Plant–arthropod interactions mediated by plant volatiles are complex. In this study, we present some data that show that not only the decomposition of known herbivore-induced signaling compounds at elevated O_3 levels but also that the plant VOC emissions still provide reliable olfactory cues for natural enemies in two different tritrophic systems. This has not been demonstrated previously. Herbivore-induced blends consist of a series of compounds that vary in their reactivity in the atmosphere. Natural enemies might have adapted to use chemically stable compounds, such as benzyl cyanide or MeSA, which may be detected at long distances from the attacked plant. Other compounds with a long atmospheric lifetime, and released by herbivore-injured leaves, such as methanol (Atkinson and Arey, 2003; Peñuelas et al., 2005; Von Dahl et al., 2006), might also play roles as long-distance cues. Terpenes in the boundary layer of the plant might contribute in further steps of the foraging process. Some compounds that decreased below the detection limits of the GC-MS may still have played a role in the present study because insects have highly sensitive chemoreceptors (Schoonhoven et al., 2006). However, terpenes are highly reactive compounds that under natural conditions may be readily degraded not only by O_3 but also by OH and NO_3 (Atkinson and Arey, 2003). The oxidation of terpenes results in a series of products of the carbonyl family (Calogirou et al., 1999). It is also possible that natural enemies may have learned to recognize products of the reactions that are more stable and abundant in nature. The identification of such compounds is not easily achieved, and their role in chemical communication remains unknown. It would be interesting to address the preferences of natural enemies for herbivore-induced volatiles in O_3-free and in O_3-enriched natural environments to better understand the role of reactive compounds as olfactory cues. Natural enemies, of course, do not have the possibility of choosing an O_3-free environment during O_3 episodes in nature.

Abstract Two issues have hindered the understanding of the ecology and evolution of volatile-mediated tritrophic interactions: few studies have addressed noncrop systems; and few statistical techniques have been applied that are suitable for the analysis of complex volatile blends. In this paper, we addressed both of these issues by studying the noncrop system involving the plant *Centaurea nigra*, the specialist aphid *Uroleucon jaceae*, and the parasitoid *Aphidius funebris*. In a Y-tube olfactometer, *A. funebris* was attracted to the odor from undamaged *C. nigra*, but preferred the plant–host complex (PHC) after 3 d of feeding by 200 *U. jaceae* over the undamaged plant, but not after three or 5 d of feeding by 50 *U. jaceae*. When aphids were removed, the initial preference for the damaged plant remained, but the final preference was not greater than for the undamaged plant. No qualitative differences were detected between the headspaces of *C. nigra* and the *C. nigra–U. jaceae* PHC. For quantitative analysis, we used a compositional approach, which treats each compound produced as part of a blend, and not as a compound released in isolation, thus allowing analysis of the relative contribution of each compound to the blend as a whole. With this approach, subtle increases and decreases of some green leaf volatiles and monoterpenoids on the third day of aphid infestation were detected. Mechanically damaged *C. nigra* had a volatile profile that differed from undamaged *C. nigra* and the PHC. One and 10 ng of (*Z*)-3-hexenyl acetate, and 10 or 100 ng of 6-methyl-5-hepten-2-one were attractive to the parasitoid when placed in solution on filter paper. *A. funebris* appears to be using a combination of chemical cues to locate host-infested plants.

Introduction

Many parasitoids respond to plant odors (Turlings et al., 1991; Powell et al., 1998), and many can also distinguish undamaged from host-infested or previously host-damaged plants (Guerrieri et al., 1999; Lo Pinto et al., 2004; Moraes et al., 2005). Changes in volatile profiles that lead to increased parasitoid attraction have been characterized in many plant species (De Moraes et al., 1998; Röse et al., 1998; Bukovinszky et al., 2005), and it is apparent that volatiles released from storage immediately after damage, as well as those resulting from induction of biosynthetic pathways after herbivory, are important for attraction of parasitoids (Mattiacci et al., 2001; Hoballah and Turlings, 2005). Some responses are host-herbivore specific (Du et al., 1996; De Moraes et al., 1998; Shiojiri et al., 2001; Moraes et al., 2005), and attempts to characterize individual compounds that confer specificity to parasitoid responses have revealed 6-methyl-5-hepten-2-one as important as a specific indicator of the presence of *Acyrthosiphon pisum* for the parasitoid *Aphidius ervi* (Du et al., 1998), and the green-leaf volatiles (*E*)-2-hexenal and (*Z*)-3-hexenyl acetate for the parasitoid *Cotesia glomerata* (Shiojiri et al., 2006). However, this specificity is not universal (e.g., Shiojiri et al., 2001; van Poecke et al., 2003).

Although the effects described above have been found for a wide range of parasitoids of pest insects, there is little information on the occurrence of plant volatile-mediated effects in noncrop systems. In noncrop systems, plants have not been modified by artificial selection, which could have had effects on plant metabolism that affect their volatile profiles. There is large variability in volatile production among closely related species in the maize genus *Zea* (Gouinguené et al., 2001) as well as among maize (*Z. mays*) cultivars (Turlings et al., 1998), and some domesticated species have less attractive blends than wild relatives (Bukovinszky et al., 2005). This indicates that artificial selection has led to changes in the metabolic pathways involved in the production of plant volatiles, and genetic uniformity in crops is likely to result in the loss of variability in volatile production. Thus, the identity and amount of volatiles released is likely to vary less among individuals in crop plants compared to noncrop plants. Crops come from a reduced subset of plants, mainly fast growing annual ruderals from early successional habitats (Feeny, 1976), so generalizations drawn from these studies might not always apply to natural ecosystems, for which noncrop plants need to be studied.

The aim of this study was: (a) to elucidate the olfactory responses of the parasitoid *Aphidius funebris* Mackauer (Hymenoptera, Braconidae) to the plant *Centaurea nigra* (L.) (Asteraceae, Cardueae) when it is undamaged, and when it is infested by the aphid *Uroleucon jaceae* (L.) (Aphididae, Aphidinae); (b) to determine the changes in *C. nigra* volatile chemistry that occur after attack by *U. jaceae* that might lead to increased attraction of *A. funebris* by using a compositional approach; and (c) to determine the importance of (*Z*)-3-hexenyl acetate and 6-methyl-5-hepten-2-one as attractants of *A. funebris* because these compounds have electrophysiological activity in *A. ervi* (Du et al., 1998). This system provides a good contrast to crop systems studied because *C. nigra* is a perennial plant, which spends most of the year as a rosette and then bolts for flowering in early summer, and the aphid *U. jaceae* is highly specialized on *Centaurea* species, unlike most pest aphids

of herbaceous crops, which tend to be more polyphagous than their nonpest relatives (Blackman and Eastop, 2000). *A. funebris* is a specialist on *Uroleucon* spp., and attacks its hosts from outside the colony (Völkl et al., 1995), with greater success when attacking instars L2, L3, and L4, as compared to L1 and adults (Weisser, 1995).

Methods and Materials

Plants *Centaurea nigra* seeds were purchased from Herbiseed (Twyford, UK) and Emorsgate Wild Seeds (Norfolk, UK). They were germinated on damp paper, and plants were grown in a glasshouse under a 16:8 light:dark (L:D) regime and were aged between 35 and 45 d old, but of similar size (6–8 leaf stage) when used in experiments. None of the plants used had flowered.

Insect Rearing and Preparation for Bioassays *Uroleucon jaceae* were collected from the field at Rothamsted Farm, Herts, UK, between May and July 2002, and reared at 18°C and 16:8 L:D on *C. nigra*.

Aphidius funebris cultures were set up on *U. jaceae* feeding on *C. nigra* from mummies collected during June 2002 from *U. jaceae* (also feeding on *C. nigra*) in fields on Rothamsted Farm, Herts, UK, at 18°C and 16:8 L:D. Mummies were removed from culture plants and placed in an emergence cage. On the day of the bioassay, adult females were collected in glass vials and placed in the bioassay room to acclimatize for 1 hr. All females were less than 3 d old and were assumed to have mated before collection.

Y-tube Olfactometer Bioassays A glass Y-tube of 1 cm internal diameter, a 7 cm "trunk" and 5 cm arms was used as the bioassay arena. A pump provided an air stream that was passed through an activated charcoal filter and a flow meter before being split in two. Each stream was passed through a 5-l glass vessel containing an odor source and then through a flow meter set at 400 ml/min before entering an arm of the Y-tube. All connections between the parts described were 1 mm ID Teflon (PTFE) tubing. Twenty-four hours before each bioassay, the Y-tube, glass vessels, Teflon tubing, and glass fittings were all washed and rinsed with acetone and placed in an oven at 160°C.

All bioassays were carried out at 20°C on a white Formica bench under artificial lighting. On each arm of the Y-tube, a *choice line* was drawn halfway up the arm prior to the start of the bioassay. During the bioassay, each parasitoid was introduced individually into the base of the Y-tube. A first choice was recorded if the parasitoid crossed one of the choice lines drawn on the arms. A final choice was recorded if either the parasitoid spent more than 15 sec in motion beyond the choice line without crossing back out again, or if the parasitoid was not continuously in motion, if it spent 1 min beyond the choice line without crossing back out. To control for directional bias the arms of the Y-tube through which the odor sources were presented were swapped after every three parasitoids tested. Each parasitoid was used only once.

For testing the response of *A. funebris* to undamaged *C. nigra*, a single potted plant was taken directly from the glasshouse and tested against a pot filled with soil only. To test the response of *A. funebris* to the plant–host complex (PHC) relative to an undamaged plant, a set number of aphids of mixed ages (initial aphid density) were placed on a plant 3 d before the bioassay. Both the infested plant and the undamaged control plant were individually placed in porous Cryovac bread packing bags, which prevent aphid escape but do not accumulate humidity and allow air exchange. They were left in an 18°C controlled temperature room at

16:8 L:D. The responses of *A. funebris* to the following choices were compared: (1) PHC (initial aphid density of 50) vs. undamaged plant; (2) PHC (initial aphid density of 200) vs. undamaged plant. Additionally, the response to the PHC (initial aphid density of 50) after 5 d of aphid feeding vs. an undamaged plant was tested. Finally, to confirm that any responses to the PHC were due to the plant and not to semiochemicals from the aphid, the response of *A. funebris* to aphid-damaged plants (ADP) was tested. To do this, *C. nigra* plants were treated as described above for (2), and immediately before the bioassay was started all aphids were removed, and every leaf was swabbed with warm distilled water to remove aphid traces. The plant was then rinsed with distilled water, and any excess water remaining was removed with clean tissue paper. The same process was carried out for the undamaged plant to control for any effect of the cleaning process. Each of the bioassays described above was carried out on several (2–6) different days. On each day, a single plant or combination of plants was used, and between 10 and 40 parasitoids were tested on any given day.

The dose responses of *A. funebris* to (*Z*)-3-hexenyl acetate and 6-methyl-5-hepten-2-one were measured in the Y-tube olfactometer because the related parasitoid *A. ervi* had previously shown electrophysiological responses to these compounds (Du et al., 1998). Solutions were prepared from synthetic commercial (*Z*)-3-hexenyl acetate (Aldrich, Milwaukee, WI, USA) and 6-methyl-5-hepten-2-one (Aldrich, St. Louis, MO, USA). For the bioassays, either 10 μl of the bioassay solution or 10 μl hexane (control) were placed on a 7-cm (diameter) circular piece of clean filter paper at the bottom of each of two 500 ml glass vessels, which were left for 1 min before starting the bioassay to allow the solvent to evaporate. Throughout the bioassay, the arms delivering the test and control odors were alternated after every three parasitoids tested. The amounts of (*Z*)-3-hexenyl acetate tested were 0.1, 1, 10, and 100 ng. For 6-methyl-5-hepten-2-one the amounts tested were 1, 10, 100, and 1,000 ng.

Volatile Collection by Air Entrainment Super Q 80/100 mesh (Alltech, PA, USA) was used to adsorb the volatiles and was placed in small glass tubes secured with glass wool. The adsorbent was conditioned with hexane and diethyl ether, and heated at 135°C with a flow of nitrogen for 24 hr. Between uses, the adsorbent tubes were rinsed with 1 ml ether and heated (135°C) with a nitrogen flow for at least 3 hr.

Plant volatiles were collected by placing the aerial parts of the plant in a 2.2 l glass vessel, closed at the base with two metal plates. Because the plates do not seal the vessel, the soil in which the plant was growing was covered with aluminium foil to minimize volatiles from the soil seeping into the air entrainment vessel. The adsorbent tube was secured in one of the apertures at the top of the vessel, and through another aperture a Teflon tube carrying charcoal-filtered air was inserted into the vessel. Air was pumped into the vessels at a rate of 1.2 l/min and sucked through the adsorbent tube at 1 l/min for 24 hr. Before every air entrainment, all glass, metal and nondisposable Teflon material was washed, rinsed with acetone, and heated at 160°C for 24 hr. The adsorbed compounds were eluted with 500 μl of redistilled ether, and each sample was concentrated to 100 μl under a gentle flow of filtered nitrogen gas. Blanks were regularly carried out to test the purified air for impurities.

Air Entrainments Immediately before the start of the air entrainment, 200 *U. jaceae* of mixed ages were placed on one of the two plants (randomly selected), while the other plant was left undamaged. Fourteen replicate air entrainments were carried out over 5 d, pairing undamaged *C. nigra* with the PHC in a randomized block design. The adsorbent tube was changed every 24 hr to obtain daily profiles (ignoring variation in volatile production due to the light cycle).

Air entrainments with mechanically damaged *C. nigra* were carried out by cutting 1 cm off every leaf tip of a plant to determine the compounds released upon mechanical damage (not to mimic aphid damage). Six paired (undamaged and damaged) air entrainments were carried out for 3 d, with a sample taken every 24 hr.

Compound Identification Volatile samples were injected into a coupled gas chromatography–mass spectrometry (GC–MS) system for identification (Thermo-Finnigan MAT95XP magnetic sector mass spectrometer), equipped with an ion trap analyzer, which was directly coupled to a Finnigan Trace 2000 GC with a non-polar 50 m HP-1 column (methyl siloxane, 0.52 μm film thickness, 250 μm ID, J&W Scientific, Folsom, CA, USA) with helium as carrier gas. Ionization was by electron impact (70 eV, source temperature 200°C). Two microliters were injected for each sample in a temperature ramp program (30°C/5 min, 5°C/min to 250°C/21 min).

Mass spectra for the compounds were compared against a NIST library. A tentative identification was made if the library match was greater than 75% and the KI matched when compared to a database. GC analyses (Hewlett Packard 6980) were carried out by cool-on-column injection of standards and samples in temperature ramps in a polar 25 m DB-Wax column (polyethylene glycol, 0.50 μm film thickness, 320 μm internal diameter, J&W Scientific, Folsom, CA, USA; 4.00 psi, 30°C/0.10 min, 2°C/min to 100°C/0.10 min, 3°C/min to 150°C/0.10 min, 10°C/min to 250°C/8 min), and a nonpolar HP-1 column (dimensions as above; 10.00 psi, 30°C/0.10 min, 5°C/min to 150°C/0.10 min, 10°C/min to 230°C/20 min), with an inlet temperature of 30°C and hydrogen as carrier gas. Detection was by a flame ionization detector (FID) at 250°C. Fragmentation of the compounds from the sample was compared to the fragmentation of standards when available. Peak enhancement coinjection was carried out with authentic standards to confirm the identities of compounds. The sources of authentic compounds were as follows: (*Z*)-3-hexenyl acetate (98+%): Aldrich, Milwaukee, WI, USA; alkane series, hexanal (98%), butyl acetate (99+%), (*E*)-2-hexenal (98%), 6-methyl-5-hepten-2-one (99%), α-pinene (98%), (1*S*)-(−)-β-pinene (99%), 3-carene (90%), (+)-longifolene (98+%): Aldrich, St. Louis, MO, USA; (−)-camphene (85%), sabinene (98.5%), myrcene (90%), (*R*)-(−)-α-phellandrene (50%), (*R*)-(+)-limonene (96%), γ-terpinene (97%), (+,−)-camphor (95%), (+)-cyclosativene, (−)-α-copaene (90%), β-caryophyllene (98.5%), α-humulene (98%): Fluka, Buchs., Switzerland; (*E,E*)-α-farnesene and (*E*)-β-farnesene: provided by J. Aldrich (USDA, Beltsville, MD, USA).

Volatile Quantification Volatiles from undamaged *C. nigra* and the PHC were quantified by using GC analysis with heneicosane (25 ng/μl) as the internal standard (IS). Samples were injected into an HP-1 column as described above. The total amount of each compound released in the 24 hr of each air entrainment was calculated.

Design and Statistical Analyses For the Y-tube bioassay, data analyses were carried out for first and final choices of the parasitoid. The *responsiveness* (*r*) refers to the percentage of parasitoids making a choice for one of the odors in that bioassay and only these parasitoids were used in the analyses.

The first and final choices of all responding insects were summarized into daily 2×2 contingency tables of counts classified by the arm chosen by the parasitoid (left or right) and the side the test odor was presented (left or right arm). The treatment effect on each day is hence represented by the interaction (diagonal) in each table. The counts from all days for first or final choice were then analyzed by using a generalized linear model (GLM) with Poisson errors and logarithm link function. Main effects of day (replicates) were removed

before fitting other terms. The significance of the treatment effect was assessed by comparing the deviance for the interaction term against tabulated χ^2 values with 1 *df*.

Three approaches were used for the analysis of volatile compounds. First, the mean total amounts of volatiles (transformed to natural logarithms) produced in each 24 hr period were compared between plant treatments (either aphid-infected or undamaged) by using a split-plot repeated measures analysis of variance (ANOVA), as implemented in the AREPMEASUREMENTS procedure of GenStat (Payne et al., 2005). Blocks represented groups of entrainments carried out simultaneously, and repeated measures over time were treated as split-plots within each entrainment. Degrees of freedom in the lowest (time) stratum were corrected by using Greenhouse and Geisser's (1959) epsilon statistic to account for patterns of unequal correlation among days (a violation of ANOVA split-plot assumptions). Confidence limits (95%) for means were calculated on the logarithmic scale and back-transformed for presentation.

To assess the changes in different classes of compounds, each of the compounds identified and quantified was allocated to one of five classes: (1) aldehydes, ketones, and esters (AKE); (2) hydrocarbons; (3) monoterpenoids; (4) sesquiterpenoids; and (5) *unknowns*. For each class separately, the total amount of volatiles summed over all allocated compounds was converted to logarithms and analyzed by using repeated measures ANOVA as described above for the 5 d of entrainment. Confidence limits (95%) were calculated on the logarithmic scale and back-transformed for presentation.

Finally, because the volatiles emitted are part of a blend of compounds produced by one plant, and hence are not independent, multivariate log-ratio analyses (Aitchison, 1986) were used to analyze amounts of all compounds simultaneously, both at the individual compound level within each of the five classes separately and for the class totals. This analysis considers the contribution of each component relative to the rest of the components. Thus, it is suitable for comparing multivariate data that are intrinsically interrelated, as is the case for volatile compounds produced by plants. At the compound level the data for each replicate were first standardized by expressing the amount of each compound produced as a proportion of the total amount of volatiles in that class. Similarly, at the class level, the total amount of volatiles of each type was expressed as a proportion of the total volatiles produced. One component (compound or class) was used as a baseline (see below), and the amounts of all other components were expressed as a ratio of the amount of the baseline components. These ratios were then logged (natural) and analyzed with multivariate analysis of variance (MANOVA). If one or more components were absent for any plant, a proportional correction was applied (see Aitchison, 1986).

When analyzed at the class level, the baseline was the *unknowns* class. This allowed an assessment of the differences in contribution of each class of compounds to the blend in the undamaged *C. nigra* treatment compared to the PHC treatment. When analyzing at the compound level within each class separately, the following compounds were used as the baseline: hexanal in the AKE class; octane in the hydrocarbon class; α-pinene in the monoterpenoid class; and cyclosativene in the sesquiterpenoid class.

Within each MANOVA, the overall effect of treatment was assessed by using an *F* test, but, to determine which variables contributed to any observed treatment differences, a canonical variate analysis (CVA) was also used to search for a linear combination of the variables that best discriminates between the treatments. With two treatments, there is only one possible canonical variate, and the CVA loadings are one dimensional, and represent the contribution of each particular log-ratio variable to the discrimination between treatments. Biplots of the CVA scores (for individual plants) and loadings enabled visual inspection of

which variables contributed to the separation of the undamaged *C. nigra* and PHC treatments.

Results

Full Plant Bioassays Aphidius funebris preferred the odor of *C. nigra* over clean air on first and final choice (Fig. 1a, b). The parasitoid showed no significant preference for the 3-d-50-aphid plant–host complex (PHC) odor, or for the 5-d-50-aphid PHC odor over that of undamaged *C. nigra*. However, the 3-d-200-aphid PHC odor was preferred over undamaged *C. nigra* by *A. funebris* on both first and final choice. Also, the aphid-damaged plant (ADP) odor was preferred over that from undamaged *C. nigra* on first choice, although the final choice preference was not statistically significant (Fig. 1a, b).

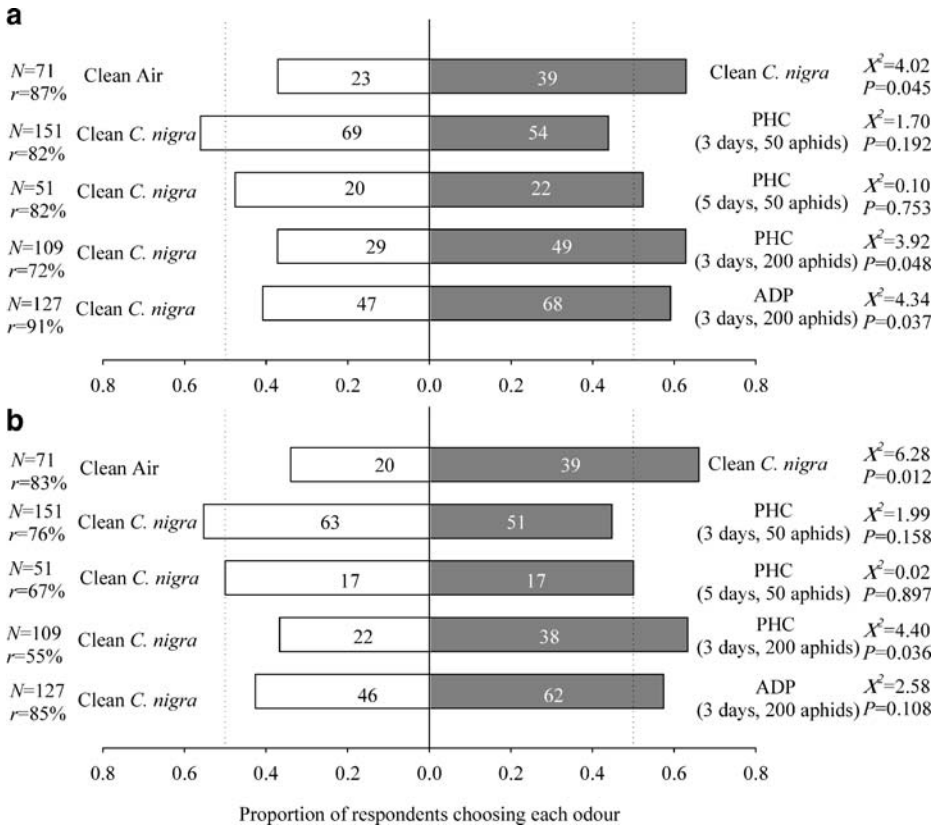

Fig. 1 First (**a**) and final (**b**) responses of *A. funebris* to *C. nigra* odors in a Y-tube olfactometer. Clean *C. nigra*=undamaged plant. For the plant–host complexes (PHC) and the aphid-damaged plant (ADP), the time they were infested before the bioassay and the initial number of aphids are indicated in brackets. *N* is the total number of parasitoids tested and *r* is the responsiveness. Within the bar is the number choosing each odor. The *horizontal axis* gives the proportion of responding insects that chose each odor, and the *dotted line* indicates no preference (50% responses in each arm). X^2 values are obtained from the change in deviance of the GLM interaction term upon deletion from the model (see text for detail)

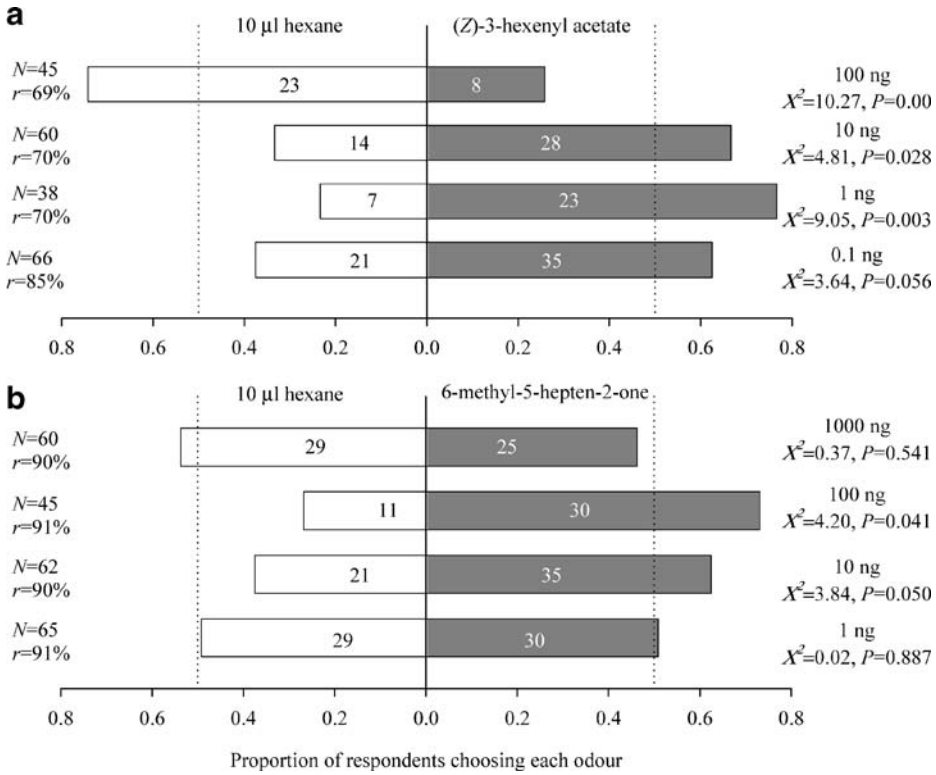

Fig. 2 Dose response of *A. funebris* to (**a**) (*Z*)-3-hexenyl acetate and (**b**) 6-methyl-5-hepten-2-one in a Y-tube olfactometer. *N* is the total number of parasitoids tested and *r* is the responsiveness and within the bar are the number choosing each odor. The *horizontal axis* gives the proportion of responding insects that chose each odor, and the *dotted line* indicates no preference. X^2 values are obtained from the change in deviance of the GLM interaction term upon deletion from the model (see text for detail)

Dose Response Curves Only the first choice responses are presented here. *Aphidius funebris* significantly avoided (*Z*)-3-hexenyl acetate at the highest dose of 100 ng, but showed a positive response to 10 and 1 ng of (*Z*)-3-hexenyl acetate. The response to the lowest dose of 0.1 ng also appeared to be positive, but was not statistically significant (Fig. 2a). The parasitoid showed a positive response to 6-methyl-5-hepten-2-one at 100 and 10 ng doses, but not at the highest (1,000 ng) and lowest (1 ng) doses (Fig. 2b).

Volatile Profiles A total of 40 compounds were identified (of which nine tentatively) (Table 1). The volatile profile of *C. nigra* and the *C. nigra–U. jaceae* PHC did not differ qualitatively.

Repeated Measures Analyses of Volatile Profiles The total amount of volatiles produced in 24 hr was neither affected by aphid infestation ($F_{1,14}$=0.40, P=0.535) nor by time ($F_{2.93,74.65}$= 1.96, P=0.128), and the effect of treatment did not change with time (no significant interaction: $F_{2.93,74.65}$=1.55, P=0.210) (Table 1).

Of the four classes of identified compounds, hydrocarbons, AKEs (aldehydes, ketones, and esters), monoterpenoids, and sesquiterpenoids, none was affected by treatment (P>

Table 1 Compounds identified from *C. nigra* and volatile amounts produced by undamaged *C. nigra* and the *C. nigra–U. jaceae* plant–host complex (PHC)

KI values were calculated on HP-1 and DB-Wax columns from standards (see text for detail). The amounts presented are the mean and SE of the natural logarithm of the amount produced in 24 hr of entrainment (N=14), calculated relative to the area of the internal standard.

(*T*) indicates tentative identifications where no peak enhancement was carried out with authentic standards; *Nq* not quantifiable

[a] KI calculated from assumed compound (from fragmentation pattern) on HP-1 column in the GC-MS and no standard available for calculation on DB-Wax.

0.05), and only the AKEs showed an effect of time ($F_{2.27,57.94}$=7.26, P<0.001) and a time by treatment interaction ($F_{2.27,57.94}$=3.88, P=0.022). For this group, there was a sharp decrease in the amount produced by undamaged *C. nigra* from the first to subsequent days, but the amount produced by the PHC increased (from a level lower than in the undamaged *C. nigra*) and then decreased.

Compositional Analyses of Volatile Profiles During the 1st d (0–24 hr) of entrainment, the contribution of the different classes to the volatile profiles of *C. nigra* plants differed between treatments ($F_{4,10}$=3.57, P=0.047). The AKE class (loading=0.42) was associated with undamaged *C. nigra*, while the sesquiterpenoids (loading=−0.42) were associated with the PHC, and these contributed to separating treatments more than the monoterpenoid or hydrocarbon classes (loadings=0.11 and 0.09, respectively) (Fig. 3a).

During the fourth day, there was a marginally nonsignificant effect of treatment ($F_{4,11}$= 3.24, P=0.055) on the contributions by the different classes of compounds, and the main contribution was by hydrocarbons (loading=0.79), which were associated with the undamaged *C. nigra*. This was opposed by the AKE class (loading=−0.62), which was associated with the PHC. The monoterpenoid and sesquiterpenoid classes were more associated with the PHC, but their loadings were lower (Fig. 3b). On the second day ($F_{4,10}$=1.71, P=0.224), third day ($F_{4,11}$=2.12, P=0.146), and fifth day ($F_{4,11}$=0.92, P=0.488), no difference between treatments were detected in the contribution of the four classes.

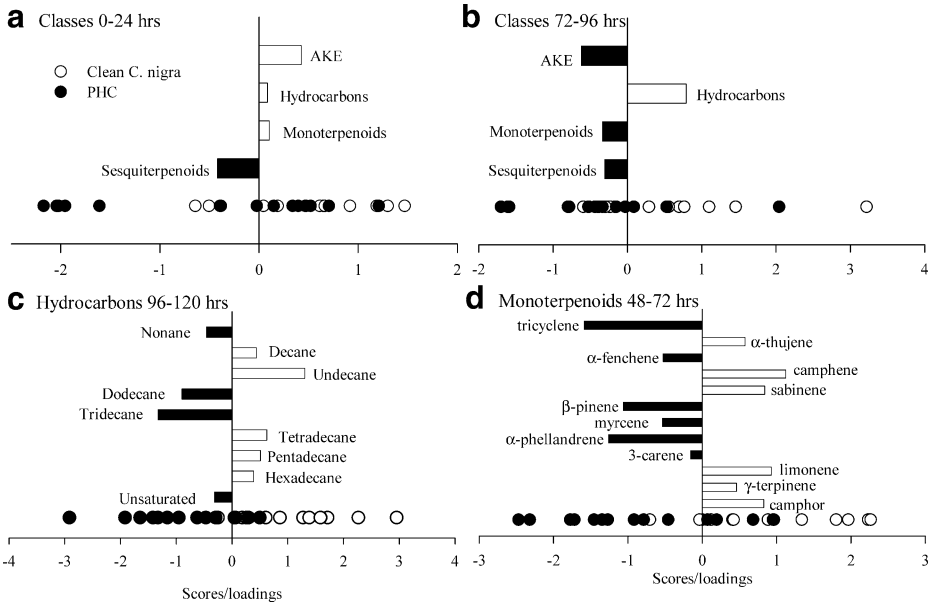

Fig. 3 Canonical variate analysis (CVA) biplots from the comparisons between undamaged (clean) *C. nigra* and the *C. nigra–U. jaceae* plant–host complex (PHC) air entrainments. **a** Compositional analysis for the classes of compounds (acetates, ketones, and esters (AKE), hydrocarbons, monoterpenoids, and sesquiterpenoids) on the first day (0–24 hr) of aphid damage. **b** Class compositional analysis for the fourth day (72–96 hr). **c** Hydrocarbon compositional analysis for the fifth day (96–120 hr). **d** Monoterpenoid compositional analysis for the third day (48–72 hr). The *points* represent the CVA scores for each individual replicate and the *bars* are the CVA loadings, indicating the contribution of each variable towards separating the treatments

Of the hydrocarbons listed in Table 1, the three unsaturated hydrocarbons (1-pentadecene, hexadecene, and 3-heptadecene) were grouped together for the analysis, and the others were included individually. Within this group, there was a marginal effect on the fifth day ($F_{9,6}$= 3.27, P=0.081), and the greatest contribution to separating the treatments came from tridecane, which was associated with the PHC, and undecane, which was associated with undamaged *C. nigra* (Fig. 3c). Dodecane was associated with the PHC. Days 1–4 revealed no differences between the treatments ($F_{9,5}$=0.34, P=0.926; $F_{9,5}$=0.41, P=0.883; $F_{9,3}$= 0.61, P=0.749; $F_{9,6}$=2.29, P=0.162, respectively).

The AKE class consisted of hexanal, (*E*)-2-hexenal, 6-methyl-5-hepten-2-one, butyl acetate, and (*Z*)-3-hexenyl acetate. The composition of the compounds within this class did not vary between the treatments on any of the days of entrainment (in order: $F_{5,8}$=1.18, P= 0.396; $F_{5,9}$=0.31, P=0.896; $F_{5,10}$=0.18, P=0.965; $F_{5,10}$=0.24, P=0.936; $F_{5,9}$=0.57, P= 0.721).

For the compounds within the monoterpenoid class, a marginally nonsignificant effect on the third day of entrainment ($F_{12,3}$=5.68, P=0.089) was observed. On this day, three compounds (tricyclene, β-pinene, and α-phellandrene) were strongly associated with the PHC, while four compounds (camphene, sabinene, limonene, and camphor) were associated with undamaged *C. nigra* (Fig. 3d).

Within the sesquiterpenoids, none of the compounds changed in its contribution to the volatile blend over the 5 d of entrainment (for the 5 d in order: $F_{10,3}$=1.48, P=0.414; $F_{10,4}$= 1.68, P=0.326; $F_{10,5}$=2.34, P=0.181; $F_{10,4}$=1.40, P=0.398; $F_{10,5}$=2.16, P=0.205).

Mechanical Damage Tests Changes due to mechanical damage trials were not quantified, but it led to an apparent increase in 1-pentadecene, 1-hexadecene, germacrene D, (*E,E*)-α-farnesene, and β-caryophyllene. This increase in volatiles occurred during the first 24 hr after damage, and then decreased back to the same levels as the undamaged plant on the second and third day of entrainment.

Discussion

We have demonstrated that the parasitoid *A. funebris* responds to odors from undamaged *C. nigra* and the *C. nigra–U. jaceae* PHC. A high initial aphid density is needed for increased parasitoid attraction, which contrasts with the *Vicia faba–A. pisum* system, where 40 aphids feeding for 3 d were enough to trigger changes in parasitoid behavior (Guerrieri et al., 1999). The species studied have important ecological differences compared to other plant–aphid systems studied in a tritrophic context. In particular, the plant is perennial and the aphid highly specialized, and such a plant-aphid relationship is likely to be tightly coupled. The aphid is likely to overcome host plant defenses efficiently, with minimal effects on plant physiology, leading to small changes in volatile chemistry. Herbivore-induced changes in plant volatile chemistry probably evolved primarily as a direct result of plant–aphid interactions, and predators and parasitoids subsequently evolved responses to the subtle changes in plant volatile profiles resulting from these interactions. This suggests that "plant signalling" was originally nonadaptive in the tritrophic context, and is a function acquired after the natural enemies evolved responses to plant volatiles (Bronstein and Barbosa, 2002).

Host plant specialization by aphids leads to morphological adaptation to those host plants (Moran, 1986), and this might be reflected in the adaptation of feeding structures to the host plant because there is within-species variation in the stylet movement in aphids (Bernays

and Funk, 2000). Such physical adaptation would be important in reducing defensive metabolic changes in the plant, and the stylet path is known to play a role in reducing plant responses to injury (Will and van Bel, 2006) via the stylet sheath, which might have a function in dampening the wound responses of the plant (Miles, 1999) and as a "plug" preventing the influx of calcium ions, which are important in activating defense proteins in the phloem (Tjallingii, 2006; Will and van Bel, 2006).

The lack of induced terpenoids observed in *C. nigra* could be due to low jasmonic acid (JA) levels, which could be a result of these reduced wound responses (Fäldt et al., 2003; Pauw and Memelink, 2004), but could also be due to inhibition by salicylic acid (SA)-dependent gene expression, which is activated by many phloem feeders, including several aphid species (Walling, 2000; Moran and Thompson, 2001; Martinez de Ilarduya et al., 2003). The interaction between JA and SA dependent responses can be antagonistic, though there are also cases of simultaneous activation of both defense pathways (reviewed by Bostock, 2005). This interaction can be important in determining the quantity and identity of induced volatiles, and can provide a mechanism of species-specific volatile emission (Kessler and Baldwin, 2002; Dicke et al., 2003; Heidel and Baldwin, 2004; Kaloshian and Walling, 2005).

The parasitoid showed a significant response to the ADP on first choice, but not on final choice. It is possible that the presence of aphids provides cues that reinforce its attraction to the plant. As it gets closer to the host it encounters and uses more reliable cues (Vet and Dicke, 1992), and if it fails to perceive these more specific cues, it might give up that particular search. It is likely that *A. funebris* uses a sequence of cues, each reinforcing the previous, to find its hosts (Vinson, 1976). The lack of qualitative changes in the volatile profile of *C. nigra* detectable by GC-FID suggests that quantitative changes in several compounds of different classes are responsible for attraction of *A. funebris* to aphid-infested plants, and this is likely due to the interactions between signalling pathways and aphid-specific responses discussed above. The small relative changes in "minor" and abundant monoterpenoids may serve as cues that *A. funebris* can exploit. In particular, the changes in relative contributions of tricyclene, β-pinene, myrcene, and α-phellandrene (greater relative presence after herbivory), and camphene, sabinene, limonene, and camphor (greater relative presence in undamaged plants) might be important. To determine this, electroantennography (EAG) and bioassays with different ratios of compounds are needed. Changes in volatile composition are often quantitative (e.g., Colazza et al., 2004b; Moraes et al., 2005), and use of ratios can provide specific information on herbivore presence and identity for some species of parasitoid (De Moraes et al., 1998; Smid et al., 2002). In individual parasitoid antennae, many different compounds show EAG activity (Du et al., 1998; Smid et al., 2002; Gouinguené et al., 2005). Specific types of damage are often needed for maximum attraction of parasitoids (Mattiacci et al., 2001; Colazza et al., 2004a; Hoballah and Turlings, 2005), and individual compounds with EAG activity are not always attractive in isolation (Ngi-Song et al., 2000), suggesting that the use of a combination of compounds might be a common strategy. *Aphidius funebris* therefore differs from *A. ervi*, which seems to use 6-methyl-5-hepten-2-one as a specific indicator of the presence of a suitable aphid (Du et al., 1998), and we agree with the conclusion by Bukovinszky et al. (2005) that subtle changes are responsible for attraction.

Aphidius funebris responds to (*Z*)-3-hexenyl acetate, a ubiquitous green leaf volatile. This has been shown for many parasitoid species (Takabayashi et al., 1991; Whitman and Eller, 1992; Röse et al., 1998; Hoballah and Turlings, 2005) and might provide a means of finding vegetation, but specificity is probably due to components present in relatively low amounts in the volatile blend (Gouinguené et al., 2005). The responses to cues of increasing reliability as

the parasitoid gets nearer to its host is likely to be highly influenced by heterogeneity at different spatial scales, many of which are absent in crop systems because the patch is usually a field of a single plant, highlighting the importance of studying noncrop systems.

The PHC showed an increased emission of sesquiterpenoids on the first day after aphid infestation (Fig. 3a). This is probably due to minor mechanical damage by the aphids because the mechanical damage tests showed an increase in several sesquiterpenoids during the first day. These compounds are probably released from storage upon damage, possibly due to the systemic JA-mediated wound response (Paré and Tumlinson, 1997), and probably indicate general damage.

This study has shown that semiochemical-mediated parasitoid attraction occurs in this noncrop system, and could help explain patterns of parasitism in the field because it has been demonstrated (Pareja, 2006) that individuals in larger colonies are at greater risk of parasitism than those in smaller colonies in the field (i.e., parasitism is directly density dependent). This suggests that response to volatiles could mediate processes such as density dependence that affect community structuring and population dynamics in the field, and are likely to be highly scale-dependent. This has been suggested in the past (Vet, 1996, 1999), but the studies that have demonstrated the potential for semiochemical interactions mediating host-parasitoid population and community processes are few (see e.g., Geervliet et al., 2000; Roßbach et al., 2005).

Effects in this system are subtle, and the parasitoid *A. funebris* is sensitive to minor changes in plant volatile profiles. The statistical technique we present for analyzing volatile data has a firm base outside ecology, but has never been utilized in chemical ecology. We believe that it is suitable for dealing with the complexity of volatile production by plants because it treats volatile compounds as parts of a blend, and not as unrelated compounds released in isolation, which makes intuitive sense when we consider the interrelated metabolic processes that give rise to these compounds. Ignoring the correlations between compounds due to these metabolic interactions could lead to erroneous conclusions on patterns of volatile release upon herbivory. There is potential for combining this analysis with EAG because this will indicate physiologically active compounds that should be included in the compositional analysis. We have also introduced the use of GLMs for the analysis of olfactometer data. Though GLM techniques are well established in ecology, they have not been widely used in behavior, despite their large potential. The introduction of these methods into chemical ecology could prove to be useful tools in the study of volatile-mediated interactions.

Acknowledgements We are grateful to K. Chamberlain, L. Wadhams, and M. Borges for providing help with the chemical analyses, J. Aldrich for providing synthetic standards, V. Brown for advice on the experiments, G. Piaggio for statistical advice and comments on previous versions of the manuscript, and M. Torrance and K. Plumb for help in rearing. We thank two anonymous reviewers and M. Hilker for valuable comments during the review process. This work was funded by a Lawes Trust–University of Reading award to MP. Rothamsted Research receives grant-aided support from the Biotechnology and Biological Sciences Research Council (BBSRC) of the United Kingdom.

Abstract *Illinoia pepperi* (MacGillivray) infests cultivated highbush blueberries, *Vaccinium corymbosum* L., in the Northeastern United States. Allopatric resistance to *I. pepperi* was examined in *Vaccinium darrowi* Camp, which evolved in the absence of *I. pepperi* in the Southeastern U.S. *V. corymbosum* cv. "Elliott", was used as a susceptible control. Between population variability in *I. pepperi* resistance was assessed by measuring length of the prereproductive period, fecundity, and survivorship on 14 *V. darrowi* accessions representing 11 discrete wild populations. Length of *I. pepperi*'s prereproductive period and survivorship were not significantly affected. However, differences were detected in fecundity and the intrinsic rate of increase (r_m). Within population variability in resistance was measured by confining first instars to 24 accessions from a single wild population of *V. darrowi* (NJ88-06). Significant differences in the mean total number of aphids occurring after 20 d were only detected between 2 of the 24 *V. darrowi* accessions. A greater degree of diversity in *I. pepperi* resistance exists between populations of *V. darrowi* compared to within a population. Constitutive leaf and stem polyphenolics were identified by HPLC-MS and quantified from 14 of the *V. darrowi* accessions. The accessions varied in concentrations of five phenolic acids and seven flavonol glycosides, but a correlation was not found between individual or total phenolics and aphid performance. Overall, screening within and between populations of *V. darrowi* identified promising sources of aphid resistance, but

phenolic acid and flavonol glycoside profiles did not predict resistance levels. The mechanism of resistance remains to be identified.

Keywords Allopatric resistance · Blueberry aphid · *Illinoia pepperi* · Metabolic profiling · *Vaccinium darrowi*

Introduction

The aphid, *Illinoia pepperi* (MacGillivary), is the dominant aphid infesting cultivated highbush blueberry, *Vaccinium corymbosum* L., in New Jersey and Michigan (Morimoto and Ramsdell, 1985; Elsner and Kriegel, 1989). The entire life cycle of *I. pepperi* is spent on a *Vaccinium* host, which may include cultivated and wild highbush blueberry, *V. corymbosum*, wild lowbush blueberry, *Vaccinium angustifolium* (Aiton), and wild velvetleaf blueberry, *Vaccinium myrtilloides* Michaux (Lockhart and Hall, 1962; Elsner and Kriegel, 1989). However, *I. pepperi* populations are highest on cultivated blueberry, and movement outside of a field to wild *Vaccinium* plants in the surrounding landscape is considered rare (Morimoto and Ramsdell, 1985).

The holocyclic life cycle of *I. pepperi* consists of overwintering eggs that hatch into wingless, parthenogenic fundatrices during the spring months (Elsner and Kriegel, 1989). Subsequent summer generations consist of alate or apterous virginoparae giving birth parthenogenetically to live young, with the highest populations occurring in June (Morimoto and Ramsdell, 1985). During the fall, sexual morphs of apterous females and alate males are produced, but Morimoto and Ramsdell (1985) collected a few alatae by using water-pan traps after mid-July.

Aphid-transmitted viruses, such as blueberry scorch virus (BlScV) and blueberry shoestring virus (BBSSV), pose economic threats to the commercial production of highbush blueberry, particularly in New Jersey, Michigan, and the Pacific Northwest (Morimoto and Ramsdell, 1985; Martin and Bristow, 1995; Hillman et al., 1996). BlScV belongs to the carlavirus group and is transmitted in a nonpersistent fashion (Hillman et al., 1996), while transmission of the sobemovirus BBSSV occurs in a persistent fashion (Ramsdell, 1979; Terhune et al., 1991). Managing the incidence of BlScV and BBSSV mainly occurs through insecticide applications to reduce aphid population densities, by rouging symptomatic plants and by planting clean root stock (Raworth, 2004). However, as BlScV has a latent period of 1–3 years before symptoms appear (Bristow et al., 2000), an infected plant could continue to serve as a source of inoculum. Therefore, simply rouging symptomatic plants does not represent an effective management strategy. Host-plant resistance can provide a multifaceted approach to vector and virus management. For example, Massonie and Maison (1986) documented reduced virus transmission by using vector-resistant peaches, *Prunus* spp., to reduce the population fitness of the green peach aphid, *Myzus persicae* (Sulzer). The use of plant resistance to limit the population growth of *I. pepperi* could aid in reducing the incidence of aphid-transmitted viruses in cultivated blueberries.

Previous studies found that high levels of insect and disease resistance were exhibited by wild *Vaccinium* spp. (Etzel and Meyer, 1986; Meyer and Ballington, 1990; Stretch et al., 2001). To identify promising sources of aphid resistance, performance parameters of *I. pepperi* were compared after being reared on several wild *Vaccinium* spp. that occur sympatrically and allopatrically with *I. pepperi* (Ranger et al., 2006). Delayed development, along with reduced fecundity and survivorship were associated with several of the *Vaccinium* spp., particularly the allopatric spp. *Vaccinium myrsinites* Lamarck, *Vaccinium*

Table 1 Between population variability in resistance of *Vaccinium darrowi* to the aphid *Illinoia pepperi*

[d] Total offspring produced over a period of 42 d after birth

hirsutum Buckley, *Vaccinium boreale* Hall and Aalders, and *Vaccinium darrowi* Camp. Wild *V. darrowi* accessions have been used to develop and improve numerous highbush cultivars (Chandler et al., 1985; Erb et al., 1990; Hancock et al., 1992), but *V. darrowi* accessions highly resistant to *I. pepperi* have yet to be identified.

As heterogeneity in resistance levels to insect herbivores occurs in wild plant populations (Fritz, 1992), we hypothesized that intraspecific variability in *I. pepperi* resistance would exist within and between populations of *V. darrowi*. Because variability in phenolics occurs within and between plant populations (Nichols-Orians et al., 1993; Hakulinen et al., 1995; Binns et al., 2002; Van Heerden et al., 2003), constitutive phenolics were also quantified to determine if such compounds could be used to predict resistance levels.

Methods and Materials

Plants and Insects A total of 37 different *V. darrowi* (2×) accessions were evaluated for within and between population variability in resistance to the blueberry aphid, *I. pepperi*, along with the standard highbush cultivar *V. corymbosum* cv. Elliott (4×) as a susceptible control. All *V. darrowi* accessions were collected from wild populations (Table 1) and are maintained in the *Vaccinium* germplasm collection at the Philip E. Marucci Center for

Blueberry and Cranberry Research and Extension, Rutgers-The State University of New Jersey, Chatsworth, NJ, USA. Collection details are described by Bruederle and Vorsa (1994). Specimens collected from different counties represent distinct populations, while those from the same county represent a single population (Table 1). The parent plants are potted in a (1:1 *v:v*) sand to peat moss mixture and maintained under greenhouse conditions. Multiple clones of each *V. darrowi* accession were established in May 2004 by excising rhizomes from individual parent plants for each accession. Clones of each *V. darrowi* accession are genetically identical. One-yr-old, *V. corymbosum* cv. Elliott plants were purchased from DeGrandchamp's blueberry farm (South Haven, MI, USA). All plants were grown in a sand: peat moss (1:1 *v:v*) mixture and maintained in a greenhouse for approximately 6 mo before their use in experiments. Osmocote 14–14–14 (N:P:K) (Scotts-Sierra Horticultural Products, Marysville, OH, USA) was used as a controlled release fertilizer.

A colony of *I. pepperi* was established in June 2004 by collecting several apterous *I. pepperi* virginoparae from a commercial blueberry planting in Atlantic Co., NJ, USA. As the overall objective was to identify allopatric sources of resistance against *I. pepperi*, multiple *I. pepperi* clones were used to establish and maintain the colony. Apterous *I. pepperi* were occasionally added to the colony to ensure the presence of multiple genotypes. Aphids were reared on excised shoots of *V. corymbosum* cv. Elliott and maintained in a laboratory under fluorescent lights with a photoperiod of 16:8 (L:D).

Between Population Variability in Aphid Resistance Heterogeneity in resistance of *V. darrowi* to *I. pepperi* was measured by using 14 *V. darrowi* accessions representing 11 discrete populations (Table 1), along with *V. corymbosum* cv. Elliott as a susceptible control. Three adult apterous *I. pepperi* were collected from the laboratory-reared colony and transferred to dialysis-tube cages (4-cm diameter, 13-cm long; Ward's National Science, Rochester, NY, USA), containing approximately 6–7 cm of an actively growing shoot, including the apical meristem, from a particular *Vaccinium* accession. Foam plugs were used to seal both ends of the cage, with the bottom plug being cut along the radius to allow for a single stem to enter and be sealed within the dialysis tube. Cages contained leaf and stem tissue and were positioned on the plants 24 hr before their use. The experiment was performed twice, and a total of nine replications were used for each accession.

Plants were arranged in a completely randomized design on a single greenhouse bench. Cages were inspected daily until nymphiposition began, at which point all individuals were removed except for two first instars. Nymphs were allowed to develop until one reached reproductive maturity, after which the second nymph was removed. Fecundity was subsequently measured every 2 d until 42 d after birth. This procedure allowed for calculating the length of time from birth to reproductive maturity, total offspring production, and survivorship over a 42-d period.

The intrinsic rate of natural increase (r_m) was estimated using the equation of Wyatt and White (1977): $r_m = 0.74(\ln M_d)/\mathrm{TTR}$, where 0.74 is a correcting constant, M_d is the number of young produced in a reproductive period equal to *TTR*, and *TTR* is the time from birth to reproduction (Wyatt and White, 1977). Doubling time ($T_d = \ln 2/r_m$), net reproductive rate ($R_o = \sum l_x m_x$), and generation time ($T = \ln R_o/r_m$) were also calculated, whereby l_x=age-specific survivorship and m_x=age-specific fecundity (Andrewartha and Birch, 1954; DeLoach, 1974). As all aphids were monitored from birth, the age specificity of each aphid was known.

Within Population Variability in Aphid Resistance Variation in aphid resistance within a population of *V. darrowi* was measured with 24 accessions from a single *V. darrowi*

population (NJ88-06) collected in Santa Rosa Co., FL, USA, namely, NJ88-06-01; -02; -03; -04; -05; -07; -08; -11; -12; -14; -17; -22; -23; -25; -27; -38; -39; -41; -42; -43; -44; -46; -49; and -51. *Vaccinium corymbosum* cv. Elliott was also used as a susceptible highbush control. Plants were arranged in a completely randomized design on a single greenhouse bench.

Three adult apterous *I. pepperi* were collected from the laboratory-reared colony and transferred to the previously described dialysis-tube cages. Inspections were made until nymphiposition occurred in each cage, at which point, the adults and all but two first instars were removed. As the instars neared reproductive maturity, one nymph was removed, leaving behind a single, robust *I. pepperi* nymph in each cage. Twenty days after birth of the first instars, the total numbers of aphids in each cage were recorded on the *V. darrowi* accessions and *V. corymbosum* cv. Elliott. The experiment was performed twice, and a total of eight replications were used for each accession. Due to the large number of NJ88-06 accessions and replicates of each, it was not feasible to document developmental rates and fecundity as in the between population experiment.

Extraction, Quantification, and Identification of Phenolics Actively growing shoots from each *V. darrowi* accession representing 11 discrete populations, along with *V. corymbosum*, were harvested on three separate occasions during May–June 2005. Excised shoots were placed in paper bags and set in a drying oven set to 60±5°C for 24 hr. After drying, leaves were separated from stems, and each was ground into a homogenous powder. Based on Witzell et al. (2003), 30 mg of leaf or stem tissue were placed in an Eppendorf tube with 1,000 μl of chilled methanol (MeOH). Samples were placed on a shaker (Labnet Shaker 20, Labnet International Inc., Edison, NJ, USA) at 1,000 rpm for 2 min, and then centrifuged at 12,000 rpm for 5 min (Eppendorf centrifuge 5417C, Eppendorf, Hamburg, Germany). The supernatant was collected, and the tissues were re-extracted as described above with 500 μl of solvent. Both supernatants were pooled, filtered, and concentrated to dryness with a Speed Vac concentrator (Thermo Model SPD 2010-220; Milford, MA, USA). Residues were redissolved in 1 ml of MeOH.

Selected phenolic acids and flavonols in leaf and stem extracts were identified by high performance liquid chromatography coupled with mass spectrometry (HPLC-MS). The HPLC system (Shimadzu Co., 10VP Series, Columbia, MD, USA) employed a C_{18} MCM column (4.6×150 mm; 5 μm; MC Medical, Inc, Tokyo, Japan). Twenty microliters were injected into the column, and a gradient elution was used for separations. Solvent A consisted of 10% MeOH in H_2O adjusted to pH 3.5 with formic acid. Solvent B consisted of 20% H_2O (pH 3.5), 20% MeOH, and 60% acetonitrile. At a flow rate of 0.3 ml min^{-1}, the following gradient was used: 0 min, 100% A; 10 min 20% A; 20 min, 40% A; 40 min, 0% A; held at 0% A for 15 min. Five minutes of equilibration at 100% A was performed before and after each injection. Effluent from the column was introduced into a single-quadrupole mass spectrometer (API 150 MCA, PE Sciex, Concord, Ontario, CA) equipped with electrospray ionization (ESI). The following parameters were used: capillary voltage at 5,500 V, nebulizer gas (N_2) at 9 (arbitrary units), curtain gas (N_2) at 10 (arbitrary units), collision gas (N_2) at 10 (arbitrary units), focusing potential at 300 V, entrance potential at 10 V, declustering potential at 75, drying gas (N_2) heated to 320°C and introduced at a flow rate of 8,000 cm^{-3} min/l. Data were acquired in both positive and negative ionization mode, with full scan acquisition being performed from *m/z* 50–1,200. Data were processed by Analyst software 1.4.1. (Applied Biosystems, Applera Co., Foster City, CA, USA).

Retention times, spectral patterns, and Electrospray ionization mass spectrometry (ESI-MS) fragmentations patterns of 5-caffeoylquinic acid and the flavonol glycosides were compared with

[a] r_m=0.74(ln M_d)/TTR, where M_d is the number of young produced in a reproductive period equal to TTR, and *TTR* is the time from birth to reproductive maturity. Bootstrap estimate of r_m. N=9 for all accessions.

[b] Nonoverlapping 95% CI corresponds to the rejection of no treatment effect ($\alpha \pm 0.05$).

[c] $R_o = \sum l_x m_x$

[d] $T = \ln R_o / r_m$

[e] $T_d = \ln(2)/r_m$

authentic standards. Authentic standards of 5-caffeoylquinic acid, and quercetin-3-galactoside, quercetin-3-glucoside, quercetin-3-rhamnoside, and quercetin-3-rutinoside were purchased from Indofine Chemical Company, Inc. (Somerville, NJ, USA). The remaining phenolic acids were identified by interpreting ESI-MS fragmentation patterns and by comparing with published data (Clifford et al., 2003; Cho et al., 2004; Vvedenskaya et al., 2004).

The selected phenolics were quantified with an HPLC (Waters, Milford, MA, USA) equipped with a Waters 996 photodiode array detector (PDA). All phenolics were quantified by using the external standard method, with quantification being based on peak area. Quantification of the chlorogenic acid derivatives was based on a standard curve prepared with 5-caffeoylquinic acid. Quercetin derivatives were quantified by using the corresponding authentic standard for each compound, except quercetin-3-oxalylpentoside and quercetin-3-*O*-(6-*p*-coumaroyl)-β-galactoside were based on a standard curve prepared with quercetin-3-rutinoside. For both the standards and extracts, 20 μl were injected and separated by using the aforementioned column and solvent system, but at a flow rate of 1 ml/min. Scanning by the PDA occurred at 320 nm, while data acquisition and processing were performed by Waters Empower™ Chromatography Software.

Statistical Analyses Aphid performance parameters and phenolic concentrations were analyzed with one-way analysis of variance (ANOVA) (PROC GLM; SAS Institute, 1996).

[a] In conjunction with Clifford et al. (2003)

[b] Based on comparisons with authentic standards

[c] In conjunction with Cho et al. (2004)

[d] In conjunction with Vvedenskaya et al. (2004)

To help stabilize the variance, data were square root transformed before analysis, but untransformed data are presented. Means were separated by using Tukey's studentized range [honestly significant difference (HSD)] test at α=0.05. Pearson's Correlation coefficient was calculated to detect a correlation between aphid performance parameters (i.e., length of prereproductive period or cumulative fecundity) and individual or total phenolics (PROC CORR; α=0.05; SAS Institute, 1996). The percentage of aphids surviving on each *Vaccinium* spp. 42 d after birth was compared by using a R×C

contingency table with PROC FREQ procedure (SAS Institute, 1996), and Fisher's exact test (two-tail) was used to test for significant differences between observed and expected frequencies (α=0.05).

The bootstrap technique was used to estimate 95% confidence intervals (CI) for r_m values associated with each *Vaccinium* spp. (Meyer et al., 1986; Petitt et al., 1994; R Project for Statistical Computing, 2005). Nonoverlapping 95% CI corresponds to the rejection of no treatment effect hypothesis at α=0.05 (Maia et al., 2000). As T_d and T are functions of r_m, and R_0 represents the population's response, statistical analyses were only performed on r_m; however, values for each are provided for comparative purposes.

Results

Between Population Variability in Aphid Resistance Length of the prereproductive period of *I. pepperi* (from birth to reproductive maturity) was not significantly affected when reared on the 14 *V. darrowi* accessions representing 11 populations or *V. corymbosum* cv. Elliott (Table 1; P>0.05). Among the *V. darrowi* accessions, length of the prereproductive period ranged from a high of 14.7 d on NJ88-06-20 and NJ88-15-09 to a low of 12.2 d on NJ88-17-27 (Table 1). The shortest time required until reproductive maturity (11.1 d) occurred on *V. corymbosum* (Table 1).

Cumulative mean fecundity of *I. pepperi* up to 42 d after birth was affected by the *Vaccinium* host (Table 1; F=5.15; df=27, 106; P<0.001). On the *V. darrowi* accessions, cumulative fecundity ranged from 22.0 nymphs on NJ88-06-20 to 45.4 nymphs on NJ88-11-32. The two lowest fecundities were associated with *V. darrowi* accessions NJ88-06-20 and NJ88-15-09, which differed significantly from NJ88-11-32, NJ88-17-27, Fla 4B, and *V. corymbosum*. The highest cumulative nymphal production of 58.9 nymphs was observed with *V. corymbosum*, which was significantly different from all of the *V. darrowi* accessions except NJ88-17-27, NJ88-11-32, NC84-06a-20, Fla 4B, and NJ88-06-01 (Table 1). Percent survivorship, 42 d after birth, ranged from 66% on NJ88-06-20 and NJ88-04-64 to 100% on *V. darrowi* Fla 4B, NJ88-17-27, and *V. corymbosum* (Table 1), but significant differences were not detected.

By using the length of the prereproductive period and the number of offspring produced over an equivalent amount of time, the intrinsic rate of increase (r_m), net reproductive rate (R_0), generation time (T), and doubling time (T_d) were calculated for *I. pepperi* when reared on the *V. darrowi* accessions and *V. corymbosum* (Table 2). Longer prereproductive periods and reduced offspring production resulted in the r_m values of *V. darrowi* NJ88-06-20 (r_m=0.132) and NJ88-13-22 (r_m=0.145) being significantly lower than those associated with *V. darrowi* Fla 4B (r_m=0.188), NJ88-11-32 (r_m=0.192), and *V. corymbosum* (r_m=0.216) (Table 2).

Considerable variability in *I. pepperi* net reproductive rates (R_0) was observed across the *V. darrowi* accessions, which represented populations across the species geographic range (Table 2). Among the *V. darrowi* accessions, the lowest net reproductive rate of R_0=18.3 occurred on *V. darrowi* NJ88-06-20, while the highest of R_0=46.8 occurred on *V. darrowi* Fla 4B (Table 2). Generation times (T) among the *V. darrowi* accessions ranged from a high of 22.5 to a low of 19.4 on *V. darrowi* NJ88-14-03 and *V. darrowi* NJ88-11-32, respectively. Doubling time (T_d) ranged from 4.9 for *V. darrowi* NJ88-15-09 to 3.6 for both *V. darrowi* NJ88-11-32 and NJ88-17-27 (Table 2). Population fitness of *I. pepperi* was best on *V. corymbosum*, which exhibited the highest R_0 (59.9) and the lowest T (18.9) and T_d (3.2) (Table 2).

Within Population Variability in Aphid Resistance As *I. pepperi* exhibited comparatively poor performance and population fitness on *V. darrowi* accession NJ88-06-20 compared with representatives from other *V. darrowi* populations (Tables 1 and 2), variability in aphid resistance was compared among 24 accessions collected from a single *V. darrowi* population (NJ88-06; Santa Rosa Co., FL). The mean total number of aphids (occurring 20 d after the confinement of a newly born first instar) was higher on *V. corymbosum* cv. Elliott (17.6±2.1) compared to all of the *V. darrowi* accessions (F=4.24; df=24, 175; P<0.001; data not shown). The fewest individuals were recorded from *V. darrowi* NJ88-06-20 (1.1±0.3 aphids). However, significant differences were only detected between 2 of the 24 *V. darrowi* accessions, namely, NJ88-06-20 and (1.1±0.3 aphids) and NJ88-06-51 (6.6± 1.5 aphids).

Identification and Quantification of Phenolics ESI-MS performed under both positive $[M+H]^+$ and negative $[M-H]^-$ modes allowed molecular masses and fragmentation patterns to be identified for several chlorogenic acid and quercetin derivatives extracted from *V. darrowi* and *V. corymbosum* cv. Elliott leaves and stems (Table 3). All of the identified compounds exhibited characteristic ESI-MS profiles and matched well with published data (Clifford et al., 2003; Cho et al., 2004; Vvedenskaya et al., 2004).

Four chlorogenic acid derivatives were identified, namely, 3- and 5-caffeoylquinic acid, and 3- and 5-*O*-*p*-coumaroylquinic acid (Table 3). 5-Caffeoylquinic acid was identified by comparing retention times and ESI-MS fragmentation patterns with an authentic standard, while the remaining chlorogenic acid derivatives were identified by interpreting their ESI-MS fragmentation patterns, parent and daughter ions, along with comparisons with published data (Clifford et al., 2003). A fifth chlorogenic acid derivative (RT 24.62 min; Table 3) was not definitively identified, but the presence of $[M-H]^-$ ions at *m/z* 338.6 and *m/z* 161 indicated a *p*-coumaric acid unit. For all of the chlorogenic acid derivatives, an intermediate ion was present that corresponded to the loss of caffeic acid or *p*-coumaric acid units, as indicated by the $[M-H]^-$ and $[M-H]^+$ fragmentation patterns (Table 3).

Seven flavonol glycosides were identified from leaves and stems of *V. darrowi* and *V. corymbosum* (Table 3), namely, quercetin-3-rutinoside, quercetin-3-glucoside, quercetin-3-glucosylpentoside, quercetin-3-oxalylpentoside, quercetin-3-rhamnoside, and quercetin-3-*O*-(6-*p*-coumaroyl)-β-galactoside. For each of the flavonol glycosides, the aglycone component was indicated by the prominent ion produced following the loss of the sugar moieties from the pseudo-molecular ion ($[M-H]^-$; Table 3). By maintaining a low source temperature and a high declustering potential in ESI-MS conditions, peak sizes of the daughter ions were intensified. Consequently, the relative intensities of the molecular ion peaks were lower compared to the daughter ion peak, which allowed for the identification of each of the sugar moieties (Table 3; Cho et al., 2004; Vvedenskaya et al., 2004). Identifications of all the flavonol glycosides were based on comparing ESI-MS fragmentation patterns and retention times with commercial standards (Table 3), except for quercetin-3-*O*-(6-*p*-coumaroyl)-β-galactoside, which was based on interpreting ESI-MS fragmentation and comparisons with published data.

The five chlorogenic acid derivatives and seven quercetin derivatives were quantified from leaf and stem tissues of *V. darrowi* and *V. corymbosum* (Tables 4 and 5). Comparisons of individual chlorogenic acid and quercetin derivatives revealed considerable variability between representatives of the distinct *V. darrowi* populations, except for quercetin-3-rutinoside extracted from stem tissues. For example, in leaves of *V. darrowi* NC84-6a-20 and NJ88-06-01, 5-caffeoylquinic acid ranged from 3,001 to 257 μg/g of leaf tissue, respectively (Table 4). Overall, 5-caffeoylquinic acid was among the more abundant leaf

Table 4 Chlorogenic acid and quercetin derivatives extracted from leaves of wild populations of *Vaccinium darrowi* and *V. corymbosum* cv. Elliott

[a] Means within columns followed by the same letter are not significantly different [α=0.05; Tukey's studentized range (HSD) test; *df*=14, 30]. *N*=3 for all accessions. Chlorogenic acid derivatives are expressed as micrograms of 5-caffeoylquinic acid equivalent per g dry weight.

[b] Means within columns followed by the same letter are not significantly different [α=0.05; Tukey's studentized range (HSD) test; *df*=14, 30]. *N*=3 for all accessions. Quantity of each quercetin derivative based on corresponding standards, except quercetin-3-oxalylpentoside and quercetin-3-*O*-(6-*p*-coumaroyl)-β-galactoside were based on quercetin-3-rutinoside

and stem phenolic acid. For example, 5-caffeoylquinic acid represented 83% of the chlorogenic acid derivatives extracted from leaves of *V. corymbosum*.

In addition to differences between populations of *V. darrowi*, variability was also detected among *V. darrowi* accessions from the same population. For instance, of the 12 quantified leaf phenolics, significant differences were detected for four compounds between NJ88-06-01 and NJ88-06-20, nine compounds between NJ88-17-13 and NJ88-17-27, and eight compounds between NC84-6a-20 and NC84-6a-37 (Table 4). Regarding stem phenolics, significant differences were detected for two compounds between NJ88-06-01 and NJ88-06-20, five compounds between NJ88-17-13 and NJ88-17-27, and four compounds between NC84-6a-20 and NC84-6a-37 (Table 5). In general, phenolic acid and flavonol glycoside concentrations were lower in stems compared to leaves (compare Tables 4–5).

To determine if concentrations of a particular compound predict levels of aphid resistance exhibited by *V. darrowi*, Pearson's correlation coefficients were calculated for each individual leaf and stem phenolic and aphid performance (i.e., length of prereproductive development or cumulative fecundity). A significant correlation was not detected for any of the 48 comparisons ($P>0.05$). Similarly, totals of the 12 phenolics quantified in this study did not correspond with resistance levels of the *V. darrowi* accessions ($P>0.05$).

Discussion

Allopatric resistance is genetically based resistance to insect pests that occurs between plants and insects that did not coevolve with each other (Harris, 1975; Kennedy and Barbour, 1992; Smith, 2005). Such is the case with *I. pepperi* and *V. darrowi*. *Illinoia pepperi* occurs in the Northeastern and upper Midwestern U.S. (Elsner and Kriegel, 1989; Blackman and Eastop, 2000), while *V. darrowi* occurs in the Southeastern U.S., occupying Florida, Georgia, and westward to eastern Texas (Lyrene and Sherman, 1980; Lyrene, 1997). Harris (1975) argued that allopatric resistance has been the most successful source of host plant resistance to insects for agricultural crops. Furthermore, due to the lack of gene-for-gene interaction between the pest and host plant, allopatric resistance is often polygenic and typically more stable (Harris, 1975; Smith, 2005). Allopatric resistance could be the result of genetic drift, immigration, or genes conferring resistance to insect herbivores found in the plant's native habitat (Kennedy and Barbour, 1992).

