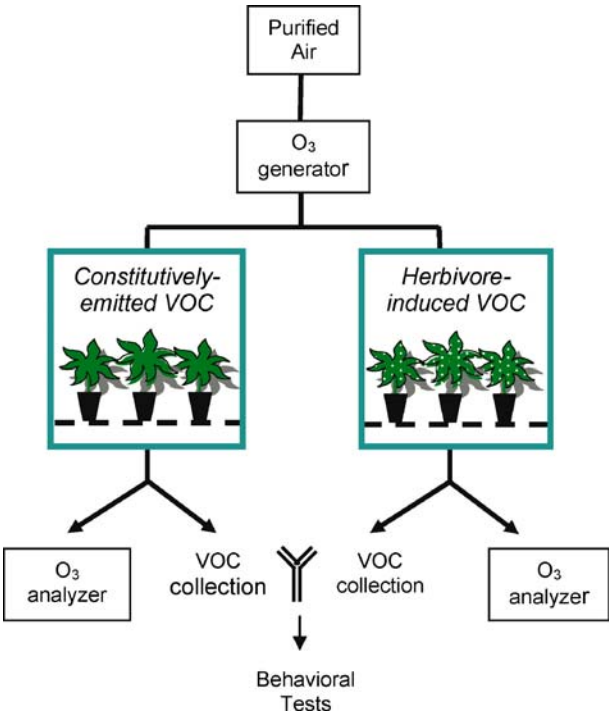

Fig. 1 Experimental setup used for VOC collection and behavioral tests. The O_3-enriched airflow (1.6 l min^{-1}) from the O_3 generator at three concentrations (0, 60, and 120 nl l^{-1}) was channeled equally and directed into each odor source. Outflowing air from the odor source was used for behavioral tests at 0.4 l min^{-1} or VOC collection at 0.2 l min^{-1} and O_3 measurements at 0.4 l min^{-1}

Behavioral Responses of the Natural Enemies Some 3- to 4-d-old *C. plutellae* mated females with a 30-min oviposition experience (Potting et al., 1999) and *P. persimilis* starved for 24 hr individually in Eppendorf tubes at 20°C were used in the bioassays as described in Vuorinen et al. (2004b). Briefly, the wasps or the predatory mites were introduced individually downwind at the end of a Y-tube olfactometer and observed for a maximum of 5 min. "A choice" was recorded when the natural enemy stayed for at least 5 sec further than two-thirds of the way along one of the arms. Otherwise, it was scored as "no choice" after 5 min. Each individual was used once. Tests were conducted under the various O_3 conditions with an airflow of 0.4 l min^{-1}. Two pairs of odor sources were used per day, and 10 observations per O_3 treatment/pair were conducted.

Statistical Analyses Statistical analyses were performed by using the SPSS 11.5 for Windows Statistical Package. The differences between the emission rates from intact and herbivore-damaged plants in the absence of O_3 were analyzed with the Mann–Whitney *U* test. The effect of the O_3 treatments on each individual compound was analyzed by using the nonparametric Friedman rank test for related samples for the headspace of both intact and herbivore-damaged plants. The behavioral responses of the natural enemies were analyzed by using the nonparametric binomial test to test for significant differences in the attraction between the two odor sources (intact vs herbivore-damaged plants) for each O_3 treatment.

Results

VOCs in the Headspace of Cabbage Plants Seven monoterpenes were quantified in the headspace of intact and *P. xylostella*-damaged cabbage plants: α- thujene, α-pinene,

sabinene, β-pinene, β-myrcene, limonene, and 1,8-cineole (Table 1). In the absence of O_3, there were greater emissions of some compounds from herbivore-damaged than from intact plants.