Resistance to a variety of abiotic and biotic stresses and the ability to be successfully crossed with *V. corymbosum* (Ortiz et al., 1999; Qu and Vorsa, 1999), has made *V. darrowi* of particular interest for improving the resistance properties of cultivated highbush blueberry, *V. corymbosum* (Chandler et al., 1985; Erb et al., 1990; Hancock et al., 1992). Fla 4B, reported as a *V. darrowi*, has been extensively used to improve highbush blueberry (Draper, 1995; Qu and Hancock, 1997). However, Fla 4B is not rhizomatous, which is characteristic of *V. darrowi* (Vander Kloet, 1977). Instead, Fla 4B appears to be the result of introgression between *V. darrowi* and *V. corymbosum*. Fla 4B was not identified as a promising source of aphid resistance traits in this study or others (Ranger et al., 2006).

V. darrowi is not unique compared to other *Vaccinium* spp. in having considerable variation for phenotypic and horticultural traits within and between wild populations (Camp, 1945; Lyrene and Sherman, 1980; Lyrene, 1997). The current study further supports this phenomenon as reflected in *V. darrowi* intra- and interpopulational variability for aphid resistance and phenolics. Such variation is likely attributed to genetic drift in

individual populations, introgression with sympatric *Vaccinium* spp., and/or by environmental differences between plant individuals (Vander Kloet, 1977; Lyrene and Sherman, 1980; Karban, 1992). By characterizing the intraspecific variability in *I. pepperi* resistance exhibited within and between populations of *V. darrowi*, discrete populations and individual accessions with promising levels of aphid resistance were identified. Identifying such individuals is useful for developing and improving resistance levels in future cultivars. While considering the variability in horticultural traits exhibited by wild *Vaccinium* spp., Lyrene and Sherman (1980) noted that selecting the best accession for a particular trait within a species is almost as important as selecting the most appropriate species.

Offspring production was the only biological parameter of *I. pepperi* that varied among populations of *V. darrowi*, which may be attributed to a phloem-based defense (Givovich et al., 1992). Since r_m values were calculated based on length of the prereproductive period and fecundity, significant differences in r_m were only detected between three of the *V. darrowi* accessions. Andrewartha and Birch (1954) argued that r_m is the only statistic that adequately represents the physiological qualities of an organism relative to its capacity of increase. Greater variability in aphid resistance within a population of *V. darrowi* may have been detected by calculating r_m values for *I. pepperi* (as was done for between population variability), rather than by measuring the mean total number of aphids after 20 d.

Due to their antioxidant capacity, considerable attention has been paid to the fruit phenolics of *Vaccinium* spp. (Häkkinen and Törrönen, 2000; Taruscio et al., 2004; Ayaz et al., 2005). *Vaccinium* leaf and stem phenolics have received less attention. To our knowledge, this study is the first quantitative description of chlorogenic acid and quercetin derivatives in leaves and stems of *V. darrowi* and *V. corymbosum* cv. Elliott. Witzell et al. (2003) quantified temporal variation in phenolic acids and flavonoids in leaves and stems of boreal bilberry, *Vaccinium myrtillus* L. Similar to our study, Witzell et al. (2003) detected quantitative differences in phenolic profiles between leaves and stems, with higher concentrations generally occurring in the leaves. Furthermore, Witzell et al. (2003) also found a chlorogenic acid derivative (tentatively identified as 5-*O*-caffeoylquinic acid) to be the most abundant compound in leaf samples, while quercetin derivatives were the most abundant flavonols in leaf and stem tissues.

Secondary metabolites, including phenolics, can serve as host-recognition cues and feeding stimulants for monophagous or oligophagous aphids (Montgomery and Arn, 1974; Joerdens-Roettger, 1979; Takemura et al., 2006). As theorized by Fraenkel (1959), the presence of such secondary metabolites can drive the evolution of arthropods from polyphagy to monophagy, whereby the compounds are no longer detrimental but instead, act as beneficial cues. As previously noted, *I. pepperi* is monophagous on *Vaccinium* spp. (Elsner and Kriegel, 1989). Thus, the phenolic acids and flavonol glycosides extracted and identified from the sympatric species *V. corymbosum* may provide host-recognition cues for *I. pepperi*. As previously noted, 5-caffeoylquinic acid represented 83% of the phenolic acids extracted from leaves of *V. corymbosum*. Due to the lack of coevolutionary history between *I. pepperi* and *V. darrowi*, unique or novel ratios of phenolics present in *V. darrowi* may have contributed to resistance.

The localization of secondary metabolites within plant tissues has greater implications for resistance against phloem-feeding insects than other feeding guilds. Phenolic compounds are typically stored in vacuoles or specific storage tissues (Harborne, 1967; Harborne and Grayer, 1993), but they may diffuse into the phloem in their glycoside form (Macleod and Pridham, 1965; Mullin, 1986; Peng and Miles, 1991). If present mainly in the mesophyll, such compounds may be encountered during probing, resulting in the deterrence of phloem feeders (Calatayud et al., 1994). For example, the phenolics

procyanidin, *p*-hydroxybenzaldehyde, and dhurrin deter *Schizaphis graminum* (Rondani) from feeding on resistant sorghum cultivars (Dreyer and Jones, 1981, Dreyer et al., 1981). If localized in the phloem, nutritional deficiencies may occur, resulting in reduced developmental rates and/or fecundity (Givovich et al., 1992). *Aphis fabae* (Scopoli) exhibits reduced fecundity on cowpea, *Vigna unguiculata* L. Walp., lines with elevated quercetin glycoside levels (Lattanzio et al., 2000). Similarly, Calatayud et al. (1994) found that three flavonoid glycosides (rutin, kaempferol glycoside-1, and kaempferol glycoside-2) and cyanogenic glycosides were translocated in the phloem of cassava, *Manihot esculenta* Crantz, and consumed by the mealybug, *Phenacoccus manihoti* Matt. Ferr.

While a direct cause and effect relationship between phenolics and plant resistance to insects is not well documented (Smith, 2005), phenolic compounds play at least a partial role in resistance to several aphid pests (Hedin and Waage, 1986). Furthermore, while identification of the specific mechanism of resistance may not be crucial for the development of resistant cultivars, such information can allow for the utilization of phenotypic or genotypic characters, thereby, facilitating breeding or selection programs (Smith, 2005). For instance, if resistance is chemically based, concentrations of allelochemicals could potentially provide a diagnostic characterization of resistant germplasm. Metabolic profiling can predict levels of plant resistance to insects (Brennan et al., 1992; Brignolas et al., 1998; see Smith, 2005), thereby aiding plant breeders in improving the resistance levels of selected cultivars (Andersson et al., 1980; Hedin et al., 1991). Concentrations of isochlorogenic acid in roots of lettuce, *Lactuca sativa* L., predict resistance levels to the lettuce root aphid, *Pemphigus bursarius* L. (Cole, 1987). Similarly, Lattanzio et al. (2000) found a positive correlation between the flavonoid glycoside content of cowpea, *V. unguiculata*, and aphid resistance.

Vaccinium darrowi and other wild *Vaccinium* spp. represent useful sources of genes providing resistance to abiotic and biotic stresses (Etzel and Meyer, 1986; Meyer and Ballington, 1990; Stretch et al., 2001). The current study characterized variability in aphid resistance and constitutive phenolics exhibited within and between populations of the wild blueberry *V. darrowi*. Several *V. darrowi* accessions were identified as being particularly disruptive to offspring production by *I. pepperi*, which resulted in poor population fitness. As a correlation was not detected between aphid performance and constitutively expressed chlorogenic acid or quercetin derivatives, additional studies should be conducted to assess the role of induced defenses following herbivory by *I. pepperi*. Phloem constituents should also be considered. Offspring resulting from crosses between *V. darrowi* and *V. corymbosum* are currently being screened for *I. pepperi* resistance in an attempt to identify molecular markers associated with insect resistance. Marker-assisted selection of plants based on genotype rather than chemotype could expedite the screening process of advanced *Vaccinium* selections.

Acknowledgments This paper is dedicated to Professor Sridhar Polavarapu (1961–2004), who served as Extension Entomologist for the Philip E. Marucci Center for Blueberry and Cranberry Research and Extension, Rutgers-The State University of New Jersey for 10 years. We thank Michael Reding (Horticultural Insects Research Lab, USDA-ARS, Wooster, OH) and Cesar Rodriguez-Saona (Marucci Center, Rutgers University, Chatsworth, NJ) for reviewing earlier drafts of this manuscript. This work was supported in part by USDA-CSREES 2005-34155-15749 and the New Jersey Agri. Exp. Station project # NJ31912.

The Distribution of Two Major Iridoids in Different Organs of *Antirrhinum majus* L. at Selected Stages of Development

Abstract Two iridoid glucosides isolated from leaves of *Antirrhinum majus* L. were identified as the known compounds antirrhinoside and antirrhide. Plants grown hydroponically demonstrated that antirrhinoside is present in all plant organs including the roots. In contrast, antirrhide is found only in leaves. Furthermore, both iridoids were identified in the main stem axillary leaves and leaves on the lateral branches. The highest concentrations of antirrhinoside were found in the main and lateral stems as well as the buds and flowers. As leaves age, for both cultivars, the levels of antirrhinoside drop significantly, and there is a corresponding increase in antirrhide. In spite of the different genetic backgrounds of the two cultivars, the overall distribution of the iridoids was similar during vegetative and flowering development. Radiolabeling of recently expanded axillary leaves with $^{14}CO_2$ showed that both antirrhinoside and antirrhide were prominently labeled in the laminar tissue. However, only ^{14}C-antirrhinoside was recovered in the subtending petiole tissue, consistent with the suggestion that it is a phloem mobile compound.

Keywords *Antirrhinum majus* · Iridoid glucosides · Plant development · ^{14}C labeling · Optimal · Defense theory

Introduction

Iridoids are a class of terpenoids that occur in plant families of the subclass Asteridae (Jensen, 1992), and over 800 structures have been identified (El-Naggar and Beal, 1980; Boros and Stermitz, 1990, 1991; Grayson, 1996). The function of iridoids in plants has largely been attributed to defense against herbivory by insects (Bowers and Puttick, 1988, 1989), but they also have phytotoxic (Pardo et al., 1998) and antifungal (Marak et al., 2002) activities as well

as medicinal value (Baruah et al., 1998; Tasdemir et al., 2005). Concentrations of iridoids can reach up to 20% dry weight of new leaves (Bowers et al., 1992). However, the functions of relatively few iridoid glycosides have been investigated. For example, the function of antirrhinoside, an iridoid glucoside commonly found in many species of the Scrophulariaceae, is unknown. In *Asarina scandens*, antirrhinoside is a phloem mobile compound (Gowan et al., 1995). These authors hypothesize that the ability to transport antirrhinoside within the plant to growing sinks could function as a defense against herbivory. However, antirrhinoside may also play a role in plant osmoregulation (Voitsekhovskaja et al., 2006). In a study of another species in the same genus, *Asarina barclaiana*, antirrhinoside comprised 39% of the total carbon transported in the phloem. It was also noted that apoplastic loading of this compound, as well as sucrose, could contribute to regulation of the osmotic pressure during long distance transport of assimilates (Voitsekhovskaja et al., 2006).

In a species of a related genus, *Antirrhinum majus*, Scarpati et al. (1968), Scarpati and Guiso (1969) and Guiso and Scarpati (1969) isolated and identified the iridoid glucosides, antirrhinoside, antirrhide, and 5-*O*-β-glucosyl antirrhinoside from the aerial parts of the plant. Since then, work has mainly focused on the biosynthesis of antirrhinoside (Breinholt et al.,1992; Damtoft et al., 1993, 1995), and we are aware of only one recent study (Høgedal and Mølgaard, 2000), in which the authors investigated the seasonal and diurnal variation in concentrations of iridoids in two field-grown *A. majus* cultivars.

Recently, *A. majus*, like *Arabidopsis thaliana* and *Petunia* spp., has been used as a model system for linking plant molecular genetics with plant architecture and leaf development (Reinhardt and Kuhlemeier, 2002). The natural variation in *A. majus* has been exploited by breeders to generate cultivars with different growth habits for both the bedding plant and cut flower markets (Ball Redbook, 2003). Many cultivars have been bred specifically for the cut flower market, and they are classified broadly into four climatic response groups (Groups I–IV). These vary in their response to key environmental conditions such as day length, light intensity, and temperature (Rogers, 1992).

In *A. majus*, the two major iridoids that represent 90 to 98% of the extractible iridoid glucosides are antirrhinoside and antirrhide (Høgedal and Mølgaard, 2000). These authors found that antirrhinoside decreased in leaf tissue after flowering, but that there was an increase in the concentration of antirrhide. In a field study, these authors were the first to indicate that there may be changes in the patterns of iridoid accumulation in *A. majus* with respect to seasonal and diurnal cycles in the leaf canopy. A more detailed analysis, under controlled environmental conditions, of iridoid concentration at specific leaf position/age as well as in other developing organs such as the stem, flower, and the root tissue is warranted.

The primary purpose of the present study was to determine the distribution of two major iridoids in the different organs of *A. majus* L. at selected stages of vegetative and flowering development. Thus, the major iridoids were first purified and spectroscopically identified. The profiles of the two iridoids among the major organs including the roots were determined for two contrasting F_1 hybrid cultivars (GI and GIV) used by the industry for cut flower production (Rogers, 1992). Potomac Ivory White (GIV) is a cultivar that is recommended for production under summer conditions where high light, long days, and warm temperatures predominate. Maryland Ivory White (GI) is a cultivar better suited for fall and winter when shorter days, lower light, and temperature conditions are prevalent during greenhouse production. Both cultivars were grown under controlled environmental conditions to the flowering stage in hydroponic conditions so that the root tissue as well as the shoot tissue could be examined during selected stages of vegetative and flowering development. Finally, we sought to determine whether or not it is likely that either of the major iridoids in *A. majus* are translocated within the plant through the use of ^{14}C labeling experiment on mature leaves.

Methods and Materials

Instruments

Final purification of compounds for NMR and quantitative analyses by high-performance liquid chromatography (HPLC) was performed on an Agilent model 1100 HPLC equipped with a degasser, quad pump, autosampler, and diode array display (DAD) (Agilent Technologies Canada Inc., Mississauga, ON, Canada). The column used was a CapCell Pak AG 120 C18 (4.6×250 mm, 5 μ particle size) (Shiseido Co. Ltd., Japan), and the HPLC had ChemStation software. The ^{1}H and ^{13}C NMR spectra of 2.0 mg each of the purified compounds in D_2O were obtained with a Bruker (Bruker Spectrospin, Milton, ON, Canada) AV-700 equipped with an UltraShield Plus magnet and cryoprobe in the Department of Chemistry, McMaster University, Hamilton, ON, Canada. A Micromass Quattro Ultima triple quadrupole mass spectrometer was used to obtain mass spectra.

For determining the ^{14}C partitioning in the fed leaf and petiole, a Beckman Intruments Inc. 118 solvent module with a refractive index detector (Beckman Instruments Inc. Altex division) and a LKB Broma 2111 fraction collector were used. The column used was a Supelcosil™ LC-NH_2 amino (4.6×250 mm, 5 μ particle size; Sigma-Aldrich, Canada Inc.). Scintillation counts of the fractions collected were obtained on a model 1414 liquid scintillation counter (Wallac Oy, Turku, Finland). All solvents used were HPLC grade.

Plant Material Used for Bulk Extraction Snapdragon F_1 hybrid seeds of *A. majus* L. cultivars Potomac White Ivory and Maryland White Ivory were provided by PanAmerican Seed™ (Chicago, IL, USA) and were sown and grown in a glass greenhouse in Guelph, ON, Canada (43.3° L.N.). Seeds were sown in a soilless growth medium (Pro-mix GPX®; Premier Horticulture Ltée/LTD Rivière du Loup, QC, Canada) in "128 cavity plug trays" (Landmark Co. Plastic, Akron, OH, USA). Germination took place on a greenhouse misting bench at 22/15°C day/night temperature regime, under natural light conditions. After 3–4 wk, snapdragon seedlings were transplanted to 1.8 l containers filled with aerated nutrient solution as described by Johnstone et al. (2005). To exclude light from the nutrient solution, which would promote the growth of algae, the containers were inserted into a larger black plastic container and its lid covered with black-on-white plastic sheeting, white side upward. Hydroponic single-plant units were positioned in a growth chamber with a 12-hr photoperiod and provided 350±50 μmol m^{-2} $s^{-1}$of photosynthetically active radiation (PAR) at plant canopy height. Day/night temperatures were approximately 23.5/18°C. Plants were fertilized with a commercial hydroponic formulation (1.15 g of 6:11:35 N–P–K supplemented with 0.85 g of $CaNO_3$ per liter, Plant Products Ltd., Brampton, ON, Canada), with a pH of 6.0, and electrical conductivity (EC) of 1.9 mS/cm. Each main stem was supported by a galvanized wire stake (gauge 12). Seedlings received a half-strength nutrient solution for 5 d after transplant. Thereafter, seedlings received full-strength nutrient solution, and the solution level was maintained during the experiment. Both cultivars have been grown successfully in our laboratory to commercial flower maturity (Ortiz-Uribe et al., 2005).

Bulk Extraction and Purification of Major Iridoids from Leaf Tissue Axillary and lateral leaf tissue for bulk extraction was taken from plants of various ages grown over the period of June–Sept. 2005 in growth cabinets at the University of Guelph. Fresh leaf tissue (108 g) from "Potomac" was frozen in liquid N_2, stored at −80°C, freeze-dried, ground to a fine powder (12.88 g), and extracted (in a glass column 6.0×36.0 cm) sequentially with 150 ml hexane, 150 ml ethyl acetate, and 100 ml MeOH. Fractions were dried as much as possible

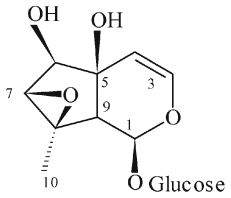
under a stream of N_2, frozen at −80°C, and then freeze-dried. Dried fractions were weighed and found to be: hexane 0.386 g, EtOAc 0.441 g, and MeOH 2.412 g. The MeOH extract contained high concentrations of the two iridoids by HPLC analysis and was subsequently fractionated on a glass column (2.0×30.0 cm), which had been packed with 23.0 g of chromatographic silica (Fisher 100–200 mesh) suspended in 100 ml $CHCl_3$:MeOH:H_2O 6:3:1 and then equilibrated with the same solvent. The *A. majus* MeOH extract (502 mg) was dissolved in 3.0 ml MeOH and loaded onto the top of the column. By using the above solvent system, the chlorophyll and carotenoids were washed off, whereas the iridoids were retained (as determined by HPLC analysis). The solvent system was then changed to 100% MeOH, and fraction 2 containing the iridoids was collected. Fractions were rotary evaporated to dryness, taken up in 3.0 ml MeOH, dried as much as possible under N_2, frozen at −80°C, and freeze-dried. Fraction 1 weighed 105.5 mg, whereas fraction 2 weighed 385.9 mg. Fraction 2 (100.4 mg) was dissolved in 1.0 ml of MeOH and streaked onto two cellulose 20.0×20.0 cm, 250 μ Avicell microcrystalline cellulose plates (Analtech Inc.) 2.0 cm from the bottom of the plates, allowed to dry, and placed in a TLC tank with *n*-butanol:acetic acid:H_2O 4:1:5 as the mobile phase. Plates were removed after the solvent front had reached 2.0 cm from the top. After removal, plates were allowed to dry, and a 0.5-cm strip on the sides of the plates was sprayed with diphenylamine/aniline/H_3PO_4 spray (Markham, 1982). The side of the plate was heated with a heat gun to visualize the bands. Two main bands were observed at R_f 0.344 (bright blue, C2, later identified as antirrhinoside) and 0.50 (light green, C3, later identified as antirrhide) under UV light (254 nm, Model UVGL-58, Mineralight® Lamp). Using the borders of these bands on the sprayed portion of the plate as a guide, the rest of the plate was marked with a razor blade, and the unsprayed band areas were scraped off and placed in 15 ml plastic centrifuge tubes to which 10 ml of MeOH were added. After vigorous shaking for 15–30 sec, the tubes were centrifuged at 3,000 rpm for 3.0 min, the supernatants were removed, filtered (Whatman 0.2 μm nylon syringe filters), rotary evaporated to dryness, taken up in 1.0 ml MeOH, and checked for purity by HPLC. C2 and C3 were still found not to be totally separated and were replated and treated as above to yield 18.6 mg C2 and 5.3 mg of C3. A further 109.2 mg and 109.7 mg of fraction 2 were plated as above to give standards for use in the HPLC analysis of the distribution of the iridoids within the cultivars and for other experiments.

Mass Spectrometry and NMR Identification Electrospray ionization mass spectrometry (ESI-MS) in the positive ion mode was used, and the following conditions were employed; cone 35 V, capillary 3 kV, desolvation gas 400 l/hr (±200), desolvation temp 200°C. Loop injections were carried out with 50 μl/min flow of MeOH/H_2O. The following NMR experiments were carried out to elucidate the structures: 1D: ^1H and ^{13}C, 2D: DQF-COSEY, HSQC, and HMBC.

Sampling and Preparation of Plant Tissue for Quantitative HPLC Analysis There are two types of leaves in *A. majus*, axillary and lateral. Axillary leaves are those directly attached to the main stem. They develop first. Lateral leaves are attached to lateral stems that branch from the main stem above the axillary. Axillary leaves and lateral stems originate from slightly enlarged areas of the main stem, defined as nodes. Axillary leaves were harvested from the fourth, eighth, and 12–14th node from the base. Lateral leaves harvested were the first pair of leaves on the lateral stem at the fourth and eighth node of the main stem. Plant organs were harvested 44, 54, 61, 68, 75, 82, 89, 96, and 106 days after sowing (DAS) for the Potomac cultivar, and 44, 54, 61, 68, 75, 82, and 89 DAS for the Maryland cultivar. Three replicate plants per cultivar were harvested at the same time of the day between 13:00–14:30 hr.

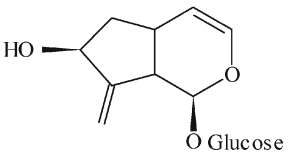
Leaves were removed at the stem, wrapped in aluminum foil, immediately frozen in liquid N_2, stored in a −80°C freezer, and freeze-dried. Nonleaf tissue was separated according to organ type (i.e., stem, root, etc.) and then treated as the leaves were.

Before HPLC analysis, the lyophilized whole stems were broken into several pieces and ground to a fine powder, from which a subsample was taken for homogenization and HPLC analysis. Flowers were separated from the green sepals, pooled for each plant, and ground to a fine powder, from which a subsample was taken. For the roots, a sample was taken from the medial portion of the freeze-dried root mass, and for the leaves, the apical portion was taken. Samples of all plant organs were weighed and placed in 1.5 ml eppendorf tubes to which 1.0 ml of MeOH and two stainless steel beads (Montreal Biotech, Inc., QC, Canada) were added. We generally extracted between 10 and 25 mg of dry plant material, but in extreme cases, such as the when the lateral stems were just forming, as little as 2 mg may have been available for analysis. Tubes were placed in a Retsch MM300 tissue homogenizer (Cole-Parmer Canada, Inc., Anjou, QC, Canada) for 5.0 min at 30 cycles per second, removed and centrifuged at 12,000 rpm for 2.0 min. Supernatants were pipetted off, and filtered through 0.2 μm nylon syringe filters (Whatman International Ltd., Maidstone, UK) into HPLC sample vials.



HPLC Conditions For quantification of the iridoids, the solvent system was initially isocratic employing 3% ACN in H_2O after Høgedal and Mølgaard (2000) with a flow rate of 1.0 ml/min and an elution period of 15 min. However, it was found that by using 6% ACN in H_2O the elution time could be reduced to 10.0 min with adequate separation of the iridoid compounds in samples. Samples were scanned (200–600 nm), and the wavelength used for quantitation was 205 nm. For determining the ^{14}C partitioning in the fed lamina tissue and petiole, the solvent system was 75% ACN in H_2O with a flow rate of 1.0 ml/min.

Steady-state $^{14}CO_2$ Labeling Plants were grown under the conditions described above. When plants had 14–18 axillary leaves, they were used in the labeling experiment. $^{14}CO_2$ steady-state labeling of the most physiologically mature leaves (fourth or fifth node) was conducted for 3 hr by using an open-flow system described previously by Jiao and Grodzinski (1996). Detailed descriptions of the leaf cuvette system, the steady state gas exchange, and the $^{14}CO_2$ labeling protocol were similar to Leonardos et al. (2003). The specific activity of the $^{14}CO_2$ gas among experiments varied from 0.28 to 0.36 kBq μmol^{-1} C depending on the leaf photosynthesis rate. However, during each feeding, the specific activity of the $^{14}CO_2$ was constant.



Before the 3-hr feed period, vegetative seedlings were transferred to the growth chamber at the beginning of the photoperiod where they were allowed to acclimate and reach a steady rate of photosynthesis for 1 hr. The growth chamber conditions were as follows: the light level supplied by 1000 W metal halide lamps (Sylvania GTE, Toronto, ON, Canada) was set at 1,000 $\mu mol\ m^{-2}\ s^{-1}$ PAR at the leaf surface; the temperature was at 25±1°C and a relative humidity of 50% was maintained inside each cuvette by passing the gas stream through a gas bubbler in a controlled-temperature water bath. The mean (N=8) photosynthetic rate was 16.5±0.48 $\mu mol\ C\ m^{-2}\ s^{-1}$. At the end of the labeling period, the fed leaf was separated into two parts: the $^{14}CO_2$-fed laminar tissue was inside the cuvette, whereas the subtending petiole was positioned outside the feeding cuvette and, therefore, not exposed to the $^{14}CO_2$. Both lamina and petiole tissue were wrapped in aluminum foil, immediately frozen in liquid N_2, stored in a −80°C freezer, and freeze-dried. The fed leaf area and petiole dry weights were obtained. Each sample was placed in a 1.5-ml eppendorf tube to which 1 ml of methanol (MeOH) and two stainless steel beads (Montreal

Biotech, Inc., QC, Canada) were added. Samples were homogenized in a Retsch MM300 tissue homogenizer for 5 min at 30 cycles per sec, removed, and passed through a 0.2 μm filter (Whatman International, Ltd., Maidstone, UK). Individual sugars and iridoids were separated by HPLC at ambient temperature. Effluent was collected, and the radioactivity in the individual sugars and iridoids was determined by liquid scintillation counting.

Statistical Analyses As the cultivars differ in their development, plants were grouped according to their developmental stage (vegetative, budding, or flowering) for comparisons. A two-way analysis of variance (ANOVA) was carried out for plant organ type and cultivar as the main effects (PROC GLM) with SAS® (2005) statistical software package. One-way ANOVAs with Student–Newman–Keuls means difference tests were used to determine differences in iridoid concentrations in different plant tissues by using the (PROC GLM, Means SNK).

Results

Identification and Quantification of the Two Major Iridoids in A. majus In Table 1, the proton and carbon assignments, and coupling constants are given along with the corresponding structures for antirrhinoside and antirrhide obtained from bulk extraction

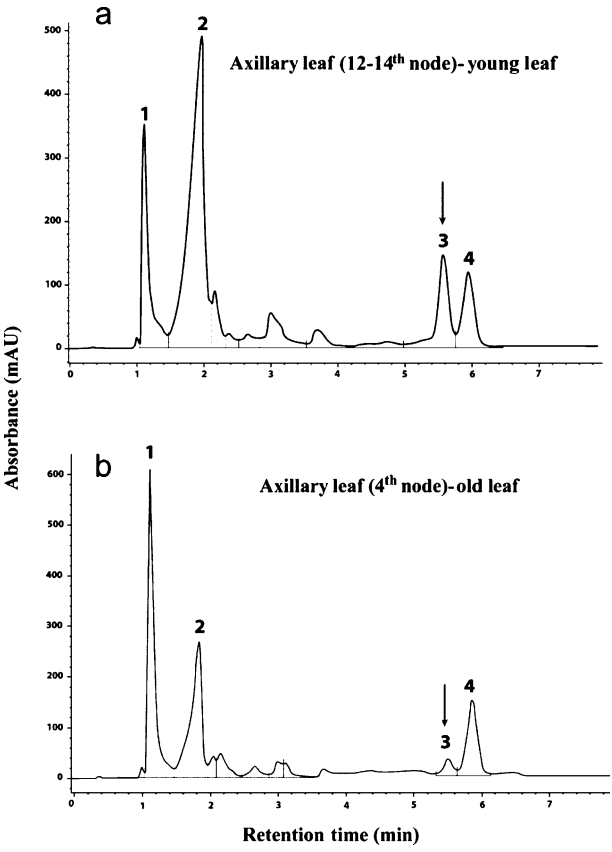

Fig. 1 (a) Chromatogram of MeOH extract from an axillary leaf taken from the 12th node showing the levels of antirrhide relative to antirrhinoside. 1=unidentified carotenoid, 2=mixture of unidentified non-iridoid compounds, 3=antirrhinoside, 4=antirrhide. (b) Chromatogram of axillary leaf taken from the fourth node of the same plant

Cultivar	1	3,123.84	3,123.84	8.07	0.005
Organ–cultivar	4	839.75	209.93	0.54	0.705

of the leaves. The ES-MS data yielded a primary *m*/*z* ion corresponding to the hydrated molecular ion of antirrhinoside at *m*/*z* 380.3 [362+H_2O(18)], and at *m*/*z* 348.0 [330+H_2O(18)] for the hydrated molecular ion of antirrhide.

The modified HPLC method of Høgedal and Mølgaard (2000), as described in "Methods and Materials," was used to quantify antirrhinoside and antirrhide levels in different tissues. For example, the HPLC trace (Fig. 1a,b), shows graphically how young axillary leaves near the top of the plant canopy (e.g., 12th node) had higher levels of antirrhinoside than did the older leaves (e.g., fourth node) within the canopy. Calibration curves were constructed by using the purified and identified compounds at concentrations of 1.0, 0.5, 0.25, 0.125, and 0.0625 mg/ml injected into the HPLC giving curves with R^2 values of 0.9991 and 0.9998 for antirrhinoside and antirrhide, respectively.

Comparison of Iridoid Concentrations in Plant Organs Between Cultivars The two-way ANOVA with plant organ and cultivar as the main effects showed that the main effects were significant for both antirrhinoside and antirrhide, but that the interaction was significant only for antirrhinoside (Table 2). This indicates that the pattern of antirrhinoside allocation in plant tissues differs between the two cultivars. Figure 2 shows the pattern of allocation of the major iridoids antirrhinoside and antirrhide for the two cultivars Potomac and Maryland at two specific stages of development, the budding and flowering stage. Maryland develops and flowers faster than Potomac, and has fewer axillary leaves. A comparison of the two cultivars at the same morphological stage indicates that the only significant difference is for budding and flowering tissue, which has only antirrhinoside (Fig. 2c,d). There were no significant differences in the levels of antirrhinoside or antirrhide between the two cultivars in the vegetative stage (data not shown). At other stages, when the concentrations of individual compounds were examined, statistically significant differences are apparent. During budding, Maryland (N=5) had more antirrhinoside in the axillary leaf at node 4 than Potomac (N=7), but Potomac had more of this iridoid in the lateral stems (Fig. 2c) than did Maryland. During flowering, Maryland (N=8) had more antirrhinoside in the 12th node leaf, whereas Potomac (N=7) had more in the flowers (Fig. 2d). However, during budding Potomac had more antirrhide in the axillary leaves than did Maryland (Fig. 2e), but there were no differences for the lateral leaves. During the flowering stage, Potomac had more antirrhide than Maryland in axillary leaves at nodes 8 and 12, and node 4 for the laterals (Fig. 2f).

Comparison of Iridoid Concentrations in Plant Organs Within Each Cultivar It is apparent from Tables 3 and 4 that younger leaf tissue, both axillaries and laterals, initially have relatively high levels of antirrhinoside, but this gradually declines as the leaves age.

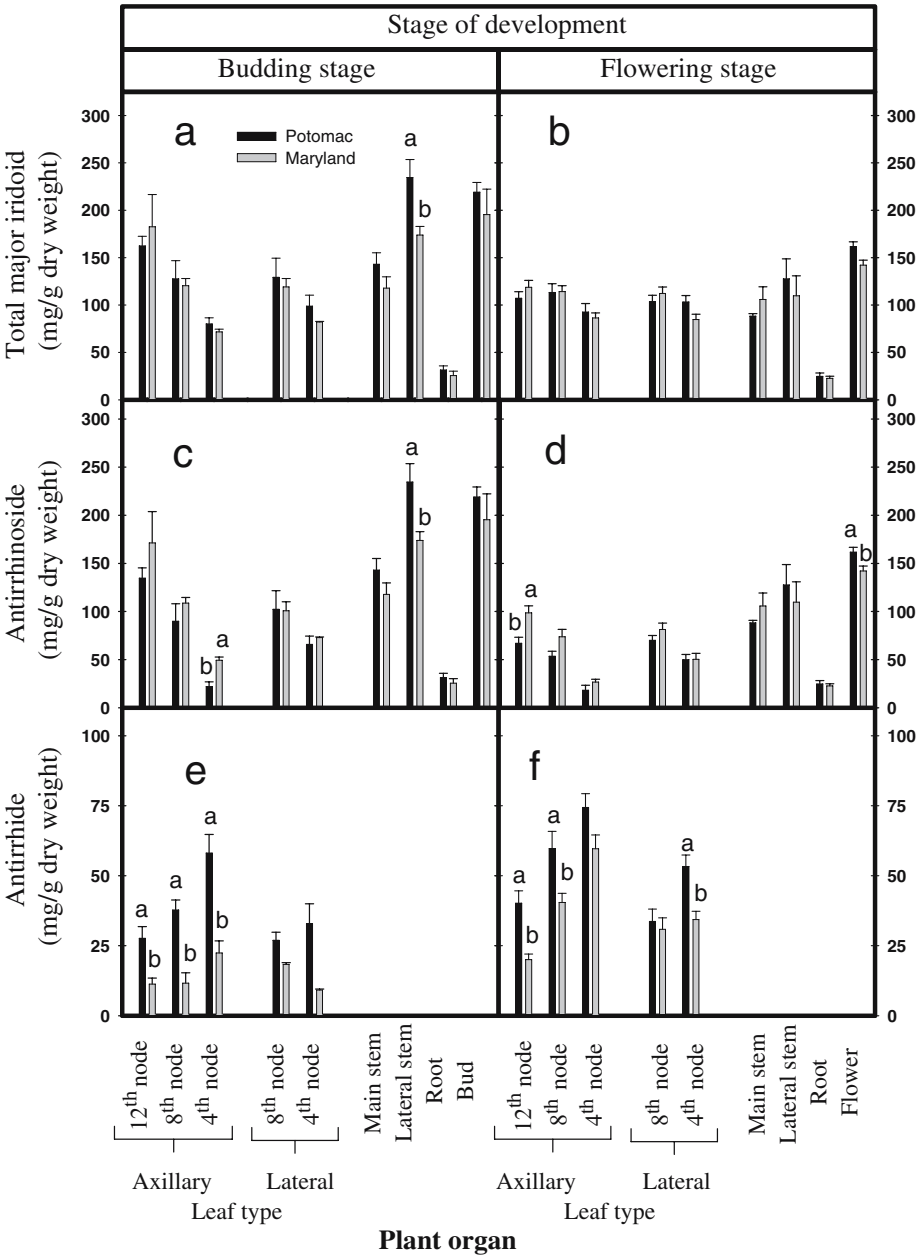

Fig. 2 Distribution of the total major iridoids (a, b), antirrhinoside (c, d), and antirrhide (e, f) among plant organs sampled at two stages of flowering development (budding and flowering) in two snapdragon cultivars (Potomac and Maryland Ivory White). Bars represent means with SE and letters indicate significant differences ($P<0.05$)

Conversely, antirrhide is found at low concentrations in young leaves, but this increases with leaf age. However, the concentration of these iridoids in different plant tissues varies dramatically. For example, at 75 DAS, Potomac has high levels of antirrhinoside in stems and young (developing) leaves (Table 3). What is particularly striking is the magnitude of differences in antirrhinoside concentrations in different organs of the same plant at a given time. For example, at 82 DAS, the buds and lateral stems of Potomac have concentrations of antirrhinoside that are close to an order of magnitude greater than that of the roots and fourth node axillary leaves (Table 3). The Maryland cultivar (Table 4) shows a similar pattern except earlier in development (68 DAS).

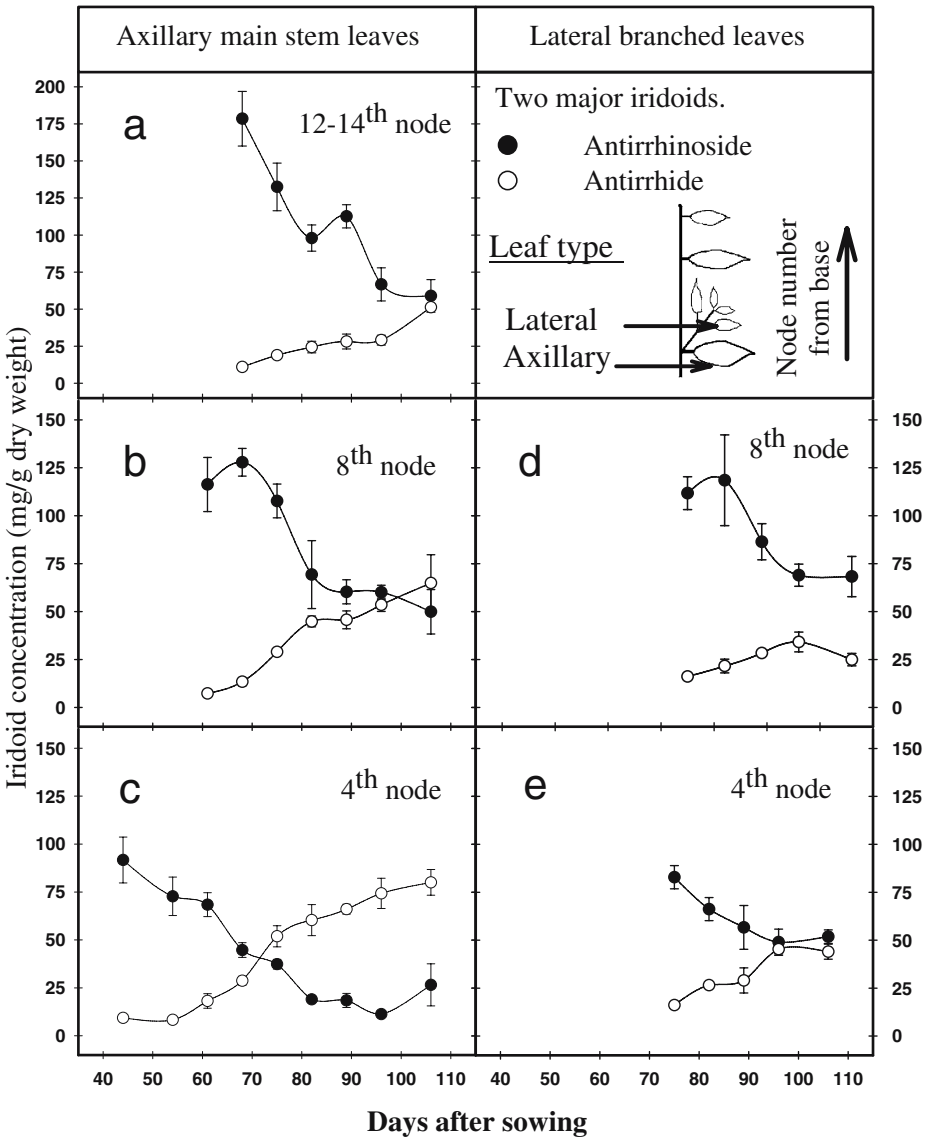

Fig. 3 Distribution of the total major iridoids, antirrhinoside, and antirrhide in axillary (a, b, c) and lateral leaves (d, e) analyzed by pooling data from the two snapdragon cultivars (Potomac and Maryland Ivory White) at similar stages of shoot development. Data represent the means and SE of at least six samples except for days 96 and 106 where only three samples were available from Potomac Ivory White. Bars represent SE of the mean

With regard to other plant organs and concentration of antirrhinoside, no pattern as observed for the leaves was apparent. The roots, except for the first sampling period, had consistently low values for both cultivars, whereas the lateral stems had consistently high levels. Bud tissue had the highest level of antirrhinoside compared to all other tissues for both cultivars. At the time of final harvest, flowers had the highest level of antirrhinoside compared to all other plant organs. Antirrhide was not detected in nonleaf tissue.

Table 5 Labeling pattern of antirrhinoside and antirrhide in the fed lamina tissue and the connecting petiole tissue of the lamina of *A. majus* that was labeled with $^{14}CO_2$ for 3 hr under steady-state conditions as described in "Methods and Materials"

	Percent label relative to total label		Percent label relative to sucrose label	
	Fed lamina tissue	Petiole	Fed lamina tissue	Petiole
Antirrhinoside	22.1 (1.5)	14.5 (1.3)	44.7 (4.4)	47.2 (4.7)
Antirrhide	8.0 (0.01)	nd	16.4 (2.0)	nd
Iridoid total	30.1	14.5	61.1	47.2

Labeling patterns for the two major iridoids were expressed as a percentage of the total label recovered in the tissue and also relative to a primary photoassimilate, sucrose (after Gowan et al., 1995). Data are the means with SE in brackets of at least eight leaves, four leaves for each cultivar
nd = not detected

Iridoid Distribution in the Leaf Canopy In *A. majus*, the leaf canopy is composed initially only of axillary leaves. However, as the plant matures, lateral branches and leaves develop, and at the time of flowering the lateral leaves are the dominant photosynthetic organs. As seen above there are differences in the rate of development of the two cultivars, but they have similar patterns of accumulation of the two major iridoids in the leaf tissue. When the accumulation of leaf iridoids is combined, based on the same DAS, the general pattern of concomitant decrease in antirrhinoside and increase in antirrhide is striking (Fig. 3). Young axillary leaves initially have high levels of antirrhinoside, but as they age the amounts drop to much lower levels at all node positions (Fig. 3a,b,c). A similar trend is seen in the laterals as the canopy develops (Fig. 3d,e). In all leaves, there was also a corresponding increase in the amount of antirrhide produced as the leaves matured (Fig. 3a–e).

Partitioning of ^{14}C in the Fed Leaf and Petiole Tissue Table 5 shows the labeling pattern of antirrhinoside and antirrhide in the laminar and petiole tissues of a physiologically mature, expanded, source leaf following a 3-hr period of steady-state photosynthesis in the presence of $^{14}CO_2$. There were no significant differences in the labeling patterns between cultivars (data not shown). The data for the two cultivars when combined show that antirrhide was found only in the labeled leaf, whereas labeled antirrhinoside was present in both the lamina and the petiole of each cultivar. On average, the two major iridoids contained 30% of the total fixed ^{14}C in the laminar tissue. In relation to sucrose in the laminar tissue, these two compounds accounted for ca. 60% of the labeling. In the laminar tissue, the antirrhinoside pool contained three times as much ^{14}C label as did the antirrhide pool. In the petiole, labeled antirrhinoside, the only labeled iridoid, accounted for 15% of the total newly fixed ^{14}C recovered or 47% of the ^{14}C-photoassimilates in relation to sucrose.

Discussion

For antirrhinoside, our ^{1}H and ^{13}C chemical shifts agree closely with those published using either D_2O (Kitagawa et al., 1973; Bianco et al., 1981; Franzyk et al., 1999) or CD_3OD (Ercil et al., 2004; Al-Rehaily et al., 2006) as an NMR solvent, with the exception that we were able to resolve most of the glucose protons (Table 1). For antirrhide, the only published ^{1}H spectrum that we are aware of is that of Kitagawa et al. (1973) in which only

ranges for the chemical shifts are estimated. Therefore, in Table 1, we provide the full assignment of the chemical shifts as well as coupling constants. The ^{13}C spectrum for antirrhide in Table 1 is in general agreement with that of Otsuka (1993) in CD_3OD.

Following the identification of the two major iridoids, we quantified their distribution in all organs of *A. majus* L. during vegetative and flowering development. The two cultivars were sampled over a period of 45 (Maryland) and 62 (Potomac) days, respectively, under controlled environmental conditions. With respect to leaf iridoid concentration, we found that, regardless of cultivar, the concentration of antirrhinoside and antirrhide changed with leaf position, suggesting that leaf age may be a determinant of not only the amount, but also the type of iridoid present (Tables 3 and 4). Specifically, axillary and lateral leaves show a change in the pattern of iridoid accumulation where antirrhinoside decreases with leaf age and antirrhide increases.

A rise in one iridoid and fall in another, which is dependant on leaf age, has been found for *Plantago lanceoleta* (Plantaginaceae), where older leaves had no iridoids or predominantly aucubin, and younger leaves primarily or only catalpol (Klockars et al., 1993). These authors suggest that as aucubin is a precursor to catalpol it is rapidly converted in the newest leaves and, therefore, undetectable. As leaves age, catalpol may be transported out, broken down, or aucubin may no longer efficiently be converted to catalpol. However, antirrhide is not known to be a precursor to antirrhinoside (Damtoft et al., 1993, 1995), and it may be in our study that antirrhinoside was transported out of older source leaves to developing sinks, such as younger leaves, buds, and flowers. There is little information in the literature about either the amount or types of iridoids found in flowers (but see Mead and Stermitz, 1993 and Song et al., 2006). This is, to our knowledge, the first study that documents the presence of antirrhinoside in flowers of any species in the Scrophulariaceae.

Antirrhinoside is phloem mobile in other species within the Scrophulariaceae (Gowan et al.,1995; Voitsekhovskaja et al., 2006). The absence of antirrhide in nonleaf tissue may indicate that it is synthesized in the leaves but not transported within the plant as antirrhinoside is. Our study demonstrates the different allocation of these two major iridoids within the different plant organs of *A. majus*, and we also document for the first time the presence of antirrhinoside in the root tissue. Antirrhide is not found in the roots of either cultivar.

Overall, the total leaf amounts of antirrhinoside and antirrhide are higher than those reported by Høgedal and Mølgaard (2000). However, in their seasonal study, field-grown plants were subjected to changing weather conditions, and the collected tissue samples were pressed and dried at 40°C for 24 hr. In contrast, our plants were grown under hydroponic conditions where nutrients were nonlimiting and temperature and light were controlled. In addition, samples in our study were frozen in liquid N_2, stored at −80°C, and lyophilized before analysis.

Although there is lack of information on the potential of antirrhinoside as an allelochemical, its distribution and concentration within *A. majus* cultivars follow what would be expected based on Optimal Defense (OD) theory (McKey, 1974). This theory proposes that the allocation of defense compounds within a plant is related to the fitness value of the plant parts and the probability that they will be attacked by herbivores. In *A. majus*, the highest levels of antirrhinoside were found in the buds and flowers, followed by young vs. older leaves, and finally by roots, which have the lowest levels as predicted by OD theory. Although antirrhinoside is not known to be deterrent to insect herbivores, it is sequestered by two species of moths that are aposematic as larvae and adapted to feeding on high antirrhinoside-containing plants (Boros et al., 1991). However, antirrhinoside is not found in the cryptic adults of the two species. Furthermore, catalpol, which has a structure

similar to antirrhinoside, significantly reduced the growth of the generalist gypsy moth (*Lymantria dispar* L.) larvae when fed at 0.18% in artificial diet (Bowers and Puttick, 1988).

It is also known that iridoids deter feeding by generalist insect herbivores, but stimulate feeding in specialists (Bowers and Puttick, 1988), and also are induced in response to fungal infection (Marak et al., 2002). Iridoids are present in higher concentrations in younger leaves of *Plantago lanceolata* (Klockars et al., 1993; Stamp and Bowers, 1994), and it has been hypothesized that this tissue is more active photosynthetically and thus costly for the plant to lose to herbivores or infection (McKey, 1974; Ohnmeiss and Baldwin, 2000). If one of the functions of antirrhinoside is as a defensive compound, then given the above it is not unexpected that there is more in developing sink tissues such as young leaves, buds, and flowers.

The ^{14}C labeling data (Table 5) show that labeled antirrhide is found only in the lamina tissue, whereas labeled antirrhinoside is found both in the petiole and lamina tissue. These observations parallel those of two other species in the Scrophulariaceae, *A. scandens* (Gowan et al., 1995) and *A. barclaiana* (Voitsekhovskaja et al. 2006) where antirrhinoside is phloem mobile. In Table 5, the amount of label relative to that in sucrose (after Gowan et al., 1995) and to the total label recovered in the tissue at the end of 3 hr is given. This indicates that almost 15% of the total labeled carbon in the petiole is recovered in the antirrhinoside pool. In contrast, antirrhinoside represented 39% of the total carbon transported for the species for *A. barclaiana* (Voitsekhovskaja et al., 2006). Both our ^{14}C labeling experiment and the general pattern of distribution of antirrhide in the laminar tissue only, suggest that it is not phloem mobile. Our data, however, do not provide conclusive evidence that antirrhinoside is made only in the leaves and that this is the only iridoid glucoside translocated throughout the plant, as it is possible that antirrhinoside could have been synthesized in sink tissues from exported labeled sucrose.

At this time, it is not known with any certainty what the function of antirrhinoside is in *A. majus* and what, if any, relationship it may have with antirrhide. The high concentration of antirrhinoside in the growing sinks and its probable movement indicates that one of its roles may be as an osmoregulator that maintains water balance within the plant (Voitsekhovskaja et al., 2006). However, its concentration and distribution also suggests that it may be important in defense. The finding that in the oldest axillary leaves (fourth node) antirrhide can be present at up to three times the concentration of antirrhinoside indicates that it probably has a function within those tissues, but what that function is and why it is not translocated as antirrhinoside may be, is unclear.

Acknowledgments We thank Dr. Don Hughes of the Department of Chemistry, McMaster University, Hamilton, Ontario, Canada for obtaining the NMR spectra and George Lin for help in the laboratory. We also thank the following funding agencies: National Sciences and Engineering Research Council Canada, Flowers Canada (Ontario) Ltd. and Ontario Ministry of Agriculture, Food and Rural Affairs. This work was also supported by an Ontario Centers of Excellence ETech Cooperative Research Award held by R.R.C.

Abstract The floral scent composition of 32 European and two Asian *Salix* L. species (Salicaceae) was analyzed. Intra- and interspecific variation was compared for a subset of 8 species. All *Salix* species are dioecious and floral scent was collected from both male and female individuals by using a dynamic headspace MicroSPE method, and analyzed by GC-MS. A total of 48 compounds were detected, most of them being isoprenoids and benzenoids. Commonly occurring compounds included *trans*-β-ocimene, *cis*-β-ocimene, benzaldehyde, D-limonene, α-pinene, *cis*-3-hexenyl aceatate, linalool, 1,4-dimethoxybenzene, and β-pinene. Two compounds, 1,4-dimethoxybenzene and *trans*-β-ocimene, were responsible for most of the interspecific variation. In a subset of eight extensively sampled species, six had a characteristic floral scent composition; half of the pairwise species comparisons confirmed significant differences. In three of these eight species, intraspecific variability could be explained by sex differences. Variation in *Salix* floral scent may provide specific signals that guide pollinators and thus contribute to the reproductive isolation of compatible and cooccurring species.

Introduction

The genus *Salix* L., composed of approximately 400 to 500 species (Skvortsov, 1999), has an almost worldwide distribution, but occurs predominantly in temperate to arctic regions of the northern hemisphere. In Central Europe, about 40 species occur and many are sympatric.

From the taxonomic point of view, *Salix* is a problematic genus with difficulties delimiting many species because of high morphological variability (Argus, 1997; Skvortsov, 1999) and supposed widespread hybridization and introgression (Mosseler, 1990). There are several, in some parts dissentient, phylogenetic classifications of the genus available, all based on morphological characters (Dorn, 1976; Argus, 1997: American species; Skvortsov, 1999: Eurasian species). Because it is the most comprehensive for Eurasian species, the classification of Skvortsov (1999) is used here. Skvortsov (1999) divided *Salix* into three subgenera (Chamaetia, Salix, and Vetrix), each with several sections.

Normally, willow species are dioecious with flowers arranged in catkins. The plants show traits of insect as well as wind pollination. Stiff erect catkins and the availability of nectar fit with insect pollination, whereas small flower size, the absence of a perianth, and the predominant flowering early in spring before leaf unfolding, match with the wind pollination syndrome. Hence, the importance of either mode of pollination in *Salix* is controversial (Karrenberg et al., 2002). Nevertheless, most species are thought to be mainly entomogamous, though in certain species wind contributes to some degree to pollination (Argus, 1974; Sacchi and Price, 1988; Vroege and Stelleman, 1990; Totland and Sottocornola, 2001; Karrenberg et al., 2002). Flowers of both sexes are visited by a wide variety of insects, including Diptera (Vroege and Stelleman, 1990; Tollsten and Knudsen, 1992; Totland and Sottocornola, 2001), Hymenoptera (van der Werf et al., 1982; Vroege and Stelleman, 1990; Tollsten and Knudsen, 1992; Totland and Sottocornola, 2001), Lepidoptera (Vroege and Stelleman, 1990; Totland and Sottocornola, 2001), Coleoptera (Vroege and Stelleman, 1990), and occasionally birds (Kay, 1985). Flower-visiting animals are rewarded with easily accessible pollen and nectar (male flowers) or solely with nectar (female flowers). In most cases, it is not clear to what extent particular flower visitors contribute to effective pollination (van der Werf et al., 1982).

From hybridization experiments (Argus, 1974; Salick and Pfeffer, 1999; Palme et al., 2003) and analyses of natural populations (Mosseler and Papadopol, 1989; Mosseler and Zsuffa, 1989; Rechinger, 1992; Triest et al., 1999), it is clear that many willow species are able to hybridize. For example, more than 50 different hybrid combinations are known from the approximately 30 species that occur in Germany (see Rothmaler, 2002). However, how often hybridization occurs under natural conditions and what role introgressive hybridization plays (Dorn, 1976; Triest et al., 1997; Salick and Pfeffer, 1999; Totland and Sottocornola, 2001) is still a matter of discussion. Our understanding of the nature and efficiency of isolating mechanisms in sympatric compatible willow species, e.g., phenological differentiation (Argus, 1974; Dorn, 1976; Mosseler and Papadopol, 1989) or incongruity (Argus, 1974; Mosseler, 1989; Adler, 2000) is still incomplete. Floral scent is one trait that might function as a reproductive isolating mechanism in entomogamous species by guiding pollinating insects to specific species. However, there are few studies available that compare floral scent across several species within a genus to test this hypothesis. The only study in *Salix* that investigates floral scent variability within and among species was done by Tollsten and Knudsen (1992). They studied two sympatrically occurring, insect-pollinated species, *Salix caprea* and *Salix cinerea*, and both displayed relatively similar floral scent profiles. They concluded that floral scent does not promote reproductive isolation between these two species, resulting in the frequently observed hybridization.

In dioecious plants, such as *Salix* species, it is essential that pollen is transported from male to female flowers and that pollinators fly among them. Tollsten and Knudsen (1992) hypothesized that the floral scent of males and females should not differ within a species; otherwise, pollinators could learn to associate the scent of either gender with its rewards, resulting in preference for one sex. Indeed, they found no difference in scent between male and female flowers within either *S. caprea* or *S. cinerea*, suggesting that pollinating insects cannot discriminate among the sexes of these species.

In the present study, the floral scent of 34 willow species was analyzed by using a dynamic headspace MircoSPE method. The main objectives were to provide an overview of scent production in this interesting genus, with respect to its pollination biology, and to determine intrageneric, interspecific, and intraspecific variation. Based on our results, we discuss the potential of floral scent patterns as reproductive isolation barriers, and as cues for pollen collecting bees to discriminate between male and female individuals.

Methods and Materials

Plant Material Among the 34 species of *Salix* studied, 23 had been planted in the Ecological–Botanical Garden Bayreuth, Germany (EBG). Details on the geographic origin of these plants are listed in Table 1. All other species studied either grew wild in the EBG and/or at sites near Bayreuth. Thirty-two of the studied species are native to Europe; two occur naturally in Asia only (*Salix babylonica*, *Salix gracistyla*).

For 26 species, only a few individuals were available (Table 1), and floral scent could be collected only from one or two male and/or female specimens. For 8 species, several plants of both sexes were available and at least two male and three female specimens were sampled for variability among sexes within these eight species, and to compare intraspecific with interspecific variability. Five out of these eight extensively sampled species (*S. caprea*, *S. cinerea*, *Salix fragilis*, *Salix triandra*, and *Salix viminalis*) grow wild at sites near Bayreuth. Specimens of the other three species—*Salix bicolor*, *Salix myrsinifolia*, and *Salix repens*—have been planted at the EBG and have different geographical origins each (Table 1).

Volatile Collection Floral scent samples were collected from individuals in full bloom in the field from March to May 2005. Scent samples were taken during the day (10:00–17.00) by using a dynamic headspace method. For each individual plant, one twig with four to ten flowering catkins, depending on catkin size, was enclosed for 10 min in an oven bag (Nalophan). The emitted floral scent was subsequently trapped for 2.5 min in a microtube filled with absorbent (3 mg of a 1:1 mixture of Tenax-TA 60–80 and Carbotrap 20–40) by using a membrane pump (G12/01 EB, Rietschle Thomas, Puchheim, Germany). Airflow rate during volatile collection was 200 ml min^{-1}. After sampling, the microtubes were stored in a freezer (at −20°C) until analysis.

Gas Chromatography and Mass Spectrometry (GC–MS) The samples were analyzed on a Varian Saturn 3800 gas chromatograph (GC) fitted with a 1079 injector, and a Varian Saturn 2000 mass spectrometer (MS). A ZB-5 column (5% phenyl polysiloxane, length 60 m, inner diameter 0.25 μm, film thickness 0.25 μm, Phenomenex) was used for the analyses. Microtubes were inserted via Varians' Chromatoprobe into the GC injector. The injector vent was opened (1/20) and the injector heated at 40°C to flush any air from the system. After 2 min, the split vent was closed and the injector heated at 200°C min^{-1}, then held at 200°C for 4.2 min, after which the split vent was opened (1/20) and the injector cooled down.

Table 1 Species, systematic position (according to Skvortsov, 1999), number of samples from males (M) and females (F), location of sampled plants, and geographic origin (data as far as available) of willow plants studied

[a] The geographic origin is described with the shortcut of European countries and m declared the level above sea.

[b] EBG = individuals cultivated in the Ecological-Botanical Garden Bayreuth.

[c] Wild = growing wild in natural habitats.

Electronic flow control was used to maintain a constant helium carrier gas flow of 1.8 ml min^{-1}. The GC oven temperature was held for 7 min at 40°C, then increased by 6°C min^{-1} to 260°C, and held for 1 min at this temperature. Mass spectra were taken at 70 eV with a scanning speed of 1 scan/sec from *m*/*z* 30 to 350.

The GC-MS data were processed with the Saturn Software package 5.2.1. To identify floral scent components, GC-MS spectra were compared to, the NIST 02 and MassFinder 3 databases. Identifications were confirmed by comparison of retention times with published data (Adams, 1995). Identification of some compounds was also confirmed by comparison of mass spectra and retention times with those of authentic standards.

Statistics To determine (semi)-quantitative differences among single samples, we used chord-normalized expected species shared (CNESS) dissimilarity index, ranging between 0 and square root of 2. These semiquantitative comparisons were based on the percentage amount of components. Comparison of the absolute peak areas and the amounts were impractical because emission rate varied extensively both within and among species across individuals and flowering period. In cases where more individuals per species had been sampled, mean relative amounts per species were calculated. The CNESS index was calculated by using the updated version of the Combinatorial Polythetic Agglomeration Hierarchical Clustering (COMPAH) program (Boesch, 1977), provided by Gallagher at UMASS/Boston (http://www.es.umb.edu/edgwebp.htm).

Qualitative differences in floral scent (presence or absence of compounds) among samples were determined by using Sørensen's index of similarity (Sørensen, 1948). RELATE was used (program package Primer, version 5.2.9) to correlate and compare the CNESS with the Sørensen matrix (Kendall correlation coefficient).

We utilized nonmetric multidimensional scaling (NMDS) in the STATISTICA 7 package to identify meaningful dimensions and to visualize both similarities and dissimilarities among individual samples or different species (see Borg and Lingoes, 1987). A stress value is given to calculate how well the particular configuration produces the observed distance matrix. The smaller this value, the better is the fit of the configuration to the reproduced distance matrix (Clarke, 1993).

Analysis of similarities (ANOSIM, one-way design) in the program package Primer (version 5.2.9) was used to test for differences in floral scent among species of subgenera *Salix* and *Vetrix*, and within subgenus *Vetrix* among species of sections *Arbuscella* and *Vetrix*. We used these combinations because too few species were sampled in subgenus *Chamaetia* and the other sections making a statistical test less powerful.

Analysis of similarities (two-way crossed design; factors: species and sex) was further used to test for differences in floral scent among eight species (with five or six individuals sampled), and within these species between male and female individuals.

CNESS dissimilarity matrices were used for all ANOSIM analyses. This test calculates the test statistic R as well as a level of significance. R value ranges between 0 and 1 (−1) and can be interpreted as follows: 1 indicates complete separation of the sample groups (e.g., subgenera), and small values (close to zero) imply no segregation (Clarke and Warwick, 2001).

We used ANOVA as a global test and subsequently the Tukey–Kramer test as a *post hoc* test to compare the mean relative amount of the two most variable scent compounds between species. Normality was tested by using the Kolmogorov–Smirnov test and homogeneity of variances was tested with the Hartley test.

A variance component analysis in the STATISTICA 7 package was utilized to estimate the contribution of single floral scent compounds to the total observed variation (relative amount) between species.

Results

The compounds found in the floral scent samples of 93 willow plants from 34 species, are listed in Table 2. A total of 48 compounds were detected and 43 were identified. Dominant compound classes included isoprenoids and benzenoids, but fatty acid derivates and N-containing compounds were also present. The most commonly occurring compounds were *cis*-

and *trans*-β-ocimene (found in 33 and 34 species, respectively), D-limonene (31 species), benzaldehyde (31species), *cis*-3- hexenyl aceatate (28 species), linalool (25 species), 1,4-dimethoxybenzene (21 species), and α- and β-pinene (29 and 20 species, respectively). The number of compounds detected in each species ranged from a low of four in *Salix acutifolia*, and five in *S. silesiaca*, and *S. glauca* to a high of 29 in *S. myrsinifolia*. The scent profiles in all species were dominated by few components only. Dominant compounds reaching on average at least 50% of the total scent mixture within a species were *trans*-β-ocimene (in *S. viminalis*, *S. daphnoides*, *S. repens*, *S. triandra*, *S. apennina*, *S. bicolor*, *S. glabra*, *S. acutifolia*, *S. babylonica*, and *S. gracilistyla*) and 1,4-dimethoxybenzene (in *S. caprea*, *S. atrocinerea*, *S. aurita*, and *S. cinerea*).

Interspecific Variation Comparing the relative amounts of floral scent compounds among all species (by using a variance component analysis), seven compounds explained 94.7% of the total observed variation among the species. Two compounds, 1,4-dimethoxybenzene (35.9%) and *trans*-β-ocimene (32.5%), were responsible for most of the interspecific variation, followed by α-pinene (11.1%), *cis*-3-hexenyl acetate (9.2%), linalool (3.0), D-limonene (1.8%), and D-verbenone (1.2%).

Differences in floral scent composition (relative amounts) among 34 *Salix* species based on the CNESSm=1 index are shown in Fig. 1, using nonmetric multidimensional scaling (stress=0.19). In general, no clear separation of species groups was found. Most species

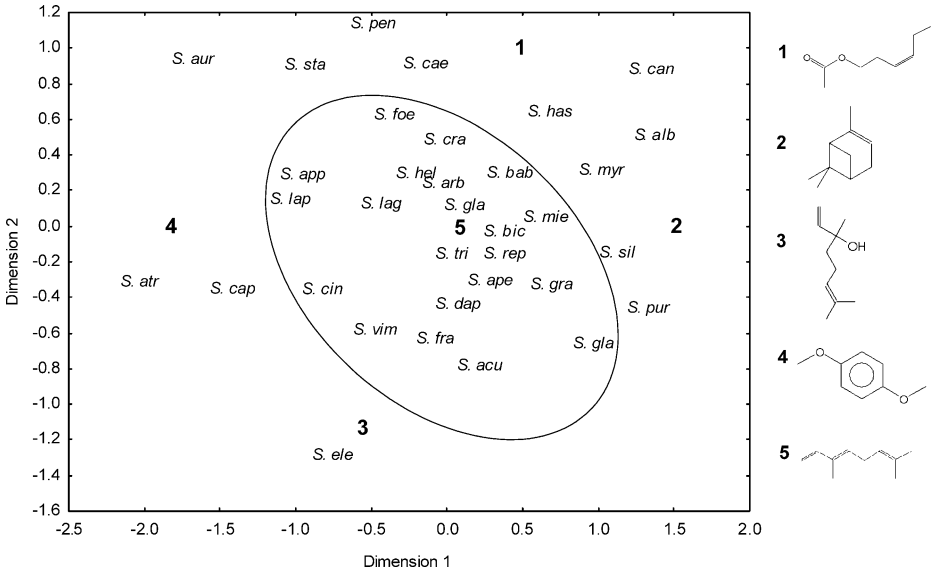

Fig. 1 Nonmetric multidimensional scaling (NMDS) of floral scent profiles of 34 *Salix* species based on the CNESSm=1 index (stress=0.19). The structures and names of the five main compounds: *1 cis*-3-hexenyl acetate, *2* α-pinene, *3* linalool, *4* 1,4-dimethoxybenzene, 5 *trans*-β-ocimene dominating the scent of different species are presented in the figure. The *circle* comprises species with more than 30% relative amount of *trans*-β-ocimene

were more or less evenly distributed, and clear separation of subgroups was hardly possible. Species in the center of the scatter plot were characterized by the emission of high relative amounts of *trans*-β-ocimene, while the amount of this monoterpene was lower in species at the margins. In *S. caprea*, *S. atrocinerea*, *S. aurita*, and *S. cinerea,* high amounts of 1,4-dimethoxybenzene were found. In other species (*S. mielichhoferi*, *S. myrsinifolia*, and *S. silesiaca*), high amounts of α-pinene (25–35%) were detected. High amounts of the green leaf volatile *cis*-3-hexenyl acetate (50–65%) were emitted by *S. starkeana* and *S. pentandra*, and the isoprenoid linalool occurred in large amounts (32%) in *S. eleagnos*.

When analyzing the data qualitatively by using the Sφrensen index, which considers similarity based on the presence or absence of single compounds for comparison and not their relative amount, the results were similar with most species being evenly distributed according to nonmetric multidimensional scaling (stress=0.17), indicating that categorization of species based on scent composition is hardly possible. The CNESS and Sørensen matrices were strongly correlated (RELATE Kendall: R=0.181; P<0.001), and the results of both analyses were generally consistent. Therefore, the NMDS representing the Sørensen matrix is not displayed here.

Analyses of floral scent composition of species from the two subgenera *Salix* (N=5) and *Vetrix* (N=28) revealed no differences between these subgenera (CNESS, ANOSIM: R=−0.035; P=0.66). However, within the *Vetrix* subgenus, significant differences between species of section *Arbuscella* (N=4) and *Vetrix* (N=8) were found (CNESS, ANOSIM: R=0.274; P<0.005). A variance component analysis revealed *cis*-3-hexenyl acetate and 1,4-dimethoxybenze as the main variable compounds between these two sections. A relatively high amount of *cis*-3-hexenyl acetate was found in section *Arbuscella* and 1,4-dimethoxybenze in section *Vetrix*.

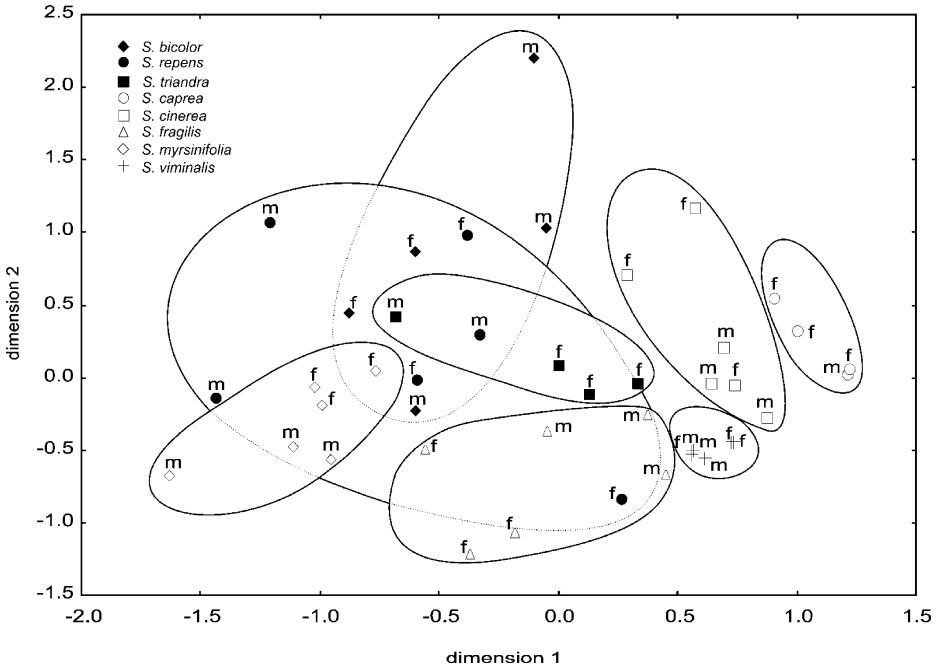

Fig. 2 Intraspecific comparison of floral scent between males (*m*) and females (*f*): nonmetric multidimensional scaling (NMDS) of eight *Salix* species based on the CNESSm=37 index (stress=0.18)

The variability of floral scent among and within the eight extensively sampled species is shown in Fig. 2. Variability within species (based on all samples from both sexes) was lower than variability among species (ANOSIM: R=0.598; P<0.001). When ignoring *S. bicolor* and *S. repens*, the two relatively variable species, the remaining six species had characteristic floral scent profiles, as revealed by grouping of individual samples of each taxon together in a NMDS analyses (Fig. 2). Out of 28 pairwise species combinations, 14 revealed significant differences (Table 3). As already shown in the overall comparison of 34 species, differences were mainly based on the variability of 1,4-dimethoxybenzene and *trans*-β-ocimene. These two compounds explained 84% of the observed total variability among this subset of eight

Table 3 Test statistics (R) of pairwise species comparison (ANOSIM)

S. bicolor	**0.728**	**0.709**	0.644	**0.745**	**0.781**	0.017	0.106	

[a] Bold values indicate significant differences between two species. All species are likely to grow sympatrically, except for the subalpine *S. bicolor*.

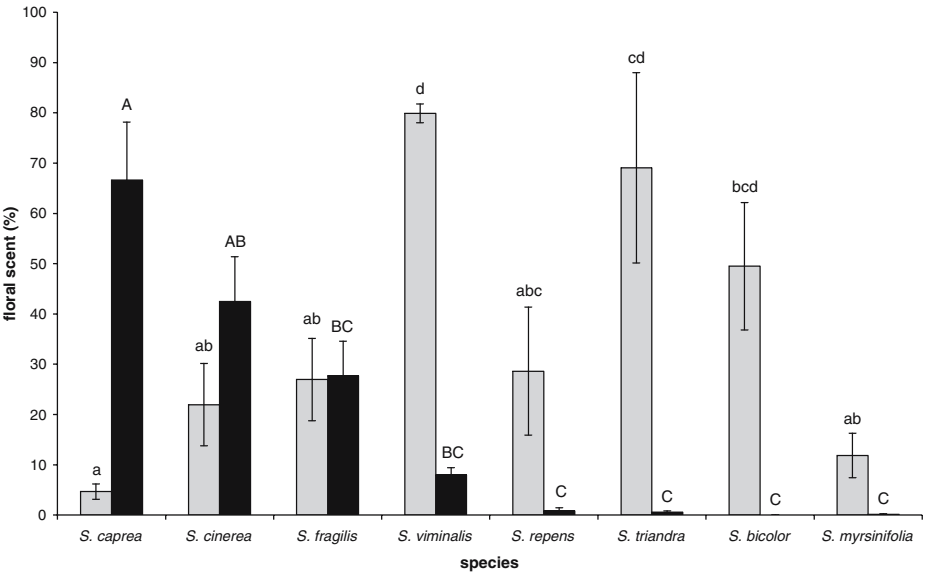

Fig. 3 Relative amount of 1,4-dimethoxybenzene (black) and *trans*-β-ocimene (*grey*) of the total floral scent in the most extensively sampled *Salix* species (ANOVA with Tukey–HSD test as post hoc procedure: $F_{df=7;55}=17.0$; $P<0.001$). *Different small letters* indicate significant interspecific differences in the amount of *trans*-β-ocimene and, *different capital letters* indicate significant interspecific differences in the amount of 1,4-dimethoxybenzene

species. For example, *S. caprea* and *S. cinerea* emitted much higher amounts of 1,4-dimethoxybenzene compared to *trans*-β-ocimene. Others, e.g., *S. viminalis*, *S. triandra*, and *S. bicolour*, were dominated by *trans*-β-ocimene (Fig. 3). *S. fragilis* was characterized by equally high amounts of 1,4-dimethoxybenzene and *trans*-β-ocimene. In *S. repens* and *S. myrsinifolia*, there was no clear predominance of a single compound; *trans*-β-ocimene content was below 30% and 1,4-dimethoxybenzene occurred only in traces.

Intraspecific Variation The variability within species in at least three out of eight species can be explained by sex differences (ANOSIM: $R=0.405$; $P<0.001$; Fig. 2). In *S. fragilis* ($N=6$), males emitted higher relative amounts of *trans*-β-ocimene and 1,4-dimethoxybenzene, whereas females contained more D-limonene and D-verbenone. In *S. myrsinifolia* ($N=6$), males emitted higher amounts of α-and β-pinene, while females emitted higher amounts of *cis*-3-hexen-1-ol, *cis*-3-hexenyl acetate, and *trans*-β-ocimene. In *S. triandra* ($N=5$), females emitted higher amount of *trans*-β-ocimene while males released more β-pinene, *cis*-3-hexenyl acetate, D-limonene, and linalool. In the remaining five species, intraspecific variation as shown in Fig. 2 cannot be explained by sex differences.

Discussion

Floral scent emission as found in *Salix* is typical for entomogamous species. Indeed, willows are visited during the day and also at night by many insect species, e.g., bees, flies, beetles, butterflies, and moths (Vroege and Stelleman, 1990; Tollsten and Knudsen, 1992;

Tollsten and Sottocoornola, 2001; Karrenberg et al., 2002), and floral scents are probably important attractants.

Many floral scent compounds identified in *Salix* species are typical floral odors (compare e.g., Knudsen et al., 2006) and several are effective attractants for different insects (see below). This supports that in most willow species, flower-visiting insects are probably attracted by floral scents and thereby promote pollination. However, some of the detected components have been described as typical green leaf volatiles (e.g., *cis*-3-hexen-1-ol, *cis*-3-hexenyl acetate, and (*E*)-4,8-dimethyl-1,3,7-nonatrien; Andersen et al., 1988; Whitman and Eller, 1990; Pare and Tumlinson, 1999; Ruther, 2000; Tholl et al., 2006) or have been found in leaves and/or other vegetative parts of different *Salix* species (Füssel et al., unpublished data). Green leave volatiles are likely to be produced in vegetative parts of the inflorescences, e.g., rhachis, flower bracts, and especially the leaves at the base of the catkins, which are, depending on species, more or less developed during flowering. Nevertheless, pollinators may detect, especially from long distances, the odor emitted from a whole plant and can use it as an olfactory cue to find their host plant and its flowers (e.g., Grison-Pigé et al., 2002). Therefore, in terms of pollinator attraction, we did not discriminate among compounds emitted by vegetative parts and by flowers, and refer to both as flower scent.

Compared with Tollsten and Knudsen (1992), who investigated floral scents in three species that we studied also—i.e., *Salix caprea*, *S. cinerea*, and *S. repens*, the results are similar considering both qualitative and quantitative aspects of scent composition. Tollsten and Knudsen (1992) identified 31 compounds, while we detected 34. Both studies found that *S. caprea* and *S. cinerea* are dominated by 1,4-dimethoxybenzene, while *S. repens* is dominated by a set of isoprenoids. However, despite these similarities, small differences exist. Tollsten and Knudsen (1992) identified four components (myrcene, 1,8-cineole, an oxygenated monoterpene, 2-phenyl ethyl methylether), which we did not detect. We identified α- and β-phellandrene, D-verbenone, and indole, which were not reported by Tollsten and Knudsen (1992). Surprisingly, we found one compound, benzaldehyde, in 31 of 34 species including *S. caprea*, *S. cinerea*, and *S. repens*, that was not reported by Tollsten and Knudsen (1992). However, all these differences concern only minor components of the total floral scent bouquet of a species. They might have been found in one study but not in the other because they fall below detection limits in some samples. In particular, benzaldehyde may be an artifact built by heating Tenax TA during desorbtion of the volatiles in the injector of the gas chromatograph (Peters et al., 1994). Several other factors also may be responsible for differences. First, different methods were used in the two studies (different adsorbents, thermodesorption vs. extraction of volatiles from filter using solvent). Second, Tollsten and Knudsen (1992) collected scent from cut twigs that were placed into water, whereas we collected scent from flowering twigs *in situ*. Some studies have shown differences in scent composition of flowers still attached to the living plant compared to that of flowers from cropped twigs (Mookherjee et al., 1990). Finally, geographic variability in floral scent of the three species could explain observed differences. Tollsten and Knudsen (1992) analyzed Swedish specimens growing wild while we analyzed specimens growing in southern Germany. Studies of other plant species document that that specimens originating from different populations emit differing relative amounts of compounds or even different compounds (e.g., Knudsen, 2002; Dötterl et al., 2005b; Svensson et al., 2005; Raguso et al., 2006).

Indeed, differing geographic origin might explain the intraspecific variability found in two of eight extensively sampled *Salix* species. The two species with samples originating from four or more origins (*S. repens* and *S. bicolor*), show a similarly high variability, while

the other six extensively sampled species originating from one or two origins are less variable. We cannot confirm Tollsten and Knudsen's (1992) finding that sex differences are responsible for the highly variable pattern of compounds in *S. repens* because plants studied in the Ecological–Botanical Garden of Bayreuth originated from five different geographic regions, thus masking possible sex differences within populations. *S. repens* is also morphologically a variable taxon, and floral scent might follow the same trend.

Relatively little is known about sex-specificity of floral scent in dioecious species. At least small differences in profiles between sexes have been found in some studies (e.g., Tollsten and Knudsen, 1992; Ashman et al., 2005). Ashman et al. (2005) reported that pollinators discriminated in gynodioecious *Fragaria* the scent of hermaphrodite flowers over those of females primarily because of the scent of hermaphrodite anthers. The anthers emitted high amounts of 2-phenylethanol, a benzoid compound found only in small amounts in female flowers. A comparison of the floral scent profiles of the three *Salix* species having significant sex differences with pollen scent profiles showed only differences in relative amounts, but no qualitative differences (U. Füssel et al., unpublished data) indicating that observed differences in scent between sexes cannot be explained by the emission of additional pollen-specific compounds in male flowers. Compared to male plants, which offer both pollen and nectar, female plants offer only nectar, and are, therefore, less attractive to insects collecting or eating pollen, such as beetles or bees (see also Ashman et al., 2005). Nevertheless, potential pollinators must be attracted to both male and female flowers for pollination to occur. The general view is that signals of male and female flowers have to correspond to promote successful pollen transfer. Consequently, it is usually assumed that flower visitors use similar cues to obtain rewards from female and male flowers (see reviews in Chittka and Thompson, 2001). This implies that insects seek similar rewards from both sexes. If this is not the case, e.g., when pollen is the desired reward (or females produce less or no nectar), nonrewarding female flowers are apparently pollinated by deceit due to their resemblance to rewarding male flowers (Baker, 1976). Contradictory to this intersexual mimicry hypothesis, the overall resemblance of male and female flowers in willows, especially with respect to visual cues, is low, and selection for resemblance of olfactory but not of visual cues seems to be unlikely, unless we assume that visual cues are of negligible importance for pollinator attraction. However, while nocturnal moths are probably more dependent on olfactory cues than day-active flower visitors, the situation might be completely different in day-active bees. For example, Galizia et al. (2004) found no evidence of olfactory mimicry in a (nectar) food-deceptive flower mimicry system. Their results indicate that in a bee-visited orchid evolutionary pressure acts on visual, but not olfactory traits toward a higher similarity to its model. Odor mismatch did not prevent bees from landing on flowers that had the expected visual display.

An alternative hypothesis, the specialized female reward hypothesis offered by Hemborg and Bond (2005) challenges the idea that pollinators search for the same reward in all conspecific flowers. According to Hemborg and Bond, males and females both offer essential, but different, components to the pollinators, and these sex-specific rewards may be advertised by sexually dimorphic floral signals. Kay (1985) and Elmqvist et al. (1988) found that female *Salix* flowers produce more nectar than male flowers, and Katoh et al. (1985) reported that females tend to have hexose dominated nectar in contrast to sucrose dominated nectar in males. Our own observations (Füssel et al., unpublished data) support these findings. Moreover, in case of the pollen specific bee *Andrena vaga*, it is known that females mainly collect pollen (and nectar) on some days, and on other days they feed on and/or collect only nectar from *Salix* (see Bischoff et al., 2003). Bees could use differences in scent of sex morphs to distinguish sexes, and to visit primarily/exclusively females when

focusing on nectar, and males when focusing on pollen. Additionally, nectar-seeking flower visitors in general could choose their preferred nectar source from the two sexes, thus fulfilling their actual needs. However, studies of specialization of female nectar rewards in entomogamous willows are scarce, and bioassays that prove if and how flower visitors differentiate between male and female attractants are lacking. Furthermore, pollen carry over only during occasional behavioral switches might be insufficient to ensure pollination. Therefore, from the plant point of view, similarity between the sexes is probably desirable to prevent pollinators from discriminating between male and female plants and to promote frequent cross-pollination.

It is interesting to note that *S. repens*, which emits a weak (Tollsten and Knudsen, 1992) and highly variable (Tollsten and Knudsen, 1992; present study) scent in comparison to other *Salix* species, seems to be primarily wind-pollinated (Vroege and Stelleman, 1990). Thus, the selective pressure to display a consistent pollinator-type specific floral scent profile across populations, sexes, and individuals might be lower, compared to species that are strongly dependent on insect pollination. Only in predominantly entomophilous species can distinct species-specific scent profiles promote flower constancy thus avoiding pollen waste, and functioning as reproductive isolation barriers between species.

On one hand, plants from quite different systematic positions have evolved the same pollination system involving the emission of similar floral scent spectra (e.g., Knudsen and Tollsten, 1993; Andersson et al., 2002). On the other, closely related plant species may have evolved quite different floral scent profiles that function as reproductive isolation barriers (e.g., Mant et al., 2005). If floral scent is to act as a willow specific attractant, pollinators must be able to perceive willow-specific floral scent compounds. If floral scent is to function as a reproductive isolation mechanism among willows, a second assumption has to be fulfilled: species must emit species-specific scents that pollinators may use to discriminate.

Dötterl et al. (2005a) demonstrated that floral scent compounds of *Salix* can act as cues for the attraction of oligolectic bees that collect pollen for their larvae exclusively on willows. *A. vaga* Pz. (Andrenidae) responded in GC-EAD tests to 1,4-dimethoxybenzene and other willow compounds; 1,4-dimethoxybenzene, in particular, attracted female bees in bioassays. Also many other *Salix*-visiting bee taxa respond strongly in GC-EAD tests to 1,4-dimethoxybenzene (Füssel et al., personal observation). It might be that 1,4-dimethoxybenzene, one of the two most common floral volatiles in willows, is the specific cue that provokes the flower constancy in these bees. It would be interesting to test whether *A. vaga* prefers 1,4-dimethoxybenzene dominated willow species over *trans*-β-ocimene dominated species.

Several other compounds found in this study are known to be attractive also to different insects or are at least active in electrophysiological studies. Beetles can be attracted by 1,4-dimethoxybenzene (Ventura et al., 2000); phenylacetaldehyde is attractive to flies (Howse, 2003), butterflies (Honda et al., 1998; Omura et al., 1999; Andersson, 2003), and moths (Haynes et al., 1991; Cunningham et al., 2004); and lilac aldehydes are known to be detected by butterflies (Andersson, 2003) and to be highly attractive to noctuid moth species (Dötterl et al., 2006). Besides *Andrena vaga* (Dötterl et al., 2005a), many other *Salix*-visiting bee taxa respond strongly in GC-EAD tests to 1,4-dimethoxybenzene and other typical willow volatiles (Füssel et al., personal observation.). Moreover, different willow-visiting moth species (e.g., *Orthosia* spp.) respond strongly in GC-EAD tests to several of the volatile compounds found in *Salix* (such as benzyl nitrile, lilac aldehyde A, and 4-oxoisopherone). It can be hypothesized that, besides 1,4-dimethoxybenzene and *trans*-β-ocimene that mainly distinguish species, several other flower scent compounds that are frequently found in *Salix* species may be effective specific attractants of potential pollinators. It is likely that they also

provide species-specific signals that serve as reproductive isolation barriers. In a subset of eight extensively sampled species, we showed a characteristic floral scent composition for six species, and half of the pairwise species comparisons confirmed significant differences. The observed differences are mainly based on the variability of only two compounds—1,4-dimethoxybenzene and *trans*-β-ocimene that together explain 84% of variability among these eight species. Of special interest are compatible species that grow sympatrically in the same habitats. According to Lautenschlager-Fleury and Lautenschlager-Fleury (1994) and Rothmaler (2002), this is the case for seven of the eight; only the subalpine *S. bicolor* is unlikely to cooccur with any of the other species. Nevertheless, even though these willows show significantly different scent profiles, natural hybrids are observed between most (see Rothmaler, 2002); even the subalpine *S. bicolor* is known to hybridize naturally with *S. caprea* and *S. myrsinifolia*.

Our results confirm those of Tollsten and Knudsen (1992) who found no significant differences between *S. caprea* and *S. cinerea*. However, their hypothesis that this high similarity in scent is responsible for frequently occurring hybridization between these species is not supported by our data on six other extensively sampled species. It seems that neither different scent profiles hamper hybridization, nor that similar scent profiles imply a higher risk of hybridization. However, because quantitative data on hybridization events between species pairs are lacking, this hypothesis needs further investigation.

Acknowledgements Parts of the study were supported by the German Research Foundation (Research Training Group 678). The authors thank F. Beyer and I. Schäffler for floral scent collection, and A. Lieflaender, A. Reuter, M. Suckling, T. Witt, and two anonymous reviewers for valuable comments on the manuscript.

Abstract *Diaeretiella rapae*, a parasitoid that predominately specializes in the parasitism of *Brassica*-feeding aphids, attacks *Lipaphis erysimi*, a specialist feeding aphid of the Brassicaceae and other families in the Capparales, at a greater rate than the generalist-feeding aphid, *Myzus persicae*. In this study, we investigated the orientation behavior of *D. rapae* to the volatile chemicals produced when these two aphid species feed on turnip (*Brassica rapa* var *rapifera*). We showed no significant preference orientation behavior to either aphid/turnip complex over the other. Isothiocyanates are among the compounds emitted by plants of the Brassicaceae in response to insect feeding damage, including by aphids. We assessed parasitoid orientation behavior in response to laboratory-formulated isothiocyanates. We tested two formulations and discovered significant orientation toward 3-butenyl isothiocyanate. We also assessed plant and aphid glucosinolate content, and showed large levels of glucosinolate concentration in *L. erysimi*, whereas there was little change in plant content in response to aphid feeding. Our results suggest that during the process of host location, similar cues may be utilized for locating *L. erysimi* and *M. persicae*, whereas the acceptance of hosts and their suitability may involve aspects of nonvolatile aphid chemistry.

Introduction

For insect parasitoids to reproduce they need to find suitable hosts. They must be efficient at using cues that indicate the presence of their hosts, and upon finding a potential host they must accurately assess its suitability. Vinson (1976, 1985) described successful host foraging behavior by insect parasitoids as a succession of five steps; host-habitat location, host location, host acceptance, host suitability, and host regulation. During the first three stages, collectively termed host selection, a range of volatile chemical species provide olfactory cues. These chemicals may be derived from host plants, hosts, or a complex of the two, which have been shown to be more attractive to foraging parasitoids or predators than the individual components of the system (see reviews by Dicke et al., 1990; Vet and Dicke, 1992; Vinson, 1999; and specifically for aphids Guerrieri et al., 1993, 1997; Reed et al., 1995; Du et al., 1996, 1997, 1998; Micha et al., 2000; Havill and Raffa, 2000).

Diaeretiella rapae is a braconid that predominately specializes in the parasitism of aphids feeding on the order Capparales, especially the Brassicaceae. *Diaeretiella rapae* attacks *Lipaphis erysimi*, a specialist feeder on the Capparales, at a greater rate than the generalist-feeding aphid *Myzus persicae* (Blande et al., 2004). This behavior is linked to cues detected by parasitoids upon emergence from their mummy cases, possibly glucosinolates that are characteristic, but not limited to the Brassicaceae. *D. rapae* would gain an advantage if they had the ability to orient toward the odor of a *L. erysimi*/brassica complex over that of a *M. persicae*/brassica complex.

In Brassicaceous plants, cell damage facilitates the hydrolysis of glucosinolates by myrosinase enzymes to produce a range of volatile catabolites that include nitriles and isothiocyanates (reviewed by Bones and Rossiter, 2006). After myrosinase catalyzed hydrolysis, the presence of epithiospecifier protein (ESP) generates the production of nitriles and epithionitriles from alkyl and alkenyl glucosinolates, respectively, whereas isothiocyanates are produced from any glucosinolate when ESP is absent (Kliebenstein et al., 2005). Isothiocyanates are thought to be important plant defense compounds that may provide parasitoids with cues that can be utilized in the host foraging process (Reed et al., 1995; Vaughn et al., 1996; Bradburne and Mithen, 2000). Preliminary analysis of the isothiocyanates produced by turnip indicated that infestation by both *L. erysimi* and *M. persicae* is responsible for elevating emissions of 3-butenyl isothiocyanate and 4-pentenyl isothiocyanate (Blande, 2004).

We hypothesized that differences in the strategies of the two aphid species would result in differences in the volatile profiles emitted by the plants, and that foraging *D. rapae* would preferentially orient toward the *L. erysimi*/turnip complex over the *M. persicae*/turnip complex. To explore the foraging behavior of *D. rapae* we utilized a Y-tube olfactometer and conducted a series of choice tests with naïve parasitoids and individuals that had previously experienced a plant/aphid complex. We also looked at the responses of aphid parasitoids to pure laboratory formulations of isothiocyanates.

In addition to the orientation behavior of *D. rapae*, we investigated the nonvolatile glucosinolate chemistry of the plants and aphids in the system. Previous analyses have been conducted on turnip, *Brassica rapa* var *rapifera* (Carlson et al., 1981, 1987). Other studies have documented evidence of glucosinolate accumulation in several insect species that specialize at feeding on the Brassicaceae (Aplin et al., 1975; Weber et al., 1986; Müller et al., 2001; Bridges et al., 2002).

The brassica-specializing aphids *Brevicoryne brassicae* and *L. erysimi* are further adapted to feeding on the Brassicaceae by producing their own myrosinase (MacGibbon and Allison, 1970; MacGibbon and Beuzenberg, 1978; Jones et al., 2001), which can

hydrolyze sequestered glucosinolates that act synergistically with (*E*)-β-farnesene in an alarm system (Dawson et al., 1987; Jones et al., 2001; Bridges et al., 2002; Husebye et al., 2005). This myrosinase is localized to the muscle tissue of the head and thorax in *B. brassicae*, and is also present in *L. erysimi*. It has been categorized down to its X-ray structure (Husebye et al., 2005). We hypothesized that like the better categorized specialist *B. brassicae* (Bridges et al., 2002), *L. erysimi* would accumulate glucosinolates that can be used in defense whereas the generalist-feeding *M. persicae* would pass glucosinolates through the gut (Weber et al., 1986; Cole, 1996). We also hypothesized that the glucosinolate content of the plants could be differentially affected by aphid feeding because of variable plant defense responses. We addressed this by analysis of desulfoglucosinolates in the plant and aphid tissue.

Methods and Materials

Parasitoid Rearing and Standardization of Insects *Diaeretiella rapae* (McIntosh) from stocks at Rothamsted Research reared on *Myzus persicae* on Chinese cabbage were established as separate cultures on *M. persicae* and *L. erysimi*, both on turnip. The original stocks were started in 1990, and were supplemented in 1995 with 30 females and 20 males collected from oilseed rape.

Some experiments utilized "naïve" female parasitoids that had no adult experience of aphids or plant material besides that received from the surface of the mummy case during and after emergence (Poppy et al., 1997). All experimental parasitoids were removed from turnip plants as mummified aphids with watchmaker forceps and stored in darkened plastic containers attached to glass jars. Newly emerged adult parasitoids congregated in the jars as they displayed positive phototaxis. At 24-hr intervals, the glass jars containing parasitoids were removed and screwed onto a lid supporting a cotton wool ball soaked with 25% honey solution. At the same time, a clean jar was affixed to the plastic container. Parasitoids collected in the glass jars were left for 3 d so that all experimental insects were standardized mated females, with no adult experience of aphids or plants (Du et al., 1996, 1997, 1998). Before experiments, parasitoids were sexed and separated into glass vials with honey solution provided on tissue paper twists. All experiments were conducted at 21°C under a laminar light source, with a light intensity of 115 μmol s^{-1} m^{-2} measured at bench level.

Preparation of Plants Turnip plants, *B. rapa* var *rapifera* cv Tokyo Cross, were cultivated in glasshouses at Rothamsted Research, Harpenden, U.K. Before they were used as odor cues, plants aged 4 wk were removed from glasshouses and transferred to controlled environment rooms with a photoperiod of 16 light/8 dark; plants were infested with *L. erysimi* (Kaltenbach), *M. persicae* (Sulzer), or left uninfested. Individual plants were infested with approximately 500 aphids of mixed instars. All plants were left for 5 d before use as odor sources in Y-tube bioassays.

Y-tube Experiments A Y-tube olfactometer, described in detail in Du et al. (1996, 1997), was used to compare the orientation behavior of *D. rapae* to different odors. Air was pumped by a Capex L2× pump (Charles Austen Pumps Ltd., Byfleet, Surrey, UK) through an activated charcoal filter, and was subsequently limited by a flowmeter to 800 ml/min, then split by a brass T-junction fitting (Swagelock, OH, USA), and passed into two airtight glass chambers (Soham Scientific) that contained the test odor sources. Flow meters were used to adjust the airflow from the chambers to 400 ml/min, which was then channeled into

the two short ends of a glass Y-tube olfactometer (diam. 1 cm) (Soham Scientific). Teflon tubing (diam 1 mm) was used to channel air through the system. This tubing was affixed to the ends of the Y-tube with rubber bungs. Individual female parasitoids in glass vials were released into the Y-tube by placing the vials next to the opening of the tube. Parasitoid behavior was observed, and the arms of the olfactometer selected by the parasitoids were recorded. In all experiments, an odor selection was recorded when a parasitoid advanced further than halfway along a Y-tube arm, touched the rubber bung at the end of the arm, and remained in that half of the Y-tube arm for 15 sec. Between bioassay sets, the glass vessels and Y-tubes were washed in soapy water and rinsed with bulk acetone and glass distilled water. Charcoal filters were baked overnight at 180°C with a constant nitrogen stream passed through them.

Experiment 1: Response of Naïve D. rapae to Plants and Plant/Host Complexes Naïve female *D. rapae*, reared on both *L. erysimi* and *M. persicae*, were used in these bioassays to compare responses to odors of different plant/host complexes. Plant/host complexes (turnip/*L. erysimi* and turnip/*M. persicae*) were used in bioassays vs. blanks, which consisted of distilled water on filter paper (Whatman no. 1) to reduce differences in humidity of the air entering each arm of the Y-tube and clean undamaged plants. The plant/host complexes were also bioassayed opposite each other.

Experiment 2: Effect of Adult Associative Learning Experience on Parasitoid Response to Odors Diaeretiella rapae reared on both *L. erysimi* and *M. persicae* were used in these bioassays. Parasitoids reared and treated in the same way as naïve parasitoids were provided with a postemergence experience. This was implemented by releasing parasitoids into a cage that contained a turnip plant infested with 500 aphids 5 d previously, exactly the same treatment given to plants used as odor sources in the subsequent bioassays. Each experience period lasted for approximately 3 min, and all parasitoids utilized in bioassays were observed to have made an ovipositional attack. After 3 min, the parasitoids were collected by using an electric pooter, and then separated into glass vials containing honey solution on tissue paper twists and left for approximately 2–3 hr before they were used in bioassays (Du et al., 1996, 1997). The plant/host complexes used in the bioassays were *L. erysimi* on turnip and *M. persicae* on turnip. These complexes were bioassayed opposite clean turnips and each other.

Experiment 3: Responses of D. rapae to Synthetic Isothiocyanates 3-Butenyl isothiocyanate and 4-pentenyl isothiocyanate were synthesized at Rothamsted Research (Dawson et al., 1993). The isothiocyanates were of greater than 97% purity and made to a concentration of 1 mg/ml in redistilled ether. Isothiocyanate solution was applied to Whatman no. 1 filter paper in 50 µl volumes with a Gilson pipette. Isothiocyanates were bioassayed opposite blanks, which consisted of 50 µl of redistilled ether on filter paper, and in opposition with each other. Naïve female *D. rapae* reared on *L. erysimi* and *M. persicae* were utilized in the bioassays.

Statistical Analysis Data collected from all behavioral bioassays were analyzed by using chi-square tests, which were adjusted for data containing just two categories by using Yates' correction. Parasitoids not making a selection were removed from the data set used in the chi-squared analysis. At least 50 parasitoids were tested for each bioassay combination.

Plant Preparation for Glucosinolate Analysis Turnip plants aged 30 d were infested with 250 aphids of mixed instars, three plants with *M. persicae*, and three with *L. erysimi*. Three

plants were not infested. All plants were kept at 18°C for 5 d before preparation for glucosinolate analysis. Four leaves were incised from the whorl within the outer two leaves of the now 35-d-old turnip plants. Aphids were removed by washing with distilled water, and leaves from the noninfested control plants were also washed. Leaves were shaken dry and wrapped in tin foil. Leaves from each plant were separately wrapped and placed in a freeze drier for 72 hr before being ground into a fine powder with a pestle and mortar and packaged into plastic tubes (Bibby Sterilin Ltd., Staffordshire, UK).

Aphid Preparation for Glucosinolate Analysis Aphids were removed from two plants heavily infested with *M. persicae* and two heavily infested with *L. erysimi*. A fine paintbrush was used to transfer the aphids from the plants into plastic tubes. Thousands of aphids were required to provide sufficient material for analysis. Tubes were sealed with gauze, which was fastened to the top of the tubes with elastic bands, and then freeze dried for 48 hr. Aphids were ground into a fine powder with a pestle and mortar and packaged into plastic tubes.

The glucosinolate content of the prepared plant and aphid samples was qualitatively and quantitatively analyzed by J. Marquez (School of Biosciences, University of Nottingham). The procedure used involved processing the material to produce desulfoglucosinolates, which were then separated and quantified by using high-performance liquid chromatography (HPLC) with sinigrin as an internal standard; the methods are described in detail in Magrath et al., (1993).

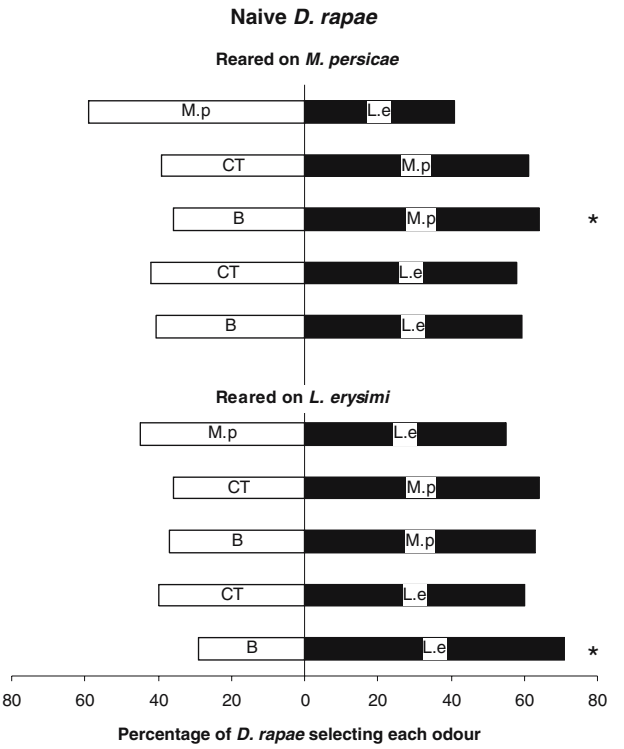

Fig. 1 Response of naïve female *D. rapae* in a Y-tube olfactometer when offered *M. persicae*-infested turnip (M.p), *L. erysimi*-infested turnip (L.e), clean turnip (CT), and distilled water blanks (B). *Diaeretiella rapae* were reared on either *M. persicae* or *L. erysimi*, as indicated. Asterisk indicates a significant difference ($P<0.05$; $N\geq50$)

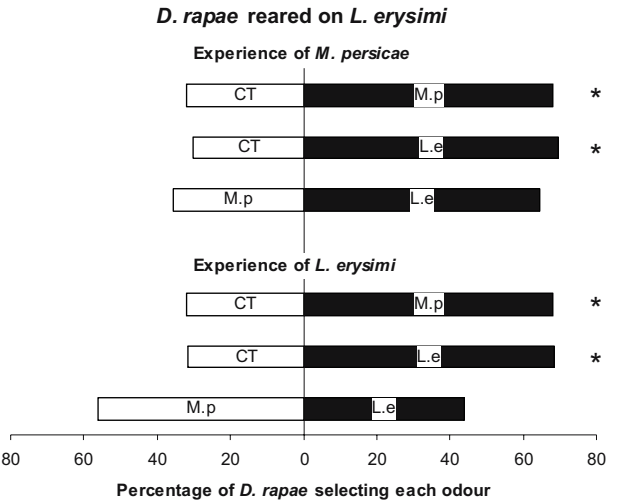

Fig. 2 Response of experienced female *D. rapae* in a Y-tube olfactometer when offered *M. persicae*-infested turnip (M.p), *L. erysimi*-infested turnip (L.e), or clean turnip (CT). *Diaeretiella rapae* were reared on *L. erysimi* and exposed to either *M. persicae*- or *L. erysimi*-infested turnip to provide an experience. Asterisk indicates a significant difference ($P<0.05$; $N\geq50$)

Results

Responses of Naïve D. rapae to Turnip Plants and Turnip/Aphid Complexes Naïve *D. rapae* reared on *M. persicae* made significantly more selections of a Y-tube arm leading toward a *M. persicae*-infested turnip plant than a blank ($P<0.05$), but other bioassays revealed no significant differences in the response to the odors presented (Fig. 1). *Diaeretiella rapae* reared on *L. erysimi* selected *L. erysimi*-infested turnip significantly more often than blanks ($P<0.05$). There were no other significant odor selections (Fig. 1).

Effect of Postemergence Experience on Parasitoid Response to Odors Diaeretiella rapae parasitoids reared on both *L. erysimi* and *M. persicae* were given postemergence experience of either the host/plant complex or the alternative host/plant complex. The host/plant complex is exactly the same system upon which the parasitoids were reared. Experience of

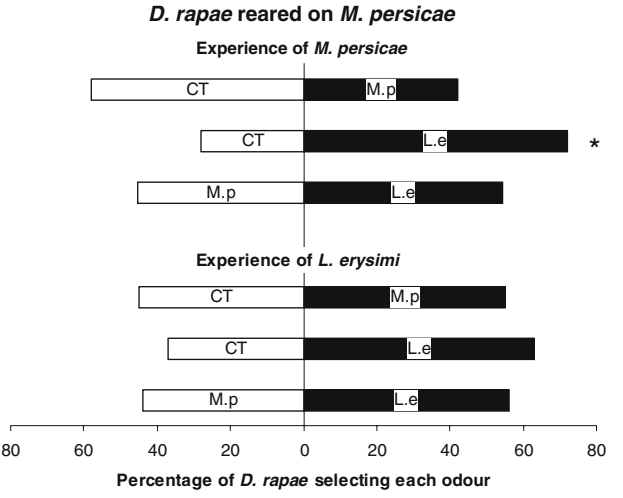

Fig. 3 Response of experienced female *D. rapae* in a Y-tube olfactometer when offered *M. persicae*-infested turnip (M.p), *L. erysimi*-infested turnip (L.e), or clean turnip (CT). *Diaeretiella rapae* were reared on *M. persicae* and exposed to either *M. persicae*- or *L. erysimi*-infested turnip to provide an experience. Asterisk indicates a significant difference ($P<0.05$; $N\geq50$)

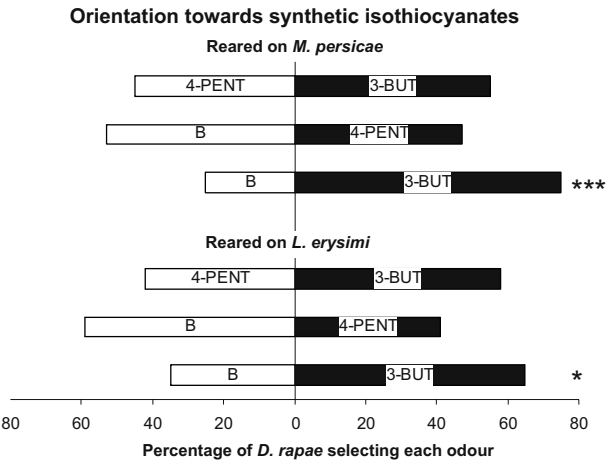

Fig. 4 Response of naïve female *D. rapae* in a Y-tube olfactometer when offered 4-pentenyl isothiocyanate, 3-butenyl isothiocyanate, or redistilled ether blanks (B). *Diaeretiella rapae* were reared on either *M. persicae* or *L. erysimi*, as indicated. Single asterisk indicates a significant difference ($P<0.05$); triple asterisks indicate a significant difference ($P<0.001$; $N\geq50$)

this system is referred to as a "home" experience. An experience of the alternative host/plant complex that is the same plant that the parasitoids were reared on but an alternative aphid species is referred to as an "away" experience. *Diaeretiella rapae* reared on *L. erysimi* selected the odor of both home and away complexes on a significantly greater number of occasions than that of clean plants ($P<0.05$), irrespective of the complex experienced (Fig. 2). *Diaeretiella rapae* reared on *M. persicae* given a home experience showed a significant attraction to the away complex ($P<0.05$), but there was no other significant attraction displayed (Fig. 3).

D. rapae Response to Synthetic Isothiocyanates Naïve female *D. rapae* significantly oriented toward 3-butenyl isothiocyanate when bioassayed opposite a blank consisting of an equal volume of ether, irrespective of whether they were reared on *M. persicae* ($P<0.001$) or *L. erysimi* ($P<0.05$). There was no significant attraction to 4-pentenyl isothiocyanate. When the two isothiocyanates were in competition with each other, there was no significant attraction to either (Fig. 4).

Table 1 Glucosinolate composition of turnip plants infested with *M. persicae* or *L. erysimi*, and the glucosinolate composition of the aphids

Glucosinolates	Le Turnip (%)	Mp Turnip (%)	Cl Turnip (%)	Le aphids (%)	Mp aphids (%)
3-Butenylglucosinolate	7.8±1.5 (73.7)	6.3±1.83 (76.1)	6.4±1.29 (72.6)	4.02 (37.1)	0.29 (65.9)
Hydroxyindolylmethylglucosinolate	0±0 (0)	0±0 (0)	0±0 (0)	0.15 (1.39)	0 (0)
4-Pentenylglucosinolate	2.2±0.31 (20.9)	1.7±0.52 (20.5)	2.0±0.5 (22.7)	1.27 (11.7)	0.06 (13.6)
Indolylmethylglucosinolate	0.16±0.08 (1.5)	0.06±0.017 (0.72)	0.07±0.02 (0.79)	4.12 (38.1)	0.07 (15.9)
4-Methoxyindolylmethylglucosinolate	0.10±0.003 (0.95)	0.09±0.059 (1.1)	0.08±0.0089 (0.91)	0.41 (3.79)	0 (0)
2-Phenylethylglucosinolate	0.25±0.06 (2.4)	0.12±0.035 (1.45)	0.21±0.074 (2.38)	0.81 (7.5)	0 (0)
1-Methoxyindolylmethylglucosinolate	0.08±0.01 (0.76)	0.06±0.017 (0.72)	0.09±0.022 (1.02)	0.05 (0.46)	0.01 (2.27)
Total	10.5±2.08 (100)	8.3±2.44 (100)	8.8±1.85 (100)	10.82 (100)	0.44 (100)

The mean±SE quantities of the glucosinolates present in turnip leaf tissue ($N=3$) and aphids ($N=1$) are in micromoles per gram dry weight. Values in parentheses indicate the percentage of the total glucosinolate content represented by each individual component.

Le = *L. erysimi*, Mp = *M. persicae*, Cl = clean

Glucosinolate Analysis Analyses were conducted on clean turnip plants and plants that had been infested with *M. persicae* or *L. erysimi*. Six different glucosinolates were analyzed and were present in all the samples. These were the aliphatic glucosinolates, gluconapin (3-butenylglucosinolate) and glucobrassicanapin (4-pentenylglucosinolate), the simple aromatic gluconasturtin (2-phenylethylglucosinolate), and the indolylglucosinolates, glucobrassicin (indolylmethylglucosinolate), neoglucobrassicin (1-methoxyindolylmethylglucosinolate), and 4-methoxyglucobrassicin (4-methoxyindolylmethylglucosinolate).

The mean total glucosinolate content was greatest in *L. erysimi*-infested turnip, and lowest in *M. persicae* infested turnip, although the differences between the three treatments were small, and variation among plants receiving the same treatment was great. 3-Butenylglucosinolate was present in the greatest quantity, followed by 4-pentenylglucosinolate (Table 1).

Analysis of the glucosinolates present in the tissue of freeze-dried *L. erysimi* and *M. persicae* revealed large differences. *Lipaphis erysimi* contained large quantities of all the plant glucosinolates (3-butenylglucosinolate, 4-pentenylglucosinolate, 2-phenylethylglucosinolate, indolylmethylglucosinolate, 1-methoxyindolylmethylglucosinolate, and 4-methoxyindolylmethylglucosinolate) with the inclusion of hydroxyindolylmethylglucosinolate. *Myzus persicae* contained traces of 3-butenylglucosinolate, 4-pentenylglucosinolate, indolylmethylglucosinolate, and 1-methoxyindolylmethylglucosinolate, but 4-methoxyindolylmethylglucosinolate, 2-phenylethylglucosinolate, and hydroxyindolylmethylglucosinolate were absent, or in traces too small for detection by HPLC (Table 1).

Discussion

Naïve *D. rapae* tended to orient toward both home and away aphid/turnip complexes in preference to the clean turnip plants or blanks. This was irrespective of the original host aphid species. These results complement previous studies that showed orientation of aphid parasitoids to plant/aphid complexes (Read et al., 1970; Reed et al., 1995; Vaughn et al., 1996; Powell et al., 1998). However, the only statistically significant orientations were toward the home complex opposed to a blank, and this was the same irrespective of the original host. Parasitoids did not orient toward one complex over the other.

The environment in which parasitoids develop has been shown to influence adult response to volatile chemicals (Sheehan and Shelton, 1989; van Emden et al., 2002), and emergence from mummy cases provides parasitoids with an experience that can prime behavioral responses (van Emden et al., 1996; Storeck et al., 2000). It was expected that naïve *D. rapae* would orient toward aphid-infested turnip plants in preference to clean plants. However, further experiences of aphid/plant complexes postemergence also influence behavior. Providing parasitoids with a positive experience that is associated with an odor can facilitate the effective use of volatile chemicals by parasitoids, or enhance their ability to respond to these odors, thus increasing foraging efficiency (Godfray and Waage, 1988; Vet and Groenewold, 1990; Micha et al., 2000; Mölck et al., 1999, 2000; Grasswitz and Paine, 1993).

The provision of *D. rapae* with an experience of an aphid/turnip complex appeared to heighten their ability to orient toward an aphid/turnip complex. This was particularly clear when the parasitoids had been reared on *L. erysimi*. However, there was still no difference in orientation to one complex in preference to the other. Our results conflicted with our hypothesis, which was based on attack rates (Blande, 2004), indicating that *D. rapae* would orient preferentially toward the odor of the *L. erysimi*/turnip complex. Previous studies by Du et al. (1996, 1997, 1998) on a broad bean (*Vicia faba*) system showed that *Aphidius ervi* parasitoids were able to orient toward the odor of their host/plant complex at a greater frequency

than to a nonhost/same plant complex. This indicates a specificity of the volatile signals emitted by plants in response to damage by different aphid species. However, it appears that *D. rapae*, irrespective of their original host or experience, are either incapable of distinguishing between the odors of the two complexes, or else do not have a preference for either of the odor options.

Earlier studies have suggested that feeding by different aphid species can elicit the emission of variable volatile blends because of differences in their saliva (Du et al., 1998; Guerrieri et al., 1999). Oral secretions from the Lepidoptera alter the volatile composition of corn seedlings, resulting in odors that parasitoids can distinguish as different from those produced by physical damage alone (Turlings et al., 1990). However, preliminary work in our system (Blande, 2004) indicated only quantitative differences between the volatile isothiocyanates produced by turnip infested by *M. persicae* and *L. erysimi*. It would be interesting to analyze the different gene transcriptional activity during feeding by these two species.

The volatile chemistries of the complexes did not appear differentially attractive when presented in a choice scenario. Previous work by Du et al. (1996), showed clear orientation toward a host/plant complex in preference to a nonhost/plant complex, but in this study, both aphid species used were suitable hosts for *D. rapae*. Foraging parasitoids would benefit from the ability to orient toward the volatiles emitted by either complex in the absence of the other, and it is possible that when volatiles from the complexes are present concurrently, other cues such as visual cues are also utilized.

Isothiocyanates have been suggested as important signaling chemicals in a few previous studies (Reed et al., 1995; Vaughn et al., 1996; Bradburne and Mithen, 2000), and we know that feeding by both *L. erysimi* and *M. persicae* induces the emission of 3-butenyl and 4-pentenyl isothiocyanates. In Y-tube bioassays, we showed that 3-butenyl isothiocyanate was significantly more attractive than the solvent alone, irrespective of the host aphid, but we did not observe orientation toward 4-pentenyl isothiocyanate. However, when the two isothiocyanates were used in opposing arms of the olfactometer, there was no significant attraction to 3-butenyl isothiocyanate. This might be because of the odor of 4-pentenyl isothiocyanate disrupting the *D. rapae* response to 3-butenyl isothiocyanate, without actually attracting the parasitoids. It appears that 3-butenyl isothiocyanate provides an important foraging cue for *D. rapae.*

The results of this investigation are interesting when considered alongside the attack behavior of *D. rapae* in which *L. erysimi* is attacked at a greater rate than *M. persicae*, irrespective of whether the original host was *L. erysimi* or *M. persicae* (Blande et al., 2004). This behavior suggests that *L. erysimi* may be a preferable host for *D. rapae*, and that *D. rapae* may orient toward this complex in preference to the *M. persicae* alternative. However, in this investigation, neither complex appeared more attractive than the other, although we have shown an attraction toward laboratory-formulated 3-butenyl isothiocyanate in Y-tube olfactometers. Our results suggest that during the process of host-habitat and host location the cues used to locate *L. erysimi* and *M. persicae* hosts are probably the same. Perhaps glucosinolate processing by aphids may influence host acceptance behavior.

Glucosinolates in turnip leaf tissue were not significantly altered in response to aphid feeding, whereas damage by the cabbage stem flea beetle (*Psylliodes chrysocephala* L.) has been shown to facilitate glucosinolate accumulation (Koritsas et al., 1989; Bartlet et al., 1999). As feeding by aphids causes minimal cellular damage (Miles, 1999), it is not surprising that plant responses may be different from those elicited by chewing herbivores. A recent study by De Vos et al. (2005) showed that three insect herbivore species with different feeding strategies and infection with a fungal or bacterial pathogen all result in different gene transcription activity in the model plant *Arabidopsis thaliana*. Surprisingly, feeding by *M. persicae* induced 10 times more gene transcriptional changes than feeding by the chewing herbivore *Pieris rapae* or the cell-content-feeding *Frankliniella occidentalis*. Although *M.*

persicae feeding elicits a large number of gene transcriptional changes in *A. thaliana*, the glucosinolate content of our plants did not increase in response to aphid feeding, perhaps suggesting that the cytochrome P450s encoded by the *CYP79* and *CYP83* gene families responsible for stages of glucosinolate biosynthesis (Grubb and Abel, 2006) were not upregulated. Possibly, plants under heavier aphid stresses and showing more physical damage symptoms will exhibit more differences in glucosinolate content, but the indications here are that the early stages of aphid infestation do not facilitate changes in plant glucosinolate content.

The results of the glucosinolate analysis of dried aphid material showed huge differences between the two species. *Myzus persicae*, as previously indicated, contained small quantities of glucosinolate, indicative of a strategy involving the passing of glucosinolates straight through the gut (Weber et al., 1986; Cole, 1996; Bridges et al., 2002), whereas *L. erysimi*, like *B. brassicae* (Bridges et al., 2002), sequestered these compounds. This supported our hypothesis and might be explained by previous work conducted that showed the presence of a myrosinase in the head and thorax regions of this aphid species (MacGibbon and Allison, 1970; MacGibbon and Beuzenberg, 1978; Bridges et al., 2002). Interestingly, the proportions of the different glucosinolate components in the aphid tissue did not match those of the plant leaf material. Plants leaves were dominated by 3-butenylglucosinolate and 4-pentenylglucosinolate, whereas although these glucosinolates were significant components in the aphid tissue, there was a large accumulation of indolylmethylglucosinolate, which was only a minor constituent of the total plant leaf glucosinolate. Furthermore, hydroxyindolylmethylglucosinolate was found only in *L. erysimi* tissue. The most likely explanation is that quantities were so low within the plants that they fell below the HPLC detection limits, but concentration in the aphid tissue allowed for detection in those samples.

The glucosinolates stored in the aphid tissue are likely to provide foraging parasitoids with cues that can be used to assess the quality of the prospective host for their eggs. Chemical compounds present in aphid cornicle secretions have been shown to stimulate oviposition attack responses in *Aphidius ervi* (Battaglia et al., 1993, 2000). As *D. rapae* attack *L. erysimi* at a greater rate than *M. persicae* (Blande et al., 2004), it is likely that glucosinolates provide important chemical signals. Sensory cells on the antennae and ovipositor (De Faris and Hopper, 1999; reviewed by Mackauer et al., 1996) are essential in the processes of host acceptance and suitability. However, in the process of host location, it is insect-induced volatile emissions that provide the signals to foraging parasitoids.

Acknowledgements We thank Julietta Marquez for her work on the glucosinolate analysis. J. Blande was supported by a Biotechnology and Biological Sciences Research Council of the United Kingdom (BBSRC) Quota studentship. Funding for this work was provided in part by the Department of the Environment, Food and Rural Affairs. Rothamsted Research receives grant-aided support from the BBSRC.

Abstract The evolution of increased competitive ability (EICA) hypothesis predicts that invasive plant species may escape their specialized natural enemies in their introduced range and subsequently evolve with a decrease in investment in anti-herbivore chemical defenses relative to native conspecifics. We compared the chemical profile of 10 populations of US native and 20 populations of European invasive *Solidago gigantea*. To test for differences in inducibility between native and invasive populations, we measured secondary chemistry in both damaged and undamaged plants. We also performed bioassays with three specialist and two generalist insect herbivores from four different feeding guilds. There was no evidence that invasive populations had reduced concentrations of sesquiterpenes, diterpenes, or short-chain hydrocarbons (SCH), although significant variation among populations was detected. Sesquiterpene and diterpene concentrations were not influenced by damage to the host plant, whereas SCH concentrations were decreased by damage for both native and invasive plants. Performance of the three specialist insects was not affected by the continental origin of the host plant. However, larval mass of the generalist caterpillar *Spodoptera exigua* was 37% lower on native plants compared to invasive plants. The other generalist insect, a xylem-tapping spittlebug that occurs on both continents, performed equally well on native and invasive plants. These results offer partial support for the defense predictions of the EICA hypothesis: the better growth of *Spodoptera* caterpillars on European plants shows that some defenses have been lost in the introduced range, even though our measures of secondary chemistry did not detect differences between continents. Our results show significant variation in chemical

Introduction

In the United States, nonnative and invasive plants cause damage and losses totaling more than US$34 billion per year (Pimentel et al., 2000) and threaten native ecosystems (Mack et al., 2000). Despite the economic importance of invasive plants and the attention devoted to understanding biological invasions, the mechanisms that allow plants to become invasive are poorly understood (D'Antonio and Kark, 2002). The enemy release (ER) hypothesis predicts that invading plants experience success in novel habitats due to a decrease in regulation by specialized herbivores and other natural enemies in the introduced range (Elton, 1958; Keane and Crawley, 2002). The loss of enemies in the introduced range can result in reduced herbivore and parasite loads on invasive species compared to native species (Wolfe, 2002; Mitchell and Power, 2003; Carpenter and Cappuccino, 2005; Cappuccino and Carpenter, 2005; Agrawal et al., 2005; Vilà et al., 2005), potentially allowing invasive species to outperform natives.

Blossey and Nötzold (1995) extended the ER hypothesis by reasoning that if natural enemy pressure on exotic plants is reduced in the introduced range, then plants should evolve and permanently decrease their investment in defenses and maximize their investment in growth and reproduction. The evolution of increased competitive ability (EICA) hypothesis (Blossey and Nötzold, 1995) predicts that in the absence of herbivores, costly chemical defenses should be reduced in invasive plants. In addition, this loss should increase host plant quality to herbivores. However, this prediction should only apply to specialist herbivores, as generalist herbivores are likely to be encountered in the introduced range (Müller-Schärer et al., 2004; Joshi and Vrieling, 2005). It is also possible that introduced plants could retain their ability to induce defenses against herbivores, as induced defenses should be less costly than constitutive defenses.

Some studies have supported the EICA hypothesis. Siemann and Rogers (2003a) showed that in common gardens, invasive Chinese tallow (*Sapium sebiferum*) were more prone to attack by natural enemies and that generalist herbivores preferred invasive over native genotypes (Siemann and Rogers, 2003b). In addition, invasive Chinese tallow tree genotypes planted in the invasive range had enhanced growth relative to native genotypes and had significantly lower levels of foliar tannins (Siemann and Rogers, 2003b). Other work has yielded mixed results. Invasive purple loosestrife (*Lythrum salicaria*) had significantly lower plant secondary metabolites than native plants; however, herbivore bioassays did not reveal differences between introduced and native populations (Willis et al., 1999). In multiple common gardens, invasive St. John's wort (*Hypericum perforatum*) were neither larger nor more fecund than native plants (Maron et al., 2004b), although they had lower pathogen resistance and exhibited lower levels of the chemical hypericide in invasive range gardens and lower pseudohypercide levels in native range gardens (Maron et al., 2004a). Reduced herbivore damage in European gardens of the invasive ragweed (*Ambrosia artemisifolia*) translated to increased plant growth, but not size or vigor (Genton

et al., 2005), and native genotypes were as damaged as invasive genotypes in multiple gardens, suggesting no evolutionary loss of defense against herbivores.

A few studies that test the EICA hypothesis have measured levels of defensive chemicals (see Hinz and Schwarzlaender, 2004 for review) and those that do typically only measure single compounds (but see Cipollini et al., 2005). In a comprehensive test of the chemical defense predictions of the EICA hypothesis, Cipollini et al. (2005) examined constitutive and induced levels of five chemical defense traits for native and introduced populations of *Alliaria petiolata*. Their results generally did not support the EICA hypothesis, as two compounds were found at higher constitutive levels in invasive plants, and there were few other continental differences. However, there was a tendency for plants from the introduced range to have lower constitutive levels of glucosinolates but higher inducibility. Previous studies that have used insect herbivores as bioassays for plant defenses generally use leaf-chewing insects and do not examine more than one or two insect herbivores (e.g., Willis et al., 1999; Siemann and Rogers, 2003a,b; Bossdorf et al., 2004; Stastny et al., 2005; Leger and Forister, 2005).

In the study reported here, we determined end-of-season secondary chemistry and its possible effects on multiple insect herbivores for *Solidago gigantea* Ait. (late goldenrod). *S. gigantea* is native to North America and was introduced into Europe as an ornamental (circa 1758), where it naturalized and began to spread by 1850 (Weber, 1998). Today, it is among the most aggressive invasive species in Europe (Weber and Schmid, 1998). *S. gigantea* is a clonal perennial that commonly spreads throughout an area via asexual rhizomes. There are several characteristics that make it particularly appropriate for a test of the EICA hypothesis. First, there is evidence that it has escaped its specialist natural enemies in Europe. In a comparison of 46 North American populations and 45 European populations of *S. gigantea*, Jakobs et al. (2004) found that most North American populations had signs of insect herbivory, and 70% were severely damaged, while none of the European populations was infested by insects (although two populations had limited damage). Similarly, Jobin et al. (1996) concluded that few of the insects feeding on the native European goldenrod, *Solidago virgaurea*, have switched to *Solidago altissima*, another North American invasive species, perhaps because *S. virgaurea* and the introduced *Solidago* spp. do not generally occur together in the same locations. Second, *S. gigantea* has been present in Europe for about 250 years, allowing time for genetic changes to occur. Third, *S. gigantea* plants growing in the field in Europe are larger and grow more densely than conspecifics in the US, consistent with predictions of the EICA hypothesis (Jakobs et al., 2004). Finally, when *Solidago canadensis* was treated with jasmonic acid, an elicitor of plant defensive compounds, the inflorescence biomass decreased, and flowering was delayed, indicating that in a closely related *Solidago* spp., the production of defensive compounds incur a fitness cost (van Kleunen et al., 2004).

Previous research with *S. gigantea* has shown some loss of defenses against natural enemies in European populations. When grown in a common garden in the US and exposed to naturally occurring insects and leaf pathogens for 2 years, European plants were consistently more susceptible to a rust fungus and a bacterial pathogen than US plants (Meyer et al., 2005). Results for insect herbivores were more equivocal, with European plants supporting a greater biomass of insect herbivores in the first year but not the second. A variety of insects colonized the garden over the 2-year study, with changing species composition and abundance between the 2 years, making this result hard to interpret (Meyer et al., 2005).

In the study reported here, we grew *S. gigantea* plants derived from multiple populations from the introduced range and the native range in common gardens. In accordance with EICA, we predicted that chemical defenses would be lower in the introduced range. We

also predicted that specialist insect herbivores would perform better on invasive plants, and generalist herbivores would either perform better on the native plants, or there would be no effect of plant origin. To examine whether chemical defenses have been reduced in the introduced range, we measured foliar terpenoid concentrations known to influence both generalist and specialist herbivores (LeQuesne et al., 1986; Cooper-Driver and LeQuesne, 1987). As a by-product of our chemical analysis, we collected data on alkane short-chain hydrocarbons (SCH) concentrations. To test for differences in inducibility of chemical defense between native and invasive *S. gigantea*, we conducted the chemical assays on leaves of both damaged and undamaged plants. Finally, to assess how possible differences in leaf chemistry affected insect herbivores, we performed bioassays with five insect species. We chose a diverse set of insects to test, including both specialist and generalist insects that required four different feeding guilds (leaf chewer, gall-maker, phloem-sap feeder, and xylem-sap feeder).

Methods and Materials

Insect Herbivores Five insects were chosen for study. Two are widespread, generalist insects that frequently become pests in agricultural settings. The meadow spittlebug, *Philaenus spumarius* (Homoptera: Cercopidae), is a xylem-sap feeder that is abundant in both Europe and North America (Weaver and King, 1954). The beet armyworm, *Spodoptera exigua* (Lepidoptera: Noctuidae), is a leaf-chewer that is native to Asia but now occurs worldwide in tropical and temperate areas, with the exception of South America. Both insects are highly polyphagous: *P. spumarius* has been recorded from over 500 host plant species (Weaver and King, 1954) and *S. exigua* uses hosts drawn from over 20 plant families (Greenberg et al., 2001). Whereas *P. spumarius* is frequently found on *S. gigantea* in the field, at least in the US, *S. exigua* is not typically found on *Solidago*. The three other insects studied are all specialists, with each representing a different feeding guild. *Epiblema scudderiana* (Lepidoptera: Tortricidae) is a stem-galler, *Trirhabda virgata* (Coleoptera: Chrysomelidae) is a leaf-chewer, and *Uroleucon nigrotuberculatus* (Homoptera: Aphididae) is a phloem-feeder. All three species feed only on closely related species within the genus *Solidago* (Root and Cappuccino, 1992).

Plant Material S. gigantea is a clonal perennial that is easily propagated from rhizome cuttings. All plants used were grown from rhizomes that were derived from seed collections made in autumn of 1999 from 10 populations in the US and 20 populations in Europe (EU). Seeds were germinated in spring 2000 and transplanted to a field plot at the University of Wisconsin Milwaukee Field Station in Saukville, WI, where they were used for an experiment reported in Meyer et al. (2005). At the conclusion of this experiment in October 2001, rhizomes of all plants were harvested from the field and over-wintered in a refrigerator in closed plastic bags. Thereafter, rhizomes were planted in pots each spring and grown until senescence in the autumn, at which time, the rhizomes were harvested and refrigerated in closed plastic bags over the winter. These methods allowed the same genotypes to be propagated over time. Plants were grown in pots in a 12×12 m screenhouse constructed from aluminum window screen to protect the plants from extraneous insect herbivory. Light levels in the screenhouse were ~70% of those outside. We used a commercial potting mix (Farfard Grow Mix #2, Conrad Farfard, Inc., Agawam, MA, USA), and plants were watered as needed. The only exception was the bioassay with the stem-galler *Epiblema*, where field plots were utilized.

Leaf Secondary Chemistry Plants were grown undamaged in the screenhouse over the 2003 season to minimize any effects of previous treatments. At the end of the 2003 growing season, carry-over effects were assumed to be minimal because European and US plants did not exhibit significant differences in plant height, infructescence mass, or stem diameter (Meyer et al., 2005). On May 4 and 5, 2004, two rhizomes from each of 80 US and 80 EU genotypes were cut to 7–15 cm in length, weighed, and individually potted in 6.6 l pots, for a total of 320 pots. Thinner rhizomes were cut longer in an effort to achieve approximately equal weights. Rhizomes were removed from the refrigerator just before planting and were dormant when planted. Shoots generally emerged in about 7–10 d. Pots were randomly arranged within the screenhouse, with the exception that paired genotypes were kept adjacent to each other. One member of each paired genotype was randomly assigned to receive insect damage, and the other was left undamaged. On May 24, 10–14 larvae of *T. virgata* collected from a local outbreak site were placed on each plant assigned to the damage treatment. Larger plants received more larvae in an effort to achieve approximately equal levels of defoliation. *Trirhabda* larvae are sluggish and do not readily move from plant to plant as long as the pots are not touching. Control (undamaged) plants were examined frequently, and any larvae that had managed to colonize them were removed. Larvae were removed after 18 d of feeding, when defoliation on plants assigned to the damage treatment ranged from 40–100% (mean 77%). Control plants were essentially undamaged (range 0–8%, mean 1% leaf area loss).

Because many of the plants had experienced severe defoliation, and we were concerned about survival, they were given an extended period of recovery before leaves were harvested for chemical analysis. Beginning June 15, plants were sprayed every 7–10 d with the broad spectrum fungicide, Mancozeb, and insecticide, Carbaryl, to control fungal disease and to reduce extraneous herbivory. On July 22 and 27, we switched to the pesticide Camelot (Whitmire Micro-Gen, St. Louis, MO, USA) to control both fungal and bacterial disease. All three pesticides are nonsystemic, and they were effective in keeping extraneous damage to low levels. Spray treatments were discontinued after July 27. On August 16–17, after plants had produced numerous undamaged leaves, five fully expanded leaves from the upper third of the plant stem were harvested from each plant. Leaves were dried at 60°C for 72 hr. Dried leaves were express shipped to Buffalo, NY; upon arrival, leaves were maintained in sealed silica-gel desiccators until processed. Dry leaves were weighed just before chemical analysis. Final sample size was 319 plants because one plant experienced extraneous damage over the growing season.

For chemical analysis, dried leaves from each plant were placed into 15 ml of 70% hexane–30% ethyl acetate solution to which 0.26 mg of nonadecane (internal standard) was added. Leaves were disrupted by using a Polytron tissue homogenizer, centrifuged for 10 min at 2,500 rpm and decanted into 20-ml glass scintillation vials. Vial contents were concentrated under a fume hood to a final volume of ~1.5 ml and analyzed by using a Varian 3900 gas chromatograph (GC) with a flame ionization detector (FID). Compounds were separated on an RTx-5ms column (30 m×0.25 mm id), at an initial temperature of 80°C (3 min) increasing to 280°C at 5°/min. Injector temperature was maintained at 250°C, and the FID kept at 300°C. Sesquiterpene, diterpene, and short chain hydrocarbon FID peaks were grouped by retention times and integrated separately to differentiate concentrations. Identities of the sample peaks were confirmed with an Agilent 6850 GC-5973 MSD by using a similar RTx-5-ms column and the same thermal elution program used for the quantitative runs. The resulting mass spectral ion patterns for each peak were compared to the Agilent NIST98 software database and literature spectra (Anthonsen et al., 1973; Henderson et al., 1973) for compound confirmations.

Insect Bioassays The 2001 field garden was used for the *E. scudderiana* bioassay. This garden was designed to measure colonization of EU and US goldenrods by native insect fauna and consisted of 12 1 m×5 m plots, with half of the plots sprayed to exclude insect herbivores and the other half left unsprayed to measure insect abundances. Each plot had 12 European and 12 US plants drawn from the same 10 US and 20 European populations that were used in the other experiments reported here. Populations were randomly distributed among the plots, and within each plot, European and US plants were alternated. Further details on the design of this garden can be found in Meyer et al. (2005).

Sampling for *E. scudderiana* was restricted to the unsprayed plots of this garden because the spray treatment could affect larval development. There were 135 plants available for colonization by gallmoths (69 EU and 66 US, 6 plots×24 plants/plot minus 9 plants that died). Of these, 51 developed *E. scudderiana* stem galls in 2001, including five plants with double galls. Plants with galls were spread throughout the garden and were not confined to a single location. Taller plants at the time of insect oviposition were more likely to develop galls (Meyer, unpublished data), but there were no significant differences in height between European and US plants (Meyer et al., 2005). *E. scudderiana* showed no preference for European or US plants: 24 US plants and 27 EU plants developed galls, drawn from all 10 US populations and 12 of 20 EU populations. Galls on three plants were empty (two EU and one US), so the final sample size was 23 US plants and 25 EU plants.

All visible galls were collected from the garden on Sept. 27, 2001, and caterpillars were extracted from them. Galls collected in fall generally contained a single caterpillar that hatched in spring and spent the summer feeding within the gall. The caterpillar overwinters in the gall and pupates the following spring. Thus, galls collected in fall contain fully grown larvae. Caterpillars were frozen, dried at 70°C for 48 hr, and then weighed to the nearest 0.01 mg.

The *P. spumarius* bioassay was conducted in 2002 by using rhizomes derived from the 2001 field garden (described in Meyer et al., 2005). This garden consisted of paired plots that were either sprayed with insecticide or left unsprayed in 2000 and 2001. On April 17, 2002, rhizomes from eight US and eight EU populations were removed from the refrigerator, cut to 10 cm in length, and planted in 7.6-l pots. The original 10 US and 20 EU populations came from 6 EU countries and 10 US states; populations included in the *Philaenus* trial were selected so that all countries and states were represented. Four rhizomes were planted from each population: two each from previously sprayed and previously unsprayed plots. Two spittlebug nymphs collected from a local population were placed on each experimental plant with a fine-hair paintbrush on May 15. Plants were monitored daily until the nymphs were nearing their final molt. All insects were collected from the experimental plants on June 17, after a single adult spittlebug was seen in the screenhouse. Insects were frozen overnight, dried at 65°C for 48 hr, and then, weighed to the nearest 0.1 mg. Final sample size was 58 plants (two rhizomes failed to emerge and four plants, 2 US and 2 EU, lacked spittlebugs at harvest).

Bioassays for *T. virgata*, *S. exigua*, and *U. nigrotuberculatus* were conducted in 2005 with rhizomes harvested from the plants used in 2004 to measure leaf secondary chemistry. The insect bioassays included plants that had been damaged or undamaged in the previous year, to look for carry-over effects of damage on insect performance. Three rhizomes from each of the 320 plants used in 2004 were removed from the refrigerator, cut to ~1 g (range 0.8±1.2 g) and individually potted in 4.16-l pots. The pots were arranged in three sets within the screenhouse. Plants were randomly arranged within each set, except that the paired previously damaged and previously undamaged members of each genotype were kept adjacent to each other. One set of plants was used for each of the 3 insects.

Plants for the *T. virgata* bioassay were planted on May 4-5, and plants for the *S. exigua* and *U. nigrotuberculatus* bioassays were planted on May 17-19. Final sample sizes for plants were less than the 320 originally planted because a few rhizomes failed to emerge in each set of plants.

For the *T. virgata* bioassay, larvae were collected from a local outbreak site on June 6. Two first-instars were placed on each plant in the first set. The insects fed for 14 d, until just before. Larvae were then transferred to individual petri dishes with moistened filter paper and monitored until pupation. Fresh excised leaves from the corresponding host plant were added daily until larvae discontinued feeding. Fresh pupal mass was measured to the nearest 0.1 mg. At least one insect survived to pupation on 137 out of 153 European plants, and 142 out of 155 US plants, for a final sample size of 279.

The *S. exigua* assay was conducted with eggs obtained from the United States Department of Agriculture (USDA) insect-rearing facility in Stoneville, MS, USA. Five to 10 first instars were collected by using a fine-hair paintbrush and transferred to 237-ml plastic cups with lids. We started with multiple caterpillars because we expected some mortality and wanted to ensure that each plant had at least one surviving caterpillar. Caterpillars were fed on excised leaves from the second set of plants, with fresh leaves provided at least every third day. After 7 d, cups were reduced to five randomly chosen caterpillars to reduce the demand for leaf material to feed the growing caterpillars, and after 14 d, survivors were separated into individual cups. The feeding trial was discontinued when the first pupa appeared on day 21. Fresh mass of all surviving insects was measured to the nearest 0.1 mg. The majority of insects were still caterpillars at the time they were weighed, as only two pupae were found. Over the 3-wk bioassay, a total of 85 plants lost all caterpillars to mortality. US plants seemed somewhat more likely to lose all of their caterpillars than EU plants (49/156 US plants had mortality of all caterpillars, compared to 36/152 European plants), but this trend was not significant (χ^2=2.3, *df*=1, *P*=0.13).

On July 29, 2005, we observed that the third set of plants in the screenhouse had been voluntarily colonized by *U. nigrotuberculatus* aphids. We used this as a natural experiment and monitored the population growth of aphids on the experimental plants. The number of aphids on each of 303 plants was counted on August 29, after approximately 1 mo of population growth. European and US plants were equally likely to support aphids (58/150 European plants and 63/153 US plants had aphid colonies).

Data Analysis All data were tested for normality and homogeneity of variance before analysis; chemical yields, *Spodoptera* caterpillar mass, and aphid counts were log transformed to meet test assumptions. Analyses were performed by using SAS (version 8.2; SAS Institute, 2001).

The effects of continent of origin and damage on sesquiterpene, diterpene, and short chain hydrocarbon chemical yields were analyzed by using nested analysis of variance. Continental origin and damage were treated as fixed effects, and population of origin was included in the model as a nested, random effect. *F*-statistics were constructed by following methods detailed by Neter et al. (1996). Insect performance data for *Trirhabda* beetles, *Spodoptera* beet armyworms, *Uroleucon* aphids, and *Philaenus* spittlebugs were initially analyzed with a model that included continent of origin and previous damage to the host plant as fixed terms, and population of origin as a nested random term. These analyses showed that there were no significant effects ($P>0.10$) of previous damage on insect performance for any of the four insects, so previous damage was dropped from the model and pooled into the error term. For *Epiblema*, insect performance data were analyzed by using a one-way ANOVA that included only continent of origin. This insect bioassay did

not incorporate the effects of previous damage, and it lacked replication within some populations, so the nested ANOVA could not be used.