In O_3, the headspace of the intact plants showed reduced levels of α-pinene (P=0.018), sabinene (P=0.039), β-myrcene (P=0.022), and limonene (P=0.018), and increased levels of 1,8-cineole (P=0.018) (Table 2). The headspace of damaged plants showed reductions of α-thujene (P=0.018), α-pinene (P=0.018), β-myrcene (P=0.024), and limonene (P=0.018) and increases of 1,8-cineole (P=0.018). The *P. xylostella*-induced terpenes (Table 1), DMNT (P=0.023), a homoterpene, and (*E,E*)-α-farnesene (P=0.018), a sesquiterpene, decreased significantly in O_3 (Fig. 2a). Some traces of DMNT were detected at both 60 nl l^{-1} (with an exception of one sample) and 120 nl l^{-1} but below the quantification level. Linalool was found only in one sample at 0 nl l^{-1} of O_3, but it was not detected after increasing the O_3. In addition to terpenes, two GLVs, (*Z*)-3-hexen-1-ol and (*Z*)-3-hexenyl acetate, and the nitrile, benzyl cyanide, were induced by *P. xylostella* (Table 1). Of these, only quantities of the (*Z*)-3-hexen-1-ol significantly decreased in O_3 (P=0.018), and there was a trend for (*Z*)-3-hexenyl acetate to decrease (Fig. 2a).

VOCs in the Headspace of Lima-Bean Plants The monoterpenes α-pinene and limonene were found in the headspace of intact and *T. urticae*-damaged plants in the absence of O_3 (Table 1).

Table 1 VOC emissions (nanogram per gram of DW per hour) from intact and *P. xylostella* (*PX*)-damaged cabbage and intact and *T. urticae* (*TU*)-damaged lima-bean plants in filtered air

	Cabbage		Lima bean	
	Intact	*PX*-damaged	Intact	*TU*-damaged

α-Pinene	0.28±0.04	0	0	0.018
Limonene	1.64±0.50	0.21±0.16	0.08±0.08	0.024

Data are expressed as means±SE (N=4). *P* values shown by Friedman rank test between O_3 treatments

In O_3, the headspace of intact plants showed reduced levels of α-pinene (P=0.018) and limonene (P=0.024) (Table 2). The headspace of damaged plants also showed reduced levels of α-pinene (P=0.018) and limonene (P=0.018). The *T. urticae*-induced terpenes (Table 1), (*E*)-β-ocimene (P=0.023), a monoterpene, and the homoterpenes DMNT (P=0.039) and TMTT (P=0.022), decreased in O_3 (Fig. 2b). Linalool was induced, but it was only detected in two samples at 0 nl l^{-1}. In addition to the terpenes, the GLV (*Z*)-3-hexen-1-ol, the ketone 2-butanone, and methyl salicylate (MeSA) were also emitted (Table 1). Of these, (*Z*)-3-hexen-1-ol decreased (P=0.023), whereas MeSA increased (P=0.039) in the presence of O_3, and there was a trend for 2-butanone to increase (Fig. 2b). (*Z*)-3-Hexenyl acetate was found at 0 and 60 nl l^{-1}, but the fact that this compound was not separated from octanal on the column and that octanal remained unaffected by O_3 made it difficult to quantify. The traces of this compound disappeared at 120 nl l^{-1}.

Behavioral Responses of the Natural Enemies C. plutellae and *P. persimilis* were able to discriminate between the odor of intact and herbivore-damaged cabbage and lima-bean plants, respectively, in clean air and at both elevated levels of O_3, 60, and 120 nl l^{-1}, showing a highly significant preference for the damaged plants (P<0.001) (Fig. 3).

Discussion

Terpenes with two or more double bonds are readily decomposed by O_3, whereas saturated terpenes, such as 1,8-cineole, remain intact (Calogirou et al., 1996). In our study, O_3 lead to the unequal decomposition of terpenes. In general, they decreased either significantly or showed a trend to decrease in the headspace of both intact and damaged cabbage and lima-bean plants in increasing O_3. Only 1,8-cineole, emitted by cabbage plants, increased with increasing O_3 as previously observed in a reaction chamber (Pinto et al., unpublished results).