Insect mass per plant was used to measure performance for *Trirhabda*, *Spodoptera*, *Philaenus*, and *Epiblema*. For cases where there was more than one surviving insect per plant, the mean mass of the surviving insects was used for *Trirhabda*, *Philaenus*, and *Epiblema*, and the mass of the largest surviving individual was used for *Spodoptera*. The mass of the largest surviving individual was used for *Spodoptera* because these individuals were assumed to be closest to pupation, and thus, near a similar stage of development to *Trirhabda* and *Epiblema*. Insect number per plant was used for *Uroleucon* aphids. Female *Trirhabda* pupae were significantly larger than male pupae, but inclusion of beetle sex in the model did not alter conclusions, and these analyses are not shown.

The effects of sesquiterpene, diterpene, and short-chain hydrocarbon foliar concentrations on performance of *Trirhabda* and *Spodoptera* were analyzed by using analysis of covariance and regression analyses. We chose to focus on the two leaf-feeding insects for these analyses because it is not clear to what extent chemicals measured in the leaves would affect the performance of the aphid or spittlebug, which feed on plant saps. The chemical yield measured for each plant in 2004 was matched with the performance of insects grown on plants derived from the rhizomes of that plant in 2005. Thus, chemistry was not measured on the same leaves on which the insects fed, but these analyses can reveal relationships between insect growth and plant chemistry, if there is a strong genetic component to leaf secondary chemistry.

The analysis of covariance (ANCOVA) model included chemical yield as a continuous variable, continental origin as a fixed effect, population nested within continental origin as a random effect, and all interactions. A significant effect of chemical yield indicates that insect performance is affected by varying concentrations of that chemical. We predicted that leaf-chewing insect performance would be negatively affected by increasing concentrations of sesquiterpenes, diterpenes, or SCH. Continental origin was included in the model to detect whether or not insect responses to plant chemistry depended on the origin of the plant. This might occur if the composition of each class of chemicals varied between ranges and would be shown by a significant interaction between continent and chemical yield. The population term was included in the model to account for variation within the range on each continent. For cases where the population term or interactions with population were not significant ($P>0.10$), the population term was removed from the model and pooled into the error term. Regressions that related the levels of secondary chemicals to insect performance were run when the ANCOVA indicated a significant effect of chemical yield. If the ANCOVA revealed a significant or marginally significant ($P<0.10$) interaction between chemical yield and plant origin, regressions between insect performance and chemical yield were run separately for each continental source.

Results

The continental origin of the plants did not significantly affect sesquiterpene, diterpene, or SCH (Table 1, Fig. 1), but there was highly significant variation across populations for all three chemicals (Table 1). Whereas mean diterpene concentrations were 11% higher in US compared to European plants (pooled across damaged and undamaged plants), this difference was not significant because of high levels of variation among populations within each continent. Damage did not affect sesquiterpene or diterpene yield, but did significantly reduce SCH concentrations (Table 1, Fig. 1). Short chain hydrocarbon concentrations were

28% lower in damaged plants compared to undamaged plants (pooled across European and US plants) (Fig. 1).

Of the five insects tested, only the generalist leaf-chewer *Spodoptera* performed significantly better on plants from the invasive range (Table 2): mean insect mass was 37% lower on US compared to European plants (Table 3). In addition, *Spodoptera* growth response to European host plants exhibited greater variability than to US host plants as evidenced by the greater standard deviation within the EU plants (Levene's test: s^2 ratio= 15.607; $P<0.001$). Coefficients of variation for *Spodoptera* growth ranged from 17.06 to 75.90% among European populations and from 18.74 to 61.97% among US populations. The other four insects performed equally well on plants from the invasive range and the native range (Tables 2 and 3). Population effects were significant for the generalist leaf-chewer *Spodoptera*, the specialist leaf-chewer *Trirhabda*, and the specialist aphid *Uroleucon*, whereas growth of the generalist xylem-sap feeder *Philaenus* was not influenced by the host plant's population of origin. Population effects could not be tested for the stem-gall maker, *Epiblema*, because of small sample size and lack of replication within some populations.

The effect of increasing concentrations of foliar chemicals on performance of the two leaf-chewing insects differed for the generalist *Spodoptera* and the specialist *Trirhabda*. Increasing concentrations of diterpenes decreased the growth of *Spodoptera* caterpillars, and there was no interaction with continental origin (Table 4). Regression analysis revealed a significant negative relationship between diterpene concentration and *Spodoptera* mass (Fig. 2, slope=−0.007, $P=0.002$, $R^2=0.04$). In contrast, *Trirhabda* growth was not affected by foliar diterpene concentration (Table 4, Fig. 2). While the interaction between diterpene yield and continental origin was marginally significant for *Trirhabda* ($P=0.08$), an examination of the relationship between diterpene yield and beetle mass for European and US plants separately did not reveal any significant effects (EU: $P=0.27$, US: $P=0.17$, *P* value of slope in simple regression). However, *Trirhabda* growth was affected by foliar short chain hydrocarbon concentrations (Table 4). The effect of short chain hydrocarbon yield on *Trirhabda* growth seemed to depend on the continental origin of the plants ($P=0.059$), so simple regressions were run for EU and US plants separately (Fig. 3). *Trirhabda* growth

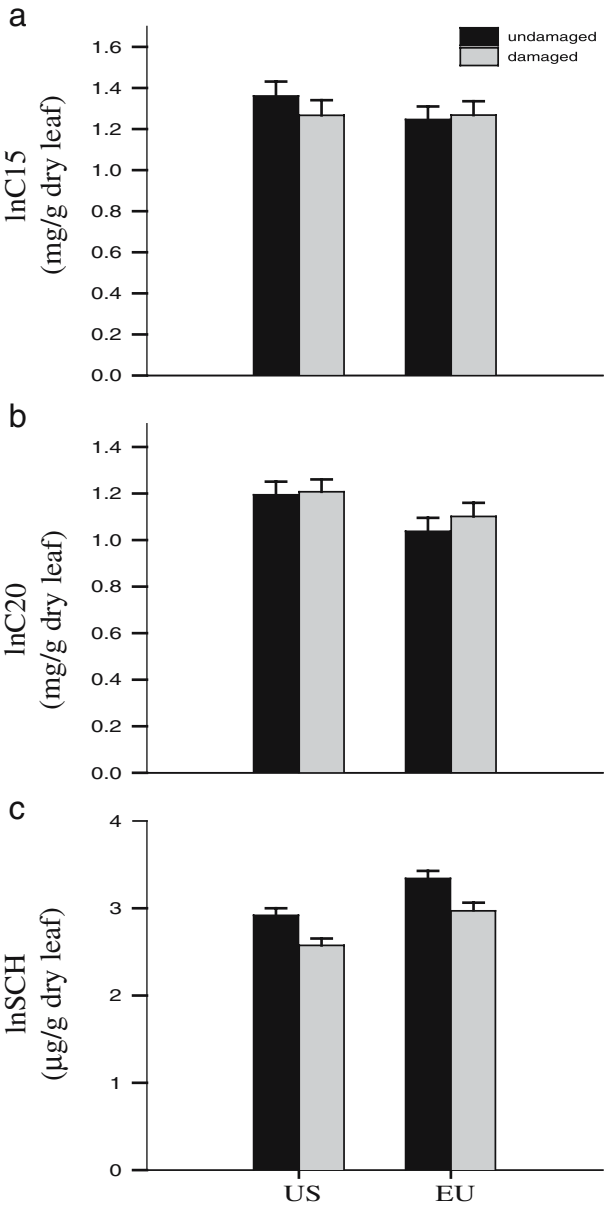

Fig. 1 Chemical yields of **a** Sesquiterpene (C15) yields, **b** diterpene (C20) yields, and **c** straight chain hydrocarbons (SCH) in damaged and undamaged (mean± SE) leaves of end of season plants of US and European (EU) populations of *Solidago gigantea*, grown under common screenhouse conditions at the University of Wisconsin—Milwaukee Field Station, Saukville, WI. *Ln* transformed values are shown

declined with increasing short chain hydrocarbon concentrations, but only for US host plants (EU: slope=0.002, P=0.09, R^2=0.02, US: slope=−0.004, P=0.002, R^2=0.07, simple regressions). *Spodoptera* growth was not significantly affected by short chain hydrocarbon yield, continent of origin, or their interaction (Table 4); however, at concentrations of >0.75 mg/g dry leaf, only one out of eight US plants supported any surviving caterpillars, whereas 13 out of 15 EU plants had at least one surviving caterpillar. Increased concentrations of sesquiterpenes did not affect the performance of either *Trirhabda* or *Spodoptera*, and there were no interactions (Table 4).

Discussion

The results of our study do not provide strong support for the EICA hypothesis. There was no evidence that concentrations of sesquiterpenes or diterpenes, chemicals in mature plants associated with defense, were lower in invasive plants from Europe, whether plants were

damaged or undamaged. Similarly, all three of the specialist insects that we tested performed equally well on plants from the invasive and the native range. Under the predictions of the EICA hypothesis, reduced host plant resistance to all three insects should have been seen in European plants, as none of these insects are found in Europe. In particular, we expected to see reduced defenses against *Trirhabda* beetles because this insect is among the most abundant herbivores on *Solidago* in North America and exerts a strong selective force on its host plant (Root and Cappuccino, 1992). *Trirhabda* beetles can reach outbreak densities where entire fields of goldenrod are completely defoliated, and plant mortality after such outbreaks has been documented (McBrien et al., 1983). We also expected to see altered performance of the *Epiblema* stem-galler on European plants because of the intimate relationship between this internally feeding insect and its host plant. Reduced defenses against the specialist aphid *Uroleucon* were perhaps less likely because

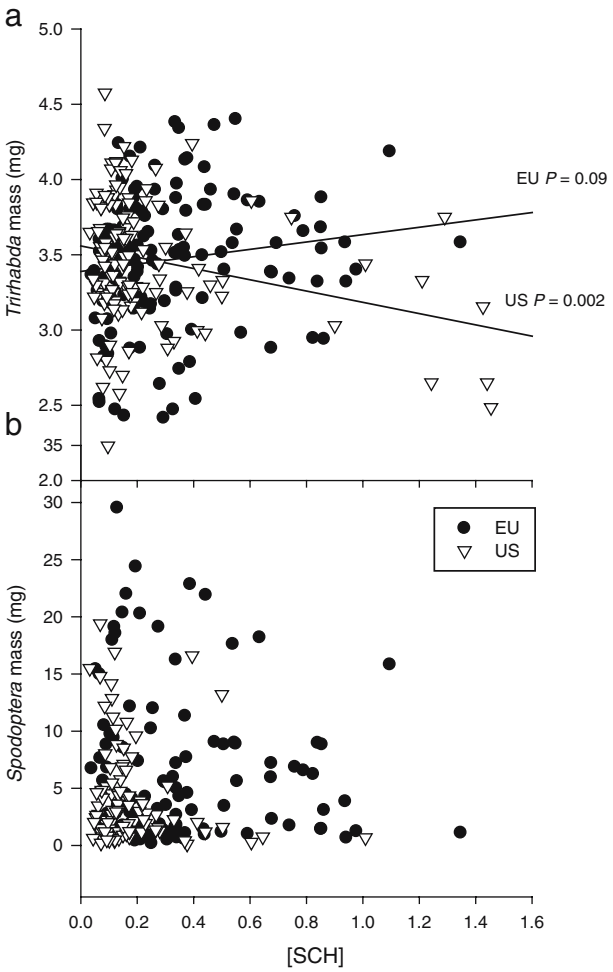

Fig. 3 Effects of straight chain hydrocarbon (SCH) yield (mg/g dry leaf) of US native and European (EU) invasive *Solidago gigantea* plants on **a** *Trirhabda virgata* pupal mass (mg) and **b** *Spodoptera exigua* larval mass at 21 d (mg). The lines shown in **a** are from simple regressions relating *T. virgata* mass to SCH concentration and the *P*-values are for the slopes of the lines

aphid feeding is less damaging to the host plant than other types of herbivore feeding (Meyer, 1993; Meyer and Root, 1993). However, aphids may respond to plant characteristics that have been selected for by other herbivores (Pilson, 1992). We expected that European plants would retain defenses against the generalist spittlebug, *Philaenus*, because this insect would be encountered on both continents. Native to Europe, *Philaenus* is also abundant in North America, where it has been introduced and has become an invasive crop pest (Weaver and King, 1954).

Nevertheless, our study did reveal changed defenses in invasive plants, as the generalist leaf-chewer *Spodoptera* performed significantly better on European plants. This result fits the prediction of the EICA hypothesis that defenses should be lower in the introduced range, but is counter to the corollary that invasive plants should maintain sufficient defenses to deter generalist herbivores (Maron and Vilà, 2001; Joshi and Vrieling, 2005). While the relationships between generalist insects, specialist insects, and invasive plants are just beginning to be explored, studies to date have shown that invasive plants tend to retain defenses against generalists (Bossdorf et al., 2004; Joshi and Vrieling, 2005; Leger and Forister, 2005; Hansen et al., 2006). Our results, revealing retention of defenses against

specialist insects and loss of defenses against a generalist insect, are difficult to interpret. It is possible that the defenses that *Spodoptera* were responding to are also effective against some other natural enemy that may have been absent in the introduced range. *Spodoptera* larval mass declined with increasing foliar diterpene concentration, suggesting that these caterpillars were responding to host plant secondary chemistry. While these diterpenes were not effective against the specialist *Trirhabda* beetles (i.e., no loss in larval mass with increasing foliar concentration), they could be acting against some other natural enemy, such as foliar pathogens. Previous research with *S. gigantea* has shown that European plants are more susceptible than US plants to two foliar pathogens (Meyer et al., 2005), a rust fungus and a bacterial leaf blight, that are not known to occur widely on plants in Europe. Many secondary plant metabolites have traditionally been regarded as compounds that are specifically active against either herbivores *or* pathogens (Harborne, 1993); however, several classes can affect the performance of both herbivores and pathogens (Barbosa, 1991; Krischik, 1991; Karban and Baldwin, 1997) and are, therefore, considered to function as "generalized" defense compounds (Krischik et al., 1991). Biere et al. (2004) found that the terpene derivatives, such as iridoid glycosides, deterred feeding by generalist herbivores and reduced spore production by fungal pathogens.

There was no evidence for enhanced levels of secondary chemicals after herbivore damage. This result should be interpreted with caution, as several features of our experimental design may have weakened our ability to detect induced defenses. First, leaves for chemical analysis were harvested approximately 9 weeks after herbivore damage. We expected that defenses directed against larval *Trirhabda* might still be present later in the season because larval and adult *T. virgata* feed on the same host plant. In the field, defoliation by larvae is usually followed by adult damage that can last through the summer. While we found no evidence that feeding by larvae changed host quality later in the season, the possibility remains that chemical changes may have occurred over shorter time scales than utilized in our experiment. Second, the high levels of defoliation experienced by plants in our experiment may have limited their ability to boost their level of defense. The plants were left with little remaining leaf area after the insects were removed, and investing in growth may have had priority over enhancing defenses as the plants recovered. Third, the plants might have responded differently if we had used a generalist insect rather than a specialist. Finally, we looked at broad chemical classes and did not examine individual compounds. Previous work with *S. gigantea* has shown that the occurrence of major sesquiterpene and diterpene peaks is similar for European and US plants, at least when plants are undamaged (Johnson and Meyer, unpublished data).

Our experiment did reveal effects of damage on SCH, but in this case, concentrations were reduced by herbivory, with European and US plants responding similarly. The role of SCH in plant defense is not clear, but they are known to function as volatile signals that can attract insects to plants. For example, SCH extracted from insects (Lewis et al., 1975; Padmavathi and Paul, 1998) or leaves and flowers of plants (Tandon and Bakthavatsalam, 2005) are a component of odor volatiles that increase the recruitment of *Trichogramma* sp. parasitoids; SCH also attract pseudo-copulating bees to pollinate orchids (Paxton and Tengo, 2001). Our results suggest a more direct role for SCH in plant defense, as *Trirhabda* beetle growth declined, and *Spodoptera* mortality may be greater with increasing SCH concentration, but only for US plants. It is also possible that SCH were acting as a volatile signal of some kind in our experiment because the decreased concentrations in damaged plants suggests that, in the presence of insect herbivores, these compounds were released or depleted in some way. Our experiment was not designed to detect any effects of volatile signals on herbivore natural enemies, so this possibility remains unexplored. One intriguing

potential explanation for our failure to detect induced chemical defenses in this experiment is the possibility that volatile signals from damaged plants may have induced neighboring undamaged plants to increase their chemical defenses. While we are unaware of any work documenting volatile signals in *Solidago*, it is now well-accepted that volatile organic compounds can induce defenses in neighboring, undamaged plants (see Baldwin et al., 2006 for review). This might have been possible in our experiment as damaged and undamaged plants were grown intermixed in close proximity, and defoliation levels were high.

Previous work on the secondary chemistry of *S. gigantea* has shown significantly greater levels of diterpenes in native plants compared to invasive plants, as the EICA hypothesis predicts. In an experiment that used undamaged plants grown from seed, Johnson and Meyer found that diterpene concentrations of US plants were 44.5% greater than those of European plants (unpublished data). While the trend was the same in the experiment reported here, differences between EU and US plants were much smaller (11%) and not significant. Diterpene concentrations measured in the present experiment were also more than twice as high as those in the other study (mean calculated across all plants=3.5 mg/g dry leaf this study, vs. 1.5 mg/g dry leaf, Johnson and Meyer, unpublished data). Diterpene concentrations measured in seedling plants unexposed to herbivores, as in the other study, represent constitutive levels of defenses. The increased amounts seen in the current experiment are consistent with the idea that all plants were induced to increase their chemical defenses, either directly via herbivore feeding or indirectly via a volatile signal. While we cannot rule out other explanations, such as different energy reserves available to seedlings and rhizome-derived plants, it is possible that we did not detect differences in chemistry between European and US plants or effects on specialist herbivores because all plants were induced. Recently, Cipollini et al. (2005) reported that invasive populations of *Alliaria petiolata* tended to have lower constitutive levels but greater inducibility of glucosinolates. The possibility that other introduced plants retain their ability to induce defenses while maintaining lower constitutive levels of defense deserves further exploration.

Our study represents one of the most complete tests of the defense predictions of the EICA hypothesis to date, as it incorporates direct measures of secondary chemistry along with bioassays of both generalist and specialist insects across a greater spectrum of feeding guilds than have been tested previously. *S. gigantea* has been present in Europe for over 250 years (Weber, 1998) and experiences little herbivory there (Jakobs et al., 2004), so the prerequisites that might lead to an evolutionary loss of defenses seem to be in place. We found little support for two major predictions of the EICA hypothesis: that invasive plants should have lower levels of chemical defenses and support better growth of specialist insects. However, our results do reveal genetically based changes in the defenses of European plants, as we found increased growth of *Spodoptera* on invasive plants, and previous work has revealed lower levels of diterpenes and increased susceptibility to pathogens in invasive plants (Johnson and Meyer, unpublished data; Meyer et al., 2005). These results suggest that changes in plant defenses in the introduced range of *S. gigantea* are more complex than would be expected under the current predictions of the EICA hypothesis, even including extensions incorporating the difference between specialist and generalist insects (Müller-Schärer et al., 2004; Joshi and Vrieling, 2005; Leger and Forister, 2005; Hansen et al., 2006). Our study also demonstrated strong population effects for all three chemical classes that we measured and for three of the four insects where we had sufficient replication to test for differences among populations. Our results suggest that future studies testing the defense predictions of the EICA hypothesis should incorporate a broad spatial scale and include a diversity of herbivores. In addition, the possibility that invasive plants retain the ability to induce defenses against herbivores should be further explored.

Abstract *Halyomorpha halys* (Stål) (Pentatomidae), called the brown marmorated stink bug (BMSB), is a newly invasive species in the eastern USA that is rapidly spreading from the original point of establishment in Allentown, PA. In its native range, the BMSB is reportedly attracted to methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate, the male-produced pheromone of another pentatomid common in eastern Asia, *Plautia stali* Scott. In North America, *Thyanta* spp. are the only pentatomids known to produce methyl 2,4,6-decatrienoate [the (*E*,*Z*,*Z*)-isomer] as part of their pheromones. Methyl 2,4,6-decatrienoates were field-tested in Maryland to monitor the spread of the BMSB and to explore the possibility that *Thyanta* spp. are an alternate host for parasitic tachinid flies that use stink bug pheromones as host-finding kairomones. Here we report the first captures of adult and nymph BMSBs in traps baited with methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate in central Maryland and present data verifying that the tachinid, *Euclytia flava* (Townsend), exploits methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate as a kairomone. We also report the unexpected finding that various isomers of methyl 2,4,6-decatrienoate attract *Acrosternum hilare* (Say), although this bug apparently does not produce methyl decatrienoates. Other stink bugs and tachinids native to North America were also attracted to methyl 2,4,6-decatrienoates. These data indicate there are Heteroptera in North America in addition to *Thyanta* spp. that probably use methyl 2,4,6-decatrienoates as pheromones. The evidence that some pentatomids exploit the pheromones of other true bugs as kairomones to find food or to congregate as a passive defense against tachinid parasitism is discussed.

Introduction

Much has been learned about stink bug communication, both chemical and acoustic, since *Thyanta custator* (F.) (Pentatomidae) rained from the sky in a line across Kansas on October 14, 1939, requiring truck-loads of bugs to be hauled off in the subsequent cleanup (Wilbur, 1939). It is now known that pentatomid males produce pheromones attractive to conspecific females, males, and nymphs, as well as tachinid flies and other parasitoids (Aldrich, 1988b, 1995; McBrien and Millar, 1999). Ultimately, adult stink bugs recognize and court each other acoustically (Çokl and Virant-Doberley, 2003). Males of *Thyanta* spp., for example, produce methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate with (Millar, 1997; McBrien et al., 2002b) or without particular sesquiterpenes (Moraes et al., 2005) that attract a mate, while at close range, a dialog of substrate vibrations facilitates species recognition and isolation (McBrien et al., 2002a). The methyl 2,4,6-decatrienoate pheromone theme has also been reported for one other pentatomid bug native to eastern Asia, *Plautia stali* Scott, whose males produce methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate (Sugie et al., 1996).

Halyomorpha halys (Stål) (Pentatomidae), called the brown marmorated stink bug (BMSB), is a newly invasive species in the eastern USA (Hoebeke and Carter, 2003) that is rapidly spreading from its original point of establishment in Allentown, PA. The pheromone for *H. halys* is unknown, but in Japan, this bug is reportedly cross attracted to the pheromone of *P. stali* (Tada et al., 2001a, b).

Perhaps the best known pheromone system among the true bugs (Hemiptera: Heteroptera) is that of the spined soldier bug, *Podisus maculiventris* (Say) (Pentatomidae) (Aldrich et al., 1978, 1984a, b, c; Aldrich, 1985; Sant'Ana et al., 1997). Males of this predacious bug produce an attractant pheromone consisting of two essential components, (*E*)-2-hexenal and α-terpineol. Among various parasitoids that exploit this pheromone as a host-finding kairomone, the most commonly encountered species is the tachinid fly, *Euclytia flava* (Townsend). However, *E. flava* is seldom captured in traps baited with synthetic *P. maculiventris* pheromone late in the summer or early fall, and this fly almost never emerges from over wintering spined soldier bugs caught in pheromone-baited traps in the spring. *Euclytia flava* has been reared from *Thyanta* spp. field-collected from late July through September (Eger and Ables, 1981; Jones et al., 1996), suggesting that *Thyanta* bugs might be a late-season alternate host for *E. flava*.

Thus, we became interested in field-testing methyl 2,4,6-decatrienoates for two reasons: (1) in an effort to monitor the spread of the BMSB, *H. halys*, and (2) to explore the possibility that *Thyanta* spp. are an alternate host for the tachinid fly, *E. flava*. Here, we report data pertinent to these two avenues of investigation but also report the unexpected finding that various isomers of methyl 2,4,6-decatrienoate are potent attractants for native stink bugs and their tachinid parasitoids although efforts to isolate these compounds from the bugs themselves have thus far failed.

Methods and Materials

Chemical Standards and Treatments Standards of the following were purchased: (*E*)-2-hexenal, methyl (*E*,*Z*)-2,4-decadienoate (Bedoukian Research, Danbury, CT, USA); α-terpineol (Fisher Scientific, Fair Lawn, NJ, USA); and bisabolene (International Flavors & Fragrances, Union Beach, NJ, USA). Methyl (*E*,*Z*,*Z*)-, (*Z*,*E*,*Z*)-, and (*E*,*E*,*Z*)-2,4,6-decatrienoates were synthesized as previously described (Khrimian, 2005), as were (4*S*)-*cis*- and (4*S*)-*trans*-(*Z*)-α-bisabolene epoxides [(*Z*)-(1*R*,2*S*,4*S*)-4-(1′,5′-dimethyl 1′,4′-hexadienyl)-1,

2-epoxy-1-methylcyclohexane and (*Z*)-(1*S*,2*R*,4*S*)-4-(1′,5′-dimethyl 1′,4′-hexadienyl)-1,2-epoxy-1-methylcyclohexane, respectively] (Chen et al., 2000). Zingiberene [5-(1,5-dimethyl-4-hexenyl)-2-methyl-1,3-cyclohexadiene] was the most convenient sesquiterpene to use for the pheromone because this compound could be isolated from ginger essential oil by using the procedure of Millar (1998). Structures of known pheromone molecules that were tested are shown in Fig. 1.

Lures for the initial experiment (Exp. 1) included treatments mimicking the natural pheromones of *P. maculiventris* (Aldrich et al., 1984a) and *T. custator accerra* McAtee (McBrien et al., 2002b), with five replicates per treatment prepared as follows. (*E*)-2-hexenal and racemic α-terpineol were mixed in a molar ratio of 1:0.843. Batches of 40 ml of pheromone were prepared by combining 17.6 ml hexenal and 21.4 ml of α-terpineol. A 20% (vol/wt) formulation of pheromone in plasticized polyvinyl chloride (PVC) was prepared by mixing 107 g of powdered PVC (Tenneco, Piscataway, NJ, USA) with 53 g of dioctyl phthalate (Aldrich Chemicals, Milwaukee, WI, USA) (Fitzgerald et al., 1973). The

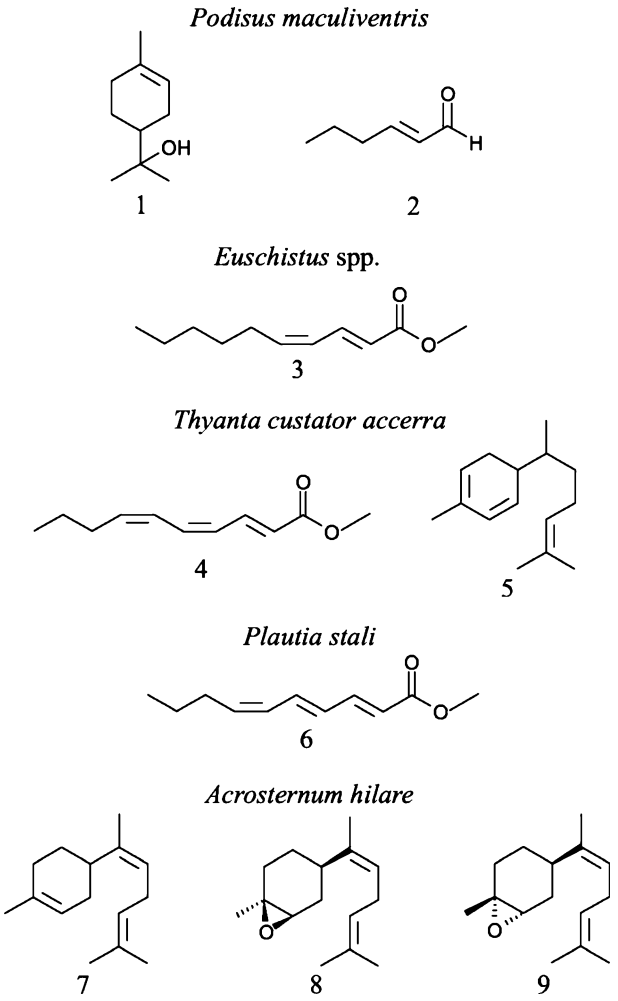

Fig. 1 Chemical compounds tested and the pentatomid species with which the compounds have been associated: *1*, α-terpineol; *2*, (*E*)-2-hexenal; *3*, methyl (*E*,*Z*)-2,4-decadienoate; *4*, methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate; *5*, zingiberene; *6*, methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate; *7*, (*Z*)-α-bisabolene; *8*, *cis*-(*Z*)-α-bisabolene epoxide; and *9*, *trans*-(*Z*)-α-bisabolene epoxide

pheromone–PVC mixture was poured into test tubes (to the top; 16×100 mm, Kimble, Elmira, NY, USA), heated in an oven at 110°C for 30 min, removed from the tubes, and stored in sealed vials in a freezer until use (treatment = "H+α-T"). Approximately 1-g slices of the H+α-T treatment in PVC were used to bait traps.

In Exp. 1, lures for treatments based on the *Thyanta* pheromone were prepared with methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate, designated as "*EZZ*," by placing ten rubber septa (West Pharmaceutical Services, Kearney, NE, USA) in a 100-ml, round-bottom, one-neck flask, and covering the septa with an 8-ml hexane solution containing 40 mg of methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate plus 40 mg of zingiberene. The flask was rotated on a rotary evaporator (without applying a vacuum) for 1.5–2 hr or until the liquid was almost completely absorbed into the septa. One set of septa was placed directly into the bottom of traps unprotected from sunlight; this treatment is defined as "U-*EZZ*+Z." Methyl 2,4,6-decatrienoates undergo photoisomerization when exposed to sunlight (Khrimian, unpublished data); therefore, another set of septa was deployed in traps protected from light by pinning the septa inside ~7-cm-long pieces of standard PVC plumbing pipe (2.5 cm ID); this treatment is coded as "*EZZ*+Z." Analogously, a treatment consisting of methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate (4.4 mg/septum) without zingiberene was prepared (designated "*EZZ*"), and septa impregnated with only hexane served as controls (C).

Lures for a second experiment (Exp. 2) were prepared as described above for the *Thyanta*-based treatments except that a second methyl decatrienoate isomer (the *Z*,*E*,*Z*-isomer) was also used, and the compound previously identified as the main pheromone component of *Euschistus* spp. (Aldrich et al., 1991), methyl (*E*,*Z*)-2,4-decadienoate ("*D*"), was used instead of zingiberene. None of these lures was protected from light. Treatments for Exp. 2 consisted of *EZZ*, *EZZ*+*D*, *D*, *ZEZ*, *EZZ*+*D*, and C, with four replicates per treatment.

On September 10, 2004, three additional treatments (four replicates each) were added to Exp. 2 to test the possibility of an interaction between methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate and the male-specific compounds previously identified from the green stink bug, *Acrosternum hilare* (Aldrich et al., 1989; McBrien et al., 2001): (*Z*)-α-bisabolene and (4*S*)-*cis*- and (4*S*)-*trans*-(*Z*)-α-bisabolene epoxides. The commercial sample of bisabolene was determined to contain ~20% (*Z*)-α-bisabolene; therefore, septa were loaded with 20 mg of bisabolene so as to contain 4 mg of the desired isomer for one of the additional treatments ("B"), with a second treatment consisting of *ZEZ* (4 mg) + B (10 mg). The third additional treatment consisted of a 1:1 mixture of (4*S*)-*cis*- and (4*S*)-*trans*-(*Z*)-α-bisabolene epoxides ("X"). The amount of epoxides available was limiting (~12 mg); therefore, only one treatment included the epoxides: *ZEZ* (4 mg) + X (3 mg).

Lures for a third experiment (Exp. 3) were prepared by using rubber septa (four replicates per treatment) impregnated with chemicals as described above, except that each septum was loaded with 2-mg active ingredient/lure. Lures were pinned inside PVC pipe as in Exp. 1 and hung from the roof of sticky traps. Treatments consisted of hexane controls (C), methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate (*EEZ*), methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate (*ZEZ*), and *EEZ*+*ZEZ* (3:1 ratio).

A fourth experiment (Exp. 4) was conducted in 2005 as a follow-up to Exp. 2. Lures were prepared as for Exps. 1 and 2, but methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate was used in place of the (*E*,*Z*,*Z*)-isomer that was part of the Exp. 2 treatment set. Thus, treatments for Exp. 4 consisted of *EEZ*, *EEZ*+*D*, *D*, *ZEZ*, *ZEZ*+*D*, and C, with four replicates per treatment. All treatments for Exp. 4 were protected from light inside PVC pipe as in Exps. 1 and 3. The lures and conditions for the four field trapping experiments are summarized in Table 1.

Table 1 Chemical treatments tested

Exp.	Code	Compound(s)	Formulation	Trap
1	*E*-2H+α-T	(*E*)-2-hexenal +α-terpineol	PVC	Aldrich[a]
1	EZZ_a	Methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate[b]	Septum/protected[c]	Aldrich
1	EZZ_a+*Z*	Methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate + zingiberene	Septum/protected	Aldrich
1	EZZ_b+*Z*	Methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate + zingiberene[d]	Septum/protected	Aldrich
1	U-EZZ_a	Methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate	Septum/unprotected[e]	Aldrich
2	U-*EZZ*[f]	Methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate	Septum/unprotected	Sterling[g]
2	U-*D*	Methyl (*E*,*Z*)-2,4-decadienoate	Septum/unprotected	Sterling
2	U-*EZZ*+*D*	Methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate + methyl (*E*,*Z*)-2,4-decadienoate	Septum/unprotected	Sterling
2	U-*ZEZ*	Methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate	Septum/unprotected	Sterling
2	U-*ZEZ*+*D*	Methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate + methyl (*E*,*Z*)-2,4-decadienoate	Septum/unprotected	Sterling
2	U-*ZEZ*+*B*	Methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate + α-bisabolene	Septum/unprotected	Sterling
2	U-*X*	Bisabolene epoxide	Septum/unprotected	Sterling
2	U-*ZEZ*+*X*	Methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate + bisabolene epoxide	Septum/unprotected	Sterling
3	*EEZ*	Methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate	Septum[h]	Sticky[I]
3	*ZEZ*	Methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate	Septum	Sticky
3	*EEZ*+*ZEZ*	Methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate + methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate	Septum	Sticky
4	*EEZ*	Methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate	Septum/protected	Sterling
4	*D*	Methyl (*E*,*Z*)-2,4-decadienoate	Septum/protected	Sterling
4	*EEZ*+*D*	Methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate + methyl (*E*,*Z*)-2,4-decadienoate	Septum/protected	Sterling
4	*ZEZ*	Methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate	Septum/protected	Sterling
4	*ZEZ*+*D*	Methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate + methyl (*E*,*Z*)-2,4-decadienoate	Septum/protected	Sterling

[a] Custom-made clear plastic funnel trap; see text.

[b] First synthetic batch.

[c] Lure pinned inside PVC pipe to shield against sunlight.

[d] Second synthetic batch of methyl (*E,Z,Z*)-2,4,6-decatrienoate.

[e] Unprotected lures (U) were impregnated rubber septa placed in trap bottoms.

[f] Distinction between synthetic batches of methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate was dropped; see text.

[g] Clear plastic funnel trap constructed and supplied by Sterling International.

[h] Lure shielded from direct sunlight by pinning inside trap roof.

[i] Jackson delta traps with removable sticky inserts (Agrisense).

Field Trapping Field experiments were carried out at the USDA Beltsville Agricultural Research Center (BARC), Prince George's County, MD, from June through October of 2004 and August through October of 2005. Experiment 1 was conducted at the South Farm of BARC from June 15 through September 17, 2004, with clear plastic funnel traps designed to capture insects alive (Aldrich et al., 1984a). These traps were hung about 1.8 m above ground from the branches of trees (>20 m apart) in a mixed deciduous forest bordering agricultural fields. Experiment 2 was conducted at the North Farm of BARC from July 1 through October 26, 2004, with traps similar to those used for Exp. 1 supplied by Sterling International (Spokane, WA, USA) and deployed as for Exp. 1. Experiment 3 was conducted from July 9 through October 15, 2004, with Jackson delta traps with

removable sticky inserts (Agrisense, Fresno, CA, USA) (Zhang and Aldrich, 2004) deployed along East Line Road at BARC. Experiment 4 was conducted from August 11 through October 19, 2005, with traps located and positioned as in Exp. 2. Traps with the H+α-T treatment were rebaited every 2–3 d; traps with the other treatments on rubber septa were rebaited every 2 wk. Usually traps were monitored daily; insects caught inside, on, and within ~1 m of a trap were counted. Field-collected insects were preserved for species identification and used for further laboratory experimentation.

Statistical Analysis The total numbers of insects responding to the treatments were analyzed with a Fisher's exact Chi-square test by using StatXact (Mehta and Patel, 2003) to determine if the distribution of the insects differed for the chemical compounds. For each species, the treatment counts were analyzed as a multinomial distribution with StatXact. The probabilities that an individual of the particular species would be attracted to the chemical compound were calculated. Confidence intervals were also calculated for the probabilities. If the confidence intervals overlapped for two treatments, then they were not statistically different. The confidence intervals were calculated by using Sidak adjusted *P* values so that the experiment-wise error was 0.05.

Results

Experiment 1 Although treatments containing methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate with or without zingiberene were deployed with the expectation of attracting *Thyanta* spp. pentatomids (McBrien et al., 2002b) and their parasitoids, only six individuals of *T. custator accerra* McAtee [one male and five females (1M:5F)] were captured. In fact, three other stink bug species were more abundantly encountered in or around these traps than was *T. custator accerra* (Fig. 2): *A. hilare* (Say) (5M:11F), *Euschistus tristigmus* (Say) (2M:9F), and *Banasa dimidiata* (Say) (5M:3F). Other pentatomids that were caught included *Euschistus servus* (Say) (2F), *P. maculiventris* (Say) (1M:1F), and *Banasa calva* (Say) (1F). No stink bugs were caught in control traps in Exp. 1.

Five species of tachinid flies were captured in or on traps baited with chemical treatments in Exp. 1: *E. flava* (Townsend), *Gymnosoma par* (Walker), *Euthera tentatrix* Loew, *Hemyda aurata* Robineau–Desvoidy, and *Cylindromyia fumipennis* (Bigot) (Fig. 3).

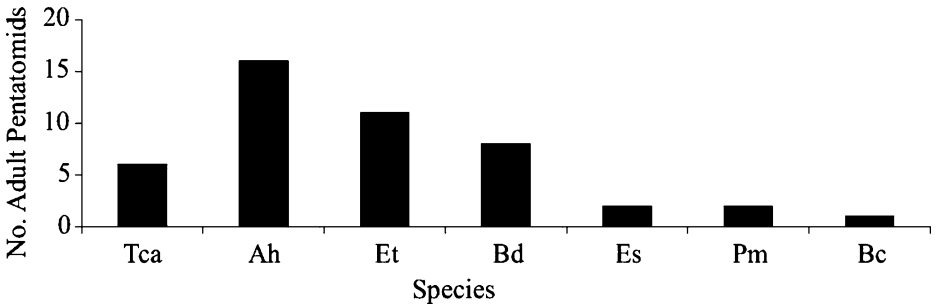

Fig. 2 Adult pentatomid species caught in or around traps baited with lures containing methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate from June 15 through September 17, 2004 (Exp. 1): *Tca*, *T. custator accerra* McAtee; *Ah*, *A. hilare* (Say); *Et*, *E. tristigmus* (Say); *Bd*, *B. dimidiata* (Say); *Es*, *E. servus* (Say); *Pm*, *P. maculiventris* (Say); and *Bc*, *B. calva* (Say)

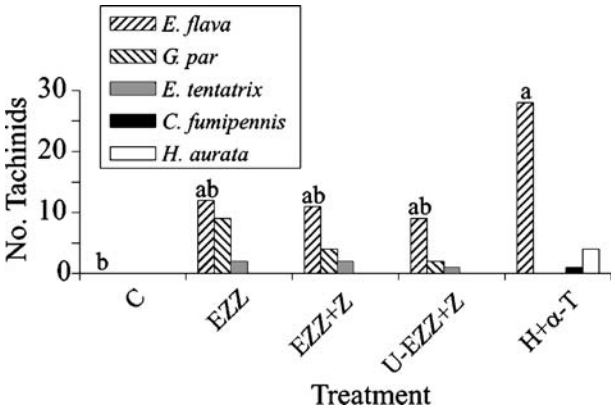

Fig. 3 Tachinid flies caught in or around traps baited with lures containing methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate (*EZZ*) with or without zingiberene (*Z*) [components of *Thyanta* spp. pheromones (McBrien et al., 2002b)], and (*E*)-2-hexenal with α-terpineol [components of the *P. maculiventris* pheromone, H+α-T (Aldrich et al., 1984a)], from June 15 through September 17, 2004 (Exp. 1): *E. flava* (Townsend), *G. par* (Walker), *E. tentatrix* Loew, *H. aurata* Robineau–Desvoidy, and *C. fumipennis* (Bigot). Bars for *E. flava* with different letters are significantly different ($P<0.05$) (trienoate treatments with the prefix "*U*" were unprotected from light; those without a prefix were protected from light as described in the text)

Two of these tachinid parasitoids (*H. aurata* and *C. fumipennis*) were restricted to traps baited with the major pheromone components of the spined soldier bug, *P. maculiventris*, and two other species (*G. par* and *E. tentatrix*) were restricted to traps with treatments containing methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate. The most abundantly encountered species was *E. flava*, and this fly was captured in and around traps containing either methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate or the *P. maculiventris* synthetic pheromone. In the former treatments, the presence or absence of zingiberene did not significantly affect attraction of *E. flava*. No tachinids were caught in or around control traps.

In addition to pentatomids and tachinids, one species of solitary wasp was also attracted in Exp. 1 to treatments containing methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate: *Astata occidentalis* Cresson (Hymenoptera: Sphecidae). A total of seven females were caught inside traps (none in controls) and, as with *E. flava*, the presence of zingiberene appeared not to affect attraction.

Experiment 2 This experiment was designed to further test methyl 2,4,6-decatrienoates by themselves or combined with methyl (*E*,*Z*)-2,4-decadienoate, the previously identified male-specific pheromone component of various *Euschistus* spp. (Aldrich et al., 1991), for attraction of native stink bugs. Methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate was included as an extension of Exp. 1 and methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate was included based on preliminary gas chromatography–electroantennogram detector data with tachinid flies (Aldrich et al., 2006) and *H. halys* (Zhang and Aldrich, unpublished data).

Substantial numbers of the dusky stink bug, *E. tristigmus*, and the green stink bug, *A. hilare*, were caught during Exp. 2 at chemically treated traps, but none were caught in or around control traps (Fig. 4). For *A. hilare*, almost 38% of the individuals that were attracted were second- to fifth-instar nymphs, and nymphs were often caught in the absence of adults. Methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate alone was significantly attractive to *A. hilare*, whereas methyl (*E*,*Z*)-2,4-decadienoate alone was not attractive to green stink bugs (Fig. 4a). Methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate alone was more attractive to green stink bugs

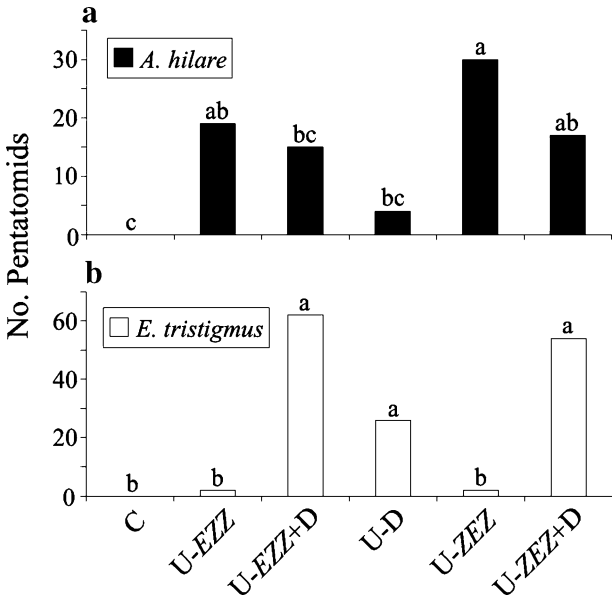

Fig. 4 Total number of pentatomids (adults and nymphs) of **a** the green stink bug, *A. hilare* (Say), and **b** the dusky stink bug, *E. tristigmus* (Say), caught in or around traps baited with lures containing methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate (*EZZ*), methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate (*ZEZ*), methyl (*E*,*Z*)-2,4-decadienoate (*D*), or the binary combinations *EZZ*+D or *ZEZ*+D from July 1 through October 26, 2004 (Exp. 2). The prefix "*U*" indicates that the lures were unprotected from light. Bars for a species with different letters are significantly different ($P<0.05$)

than control traps, but the number of bugs caught with this decatrienoate isomer was not significantly greater than the number of *A. hilare* captured in and around traps baited with methyl (*E*,*Z*)-2,4-decadienoate alone. Combining either the methyl (*Z*,*E*,*Z*)- or (*E*,*Z*,*Z*)-2,4,6-decatrienoates with methyl (*E*,*Z*)-2,4-decadienoate did not increase attraction over that of the methyl decatrienoates alone (Fig. 4a). More female (33) than male (20) green stink bugs were captured, but this difference was not significant ($X^2=3.19$; $P_{0.05}=3.84$, 1 *df*). No green stink bugs were captured in or around control traps.

For the dusky stink bug, predominantly adults were attracted, with nymphs comprising only about 5% of the *E. tristigmus* individuals caught. Methyl (*E*,*Z*,*Z*)- and (*Z*,*E*,*Z*)-2,4,6-decatrienoates alone were insignificantly attractive to *E. tristigmus*, and the previously known pheromone component [methyl (*E*,*Z*)-2,4-decadienoate] by itself appeared only moderately attractive (Fig. 4b); however, the combination of either methyl (*E*,*Z*,*Z*)- or (*Z*,*E*,*Z*)-2,4,6-decatrienoate with methyl (*E*,*Z*)-2,4-decadienoate did not attract significantly more individuals of *E. tristigmus* than did traps baited with methyl (*E*,*Z*)-2,4-decadienoate alone (Fig. 4b). More *E. tristigmus* females (83) than males (56) were captured ($X^2=5.24$, $P<0.05$). No *E. tristigmus* were caught at control traps.

In Exp. 2, significant numbers of two tachinid species were caught from July 1 through October 26 in or around traps baited with treatments containing methyl (*E*,*Z*,*Z*)- and (*Z*,*E*,*Z*)-2,4,6-decatrienoates, with or without methyl (*E*,*Z*)-2,4-decadienoate: *E. flava* and *G. par* (Fig. 5). *Euclytia flava* was attracted to methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate, but methyl (*E*,*Z*)-2,4-decadienoate was completely unattractive to this fly (Fig. 5a). Methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate was not attractive to *E. flava* in this experiment, and combining methyl (*E*,*Z*)-2,4-decadienoate with methyl (*E*,*Z*,*Z*)- and (*Z*,*E*,*Z*)-2,4,6-decatrienoate did not increase attraction of *E. flava* over that of these decatrienoates alone. For *G. par* (Fig. 5b), only treatments containing methyl (*E*,*Z*)-2,4-decadienoate were attractive, and the combinations of either methyl (*E*,*Z*,*Z*)- or (*Z*,*E*,*Z*)-2,4,6-decatrienoates with methyl (*E*,*Z*)-2,4-decadienoate were not more attractive than the decadienoate alone. Single specimens of *E. tentatrix* were caught with each chemical treatment, but no tachinids were caught at control traps.

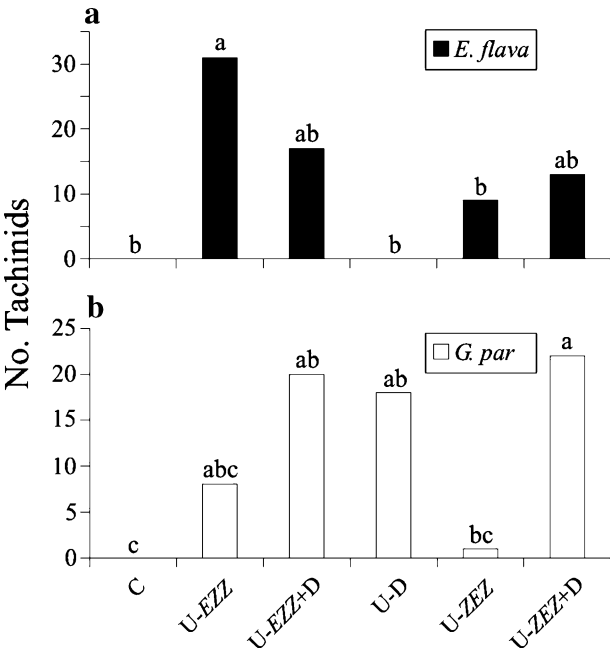

Fig. 5 The tachinid flies, **a** *E. flava* (Townsend) and **b** *G. par* (Walker), caught in or around traps baited with lures containing methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate (*EZZ*), methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate (*ZEZ*), methyl (*E*,*Z*)-2,4-decadienoate (*D*), or the binary combinations *EZZ*+D or *ZEZ*+D from July 1 through October 26, 2004 (Exp. 2). The prefix "*U*" indicates that the lures were unprotected from light. Bars for a species with different letters are significantly different ($P<0.05$)

Figure 6 shows the numbers of pentatomids (Fig. 6a) and tachinids (Fig. 6b) caught in or around traps for Exp. 2 from September 10 through October 26, 2004, when treatments were added containing (*Z*)-α-bisabolene or (4*S*)-*cis*- and (4*S*)-*trans*-(*Z*)-α-bisabolene epoxides. Treatments containing (*Z*)-α-bisabolene or (*Z*)-α-bisabolene epoxides did not significantly attract either *E. tristigmus* or *A. hilare* (Fig. 6a). Among the tachinids, *Trichopoda pennipes* (F.) was encountered for the first time, but only in the treatment containing methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate with (4*S*)-*cis*- and (4*S*)-*trans*-(*Z*)-α-bisabolene epoxides (Fig. 6b); 12 individuals of this species (six males and six females) were caught.

Experiment 3 This experiment was conducted to determine if there are native tachinids preadapted to recognize the two methyl decatrienoate isomers thought most likely to attract *H. halys*; i.e., methyl (*E*,*E*,*Z*)- and (*Z*,*E*,*Z*)-2,4,6-decatrienoates. The isomer identified from *P. stali* (Sugie et al., 1996) that is reportedly cross-attractive to *H. halys* in Japan [methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate] (Tada et al., 2001a, b) is, in fact, highly attractive to females of *G. par* (Fig. 7). However, the (*Z*,*E*,*Z*)-isomer was totally unattractive to *G. par*.

Experiment 4 As in Exp. 2, for *A. hilare*, a substantial number of the attracted individuals were nymphs, about 16% of the 127 green stink bugs that were caught. Methyl (*Z*,*E*,*Z*)- and (*E*,*E*,*Z*)-2,4,6-decatrienoate alone were significantly attractive to *A. hilare*, whereas methyl (*E*,*Z*)-2,4-decadienoate alone was not attractive to green stink bugs (Fig. 8a). Combining methyl (*E*,*Z*)-2,4-decadienoate with methyl (*Z*,*E*,*Z*)- or (*E*,*E*,*Z*)-2,4,6-decatrienoates did not increase attraction. The number of females captured (50) was not significantly different than the number of males caught (54). No green stink bugs were captured in or around control traps.

For the dusky stink bug, predominantly adults were attracted, with nymphs comprising about 8% of the *E. tristigmus* individuals caught. Methyl (*E*,*E*,*Z*)- and (*Z*,*E*,*Z*)-2,4,6-decatrienoates alone were insignificantly attractive to *E. tristigmus*. The previously known pheromone component [methyl (*E*,*Z*)-2,4-decadienoate] by itself was attractive (Fig. 8b).

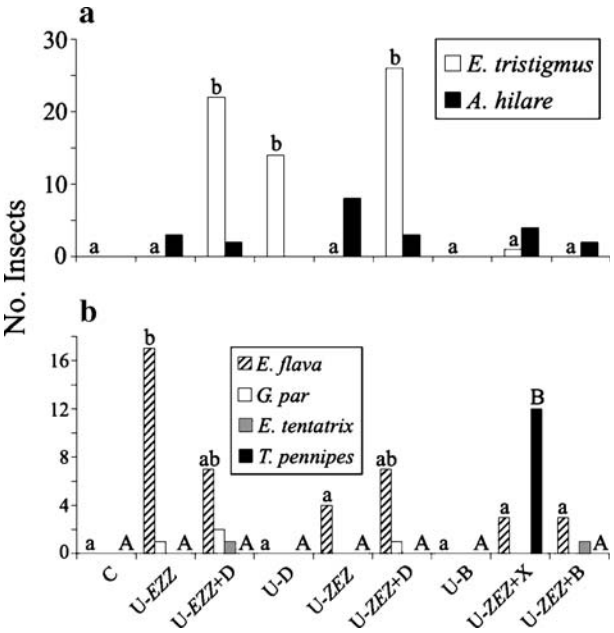

Fig. 6 The total numbers of pentatomids (**a**) and tachinids (**b**) caught in or around traps when treatments containing (*Z*)-α-bisabolene (*B*) or (4*S*)-*cis*- and (4*S*)-*trans*-(*Z*)-α-bisabolene epoxides (*X*) were added to Exp. 2 from September 10 through October 26, 2004 (see text for details). The prefix "*U*" indicates that the lures were unprotected from light. Bars for a species with different letters are significantly different ($P<0.05$)

As in Exp. 2, the addition of methyl 2,4,6-decatrienoates [in this experiment, the (*E*,*E*,*Z*)- and (*Z*,*E*,*Z*)-isomers] to methyl (*E*,*Z*)-2,4-decadienoate did not increase the number of *E. tristigmus* individuals caught relative to traps baited with methyl (*E*,*Z*)-2,4-decadienoate alone (Fig. 8b). In this experiment, the number of *E. tristigmus* females caught (121) was not significantly greater than the number of males captured (108). No *E. tristigmus* were caught at control traps.

Finally, the first captures of the BMSB, *H. halys*, were recorded in Beltsville, MD, during Exp. 4. Three fifth-instar *H. halys* nymphs were caught inside traps baited with methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate on August 15 and 18, and one adult *H. halys* male was captured inside a trap baited with methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate plus methyl (*E*,*Z*)-2,4-decadienoate on September 1, 2005. The cuticle of the adult male was soft and pale in coloration, suggesting it recently eclosed to adult.

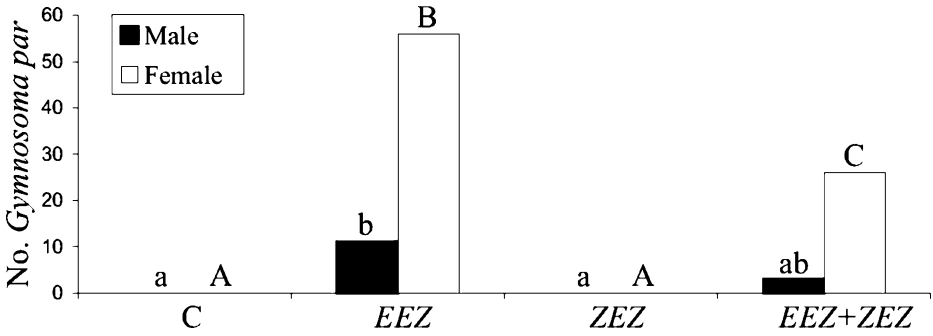

Fig. 7 The total number of *G. par* (Walker) caught in sticky traps baited with methyl (*E*,*E*,*Z*)- and/or (*Z*,*E*,*Z*)-2,4,6-decatrienoate (*EEZ* and *ZEZ*) from July 9 through October 15, 2004. Bars for a species with different letters are significantly different ($P<0.05$)

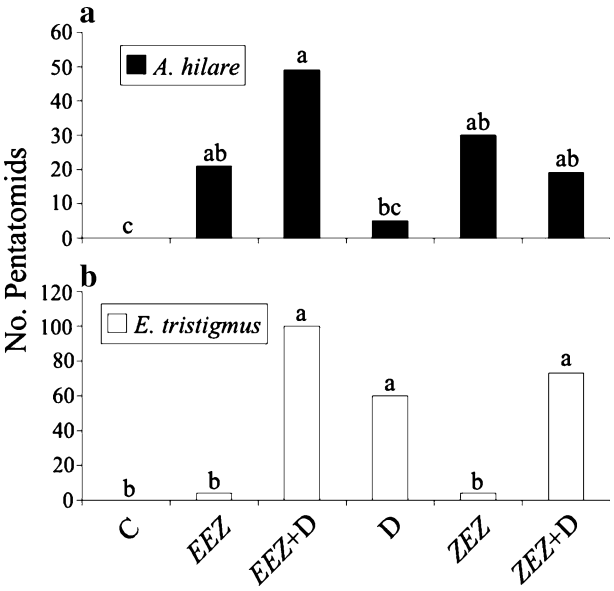

Fig. 8 The total number of pentatomids (adults and nymphs) of **a** the green stink bug, *A. hilare* (Say), and **b** the dusky stink bug, *E. tristigmus* (Say) caught in or around traps baited with lures containing methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate (*EEZ*), methyl (*Z*,*E*,*Z*)-2,4,6-decatrienoate (*ZEZ*), methyl (*E*,*Z*)-2,4-decadienoate (*D*), or the binary combinations *EEZ*+D or *ZEZ*+D from August 11 through October 19, 2005 (Exp. 4). Bars for a species with different letters are significantly different ($P<0.05$)

Discussion

Results presented herein, along with data from field tests conducted near Allentown, PA (Khrimian et al., 2006), verify that the BMSB, *H. halys* (Stål) (Pentatomidae) is, indeed, attracted to methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate (Tada et al., 2001a, b) and related geometric isomers. In addition, tests of synthetic pheromone for *T. custator accerra* McAtee show that the tachinid fly parasitoid, *E. flava* (Townsend), does use the pheromone of *Thyanta* as a host-finding kairomone. However, the most surprising result from our field research is the discovery that other native stink bugs and tachinids are also attracted to methyl 2,4,6-decatrienoates.

Two species, in particular, were significantly attracted to certain methyl 2,4,6-decatrienoates: the green stink bug, *A. hilare* (Say), and the tachinid fly, *G. par* (Walker). Each of these species is native to North America, yet what is known of their chemical ecology raises more questions than answers as to why they are attracted to methyl decatrienoates.

Gymnosoma spp. are known parasitoids of *Euschistus* stink bugs (Arnaud Jr., 1978; Aldrich, 1995) but do not normally parasitize *A. hilare* (see also: Eger and Ables, 1981; Jones et al., 1996). We found that *G. par* females are attracted to methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate, the methyl decatrienoate isomer seemingly most attractive to the BMSB, suggesting to us that this fly might be preadapted to recognize *H. halys* in the USA. In fact, field-collected *G. par* caged in the laboratory with *H. halys* adults did profusely oviposit on the bugs (exclusively underneath the wings) (Aldrich et al., 2006). However, examination of several hundred wild BMSB adults from Allentown failed to reveal any eggs underneath the wings of these bugs. On the other hand, two *T. pennipes* (F.) were reared from field-collected *H. halys* adults (Aldrich et al., 2006); *T. pennipes* is the only known tachinid parasitoid of *A. hilare* in North America (Arnaud Jr., 1978). While *G. par* was highly attracted to methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate, this fly was totally indifferent to the (*Z*,*E*,*Z*)-isomer. The fact that this abundant North American tachinid parasitoid of pentatomids is so

finely tuned to a compound yet to be found from any native heteropteran is probably an indication of our semiochemical ignorance; there must be other bugs in North America that produce methyl decatrienoates as part of their attractant pheromones.

A clue as to which pentatomid species might be producing methyl 2,4,6-decatrienoates as pheromone components comes from prey records of the solitary wasp, *A. occidentalis* Cresson (Sphecidae). Females of this sphecid use methyl (*E*,*Z*,*Z*)-2,4,6-decatrienoate as a kairomone to find *Thyanta* adults with which to provision their nests (Millar et al., 2001, and data presented herein). In addition to *Thyanta* spp., Evans (1957) lists *Hymenarcys nervosa* (Say) (Pentatomidae) as the most abundant prey of *A. occidentalis* in Indiana, and also recorded *B. calva* (Say) (Pentatomidae) as prey. Notably, in our 2004 test of synthetic *T. custator accerra* pheromone, more individuals of *B. dimidiata* (Say) were attracted than *Thyanta*, and one individual of *B. calva* was captured.

Why are nymphs and adults of the green stink bug, *A. hilare*, attracted to methyl 2,4,6-decatrienoates? Male-specific volatiles identified from *A. hilare* include straight-chain hydrocarbons, a cyclic sesquiterpene [(*Z*)-α-bisabolene], and *cis*- and *trans*-(*Z*)-α-bisabolene epoxides (Aldrich et al., 1989, 1993); compounds quite unlike methyl decatrienoates. McBrien et al. (2001) reinvestigated the suspected pheromone chemistry of *A. hilare*, demonstrating that females are significantly attracted to a blend of synthetic (*Z*)-α-bisabolene epoxides mimicking the natural blend, but methyl decatrienoates were not among the volatiles isolated from *A. hilare* in this study either, nor are there records of these types of methyl esters from plants. To our knowledge, the most closely related known phytochemicals are 2,4,6-decatrienoic acids from certain *Euphorbia* spp. (Warnaar, 1977, 1981), plants unlikely to be hosts of any of the stink bugs in question here (McPherson, 1982).

If the only natural sources of methyl decatrienoates are *Thyanta* and some other yet-to-be-discovered species of bugs, then one possible explanation for the observed attraction of *A. hilare* to these esters is that green stink bugs are cross-attracted to the pheromones of these other bugs. How plausible an explanation is this? Certainly the most clear-cut examples of heteropterans exploiting the signals of other species are cases involving predation, such as kairomonal attraction of predacious anthocorid bugs to sex pheromones of pine bast scales (Hemiptera: Matsucoccidae) (Mendel et al., 2004), and chemicals (Yasuda, 2000), or even vibrations (Pfannenstiel et al., 1995), associated with the prey of predacious pentatomids. A convincing case of cross-attraction between heteropterans within the same trophic level, however, has recently been reported by Endo et al. (2006). While investigating a complex of bugs that are pests of soybean in Japan, these authors found that the pentatomid, *Piezodorus hybneri* (Gmelin), is significantly attracted to a pheromone component of a competitor, *Riptortus clavatus* (Thunberg) (Heteroptera: Alydidae). These two species have no pheromone compounds in common, nor do soybean plants produce the cross-attractive compound. Endo et al. (2006) speculated that *P. hybneri* utilizes the aggregation pheromone of *R. clavatus* as a kairomone to search for food plants. In fact, the reported cross-attraction of *H. halys* to the pheromone of *P. stali* [i.e., methyl (*E*,*E*,*Z*)-2,4,6-decatrienoate] (Tada et al., 2001a, b) may be another example of such a kairomone.

Acrosternum hilare has a distinct preference for certain native hosts, mainly wild bushes and trees, and a succession of hosts appears to be necessary to sustain a population (Schoene, 1933). Cultivated crops are usually damaged only when the wild-host succession is broken. Given this phenology, it may be adaptive for green stink bug adults and nymphs to go to the pheromones of congeneric bugs in the habitat. The fact that pentatomid nymphs, even young nymphs, are often attracted to the pheromones of conspecific males (Aldrich, 1988a, 1995) supports the idea that pheromones may be associated with food because nymphs are obviously not seeking a mate.

Aside from finding food or a mate, another possible advantage of gregariousness for animals is defense, due to the so-called selfish herd effect, whereby the probability of an individual being attacked by a predator decreases (is diluted) the larger the group (Hamilton, 1971). The concept is relevant not just in cases of predation but also as a passive means of defense against parasites (Mooring and Hart, 1992) and parasitoids (Wcislo, 1984) and applies to mixed species aggregations as well (Hamilton, 1971; Watt and Chapman, 1998; Gibson et al., 2002; Pereira et al., 2004).

The extent to which tachinid parasitoids cue on heteropteran semiochemicals to find these hosts is striking (Aldrich, 1995; Aldrich and Zhang, 2002; Aldrich et al., 2006). Ironically, the stink gland secretions of stink bugs are, by and large, ineffective against tachinids, and the allomones of bugs are even occasionally usurped as kairomones by these flies (Aldrich, 1995). Early tests of the aggregation pheromone for the predatory spined soldier bug, *P. maculiventris* (Say) (Pentatomidae), demonstrated that the bugs avoid entering traps on which tachinid parasitoids are perched (Aldrich et al., 1984a). Thus, tachinids probably have been and continue to be a major selective agent of Heteroptera. Most tachinid parasitoids of Heteroptera belong to the subfamily Phasiinae, which lay a single macrotype egg on a host with only one tachinid larva able to develop per host. Phasiines do not scent-mark their hosts and seem unable to recognize the presence of other eggs on a bug (Stireman et al., 2006); therefore, when these flies are confined in cages with potential hosts, they usually oviposit repeatedly on the same bugs (Aldrich et al., 2006). It is unlikely that this is how phasiines behave in nature. One can imagine that these flies search for a potential host, oviposit on one host whether it is part of an aggregation or solitary, and then fly off to find another host patch. If this scenario is accurate, then the common gregarious behavior of bugs may represent a selfish herd passive defense against tachinid parasitism. Interestingly, mixed aggregations of *H. halys* and *A. hilare* nymphs have occasionally been seen in the field near Allentown, PA (Gary Bernon, USDA-APHIS, personal communication).

Despite the mystery of why various heteropterans and their parasitoids are attracted to methyl decatrienoates, the discovery that these compounds are attractive to economically important bugs may provide another useful semiochemical tool for monitoring and management (e.g., Cullen and Zalom, 2005). This is especially important now that there is a resurgence of problems with bugs because of their immunity to the Bt endotoxin in genetically modified crops (Millar et al., 2002).

Acknowledgements We thank T. J. Henry, Systematic Entomology Laboratory (SEL), USDA-ARS, Beltsville, MD, and David Rider, North Dakota State University, Fargo, for identification of pentatomid species, and Norman Woodley, SEL, for identification of tachinids. We are also grateful to Peter Shearer, Rutgers University, Agricultural Research & Extension Center, Bridgeton, NJ, for supplying *H. halys*, and to John Reese, Department of Entomology, Kansas State University, Manhattan, for helpful discussions and assistance with field work.

RAPID COMMUNICATION

Acetophenone as an Anti-attractant for the Western Pine Beetle, *Dendroctonus Brevicomis* LeConte (Coleoptera: Scolytidae)

Abstract Host location and colonization by bark beetles is dependent upon the relative and absolute amounts of attractant and antiattractant compounds available. Many investigations have lead to use of antiattractants for the management of these pests and have been especially focused on verbenone. However, recent studies have identified new anti-attractants for several species of bark beetles. We report results of recent investigations of the response of western pine beetle, *Dendroctonus brevicomis* LeConte, to two recently identified antiattractants, acetophenone, and fenchyl alcohol, with verbenone as a standard of comparison, in northern California. Release of both acetophenone and verbenone resulted in significantly lower trap catches of *D. brevicomis* in aggregation pheromone-baited traps, while fenchyl alcohol was inactive. Acetophenone was the only antiattractant that did not reduce numbers of the most abundant predator of *D. brevicomis*, *Temnochila chlorodia* (Mannerheim), responding to the attractant pheromone of its prey. Aggregation pheromone-baited traps with acetophenone also had the highest predator/prey ratio. Our results suggest that acetophenone may be part of the intra- and interspecific interactions among sympatric species of bark beetles and may have application in their control.

Introduction

The western pine beetle (WPB), *Dendroctonus brevicomis* LeConte (Coleoptera: Scolytidae), is indigenous to western conifer forests. Its hosts are ponderosa pine, *Pinus ponderosae* Lawson, and Coulter pine, *Pinus coulteri* D. Don. In order for WPB progeny to survive, the parent beetle population must kill the tree, so large numbers of beetles must aggregate in synchrony on a single host tree. Many species of bark beetles release aggregation pheromones that attract both mates and additional colonizers, thus enhancing their tree killing ability (Wood 1982). WPB releases *exo*-brevocomin ((+)-*exo*-7-ethyl-5-methyl-6,8-dioxabicyclo[3.2.1] octane), (−)-frontalin ((−)-1,5-dimethyl−6,8-dioxabicyclo [3.2.1]octane), and a host terpene, myrcene, which attracts large numbers of conspecifics during the aggregation phase of host colonization. In addition, some bark beetles, including WPB, produce antiaggregation pheromones that inhibit attraction of conspecifics to aggregation pheromones to optimize resource partitioning (Paine and Hanlon 1991).

Many investigations have led to the use of antiaggregation pheromones, such as verbenone, to prevent or minimize damage caused by beetle infestation (Borden 1996). Verbenone, an antiaggregation pheromone of several bark beetle species, was the focus of earlier studies with WPB (Paine and Hanlon 1991). Earlier studies investigated the inhibitory effect of verbenone in combination with semiochemicals produced by heterospecific bark beetles (Paine and Hanlon 1991; Bertram and Paine 1994a,b). Tests of verbenone to interrupt host colonization by WPB, in some cases, reduced trap catch, but in others were inconsistent in protecting individual trees (Paine and Hanlon 1991; Bertram and Paine 1994a,b).

Recent investigations identified previously unknown semiochemicals for several species of bark beetles (Pureswaran and Borden 2004; Sullivan 2005). Some of these semiochemicals are potential inhibitors of bark beetle attraction (Pureswaran and Borden 2004; Sullivan 2005). In the current study, we tested two of these recently identified antiattractant compounds—acetophenone and fenchyl alcohol. Our objective was to compare the inhibition of WPB response by these compounds relative to verbenone to its aggregation pheromone.

Methods and Materials

(*1S*)-(−)-Verbenone (chemical purity: ≥93%, enantiomeric purity ~97%) and two antiattractant compounds, acetophenone (chemical purity: ≥98%) and (*1R*)-(+)-fenchyl alcohol (chemical purity: ≥97%, enantiomeric purity ~97%), each combined with the aggregation pheromone of WPB, as well as WPB aggregation pheromone alone, were presented to WPB in a replicated test in a ponderosa pine forest managed by Hancock Forest Management, Siskyou County in northern California. All chemicals except for the aggregation pheromone were obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). The aggregation pheromone (racemic, chemical purity: >97%) was obtained from Phero Tech International, Inc. (Delta, British Columbia, Canada). All antiattractant compounds were released from 15-ml polyethylene bottles (Synergy Semiochemicals, Burnaby, British Columbia, Canada), each filled with 8 ml of one compound. The aggregation pheromone was released from membranes with bubble cap reservoirs. To ensure that the entire contents of each vial were exposed to the release surface, the bottles were squeezed until the liquid reached the shoulder, and then were tightly capped leaving the bottles slightly collapsed. Each bottle also contained 100 mg of the antioxidant BHT

(butylhydroxytoluene) (Sigma-Aldrich Chemical Co.). Approximate release rates of verbenone, fenchyl alcohol, and acetophenone were 2.5, 4.9, and 7.25 mg/d, respectively, at 15.1±4.3°C with a wind velocity of 16.2 km/hr±5.3 for at least 30 d in the field. The release rates of chemicals were determined by daily weight loss under the same conditions. The release rates of different compounds of WPB pheromone, frontalin, *exo*-brevicomin, and myrcene are 3.0, 3.0, and 18.0 mg/d at 24°C, respectively (data provided by Phero Tech International).

The experimental design consisted of six replications/treatment (six traps), completely randomized with repeated measurements of one data collection per week during 5 wk (30 counts/treatment samples for pheromone or pheromone with acetophenone; 29 counts for pheromone with verbenone or pheromone with fenchyl alcohol due to missing data for one trap on the third and second collection period, respectively); in some sampling occasions, the traps were rotated between sites. Release devices were suspended in the middle of flight intercept traps (Advanced Pheromone Technologies, Marylhurst, OR, USA). Traps were suspended from metal standards more than 2 m above ground and spaced at least 15 m from any other trap. An insecticidal strip (Hercon Environmental Co., Emigsville, PA, USA) was placed in each collection cup to prevent predation. Trapped beetles were collected every 7 d from June 21 to July 27, 2006. Beetles captured in each trap were identified, counted, and recorded; voucher specimens were stored at the USDA Forest Service Institute of Forest Genetics, Placerville, CA, USA, and the University of California, Berkeley.

Statistical Analyses Mean numbers of beetles per trap per sampling intervals (week) were analyzed with Poisson Regression Models for overdispersed Poisson distributed responses (counts) to address potential overdispersion arising from the repeated measurements (McCulloch and Searle 2001). This Poisson Regression model belongs to the family of the Mixed Generalized Linear Model (G LM). Model:

$$\text{Expected}\left[\text{count}_{i,j,\text{site}}|\varepsilon_{\text{site}}\right] = e^{\text{Treat}*\text{week}_{ij}+\varepsilon_{\text{site}}}$$

Where i=1,2,3,4 (four treatments) and j=1,2,3,4,5 (five weekly periods), ε is the overdispersion error due to the same site being used for measurements in different weeks (Julian days), "|" means "conditioned to", and "*" means "interaction".

The predator/prey ratio was estimated by using a similar model for the predator counts with the logarithm of number of prey as an offset:

$$\text{Expected}\left[\text{Predator count}_{i,j,\text{site}}|\varepsilon_{\text{site}}\right] = e^{\text{Treat}_i+\text{week}_j+\log\left(\text{Prey count}_{i,j,\text{site}}\right)+\varepsilon_{\text{site}}}$$

The generalized estimating equations (Liang and Zeger 1986) method was used to estimate the model's parameters with SAS (v. 9.1.3) GENMOD procedure, and the Wald chi-square test with the Bonferroni adjustment was used for multiple comparisons for an experiment-wise error rate of 0.05. The data per trap are not independent because the same site is measured during the five occasions (five sampling periods). The statistical analysis accounted for these repeated measurements. The analysis was done per week as is shown in the statistical model above. The counts for the whole period per trap were obtained by summing the estimated weekly counts.

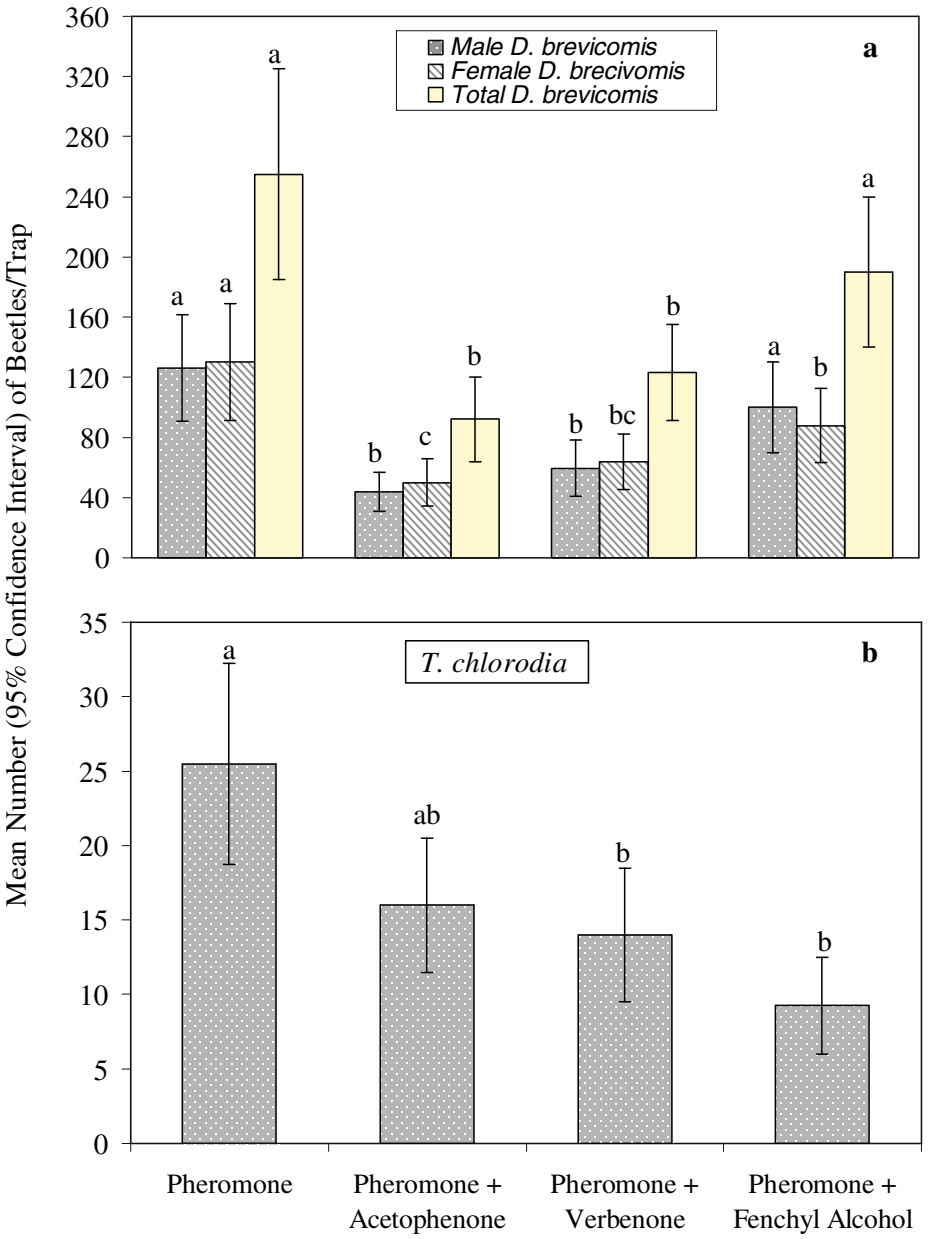

Fig. 1 Field responses of *Dendroctonus brevicomis* and *Temnochila chlorodia* to flight intercept traps baited with aggregation pheromone (P) of *D. brevicomis* alone or with acetophenone (A), verbenone (V), or fenchyl alcohol (F) in a ponderosa pine forest in Northern California. Data show mean numbers (95% lower and upper confidence interval) of beetles per trap summed over the sampling period (five sampling periods) for each treatment level from June 28 to July 27. There were a total of six traps/treatment (30 counts for P or P+A, 29 counts for P+V or P+F due to missing data for one trap on the third and second collection period, respectively). Means followed by the same letter are not significantly different from each other (P − values $< 0.05/6 = 0.008$, Bonferroni adjusted). The weekly mean counts per trap were estimated assuming the Generalized Linear Models (GLM) for overdispersed Poisson counts. **(a)** Mean numbers of males and females and total numbers of *D. brevicomis*. Note that intervals can overlap and still the treatment level can be significant as for the case F versus V. **(b)** Mean numbers of *T. chlorodia*

Results and Discussion

A total of 4,461 beetles representing two species were caught over the experimental period. The WPB was 91.3% of total catch, and the remaining 8.7% was the predator *Temnochila chlorodia* (Mannerheim) (Coleoptera: Trogositidae). The overall male/female ratio of *D. brevicomis* was 1.008.

We found significant treatment effects in the response of both WPB and *T. chlorodia* ($P-$ values $< 0.05/6 = 0.008$, Bonferroni adjusted). Both acetophenone and verbenone reduced the catch of WPB attracted to its aggregation pheromone, whereas fenchyl alcohol did not (Fig. 1a). Although the mean number of WPB caught in traps baited with the aggregation pheromone and acetophenone was about 30% lower than that in traps baited with the aggregation pheromone and verbenone, this difference was not significant. The sex ratio of WPB trapped by the aggregation pheromone was not altered by combination with any antiattractant compound except fenchyl alcohol (Fig. 1a), which significantly reduced the relative proportion of females trapped by the aggregation pheromone alone (M:F= 1.15:1).

Inhibition of the response of WPB to its aggregation pheromone by acetophenone is the first report for this species. Acetophenone has been shown to inhibit attraction of the southern pine beetle, *Dendroctonus frontalis* Zimmermann, and the female Douglas-fir beetle, *Dendroctonuspseudotsugae* Hopkins, to their aggregation pheromones in the field (Pureswaran and Borden 2004; Sullivan 2005).

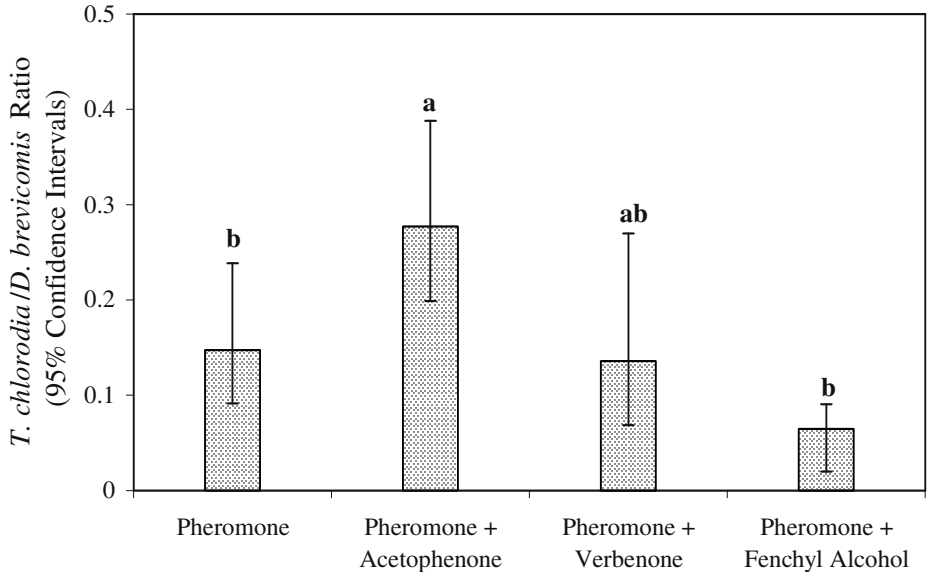

Fig. 2 Estimated mean and 95% confidence intervals of *T. chlorodia*/*D. brevicomis* ratio to flight intercept traps baited with aggregation pheromone (P) of *D. brevicomis* alone or with acetophenone (A), verbenone (V), or fenchyl alcohol (F) in a ponderosa pine forest in Northern California. Data show mean numbers (95% lower and upper confidence interval) of beetles per trap summed over the sampling period (five sampling periods) for each treatment level from June 28 to July 27. There were a total of six traps/treatment (30 counts for P or P+A, 29 counts for P+V or P+F due to missing data for one trap on the third and second collection period, respectively). Means followed by the same letter are not significantly different from each other ($P-$ values $< 0.05/6 = 0.008$, Bonferroni adjusted)

We do not know if WPB produces acetophenone, but it has been identified in volatiles from female *D. pseudotsugae* Hopkins, *Dendroctonus rufipennis* (Kirby), and *Dryocoetes confuses* Swaine; male *Taphrorychus bicolor* (Herbst); and both male and female *D. ponderosae* and *Ips pini* (Say) (references in Pureswaran et al. 2000). The inhibitory effect of acetophenone on WPB attraction suggests that either it is a part of the antiaggregation pheromone of WPB, as suggested for *D. ponderosae* (Pureswaran et al. 2000), or it is used to avoid competition with other bark beetle species. *Ips paraconfusus* Lanier, *I. Pini*, and *D. ponderosae* compete with WPB in the same host trees. Both *I. pini* and *D. ponderosae* produce and respond to acetophenone (Pureswaran et al. 2000). It has also been demonstrated that pheromones of competitors of WPB reduced trap catches of WPB responding to its pheromone (Wood 1982; Paine and Hanlon 1991; Bertram and Paine 1994a,b). Hence, production of acetophenone combined with aggregation pheromones of coinhabiting species may indicate unsuitable hosts for further colonization (Bertram and Paine 1994a,b; Pureswaran et al. 2000).

Catches of *T. chlorodia* were also altered by addition of antiattractants to the aggregation pheromone of WPB (Fig. 1b). Acetophenone was the only antiattractant that did not reduce numbers of *T. chlorodia* responding to the attractant pheromone of its prey. Moreover, the *T. chlorodia*/WPB ratio was highest for traps with acetophenone (0.28), which was 1.9 times higher than with the aggregation pheromone alone (0.15), 2.2 times higher than with verbenone (0.13), and 4.7 times higher than with fenchyl alcohol (0.06) (Fig. 2). Likewise, Sullivan (2005) found no difference in attraction of predators of *D. frontalis* to its pheromone when released with various antiattractants produced by *D. frontalis*, including acetophenone, in southern US. This result has important implication for the pest management of WPB. Although both acetophenone and verbenone reduced the catches of WPB, they did not completely stop WPB from reaching traps baited with its aggregation pheromone. Hence, arrival of higher number of predators may help to reduce WPB population in WPB attacked trees. However, the relationship between trapping the WPB and subsequent tree mortality needs to be evaluated with respect to the impact on predator populations.

For three reasons, our results suggest that acetophenone has promise for pest management strategies against the WPB. First, among the compounds we tested, acetophenone appears to be at least as effective as verbenone in inhibiting the response of WPB. Second, acetophenone was the only compound tested that did not interfere with the attraction of predators, and it produced the highest predator/prey ratio of the four treatments tested. Third, acetophenone is currently much more economical than verbenone. The cost for 1 kg of acetophenone and verbenone are $34 and $400, respectively, as of September, 2006 (Sigma-Aldrich Chemical Co.). This price difference may allow acetophenone to be used for large-scale experiments. Our study is the first step in a series of field bioassays for demonstrating the antiattractant activity of acetophenone for WPB. Before the effectiveness and utility of a potential treatment can be determined, further experiments are needed to determine the threshold ratio of aggregation pheromone to acetophenone and verbenone.

Acknowledgements We thank Jeffrey Webster (Total Forestry, Redding, CA), Fabian Uzoh (USDA Forest Service, Redding, CA), and Emmanuel Uzoh (USDA Forest Service, Redding, CA, volunteer) for valuable assistance with installation and maintenance of the study. We thank James Wolter (Hancock Forest Management) for permission to conduct this study on private lands. The authors are also thankful to three anonymous reviewers and an associate editor (Dr. Monika Hilker) for their help on the previous draft of this manuscript.

Abstract Cuticular hydrocarbons play a significant role in the regulation of cuticular permeability and also in the chemical communication of insects. In the parasitoid *Lariophagus distinguendus* (Hymenoptera: Pteromalidae), male courtship behavior is mediated by a female-produced sex pheromone. Previous studies have shown that the chemicals involved are already present in the pupal stage of both males and females. However, pheromonal activity in males decreases shortly after emergence. This pheromonal deactivation occurs only in living males, suggesting an active process rather than simple evaporation of bioactive compounds. Here, we present evidence that the sex pheromone of *L. distinguendus* is composed of a series of cuticular hydrocarbons. Filter paper disks treated with nonpolar fractions of cuticular extracts of freshly emerged males and females, 72-hr-old females, and yellowish pupae caused arrestment and stimulated key elements of courtship behavior in males, whereas fractions of 72-hr-old males did not. Sixty-four hydrocarbons with chain length between C_{25} and C_{37} were identified in the fractions by gas chromatography-mass spectrometry (GC-MS). Methyl-branched alkanes with one to four methyl groups were major components, along with traces of *n*-alkanes and monoalkenes. Principal component analysis, based on the relative amounts of the compounds, revealed that cuticular hydrocarbon composition differed among all five groups. By using partial least squares-discriminant analysis, we determined a series of components that differentiate bioactive and bioinactive hydrocarbon profiles, and may be responsible for pheromonal activity of hydrocarbon fractions in *L. distinguendus*.

Introduction

Hydrocarbons are found on the cuticle of almost all insects. In addition to their primary function as a water loss barrier (Nelson and Blomquist, 1995; Gibbs, 1998), cuticular hydrocarbons are known to be involved in semiochemical communication of insects (Howard, 1993; Blomquist et al., 1993, 1998; Howard and Blomquist, 2005). In social insects, cuticular hydrocarbons contribute to the recognition of species, caste, and nestmates (Blomquist et al., 1998), and may facilitate orientation toward the nesting site (Steinmetz et al., 2003). Furthermore, cuticular hydrocarbons are involved in short-range sexual communication of insects, enabling recognition of sexual mates, causing aggregation, or acting as a courtship inhibitor to reduce the attractiveness of mated females (Blomquist et al., 1993; Ferveur, 2005).

Compared to other insect taxa, there are relatively few studies dealing with the composition of cuticular hydrocarbons with respect to their potential role as semiochemicals in parasitic wasps. A number of investigations have focused on comparisons of qualitative and quantitative differences in hydrocarbon profiles of parasitoids with respect to species, sex, or the host used for development (Howard, 1992, 2001; Howard and Infante, 1996). However, few studies have included bioassays demonstrating behavioral activity of synthetic hydrocarbons or hydrocarbon fractions. In *Cardiochiles nigriceps* (Braconidae), elements of male courtship behavior are elicited by a series of female-specific alkadienes (Syvertsen et al., 1995). Recent studies on the pteromalids *Roptrocerus xylophagorum* (Sullivan, 2002), *L. distinguendus* (Steiner et al., 2005), and *Nasonia vitripennis* (Steiner et al., 2006) have demonstrated that nonpolar hydrocarbon fractions from females arrest males and elicit courtship behavior. Interestingly, in *L. distinguendus*, pupae of both sexes also elicited male courtship behavior. However, 32 hr after emergence, males became behaviorally inactive to male conspecifics. To date, it is not known which components contribute to the biological activity of extracts in Pteromalidae.

Cuticular hydrocarbon profiles of insects are generally complex, often consisting of more than a hundred components, mainly saturated and unsaturated (one to three double bonds) straight chain and methyl-branched (one to four branches) alkanes (Lockey, 1988). Studies on social insects have shown that subtle quantitative differences in cuticular hydrocarbon profiles can be detected by analyzing chemical data with multivariate statistical methods. By this approach, cuticular hydrocarbon profiles of social insects have been shown to be species- (e.g., Kaib et al., 1991; Page et al., 2002), caste- (e.g., Bagnères et al., 1990; Klochkov et al., 2005), and colony-specific (e.g., Butts et al., 1995; Lorenzi et al., 1997).

In the present study, we investigated the role of hydrocarbons as a short-range sex pheromone in *L. distinguendus* by combining chemical analyses and behavioral bioassays. First, we showed that hydrocarbon fractions from females, as well as from freshly emerged males and pupae of either sex, can mediate male courtship behavior. Second, we compared the composition of behaviorally active hexane fractions with inactive ones from older males by principal component analysis (PCA) and partial least squares-discriminant analysis (PLS-DA) (Wold et al., 1989). The latter method was used to characterize chemical components that contribute strongly to the differentiation of active and inactive hydrocarbon profiles. The results are discussed with respect to putative function of these chemicals as constituents of the courtship pheromone of *L. distinguendus*.

Methods and Materials

Insects Parasitoids were reared on larvae of the granary weevil, *Sitophilus granarius*, as described by Steidle and Schöller (1997), at 25°C, 60% RH, and a photoperiod of 16:8

(L/D). To obtain naive parasitoids, single grains containing parasitoids about to emerge were transferred to 1.5-ml microcentrifuge tubes (Sarstedt, Nümbrecht, Germany) and kept under rearing conditions. Emerging parasitoids were held in single-sex groups of 10 individuals, in Petri dishes lined with moistened filter paper, until used in the experiment.

General Procedures for Bioassay The experiment was conducted in a bioassay chamber (10 mm diameter×3 mm height) as described elsewhere (Ruther et al., 2000). Behavioral parameters were observed under a stereo microscope, with illumination by a microscope light, and recorded by using the computer software The Observer 3.0 (Noldus Information Technology, Wageningen, The Netherlands). Males were tested 2–3 d after emergence. One hour before being used in the bioassay, parasitoids were placed individually in micro-centrifuge tubes and kept at ambient temperature. The following behavioral parameters were recorded: (1) Arrestment time, the time males stayed on the sample, (2) antennation time, the time males explored the sample by regular, alternating movements of the antennae, and (3) wing fanning behavior, characteristic high-frequency wing fanning shown by males in the presence of the sex pheromone (Ruther et al., 2000).

Preparation of Hydrocarbon Fractions Batches of 10 individuals each of: (1) freshly emerged females, (2) freshly emerged males, (3) 72-hr-old females, (4) 72-hr-old males, and (5) yellowish pupae from *L. distinguendus* were extracted for 4 d with 60 μl dichloromethane at room temperature. Resulting extracts were concentrated under a gentle stream of nitrogen to 15 μl, applied to a 25-mg silica gel cartridge for solid phase extraction (IST, Mid-Glamorgan, UK) and eluted with 100 μl of hexane. The volume of each hydrocarbon fraction was concentrated under nitrogen to 20 μl (0.5 individual equivalent per microliter) and stored at −80°C until used for bioassay and chemical analysis.

Bioassay: Activity of Hydrocarbon Fractions The behavioral responses of *L. distinguendus* males to filter paper disks (5 mm diameter) treated with four individual equivalents of the five different hexane fraction types (see above) was investigated. After leaving the solvent to evaporate for 15 min, single paper disks were offered to a male in the bioassay chamber, and arrestment time, antennation time, and wing-fanning behavior to the paper disks were recorded over 5 min. For the control, filter paper disks were treated with solvent. Each wasp was tested only once. Males that did not respond to the filter paper disk by wing-fanning behavior were released into another bioassay chamber containing an unmated *L. distinguendus* female. Males that did not show wing fanning in this control test were discarded from the data set. After five parasitoids had been tested, the paper disk was renewed. The bioassay chamber was cleaned regularly with ethanol and deionized water to remove contamination by the walking males. Ten parasitoids were tested to each treatment.

Chemical Analysis Hydrocarbon fractions (N=10 for adults, N=5 for pupae) were analyzed by gas chromatography-mass spectrometry (GC-MS) on a Fisons GC 8060 equipped with a 30 m×0.32 mm DB-5ms fused silica column (film thickness 0.25 μm) and connected to a Fisons MD 800 quadrupole MS (Thermo Finnigan, Egelsbach, Germany). Helium was used as carrier gas, with an inlet pressure of 10 kPa. The temperature program was started at 150°C, raised by 2°C/min to a final temperature of 280°C, and then held for 30 min.

One microliter of each hexane fraction, representing 0.5 of an individual equivalent, was injected together with 25 ng of tetracosane as an internal standard. Relative retention indices (LRI) of methyl-branched and unsaturated hydrocarbons were estimated by coinjection of straight-chain hydrocarbons. Methyl-branched hydrocarbons were identified

by diagnostic ions resulting from the favored fragmentation at the branching points (Lockey, 1988; Nelson, 1993) and by comparing LRI values with literature data (Carlson et al., 1998). Double bond position was determined by iodine-catalyzed methylthiolation using dimethyl disulfide (Francis and Velant, 1981; Howard, 1993). Peak areas for each compound were calculated and related to total peak area for each run.

Statistical Analysis Statistical analysis for the behavioral experiment was performed with the software package Statistica release 4.5 (StatSoft, Tulsa, OK, USA). Arrestment time and antennation time of males on filter paper disks treated with hexane fractions or solvent were analyzed by Mann–Whitney *U* test. Numbers of males responding to the paper disks with wing-fanning behavior were analyzed by a 2×2 Chi^2 test.

The quantitative composition of the five different hydrocarbon fraction types was evaluated by PCA and PLS-DA by using the software program SIMCA-P 10.5 (Umetrics AB, Umeå, Sweden) (Wold et al., 1989; Eriksson et al., 2001). PCA and PLS-DA were conducted as described in detail by Mumm et al. (2004) to extract and display the systematic variation in the data set consisting of 48 different hydrocarbon peaks (Table 1) (Eriksson et al., 2001). In PCA, so-called "scores" are obtained by projecting data observations onto model planes, which are defined by the extracted principal components.

Raw data (integrated peak areas) were normalized, i.e., peak areas of all analyzed compounds (*X* variables) were summed and the relative amount of each variable was calculated. The normalized data were transformed to log (X+0.00001). The constant 0.00001 was added to provide nondetectable components with a small nonzero value (Sjödin et al., 1989). Transformed variables were then mean-centered, Pareto-scaled, and represented as a matrix X. Pareto scaling gives each variable a variance equal to its standard deviation by dividing by the square root of the standard deviation of each column (Eriksson et al., 2001). The ellipse shown in score plots defines the Hotelling's T^2 confidence region (95%). The number of significant principal components was determined by cross-validation (Wold et al., 1989; Eriksson et al., 2001).

In PLS-DA, the data set is modeled in a way similar to PCA, but in combination with a discriminant analysis. The objective of PLS-DA is to find a model that discriminates the *X* data, according to pheromone activity, as well as possible (Eriksson et al., 2001). In contrast to PCA, PLS-DA is a supervised technique, so class memberships of the observations need to be predefined. Therefore, an additional Y matrix was made up with G columns containing the values 1 and 0 as dummy variables for either behaviorally active group or nonactive parasitoid group, respectively. In addition, we calculated the variable importance in the projection (VIP), which is a numerical value describing the importance of the *X* variables, both for the *X* and the *Y* parts (Wold et al., 1993, 2001). Variables with VIP values larger than 1 are most influential for the model (Eriksson et al., 2001; Paolucci et al., 2004).

Results

Bioassay: Activity of Hydrocarbon Fractions Hydrocarbon fractions from freshly emerged males and females, and those from 72-hr-old females and pupae, caused arrestment and stimulated wing fanning in responding males when compared to the solvent control (Fig. 1a–c). In some cases, even more complex elements of male courtship behavior, such as antennal stroking and copulation attempts, were observed during the test period (data not

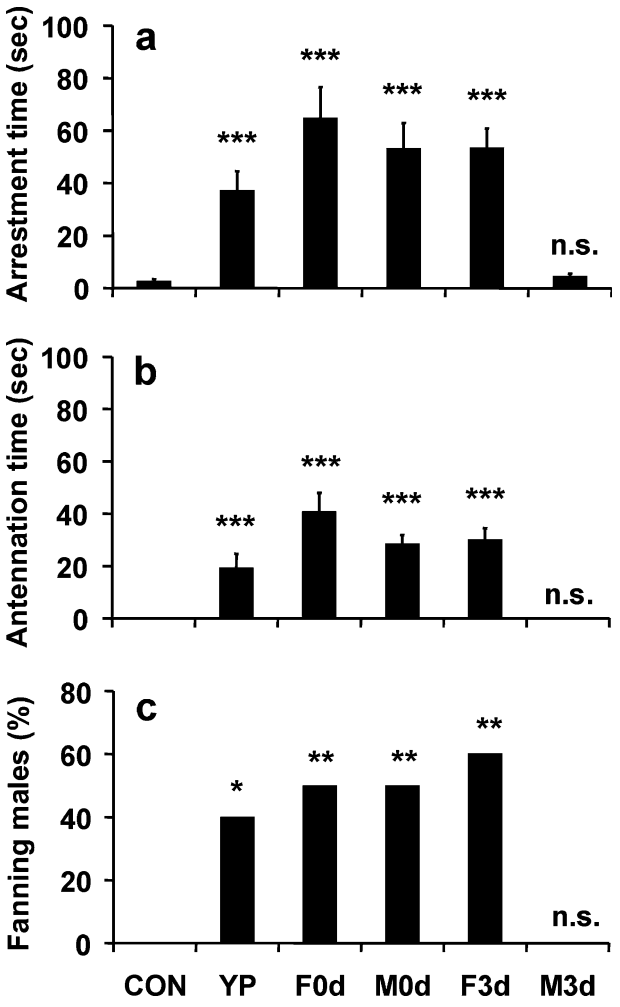

Fig. 1 Response of *L. distinguendus* males to filter paper disks treated with hexane fractions of cuticle extracts from freshly emerged females (F0d) and males (M0d), 72-hr-old females (F3d) and males (M3d), yellowish pupae (YP), and solvent control (CON). (a) Mean arrestment time (±SE), (b) mean antennation time (±SE), and (c) percentages of males showing wing-fanning behavior. Asterisks indicate significant preferences for fractions when compared to control (***$P<0.001$, **$P<0.01$, *$P<0.05$; n.s.=not significant). Mean arrestment times and antennation times were compared by Mann–Whitney *U* tests; wing-fanning behavior was analyzed by 2×2 chi-square tests ($N=10$)

shown). In contrast, males did not respond to hydrocarbon fractions from 72-hr-old males or to control paper disks.

Chemical and Statistical Analysis The 64 compounds identified in the hexane fractions were exclusively cuticular hydrocarbons with chain lengths between 25 and 37 carbon units (Table 1). Hydrocarbons of *L. distinguendus* were comprised of homologous series of *n*-alkanes (C_{25}–C_{33}), monomethyl alkanes (19-, 17-, 15-, 13-, 11-, 7-, 3-methyl), dimethyl alkanes (4,8-, 3,7-, and 5,9-dimethyl), trimethyl alkanes (3,7,11-trimethyl), tetramethyl alkanes (3,7,11,15-tetramethyl), and monoenes with double bonds at position 9 or 7. Additionally, squalene was found as a trace component in all life stages of both sexes. Hydrocarbon profiles were dominated by methyl-branched alkanes with odd carbon chains. The most prominent compounds were 3,7,11,15-TetraMeC_{33}, 11,21-DiMeC_{33}, and 13,17-DiMeC_{35}. Fractions that stimulated male courtship in bioassays showed quantitative but no qualitative differences. In behaviorally inactive fractions of 72-hr-old males, however, a series of hydrocarbons present in the active fractions was missing (Fig. 2).

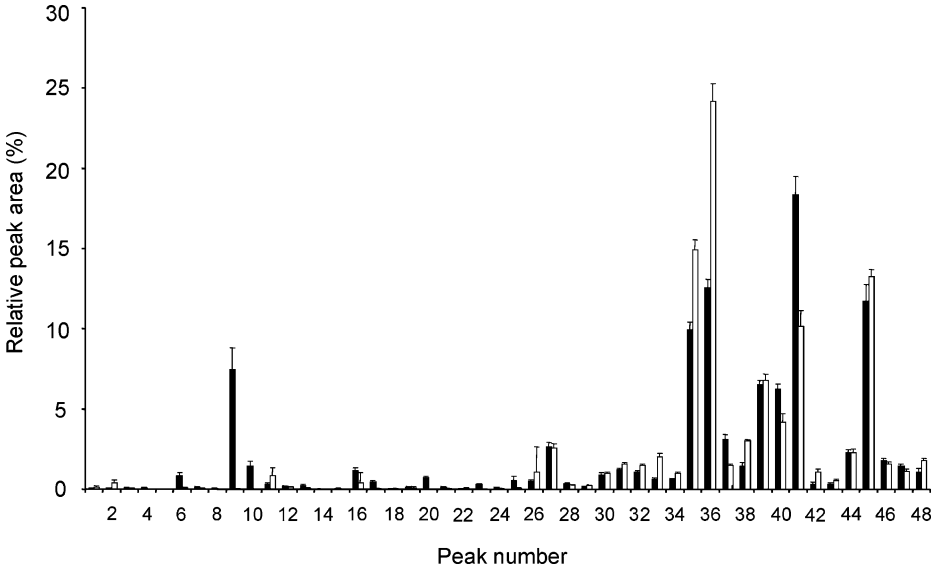

Fig. 2 Relative peak areas of cuticular hydrocarbons from freshly emerged *L. distinguendus* females (black bars; highest bioactivity) and 72-hr-old males (white bars, no bioactivity). Peak numbers correspond to those in Table 1

A PCA, based on relative peak areas found in the five different types of hydrocarbon fractions, was conducted. In this model, four principal components were extracted, explaining a total variation (R^2X) of 79%. A score plot of the first two principle components (PCs) showed that the cuticular hydrocarbon composition was different among all groups (Fig. 3).

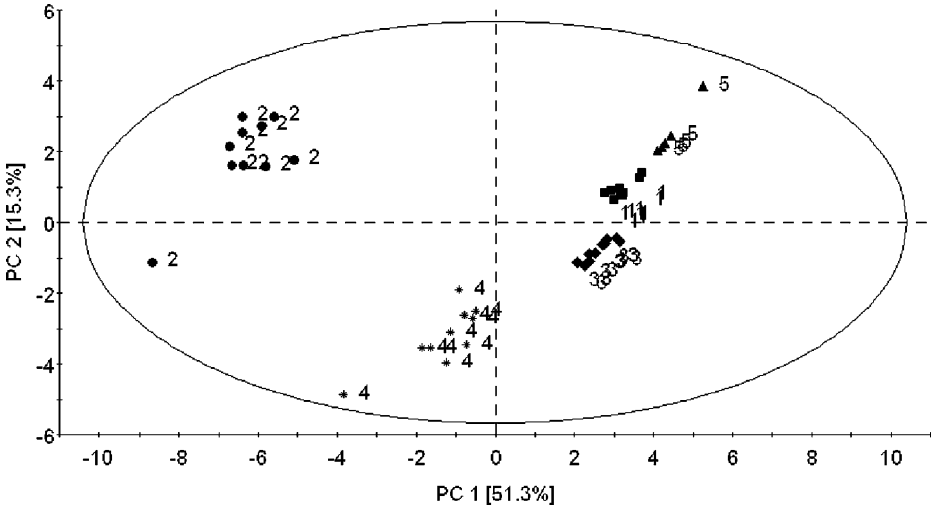

Fig. 3 Analysis of the cuticular hydrocarbon profiles from different *L. distinguendus* life stages. Score plot from principal component analysis (PCA) based on relative amounts of all analyzed hydrocarbons shown in Table 1; 66.5% of the variance in the data is explained by the two first significant principal components, as judged by cross-validation. The ellipse shown in the score plot defines the Hotelling's T^2 confidence interval (95%). 1=freshly emerged males; 2=72-hr-old males; 3=freshly emerged females; 4=72-hr-old females; 5=yellowish pupae. Data were subjected to log-transformation, mean centering, and Pareto scaling

The samples of 72-hr-old male parasitoids were dissimilar to all other samples, as indicated by the projection on the left hand side of the plot. The first PC mainly divided samples of different age, whereas the second PC tended to separate gender of adult parasitoids.

To elucidate which chemical compounds may be responsible for pheromonal activity a PLS-DA was performed. Two parasitoid classes were constructed based on pheromonal activity in the bioassays. Hydrocarbon fractions of freshly emerged males, freshly emerged females, 72-hr-old females, and pupae were combined in one class, and 72-hr-old males represented the second. PLS-DA resulted in a model with three significant discriminant components with R^2X of 70.9%, R^2Y of 99.5%, and Q^2Y of 98.7%. Q^2Y denotes the predictive power of the model, i.e., how class membership can be predicted by the model. The PLS score plot showed that the hydrocarbon fractions of 72-hr-old male parasitoids, which are not behaviorally active, are separated from the active groups (Fig. 4a). The corresponding loading plot depicts which chemical variables contribute strongly to separation of classes. Variables projected close to the dummy variables Y (shown as active and not active) contribute strongly to class separation, and thus have a high discriminatory power (Fig. 4b). A more quantitative way to estimate variable influence is described by the VIP-parameter. Chemical variables most important for resolving behaviorally active parasitoid groups have VIP-parameter values above 1 (Eriksson et al., 2001). Compounds showing VIP-parameter > 1 are, in descending order, peak numbers 10, 20, 23, 4, 14, 9, 17, 15 (data not shown). These compounds are marked with an asterisk in Fig. 4b.

Our PLS-DA model resulted in three significant PLS components. However, with G=2 well-separated classes one expects G - 1 significant PLS components (Eriksson et al., 2004); more components can indicate presence of subclusters. In our model, the higher number of expected components was presumably caused by the samples from the 72-hr-old females. The hydrocarbon composition of these samples was slightly different from the composition of the freshly emerged parasitoids and pupae. This might be ascribed to the age of the parasitoids, which apparently influenced the composition of hydrocarbons (Figs. 3 and 4a).

Discussion

This study reports the characterization of individual cuticular hydrocarbons with respect to their potential role as a short-range sex pheromone in *L. distinguendus*. Behavioral experiments that used hydrocarbon fractions from different life stages demonstrated pheromonal activity from females and from freshly emerged males and immature stages of both sexes. In contrast, there was no pheromonal activity from extracts of 72-hr-old males. Chemical analysis by GC-MS revealed qualitative and quantitative differences in the hydrocarbon profiles of behaviorally active and inactive fractions of *L. distinguendus*. PLS-DA was applied to assess which hydrocarbons are of particular importance in separating the different life stages by pheromone activity. Methyl-branched alkanes (3-MeC27, 3,7-DiMeC27, 4,8-DiMeC28, 3-MeC29, 3,7-DiMeC29, and 13-MeC29) had the strongest impact in the discriminant analysis. However, some alkenes (C27:1(9), C29:1 (7)) also had a high discriminating power. Apart from 3-MeC27, all chemicals that have been found to possess high discriminating power are minor components of the bioactive hydrocarbon profiles. Some of these compounds were totally absent in the profiles of (inactive) extracts from 72-hr-old males (Table 1, Fig. 2) and thus are good candidates for

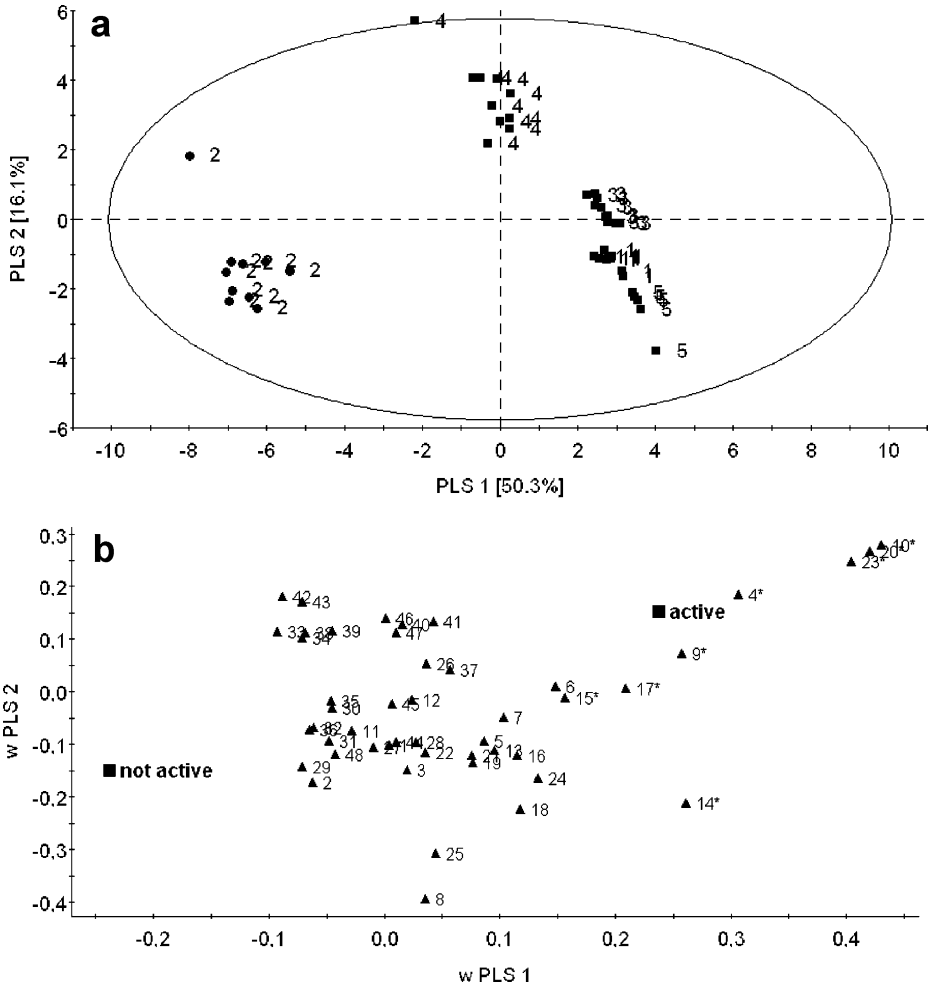

Fig. 4 Analysis of the cuticular hydrocarbon profiles from different *L. distinguendus* life stages. (a) Score plot and (b) loading plot from partial least squares-discriminant analysis (PLS-DA) based on relative amounts of all analyzed hydrocarbons shown in Table 1. A total of 66.4% of the variance of the *X* variables and 98.5% of the variance of the dummy variable *Y* is explained by the two significant principal components, as judged by cross-validation. *Y* variables are shown as "active" or "not active". 1=freshly emerged males; 2=72-hr-old males; 3=freshly emerged females; 4=72-hr-old females; 5=yellowish pupae; box=no pheromone activity; dot=pheromone activity. Data were subjected to log-transformation, mean centering, and Pareto scaling

mediating pheromone activity in *L. distinguendus*. In recent years, the number of studies on the role of cuticular hydrocarbons as insect semiochemicals has grown immensely (reviewed by Howard and Blomquist, 2005). Evidence is increasing that cuticular hydrocarbons play a general role as courtship pheromones in parasitoids, by mediating arrestment and other, more complex behavioral elements. However, few studies have identified which cuticular hydrocarbons are bioactive. Syvertsen et al. (1995) reported a series of female-specific C_{25}–C_{35} (*Z*,*Z*)-alkadienes with pheromonal properties in the braconid wasp *Cardiochiles nigriceps*. In the ichneumonid parasitoid *Eriborus terebrans*,

Shu and Jones (1993) reported a synergism between a polar female-derived sex pheromone and nonpolar components, most probably cuticular hydrocarbons. Apart from *L. distinguendus*, evidence for the function of cuticular hydrocarbons as courtship pheromones has been provided in two other pteromalids. Sullivan (2002) identified 28 compounds, consisting of aliphatic and methyl-branched alkanes with up to two methyl groups, in female extracts of *Roptrocerus xylophagorum* that correlated with the male response. Steiner et al. (2006) found numerous gender-related differences in *N. vitripennis* when comparing the composition of bioactive hydrocarbon fractions from females with inactive ones from males.

Our bioassays with hydrocarbon fractions from different life stages support recent investigations showing that *L. distinguendus* produces sex pheromone during pupal development (Steiner et al., 2005). The authors demonstrated that searching *L. distinguendus* males were arrested on parasitized grains containing females about to emerge. A similar phenomenon has been reported in *Anisopteromalus calandrae* (Pteromalidae) (Yoshida, 1978) and *Apanteles glomeratus* (Braconidae) (Tagawa, 1977). This pre-emergence pheromone release may increase the chances of females being inseminated before leaving the emergence site to search for hosts.

Interestingly, bioactive hydrocarbons are also present in developing and newly emerged males of *L. distinguendus*. After emergence, males become less bioactive within 32 hr, suggesting the production and/or degradation of the bioactive hydrocarbons is regulated differently from that in female parasitoids, which remain bioactive to courting males. The mechanism of this deactivation is not yet understood. However, we demonstrated that only living males lose bioactivity; dead males stored under the same conditions had bioactivity for several days. This suggests that the loss of pheromonal activity in males is caused by an active process rather than simple evaporation of the bioactive compounds. This may be achieved by selective metabolism or translocation of individual hydrocarbons from the cuticle to inner regions of the insect. In termites, for example, radiolabeling experiments have demonstrated that topically applied hydrocarbons are transported to the hemolymph by the lipid carrier protein lipophorin (Sevala et al., 2000).

Developing *L. distinguendus* males may benefit from possessing the pheromone. Steiner et al. (2005) showed that searching males are unable to distinguish between grains containing female or male conspecifics that are about to emerge. They suggested that developing males inside the grains might fool their already emerged competitors by distracting them away from searching for actual females. Another parasitoid species in which young males elicit courtship behavior in male conspecifics is the ichneumonid *Itoplectis conquisitor*. Robacker et al. (1976) demonstrated that extracts of both freshly emerged males and females elicit sexual behavior in older males. However, bioactive constituents of this multicomponent pheromone are terpene aldehydes rather than hydrocarbons (Robacker and Hendry, 1977).

By applying discriminant analysis to the hydrocarbon composition of parasitic Hymenoptera, we identified a set of compounds that allow discrimation of bioactive from bio-inactive life stages and which may be responsible for pheromonal activity in *L. distinguendus*. As our findings are based on mathematical modeling, future studies will focus on behavioral experiments using synthetic reference compounds to ascertain whether these hydrocarbons function as courtship pheromone in *L. distinguendus*.

Abstract The grass webworm *Herpetogramma licarsisalis* (Lepidoptera: Crambidae), which has recently established in pasture in Northland, New Zealand, is an important pest of many tropical and subtropical grasses. Two pheromone components, (*Z*)-11-hexadecen-1-yl acetate (*Z*11–16:Ac) and (11*Z*,13*E*)-hexadecadien-1-yl acetate (*Z*11,*E*13–16:Ac), were identified in pheromone gland extracts of female moths by gas chromatography (GC), GC-electroantennographic detection, and GC-mass spectrometry in conjunction with micro-chemical tests (dimethyldisulfide and 4-methyl-1,2,4-triazoline-3,5-dione derivatizations). *Z*11,*E*13–16:Ac and its geometric isomer (11*E*,13*Z*)-hexadecadien-1-yl acetate (*E*11,*Z*13–16:Ac) were synthesized via stereoselective Wittig reactions, and the identity of the diene present in the pheromone glands was confirmed to be *Z*11,*E*13–16:Ac. Field bioassays at Indooroopilly in Brisbane, Australia, established that *Z*11,*E*13–16:Ac was necessary and sufficient for attraction of male grass webworm moths and that the corresponding alcohol, (11*Z*,13*E*)-hexadecadien-1-ol (*Z*11,*E*13–16:OH), had a strong inhibitory effect on trap catches at the ratios tested. When mixed with *Z*11,*E*13–16:Ac in various ratios, *Z*11–16:Ac had no effect on the attractiveness of lures.

Introduction

The grass webworm *Herpetogramma licarsisalis* (Walker, 1859) (Lepidoptera: Crambidae) is an important pest of many tropical and subtropical grasses used for pasture and ornamental turf. *H. licarsisalis* is widely distributed globally as it is present in central Africa, Sierra Leone, Egypt, Saudi Arabia, India, Japan, Southeast Asia, Hawaii, and northern Australia (Tashiro, 1976; Common, 1990; Goater and Knill-Jones, 1999). Infestations have also been reported from Spain and Portugal, and the species has recently been recorded in Britain and Sweden (Goater and Knill-Jones, 1999; Svensson, 2003).

In 1999, *H. licarsisalis* larvae were confirmed in kikuyu (*Pennisetum clandestinum* Hochst. Ex Chiov. South) dairy pasture on the Aupouri Peninsula in Northland, New Zealand (Hardwick et al., 2000). During the outbreak, densities of up to 1,500 caterpillars per square meter were recorded that were associated with significant damage to kikuyu swards (S. Hardwick, personal communication). Despite the fact that the infestation was considered to be at the margins of the moth's climatic and geographical range (Hardwick et al., 2000; Willoughby and Barns, 2002; Jensen and Cameron, 2004), low-density grass webworm populations still persist on the Aupouri Peninsula.

Our objective was to identify the sex pheromone of *H. licarsisalis* to use as a monitoring tool of the existing populations for deployment in delimitation surveys and for collection of phenological data for pest management. A pheromone attractant would also be useful as a basis of an early warning system for any future outbreaks in the Northland area, including the detection of new incursions from the east coast of Australia (Fox, 1978).

To date, sex pheromone attractants for more than 40 crambid moth species have been identified (El-Sayed, 2006), but none is known from the genus *Herpetogramma*. We report in this study the identification of two compounds in pheromone gland extracts of *H. licarsisalis* and the evaluation of their biological activity in a series of field bioassays in Queensland, Australia.

Methods and Materials

Insects Approximately 50 *H. licarsisalis* pupae were obtained from AgResearch, Ruakura (see Jensen and Cameron, 2004 for a review). A colony was established at HortResearch, Lincoln, and maintained for five generations at 22°C and 60% relative humidity. Freshly emerged adults were placed in 400×600 mm polyethylene bags (one to two males and one to two females per bag). Each of the bags was supported by a stainless steel wire frame. Each bag contained six 'Pioneer' hybrid maize (*Zea mays* ssp. *mays*) seedlings on which female moths readily deposited egg batches. Maize leaves infested with egg batches were collected daily and placed into 680 ml plastic containers (Huhtamaki Henderson Ltd., Auckland, NZ).

After eclosion, groups of ca. 10 early-instar larvae were transferred to additional plastic containers to avoid cannibalism. The larvae were supplied with fresh maize leaves as required. Pupae were collected and held individually until adult emergence in 35 ml plastic containers (Lily® portion cups with lids; Huhtamaki Henderson Ltd.). The antennae of males were used for coupled gas chromatographic-electroantennographic detection (GC-EAD),

whereas females had their pheromone glands excised and extracted for analysis by GC-EAD, GC, and GC-mass spectrometry (MS).

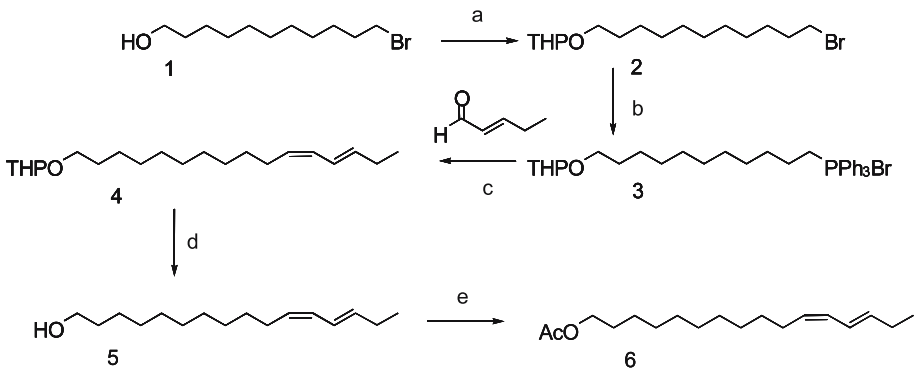
Pheromone Gland Extraction and Analyses Pheromone glands were removed from actively calling 24- to 48-hr-old female *H. licarsisalis* during the third and fourth hours of the scotophase. Excised glands were extracted in 20–40 μl of *n*-hexane for 5 min. The resulting supernatant was stored at −20°C until analysis. For quantitative analysis, the pheromone glands of 10 48-hr-old females were extracted with a 40-μl aliquot of *n*-hexane containing 4 ng of tetracosane as an internal standard. Two pheromone gland extracts were also derivatized, with either 4-methyl-1,2,4-triazoline-3,5-dione (MTAD; Sigma-Aldrich, NSW, Australia) or dimethyldisulfide (DMDS; Merck, Darmstadt, Germany), to determine the double-bond positions of the two MS-detectable compounds that elicited EAD responses. For the MTAD derivatization of a 26-female gland extract, we followed the procedure of McElfresh and Millar (1999). For the DMDS derivatizations of a 96-female gland extract, and (11*Z*)-hexadecen-1-yl acetate (*Z*11–16:Ac) and (11*E*)-hexadecen-1-yl acetate (*E*11–16:Ac) standards, we followed the procedure described by Buser et al. (1983).

Gas Chromatography-Electroantennographic Detection We analyzed pheromone gland extracts (five batches of 10, 13, 27, 18, and 10 pheromone glands) by GC-EAD, with a Varian 3800 GC coupled to an EAD Recording Unit (Syntech, Hilversum, The Netherlands). For details of the preparation of moth antennae, and our setup of associated equipment for GC-EAD analyses, see the work of Gibb et al. (2006). Extracts were run on DB-5 (30 m × 0.25 mm i.d. × 0.5 μm film; Agilent Technologies, Palo Alto, CA, USA) and DB-Wax columns (30 m × 0.25 mm i.d. × 0.5 μm film; Agilent) with 1:1 split outlets. Helium was used as the carrier gas (1 ml min^{-1}), and injections were splitless for 0.6 min. Injector and detector temperatures were 220° and 300°C, respectively, and the GC temperature program was 80°C for 1 min, 10°C min^{-1} to 240°C, and held for 35 min. Kováts retention indexes (KIs) (Kováts, 1965; Marques et al., 2000) were calculated for the compounds that elicited antennal responses to compare relative retention times and, thus, to obtain rudimentary information about the identity of the EAD-active compounds.

Gas Chromatography-Mass Spectrometry We compared the retention times and mass spectra of the EAD-active compounds detected in a gland extract (1 μl, ca. 18-female equivalents) with those of known standards by using a Varian 3800 GC coupled to a Varian 2200 mass spectrometer (GC-MS). Helium was used as the carrier gas (1 ml min^{-1}), and injections were splitless for 0.6 min. Transfer line and ion trap temperatures were 250° and 200°C, respectively. The GC injector temperature was 220°C, and the temperature program was 100°C for 1 min, 10°C min^{-1} to 210°C, and held for 18 min using a VF-5ms column (30 m × 0.25 mm i.d. × 0.25 μm film; Varian Inc., Walnut Creek, CA, USA). The MTAD- and DMDS-derivatized pheromone gland extracts, and the DMDS-derivatized standards, were also analyzed by GC-MS (injector temperature 250°C; 8 min solvent delay for MS) on the VF-5ms column, using oven ramps of 15°C min^{-1} from 100° to 300°C, and held for 20 min (MTAD), or 15°C min^{-1} from 100° to 260°C, and held for 20 min (DMDS).

Chemicals *Z*11–16:Ac and E11–16:Ac (both >98% isomerically pure by GC analysis) were obtained from Pherobank (Wageningen, The Netherlands). (10*E*,12*Z*)-Hexadecadien-1-yl acetate (*E*10,*Z*12–16:Ac) and (10*E*,12*Z*)-hexadecadien-1-ol (*E*10,*Z*12–16:OH) were available from previous work (Suckling et al., 2005). (11*Z*,13*E*)-Hexadecadien-1-ol (*Z*11,*E*13–16:OH) and the corresponding acetate (11*Z*,13*E*)-hexadecadien-1-yl acetate (*Z*11,*E*13–16:

Ac) were synthesized as shown in Scheme 1 and as described in detail in the online supplement. The synthesis of (11*E*,13*Z*)-hexadecadien-1-yl acetate (*E*11,*Z*13–16:Ac) is also described in the online supplement.



Field Bioassays We undertook a series of field bioassays in kikuyu turf at the Indooroopilly Golf Course (27.5090° S, 152.9948° E), Brisbane, Australia (trials A, B, and C). Test compounds, based on ratios established from GC analyses of *H. licarsisalis* gland extracts, were loaded onto red rubber septa (Thomas Scientific Inc., Philadelphia, PA, USA). In all trials, green delta traps (Clare et al., 2000) were attached to fencing wires, at a height of ca. 0.5 m, with 10 m spacings between treatments and >50 m spacings between replicates. Trap positions within each replicate were rerandomized, and sticky inserts were replaced, at each check for capturing male *H. licarsisalis*.

In trial A (April 8–28, 2005), the attraction of *H. licarsisalis* males to various combinations of the three sex pheromone candidate compounds was investigated. Traps were checked seven times at intervals of 1–4 d. Treatments were (1) blank control, (2) 100:0:0, (3) 0:100:0, (4) 0:0:100, (5) 30:70:0, (6) 30:70:1, and (7) 30:70:10 μg loadings of *Z*11–16:Ac, *Z*11,*E*13–16:Ac, and *Z*11,*E*13–16:OH ($N = 5$).

In trial B (January 24 to February 15, 2006), the attraction of *H. licarsisalis* males to 100 μg of *Z*11,*E*13–16:Ac was compared with the attraction of *H. licarsisalis* males to binary mixes comprising 100 μg of *Z*11,*E*13–16:Ac and various doses of *Z*11–16:Ac. Traps were checked six times at intervals of 1–5 d. Treatments were (1) blank control, (2) 100:0, (3) 100:11, (4) 100:25, (5) 100:42, and (6) 100:66 μg loadings of *Z*11,*E*13–16:Ac and *Z*11–16:Ac ($N = 4$).

Trial C was a dose response trial based on treatment 3 from trial A. Traps were checked four times at intervals of 3 d from February 21 to March 5, 2006. Treatments were (1) blank control, (2) 10, (3) 100, and (4) 1000 μg doses of *Z*11,*E*13-16:Ac ($N = 5$).

Statistical Analyses Only treatments that attracted moths were included in the statistical analyses. For each trial, the sum of moths captured per trap was analyzed for treatment and block effects using two-way analysis of variance (ANOVA) (MINITAB, version 14). Residual plots were used to check the validity of the ANOVA assumptions, and square root

Scheme 1 Syntheses of (11*Z*,13*E*)-hexadecadien-1-ol (**5**) and (11*Z*,13*E*)-hexadecadien-1-yl acetate (**6**). Reaction conditions: (**a**) Amberlyst 15, *t*-butylated hydroxyanisole (BHA), 3,4-dihydropyran, diethyl ether, 0°C to room temperature (RT); (**b**) PPh_3, MeCN, reflux; (**c**) sodium ethoxide, THF, reflux then −100°C, addition of (*E*)-2-pentenal, then to RT; (**d**) Amberlyst 15, BHA, MeOH; 45°C; (**e**) Ac_2O/pyridine, RT

($x + 0.5$) transformations of the summed captures were undertaken to remove variance heterogeneity. Means were compared by Fisher's protected least-significant difference test ($P = 0.05$) (MINITAB, version 14).

Results and Discussion

Identification of Gland Components Eliciting Antennal Responses In GC-EAD assays, male *H. licarsisalis* antennae responded repeatedly to three compounds in pheromone gland extracts. Only two of these compounds (X and Y, Fig. 1) were visible in the flame ionization detector (FID) trace (KIs of 2001 and 2037, respectively, on the DB-5 column, and 2365 and 2508, respectively, on the DB-Wax column). Antennal response times were the only indication of the presence of compound Z in the extracts. On the DB-5 column, no peak for compound Z was visible in the FID trace, whereas on the DB-Wax column, the antennal response time suggested that the compound was co-eluting on the tail of another unidentified compound (Fig. 1).

The retention times of compound X on DB-5 and DB-Wax columns suggested the presence of a monounsaturated hexadecen-1-yl acetate (Marques et al., 2000), and KIs were identical with those of the *Z*11–16:Ac standard. In addition, the mass spectrum of compound X [*m*/*z* (relative intensity—rel. int.) 222 (4), 166 (2), 137 (5), 123 (13), 109 (23), 95 (56), 81 (100), 67 (98), 61 (7), and 55 (49)] was virtually identical with that of *Z*11–16:Ac, and the retention time of X was the same as the retention time of *Z*11–16:Ac on the VF-5ms column. A comparison of the retention times of the DMDS adducts of *Z*11–16:Ac and *E*11–16:Ac, with the DMDS derivatization products of a grass webworm pheromone gland extract, unequivocally confirmed that compound X was *Z*11–16:Ac rather than *E*11–16:Ac. Both hexadecen-1-yl acetate DMDS adducts have a molecular ion at *m*/*z* (rel. int.) 376 (7) and diagnostic ions at *m*/*z* (rel. int.) 117 (20, $[C_5H_{10}SCH_3]^+$) and 259 (100, $[O_2C_{13}H_{24}SCH_3]^+$) corresponding to the addition of DMDS to a double bond at position 11.

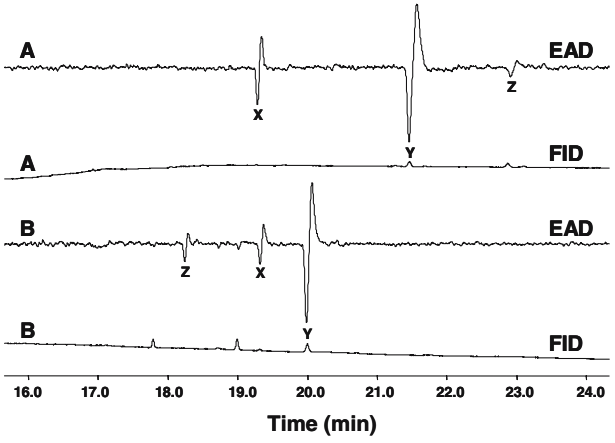


Fig. 1 Coupled gas chromatogram-electroantennograms of *Herpetogramma licarsisalis* male antennae responding to compounds (X = (*Z*)-11-hexadecen-1-yl acetate, Y = (11*Z*,13*E*)-hexadecadien-1-yl acetate, and Z = tentatively identified as (11*Z*,13*E*)-hexadecadien-1-ol), in pheromone gland extracts (ca. 1-female equivalents), eluting from DB-Wax (**A**) and DB-5 (**B**) columns

The retention times of compound Y on the DB-5 and DB-Wax columns suggested a C_{16}-conjugated dien-1-yl acetate after a comparison with a number of C_{16}-conjugated and C_{16}-nonconjugated dien-1-yl acetate standards. Similarly, the antennal response time for compound Z on the DB-5 and DB-Wax columns suggested a C_{16}-conjugated dien-1-ol by comparison with a number of C_{16}-conjugated and C_{16}-nonconjugated dien-1-ol standards. Furthermore, the retention times of *E*10,*Z*12–16:Ac and *E*10,*Z*12–16:OH were the same as those of compounds Y and Z, respectively. Both of these standards elicited strong EAD signals from male grass webworm antennae, and when *E*10,*Z*12–16:Ac was added to an aliquot of pheromone extract, it co-eluted with compound Y on both columns. However, a trapping trial in Northland in early 2003, using these two conjugated dienes in various combinations with *Z*11–16:Ac, failed to trap any moths at a time when moths were observed flying (Willoughby, unpublished data).

We hypothesized that although compounds Y and Z were C_{16}-conjugated dienes, the diene was probably at either the 9,11 or 11,13 position. The analysis of the MTAD-derivatized pheromone gland extract by GC-MS revealed an adduct with a molecular ion at *m*/*z* (rel. int.) 393 (1), and diagnostic ions at *m*/*z* (rel. int.) 364 (21, $[C_{19}H_{30}N_3O_4]^+$) and 194 (100, $[C_9H_{12}N_3O_2]^+$), indicative of a C_{16} dien-1-yl acetate with the diene in the 11,13 position. Thus, compound Y was identified as an 11,13-hexadecadien-1-yl acetate. We could not confirm the identity of compound Z due to the small amount of material in gland extracts (not detectable by GC-FID or GC-MS), but we hypothesized that compound Z was likely to be the C_{16} dien-1-ol precursor of the insect-produced C_{16} dien-1-yl acetate (see Jurenka, 2004 for a review).

Stereoselective syntheses of the (*Z*,*E*) and (*E*,*Z*) isomers of 11,13-hexadecadien-1-yl acetate were carried out. These syntheses also made the (*Z*,*Z*) and (*E*,*E*) isomers as trace by-products, giving us access to all four stereoisomers. A comparison of the spectrum [*m*/*z* (rel. int.) 280 (1, M^+), 220 (4), 177 (3), 163 (4), 149 (8), 135 (15), 121 (27), 107 (14), 95 (43), 81 (54), 67 (100), 55 (21), and 43 (44)] and retention times of compound Y in pheromone gland extract, with the four spectra of the 11,13-stereoisomers, unambiguously confirmed compound Y as *Z*11,*E*13–16:Ac. Analysis of an *H. licarsisalis* gland extract by GC on the DB-Wax column showed that *Z*11,*E*13–16:Ac and *Z*11–16:Ac were present in a ca. 70:30 ratio. The amount of *Z*11,*E*13–16:Ac and *Z*11–16:Ac per female was calculated to be ~280 and 100 pg, respectively ($N = 10$).

Synthesis of Pheromone Compounds The synthesis of (11*Z*,13*E*)-hexadecadien-1-ol **5** (Scheme 1) and the corresponding acetate **6** (Scheme 1) started with 11-bromoundecanol **1**, which was protected using dihydropyran with Amberlyst 15 as catalyst (Santangelo et al., 2002). The THP-protected bromide **2** was transformed to the phosphonium salt **3** with PPh_3 (Legrand et al., 2004). A Wittig reaction between **3** and (*E*)-2-pentenal in the presence of sodium ethoxide made, after deprotection, the (*Z*,*E*)-dien-1-ol **5** as the major product. Acetylation of **5** using acetic anhydride in pyridine produced acetate **6** (Santangelo et al., 2002).

Field Bioassays In the field bioassays, we established *Z*11,*E*13–16:Ac as the main sex pheromone component of *H. licarsisalis*. In trial A, the treatments with *Z*11,*E*13–16:Ac as a single component or in combination with *Z*11–16:Ac (treatments 3 and 5, respectively) were equally attractive to male moths ($P < 0.05$) (Fig. 2a). Single-component lures loaded with *Z*11,*E*13–16:OH were not attractive, and the addition of *Z*11,*E*13-16:OH to the binary mix of *Z*11,*E*13-16:Ac and *Z*11–16:Ac was strongly inhibitory at the ratios tested ($P < 0.05$).

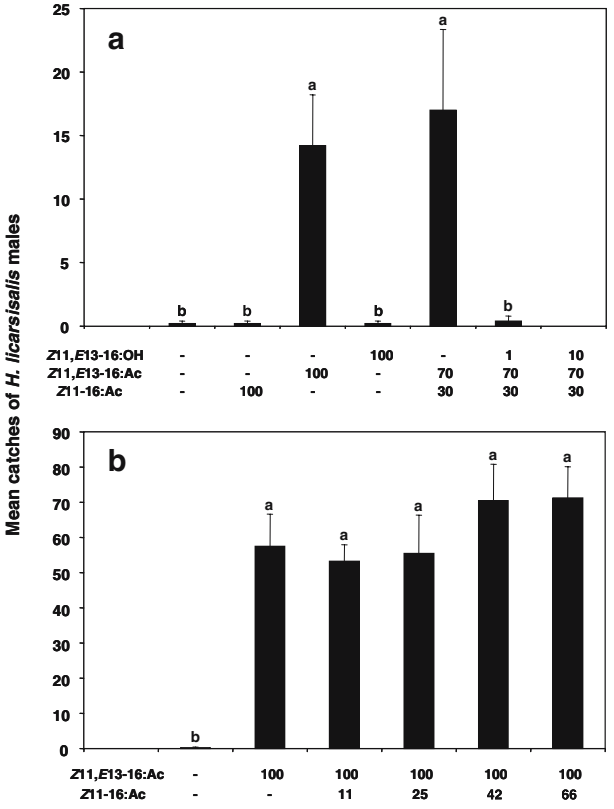

Fig. 2 Mean (+SEM) total catches of *Herpetogramma licarsisalis* male moths at Indooroopilly Golf Course (Brisbane, Australia) in a blend trial (trial A) of the three compounds that elicited responses from moth antennae (two-way ANOVA for treatment effect, $F = 23.18$; $df = 5, 29$; $P < 0.001$, and for block effect $F = 2.9$; $df = 4, 29$; $P = 0.048$, followed by Fisher's protected least significant differences (PLSD test), and in a two-component blend trial (trial B), using (11*Z*,13*E*)-hexadecadien-1-yl acetate and (*Z*)-11-hexadecen-1-yl acetate (two-way ANOVA for treatment effect, $F = 53.29$; $df = 5, 23$; $P < 0.001$, and for block effect $F = 5.4$; $df = 3, 23$; $P = 0.01$, followed by Fisher's PLSD test). Amounts on the *x*-axis are micrograms per lure, and treatments labeled with the *same letter* are not significantly different ($P > 0.05$)

Although we identified *Z*11–16:Ac from gland extracts, male grass webworm moths were not attracted to lures loaded with this compound only. Furthermore, *Z*11–16:Ac, when added to *Z*11,*E*13–16:Ac over a range of ratios, did not increase attraction to lures ($P > 0.05$) (Fig. 2b).

In trial C (Fig. 3), we tested the optimal dose of *Z*11,*E*13–16:Ac required for attracting male grass webworm moths. Lures loaded with 10 μg of *Z*11,*E*13–16:Ac attracted few moths ($P < 0.05$), and a 1,000-μg dose was not better than the 100-μg dose ($P > 0.05$).