Herbivore-inducible terpenes, such as DMNT and TMTT, have been shown to be involved in the attraction of natural enemies by herbivore-damaged plants (Holopainen, 2004). It has been proposed that differences in the amount of DMNT emitted by *P. xylostella*-damaged plants and *P. xylostella*+*Pieris rapae*-damaged plants are responsible

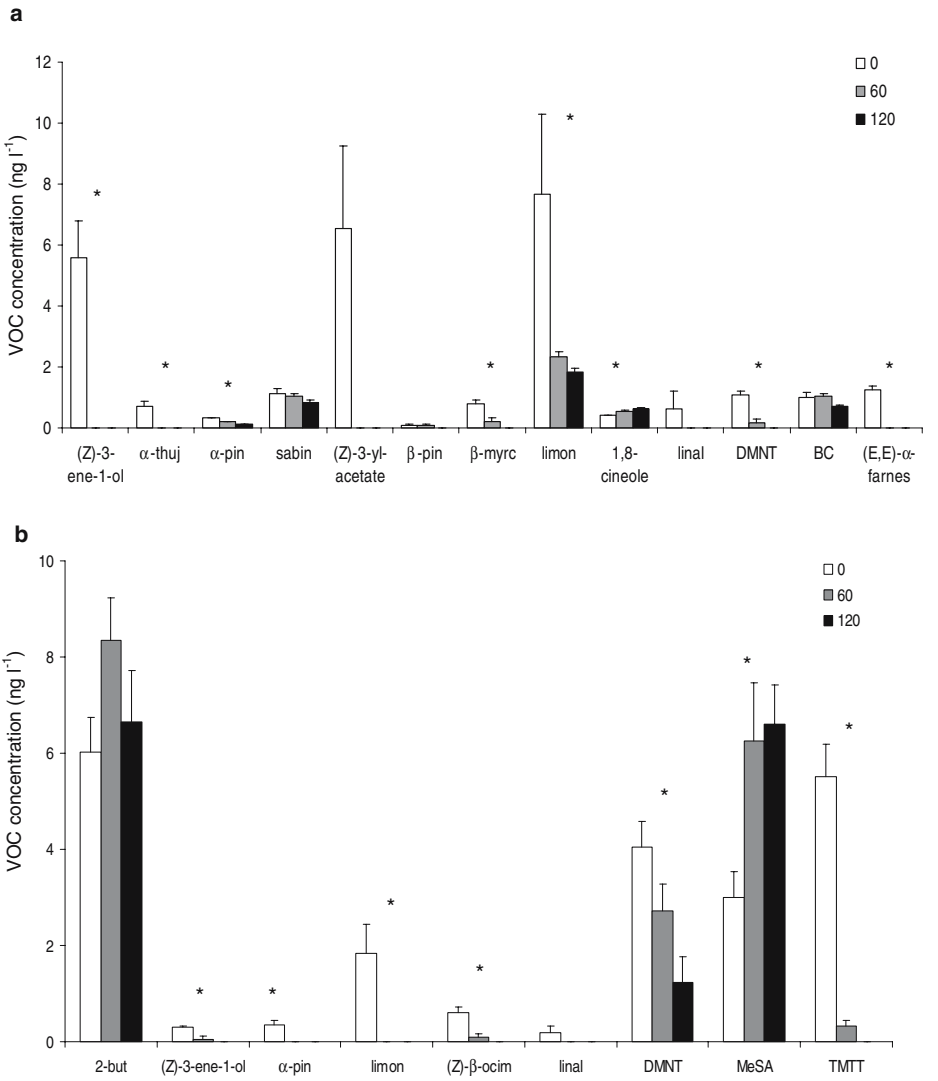

Fig. 2 VOCs (nanogram per liter) in the headspace of **a** a set of four *P. xylostella*-damaged cabbage plants and **b** a set of 4 *T. urticae*-damaged lima-bean plants at different O_3 concentrations. The abbreviations of the compounds refer to those listed in Tables 1 and 2. The amounts of each compound at 0, 60, or 120 nl l^{-1} of O_3 are shown in *white*, *gray*, and *black bars*, respectively, in each series. Data are expressed as means±SE (N=4). *Asterisks* show significance by Friedman rank tests (P<0.05)

for the preferences displayed by *C. plutellae*. *P. xylostella*-damaged plants emit more DMNT than *P. xylostella*+*P. rapae*-damaged plants (Shiojiri et al., 2001). It has been suggested that homoterpenes might also be effectively oxidized and, therefore, contribute to further gas/particulate partitioning of the reaction products (Joutsensaari et al., 2005). In our study, *P. xylostella* and *T. urticae* induced the emission of DMNT. This homoterpene was significantly affected by O_3 after elevating the concentration of the oxidant to 60 nl l^{-1} in the headspace of damaged cabbage plants but not in the headspace of damaged lima bean. However, this compound decreased between 60 and 120 nl l^{-1}. The amount of