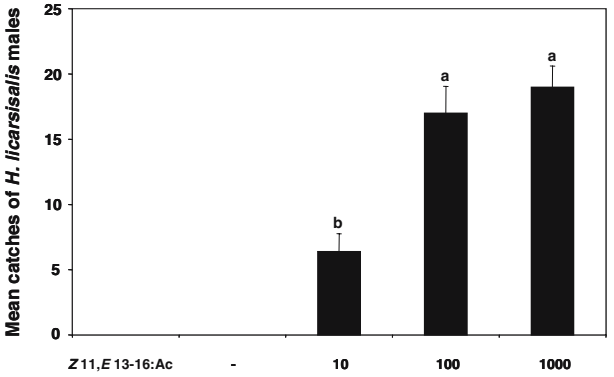

Fig. 3 Mean (+SEM) total catches of *Herpetogramma licarsisalis* male moths to various doses of (11*Z*,13*E*)-hexadecadien-1-yl acetate (trial C) at Indooroopilly Golf Course (Brisbane, Australia) (two-way ANOVA for treatment effect, $F = 25.98$; $df = 2, 14$; $P < 0.001$, and for block effect $F = 2.28$; $df = 4, 14$; $P = 0.149$, followed by Fisher's PLSD test). Amounts on the *x*-axis are micrograms per lure, and treatments labeled with the *same letter* are not significantly different ($P > 0.05$)

*Z*11,*E*13–16:Ac has already been used for monitoring male grass webworm moths in the infested area in Northland. Lures containing 100 μg of *Z*11,*E*13–16:Ac have also successfully attracted male grass webworm moths in Hawaii (Suckling, unpublished data), where the insect is the major pest of turf grass (Tashiro, 1977). Although the 11,13 position for a C_{16}-conjugated diene has previously been reported for pheromone components of moths in the family of Crambidae (Arai et al., 1982; Millar et al., 2002), this is the first identification of an (11,13)-hexadecadien-1-yl acetate as a sex pheromone component of a crambid moth. *Z*11,*E*13–16:Ac also has been found as a minor component in the pheromone glands of two Notodontidae (Bestmann et al., 1991, 1993).

Acknowledgments We thank Julie Hackett, Peter Jones, and Kirsten Moss for the technical assistance in rearing insects, and Barry Bunn and Dave Rogers for commenting on an earlier version of the manuscript. Eric Jang (USDA-ARS) and his team assisted in trapping in Hawaii. Funding was provided by the New Zealand Foundation for Research, Science, and Technology (FRST), under the "Better Border Biosecurity" and previous programs, to develop scientific capability to respond to biosecurity incursions. We are also grateful to the University of Kalmar, Sweden, for the additional financial support.

Food Wrapping with the Postpharyngeal Gland Secretion by Females of the European beewolf *Philanthus triangulum*

Gudrun Herzner · Thomas Schmitt · Klaus Peschke · Andrea Hilpert · Erhard Strohm

Abstract Ground-nesting animals share their habitat with countless microorganisms that can play important roles as pathogens or competitors for food resources. Thus, species that store food in the soil, either for themselves or for their progeny, must protect these resources against microbial degradation. Females of the European beewolf, *Philanthus triangulum*, hunt honeybees as provisions for their brood and store the paralyzed prey in their subterranean nests. A previous study had shown that females lick the surface of prey before oviposition and that this licking treatment delays mold growth. Here, we showed that females apply large amounts of a secretion from their postpharyngeal glands onto the surface of their prey during the licking behavior. Inhibition-zone assays showed that comparatively large amounts of the gland secretion had no direct antimycotic effect. We discuss our findings with regard to other possible mechanisms of the postpharyngeal gland secretion against fungal growth.

Introduction

Brood-caring insects provision their progeny with highly nutritive food (pollen, paralyzed prey, or carcasses) that must remain consumable for the feeding period of the larvae

(Vander Wall, 1990; O'Neill, 2001). In particular, ground-nesting species, like many aculeate Hymenoptera, are adversely affected by fungal contamination of their provisions (Eickwort et al., 1981; Cane et al., 1983; Strohm and Linsenmair, 2001). Fungal infestations of the stored resources can decrease the parent's fitness returns, either by killing the larvae (Janzen, 1977) or by decreasing progeny size and reproductive success (Strohm, 2000). Insects should, therefore, have evolved defense mechanisms against fungal infestations of the provisions and their brood. Mostly, antifungal mechanisms are mediated by chemical compounds that interfere with the fungi at different stages of their growth (Gross et al., 1998, 2002; Bot et al., 2002). In the present study, we investigated a prey-preservation mechanism in a solitary ground nesting wasp, the European Beewolf *Philanthus triangulum* F. (Hymenoptera: Crabronidae; formerly Sphecidae).

Females of the European beewolf hunt and paralyze exclusively honeybee workers (*Apis mellifera*) and deposit one to six prey in a brood cell as food for a larva (Strohm, 1995, 2000; Herzner et al., 2005). The larva hatches 2–3 d after oviposition and feeds on the bees for another 5–8 d. Under the humid and warm conditions in the brood cell, the nutrient-rich provisions are susceptible to spoilage due to microbial degradation. Surprisingly, in the field, only about 5% of brood cells are seriously infected with fungi (Strohm and Linsenmair, 2001). This low rate can be attributed to a treatment of the prey by beewolf females that delays the onset of fungal growth (Strohm and Linsenmair, 2001). Beewolf females extensively lick the whole surface of the paralyzed prey before oviposition. Strohm and Linsenmair (2001) hypothesized that, during this licking, females apply an antifungal secretion from large postpharyngeal glands (PPG; Strohm et al., 2007) to the surface of the honeybees. Here, we compared the composition of the PPG content and the surface of provisioned honeybees from brood cells by using combined gas chromatography-mass spectrometry (GC-MS). We tested also for an antifungal effect of the PPG secretion by using inhibition-zone assays.

Methods and Materials

Beewolves Beewolf females were obtained either from a field population close to the Biocenter of the University of Würzburg, Germany, or from a laboratory population kept at the University of Würzburg (daughters of field-caught females). They were housed individually in observation cages in a climate chamber (26/22°C day/night 14/10 hr light/dark cycle) and provided with honeybees as prey and honey *ad libitum*. The observation cages allow the withdrawal of paralyzed bees immediately after paralyzation and the removal of regularly provisioned bees from brood cells shortly after oviposition. A detailed description of the observation cages is given in Strohm and Linsenmair (1994/1995).

Postpharyngeal Secretion and Cuticular Extracts of Provisioned and Paralyzed Bees To obtain PPG extracts for chemical analysis, glands were removed from the heads of freshly killed beewolf females (N=5) by grasping the hypopharynx with tweezers and gently pulling the attached gland out through the mouth. The glands were immediately transferred to 250 µl distilled *n*-hexane (Fluka, Deisendorf, Germany) and extracted for 1 hr.

To test whether chemical compounds are applied to the surface of the honeybees during the licking by beewolf females and to test whether these are derived from the PPG, we extracted honeybees that were removed from females within a few minutes after paralyzation (paralyzed bees, N=6) and honeybees from brood cells that had been regularly provisioned and licked (provisioned bees, N=6) by females. All bees were taken from the

same stock population of the Department of Animal Physiology and Sociobiology, University of Würzburg. Analyses of provisioned and paralyzed bees were done at the same time during the season. The bees were extracted individually for 10 min in 500 µl distilled *n*-hexane (Fluka, Deisendorf, Germany). A known amount of an internal standard (octadecane) was added to each extract for quantification.

All samples were reduced in volume to approximately 100 µl by a gentle stream of nitrogen. An aliquot of 1 µl of each sample solution was analyzed by GC-MS.

Capillary Gas Chromatography-Mass Spectrometry GC-MS analysis was performed with an Agilent 6890N Series gas chromatograph (Agilent Technologies, Böblingen, Germany) coupled to an Agilent 5973 mass selective detector. The GC was equipped with an RH-5ms+ fused silica capillary column (30 m×0.25 mm ID; film thickness=0.25 µm). The temperature program used was 60°C for 1 min, then to 300°C at 5°C min^{-1} and held for 10 min. A splitless injector (250°C) was used with helium, at a constant flow of 1 ml min^{-1}, as the carrier gas. Electron ionization mass spectra (EI-MS) were recorded at 70 eV.

The chemical composition of PPG content and cuticular hydrocarbons of honeybees have been determined in other studies and are described elsewhere in detail (Schmitt et al., 2007; Strohm et al., unpublished data). In earlier analyses, we used different solvents and solid phase microextraction to obtain a full inventory of all compounds. These analyses showed that hexane extracts gave representative profiles of the compounds present. In the present study, *n*-alkanes were identified by comparing retention times and mass spectra of the extracts with data from the earlier analyses and with data from a commercial MS library (NIST, Gathersburg, MD, U.S.A.). Alkenes were identified by mass spectra and their retention times. The position and configuration of double bonds were inferred by comparison with earlier analyses on the chemistry of the PPG and cuticular hydrocarbons of beewolf females that used Fourier transform infrared (FTIR) spectrometry and dimethyl disulfide (DMDS) derivatization (Strohm et al., unpublished data); peaks with identical retention times were considered to be the same isomers. Some alkenes were present only at trace amounts and could not be characterized completely. Alkadienes were identified by mass spectra and retention times. Due to the small amounts of these compounds, the position and configuration of the double bonds were not determined. Methyl alkanes were identified by diagnostic ions (Blomquist et al., 1987) and by determining Kovats indices according to the method of Carlson et al. (1998). The ketones, Δ-16-pentacosen-8-one and Δ-18-heptacosen-10-one, were identified by comparing retention times and mass spectra with data from our earlier analyses (Strohm et al., unpublished data). Some chemicals that were identified in our previous analyses of the PPG, by using pooled extracts of several females, were not detected in extracts of single females analyzed in this study.

Peak areas were obtained by manual integration, and the amounts of compounds were calculated by comparing peak areas to the internal standard. Some peaks were not separated satisfactorily and were treated as one peak for integration (see Table 1). In particular, (*Z*)-9- and (*Z*)-7-alkene isomers and corresponding alkadienes were generally not resolved. The (*Z*)-9-alkene was always the most dominant peak among the three.

Data Analysis For each individual bee extract, the total peak area was standardized to 100%, and a multivariate analysis was performed to assess the similarity or divergence of the chemical profiles of paralyzed honeybees, provisioned honeybees, and the PPG secretions. Because peak areas represent compositional data, they were transformed to logcontrasts (Aitchison, 1986; Reyment, 1989) before analysis. However, the original transformation procedure makes it necessary to exclude compounds that do not occur in all

samples. We, thus, modified the transformation (log(relative peak area+0.1/(geometric mean of all peak areas+0.1))) to avoid undefined values for peaks with an area of zero.

The transformed relative peak areas were subjected to a *principal component analysis (PCA)* to reduce the number of describing variables. The extracted PCA factors were subjected to a *discriminant analysis (DA)* to assess whether the three different groups (paralyzed bees, provisioned bees, PPG secretions) could be separated on the basis of their chemical profile.

To assess the pattern of similarity between paralyzed bees, provisioned bees, and PPG secretions without an *a priori* grouping (unlike in the DA), we performed a *hierarchical cluster analysis*. We used the squared Euclidean distance as a measure of distance for cluster analysis and within groups average linkage as the method for combining clusters (other methods of combining clusters yielded qualitatively identical results).

The overall amounts of cuticular compounds on provisioned and paralyzed bees were compared with an exact test for independent samples. All analyses were calculated by using SPSS 13.0.

Antifungal Activity of the Postpharyngeal Gland Secretion Activity of the PPG secretion against fungal growth was measured by an inhibition-zone assay (see e.g., Gross et al., 1998, 2002). An extract of provisioned bees was tested and compared against a known antifungal compound (see below). The extract of provisioned bees was obtained by soaking 75 provisioned bees in distilled hexane twice for 10 min. Extracts were combined, and the amounts of hydrocarbons were determined by GC-MS analysis as above.

The test fungi used were (1): the predominant, naturally occurring fungus in original brood cells (not yet identified fungus of the genus *Aspergillus*) taken directly from an infested bee in a brood cell ("brood cell fungus"), (2): *Aspergillus fumigatus* (Deutsche Sammlung von Mikroorganismen und Zellkulturen, # DSM 819), and (3): *Penicillium roquefortii* (Department of Hygiene, University Hospital of Würzburg, # V 308). Fungal spores were obtained from solid medium cultures and suspended in liquid medium for inoculation. Agar plates (9 cm diameter) were prepared with a standard fungus medium (4 g yeast, 10 g maltose, 12 g agar, 8 ml 50% glucose solution, and 992 ml distilled water). For inoculation, 10 µl of the spore suspension were evenly spread over the sterile agar surface.

The test chemicals or secretions were applied to disks of sterile filter paper (5 mm diameter), which were then placed on the agar surface. Different amounts of extracted hydrocarbons from licked honeybees, and the monoterpenoid citral, were tested. Citral is a known antifungal agent produced by different arthropods (Cole et al., 1975; Okamoto et al., 1981; Cane et al., 1983) and was applied in the same amounts as the PPG secretion to allow for a comparison of the effect. We chose 160 µg as the maximum amount tested because this was the maximum amount of hydrocarbons found on a single bee in our analyses. To each filter paper disk, we applied 10 µl of hexane containing different amounts of hydrocarbons extracted from provisioned bees (a: 20 µg, b: 40 µg, c: 80 µg, d: 160 µg) or different amounts of citral (e: 20 µg f: 40 µg, g: 80 µg, h: 160 µg, Fluka, Deisendorf, Germany). The control (i) was treated with *n*-hexane. Each Petri dish received nine differently treated (solutions a–i) filter paper disks.

Tests were replicated six times for the brood cell fungus and *P. roquefortii* and five times for *A. fumigatus*. After a 3-d incubation of the parafilm-sealed agar plates at 26–29°C, the diameters of the halos in fungal mats, caused by the antifungal action of the samples, were measured. We tested for a dose–effect relationship by conducting regression analyses.

Results

PPG Secretion and Cuticular Extracts of Paralyzed and Provisioned Bees Typical gas chromatograms of hexane extracts of paralyzed honeybees and provisioned honeybees and the content of the PPG of *P. triangulum* females (Fig. 1), showed a qualitative concordance (see also Table 1). Of the total of 52 substances detected, 42 occurred in all three types

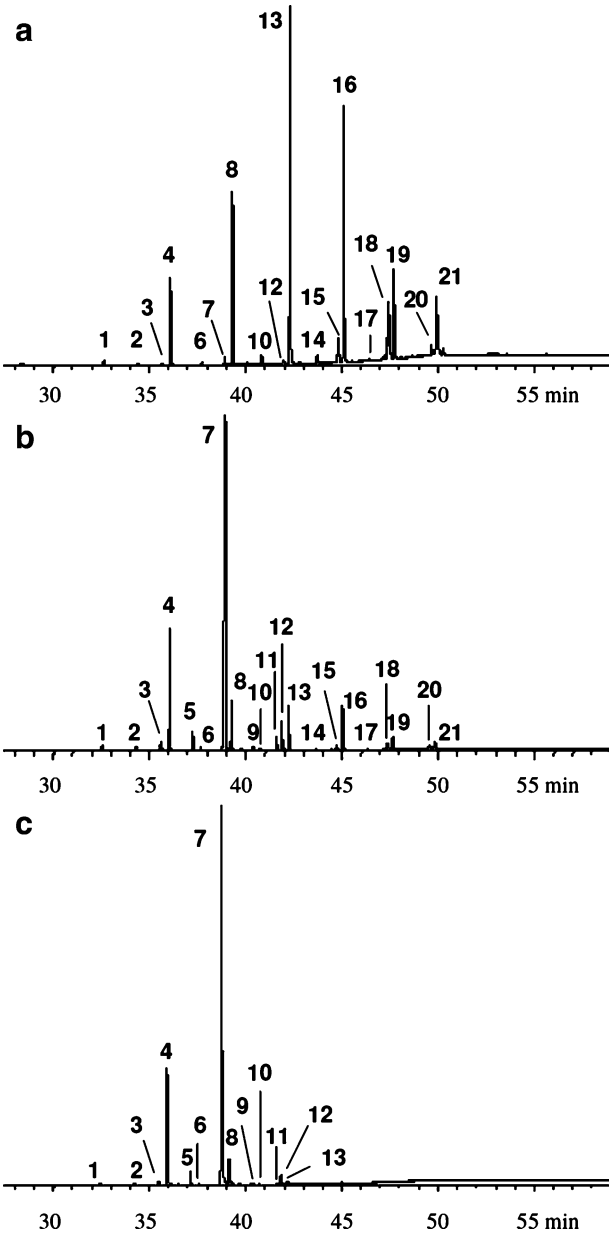

Fig. 1 Gas chromatograms of hexane extracts of **a** a paralyzed but not provisioned honeybee (*A. mellifera*), **b** a honeybee provisioned by a beewolf female, and **c** a postpharyngeal gland of a beewolf female (*P. triangulum*). The peaks of minor components are not visible due to the scale used. The peaks correspond to the following substances: *1* heneicosane; *2* docosane; *3* Δx,y-tricosadiene, (*Z*)-9-tricosene, (*Z*)-7-tricosene; *4* tricosane; *5* (*Z*)-9-tetracosene; *6* tetracosane; *7* (*Z*)-9-pentacosene, (*Z*)-7-pentacosene; *8* pentacosane; *9* (*Z*)-9-hexacosene; *10* hexacosane; *11* Δ-16-pentacosen-8-one; *12* (*Z*)-9-heptacosene, (*Z*)-7-heptacosene; *13* heptacosane; *14* octacosane; *15* (*Z*)-9-nonacosene; *16* nonacosane; *17* triacontane, *18* Δx,y-hentriacontadiene, (*Z*)-9-hentriacontene, (*Z*)-7-hentriacontene; *19* hentriacontane; *20* Δx,y-tritriacontadiene, Δx-tritriacontene; *21* tritriacontane (the chromatograms were obtained from extracts not containing the internal standard)

of extracts. Δx-heineicosene, Δx-docosene, (*Z*)-9-hexacosene, and the ketones, Δ-16-pentacosen-8-one and Δ-18-heptacosen-8-one, could be detected only in the PPG and on provisioned bees. The methyl-hentriacontanes and Δx-dotriacontene were not detected on provisioned bees. The PPG extracts contained no detectable amounts of Δx-dotriacontene and tritriacontane.

Although the cuticular chemicals found in extracts of paralyzed and provisioned bees were qualitatively similar, there were pronounced quantitative differences between them

Table 1 Comparison of the relative amounts of cuticular substances[a] on paralyzed and provisioned bees[b]

Tritriacontane	1.34±0.53	0.09±0.05	−

The last column indicates whether the substance was present in at least one of the PPG samples.

[a] Mean ± standard deviation

[b] $N=6$

[c] + Yes, − no

(Fig. 1 and Table 1). On average, the total amount of cuticular compounds was about five times higher on provisioned bees (109.9±28.2 μg) compared to paralyzed bees (23.2±5.0 μg; exact P=0.002, two-tailed). The cuticular profile of paralyzed bees was dominated by the saturated hydrocarbons, heptacosane, nonacosane, and pentacosane. On the cuticle of provisioned bees, the unsaturated hydrocarbon (*Z*)-9-pentacosene was by far the most abundant compound. (*Z*)-9-Pentacosene was also the predominant compound in four of the five PPG extracts. In PPG extract 4 (*Z*)-9-heptacosene was the major compound.

To analyze statistically the similarity or discrepancy of the chemical profiles of paralyzed bees, provisioned bees, and PPG secretions, multivariate data analysis was performed. The two principal components produced by the *PCA*, explained 70.3% of the total variance. A *DA* on these principal components significantly differentiated extracts of paralyzed bees, provisioned bees, and PPGs (Wilks' λ=0.018, χ^2=54.4, df=4, P<0.001, Fig. 2). Discriminant function 1 explained 98.9% of the total variation extracted by the *PCA*, and discriminant function 2, only 1.1%. By far, the largest effect was between paralyzed bees versus provisioned bees and PPG secretions.

The *cluster analysis* (Fig. 3) separated paralyzed bees from both provisioned bees and PPGs in the first bifurcation. The distinction was less pronounced between provisioned bees and PPG secretions. The second bifurcation separated PPG extract 4 from all other PPG extracts, and the provisioned bees, and thus, placed it in a unique branch. The third bifurcation separated provisioned bees from PPGs, with the exception of provisioned bee 1, which clustered within the PPG extracts. According to this analysis, provisioned bees are very similar to PPG content but dissimilar from paralyzed bees. Furthermore, the amount of hydrocarbons on provisioned bees was considerably increased. Thus, beewolf females seem to apply the secretion of their PPG to the surface of their prey before oviposition.

Antifungal Activity of the Postpharyngeal Gland Secretion The diameters of the inhibition zones are given in Table 2. Hexane had no fungistatic effect on any of the fungi (except for one disk in an *A. fumigatus* Petri dish that showed an inhibition zone of about 1.4 mm). The extract of provisioned bees showed no effect on growth of any of the fungi at any concentration in the inhibition-zone assay. Not only did the extract fail to produce inhibition

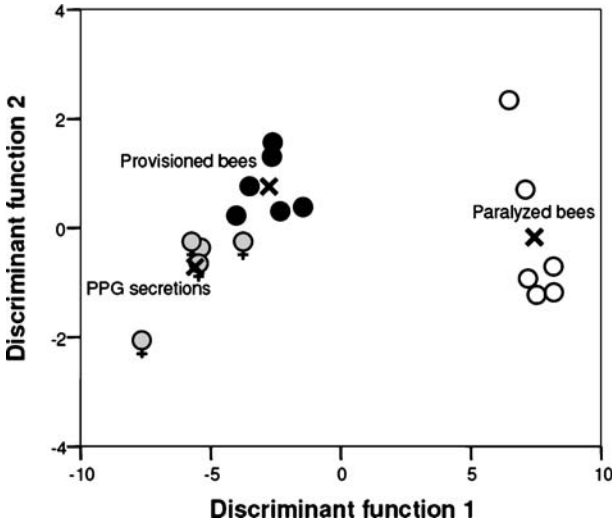

Fig. 2 Plot of the two discriminant functions obtained by the discriminant analysis based on the relative peak areas of extracts from paralyzed honeybees (N=6, *open circles*), provisioned honeybees (N=6, *closed circles*), and postpharyngeal glands of *P. triangulum* females (N=5, *grey symbols*) (*x* Group means; see text for details)

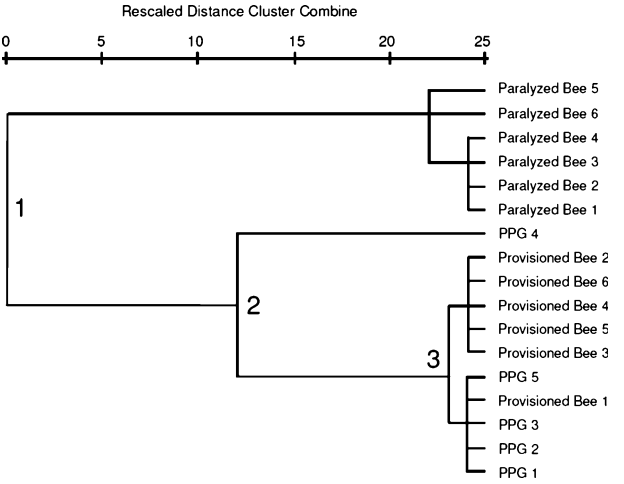

Fig. 3 Dendrogram based on the cluster analysis of cuticular compounds of individual extracts of paralyzed bees, provisioned bees, and postpharyngeal glands of *P. triangulum* females (numbers indicate the different individuals). Numbers in the dendrogram indicate the first three bifurcations (see text)

zones, but fungi grew even on the filter paper disks. Citral was active against *A. fumigatus*, causing clear halos, but not against the brood cell fungus and *P. roquefortii* (Table 2). For citral, we found a significant positive dose–effect relationship on *A. fumigatus* (r=0.87, P< 0.001, N=25). There was no such effect for provisioned bee extract (r=0.11, P=0.30, N=25). A comparison of the two regression lines (citral: y=0.0569x + 1.3158, provisioned bee extract: y=−0.0011x + 0.1267) showed that the slopes were highly significantly different (Z=8.754, P<0.001).

Discussion

We showed that provisioned bees carry roughly five times more hydrocarbons than paralyzed bees and that the cuticular chemical profile of provisioned prey bees is similar to

Table 2 The effect of provisioned bee extract, citral, and hexane (Control) [mean halo diameter (mm) ± standard deviation] on the three tested fungi

the content of the PPG of beewolf females. The two ketones, Δ-16-pentacosen-8-one and Δ-18-heptacosen-8-one, were present only in the PPG of beewolf females and on provisioned bees and were not present on paralyzed bees. These results, together with the behavioral observations of an extensive licking of the surface of prey bees by beewolf females (Strohm and Linsenmair, 2001), provide evidence that females apply large amounts of PPG secretion to the surface of paralyzed honeybee prey during the licking treatment.

PPG extract number 4 was separated in the cluster analysis from all other PPG secretions and was placed in a unique branch. PPG content of female *P. triangulum* shows a marked dimorphism: the predominant compound in the hydrocarbon mixture is either (*Z*)-9-pentacosene, or less frequently, (*Z*)-9-heptacosene (Strohm et al., unpublished data). Female number 4 was of the heptacosene type, whereas all others were of the pentacosene type. All provisioned bees were randomly selected, but turned out to be of the pentacosene type. Provisioned bee number 1 clustered within the PPG secretions of the pentacosene type, probably because this bee carried larger amounts of the secretion (160 μg) than all other bees (mean: 109.9±28.2 μg) and was, thus, more similar to the pure PPG secretion.

Previous studies have shown that the licking treatment of prey by female beewolves delays fungus growth on prey bees (Strohm and Linsenmair, 2001; Herzner and Strohm, 2007). The results of the present study suggest that this effect is not due to direct chemical (toxic) activity of the PPG secretion against fungi. Even 160 μg of hydrocarbons, corresponding to the maximal amount found on a single provisioned bee in our study, on a 5-mm filter paper disk failed to impede fungal growth in our assays. The surface area of the honeybee, including its hairs, setae, and sensilla, is larger than the surface of the filter paper disk. Therefore, the concentration of secretion on provisioned bees is likely to be considerably lower than that used on the disks in our tests.

Citral was active against *A. fumigatus*, but not against the other two fungi. The antifungal effect of citral, a component of mite alarm pheromones, on *A. fumigatus* was previously reported by Okamoto et al. (1981). Citral has also proven to be active against several other fungi and bacteria (Cole et al., 1975; Cane et al., 1983). A similar selectivity against microorganisms has been observed previously for some other insect-derived substances or secretions (Cole et al., 1975; Sosa-Gomez et al., 1997; Bot et al., 2002; Gross et al., 2002).

Inhibitory effects of exocrine gland secretions on microorganisms have been reported from a variety of insect species (e.g., solitary bees: Cane et al., 1983; ants: Cole et al., 1975, Bot et al., 2002; leaf beetles: Gross et al., 2002, stink bugs: Sosa-Gomez et al., 1997). Usually, these secretions have a direct antimicrobial effect. That the observed delay in growth of fungus on provisioned bees (Strohm and Linsenmair, 2001; Herzner and Strohm, 2007) does not appear to be mediated by a direct antifungal effect of the PPG secretion is thus unusual. The PPG secretion comprises predominantly hydrocarbons, a class of chemicals that is not expected to have antimicrobial effects. Therefore, how does the licking treatment and the PPG secretion interfere with mold fungi on the prey bees?

First, by licking the surface of the bees, beewolf females might clean the surface and remove fungal spores. Second, the treatment could change physico-chemical properties of the surface. The cuticle is the first contact between host and fungal conidia, and it is plausible that physico-chemical characteristics of the cuticle influence conidial adhesion and germination and fungal proliferation. The attachment of fungal propagules to host cuticle is mediated by chemical components on the epicuticle (Fargues, 1984; Boucias et al., 1988; Boucias and Pendland, 1991; Sosa-Gomez et al., 1997; Pavlukova et al., 1998). In the southern green stink bug, *Nezara viridula*, for example, the removal of hydrocarbons caused a significant reduction of conidial binding to the cuticle (Sosa-Gomez et al., 1997).

The hydrocarbons extracted (with hexane) from *N. viridula* exuvia, and applied to glass substrates, allowed the attachment of conidia, suggesting that hydrocarbons play an important role in this first step of infection. The PPG treatment changes the hydrocarbon profile of the bees considerably and might, therefore, alter or mask particular physico-chemical characteristics of the cuticle (e.g., hydrophobicity or charge) that are necessary for adhesion of conidia (Sosa-Gomez et al., 1997; Fletcher et al., 1980).

Third, the treatment could affect the next step in the infection process of fungi, conidial germination. Germination often requires exogenous carbon sources; chitin and other cuticular constituents have been shown to serve this purpose (Smith and Grula, 1981; Napolitano and Juárez, 1997; Crespo et al., 2002). The secretion from the PPG might act as a barrier to the bee surface, preventing conidia from coming into contact with nutrients or other cues that could trigger germination. Finally, the germination of conidia also requires sufficient water. In a related study, we showed that the PPG secretion considerably reduces water condensation on the surface of prey (Herzner and Strohm, 2007), thereby indirectly impairing fungal germination. Therefore, hydrocarbons from the PPG, applied in large amounts to the bees' surface, mediate a protective effect by an indirect, physical, rather than a direct, chemical mechanism.

Acknowledgements We thank the Department of Behavioral Physiology and Sociobiology, Würzburg University, for providing honeybees, and Sigrid Lempert, Department of Hygiene, Würzburg University, for providing fungus cultures. This study was partly supported by the DFG (SFB 554, TP B3, STR 532/1-2).

Abstract The analysis of expression of pheromone-carrying major urinary proteins (MUPs) from two subspecies of house mice (*Mus m. musculus*, *Mus m. domesticus*) was studied. It has been previously shown that commensal populations of the two subspecies can discriminate on the basis of urinary signals. MUPs are predominant urinary proteins that protect pheromones from rapid degradation in a hydrophilic environment, and individuals of *M. m. musculus* tend to rely on these urinary cues in the process of subspecies discrimination more than *M. m. domesticus* individuals. Although it is not precisely known what triggers phenotypic and epigenetic changes of MUP expression, our results show that in the subspecies *M. m. musculus*, sex is a significant factor influencing variations in the regulation of selected MUPs in the liver. Furthermore, male *M. m. musculus* individuals expressed all the studied MUPs' mRNA significantly more than females or individuals of either sex in *M. m. domesticus*. Correspondingly, the pattern of mRNA abundance was corroborated with the level of total MUP concentration in the urine, such that the level of sexual dimorphism was also significant and species-specific. Our finding introduces a hypothesis that quantitative variation of these proteins may be an essential part of a subspecies recognition system that maintains homospecific mixing.

Introduction

The urine of *M. musculus* Linnaeus, 1758 contains large quantities of acidic protein isoforms called major urinary proteins (MUPs) with a molecular mass 18–19 kDa (Cavaggioni and Mucignat-Caretta, 2000). These proteins are synthesized in the liver and released through the kidney into the urine. Although, the production of MUPs indicates that it must have advantages, little is known about the constraints that have shaped the evolution of expression differences of this protein family. In *M. m. domesticus*, Schwartz & Schwartz, 1943, it has been repeatedly shown that MUPs carry volatile nonpolar pheromones in their hydrophobic pocket (Bacchini et al., 1992; Žídek et al., 1999). The combination of volatile pheromones and their protein carriers may facilitate individual/status recognition and estrus synchronization through a slow release of these ligands from proteins when the urine mark is deposited (Hurst et al., 1998, 2001; Novotny et al., 1999; Marchlewska-Koj et al., 2000). Therefore, these proteins are advantageous for an individual, as the essential information on sex and status is present even in the absence of the territory owner (Hurst et al., 2001). In addition to the information on genetic relatedness that is manifested by the highly polymorphic major histocompatibility complex (MHC), MUPs are important in their ability to reveal temporal individual-status information. If common androgen regulators correlate with the temporal individual status, they may also constitute a method of honest signaling.

One of the remarkable characteristics that have emerged from the study of MUPs is their diversity. This variation is largely caused by single nucleotide and/or single codon mutations (Robertson et al., 1996; Beynon et al., 2002). MUPs are the product of a multigene family of approximately 30 genes and pseudogenes located on chromosome 4 (Bishop et al., 1982). Their expression is largely sex-dependent, such that males produce more than females do (Wicks, 1941), with the pattern and amount probably regulated by testosterone, growth hormone, and thyroid hormone levels (Knopf et al., 1983). For example, females injected with testosterone produce amounts of MUPs similar to those of their male counterparts (Cavaggioni and Mucignat-Caretta, 2000). Sequence variations and different expression patterns have been reported for various laboratory strains (Finlayson et al., 1965), and it is likely that these differences represent polymorphisms that have been detected in wild populations (Pes et al., 1999; Robertson et al., 1997). What has yet to be determined is the species-specific expression pattern of MUPs in wild mice of the genus *Mus* and to what extent these "expression profiles" may influence or represent a signal for either species recognition and/or a sexually selected behavior. Such testing may further the understanding of natural hybridization between the two subspecies under study.

To further elucidate whether major urinary proteins in mice are a product of sexual selection, we tested the hypothesis that differences between male and female expression patterns are greater than differences between the two subspecies. Sampsell and Held (1985) discovered—with an application of a technique known as dot-blot—little variation in MUP mRNA quantity between male and female *M. m. domesticus* but larger differences in *M. m. musculus*. Our study aimed for a more precise quantification of the expression variation in wild caught mice of both subspecies. Our model organisms, *M. m. musculus* and *M. m. domesticus*, recolonized Europe after glaciation and formed a narrow hybrid zone about 20 km wide spanning across Europe from Denmark to Bulgaria. Regarding their ecology, populations of both subspecies live commensally (i.e., syn-anthropically), and to date no published data suggest that there are significant ecological differences between them (Boursot et al., 1993). The rationale for testing this hypothesis is highlighted by the fact that it would be advantageous for an individual to recognize individuals of the same species and those of another to avoid potential problems with F1 hybrid sterility. One can

envisage two likely, yet understudied, scenarios: (1) MUP quantity and expression pattern are a product of sexual selection and, therefore, females choose males on the basis of their MUP-related smell, regardless of the species, or (2) MUP signals are a trait under purifying selection and form an efficient species-specific barrier to diminish the cost of producing sterile litters. The former scenario could partially explain an introgression of several *domesticus* genes into *musculus* populations (Munclinger et al., 2002) as a consequence of such a recognition error, whereas the latter scenario may partially explain why the narrow hybrid zone is relatively stable. Our approach in analyzing MUP expression profiles combines real-time polymerase chain reaction (PCR) of unique mRNA/cDNA sequences and densitometry analysis of isolated urinary MUPs run on polyacrylamide gel electrophoresis under denaturating condition (i.e., SDS-PAGE).

Methods and Materials

Subjects Eighty-three reproductively active (approximately 70-d-old) mice were used. Different mice were used for the isolation of mRNA (29 individuals, i.e., *M. m. domesticus*—eight males + seven females, *M. m. musculus*—eight males + six females) and for the urine collection (54 individuals, i.e., *M. m. domesticus*—12 males+14 females, *M. m. musculus*—15 males+13 females). The mice were trapped at three *domesticus* sites in Germany (i.e., Straas, Neunreuth, and Wuppertall), and at six *musculus* sites in the Czech Republic (i.e., Sedlecko, Vintirov, Praha, Brandys, Studenec, and Svetla Hora).

RNA Isolation and cDNA Synthesis Total RNA from a 50-mg liver tissue was extracted with ToRNAzol reagent (GeneAge Technologies, a.s., Prague, Czech Republic) according to the manufacturer's protocol. The purity of RNA was assessed from the ratio of the optical densities at 260 and 280 nm, and the integrity was controlled by electrophoresis on 1% agarose gel containing ethidium bromide.

Five micrograms of total RNA were used for synthesis of single-stranded cDNA according to a first-strand cDNA synthesis protocol (Fermentas UAB, Vilnius, Lithuania) with RevertAid™ M-MulV Reverse Transcriptase and oligo$(dT)_{18}$ primer. To minimize variation in the reverse transcription, all RNA samples were reverse-transcribed simultaneously.

*Hypoxanthine phosphoribosyltransferase

Quantitative Real-Time PCR The resultant cDNA was amplified with PCR by using primers given in Table 1. The target sequences belong to the six most abundant MUP variants in mice (Shahan et al., 1987). Amplified PCR products were consequently sequenced to ensure correct priming with the target sequences of given MUPs. Real-time PCR was performed in a Rotor-Gene 2000 from Corbett Research by using the SYBR® Green detection method. Total reaction volume was 25 μl of buffer solution containing 1 μl of cDNA sample, 3 mM $MgCl_2$, 0.2 mM dNTP, SYBR® Green 1: 25,000, 0.4 U/μl taq polymerase, and 0.2 μM primers. PCR amplifications were always performed in duplicate wells under the following conditions: 2 min at 95°C, then 30 repetitive cycles: 30 sec at 95°C, 30 sec at 56°C, 30 sec at 72°C, and an additional fourth step of 15 sec at 82°C where the fluorescent data were collected to avoid any nonspecific signals derived by eventual primer dimers or unspecific minor product (Pfaffl, 2003). This fourth step ensures accurate quantification of desired product, and the appropriate product compound is checked in all samples by the melting analysis. The beta-2-microglobulin, out of five tested housekeeping genes, was assayed as a normalization control to correct any loading discrepancies (Bustin, 2000; 2002), and hypoxanthine phosphoribosyltransferase (HPRT) was used as a control gene for each individual. Control reactions with "RT minus template" did not produce significant amplification product (Vandesompele et al., 2002).

Relative quantitation of target gene expression was evaluated by using the comparative Ct method (Giulietti et al., 2001) by determining the cycle threshold (Ct) based on the fluorescence detected within the geometric region of the semilog view of the amplification plot. The ΔCt value was determined by subtracting the target Ct of each sample from its respective beta-2-microglobulin Ct value. Calculation of ΔΔCt involves using the highest sample ΔCt value as an arbitrary constant to subtract from all other ΔCt sample values. Fold changes in gene expression of the target gene are equivalent to $2^{-\Delta\Delta_{Ct}}$ (Livak and Schmittgen, 2001). Relative fold change (i.e., a change in an order of magnitude), therefore, represents an exponent value, whereas the threshold value of the amplification cycle (i.e., Ct) ensures that the levels are measured at a linear range.

Protein Analysis Urine was collected by a gentle bladder massage and frozen at −20°C. The volume of 0.2 μl of male and 0.4 μl of female urine, respectively, was used for protein analysis. SDS-polyacrylamide gel electrophoresis was performed on Mini-PROTEAN III Electrophoresis System (BioRad Laboratories, Hercules, CA, USA) according to modified protocol by Laemmli (1970). To avoid potential errors caused by a loading inaccuracy, we used Carbonic Anhydrase (29 kDa) marker for SDS-PAGE (Sigma-Aldrich, St. Louis, MO, USA) as standard. Thirteen microliters of sample buffer (containing 1,000 ng of carbonic anhydrase) were added to each sample. The gels were stained with Coomassie® G-250 (SimplyBlue™ Safe Stain, Invitrogen Life Technologies, Paisley, UK). The gel images were acquired by using Gel Doc XRS, and Quantity One 1-D Analysis Software (BioRad Laboratories, Hercules, CA, USA) was used for the densitometry analysis. The total urinary MUP concentrations were calculated from the adjusted volumes that were obtained after corrections by using carbonic anhydrase of known volumes as internal standards.

Statistical Analysis As the mRNA expression and protein concentration were collected from different individuals, we performed two separate analyses. General Linear Model (GLM-Factorial ANOVA) was used to test for dependences on two categorical variables (sex and species). Two separate models were used for detecting differences on the level of mRNA abundance or the level of protein.

Results

Quantitative analysis of mRNA expression by using real-time PCR techniques traditionally employs reference or housekeeping genes to control any errors between samples. To ensure the robustness of our housekeeping system of normalization, we used two reference genes. Beta-2-microglobulin was used as a primary housekeeping gene for this system (i.e., housekeeping by which all other genes including second housekeeping—HPRT—were normalized). Main effects ANOVA revealed that none of the tested factors (i.e., species, individual, sex) had significant effects on the variation of the mRNA abundance of a second housekeeping gene HPRT that was normalized by the first one (MANOVA, factor sex: F=0.931, df=1, P=0.34; species F=0.59, df=1, P=0.45; sex × species F=0.6, df=1, P=0.43). Thus, the following expression variations represent biologically relevant differences.

Predominant urinary MUPs, originally described as MUP1, 2, 3, and 5, are abundant in the liver in both *M. m. musculus* and *M. m. domesticus*. The factorial MANOVA revealed that the major source of variation in mRNA abundance is influenced by sex (F=8.38, df=1, P=0.005), sex × species (F=6.02, df=1, P=0.016), species (F=5.55, df=1, P=0.02), and also marginally by genes (F=2.8, df=3, P=0.042) because of a lower activity of MUP5. *Post hoc* Tukey HSD test further revealed that the major source of variation was differences in mRNA abundance between *M. m. musculus* males and females (df=99, P=0.003) as well as differences (df=99, P<0.002) between *M. m. musculus* males and individuals of both sexes belonging to *M. m. domesticus* (Fig. 1). The major result of this analysis, therefore, is the finding that sexual dimorphism in the expression of selected MUP RNAs is species-specific.

Sexual dimorphism and species specificity of MUP expression was further tested by using calibrated densitometry analysis of total MUPs present in the urine. Correct assignment of an ~18-kDa band as a MUP was confirmed by isoelectric focusing and Western blotting (data not shown) using goat anti-mouse MUP serum (YN-GMMUP, Accurate Chemical & Scientific Corporation, Westbury, NY, USA) as a primary antibody. For this antibody, characteristic precipitin lines are obtained against normal mouse urine and purified mouse MUP, and gives a reaction of full intensity. The result of this analysis is depicted in Fig. 2 and demonstrates that the pattern of sexual dimorphism is significant

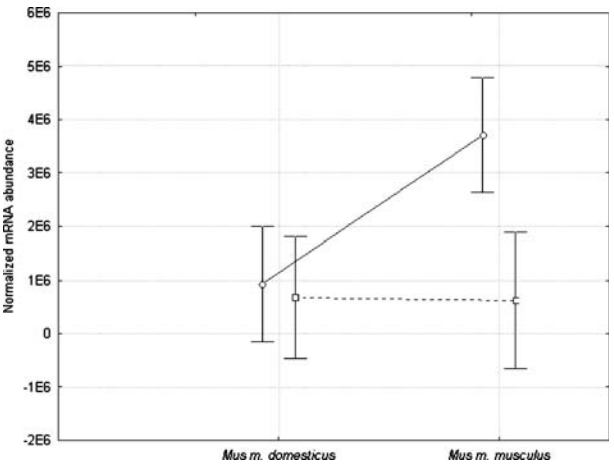

Fig. 1 Subspecies differences in normalized mRNA abundance between *M. m. domesticus* and *M. m. musculus*. Circles connected by a solid line represent differences in mean between males, squares connected by a dashed line represent differences in mean between females with error bars representing confidence intervals (α=0.05)

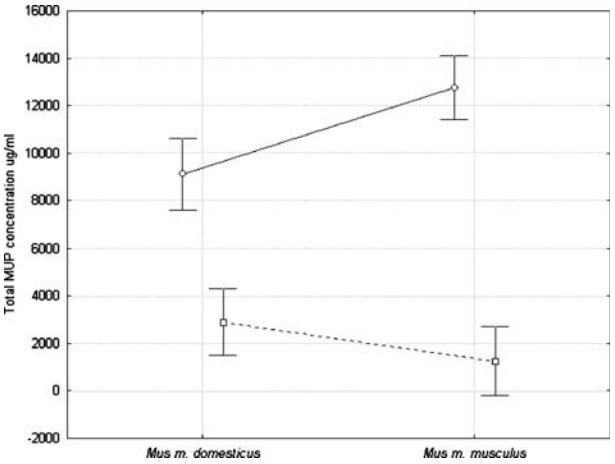

Fig. 2 Subspecies-specific sexual dimorphism in the concentration of major urinary proteins. Circles connected by a solid line represent differences in mean between males, squares connected by a dashed line represent differences in mean between females of both subspecies with error bars representing confidence intervals (α=0.05). It is worth noting that a little difference on the level of mRNA between males and females *M. m. domesticus* (in Fig. 1) yields significant differences on the level of total protein concentration—here demonstrated by nonoverlapping confidence intervals

(F=154.5, df=1, P<0.001) and species-specific (F=13.7, df=1, P<0.001). Our analysis further revealed that MUP production was slightly higher in estrus females, but this trend was not significant (Wilcoxon paired t test: Z=1.153, df=1, P=0.248). However, it is obvious from Fig. 2 that such influence is of limited value as a result of nonoverlapping confidence intervals in each category. It is also worth pointing out that our analysis revealed significant differences between *M. m. domesticus* males and females where other studies have reported no variation (Sampsell and Held, 1985).

Discussion

Differences in gene expression between males and females have been regularly reported in various publications that use high-throughput technologies for arraying large sample sets. Usually, such sexually dimorphic genes are further studied at the level of translation, modifications, and effects on phenotype of studied individuals. The importance of this study is that it shows that species-specific and significant sexual dimorphism at the level of selected MUP mRNA abundance can be corroborated with the level of actual protein concentration in the urine. The strength of this finding is accented by the fact that such species-specific sexual dimorphisms may be a potential mechanism for mate selection differences that have been reported in this species (Smadja and Ganem, 2002).

Our study shows that the abundance of mRNA coding for several major urinary proteins is sexually dimorphic, and that the level of such dimorphism is (sub)species-specific. Major urinary proteins are known to carry volatile pheromones in their hydrophobic beta barrel, and these are released when the urine mark is deposited, and as it slowly dries (Robertson et al., 1993; Hurst et al., 1998). If the intensity of signals directly relates to the abundance of proteins secreted into urine, then this study indicates that individuals of the opposite sex may differentially invest in signaling. Furthermore, we also detected that the level of differences between males and females is smaller in *M. m. domesticus*. This suggests that *M. m. musculus* males invest relatively more energy into MUP production, and that this may potentially be important in the process of female choice. It is also worth noting that our

analysis revealed significant differences in the level of protein concentration and somewhat less reliably (i.e., not significantly) in the level of mRNA between *M. m. domesticus* males and females in which other studies have reported no variation (Sampsell and Held, 1985).

At the behavioral level, Smadja and Ganem (2002) showed that individuals from both populations of the two subspecies can discriminate each other on the basis of urinary signals. However, they also demonstrated that *M. m. musculus* females were choosier than females of *M. m. domesticus*, as when given a choice, they systematically mated with individuals of the same subspecies. Their results, as well as the study by Christophe and Baudoin (1998), corroborate our interpretation of the expression differences detected here, i.e., that males in a more choosy subspecies have to produce more MUPs to outcompete other males in the process of intermale competition and female choice. Moreover, Munclinger and Frynta (1997) lend further support to these findings by revealing that male individuals of *M. m. domesticus* (individuals from Turkey) were less choosy even when given other species (i.e., *M. spretus*, *M. spicilegus*) to choose from. Our findings, along with previously published observations of behavioral discriminations, support the already stated claim that MUPs in *M. m. domesticus* primarily serve to transfer individual specific information (Hurst et al., 2001).

This study deals with the expression differences of MUPs in wild house mice (*Mus musculus*). However, the resulting scent profile is a result of both the combination and interaction of MUPs and pheromones that these proteins carry in their hydrophobic pocket. Recent advances in understanding pheromone communication stem from seminal papers by Novotny (2003) who, following Whitten's definitions (1966) of primer pheromones, demonstrated that two androgen-dependent urinary metabolites, 3,4-dehydro-*exo*-brevicomin and 2-*sec*-butyldihydrothiazole, are effective in promoting estrus synchronization. Other pheromones such as 6-hydroxy-6-methyl-3-heptanone have a profound effect on the acceleration of puberty (Novotny, 2003). An important milestone in the study of pheromonal communication in mice was evidence that MUPs are involved in binding these pheromones (Bacchini et al., 1992) as well as the discovery that nearly all (pheromone) ligands are protein bound (Robertson et al., 1993). To date, there is sufficient evidence in the literature that the action of known and recently discovered pheromones (Novotny, 2003) influence a chain of physiological and behavioral reactions ranging from modulation of estrus to complex behavioral traits such as aggression (Mucignat-Caretta et al., 2004).

Although various published studies explain how scent molecules are transported and protected (e.g., Hurst et al., 1998), there is a need for further determination of which molecules signal identity and which molecules are rather general signals of physiological status specific for each sex. In this respect, our study is important in showing that individual variation in the expression of most of MUPs studied is relatively smaller than that between sexes and species. The abundance of one protein in our study (MUP5) was not species-specific but was highly sexually dimorphic, suggesting that some particular protein isoforms are differentially regulated in each sex regardless of species. The idea of functional specificity for given MUPs is not new (Shahan et al., 1987). However, apart from a few (Pes et al., 1999; Beynon et al., 2002), most studies have been performed on laboratory mice, and species-specificity has not yet been demonstrated in controlled experiments with wild or wild-derived mice. Here, we suggest that because of detected sexual dimorphisms in the abundance of MUP mRNA in the liver and the proteins in the urine, the function of these proteins may rather be sexual in that females use the scent information to evaluate quality of competing males before or during mating. Although, there is no direct evidence that females use marks to evaluate the quality of particular males in the process of mate choice, it is possible that male marking and overmarking (Humphries et al., 1999) may

locally reinforce individual (male) fitness benefits. Thus, the *regulation* of expression of MUPs (rather than the diversity of MUP isoforms) would be the trait under sexual selection. Further investigation is required to determine to what extent the detected variation in the expression of MUPs is genetic as opposed to phenotypic.

Acknowledgments We are grateful to Timothy Hort for language correction, Jaroslav Pialek, Milos Macholan, and Pavel Munclinger for helpful discussions. The work was funded by the Grant Agency of the Czech Republic (206-04/0493), whereas grant MSMT VZ 0021620828 from the Ministry of Education, Youth and Sport of the Czech Republic formed a framework for this study.

Abstract Bufonid toads of the genus *Melanophryniscus* represent one of several lineages of anurans with the ability to sequester alkaloids from dietary arthropods for chemical defense. The alkaloid profile for *Melanophryniscus stelzneri* from a location in the province of Córdoba, Argentina, changed significantly over a 10-year period, probably indicating changes in availability of alkaloid-containing arthropods. A total of 29 alkaloids were identified in two collections of this population. Eight alkaloids were identified in *M. stelzneri* from another location in the province of Córdoba. The alkaloid profiles of *Melanophryniscus rubriventris* collected from four locations in the provinces of Salta and Jujuy, Argentina, contained 44 compounds and differed considerably between locations. Furthermore, alkaloid profiles of *M. stelzneri* and *M. rubriventris* strongly differed, probably reflecting differences in the ecosystem and hence in availability of alkaloid-containing arthropods.

Keywords Alkaloids · Ants · Arthropods · Bufonid toads · Mites

Introduction

Amphibians produce bioactive substances and in some cases sequester bioactive substances from dietary sources (Daly et al., 1987; Daly, 1995). Such substances appear to be stored in

so-called granular or poison glands of the skin and are used as chemical defenses against predators and/or microbial infection. Substances produced by amphibians include a variety of antibiotic peptides (Bevins and Zasloff, 1990), distasteful biogenic amines and congeners (Roseghini et al., 1976, 1986), toxic steroidal bufadienolides (Flier et al., 1980; Daly et al., 2004), toxic samandarine alkaloids (Schöpf, 1961; Mebs and Pogoda, 2005), and the indolic pseudophrynamine alkaloids (Daly et al., 1990; Smith et al., 2002). The role of symbiotic microorganisms in biosynthesis of tetrodotoxins in amphibians remains unresolved. Evidence both for a role in symbiotic organisms (Daly et al., 1997b) and in production by an amphibian (Cardall et al., 2004) have been presented. The remarkable sequestration of a wide structural range of lipophilic alkaloids into skin glands of so-called poison frogs/toads of the neotropical dendrobatid genera *Dendrobates*, *Epipedobates*, *Minyobates*, and *Phyllobates* (Daly et al., 1994a,b; Jones et al., 1999 and unpublished) the Madagascan mantellid genus *Mantella* (Daly et al., 1997a), and undoubtedly the South American bufonid genus *Melanophryniscus* (Garraffo et al., 1993) suggests that these taxa either have overexpressed a primitive alkaloid-transport system or have independently evolved such a system. Myobatrachid frogs of the Australian genus *Pseudophryne* apparently have a different transport system that can transport pumiliotoxins, but not simple decahydroquinoline and izidine alkaloids that would occur in their ant diet (Smith et al., 2002).

Analysis of sequestered arthropod alkaloids has led to discovery and characterization of over 800 alkaloids during 40 year of investigation of skin extracts of poison frogs/toads (Daly et al., 2005). Fifty of such frog skin alkaloids have been detected in extracts of ants (Jones et al., 1999; Daly et al., 2000; Saporito et al., 2004; Clark et al., 2005), beetles (Dumbacher et al., 2004), millipedes (Saporito et al., 2003), mites (Takada et al., 2005), and various other arthropods (Daly et al., 2002).

The occurrence of alkaloids in different populations and species of poison frogs/toads provides information as to the distribution and availability of the arthropods that provide alkaloids to them. Thus, if species of the bufonid genus *Melanophryniscus* at a particular site and/or collection time do not have alkaloids known or presumed to be from a certain group of arthropods, then that mite, ant, beetle, or millipede is either not present or not targeted by the toad, perhaps, in the latter case because of more readily available arthropod prey that do not contain alkaloids. This question has been recently investigated and discussed both from a temporal and spatial standpoint for seven populations of the poison frog *Dendrobates pumilio* on a small island in the Bocas archipelago of Panamá (Saporito et al., 2006). Early studies of the alkaloid profile of *D. pumilio* extracts from some of the same populations also had indicated that distance between sites and the nature of habitat greatly influenced the profile (Daly et al., 2002). Similarly, the number of shared alkaloids in populations of the Colombian/Ecuadorian poison frog *Dendrobates histrionicus* was inversely related to the distance between collection sites, with frogs from sites close to each other sharing a greater number of alkaloids (Myers and Daly, 1976).

We report in this study both temporal changes in alkaloid profiles for one population of the bufonid toad *Melanophryniscus stelzneri* and spatial differences in alkaloid profiles for four populations of the bufonid toad *Melanophryniscus rubriventris*. The results are discussed in terms of possible arthropod food sources of the 72 alkaloids identified in extracts of these two toad species. Additional trace alkaloids were detected, but could not be adequately characterized. Structures of most of the major and minor alkaloids detected are shown (Fig. 1). Preliminary evidence for the postulated structures (Daly et al., 2005) of one pumiliotoxin, a dehydro-5,8-disubstituted indolizidine, and seven izidine alkaloids are presented.

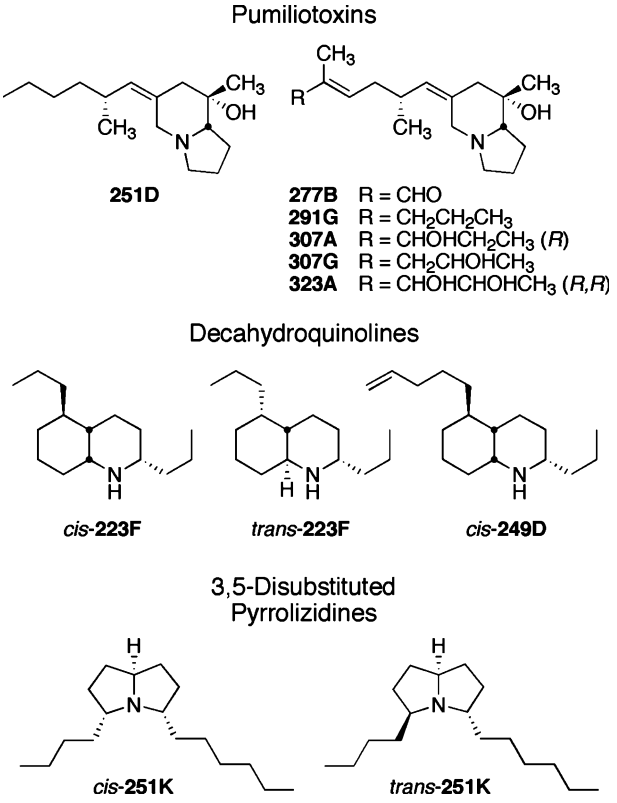

Fig. 1 Structures of major and minor alkaloids in collections of *Melanophryniscus stelzneri* and *Melanophryniscus rubriventris*. Postulated tentative structures of izidines **207S**, **207T**, and **221R** (Daly et al., 2005) are shown in Fig. 5. Structures of proposed tricyclics **203B**, **205H**, **221S**, **235I**, and **237O** and unclassified alkaloid **223T** are not known (see Daly et al., 2005)

Methods and Materials

Specimens of *Melanophryniscus stelzneri* were collected in May, 1989 (23 skins), and again in October, 1999 (eight skins), in fields with marshy streams and ponds during periods of heavy rain near the small town of Tanti, Córdoba, Argentina. Two males (combined skins) and two females (combined skins) were collected as amplexing pairs at the same site in November, 2001. *M. stelzneri* (31 skins) from another site in Córdoba were provided by Dr. Eduardo Gros.

Specimens from four populations of *M. rubriventris* were collected in 2002 in Argentina from forested sites at Cedral de Baritú (22° 29′ S, 64° 45′ W) (13 skins) and Canto del Monte (22° 22′ S, 64° 43′ W) (nine skins) in Salta and at Abra Colorada (23° 40′ S, 64° 53′ W) (11 skins) and Tiraxi (24° 01′ S, 65° 23′ W) (two skins) in Jujuy.

Skins were placed in methanol and extracts were subjected to acid-base partitioning as described (Garraffo et al., 1993). Compounds in the resultant alkaloid fraction were characterized by GC-MS and GC-FTIR spectral analysis (Garraffo et al., 1999). Arthropod stomach contents of *M. rubriventris* from the four sites were assessed as described (Bonanseal and Vaira, 2007).

Mass spectral data (EIMS, EI-MS/MS, CIMS (NH_3) and CI-MS/MS (NH_3)) were obtained with a Finnigan Thermoquest GCQ instrument, having a Restek RTX-5MS capillary column (30 m, 0.25 mm i.d.) programmed from 100° to 280° at 10° per min. GC-FTIR and EIMS spectra were obtained with a Hewlett–Packard model 5890 gas chromatograph, having

an HP-5 fused silica-bonded capillary column (30 m, 0.32 mm i.d.) programmed from 100 to 280° at a rate of 10° per min and interfaced with an HP model 5971 Mass Selective Detector and a Model 5965B IRD with a narrow band (4,000–750 cm^{-1}) detector. An HP ChemStation was used to generate EIMS and FTIR spectra.

Results and Discussion

Analysis of alkaloids in skin of the toad *Melanophryniscus stelzneri* collected in Tanti, Córdoba, Argentina, in 1989 was reported in 1993 (Garraffo et al., 1993) and has been updated in the present report with additional data (Table 1). Alkaloid profiles for two males and two females collected in 2001 were similar (Table 2). Profiles from another population of *M. stelzneri* from Las Alpacas, Córdoba were reported in 1993 (Garraffo et al., 1993). An updated profile is reported (Table 3).

The profile of alkaloids reported in 1993 (Garraffo et al., 1993) for *M. stelzneri montevidensis* from La Coronilla, Rocha, Uruguay, consists of pumiliotoxin **251D** and 3,5-disubstituted indolizidine 5*Z*,9*E*-**195B** as major alkaloids. Six trace alkaloids were also reported. This frog is now considered to be *Melanophryniscus montevidensis*, populations of which were recently reported to contain mainly pumiliotoxin **251D** (Mebs et al., 2005). However, pumiliotoxin **251D** in the La Coronilla population was present in only trace amounts (see below).

M. stelzneri (two males/two females), Tanti, Córdoba, November, 2001. Major alkaloid > 50 μg per 100 mg skin; minor 5–50 μg per 100 mg skin; trace < 5 μg per 100 mg skin.

[a] Tentative identification.

[b] Not detected in the other sex.

[c] The prime in **235E′** indicates a trace isomer, in this case, after **235E** on GC analysis.

GC-MS chromatograms for the alkaloid fractions from the 1989 and 1999 collections of *M. stelzneri* are shown (Fig. 2). The toad and the collection site near Tanti are shown in Fig. 3. The site reportedly had undergone little obvious change from 1989 to 1999. Some major and minor alkaloids were present in both the 1989 and 1999 extracts, namely pumiliotoxin **251D**, both *cis*- and *trans*-isomers of the 3,5-disubstituted pyrrolizidine **251K**, the 5,8-disubstituted indolizidine **259B**, the dehydro-5,8-disubstituted indolizidine **219G**, and the 5,6,8-trisubstituted indolizidine **235E** (Table 1). The pumiliotoxins and the 5,8-

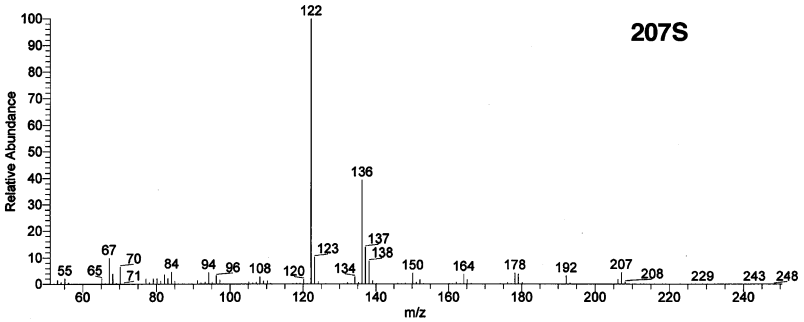
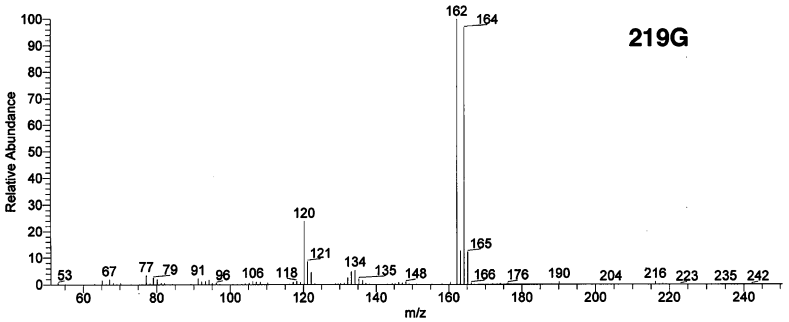
disubstituted- and 5,6,8-trisubstituted-indolizidines are likely of mite origin (Takada et al., 2005; Saporito et al., 2006), while the 3,5-disubstituted pyrrolizidines are likely of ant origin (Jones et al., 1999). However, all of the decahydroquinolines, likely of ant origin (Jones et al., 1999), present in abundance in the 1989 extract, were completely absent from the 1999 extract (Table 1). The 3,5-disubstituted indolizidines, a class likely of ant origin (Jones et al., 1999), present in the 1989 extract, were also absent from the 1999 extract. Finally, the beetle alkaloid precoccinelline (**193C**), and the millipede spiropyrrolizidine alkaloid **236** were absent in the 1999 extract. The most likely explanation is that the ants, beetles, and millipedes had come to represent a less available source of alkaloids during the 10-year period at this site, while perhaps mites had become a more dominant source of

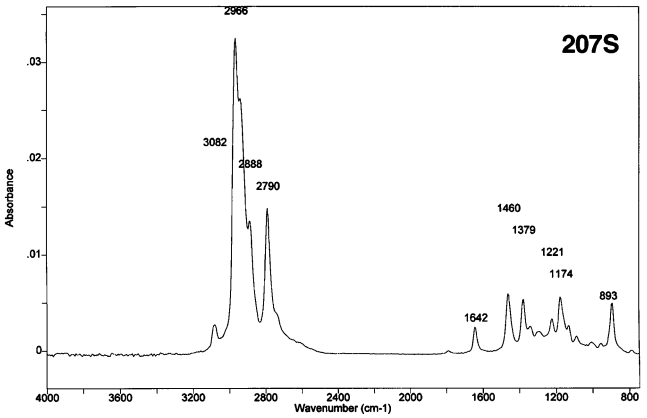
Fig. 3 A *Melanophryniscus stelzneri* toad from Tanti and the collection site



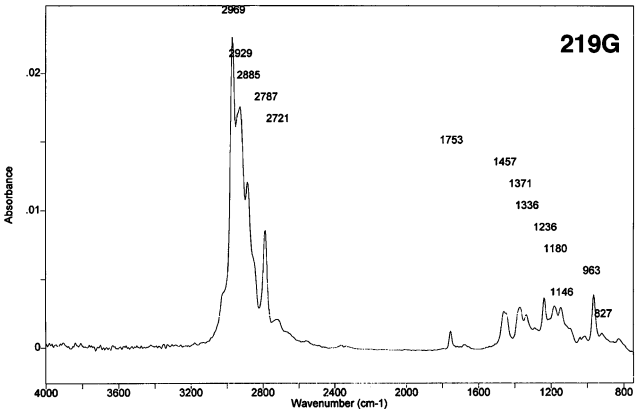
alkaloids for *M. stelzneri*. The arthropod stomach contents of *M. stelzneri* from "El Trapiche", San Luis, Argentina, have been reported (Filipello and Crespo, 1994). The three most common categories of prey items were ants, mites, and Collembola.



The proposed structure for the dehydro-5,8-disubstituted indolizidine **219G** (Daly et al., 2005) present as a minor alkaloid in the 1989 extract and as a major one in the 1999 extract, is based on chemical and spectral properties. The structure is shown (Fig. 1), as are the EIMS and FTIR spectra (Fig. 4). The FTIR band at 963 cm^{-1} indicates a *trans*-double bond. About 30 skin alkaloids are now assigned to the dehydro-5,8-disubstituted indolizidine class (Daly et al., 2005).



Two alkaloids (**193I** and **207S**) in the 1999 extract have been proposed to be "izidines" (Daly et al., 2005), based on GC-MS spectral properties, and for **207S** also on GC-FTIR spectral properties. The spectra of **207S** are shown (Fig. 4). The proposed structures (Fig. 5) are tentative, and isolation and NMR spectral analysis will be required to establish absolute structures.



The males/females from two amplexing pairs collected in 2001 from the site near Tanti had similar profiles (Table 2). Twenty-eight alkaloids, including isomers, were identified. All major/minor alkaloids except the unclassified alkaloids **233K** and **267Y** had been detected in the 1989 and/or 1999 collections. Nine of the 14 trace alkaloids (six in males, three in females) were detected in only one sex. Seven of the trace alkaloids were detected for the first time in four decades of analysis of anuran skin alkaloids. Tentative structures for the two new indolizidines **193M** and **251EE** are depicted (Fig. 5). The properties of the seven trace alkaloids (in the format of the supporting information of Daly et al., 2005) that were previously unreported are as follows: **193M**. 5,8-I. '$C_{13}H_{23}N$'. Fig. 5 Tentative structures for izidines and a pumiliotoxin in collections of *Melanophryniscus stelzneri* and *Melanophryniscus rubriventris*. Structures for those indicated by an apostrophe (*) were postulated (Daly et al., 2005), based on GC-MS and in some cases GC-FTIR data. ‡High resolution MS data now obtained

site is uncertain. Decahydroquinolines, pyrrolizidines, and indolizidines comprise 18 of the 21 alkaloids detected. All major alkaloids in this extract are likely of ant origin (cf., Jones et al., 1999).

The profile of alkaloids in a 1987 collection of *M. montevidensis* from La Coronilla, Rocha, Uruguay, was quite different. Pumiliotoxin **251D** and 3,5-disubstituted indolizidine 5*Z*,9*Z*-**195B** were the only major alkaloids (Garraffo et al., 1993). There were six others, all in trace amounts. These consist of three homopumiliotoxins **319A**, **319B**, and **321B**, the 5*E*,9*Z* isomer of indolizidine **195B**, and two 3,5-disubstituted pyrrolizidines, *cis*-**223H** and **237G**. Structures for the homopumiliotoxins have been proposed (Garraffo et al., 1993; Daly et al.,

2005). The indolizidines and pyrrolizidines are undoubtedly of ant origin (cf., Jones et al., 1999), while pumiliotoxin **251D** appears likely to be of mite origin (cf., Takada et al., 2005; Saporito et al., 2006) as are probably the structurally similar homopumiliotoxins.

Recently, alkaloids detected in whole body methanolic extracts of 81 *M. montevidensis* collected from six sites in Uruguay from October, 2003, to February, 2004, were reported (Mebs et al., 2005). La Coronilla was one of the six sites. Pumiliotoxin **251D** and indolizidine 5*Z*,9*E*-**195B** were major alkaloids (>50 μg/toad skin) in extracts from 39 skins of *M. montevidensis* collected in 1987 (see above) and supplied to us by Vittorio Erspamer (Garraffo et al., 1993). None of the whole body extracts from 20 individual toads collected in 2003–2004 had more than trace amounts (1 g/toad or less) of pumiliotoxin **251D** or of an unidentified indolizidine (perhaps **195B**, which was a major alkaloid in the 1987 collection). This seems to represent a remarkable temporal change in alkaloid content,

although it is uncertain whether the locations of the La Coronilla sites are exactly the same. Toads from two of the more southern sites had variable, but in some cases very high levels (>400 g/toad) of pumiliotoxin **251D** (Mebs et al., 2005).

The profile of alkaloids in the four different populations of *M. rubriventris* differed markedly (Table 4). GC-MS chromatograms are shown (Fig. 6) and toads from each site illustrate the variation in color and patterns (Fig. 7). The known distribution of the species in Argentina is confined to the upland portion of northwestern subtropical montane forests (Andean Yungas) and limited to six disjunct areas. Three populations are known in the north and central regions of Salta, and three are in the southeast of Jujuy. All are between 1,000 to 2,000 m elevation (Vaira, 2002). A map shows the four collection sites (Fig. 8). The collection site near Tanti, Córdoba, for *M. stelzneri* is also included in this map. The sites at which *M. rubriventris* are found, usually are well-structured cloud forests with richness in vegetation species and high vegetation density. Such steep, forested slopes are dominated by an evergreen-shaded forest, with a lush epiphytic growth mainly of bromeliads, ferns, mosses, and liverworts. Moderately steep portions of the forest allow temporary ponds that *M. rubriventris* use as breeding sites. The toads also are relatively common and easily seen in secondary forests, even on partly altered habitats, such as along montane trails or roads (Lavilla and Vaira, 1997). Toads choose small shallow ponds with rooted herbs for egg deposition. These little ponds are filled only during spring and summer rainstorms (Vaira, 2005). Further detailed studies on the botanical composition and arthropod occurrence at sites of the *Melanophryniscus* collections are needed. The spectrum of arthropods in the stomachs of toads from each of the collection sites are reported (Table 5). The spectra differed in terms of proportions of the two major prey items, ants, and mites.

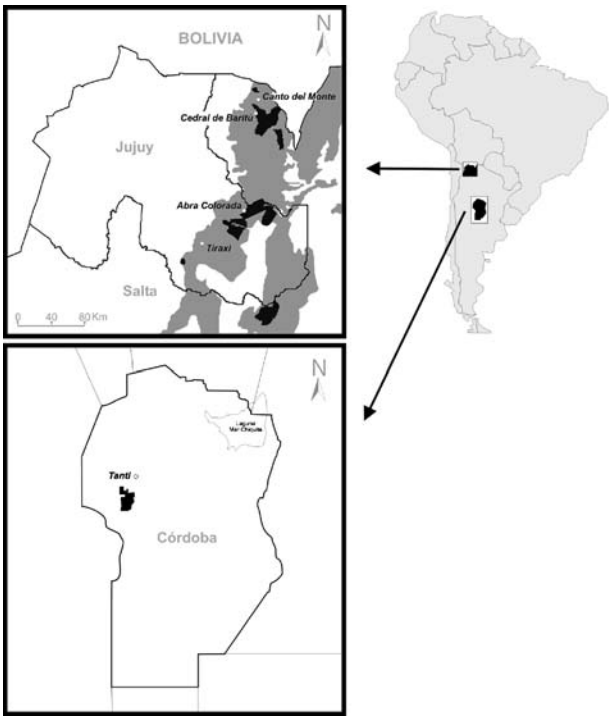

Fig. 8 Collection sites in Argentina for *Melanophryniscus stelzneri* and *Melanophryniscus rubriventris*. Protected areas in black. NW subtropical montane forests in black and in grey

Pumiliotoxins were present as major alkaloids at each site. Pumiliotoxin **307G** was a major alkaloid in extracts of toads from Abra Colorada, Cedral de Baritú, and Canto del Monte, and a minor one in extracts from Tiraxi. Other major pumiliotoxins were **323A** from Abra Colorada and Tiraxi, **291G** from Cedral de Baritú and Canto del Monte, and **251D** from Tiraxi. If mites are the source of the pumiliotoxins, different species might be used as dietary sources at the 4 sites. Only in the extract from Tiraxi, a trace of the allopumiliotoxin **267A** was detected, while a trace of the deoxyhomopumiliotoxin **207O** was detected only in the extract from Canto del Monte. One of the trace pumiliotoxins (**319C**) was detected for the first and, as yet, only time in these *M. rubriventris* extracts. This alkaloid was reported as unclassified with an unknown structure (Daly et al., 2005). Further analysis of the data indicates that it is a pumiliotoxin. A tentative structure is depicted (Fig. 5).

Decahydroquinolines, presumably of ant origin, were absent from the extracts of *M. rubriventris*, as were the ant-derived 3,5-disubstituted pyrrolizidines and 3,5-disubstituted indolizidines, with the sole exception being a trace amount of the 3,5-disubstituted indolizidine **223AB**, in the extract from Canto del Monte. In contrast, the 5,8-disubstituted indolizidines **261D** and **273C** occurred as minor alkaloids, each in one extract, while the 5,6,8-trisubstituted indolizidine **195G** occurred as a trace alkaloid in all four extracts. Two other 5,6,8-trisubstituted indolizidines (**207C** and **221Q**) also occurred in trace amounts in one or two extracts. Such indolizidines with branch points in the carbon skeleton are suspected to be of mite origin (Takada et al., 2005; Saporito et al., 2006). Several izidines (**191D**, **191E**, **205F**, **205G**, **207T**, and **221R**) occurred in minor or trace amounts usually in only one extract with the exception of **221R**, which occurred in two. Possible izidine structures have been proposed for some (Daly et al., 2005) and are shown (Fig. 5). All except **205F** and **205G** had not been detected previously and, thus, like pumiliotoxin **319C**, are as yet known only from *M. rubriventris*.

Table 5 Number of arthropods in stomach contents (expressed as percentage of each prey category by number in the total prey) from four populations of *Melanophryniscus rubriventris* in NW Argentina

Prey Categories	Abra Colorada (20)	Cedral de Baritú (26)	Canto del Monte (13)	Tiraxi (59)
Acari	35.6	8.3	39.6	20.0
Araneae	0.4	1.3	1.6	1.4
Coleoptera	8.7	6.5	4.5	4.7
Collembola	6.9	0.0	4.2	22.0
Diptera	0.7	0.0	0.3	0.3
Hemiptera	6.9	3.3	5.3	39.2
Hymenoptera (no Formicidae)	2.9	1.3	2.9	6.4
Formicidae	37.5	79.3	41.1	5.9
Plecoptera	0.4	0.0	0.0	0.0
Miriapoda	0.0	0.3	0.4	0.0

The numbers in parentheses indicate the number of toads examined.

Tricyclics were present as major or minor alkaloids in all extracts of *M. rubriventris* except the one from Abra Colorada, where tricyclic **221W** was present as a trace alkaloid. Presumably, the tricyclics, in particular precoccinelline (**193C**), a major alkaloid in the Tiraxi extract, are of beetle origin (Ayer and Browne, 1977). However, precoccinelline and another tricyclic alkaloid were recently reported from an oribatid mite (Takada et al., 2005). Except for **193C**, structures for all proposed tricyclics from *Melanophryniscus* species are not known (Daly et al., 2005).

The results suggest that the nature and/or availability of dietary sources of alkaloids found in skin of *Melanophryniscus* toads is strongly dependent on the site of collection and can change markedly with time. Alkaloid profiles from other sites and species of *Melanophryniscus* have been determined (Garraffo et al., 1993; Mebs et al., 2005; and for *Melanophryniscus klappenbachi* and *Melanophryniscus cupreuscapularis*, unpublished data with J. Faivovich and P. Cacivio). Such profiles differ markedly from the alkaloid profiles in the two species of the present report.

Individual variability in alkaloid profiles within a population does occur in *Melanophryniscus* (Mebs et al., 2005) and also in dendrobatid (Saporito et al., 2006) and mantellid frogs (Clark et al., 2005). Remarkable variability in levels of pumiliotoxin **251D** has been reported for 81 individual *M. montevidensis* from Uruguay (Mebs et al., 2005). The occurrence in trace amounts or nondetection of six other pumiliotoxins was also reported. An undefined indolizidine x was detected in all extracts, but apparently only in trace amounts. Pumiliotoxin **251D** varied from undetectable in certain individuals and present in trace amounts in others (<1 g/toad) from the two northern populations to levels of over 200 g/toad in individuals of three of the four southern populations. Mean values for the southern populations ranged from 29±16 g/toad (only two individuals) and 44± 21 g/toad (17 individuals) to very high levels of 198±51 g/toad (11 individuals) and 307± 34 g/toad (29 individuals). Obviously, both site and individual variations were considerable for pumiliotoxin **251D** in that study on *Melanophryniscus*. Pumiliotoxins were not detected in small arthropods, mainly ants collected in "various areas of Uruguay". Mites are the probable dietary source of pumiliotoxins (Takada et al., 2005; Saporito et al., 2006). However, only a limited number of mites were analyzed. Further studies on the factors responsible for temporal, individual, and site variation are needed.

The arthropod stomach contents of *M. rubriventris* are summarized (Table 5). Arthropod stomach contents were essentially similar in number of prey categories, but with a noticeable interpopulation diet variation with respect to the proportions of each prey item consumed. The high proportion of ants and low proportion of mites in the diet of toads from Cedral de Baritú was striking. However, pumiliotoxins, thought to be of mite origin, were the dominant alkaloids (Table 4). Perhaps, no simple correlation exists between the number of prey items and the alkaloid content in toad skin because some of the minor prey items might have very high alkaloid content and major prey items might be devoid of alkaloids. Toads from Tiraxi had a more generalized diet than the other populations. Ants represented a minor component of diet. Instead Acari (mites), hemipterans, and collembolans were the main prey categories. Pumiliotoxins thought to be of mite origin were the dominant alkaloids. Such differences in decreased consumption of ants may reflect changes in the composition of the arthropod assemblage or species availability.

Consumption of a different array of prey items could also be a consequence of changes in foraging habits in the individuals from the Tiraxi population. Prey-searching behavior is unknown for *M. rubriventris*, but adults are mainly diurnal and mobile with most of their reproductive activity taking place during daylight over the entire breeding season (Vaira, 2005). However, one of us repeatedly registered events of breeding activity at night in the population of Tiraxi (M.V. personal observation). Differences in diet for this population might reflect foraging adaptations to nocturnal habits, and consequently different prey communities, rather than prey selectivity or differential availability of arthropod species.

Further studies on the dietary origin of the arthropod alkaloids sequestered into anuran skin are needed. The factors that govern availability of such alkaloid-containing arthropod prey may help to understand better the ecology of *Melanophryniscus* and other anurans that depend either in part or exclusively on a diet of alkaloid-containing arthropods for protection against predators. Dendrobatid and mantellid poison frogs apparently have no other noxious substances beyond the alkaloids sequestered from their diet. However, toads of the genus *Melanophryniscus*, like other bufonids (Daly et al., 2004), have high levels of toxic bufadienolides or bufadienolide-like compounds (Flier et al., 1980), which would protect populations even where alkaloid-containing prey are not available. Myobatrachid frogs of the genus *Pseudophryne* produce their own pseudophrynamine alkaloids, in addition to sequestering pumiliotoxins from dietary arthropods (Smith et al., 2002). The evolutionary forces that led in four different anuran lineages to sequestration and use of dietary alkaloids in chemical defense remains intriguing and enigmatic.

Acknowledgments J.M.W. was supported by the NIH Undergraduate Scholarship Program. Fieldwork on *M. rubriventris* was done as part of a project supported by a grant from CONICET to M.V. Permits for sample collection of the species were provided by Delegación Técnica de Parques Nacionales, Regional Noroeste, Argentina. The research at NIH was supported by the intramural program of NIDDK.

Abstract Males of several species of longhorned beetles in the subfamily Cerambycinae produce sex or aggregation pheromones consisting of 2,3-hexanediols and/or hydroxyhexanones. We tested the hypothesis that this diol/hydroxyketone pheromone motif is highly conserved within the subfamily, and the resulting prediction that multiple cerambycine species will be attracted to compounds of this type. We also tested the concept that live traps baited with generic blends of these compounds could be used as a source of live insects from which pheromones could be collected and identified. Traps placed in a mature oak woodland and baited with generic blends of racemic 2-hydroxyhexan-3-one and 3-hydroxyhexan-2-one captured adults of both sexes of three cerambycine species: *Xylotrechus nauticus* (Mannerheim), *Phymatodes lecontei* Linsley, and *Phymatodes decussatus decussatus* (LeConte). Odors collected from male *X. nauticus* contained a 9:1 ratio of two male-specific compounds, (*R*)- and (*S*)-3-hydroxyhexan-2-one. Field trials with synthetic compounds determined that traps baited with (*R*)-3-hydroxyhexan-2-one (94% ee), alone or in blends with other isomers, attracted similar numbers of *X. nauticus* of both sexes, whereas (*S*)-3-hydroxyhexan-2-one (94% ee) attracted significantly fewer beetles. *Phymatodes lecontei* and *P. d. decussatus* also were caught in traps baited with hydroxyhexanones, as well as a few specimens of two other cerambycine species, *Neoclytus modestus modestus* Fall (both sexes) and *Brothylus gemmulatus* LeConte (only females). Male *N. m. modestus* produced (*R*)-3-hydroxyhexan-2-one, which was not present

in extracts from females. *Neoclytus m. modestus* of both sexes also responded to lures that included (*R*)-3-hydroxyhexan-2-one as one of the components. The only male-specific compound found in extracts from *P. lecontei* was (*R*)-2-methylbutan-1-ol, and adults of both sexes were attracted to racemic 2-methylbutan-1-ol in field bioassays. Surprisingly, *P. lecontei* of both sexes also were attracted to (*R*)- and (*S*)-3-hydroxyhexan-2-ones, although neither compound was detected in extracts from this species. Males of all five beetle species had gland pores on their prothoraces that were similar in structure to those that have been associated with volatile pheromone production in other cerambycine species. The attraction of multiple cerambycine species of two tribes to (*R*)-3-hydroxyhexan-2-one in this study, and in earlier studies with other cerambycine species, suggests that this compound is a widespread aggregation pheromone component in this large and diverse subfamily. Overall, the attraction of multiple species from different cerambycine tribes to this compound at a single field site supports the hypothesis that the hydroxyketone pheromone structural motif is highly conserved within this subfamily.

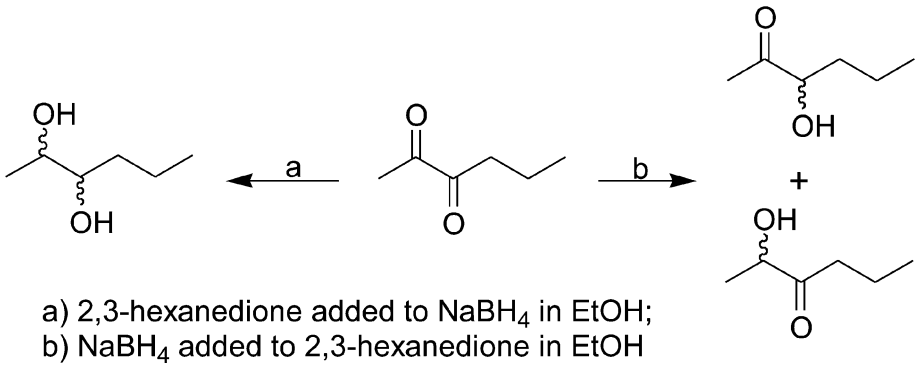
Introduction

Males of several longhorned beetle species in the subfamily Cerambycinae produce volatile sex or aggregation pheromones (Lacey et al. 2007a). These pheromones are comprised of one to three compounds that share a similar structural motif consisting of molecules that are six, eight, or 10 carbons in length, with hydroxyl or carbonyl groups at C_2 and C_3 (reviewed by Lacey et al. 2004, 2007a). The pheromones are produced by sex-specific glands in the prothorax of males that discharge through pores situated within depressions in the cuticle (Ray et al. 2006; Lacey et al. 2007b). A morphological survey of 65 cerambycine species revealed that 49 species in 14 tribes had analogous male-specific prothoracic pores, suggesting that volatile pheromones may play an important role in reproduction or other behaviors for many species in this subfamily (Ray et al. 2006). The Cerambycinae is represented by at least 1,100 species in North America alone (excluding Mexico; Yanega 1996). Given this taxonomic diversity, and the many cerambycine species that have male-specific gland pores, it is likely that multiple species that produce volatile pheromones will be present in any given geographic area.

In this paper, we report the results of studies that tested the hypothesis that the diol/hydroxyketone pheromone motif is highly conserved within the Cerambycinae, and the resulting prediction that multiple cerambycine species will be attracted to compounds of this type. We chose six-carbon compounds for this first test of the hypothesis, rather than eight- or ten-carbon homologs, because all 10 North American cerambycine species that we have worked with previously were found to produce C_6 pheromones (Lacey et al. 2004, 2007a; Ray et al. 2006; unpublished data). Thus, 2,3-hexanediols, 2-hydroxyhexan-3-ones, and 3-hydroxyhexan-2-ones were synthesized and deployed as trap lures in field bioassays. Beetles that were attracted to the test compounds were trapped live, and the volatiles that they released were collected and analyzed to identify the actual pheromone compounds produced by each species. We report here the species that responded to the synthetic hexanediol and hydroxyhexanone lures in field bioassays conducted in one area of southern California. We further report the identification of pheromone components for three of these cerambycine species, *Xylotrechus nauticus* (Mannerheim), *Phymatodes lecontei* Linsley,



and *Neoclytus modestus modestus* Fall. We also characterize the morphology of the likely gland pores for each cerambycine species that was captured.

Methods and Materials

Synthetic Pheromones

A mixture of 2,3-hexanediols (henceforth generic hexanediols) was synthesized as follows (Scheme 1a). A solution of 2,3-hexanedione (114.15 g, 1.0 mol; Aldrich Chemical Co., Milwaukee, WI, USA; >90% purity) in ethanol (EtOH, 200 ml) was added over 3 hr to a stirred mixture of $NaBH_4$ (26.5 g, 0.70 mol) in EtOH (300 ml) at 0°C under argon. The reaction was warmed to room temperature and stirred overnight. The resulting mixture was concentrated, then poured into a stirred mixture of brine (500 ml) and 6 M HCl (200 ml), and extracted with ethyl acetate (5×200 ml). The combined organic phases were washed with saturated aqueous $NaHCO_3$, dried over anhydrous Na_2SO_4, and concentrated by rotary evaporation. The residue was purified by Kugelrohr distillation (oven temperature 81–90°C, 3.0 mm Hg) affording 90.42 g (77% yield) of a mixture of racemic (2*R**,3*R**)-hexanediol and (2*R**,3*S**)-hexanediol (36:64, respectively: GC analysis on DB-5 column, 30 m×0.32 mm i.d., 0.25 μm film; J&W Scientific, Folsom, CA, USA; temperature program 40°C/1 min, 10°/min to 250°, helium carrier gas, head pressure 105 kPa, injector and detector temperatures, 250°C). The mass spectra and retention times matched those of standards (Lacey et al. 2004; GC-MS analysis, HP 5973 mass selective detector coupled to an HP 6890 GC [Hewlett-Packard, Avondale, PA, USA] fitted with an HP5-MS column, 30 m×0.25 mm i.d., 0.25 μm film, temperature program 40°C/1 min, 10°/min to 250°, helium carrier gas, 36 cm/sec linear flow, injector and transfer line temperatures, 250°C).

A blend of 2,3-hydroxyhexanones for bioassay trap lures (henceforth generic hydroxyhexanones), consisting of a mixture of racemic 2-hydroxyhexan-3-one and 3-hydroxyhexan-2-one, was synthesized as shown in Scheme 1b. A suspension of $NaBH_4$ (3.73 g, 99 mmol) in EtOH (80 ml) was added dropwise over 2 hr to a stirred solution of 2,3-hexanedione (30.00 g, 263 mmol; Aldrich Chem. Co.) in EtOH (60 ml) at 0°C. The resulting mixture was stirred for 8 hr at 0°C, and then allowed to warm to room temperature and stirred overnight. Water (150 ml) was added and the reaction was extracted with pentane:diethyl ether (Et_2O) (1:1–5×100 ml). The combined organic extracts were washed

Scheme 1 Synthesis of generic blends of 2,3-hexanediols and 2,3-hydroxyhexanones

with brine, dried over Na_2SO_4, and the solvent was removed by fractional distillation through a Vigreux column (fractional distillation was essential because concentration by rotary evaporation resulted in loss of the product). The residue was purified by vacuum flash chromatography (pentane/Et_2O 95:5 until all unreacted 2,3-hexanedione had been removed, then pentane/Et_2O 4:1). The solvent was removed by distillation through a Vigreux column, and the product was Kugelrohr distilled (oven temperature 40–45°C, 2.1 mm Hg) affording 13.81 g (45.2% yield) of a mixture of racemic 2-hydroxyhexan-3-one and 3-hydroxyhexan-2-one (59:41, respectively). Retention times and mass spectra of the two isomers matched those of authentic standards (Lacey et al. 2007a). The positional isomers were not separated on a DB-5 GC column, but both the positional isomers and the enantiomers were resolved on a chiral phase Cyclodex B column (30 m×0.25 mm i.d.× 0.25 μm film, J&W Scientific; temperature program 50°C/1 min, 5°/min to 250°, helium carrier gas, head pressure 150 kPa, injector temperature 100°C and detector temperatures 250°C). The four hydroxyhexanones eluted in the order (2*R*) (10.49 min), (3*R*) (10.56 min), (2*S*) (10.67 min), and (3*S*) (11.10 min). It was crucial to use an injector temperature of 100° C to prevent thermal isomerization of the hydroxyhexanones (Leal et al. 1995).

Racemic 3-hydroxyhexan-2-one and enantiomerically enriched (*R*)-3-hydroxyhexan-2-one and (*S*)-3-hydroxyhexan-2-one (both 94% ee) were synthesized as previously described (Lacey et al. 2007a). Racemic 2-methylbutan-1-ol (98%) was obtained from Alfa Aesar (Heysham, Lancashire, UK) and (*S*)-2-methylbutan-1-ol (99%) was obtained from Aldrich Chemical Co. The enantiomers of 2-methyl-1-butanol were resolved on the Cyclodex B column with a temperature program of 40°C/10 min, 5°/min to 200°C, with other operating conditions as described above. Under these conditions, the (*R*)-enantiomer eluted at 13.64 min, whereas the (*S*)-enantiomer eluted at 13.82 min.

Screening Bioassays to Target Species for Pheromone Identification

We targeted species for pheromone identification by baiting traps for collecting live insects with generic hexanediols, generic hydroxyhexanones, or a 1:1 blend of the two. The mixtures were diluted with absolute EtOH (Gold Shield Co., Hayward, CA, USA) (100 mg/ml for the single compounds, 100 mg/ml each for the blend), and loaded into lures (1 ml/lure) consisting of 0.5 dram glass vials with open-top screw caps closed with PTFE-faced silicone septa (Cat. no. 03-393F, Fisher Scientific, Fairlawn, NJ, USA). The septum was pierced with a 2-cm piece of glass tubing (2 mm i.d.), and a pipe cleaner wick (cotton and steel wire; 40 mm long) was inserted through the tubing. The basal 0.5 cm of the wick was bent at a 90° angle and was in contact with the bottom of the vial, and the other end protruded ~1 mm beyond the top of the glass tube. A preliminary experiment demonstrated that ethanol was an efficient carrier for the hexanediols and hydroxyhexanones, and that lures would release 1 ml of ethanol solution over the course of 2 d outdoors (conducted 23–25 May 2006, in shade, daily minimum air temperatures 13–15°C, maximum temperatures 26–31°C). Lures were hung with wire in cross-vane flight-intercept panel traps (black, 80× 30 cm, Intercept™, model PT, Advanced Pheromone Technologies, Marylhurst, OR, USA). To capture beetles alive, traps were modified by replacing the supplied collection basin with a 1.9-l plastic funnel with the spout shortened to give a 35-mm-diameter hole. The threaded lid ring from a wide mouth 960 ml canning jar (Alltrista Consumer Products Co., Muncie, IN, USA) was placed over the spout and glued to the bowl of the funnel so that the jar could be attached with the spout inside the jar. The upper halves of jar interiors, interior surfaces of funnels, and surfaces of trap panels were treated with Rain-X® (Houston, TX, USA) glass treatment to render them slippery (Sweeney et al. 2006). Trap hangers were

constructed of 1.27 cm i.d. PVC pipe (D1785, Schedule 40, Charlotte Pipe and Foundry Co., Charlotte, NC, USA), with a 1.5-m-long upright connected with a T-fitting to a 20-cm long arm having a loop of wire at the end to which the trap was attached. The upright was mounted on a 1.5-m section of 1.27-cm-diam steel reinforcing bar that was driven part way into the ground.

The three treatments (generic hexanediols, generic hydroxyhexanones, 1:1 blend of generic hexanediols and hydroxyhexanones) were randomly assigned to traps. Because the purpose of the experiment was to trap live beetles for pheromone collection, and not to identify specific attractants, controls were not used. A single set of traps was set up at the Santa Rosa Plateau Reserve (Riverside Co., CA, USA) in late afternoons of 4 d between 24 May and 2 June 2006, skies clear, maximum air temperatures 25–31°C. Traps were positioned 15 m apart in a southwesterly transect through a grassland area wooded with mature *Quercus agrifolia* Née (position of trap # 1: 33°31′58.12″N, 117°15′49.94″W). There were many dead trees and downed limbs of various ages at the site. Traps were checked daily for beetles, and captured beetles were taken to the laboratory and separated by species and sex into cylindrical aluminum screen cages (6-cm diam, 10 cm tall, with plastic Petri dishes at top and bottom). Beetles were provided a cotton roll saturated with 10% sucrose solution for water and nutrition. Treatments were rotated one position on each collection date.

Identification of Pheromone Components

Adult beetles of each sex were placed individually into two-piece glass vacuum traps (~0.3 l, ground glass fittings; UIUC School of Chemical Sciences glass shop) lined with aluminum screen as perches. A section of glass tubing containing 100 mg of 80/100 mesh SuperQ® (Alltech Associates, Deerfield, IL, USA) was attached to the outlet of each vacuum trap with a 2-cm long section of Teflon® tubing, and charcoal-purified air (6-14 mesh, Fisher Scientific, Pittsburgh, PA, USA) was pulled through the apparatus by vacuum at a rate of 1 l/min. The chambers were placed on the laboratory windowsill and volatiles were collected from adult beetles from 18:00 to 0:00 hr. The SuperQ® collectors then were eluted with 0.5 ml dichloromethane (CH_2Cl_2), and extracts were analyzed by gas chromatography-mass spectroscopy (GC-MS) on the HP5-MS column by using identical conditions as described earlier, except that injections were made in splitless mode and the injector temperature was 100°C. The absolute configurations of the insect-produced chiral compounds (see "Results") were determined by analysis of extracts on the Cyclodex B column, as described above and confirmed by co-injection of an aliquot of the insect extract spiked with the appropriate standards.

To quantify the amount of pheromone produced by *X. nauticus*, male beetles collected in field bioassays were placed individually in small aeration chambers constructed from 237-ml Ball® canning jars (Alltrista Consumer Products Co.) with two holes punched in the lid to accommodate 0.64 cm Swagelok® unions for attaching inlet and outlet lines. The inlet was fitted with a 15×1.5 cm copper tube filled with activated charcoal granules (6-14 mesh, Fisher Scientific, Pittsburgh, PA, USA), and the outlet was fitted with a trap consisting of a 4.5 cm×3 mm i.d. glass tube with a 5-mm plug of activated charcoal (50-200 mesh, Fisher Scientific, Pittsburgh, PA, USA) held in place by two glass wool plugs. Each chamber was equipped with a 1/2-dram vial filled with water, with the neck of the vial plugged with a cotton swab. Air was pulled through each chamber by vacuum at ~500 ml/min. Aerations were continued for 1–6 d (some beetles died during aerations), in a brightly lit environmental chamber at 25°C and ~50% RH, 14L:10D. Traps were eluted with 0.4 ml of CH_2Cl_2 into tared vials, and the vials were then reweighed to calculate the total weight.

Total volume of each extract was then determined by dividing the mass by the density of the solvent. One-microliter aliquots of each extract were analyzed by GC (as described above), and the total amount of pheromone in each extract was calculated by comparison with an external standard curve (5–500 μg/ml, regression r^2=0.996). Of 13 extracts collected, eight contained detectable amounts of pheromone.

Field Bioassays of Synthetic Compounds, Targeting Particular Species

We conducted field bioassays of synthetic compounds on 5 d between 13 and 19 June 2006, skies clear, maximum air temperatures 24–36°C. Compounds were formulated in EtOH, and lures were loaded with 1 ml of the resulting solutions. There were eight treatments that were randomly assigned to traps, as follows:

1) blank control (empty vial);
2) EtOH control;
3) racemic 2-methylbutan-1-ol (50 mg in 1 ml EtOH); although male *P. lecontei* produced (*R*)-2-methylbutan-1-ol (see "Results"), we used racemic 2-methylbutan-1-ol in lures because the (*R*)-enantiomer was not commercially available, and there was insufficient time left in the field season to synthesize the (*R*)-enantiomer for testing;
4) (*R*)-3-hydroxyhexan-2-one (25 mg/ml);
5) (*S*)-3-hydroxyhexan-2-one (25 mg/ml);
6) 9:1 blend of (*R*)- and (*S*)-3-hydroxyhexan-2-one (25 mg/ml; based on approximate ratios produced by male *X. nauticus*; see "Results");
7) 9:1 blend of (*R*)- and (*S*)-3-hydroxyhexan-2-one plus 2,3-hexanedione (22.5:2.5:6.6 mg, respectively, in 1 ml EtOH); 2,3-hexanedione was considered an artifact during pheromone identification of another cerambycine species (Fettköther et al. 1995), but was a possible minor component produced by male *X. nauticus* (see "Results");
8) generic blend of hydroxyhexanone stereoisomers (100 mg/ml; to determine whether responses of adult beetles would be influenced by the presence of the "unnatural" isomers).

We used three sets of eight traps (1 trap per treatment), with traps spaced 15 m apart in linear transects. One set of traps was in the same location as had been used for the screening bioassays (trap #1 in same position), and the second and third sets were set up among oak trees 0.42 km to the north and 0.54 km to the southwest, respectively, of trap # 1 of the first set. Thus, there was one replicate of each treatment in each of three sets of traps on each of 5 d (N=15 replicates per treatment). Treatments were rotated one position down the trap line on each collection date. Traps, funnels, and jars were cleaned with Windex® glass and surface wipes (S. C. Johnson & Sons, Inc., Racine, WI, USA), then treated with Rain-X®. Captured beetles were collected after 24 hr and the number and sex responding to each treatment were recorded. Lures were replaced as needed (when vials were empty, often after 24 hr).

Differences between treatments in numbers of beetles captured per trap were tested separately for the two most abundant species, *X. nauticus* and *P. lecontei*, by ANOVA (PROC GLM, SAS Institute 2001), blocked by sample day. Thus, the ANOVA model for each species was: number of beetles captured=treatment × day. We tested differences between preplanned pairs of treatment means by using orthogonal contrasts (Sokal and Rohlf 1995). Thus, we compared the EtOH control with the blank control (to determine whether EtOH itself was attractive), compared each treatment that contained synthetic compounds with the controls (blank and EtOH controls pooled because they did not differ significantly; see below), and also compared treatments containing (*R*)-3-hydroxyhexan-2-one with each other,

to determine effects of possible minor components or stereoisomers. We also compared the 2,3-hexanedione plus the 9:1 blend of (*R*)- and (*S*)-3-hydroxyhexan-2-one to the 9:1 blend alone. Structural failure of a few traps was responsible for slight inconsistencies in degrees of freedom for some analyses. Differences between treatments in the sex ratio of responding *X. nauticus* and *P. lecontei* were tested with χ^2 goodness-of-fit tests.

Location of Pheromone Glands

To confirm that sex-specific pores were present in the prothoraces of males of the species that were captured during the study (see "Introduction"), we imaged the prothorax of one adult of each sex by scanning electron microscopy (SEM). Specimens were prepared for SEM as described by Ray et al. (2006), and imaged with a Phillips XL30 environmental scanning electron microscope equipped with a field-emission electron gun (FEI Company, Hillsboro, OR, USA) operated at 5.0 kV.

To further confirm that pores in the prothorax of male *X. nauticus* and *P. lecontei* were associated with pheromone glands, we sectioned prothoraces of both sexes of each species for light microscopy. One male and one female were chilled, and the entire prothorax was excised. The prothorax samples were fixed in 2.5% glutaraldehyde and 2.0% paraformaldehyde in 0.1 M sodium cacodylate buffer, pH 7.4, and held at <10°C, then later shipped on ice to the University of Illinois where they were stored at <10°C. After a 10-min buffer rinse, the samples were postfixed in 1% osmium tetroxide in the same buffer for 90 min in the dark. After a second buffer rinse, the samples were dehydrated through an extended ascending ethanol series (3 hr each in 37, 67, and 95% ethanol), culminating at 10 hr in 100% EtOH. The samples were then infiltrated and embedded in Poly/Bed® 812 embedding resin plus 2% (wt/wt) DMP-30 per manufacturer instructions (Polysciences 2003), with the exception that infiltration times were extended to 3 hr for each change, and a 6-hr immersion in fresh resin without DMP-30 was added before the final step. Prothoraces in embedding resin plus DMP-30 were then positioned horizontally in soft plastic molds (#105; Ted Pella, Inc., Redding, CA, USA) and placed in a 60°C oven for 24 hr. One-micron-thick sections were cut using an Ultracut UCT ultramicrotome (Leica Microsystems GmbH, Wetzlar, Germany) equipped with a 6-mm histology grade diamond knife (MicroStar Technologies, Huntsville, TX, USA), affixed to standard glass microscope slides (Fisher Scientific, Fairlawn, NJ), and stained with a 1% toluidine blue solution. Sections were examined using a Nikon Eclipse E600 microscope (Nikon USA, Melville, NY, USA) operated in bright field mode, equipped with a SPOT Insight™ color camera (Diagnostic Instruments, Sterling Heights, MI, USA).

Voucher specimens of all cerambycid species caught have been submitted to the Entomology Research Museum, University of California, Riverside.

Results

Screening Bioassays to Target Species for Pheromone Identification

Traps baited with generic lures captured three cerambycine species during the four trials (Table 1): *X. nauticus* (*N*=18), *P. lecontei* (*N*=30), and *Phymatodes decussatus decussatus* (LeConte) (*N*=6). Traps baited with the generic hydroxyhexanone lures and the blend of hydroxyhexanones and hexanediols contained the majority of the beetles caught in these bioassays, with only three beetles of one species (*P. lecontei*) caught in traps baited with the

Table 1 Cerambycine adults attracted to generic blends of possible pheromone components (screening experiment, *N*=4 days) or enantiomerically enriched pheromone components (targeted experiment, *N*= 5 days)[a]

generic hexanediols alone (Table 1). A few specimens of other types of insects were caught in traps in this and the subsequent targeted studies, including earwigs, cockroaches, and bark beetles. These nontarget species were captured in all treatments, including blank controls. There was no indication that they were responding to the hydroxyhexanones or hexanediols, with the possible exception of a trogositid beetle, *Temnochila chlorodia* (Mannerheim), a few of which were captured in the targeted study (see below).

Identification of Pheromone Components

GC-MS analyses of extracts of volatiles collected from male *X. nauticus* typically showed a single major peak in the total ion chromatogram, which was absent in analogous headspace extracts of females (Fig. 1a). The retention time and mass spectrum of the compound (base peak at *m*/*z* 55, other significant fragments at *m*/*z* 43 [78%], 73 [53%], and 45 [26%]) matched those of a synthetic standard of 3-hydroxyhexan-2-one. The enantiomeric composition of the insect-produced compound was determined to be ~90% (*R*) and 10% (*S*) by analysis on the Cyclodex-B column, with baseline resolution of the enantiomers. In one extract with a particularly large amount of male-produced compounds (Fig. 1a), we also detected 2,3-hexanedione (~25% of the major peak), the identity of which was confirmed by comparison of its retention time and mass spectrum with those of an authentic standard. Under laboratory conditions, males produced 92±104 μg (mean ± S.D., range 2–310 μg/day, *N*=8), of 3-hydroxyhexan-2-one per day.

Collection and analysis of headspace volatiles from both sexes of *N. m. modestus* caught in targeted field trials (see below) revealed that males produced pure (*R*)-3-hydroxyhexan-2-one as the only detectable component (identified as described above for *X. nauticus*). This compound was not found in aeration extracts of females.

Extracts of headspace volatiles from male *P. lecontei* contained a single peak that was absent in analogous extracts from females (Fig. 1b). The compound was tentatively identified as 2-methylbutan-1-ol by matching its mass spectrum with a database spectrum (NIH-NBS mass spectral database), and the identification was confirmed by comparisons with the spectrum and retention times of an authentic standard. The absolute configuration of the insect-produced compound was determined to be (*R*) by analysis on the Cyclodex-B column. There was no evidence of hydroxyhexanones or hexanediols in extracts of headspace volatiles collected from *P. lecontei*.

Field Bioassays of Synthetic Compounds Targeting Particular Species

Five species of cerambycines were caught in the targeted field bioassays (Table 1), including the same three species captured previously in the screening bioassay, *X. nauticus* (109 females, 104 males), *P. lecontei* (120 females, 152 males), and *P. decussatus* (three females, two males). In addition, a few *Neoclytus modestus modestus* (10 females, five males), and *Brothylus gemmulatus* LeConte (six females) also were caught during these

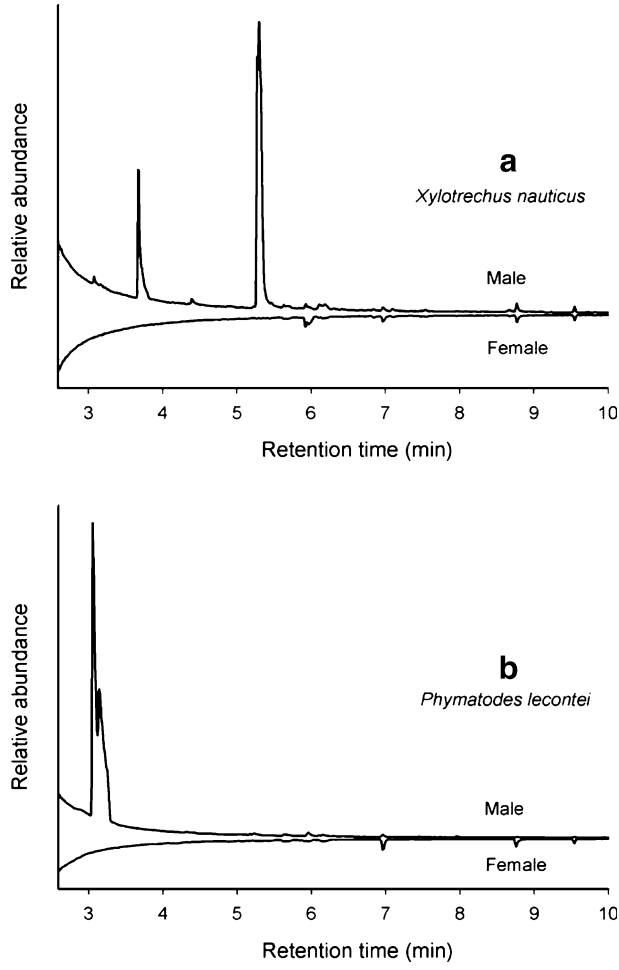

Fig. 1 Total ion chromatograms (**a**) of extracts of headspace volatiles produced by adult male (upper trace) and female (lower, inverted trace) *Xylotrechus nauticus*. The early eluting peak is 2,3-hexanedione, and the later eluting peak is a 9:1 mixture of (*R*)- and (*S*)-3-hydroxyhexan-2-one. Total ion chromatograms (**b**) of extracts of headspace volatiles produced by adult male (upper trace) and female (lower, inverted trace) *Phymatodes lecontei* (bottom). The large peak of (*R*)-2-methylbutan-1-ol in the extract from males is split because of incomplete cold trapping on the GC column during the splitless injection. An HP-5MS column was used for all analyses (see "Methods and Materials" for details)

trials. The maximum numbers of beetles caught per trap in a 24-hr period were 19 *X. nauticus* in a trap baited with generic hydroxyhexanone and 14 *P. lecontei* in a trap baited with the 9:1 blend of (*R*)- and (*S*)-3-hydroxyhexan-2-one.

Treatments differed significantly in the number of adult *X. nauticus* and *P. lecontei* that were captured (Fig. 2; sexes combined, overall ANOVA for *X. nauticus* $F_{11,\ 105}=3.67$, $P<0.001$, for *P. lecontei*, $F_{11,\ 105}=4.90$, $P<0.001$). The day effect was significant for *X. nauticus* ($P=0.005$) and *P. lecontei* ($P=0.002$). Numbers of both species captured with ethanol controls were not different from those captured with blank controls (orthogonal contrast, $P>0.65$). There was considerable variation in the numbers of beetles captured over time, with mean capture rates for the most attractive treatments (those that contained (*R*)-3-hydroxyhexan-2-one alone or in blends) ranging from 3.5±0.8 (S.E.) to 11.9±2.0 beetles of all cerambycid species per trap per day. There was no evidence that capture rates for any particular treatment were related to either air temperature or sample date (data not presented).

Mean trap catches of *X. nauticus* for all treatments that contained (*R*)-3-hydroxyhexan-2-one were significantly different from the combined controls (Fig. 2a), and were not significantly different from one another (contrast $P>0.5$). The response to (*S*)-3-hydroxyhexan-2-one was not different from the response to the controls (Fig. 2a). Sex ratios of trapped *X. nauticus* were not significantly different from 1:1 for all treatments (χ^2, $P>0.05$). Addition of 2,3-hexanedione to a 9:1 blend of (*R*)- and (*S*)-3-hydroxyhexan-2-one had no effect on trap captures (contrast $P>0.9$). The 2-methylbutan-1-ol treatment was not attractive to *X. nauticus* (Fig. 2a; orthogonal contrast *versus* controls, $P>0.7$).

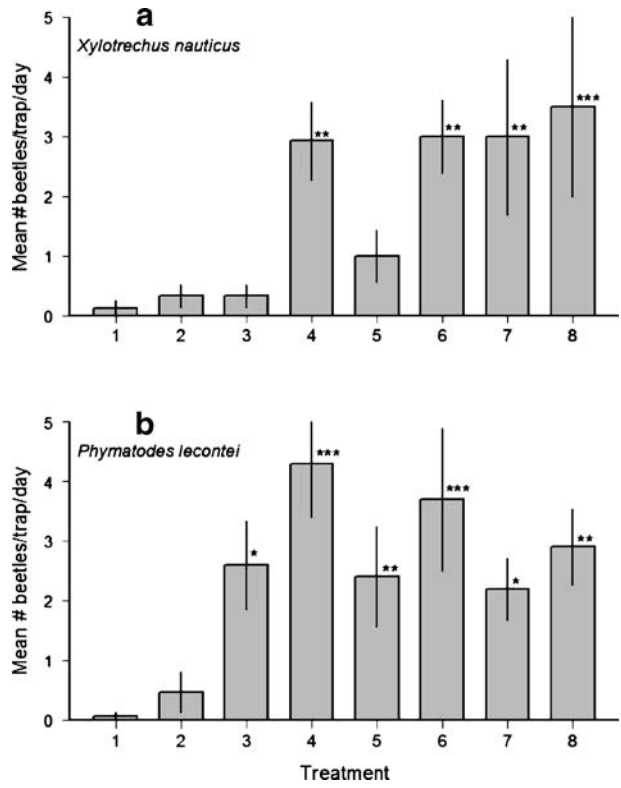

Fig. 2 Relationship between the mean number of adult *Xylotrechus nauticus* (**a**) and *Phymatodes lecontei* (**b**) captured per trap per day (sexes combined) and stereoisomeric composition of the lure. Treatments were: **1**) blank control; **2**) EtOH control; **3**) racemic 2-methylbutan-1-ol; **4**) (*R*)-3-hydroxyhexan-2-one (94% ee); **5**) (*S*)-3-hydroxyhexan-2-one (94% ee); **6**) 9:1 blend of (*R*)- and (*S*)-3-hydroxyhexan-2-one; **7**) 9:1 blend of (*R*)- and (*S*)-3-hydroxyhexan-2-one plus 2,3 hexanedione; and **8**) generic blend of all four 2,3-hydroxyhexanone stereoisomers. Error bars represent 1 S.E. ($N=15$ replicates per mean). Bars marked with asterisks are significantly different from pooled control treatments when tested with preplanned orthogonal contrasts: *, **, and *** indicate $P<0.05$, 0.01, and 0.001, respectively

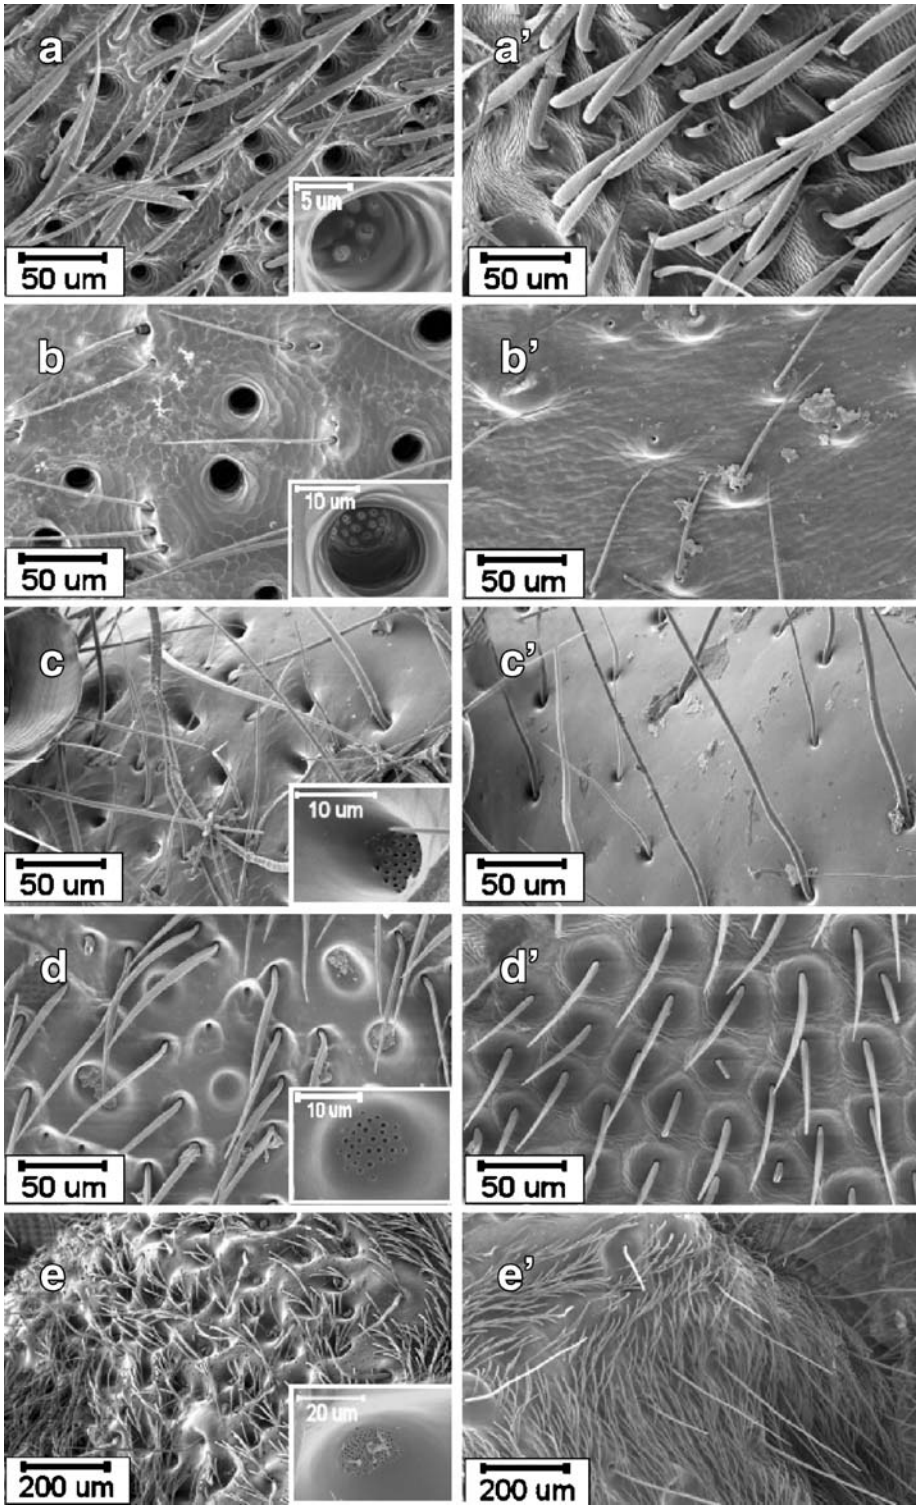
Racemic 2-methylbutan-1-ol was more attractive than controls to both sexes of *P. lecontei* (Fig. 2b), suggesting that it is a male-produced aggregation pheromone component. Furthermore, all of the treatments that contained hydroxyhexanones attracted more *P. lecontei* than controls, including the (*S*)-3-hydroxyhexan-2-one treatment. Treatments that contained the (*R*)-enantiomer were not more attractive than the (*S*)-enantiomer (contrast $P > 0.2$), and the (*R*)-enantiomer was no more attractive than the 9:1 blend of (*R*)- and (*S*)-3-hydroxyhexan-2-one ($P > 0.5$), indicating no inhibition of attraction by the (*S*)-enantiomer. In addition, the (*R*)-enantiomer was no more attractive than the generic blend of hydroxyhexanones ($P > 0.1$), suggesting that the 2-hydroxyhexan-3-one isomers in the generic blend were not inhibitory. Sex ratios of beetles were female biased for the (*S*)-treatment, and male biased in the 9:1 blend treatment (Table 1), but not significantly different from 1:1 for the remaining treatments.

Too few *N. m. modestus* were captured for rigorous statistical analysis of all the treatment effects. Nevertheless, all 15 beetles were captured in traps baited with the compound that the males produced, (*R*)-3-hydroxyhexan-2-one, alone or in blends (Table 1). The strength of the response to these compounds was revealed when data from the four treatments that contained (*R*)-3-hydroxyhexan-2-one (including 9:1 (*R*)- and (*S*)-3-hydroxyhexan-2-one, with and without 2,3-hexanedione, and the generic hydroxyhexanones) were pooled and contrasted with data from the four treatments that did not contain it (blank and ethanol controls, 2-methylbutan-1-ol and (*S*)-3-hydroxyhexan-2-one treatments) and tested by chi square analysis ($\chi^2 = 15.0$; $P < 0.001$).



The small numbers of *P. decussatus* (also captured in the generic screening study; Table 1) and *B. gemmulatus* that were caught in the targeted bioassays prevented proper assessment of their responses to the test compounds. However, it is noteworthy that adults of these species also were caught in traps baited with (*R*)-3-hydroxyhexan-2-one, as a single component or in blends, with the exception of three *P. decussatus* caught in a trap baited with racemic 2-methylbutan-1-ol (Table 1).

A total of eight adults of the trogositid beetle *Temnochila chlorodia* were caught in traps baited with ethanol (one beetle), (*R*)-3-hydroxyhexan-2-one (two beetles), (*S*)-3-hydroxyhexan-2-one (one beetle), and generic hydroxyhexanones (four beetles), but numbers were too low to determine whether catch was caused by attraction to the lures or simply because of chance. *T. chlorodia* is a predator of scolytid beetles and is attracted by their pheromones (Bedard et al. 1980; Seybold et al. 1992; Dahlsten et al. 2004). Consequently, it seems reasonable to suppose that it also might be attracted to volatiles associated with other potential prey.

Location of Pheromone Glands

The prothoraces of males of all five of the cerambycine species that were captured had pores similar in structure to the pheromone gland pores of cerambycine species previously studied (Fig. 3; Ray et al. 2006). Pores were present on the pleura of all five species, but also on the episterna and sterna of *X. nauticus*, *P. lecontei*, *P. d. decussatus*, and *B. gemmulatus*, and the pronota of *B. gemmulatus* and *N. m. modestus*. Females had cuticular depressions that contained a single central seta and no pores (Fig. 3). Pore indentations of male *X. nauticus* and *P. lecontei* (Fig. 3a,b) were more deeply invaginated than those of the remaining species, and were much broader in *B. gemmulatus* than in species examined previously (Fig. 3e; Ray et al. 2006).

Histological sectioning of prothoraces of adult *X. nauticus* and *P. lecontei* was problematical because gut and muscle tissue did not fully solidify after infiltration and embedding. As a result, the cuticle separated from underlying tissues during sectioning. Sections of *P. lecontei*

◀ **Fig. 3** Scanning electron micrographs of the pronotum of adult: *Xylotrechus nauticus* (**a**), *Phymatodes lecontei* (**b**), *Phymatodes decussatus decussatus* (**c**), *Neoclytus modestus modestus* (**d**), and *Brothylus gemmulatus* (**e**). For each species, male prothorax is on the left (inset, close-up of pore indentation) and female prothorax on the right (primed letters)

(not shown) were of such poor quality that no conclusions could be drawn about sexual differences in morphology. However, sections of *X. nauticus* revealed that males had a layer of cells underlying the cuticle, with cells connected to pores lying within depressions in the cuticle (Fig. 4a) that resembled the type III gland cells associated with pheromone glands of *Neoclytus a. acuminatus* F. and *N. mucronatus mucronatus* (F.) (Lacey et al. 2007a, b). This cellular layer was absent in prothoracic sections of females (Fig. 4b).

Discussion

The results of the initial field screening experiments provided support for our hypothesis that the 2,3-hydroxyketone pheromone structural motif is conserved among cerambycine species. Furthermore, this study demonstrated that species could be targeted for detailed pheromone identification by trapping live adults with generic blends of hydroxyhexanones,

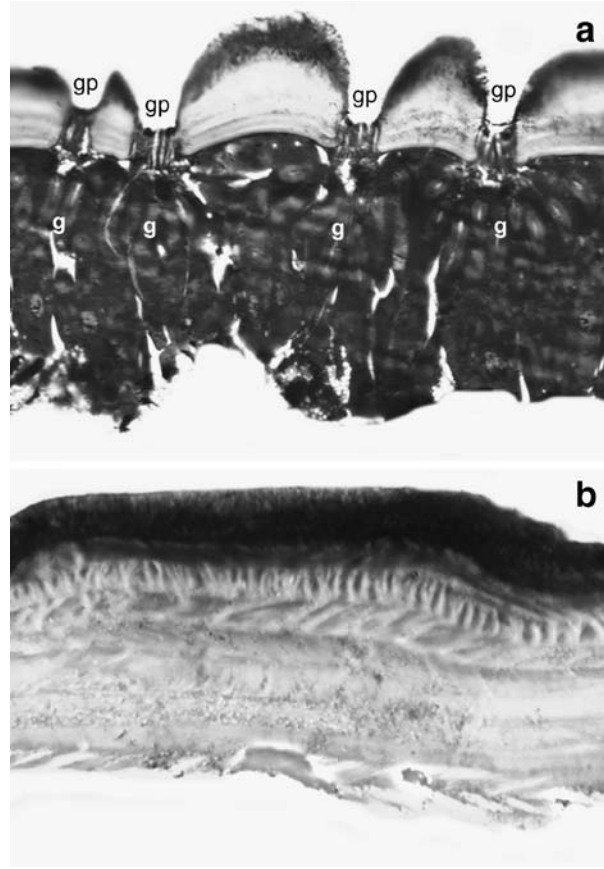

Fig. 4 Transverse histological sections through prothoraces of adult *Xylotrechus nauticus*: (**a**) male (×400; gp = gland pore; g = gland cells); (**b**) female (×400). Fig. 1

followed by collection and analysis of the volatile compounds released by the live beetles. Targeted trapping with likely pheromone components has an advantage over trapping with less selective baits such as host plant volatiles (e.g., Chénier and Philogène 1989; Sakakibara et al. 1997), because the pheromone components are likely to be much more specific to cerambycid beetles. This was borne out by the fact that our pheromone-baited traps captured only a few specimens of other types of insects, facilitating field processing of samples and collection of live beetles for pheromone identification. The selectivity of the pheromone lures may be useful in situations where pheromone-baited traps are deployed in large numbers and checked by personnel with little entomological training, as might occur during efforts to detect and delineate the range of invasive species.

The three cerambycine species that were attracted in field bioassays represent two tribes of the Cerambycinae: the Clytini (*X. nauticus* and *N. m. modestus*), and the Callidiini (*Phymatodes lecontei*; Monné and Hovore 2005). Larvae of all of these species develop in oaks (Linsley 1964), but there is scant information about their biology, life histories, or behavior (Chemsak 1963; Linsley 1964).

The structure of the pheromone components of *X. nauticus* and *N. m. modestus*, 3-hydroxyhexan-2-one, is consistent with the diol/hydroxyketone structural motif of pheromones reported for another four North American cerambycine species (see Lacey et al. 2004, 2007a). In fact, we now know from ongoing work that pheromones of several additional cerambycine species also appear to be comprised of (*R*)-3-hydroxyhexan-2-one as a single component or in combination with other structurally related compounds (Table 2). Interestingly, subsets of the species listed in Table 2 are sympatric and overlap in flight season, including most of the Californian species (Linsley 1962, 1964) and all of the Illinois species (Yanega 1996; Lacey et al. 2004). This frequent occurrence of (*R*)-3-hydroxyhexan-2-one among cerambycine species, and the response of five sympatric species to the same compound in the field trials described herein, further attest to its important role in cerambycine mating systems. The similar responses of adult *X. nauticus* to all baits that contained (*R*)-3-hydroxyhexan-2-one, including the 9:1 mixture with the (*S*) enantiomer and the generic blend of stereo- and regioisomers, suggest that the minor component, (*S*)-3-hydroxyhexan-2-one, was not necessary for attraction, and that the 2-hydroxyhexan-3-one regioisomers had no inhibitory effect for this species. In contrast, Lacey et al. (2007a) showed that *N. m. mucronatus* was more strongly attracted to (*R*)-3-hydroxyhexan-2-one than to racemic 3-hydroxyhexan-2-one, indicating that the presence of the wrong enantiomer was indeed inhibitory for that species. Furthermore, the activity of the natural pheromone of male *N. a. acuminatus*, (2*S*,3*S*)-hexanediol, was not affected by the presence of the other enantiomer, but one or both of the (2*R**,3*S**)-diastereomers were inhibitory (Lacey et al. 2004). We conclude from these limited data that certain species within communities of cerambycines may be only weakly attracted or not attracted at all to traps baited with generic lures. Nevertheless, even weak attraction may be sufficient to garner sufficient specimens for pheromone collection and identification. This is particularly true given that individual beetles produce relatively large amounts of pheromone. For example, the eight male *X. nauticus* that produced pheromone in the quantitation study yielded an average of almost 100 μg of pheromone per individual per day, with one individual producing 310 μg per day. This quantity of pheromone is sufficient for obtaining mass, GC-Fourier transform infrared (FTIR), and even nuclear magnetic resonance (NMR) spectra, as well as for microchemical tests, suggesting that it should be possible to identify even a previously unknown pheromone component from volatiles collected from a single beetle.

It must also be emphasized that it is unlikely that production of pheromone occurs at a constant rate throughout the day and night. Instead, the pheromone is probably produced

[a] Estimated relative proportion of (*R*)-3-hydroxyhexan-2-one of the total blend of hydroxyhexanones, diols, and diones of C_6 and C_8 chain length.

over a few hours or less, during the period of daily reproductive activity typical of each species. For example, in previous studies, male beetles periodically adopted a characteristic posture during which pheromone was produced (Lacey et al. 2004, 2007b), and male *X. nauticus* also adopted this posture at intervals throughout the day. Thus, beetles actually may produce pheromones at rates of 100 μg/hr or more. This may explain the relatively large doses of synthetic pheromone (in this study, 25 mg of active compound per lure, being released at ~0.5 to 1 mg/hr) that appear to be necessary to attract significant numbers of cerambycids (e.g., Lacey et al. 2004, 2007a).

The fact that male *X. nauticus* produce an aggregation pheromone and not a sex pheromone was confirmed during our field bioassays with synthetic pheromone, in which similar numbers of males and females were attracted to baited traps. Before this study, the only cerambycid species known to produce aggregation pheromones were *N. a. acuminatus* and *N. m. mucronatus* (Lacey et al. 2004, 2007a). The fact that both sexes of their congener, *N. m. modestus*, responded to synthetic pheromone in the present study also suggests an aggregative function. Although we captured only female *B. gemmulatus*, the sample size was too small to draw any firm conclusions about the sexual specificity of its pheromone.

The attraction of both sexes of *P. lecontei* to 2-methylbutan-1-ol confirmed that it also serves as a male-produced aggregation pheromone. It is possible that adults may have responded even more strongly had we had the correct, insect-produced (*R*)-2-methylbutan-1-ol to test, rather than the racemic blend. This compound had not previously been associated with cerambycids, although it has been reported as a defensive compound for other types of beetles (Dettner and Reissenweber 1991). It also has been reported as a plant-produced attractant or kairomone for nitidulid beetles (Lin and Phelan 1991) and palm weevils (Rochat et al. 2000). Males of the cerambycid *Hylotrupes bajulus* produce the related 1-butanol (Fettköther et al. 1995), which was reported to enhance attraction of adult beetles to (*R*)-3-hydroxyhexan-2-one (Reddy et al. 2005).

The absence of (*R*) or (*S*)-3-hydroxyhexan-2-one in extracts of headspace volatiles collected from male *P. lecontei* was surprising, given the strong response of both sexes to these compounds or their blend in the field (Table 1). It is possible that male *P. lecontei* do indeed produce 3-hydroxyhexan-2-one, but not under the unnatural conditions of headspace collection in the laboratory. However, this seems unlikely, given that the male-specific compound (*R*)-2-methylbutan-1-ol was present in large amounts in those extracts. Alternatively, adult *P. lecontei* may not produce hydroxyhexanones themselves, but rather may have evolved an ability to detect these compounds for exploitation of the communication channel of other cerambycine species as a method of locating larval hosts. *Phymatodes lecontei* was not only sympatric with *X. nauticus*, but both species had the same pattern of circadian activity. *Phymatodes lecontei* undoubtedly shares hosts with *X. nauticus*, but nothing is known of the ecological interactions between these species.

The presence of pheromone gland pores on the prothoraces of male *X. nauticus*, *P. lecontei*, and *N. m. modestus* was consistent with the responses of these species to synthetic pheromone. Males of the remaining two species, *P. decussatus* and *B. gemmulatus*, also had gland pores that were missing in females. The structures of pore indentations in *X. nauticus* and *P. lecontei* were similar to the deeply invaginated indentations of *Xylotrechus quadripes* Chevrolat, and also those of the cerambycine *Achryson surinamum* (L.) (Ray et al. 2006). The shallower pore indentations and the distribution of pores in *N. m. modestus*, *P. d. decussatus*, and *B. gemmulatus* were similar to those of the congeners *N. a. acuminatus* and *N. m. mucronatus*, as well as other cerambycine species (Lacey et al. 2007b; Ray et al. 2006). The layer of glandular cells associated with prothoracic pores of male *X. nauticus* provided further evidence that these pores are the site of pheromone release.

Our capture of multiple cerambycine species at a single location over a short period of time demonstrates the potential for using generic blends of likely pheromone components in the development of tools for monitoring and control of the many cerambycine species that are pests (e.g., Solomon 1995). These generic blends can be synthesized much more quickly and cheaply than the individual regioisomers or stereoisomers, providing economical lures for screening or survey trials. This study also validates the concept of using generic blends of candidate pheromones as a lead-in method for initiating the identification of pheromone components for cerambycid beetles. Furthermore, the strong attraction of several of the study species to generic hydroxyhexanones (19 beetles of one species were caught in a single trap in 1 day) demonstrates the potential for using pheromone-baited traps as a sensitive method for detecting and monitoring specific cerambycid species.

Overall, the results reported here and analogous results from previous studies of cerambycid semiochemistry suggest numerous unanswered questions relating to the production and use of pheromones within this family. For example, given that three species were attracted simultaneously at our study site with the single pheromone component (*R*)-3-

hydroxyhexan-2-one, what mechanisms might limit cross attraction between species? Despite the fact that we found several minor components in extracts (e.g., (*S*)-3-hydroxyhexan-2-one and 2,3-hexanedione in *X. nauticus*), there was no evidence that a particular species produced one or more compounds that inhibited cross-attraction of sympatric species, as frequently occurs with minor components of the pheromone blends of other insects (e.g., scarab beetles, Leal 1999; moths, Cardé and Haynes 2004). We also found no evidence that attraction to the main component, (*R*)-3-hydroxyhexan-2-one, was increased by addition of the possible minor components (*S*)-3-hydroxyhexan-2-one and 2,3-hexanedione, that might provide a unique pheromone channel for a particular species. Furthermore, some of our study species have similar diurnal patterns of reproductive activity and exploit similar hosts, and so it seems unlikely that they are partitioning their reproductive activities in time or space.

We also do not know why male cerambycid beetles produce quantities of attractant pheromones that are several orders of magnitude larger than the amounts typically produced by other insects of similar size. For example, males of the stink bug *Acrosternum hilare* (Say) produce <1 μg of pheromone per hour (McBrien et al. 2001), and the pheromone emission rates of female lepidopterans are typically much less than 1 μg/hr (e.g., *Heliothis virescens* [F.]; Pope et al. 1982). However, pheromone production is substantial in males of arctiid moths such as *Utetheisa ornatrix* (L.), females of which assess the fitness of males by their ability to produce pheromone (Eisner and Meinwald 2003). A similar situation may occur with the cerambycid species described here, with females assessing the fitness of males by their production of pheromone.

It is also unclear why the pheromones attracted both sexes of most of our study species. Typically, insects are thought to produce aggregation pheromones when there is a benefit that will accrue to all signaling and responding individuals, such as the assembly of a critical mass of bark beetles to overwhelm defenses of host trees (Schlyter and Birgersson 1999), or the aggregation of chemically defended aposematic individuals (e.g., Al Abassi et al. 1998). However, in the case of the cerambycid species in this study, there is no obvious benefit to aggregation with regard to attack of hosts because the beetles use dying or dead hosts (Linsley 1962, 1964). Furthermore, *X. nauticus* and *P. lecontei* apparently are not aposematic (Linsley 1962, 1964) and have no obvious chemical defenses, so it seems unlikely that they would aggregate for mutual defense. However, production of large quantities of pheromone is costly, and aggregation may be of selective advantage if "satellite males" assembling in the vicinity of conspecific males can intercept responding females (see Moore et al. 1995).

As this research continues, we hope to answer some of these questions and expand our understanding of the role of semiochemicals as mediators of reproductive behaviors within this diverse insect family. In particular, a more detailed understanding of taxonomic patterns of pheromone chemistry and pheromone use would be tremendously valuable for facilitating the identification of pheromones of invasive cerambycine species as they inevitably arrive in North America (see Haack 2006) or other areas of the world. This information in turn would provide the means for developing methods for detecting, controlling, and even potentially eradicating invasive species.

Acknowledgments We thank Frank Hovore (deceased), Douglas Yanega, and Ian Swift for assistance with identification of beetle species, Scott Robinson for help with SEM and histological sectioning work, Adam Martinsek for assistance with the statistical analysis, James Nardi for access to microscopy equipment, and Mariana Krugner and Ian Wright for technical assistance. We thank Carole Bell and Santa Rosa Plateau Reserve, Riverside Co., California, for access to field sites. The SEM and histology research was made

possible through collaboration with Bugscope, The Imaging Technology Group, Beckman Institute for Advanced Science and Technology, University of Illinois at Urbana-Champaign (http://bugscope.beckman.uiuc.edu/). This project was supported by funds from the Exotic/Invasive Pests and Diseases Research Program, University of California, under USDA-CSREES Grant No. 2004-34439-14691, the Alphawood Foundation of Chicago, and Hatch Project #CA-R*ENT-5181H to JGM.

Abstract The flight-tunnel response of male Z-strain European corn borer moths (ECB), *Ostrinia nubilalis*, from a population in New York State (USA), was significantly antagonized by addition of 1% (*Z*)-11-hexadecanal (Z11-16:Ald) to their sex pheromone (a 97:3 mix of (*Z*)- and (*E*)-11-tetradecenyl acetate [Z/*E*11-14:OAc]). The level of antagonism was equivalent to that observed for the previously identified ECB antagonist, (*Z*)-9-tetradecenyl acetate (Z9-14:OAc), and supports a recent report showing that Z11-16:Ald, a minor pheromone component of the Noctuid moth, *Sesamia nonagrioides*, caused antagonism of ECB pheromone communication in sympatric populations in the Iberian Peninsula. Single-sensillum recordings from ECB antennae, which included cross-adaptation experiments, showed that the same olfactory receptor neuron processing Z9-14:OAc inputs was responsible for detecting Z11-16:Ald, and that this neuron was not responsive to two other aldehydes, (*Z*)-9-tetradecanal (Z9-14:Ald) and (*Z*)-9-hexadecanal (Z9-16:Ald), found in other moth sex pheromones. Our results show that the antagonism is not confined to one geographic region, is specific for Z11-16:Ald, and that antagonist pathways might have the potential for processing a number of structurally similar compounds.

Introduction

Mate location in many insect species is mediated by female-released sex pheromones. In almost all cases, these have proven to be mixtures, with blend quality and quantity providing for varying degrees of signal specificity (Linn and Roelofs 1995). Signal specificity is also facilitated by sensitivity to pheromone components of related species that function as behavioral antagonists (Cardé and Haynes 2004). When added in very small amounts to the sex pheromone of a particular species, the new mixture results in arrestment of pheromone-mediated flight. For example, different pheromone strains of the European corn borer moth (ECB), *Ostrinia nubilalis* (Crambidae), utilize mixtures of (*Z*)-11- and (*E*)-11-tetradecenyl acetates (*Z*11/*E*11-14:OAc) in their sex pheromones (Roelofs et al. 1985, 1987). However, males are also sensitive to a non-pheromonal compound, (*Z*)-9-tetradecenyl acetate (Z9-14:OAc), and possess a separate antennal olfactory pathway for processing this compound (Hansson et al. 1987). As little as 1% Z9-14:OAc added to the Z/E11-14:OAc mixture dramatically reduced the number of males completing upwind oriented flight in a wind tunnel (Glover et al. 1989).

A study by Eizaguirre et al. (2002) showed, in pheromone mating disruption tests for the Mediterranean corn borer, *Sesamia nonagrioides* (Noctuidae), that larval counts were significantly reduced for the target species and for ECB. Combining pheromone blends of both species in the same dispenser showed further that there was mutual antagonism for both species. Subsequently, Gemeno et al. (2006) showed that the antagonism was caused specifically by addition of (*Z*)-11-hexadecanal (Z11-16:Ald) to the ECB pheromone, with as little as 1% reducing upwind flights by 83% and trap capture by 90%. The compound Z11-16:Ald is a minor pheromone component of *S. nonagrioides* and is not part of the ECB pheromone. Here, we provide results of flight tunnel and single-sensillum recording experiments to address the following questions: 1) are ECB from a population in New York State antagonized by addition of Z11-16:Ald to their pheromone blend? 2) is the sensory input for Z11-16:Ald on the same olfactory receptor neuron (ORN) as for Z9-14:OAc?, and 3) do other aldehyde components, such as Z9-14:Ald and Z9-16:Ald, that are pheromone components in several heliothine moth species (Lee et al. 2006), also act as antagonists for ECB?