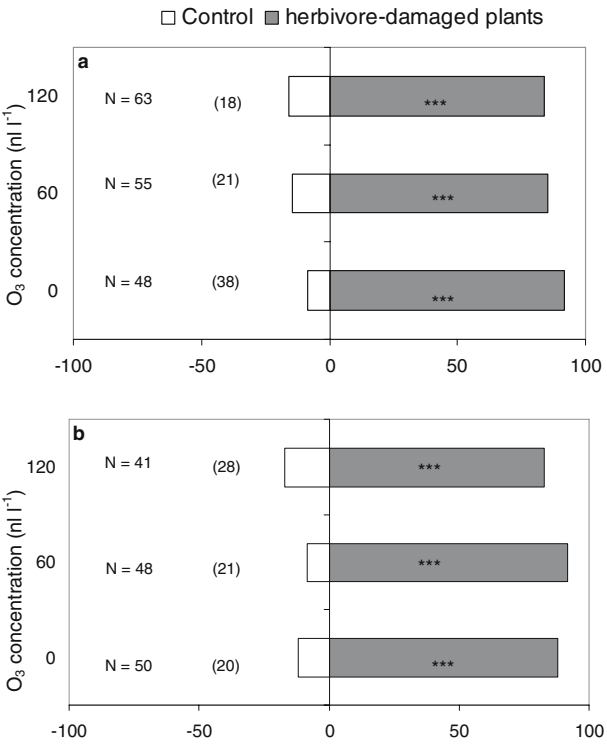

Fig. 3 Behavioral responses of **a** the solitary endoparasitoid *C. plutellae* and **b** the predatory mite *P. persimilis*. The figure shows the percentage of female wasps or predatory mites choosing intact plants (control) or the herbivore-damaged plants in the Y-tube olfactometer at three different O_3-enriched airflows. The significances of the binomial tests ($P<0.001$) are shown with *asterisks* ***. The number of individuals making a choice is shown as "*N*," and the number that did not choose between the two odor sources is in ( ) at the three different O_3 concentrations

DMNT emitted by damaged lima-bean plants was far higher than the amount of DMNT emitted by damaged cabbage plants. TMTT emitted by *T. urticae*-damaged plants was significantly reduced after elevating the O_3. This compound has one more double bond than DMNT, and for this reason, it might be more susceptible to oxidation. *T. urticae*-induced (*E*)-β-ocimene has also been proposed as an important olfactory cue for the predatory mite *P. persimilis*. This compound is emitted by herbivore-damaged but not by O_3-damaged lima-bean plants (Vuorinen et al., 2004a), and it was not detected at 60 nl l^{-1}.

GLVs also elicit behavioral responses in natural enemies, including *C. plutellae* (Reddy et al., 2002), and evoke electrophysiological responses in the antennae of species of the same genus, *Cotesia glomerata* and *Cotesia rubecula*, the parasitoids of the herbivores *Pieris rapae* and *Pieris brassicae*, respectively (Smid et al., 2002). (*Z*)-3-Hexen-1-ol and (*Z*)-3-hexenyl acetate were emitted by both herbivore-damaged plant species. We found that they were severely degraded by O_3. The calculated atmospheric lifetime of these compounds has been estimated to be just a few hours in the presence of O_3 (Atkinson and Arey, 2003). Although we were not able to quantify (*Z*)-3-hexenyl acetate emitted by *T. urticae*-damaged lima bean (octanal was in the same peak), it was evident that this compound was completely destroyed at 120 nl l^{-1}.

Despite the evidence that the herbivore-induced terpenes and the GLVs were affected by increased O_3, *C. plutellae* females and *P. persimilis* were able to discriminate between the odor of intact plants and plants damaged by their respective host and prey. In the case of damaged cabbage in our system, O_3 efficiently degraded the herbivore-induced terpenes and the GLVs. Mattiacci et al. (1994) suggested that the low increases in terpenes compared

to the higher increases of other compounds after herbivore attack may reduce their relative contribution to the headspace blend of the related species *B. oleracea* var. *gemmifera*. Therefore, our results support the possibility that compounds other than terpenes are playing an olfactory role in tritrophic interactions and that these are plant-derived VOCs that are not rapidly reacting with O_3 or are products resulting from the reaction of O_3 with emitted compounds.

Scascighini et al. (2005) found the occurrence of a cineole, two GLVs, and a nitrile, benzyl cyanide, during the 5 hr after the onset of *P. brassicae* feeding on Brussels sprouts. In their study, the response of *C. glomerata* females increased steadily during the first 3 hr after the initiation of feeding. 1,8-Cineole was also emitted in the constitutive blend of cabbage plants and, therefore, its contribution to the active attractive blend might be low. The nitrile, benzyl cyanide, evokes a strong electrophysiological response in *C. glomerata* and *C. rubecula* (Smid et al., 2002). This prompted us to estimate the emissions of benzyl cyanide in our samples and its reactivity with O_3. This compound was emitted only by the herbivore-damaged cabbage plants, and its presence was clearly evident at 120 nl l^{-1} O_3. Our quantity estimates of benzyl cyanide in the samples showed that it remained unaffected by O_3. It has been suggested that specialized parasitoids of herbivores feeding on plants in the Brassicaceae such as *C. rubecula* may at any stage of the host location process use sulfur and nitrogen–sulfur-containing compounds, which are characteristic infochemicals for this plant family (Agelopoulos and Keller, 1994; Potting et al., 1999). This has been supported by no-choice and choice tests in wind tunnel experiments, which suggested that the volatiles emitted by insect-damaged cabbage plants attract *C. plutellae* regardless of the herbivore (Cameron and Walker, 1997) although *C. plutellae* showed significant preference for *P. xylostella*-damaged plants over artificially damaged and *P. rapae*-damaged plants (Shiojiri et al., 2001).

In contrast to *P. xylostella*, an oligophagous herbivore, *T. urticae* feeds on a wide range of plant species, thus eliciting the emission of different VOC blends (Van den Boom et al., 2004). However, the attraction of *P. persimilis* by *T. urticae*-damaged plants has been shown in different plant species belonging to different plant families (Dicke et al., 1998). We hypothesized that a predator in a less-specialized tritrophic system may rely more on the induced terpenes. Our results did not support this hypothesis; however, they support the observations of De Boer et al. (2004), who found that *P. persimilis* does not show preference when given the choice between synthetic forms of DMNT or TMTT and clean air.

In addition to emitting inducible terpenes, *T. urticae*-damaged plants emitted MeSA and 2-butanone. These are known to elicit a behavioral response in predatory mites (De Boer et al., 2004). It is interesting to note that there was significantly more MeSA at elevated O_3 levels. We do not expect that the increased quantities in the headspace of damaged plants are a consequence of the O_3 exposure because this compound was not observed in the VOC profile of intact plants at any O_3 concentration; however, this suggests a synergistic effect of O_3 and feeding damage. MeSA is a semi-VOC, and its lifetime with respect to oxidation by high concentrations of O_3 has been estimated at approximately 4 yr (Canosa-Mas et al., 2002). MeSA has been shown to be an important synomone (i.e., infochemical benefiting both the emitter and the receiver) for *P. persimilis*. It is not only attractive to this species when confronted alone opposite clean air in dual-choice tests but it is as attractive as *T. urticae*-damaged plants. Moreover, the addition of MeSA can make *Spodoptera exigua*-damaged plants attractive to predatory mites (De Boer et al., 2004) although it is not a compound induced exclusively by *T. urticae* feeding (see De Boer and Dicke, 2005 for a review). The other induced non-terpene compound was 2-butanone. It has been shown to be preferred over clean air in dual-choice tests (De Boer et al., 2004). The quantification of this

ketone reveals that it was not affected by increased O_3, suggesting that it may also enable discrimination by the predatory mites.