Methods and Materials

Insects A colony of the univoltine Z-strain of ECB from New York State was maintained in a walk-in environmental chamber. The Z-strain was used in our experiments because it is the predominant population in the Iberian Peninsula, the origin of moths used in the studies by Eizaguirre et al. (2002) and Gemeno et al. (2006). Mating and larval rearing conditions were as described in Roelofs et al. (1987) at a constant 25°C, 16:8 L/D photoperiod. Pupae were sexed, and the male pupae were placed on a layer of vermiculite in plastic and screen emergence cages inside a walk-in environmental chamber (25°C; 16:8 L/D photoperiod). Cages of adults were separated daily so that individuals of known age could be used for flight tunnel tests.

Chemicals Z11-14:OAc, E11-14:OAc, and Z9-14:OAc were obtained from the Pherobank http://www.pherobank.nl). Z11-16:Ald, Z9-14:Ald, and Z9-16:Ald were obtained from Bedoukian Research, Inc. (Danbury, CT, USA). Purity of each compound was verified as >95% by gas chromatography (GC). Stock solutions were prepared in high-performance

liquid chromatography-grade hexane (HPLC-grade hexane). Solutions were applied to red rubber septa (Thomas Scientific, Swedesboro, NJ, USA; Glover et al. 1989) for flight-tunnel tests, and to filter paper strips for electrophysiological measurements (see below).

Flight Tunnel Adults were tested in the sustained-flight tunnel during their second to third night as adults, under standard conditions used in previous studies of *O. nubilalis* (Glover et al. 1989): 20–21°C, 60–65% relative humidity, 0.50 m/sec air flow, and illumination of 11 lx of red light at the tunnel floor, during the third to the sixth hour of scotophase. Adults were taken to the room housing the flight tunnel 1 hr before the start of scotophase and placed individually in screen release cages so they could acclimate to the flight tunnel room environment. The temperature during the 1-hr period of acclimation, was 25°C, then dropped after lights-off to 20–21°C. Adult moths were tested individually, and males were scored for three behaviors in the flight sequence: taking flight (TF) from the release cage; initiation of upwind flight (UP) a minimum of 20 cm toward the source; and source (SC) contact after completing upwind flight to the rubber septum.

Two experiments were conducted to study the effects of Z11-16:Ald on ECB pheromone-mediated flight behavior. The first was designed to determine whether Z11-16:Ald arrested the upwind flight behavior of males, and to compare the level of antagonism with Z9-14:OAc (Glover et al. 1989). Males were tested to four treatments: 1) the Z-strain 97:3 Z/E11-14:OAc blend (30 μg); 2) the Z-strain blend (30 μg)+1% Z9-14:OAc; 3) the Z-strain blend (30 μg)+1% Z11-16:Ald; and 4) the Z-strain blend (30 μg)+10% Z11-16:Ald. The second experiment was designed to determine the specificity of the antagonist effect of Z11-16:Ald by testing two additional, structurally related aldehydes found in other pheromone systems, Z9-14:Ald and Z9-16:Ald (Lee et al. 2006). Males were tested to three treatments: 1) the Z-strain 97:3 Z/E11-14:OAc blend (30 μg); 2) the Z-strain blend (30 μg)+10% Z9-14:Ald; and 3) the Z-strain blend (30 μg)+10% Z9-16:Ald. Over the course of both experiments, 30 males were tested to each treatment. Males were tested only once, with each of the treatments of an experiment used on each day of testing.

For each flight tunnel experiment, the number of moths in each treatment that exhibited each behavior in the upwind flight sequence was combined for all testing periods and converted to a percentage value for graphical display. *Post hoc* pairwise comparisons with Fisher's exact tests were implemented according to the JMP statistical analysis program for Macintosh ($P<0.05$).

Electrophysiology With excised antennae, ORN recordings were made by using the cut sensillum technique (Kaissling 1974; van der Pers and den Otter 1978). The basal end of each antenna was placed in a saline-filled electrode and positioned with a micromanipulator such that a single trichoid sensillum would be cut between a vertical tungsten knife and horizontal glass knife. The cut sensillum was then contacted with a saline-filled glass micropipette containing a Ag recording electrode. The AC signal passed through the built-in amplifier (DAM50, World Precision Instruments, Sarasota, FL, USA) of a portable recording unit into a computer and was recorded with Syntech software (Autospike v.32; Syntech, Kirchzarten, Germany).

A stream of purified, humidified air blew continuously over the antenna (10 ml/sec) through a 25-cm long glass tube (8 mm ID), the end of which was placed 2 cm from the antenna. With a stimulus flow controller device (SFC-2, Syntech), a 50-msec air pulse at 40 ml/sec flow rate was injected through the odor cartridge and into the air stream. Linear flow through the air stream was ~0.3 m/sec. Cartridges were created from dilutions (0.1, 1, and 10 μg/μl) of Z11-16:Ald and Z9-14:OAc, and from 10 μg/μl of Z11-14:OAc, E11-14:

OAc, Z9-14:Ald, and Z9-16:Ald in HPLC-grade hexane. For each concentration, 10 μl was pipetted onto a 0.5×2.0 cm filter paper strip held in a 15-cm-long Pasteur pipette odor cartridge. The filter paper loadings thus included 1, 10, or 100 μg for the various compounds.

By using 24 antennae from 18 moths, dose–response curves were obtained for Z11-16:Ald and Z9-14:OAc. A balanced design with respect to the order of application of treatments was employed to allow a more accurate comparison of the relative responsiveness of the ORNs to these compounds. For the first 12 antennae, recordings were performed with 1, 10, and 100 μg loadings of Z11-16:Ald in the first sensillum, whereas recordings to the same range of dosages of Z9-14:OAc were performed on a second sensillum. For the remaining 12 antennae, Z9-14:OAc was used before Z11-16:Ald. At least 30 sec was allowed to elapse between all stimulations. Spikes were counted from within 300 msec of the initiation of neuronal activity, which can occur between 50 and 200 msec after the stimulus is first applied (Fig. 1a). As previously reported, there was little spontaneous background activity (Cossé et al. 1995; Domingue et al. 2006), and the initiation of response was easily discerned by the first appearance of spikes. Analysis of variance (ANOVA) was performed by using the GLM procedure of SAS (Version 9.1), to test the effects of order of application and compound on response at the 100 μg loading. Responses at 1 μg were nearly always zero for both compounds. Responses at 10 μg to both compounds often occurred, but there were enough non-responses to cause non-normality of the data at this concentration (Wilks normality, α=0.05). However, by using the increase in spike frequency from 10+ to 100 μg, which is normally distributed, we performed a similar ANOVA.

Paired stimulations aimed at exploring cross-adaptation were also performed, in most cases by using additional sensilla from the antennae that were used to obtain dose–response curves. Air from two pheromone cartridges, with loadings of 100 μg, was pulsed as

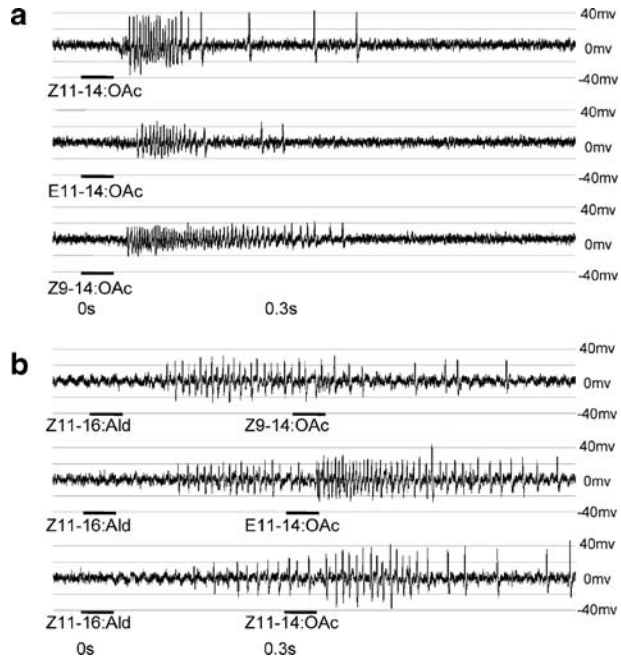

Fig. 1 Examples of ORN stimulation in Z-strain ECB in two sensilla from different individuals, using 100-μg loadings in each case: (a) Spike patterns in response to the known pheromone components Z11-14:OAc and E11-14:OAc and the antagonist Z9-14:OAc. (b) Cross-stimulation involving Z11-16:Ald with the antagonist Z9-14:OAc, the minor pheromone component E11-14:OAc, and the major pheromone component Z11-14:OAc. Horizontal bars indicate stimulus application and duration

described above, with an interval of 300 msec between the start of the pulses from the first and second cartridges. This method is similar to that employed for other moths (Ochieng et al. 2002) and was calibrated from unpublished data for this species such that for each ORN there is self-adaptation, marked by a lack of repeated stimulation by the same compound. To infer which ORN is sensitive to Z11-16:Ald, cartridge pairs used for cross-adaptation *versus* this compound included, Z9-14:OAc, Z11-14:OAc, and E11-14:OAc, which are, respectively, known to stimulate distinct ORNs (Hansson et al. 1987). It was readily apparent that cross-adaptation occurs between Z11-16:Ald and Z9-14:OAc. For comparative purposes, and to ensure the validity of our experimental technique, we also performed self-adaptation with Z9-14:OAc and Z11-16:Ald.

At least 10 replicates of all paired stimulations were performed. No more than three paired stimulations were performed per sensillum, with at most five sensilla examined per antenna. In many cases, there were two distinct bursts of neuronal activity with obviously different spike sizes (Fig. 1b). To assess the intensity of response to stimulation by the first compound, spikes were counted within 300 msec of the initiation of neuronal activity. For the second compound, initiation of the second response was noted if a different spike size from the first stimulus appeared, or if there was a period of inactivity of greater than 50 msec, which would normally not be observed in spike trains arising from a single stimulation. In a few rare cases, there were similarly sized action potentials in a continuously uninterrupted pattern for more than 300 msec after the initial response. Because the initiation of a second response was unclear in these cases, we assigned the counts for the first and second compounds to the respective periods between 0 and 300 msec and 300 and 600 msec after the first onset of neuronal activity.

To describe the process of cross-adaptation statistically we performed three separate ANOVA, considering pairings involving: (1) Z11-16:Ald by E11-14:OAc cross-adaptation; (2) Z11-16:Ald by Z11-14:OAc cross-adaptation: and (3) Z11-16:Ald by Z9-14:OAc cross-adaptation or self-adaptation of either compound. For this analysis, we discarded categorization of spike size and looked at the effect on spike frequency of being the first or second compound applied (Order), which would indicate adaptation. For all three analyses, the effect on spike frequency of compound identity (Compound) and the interaction between Compound and Order were also considered. For the third analysis only, the effect of cross-adaptation vs. self-adaptation (X-adapt) was also considered, along with its interactions with Compound and/or Order.

To explore the sensitivity of Z-strain ECB ORNs to the aldehydes, Z9-14:Ald and Z9-16:Ald, an additional experiment was performed. Responses to Z9-14:Ald and Z9-16:Ald were assessed in comparison to a control consisting of Z11-16:Ald or Z9-14:OAc, with 24 antennae from different moths. In all cases, 100 μg cartridge loadings were used. On four successive sensilla from each antenna, one of the following sequences of stimulations was performed: A) Z9-14:Ald, Z9-16:Ald, and Z11-16:Ald; B) Z9-14:Ald, Z9-16:Ald, and Z9-14:OAc; C) Z9-16:Ald, Z9-14:Ald, and Z11-16:Ald; D) Z9-16:Ald, Z9-14:Ald, and Z9-14:OAc. Across 24 moths, each of the possible combinations of treatments A–D, with respect to sensillum order, was completed once. With this design, Z9-14:Ald and Z9-16:Ald were tested 96 times, and Z11-16:Ald and Z9-14:OAc 48 times. For this last experiment, we examined both the spike frequency and presence or absence of response for each test compound and the control with respect to sensillum order. For a small number of pairwise comparisons of interest, *t* tests or Fisher's exact tests were used depending on whether the spike frequency or presence of response was considered. Similarly, least-square or logistic regressions were performed when appropriate for either type of variable, by using Proc Reg or Proc Logistic in SAS.

Results

Flight Tunnel Experiment 1: There was no difference in the percentage of males taking flight (100%) among the four treatments (Z-strain blend alone,+1% Z9-14:OAc,+1% or 10% Z11-16:Ald, Fig. 2a). Significant decreases, however, were observed in the percentage of males initiating upwind flight with Z-strain blend and any of the added compounds, compared with the Z-strain blend alone. The greatest decrease occurred with 10% Z11-16:Ald treatment (0% UP vs. 100% for Z-strain alone; Fisher's exact $P<0.001$, $df=1$), followed by 1% Z9-14:OAc and 1% Z11-16:Ald (62 and 74%, respectively, vs. 100% for Z-strain alone; Fisher's exact $P<0.001$, $df=1$, for 100% vs. 74%). Significant decreases were further observed in the percentage of males reaching the source, with 0, 4, and 8% SC for 10% Z11-16:Ald, 1% Z9-14:OAc, and 1% Z11-16:Ald, respectively, compared with the Z-strain blend alone (97% SC; Fisher's exact $P<0.001$, $df=1$, for 100% vs. 8%).

Experiment 2: As with experiment 1, male Z-strain ECB exhibited high levels of upwind flight (UP, 100%) and source contact (SC, 96%) with the Z-strain blend alone (Fig. 2b). However, addition of 10% Z9-14:Ald or Z9-16:Ald did not affect the percentage of upwind

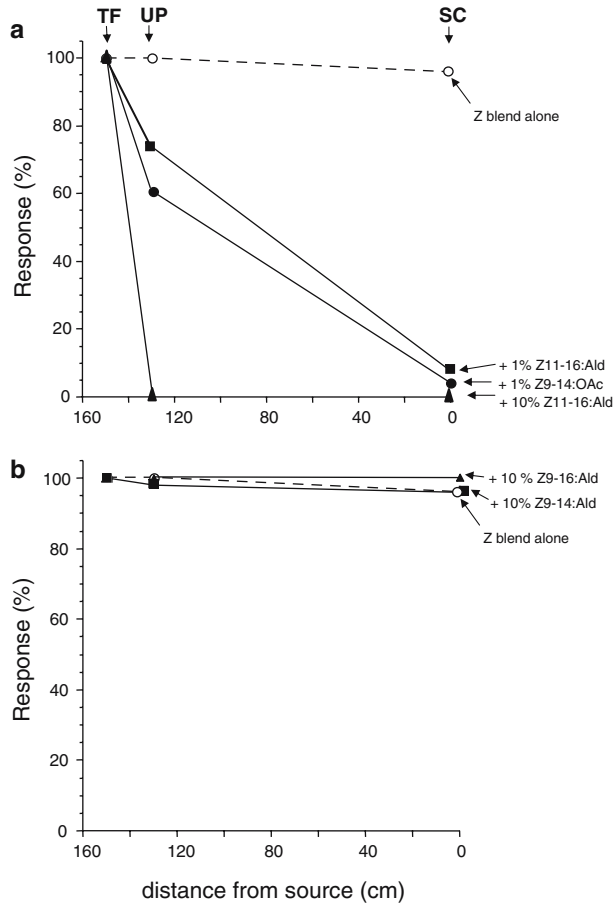

Fig. 2 Proportion of male ECB of the Z-strain exhibiting three behaviors in flight tunnel tests (taking flight, TF; upwind flight, UP; source contact, SC) to: (a) the Z-strain 97:3 Z/E11-14:OAc blend alone (30 μg), the Z-strain blend+ 1% or 10% Z11-16:Ald, or the Z-strain blend+1% Z9-14:OAc; (b) the Z-strain 97:3 Z/E11-14:OAc blend alone (30 μg), the Z-strain blend+10% Z9-14:Ald or 10% Z9-16:Ald. $N=30$ for each of the treatments. See text for statistical comparisons

flights and source contact observed with the Z-strain blend alone (100% SC with Z9-16:Ald, 96% SC with Z9-14:Ald).

Electrophysiology We were able to obtain dose–response curves to both Z11-16:Ald and Z9-14:OAc (Fig. 3a). From Fig. 3, it appears as if the sensilla are relatively more sensitive to Z11-16:Ald if it is applied first. However, statistical analyses did not confirm the significance of this pattern. At 100 μg, responses to Z9-14:OAc were greater than those to Z11-16:Ald (i.e., Compound is significant, Table 1). This result was not significantly influenced by which compound was applied first (i.e., Order and the interaction, Table 1). Similarly, for the increase in spike frequency between the 10 to 100 μg loadings, the effect of Compound was significant, but not Order or the interaction (Table 1).

In a sensillum not used for any statistical analysis (Fig. 1a), we demonstrated that ORN responses to Z11-14:OAc, E11-14:OAc, and Z9-14:OAc occurred with the same relative spike sizes as found previously (Hansson et al. 1987; Roelofs et al. 1987). It was apparent in cross-adaptation experiments that, based on spike size, Z11-16:Ald stimulated the same ORN as did Z9-14:OAc. This cross-responsive (i.e., cross-adapted) ORN was usually characterized by the smallest spike size (Fig. 1b). The ORN responding to E11-14:OAc was most often of intermediate spike size, being slightly smaller than that for Z11-14:OAc, which was always the largest (Fig. 1b).

These visual observations were supported by statistical analysis of the cross-adaptation data. When Z11-16:Ald was paired with E11-14:OAc or Z11-14:OAc, there was no effect of Order on spike frequency (Table 2, Fig. 4). Analysis of spike frequencies in stimulations involving Z11-16:Ald and Z9-14:OAc showed a strongly significant effect of Order (Table 2, Fig. 4), meaning that the second stimulation was generally inhibited by the first. In this analysis, there was also a significant effect of Compound (Table 2) demonstrating

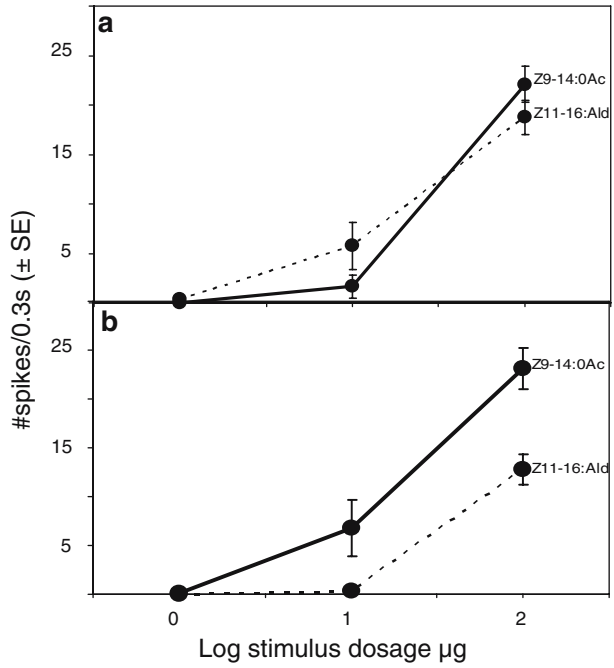

Fig. 3 Dosage-dependent response of male Z-strain ECB ORNs to Z11-16:Ald and Z9-14:OAc. (a) For $N=12$ antennae, dose-response testing was performed on the first sensillum to Z11-16:Ald, and on a second sensillum to Z9-14:OAc. (b) For another $N=12$ antennae, dose-response was performed first to Z9-14:OAc, and then to Z11-16:Ald

Table 1 Analysis of variance of spike frequency (spikes/0.3 sec) at a 100-μg loading and spike frequency increase from a 10- to 100- μg loading, both with respect to whether Z9-14:OAc or Z11-16:Ald is employed, and in which respective order per antenna these compounds were tested

Variable	Effect	*df*	*MS*	*F*	*P*
Spikes at 100 μg	Order	1	75.00	1.34	0.260
	Compound	1	560.33	9.98	0.005
	Order–Compound	1	147.00	2.62	0.120
	Error: Antenna (Order)	22	56.121		
Spike frequency increase (10 to 100 μg)	Order	1	65.33	0.84	0.370
	Compound	1	38.33	4.94	0.037
	Order–Compound	1	36.75	0.47	0.500
	Error: Antenna (Order)	22	78.07		

Order distinguishes whether the response was the first or second on an antenna. Compound distinguishes whether Z9-14:OAc or Z11-16:Ald is employed for a given stimulation. For both cases, we use the Antenna for the model error, which is nested in the specific Order treatment.

that over all treatments, the ORNs were more sensitive to Z9-14:OAc than to Z11-16:Ald. However, there was no significant effect of self- *versus* cross-adaptation (X-adapt) or any interaction effect (Table 2).

Responses by the smallest-spiking (antagonist) ORN to two other aldehydes, Z9-14:Ald and Z9-16:Ald, were generally negligible in single stimulations, yielding at most 2.4 spikes per 300 msec when Z9-14:Ald was puffed on the first sensillum of a particular antenna (Fig. 5a). It did not appear that these responses occurred in the E11- or Z11-14:OAc-tuned ORNs. On the first sensillum, when either Z9-14:Ald or Z9-16:Ald had equal opportunity to be puffed first, there was a 25% success rate of getting a response to Z9-14:Ald, (Fig. 5b).

Table 2 Analysis of variance of spike frequency (spikes/0.3 sec) for the cross-stimulation experiments grouped by the pairing of compounds with respect to Z11-16:Ald

Experiment	Effect	*df*	*MS*	*F*	*P*
E11-14:OAc vs. Z11-16:Ald	Order	1	0.319	0.01	0.935
	Compound	1	1139.147	24.26	<0.001
	Order–Compound	1	195.669	4.03	0.054
	Error: Pair(Order)	21	46.92		
Z11-14:OAc vs. Z11-16:Ald	Order	1	27.225	0.56	0.462
	Compound	1	133.225	2.76	0.114
	Order–Compound	1	0.225	0.00	0.946
	Error: Pair(Order)	18	48.225		
Z9-14:OAc vs. Z11-16:Ald	X-adapt	1	173.852	2.50	0.121
	Order	1	7896.071	113.72	<0.001
	Compound	1	775.013	11.16	0.002
	X-adapt–Order	1	20.885	0.30	0.586
	Order–Compound	1	49.613	0.71	0.403
	X-adapt–Compound	1	78.013	1.12	0.295
	Error: pair (X-adapt–Order)	42	69.437		

Order distinguishes whether a stimulus was first or second in the paired stimulation. Compound distinguishes which stimulus was provided for a given stimulation. X-adapt distinguishes whether a stimulus occurred within a cross-stimulated pair, or if the same stimulus was repeated. In each case, we use the unit of the unique paired stimulation event, Pair, as the error, which is nested in the specific Order or X-adapt treatment performed.

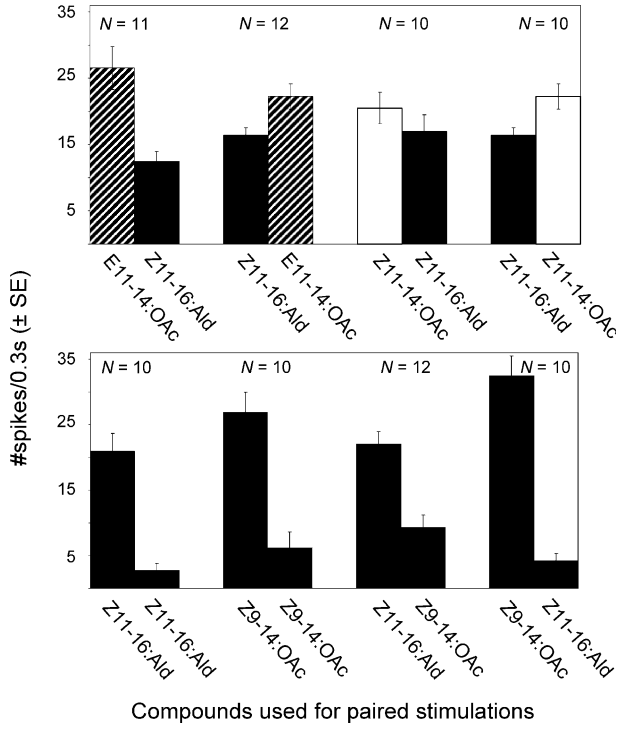

Fig. 4 Number of spikes per 300 msec for cross-stimulation involving Z11-16:Ald, Z11-14:OAc, E11-14:OAc, and Z9-14:OAc at 100-µg loadings. Differences in shading indicate ORNs with distinct spike sizes: a large spike size for Z11-14:OAc, an intermediate spike size for E11-14:OAc, and a small spike size for Z11-16:Ald and Z9-14:OAc

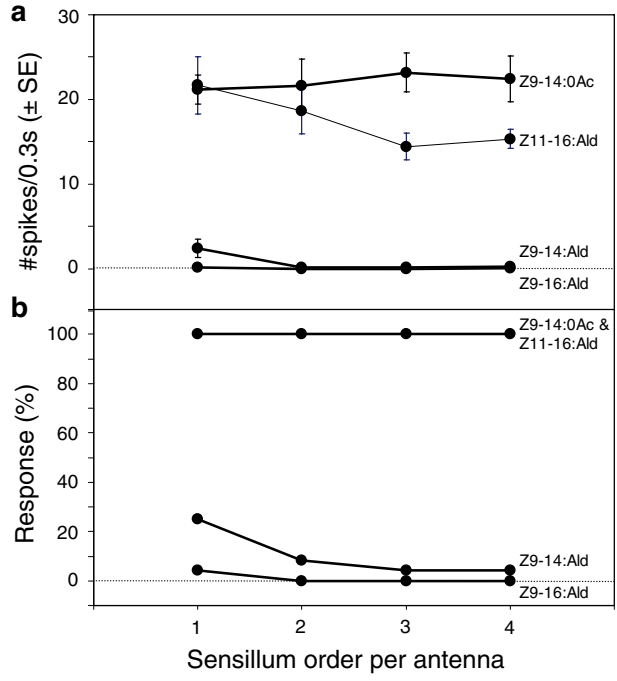

Fig. 5 Sensitivity of Z-strain ECB ORNs to Z9-14:Ald, Z9-16:Ald, Z11-16:Ald, and Z9-14:OAc in each successive sensillum tested per antenna, measured with respect to: (a) the mean (± SE) number of spikes stimulated over 300 msec at 100-µg loadings and (b) the percentage of sensillae responding. For Z9-14:Ald and Z9-16:Ald N=24 for each data point, whereas for Z11-16:Ald and Z9-14:OAc N=12

This is statistically different from the 100% response to the control compounds (Fisher's exact test, $P<0.001$). Under the same conditions, there was only a 4% success rate of this ORN responding to Z9-16:Ald on the first sensillum, which is marginally different (Fisher's exact test, $P=0.098$) from the 25% rate for Z9-14:Ald (Fig. 5b). Logistic regression for likelihood of response to Z9-14:Ald showed a significant effect of sensillum order for Z9-14:Ald ($P=0.026$), but not Z9-16:Ald ($P=0.918$).

Although designed primarily to explore the relative sensitivity of the antagonistic ORN to Z9-14:Ald and Z11-16:Ald, the final experiment also provided the opportunity to examine how the response to Z11-16:Ald and Z9-14:OAc changed with the use of multiple sensilla per moth. There was no significant difference between spike frequency for the two compounds at the first sensillum ($P=0.889$). However, a least-squares regression for Z11-16:Ald, had a significant negative slope ($P=0.031$), whereas the slope for Z9-14:OAc was not different for a similar regression involving Z9-14:OAc ($P=0.633$).

Discussion

Effects of Z11-16:Ald on Male ECB Flight Behavior Our results with males from a New York state ECB population support the finding by Gemeno et al. (2006) that Z11-16:Ald, when added to the ECB pheromone blend, can significantly arrest upwind flight behavior of male ECB. Addition of 1% Z11-16:Ald to the ECB Z-strain 97:3 Z/E11-14:OAc mixture reduced the proportions of males initiating upwind flight by 25% and the proportion reaching the source by 88%. These values compare well with the 26 and 83% reductions observed in flight tunnel tests reported by Gemeno et al. (2006). Our results show further that the antagonism by Z11-16:Ald is not restricted to the area of the Iberian Peninsula where *O. nubilalis* and *S. nonagrioides* are in sympatry, but also extends to ECB populations in North America. A third finding from our studies is that the effect appears to be specific to Z11-16:Ald because the related Z9-14:Ald and Z9-16:Ald, known pheromone components of other moth species, did not affect male flight behavior.

The effect of Z11-16:Ald was characteristic of other known pheromone behavioral antagonists (Linn and Roelofs 1995), evidenced by (1) a pronounced reduction in behavioral response when very low levels (1%) of the compound were added to the sex pheromone, and (2) significant reductions in the number of males completing upwind flights to the pheromone source (SC in Fig. 2). As for other behavioral antagonists, there was less of an effect on earlier behaviors such as taking flight or initiating upwind flight in ("locking onto") the pheromone plume (Fig. 2). Our anecdotal observations, with the 1% Z11-16:Ald treatment, showed that males typically exhibited upwind zig-zag flights, characteristic of pheromone-mediated flight, from one-half to two-thirds of the distance to the source, then began casting across wind, or hovered narrowly in place for several seconds, before exiting the pheromone plume. This flight pattern has been characterized as "arrestment" of upwind flight and is typical of the effect of behavioral antagonists (Baker 1989).

Olfactory Neuron Responses to Z11-16:Ald Gemeno et al. (2006) reported results from EAG experiments suggesting that Z11-16:Ald was not interacting with ORNs specific for the ECB pheromone components. EAG cross-adaptation experiments, however, did suggest the possibility that Z11-16:Ald and Z9-14:OAc were detected by the same ORN, one that previously had been shown to be specific for the latter compound (Hansson et al. 1987). In our study, single-sensillum recordings confirmed, via spike amplitude-matching, that a type

of ORN within the trichoid sensilla on ECB antennae is tuned to respond to both the Z11-16:Ald behavioral antagonist (Gemeno et al. 2006; this paper) and another antagonist Z9-14:OAc (Glover et al. 1989). There was negligible activity from this ORN in response to Z9-14:Ald or Z9-16:Ald, both of which were behaviorally inert. That the responses to Z11-16:Ald occurred on the same ORN that detects the presence of Z9-14:OAc was also supported by cross-adaptation studies.

(Z)-11-Hexadecanal and Pheromone Behavioral Antagonism in ECB: Adaptation or Fortuitous Mimic? The importance of behavioral antagonists in pheromone communication systems is well established (Cardé and Haynes 2004). These compounds contribute to signal specificity by lowering the probability of cross-attraction between species that utilize common pheromone components. This antagonism might involve closely related species that have the potential to mate or species that are more distantly related. In either case, signal specificity is enhanced in a "noisy" chemical environment (Linn and Roelofs 1995). In most of the known cases, the antagonist chemicals are components involved in communication channels used by species that share common pheromone components, as a result of common lineage and use of similar biosynthetic pathways. Thus, for ECB, Z9-14:OAc is a potential by-product from its pheromone biosynthetic pathways and is also a pheromone component in two related *Ostrinia* species in Japan (*O. zealis* and *O. zaguliaevi*, Ishikawa et al. 1999). Phylogenetic analysis suggests that the latter species are ancestral to the group including ECB (Kim et al. 1999). Therefore, divergence might have involved a change in functionality for Z9-14:OAc. A second, well-studied example involves the heliothine moths, *Heliothis virescens* and *Helicoverpa zea* (Vickers et al. 1998), which utilize the same major pheromone component, Z11-16:Ald. In *H. virescens*, the compound Z9-14:Ald is a pheromone component, whereas in *H. zea* it acts as an antagonist. In both of these examples, males possess a separate, specialized, sensory pathway to process the antagonist input, suggesting that there has been selection for the character to enhance reproductive isolation or interference between species sharing common components (Löfstedt 1993; Linn and Roelofs 1995; Cardé and Haynes 2004).

The examples above illustrate the point that changes in odorant receptor (OR) expression or functionality of components in a common pathway are mechanisms that could give rise to new pheromone component blends, or behavioral antagonists. Antagonism could, however, also involve a chemical that is not a member of the suite of compounds that a group of species uses for its pheromones, if that chemical binds to an OR of an established antagonist pathway. We propose that this might be the case with Z11-16:Ald and ECB. This conclusion stems firstly from the observation that Z11-16:Ald is not involved in any known sex pheromone in an *Ostrinia* species (Ishikawa et al. 1999), and second, the aldehyde is structurally similar to Z9-14:OAc with respect to chain length and position of the double bond relative to the carbonyl group and the hydrocarbon end. Both behavioral antagonists might, therefore, bind to the same OR expressed in the ORN involved in antagonism, resulting in significant firing and a reporting of their presence to higher centers via the antagonist pathway. This explanation allows for the possibility that a small number of structurally similar compounds might exert an effect without having been under selection pressure to interfere with sex pheromone communication of two species sharing the same habitat. Gemeno et al. (2006), in fact, raised caution about the adaptive significance of their finding with respect to habitat-specific interactions between ECB and *S. nonagrioides*, noting that the antagonistic effect of Z11-16:Ald was initially observed as a result of combining pheromone blends in field trapping and pheromone mating disruption tests. The two species utilize the same host plants and have seasonal overlap, but are in different

families, differ in size, have no shared pheromone components, and mate at different times in the scotophase. In this scenario, the antagonist effect of Z11-16:Ald could be considered a coincidence of chemical structural similarity.

Alternatively, two different pheromone ORs could be expressed on the same dendrite, with one specifically binding Z9-14:OAc and the other, Z11-16:Ald. Although pheromone ORNs have generally been thought to express only one OR gene, recent studies on *Drosophila* (Goldman et al. 2005) as well as on *H. virescens* and *H. subflexa* (Baker et al. 2004) provide evidence for dual OR expression on a single ORN. In *O. nubilalis*, expression of two different ORs on the ORN involved in behavioral antagonism would imply an adaptive significance. This possibility would have been better supported if our analysis of variance for the paired stimulation experiments for these two compounds had shown a significant effect of cross- *versus* self-adaptation, or an interaction between cross- *versus* self-adaptation and the compound puffed. Thus, it appears that the neuronal adaptation caused by either of these compounds has an identical effect on subsequent stimulations, a pattern that would occur if both compounds bind to the same OR. However, such a pattern remains possible for a two-ORN model if recovery from adaptation is caused by factors other than OR saturation. Whether one or two ORs are involved in the behavioral antagonism observed in response to Z11-16:Ald and Z9-14:Ac, the result would be increased conspecific pheromone blend discrimination and, therefore, less cross-attraction in an environment occupied by other species that share a subset of the same compounds in their pheromone blends.

Acknowledgment We thank Kathy Poole for her help in maintaining the ECB colonies. The project was funded by NSF IBN #034340.

Abstract The cowpea weevil, *Callosobruchus maculatus*, is a major pest of stored pulses. Females of this species produce a contact sex pheromone that elicits copulation behavior in males. Pheromone was extracted from filter-paper shelters taken from cages that housed females. Crude ether extract stimulated copulation in male *C. maculatus*. Initial fractionation showed behavioral activity in acidic and neutral fractions. Furthermore, bioassay-guided fractionation and gas chromatography-mass spectroscopy (GC-MS) analysis of active fractions revealed that the active components of the acidic fraction were 2,6-dimethyloctane-1,8-dioic acid and nonanedioic acid. These components along with the hydrocarbon fraction, a mixture of C_{27}–C_{35} straight chain and methyl branched hydrocarbons, had a synergistic effect on the behavior of males. Glass dummies treated with an authentic pheromone blend induced copulation behavior in males. The potential roles of the contact sex pheromone of *C. maculatus* are discussed.

example, sex attractant pheromone is released by one sex and attracts the other sex from a distance. Contact sex pheromone is also produced by one sex, but it works at close range to elicit courtship and/or copulation behavior in the other sex. Generally, sex attractant pheromones are highly volatile, olfactory-perceived stimuli, whereas contact sex pheromones have low volatility and act as contact or gustatory stimuli (Birch 1974). Although many sex attractant pheromones have been identified, mainly from pest species (http://www.pherobase.org), fewer contact sex pheromones have been identified, probably due to their lesser potential for pest control applications. Both attractant and contact sex pheromones can, however, be important for mating success, and in some species, both types of pheromones are used sequentially (e.g., *Blattella germanica*; Nojima et al. 2005).

Callosobruchus spp. are major pests of stored pulses, cowpeas, pigeonpeas, and other legumes (Rees 2004). Females of *Callosobruchus chinensis* produce both sex attractant and contact sex pheromones that are distinct from each other (Tanaka et al. 1981). The sex attractant pheromone of *C. chinensis* has been identified recently as a mixture of C_{16} aldehydes (Shimomura, personal communication). The contact sex pheromone of *C. chinensis* has been characterized as a mixture of a monoterpene dicarboxylic acid and C_{25}–C_{35} straight chain and methyl branched hydrocarbons (Tanaka et al., 1981). Glass rod dummies treated with a synthetic female contact pheromone blend elicited copulation behavior from males (Tanaka et al. 1982). Dummies equipped with an artificial genital opening stimulated genital insertion and ejaculation (Honda and Ohsawa 1990).

Callosobruchus maculatus is closely related to *C. chinensis* and is also an important pest of stored pulses (Rees 2004). The presence of a sex attractant pheromone in this species was demonstrated by Rup and Sharma (1978), and the pheromone was later characterized as a mixture of short-chain fatty acids (Phillips et al. 1996). Various biological and behavioral aspects of the sex attractant pheromone have been studied, including pheromone production (Qi and Burkholder 1982; Lextrait et al. 1995; Shu et al. 1996), male response patterns to the pheromone (Lextrait et al. 1994), pheromone gland morphology (Ramaswamy et al. 1995), and the role of the attractant pheromone for discrimination of conspecific males and related species (Phillips et al. 1996; Mbata et al. 2000). However, the contact sex pheromone of *C. maculatus* has not been chemically investigated. Here, we characterize the *C. maculatus* female contact sex pheromone to understand the pheromonal communication system of this species better.

Methods and Materials

Insects A laboratory-maintained colony was used in the experiments. Insects were reared on *Vigna angularis* (variety Dainagon from Hokkaido, Japan) in a dark incubator at 27°C and 60% relative humidity. Newly emerged adults were sexed and maintained under the same conditions as above. Females were kept in a group in glass containers (90 mm ID× 60 mm height) with corrugated filter paper shelters (90 mm ID, Advantec No. 2).

Pheromone Collection Virgin females were kept in containers for 3–4 wk. Filter-paper shelters were collected and Soxhlet-extracted with ether for 20 hr. The insides of the glass containers were rinsed with ether, and the ether combined with the extracts. The solvent was evaporated under reduced pressure. Extracts were accumulated from a total of ca 3,000 females and kept in a refrigerator until use.

Bioassays Newly emerged males were held singly in capped glass vials (1.5 cm i.d. and 3.0 mm in height) and kept for 1 d in the incubator under the same conditions as for

rearing. Males were taken from the incubator and acclimated to the light conditions 1 hr before the behavioral tests. A glass rod (2 mm OD and 150 mm in length) was used as a female dummy. The tip of the rod was rounded by the flame of a gas burner and abraded with # 1000 abrasive paper. Four microliters of ethereal extract were applied to the tip of the rod with a micro syringe. After the solvent evaporated, the female dummy was introduced into a vial, and a male's antennae gently rubbed with the dummy for 2 min. In response to the contact sex pheromone, males showed characteristic copulation behaviors: drumming the dummy with the antennae, holding it with the forelegs, and extruding the genital organ toward the dummy. The number of males attempting genital connection with the dummy was recorded. The dummy was changed every ten males. For semiqualitative assays, each sample was tested using 20 or 30 males, and the results were analyzed by Fisher's exact probability followed by the sequential Bonferroni test (Rice 1989). For quantitative assays, the relation between a series of dosages of a treatment and copulation-release activity was subjected to probit analysis, and the median effective dosage (ED_{50}) estimated. A parallel-line assay was conducted on a set of preparations to estimate a common regression formula by using a computer program by Sakuma (1998). The validity of the results of the parallel-line assay was examined by χ^2 analysis of heterogeneity of the observed responses deviating from the expected. If heterogeneity was significantly large ($P<0.05$), a variance ratio test [analysis of variance (ANOVA)] between parallelism and heterogeneity was used to verify the results. Ten to 80 males were tested to each dosage of a treatment, and a total of 140 to 300 males were used for a preparation to estimate the ED_{50} value of a sample. Sample dose was adjusted in terms of female equivalents (f.e.).

Purification of Pheromone Components Crude pheromone extract (ca 3,000 f.e.) was dissolved in 50 ml ether, and the solution was fractionated into neutral, acidic, and basic fractions with 5% aq. NaOH and 5% aq. HCl (Fig. 1). Acidic compounds were redissolved in ether, and the solution concentrated to dryness with Celite 545 (100 mg) in a rotary evaporator. The Celite was suspended in methanol–water–trifluoroacetic acid in a ratio of 20:80:1 (*v*/*v*/*v*), and the suspended mixture applied to the top of a prewetted ODS column [Isolute C18 (EC) 500 mg, International sorbent technology Ltd. Mid Glamorgan, UK]. Acidic components absorbed on the Celite were eluted successively with 10 ml of methanol–water–trifluoroacetic acid in a ratio of 20:80:1 (*v*/*v*/*v*) and 5 ml each of 40:60:1, 60:40:1, 80:20:1, and 100:0:0 (Fig. 1). The active fraction was further fractionated by column chromatography on 100 mg of silica gel (Wakogel C-300, Wako Pure Chemical Industries Ltd. Osaka, Japan). The column was eluted with a sequence of 1 ml aliquots of hexane–ether–trifluoroacetic acid in ratios of 80:20:0.2 (*v*/*v*/*v*), 70:30:0.2, 60:40:0.2, 50:50:0.2, and 35:65:0.2 and methanol (Fig. 1). Acidic compounds in the active fraction were derivatized to methyl esters (see below) and subjected to gas chromatography-mass spectroscopy (GC-MS) analysis. The neutral fraction was chromatographed on 5 g of silica gel (Wakogel C-200, Wako Pure Chemical Industries Ltd. Osaka, Japan) and eluted successively with 50 ml each of hexane–ether in a ratio of 100:0 (*v*/*v*), 95:5, 90:10, 80:20, 50:50, and 0:100 (Fig. 2). The active fraction was subjected to GC-MS analysis.

Methyl Esterification of Acidic Components An aliquot of the acidic fraction was placed in a small conical vial, and mixed with 5 μl methanol and 10 μl of 0.1% (trimethylsilyl) diazomethane in hexane solution (Tokyo Kasei, Co. Ltd. Tokyo, Japan). The mixture was left at room temperature for 30 min with occasional stirring, and subjected to analysis by GC-MS.

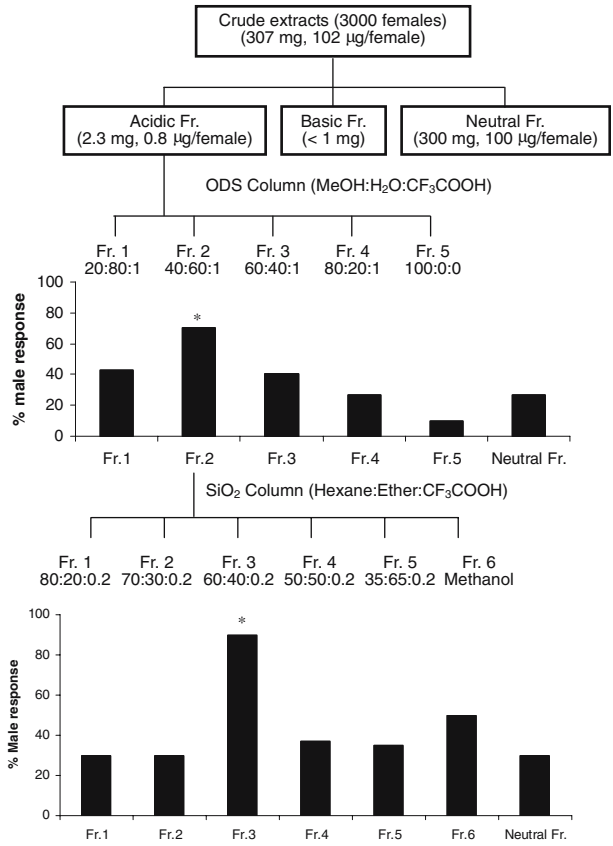

Fig. 1 Fractionation procedure for crude pheromone extract of female *Callosobruchus maculatus* and bioassay-response data for each fraction. Fractions from the reverse-phase separation were tested at 0.05 female equivalents, and fractions from the normal-phase separation at 0.1 female equivalents. All fractions were augmented with the neutral fraction at the same concentration. *Asterisks* indicate statistical differences between the neutral fraction and the test fraction (Fisher's exact probability test followed by the sequential Bonferroni test, $P<0.05$)

Identification of Hydrocarbon Components Hydrocarbon components in the hexane fraction were tentatively identified by comparison with published GC profiles, Kovats retention indices, and mass fragmentation patterns (Baker and Nelson 1981; Howard 2001).

Instruments GC-MS analysis was performed on a Shimadzu GC-17A equipped with 30 m×0.25 mm ID, 0.25 µm film thickness DB-1 or DB-23 columns (J&W scientific, Folsom, CA, USA) in splitless mode, coupled to a Shimadzu QP-5000 quadrupole MS in EI scan mode (electron ionization at 70 eV). Helium was used as the carrier gas at a head pressure of 100 kPa (flow rate, 1.3 ml/min). For analysis of methyl ester derivatives, oven temperature was initially 100°C for 2 min, then increased by 4°C/min to 220°C and held at this temperature for 2 min. Injector and interface temperatures were set at 250°C for methyl ester analysis on both nonpolar and polar columns. For hydrocarbon analysis on the DB-1 column, two temperature programs were used for measurement of Kovats retention indices: (a) initial temperature of 100°C for 2 min, increased by 16°C/min to 330°C and held for 5 min or (b) 200 to 350°C at 8°C/min. Injector and detector temperatures were set at 350 and 340°C, respectively.

Chemicals 2,6-Dimethyloctane-1,8-dioic acid was prepared by hydrogenation of dimethyl ester of (*E*)-3,7-dimethyl-2-octene-1,8-dioic acid (>95% purity), available from a previous study (Tanaka et al. 1982). Hydrogenation was performed by treating the dimethyl ester in

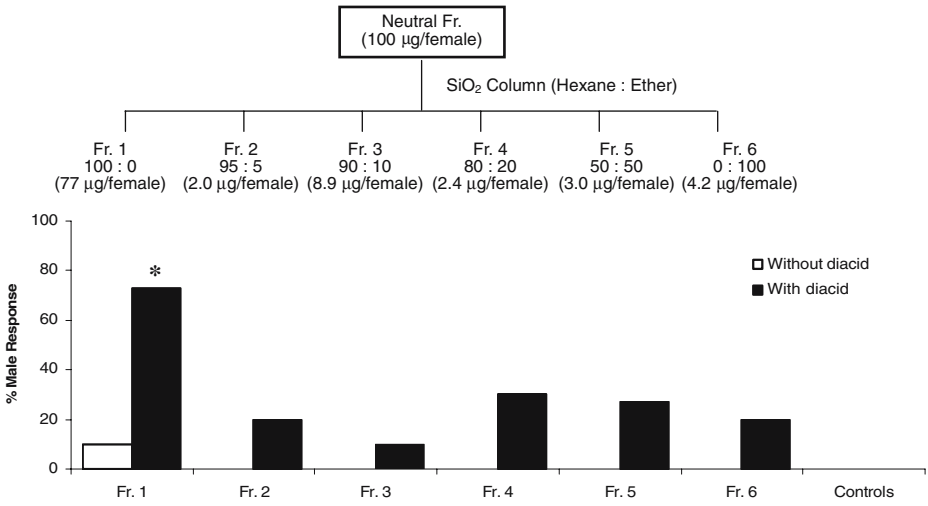

Fig. 2 Fractionation procedure for the neutral fraction of female *Callosobruchus maculatus* extracts, and bioassay-response data for each fraction at 0.05 female equivalents. Each fraction was tested with ("with diacid") and without ("without diacid") 10 ng of synthetic 2,6-dimethyloctane-1,8-dioic acid. Female dummies treated with solvent or the diacid are shown as "without diacid" and "with diacid" controls, respectively. Samples without acid were compared with the "without diacid" control, and samples with acid with the "with diacid" control. *Asterisks* indicate statistical differences between the fractions and controls (Fisher's exact probability test followed by the sequential Bonferroni test, $P<0.05$)

ether with 10% Pd on activated charcoal catalyst and passing hydrogen gas through the solution. Dimethyl ester of 2,6-dimethyloctane-1,8-dioic acid was obtained as a mixture of stereoisomers. The mixture was hydrolyzed with 20% $NaOH_{(aq)}$, and the dicarboxylic acids extracted with ether after acidification with concentrated HCl. The purity of the dicarboxylic acid, as a mixture of stereoisomers, was >95% by GC analysis after methyl ester derivatization. Nonanedioic acid, hydrocarbons, and liquid paraffin were purchased from Tokyo Chemical Industry Co., Ltd. (Tokyo, Japan) and Wako Pure Chemical Industries, Ltd. (Osaka, Japan).

Results

Preliminary Purification of the Crude Extracts Female contact sex pheromone was extracted from the filter papers taken from female containers. The yield of crude extract from 3,000 females was 307 mg. The extract elicited strong copulation behavior from males; all males tested attempted to copulate with female dummies treated with 0.05 f.e. crude extract (Table 1). The ED_{50} of crude extract was estimated at 0.0064 f.e. (Table 2). When the crude extracts were fractionated into acidic, basic, and neutral fractions (Fig. 1), only the neutral fraction elicited copulation activity, albeit weakly, with 27% of males responding to the dummies with 0.05 f.e. (Table 1). The original level of activity was restored when the acidic and neutral fractions were combined (Table 1).

Purification and Identification of Acidic Pheromone Components The acidic fraction was further fractionated by reverse-phase liquid chromatography (LC). The resultant fractions were mixed with the neutral fraction and subjected to behavioral assay. Activity was found

Table 1 Copulation responses of male *C. muculatus* to crude pheromone extract, and acidic, basic, and neutral fractions of the extract

Sample[a]	Responses (%)[b,c]
Crude extract	100
Acidic fraction	0
Basic fraction	0
Neutral fraction	27
Acidic+neutral fraction	100*
Solvent control	0

[a] Tested at 0.05 female equivalents.

[b] Thirty virgin males were used for each sample.

[c] Asterisk indicates sample response not significantly different from the crude extract (Fisher's exact probability test followed by the sequential Bonferroni test, $P>0.05$).

in the fraction that eluted with 40:60:1 (*v*/*v*/*v*) methanol–water–trifluoroacetic acid (Fig. 1). This fraction was fractionated by normal-phase LC, with activity found in the 60:40:0.2 (hexane–ether–trifluoroacetic acid) fraction (Fig. 1). Acidic components in this active fraction were converted to methyl esters and subjected to GC-MS analysis.

Two major components were found in the active fraction, compounds **1** and **2** (Fig. 3). The mass spectrum of compound **1** showed a base peak at *m/z* 55 and characteristic fragments at *m/z* 74 (22) and 88 (75), suggesting McLafferty rearrangements of two methyl ester moieties; $–CH_2–CO–OCH_3$ and $–CH(CH_3)–CO–OCH_3$, respectively. The highest observable ion of compound **1** was *m/z* 199, probably resulting from loss of a methoxy group (M-31) from a molecule with molecular weight of *m/z* 230. Thus, compound **1** was assigned as a dicarboxylic acid with a methyl branch at the α-position. A monoterpene dicarboxylic acid, (*E*)-3,7-dimethyl-2-octene-1,8-dioic acid, has been identified from a related species, *C. chinensis* (Tanaka et al. 1981, 1982). This compound has a methyl branch at the α-position, and its dimethyl ester has a molecular mass of *m/z* 228.

Table 2 Effect of synthetic chemicals on copulation release activity of males of *C. maculatus*

Groups $Y=A+BX$ (χ^2 test; ANOVA)[a] Sample	*A*	ED_{50} (fiducial limits)[b] (female equivalents)
1. $Y=A+0.7455X$ ($P<0.05$; ANOVA, $P>0.05$)		
2,6-Dimethyloctane-1,8-dioic acid (1)	−1.383	72 (21–300)
Nonanedioic acid (2)	−3.267	24,000 (6,800–150,000)
Paraffin+(1)+(2)	0.119	0.69 (0.22–2.7)
2. $Y=A+4.277X$ ($P>0.05$)		
Crude extract	9.369	0.0064 (0.0056–0.0073)
Neutral Fr.+(1)+(2)	5.863	0.043 (0.037–0.049)
Hydrocarbon Fr.+(1)+(2)	–	ND[c] (–)

[a] Regression formula by probit analysis. (A) Section for each sample. (B) Common regression coefficient. Significance was examined by a χ^2 test of heterogeneity. If it was large ($P<0.05$), parallelism was examined by ANOVA between parallelism and heterogeneity.

[b] Median effective dosage with 95% fiducial limits in parentheses. Heterogeneity was large ($P<0.05$) in group **1**, so a *t*-deviate was used for *t*, while heterogeneity was small ($P>0.05$) in group **2**, so a normal deviate was used for *t*.

[c] ND The median effective dosage was not determined due to low activity.

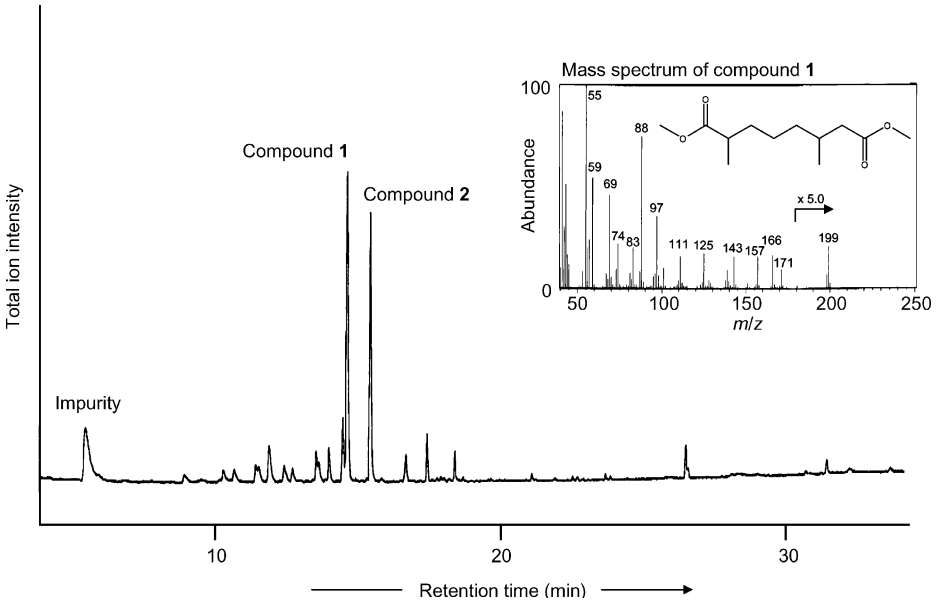

Fig. 3 Total ion chromatogram of the active fraction resulting from normal-phase liquid chromatography of the original acidic fraction. The active fraction was methyl esterified before injection into the GC-MS. *Inset* is mass spectrum and assigned structure of compound **1**

Comparison of the mass spectrum (Tanaka et al. 1981) of the methyl ester of hydrogenated (*E*)-3,7-dimethyl-2-octene-1,8-dioic acid (i.e., 2,6-dimethyloctane-1,8-dioic acid dimethyl ester; EI at 20 EV) with that of compound **1** (EI at 70 eV) showed similarities, although with some differences in the relative abundance of fragment ions. The differences are likely due to the different electron voltages used in the two studies. Therefore, we assigned compound **1** as 2,6-dimethyloctane-1,8-dioic acid dimethyl ester. The mass spectrum of compound **2** matched nonanedioic acid dimethyl ester in a library search.

The identities of compounds **1** and **2** were confirmed by comparing GC retention times on two different columns (DB-1 and DB-23) and EI-MS spectra with those of authentic standards. The amounts of compounds **1** and **2** were quantified as 3.0 and 2.5 ng/female in the extracts, respectively.

Purification and Chemical Analysis of Neutral Pheromone Components The neutral fraction was subjected to normal phase LC. Each fraction was tested in the behavioral assay, alone or with synthetic 2,6-dimethyloctane-1,8-dioic acid. The hexane fraction alone elicited slight copulatory activity. However, this activity was enhanced significantly by adding 2,6-dimethyloctane-1,8-dioic acid (Fig. 2). GC-MS analysis of this fraction revealed a number of hydrocarbons, tentatively identified as a mixture of C_{27}–C_{35} hydrocarbons, *n*-alkanes, and a homologous series of mono- and di-methyl branched alkanes (Fig. 4), by comparing retention indices and MS fragmentation patterns with those in the literature (Baker and Nelson 1981; Howard 2001). The total amount of hydrocarbons in the hexane fraction was 77 μg/female (Fig. 2).

Copulation Release Activity The copulation-release activities of 2,6-dimethyloctane-1,8-dioic acid and nonanedioic acid were investigated with authentic standards. The di-

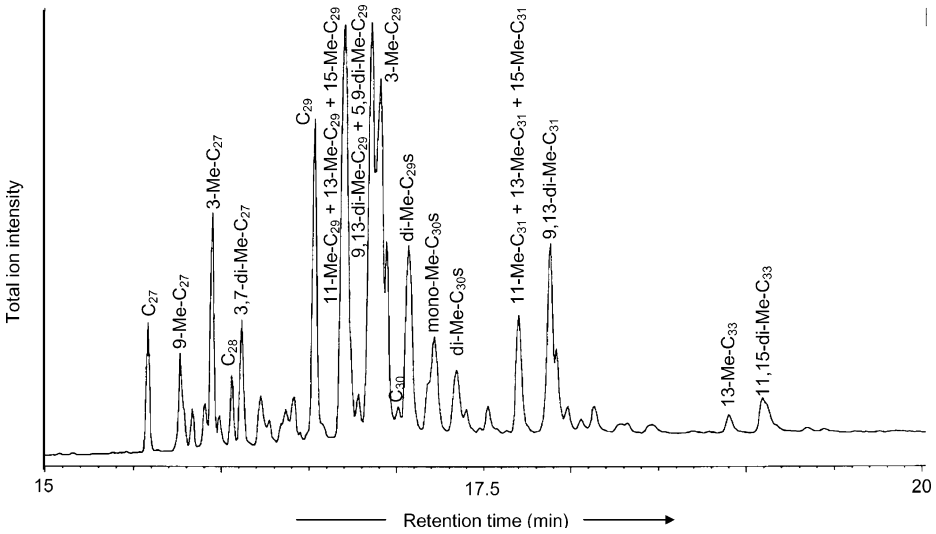

Fig. 4 Total ion chromatogram of the hydrocarbon fraction of female contact pheromone of *Callosobruchus maculatus*

carboxylic acids alone elicited full copulation behavior from the males. All tested males attempted to copulate with female dummies treated with 10 μg of 2,6-dimethyloctane-1,8-dioic acid, while 43% of males responded to 100 μg of nonanedioic acid. The ED_{50} of the dicarboxylic acids was estimated by probit analysis of the relationship between dose and response. A parallel-line analysis was conducted to compare ED_{50} values between samples. This failed ($P<0.05$) because the regression coefficient provided by independent probit analyses of each sample varied widely (0.47–5.0). Consequently, the samples were grouped as shown in Table 2 according to the regression coefficient in the independent analyses. A parallel-line assay was conducted within each group again, with validity of parallelism confirmed in each group. The ED_{50} values of 2,6-dimethyloctane-1,8-dioic acid and nonanedioic acid (group 1) were estimated at 0.22 μg (ca 72 f.e.) and 60 μg (ca 24,000 f.e.), respectively (Table 2). The activity of 2,6-dimethyloctane-1,8-dioic acid was significantly higher than that of nonanedioic acid both on a weight and a f.e. basis. It is important to note, however, that f.e. calculations are based on filter-paper extracts, not females.

The copulation release activity of the hydrocarbons was investigated by using commercially available octacosane, nonacosane, and triacontane. Nonacosane is a major component in the hexane fraction, whereas octacosane, and triacontane are minor components (Fig. 4). Hexadecane, octadecane, and liquid paraffin (a mixture of liquid hydrocarbons from petroleum) were also tested. None of the hydrocarbons tested alone at 0.05 f.e. (3.6 μg/dose) or at a higher dosage of >1 mg (data not shown) elicited copulation activity (Fig. 5). With the addition of 10 ng of authentic 2,6-dimethyloctane-1,8-dioic acid, the reference hydrocarbons, octadecane, and liquid paraffin showed significant activity ($P<0.05$, Fig. 5) relative to the control. Interestingly, in combination with the diacid, liquid paraffin, or octadecane elicited the same level of copulatory behavior as did the same amounts of the natural hydrocarbon fraction or the neutral fraction in combination with the diacid ($P>0.05$).

Copulation release activity of artificial and semi-artificial pheromone blends was investigated by comparison of their ED_{50} values. The ED_{50} of a mixture of synthetic 2,6-dimethyloctane-1,8-dioic acid, nonanedioic acid, and neutral fraction, was estimated at

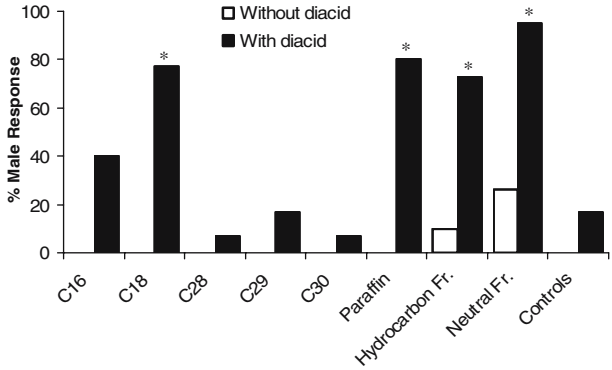

Fig. 5 Bioassay data testing various hydrocarbons and fractions added to 10 ng of the acidic pheromone component ("with diacid") or solvent ("without diacid"). The activities of samples without the diacid were compared with the "without acid" control, while samples augmented with the acid were compared with the "with diacid" control. *Asterisks* indicate statistical differences between treatment and control tests (Fisher's exact probability test, followed by the sequential
Bonferroni test, $P<0.05$)

0.043 f.e. (group 2), whereas a blend of authentic dicarboxylic acids and the natural hydrocarbon fraction showed less activity; its ED_{50} was not determined due to low activity. On the other hand, the ED_{50} of a blend of authentic dicarboxylic acids and liquid paraffin (group 1) was estimated to be 0.69 f.e. (Table 2).

Discussion

The female contact sex pheromone of *C. maculatus* was characterized as a mixture of dicarboxylic acids and hydrocarbons. Behavioral assays with authentic standards revealed that high doses of the acids alone induced full copulation behavior in males, with the activity significantly enhanced by addition of hydrocarbons. Hydrocarbons alone were marginally active.

In this study, the female contact sex pheromone of *C. maculatus* was collected from filter papers taken from containers with virgin females because in a preliminary experiment, body extracts did not consistently elicit copulation activity from males. After contact with dummies treated with female body extracts, most males groomed their antennae and did not attempt to copulate, possibly due to the large quantities of chemicals and the sticky nature of the extracts. In contrast, the extracts of filter papers from the female containers elicited consistent copulation activity in males. The female contact sex pheromone is probably transferred to the filter paper when females rub against it. It seems likely that the active chemicals are cuticular in origin as ca 75% of the mass of crude extracts was hydrocarbons with a GC profile almost identical to that reported previously (Baker and Nelson 1981).

Insect cuticular hydrocarbons play important roles in chemical communication, as well as having ecological and physiological roles (Howard 1993). Many insect species use cuticular hydrocarbons as mate recognition signals with the composition, or specific structures, of the hydrocarbon components apparently important (Howard 1993). In *C. maculatus*, female cuticular hydrocarbons are important in pheromonal communication. However, the specificity of these cuticular hydrocarbons may not be great as non-native hydrocarbons such as hexadecane, octadecane, and liquid paraffin elicited similar or even

greater behavioral activity than the natural hydrocarbon fraction. Interestingly, octacosane, nonacosane, and triacontane, which are solid at room temperature (m.p. 57–62, 63–66, and 64–67°C, respectively), did not increase activity when added to the acids, whereas hexadecane, octadecane, and liquid paraffin, which are liquids at room temperature (m.p. of C_{16} and C_{18} are 18 and 26–29°C, respectively), did. Although our experiments were not designed to investigate the relationship between activity and physical properties of the hydrocarbons, perhaps, in this insect, the physical nature of cuticular hydrocarbons is more important than their specific structure or composition.

A female contact sex pheromone of *Callosobruchus* spp. was first characterized for *C. chinensis*. The pheromonal mixture of (*E*)-3,7-dimethyl-2-octene-1,8-dioic acid and C_{25}–C_{35} straight chain and methyl branched hydrocarbons (Tanaka et al. 1981, 1982) is chemically similar to that which we found for *C. maculatus*. In fact, high proportions of males, of both *C. chinensis* and *C. maculatus*, exhibited copulation behavior to females of the other species in laboratory bioassays (Noijima et al. unpublished observation). Although the respective contact sex pheromones of these two species appear to lack species specificity, their different sex attractant pheromones likely preclude males from finding and encountering females of the other species.

In the artificial pheromone blend experiments, a synthetic mixture of 2,6-dimethyloctane-1,8-dioic acid, nonanedioic acid, and liquid paraffin elicited copulation activity in males with an ED_{50} value much higher than that of crude pheromone extract (ED_{50}, 0.0064 f.e.), suggesting that additional active chemicals may be present in the filter paper extract. The yellow mealworm, *Tenebrio molitor* L. (Coleoptera, Tenebrionidae) has a similar pheromone system, with a female sex attractant and nonvolatile contact sex pheromone (Tanaka et al. 1986). The attractant sex pheromone, in combination with the contact sex pheromone, enhances copulation activity as much as 25 times over the contact pheromone alone (Tanaka et al. 1986). A female sex attractant pheromone for *C. maculatus* was first demonstrated with extracts of filter paper from a vial containing a female (Qi and Burkholder 1982), similar to that used in our study. Therefore, the greater amount of copulation activity elicited by crude extracts, compared to fractions or synthetic components, may have been due to the presence of sex attractant pheromone in the crude extracts. In addition, there may be other components in the contact pheromone, as the neutral fraction alone elicited more behavioral activity than its hydrocarbon subfraction.

In insect pheromone communication, the absolute configuration of pheromone components is often important for behavioral activity (Mori 1997, 2000). The female contact sex pheromone component of *C. maculatus*, 2,6-dimethyloctane-1,8-dioic acid, has two chiral centers, and thus, four stereoisomers are possible. Recently, all four enantiomers of this chemical were synthesized, and it was shown that the natural pheromone of *C. maculatus* is a mixture of all four (Nakai et al. 2005; Yajima et al. 2006). Moreover, each enantiomer elicits copulation behavior in males at similar doses, without antagonism to the others. This is similar to the situation in the related species, *C. chinensis*. In this species, the contact sex pheromone component, (*E*)-3,7-dimethyl-2-octene-1,8-dioic acid, has one chiral center (Tanaka et al. 1981), and the two enantiomers elicit similar behavioral activity (Mori et al. 1983). Further study will be carried out to clarify the structure–activity relationships of chemicals in the contact pheromone of *C. maculatus*.

Abstract Workers of the slave-making ant, *Polyergus breviceps*, raid nests of *Formica* ants and return with *Formica* pupae that mature into worker ants in the slave-makers' colony. These *Formica* workers then tend the *Polyergus* brood, workers, and reproductives. During raids in the mating season, winged virgin *Polyergus* queens accompany the workers in the raiding columns. During the raid, the virgin queens release a pheromone that attracts males that quickly mate with the queens. We report the identification, synthesis, and bioassay of the sex attractant pheromone of the queens as an approximately 1:6 ratio of (*R*)-3-ethyl-4-methylpentan-1-ol and methyl 6-methylsalicylate. The ants produce exclusively the (*R*)-enantiomer of the alcohol, and the (*S*)-enantiomer has no biological activity, neither inhibiting nor increasing attraction to blends of methyl 6-methylsalicylate with the (*R*)-enantiomer.

Keywords *Polyergus breviceps* · Queen sex pheromone · Methyl 6-methylsalicylate · (*R*)-3-ethyl-4-methylpentan-1-ol · Ant · Formicidae · Hymenoptera

Introduction

Ant species in the genus *Polyergus* Latreille (Hymenoptera: Formicidae) are obligate social parasites that have lost the ability to forage for food, rear brood, or care for the queen and the nest. They are entirely dependent upon workers of slave ant species to carry out the tasks that enable a colony to survive (Topoff 1999). Because the slave species do not breed within the *Polyergus* nest, slave ants are captured as pupae during periodic raids conducted by *Polyergus* workers against related ants in the genus *Formica* Linneaus. The captured

pupae are carried back to the *Polyergus* nest, and as the adults of the slave species emerge they are integrated into the nest, where they assume all the typical foraging and "housekeeping" functions that workers normally carry out.

In the deserts of southwestern Arizona, USA, closely corresponding with summer rains in early July, *Polyergus breviceps* Emery males and virgin queens start to congregate at nest entrances in mid-afternoon. Males are usually seen first and may start flying from the nest at this time. If the *Polyergus* workers initiate a slave raid against a *Formica* colony (usually between 1500 and 1800 hours), winged virgin *Polyergus* queens accompany the raiding workers. During the course of the raid, the virgin queens release a pheromone that rapidly attracts males. Copulation lasts for about 15 sec to several min, after which the mated queen sheds her wings. Then, the newly mated *Polyergus* queens independently search for, invade, and take over a colony of *F. gnava* Buckley (the common slave species at this location), first killing the resident *Formica* queen (Topoff et al. 1985; Topoff and Zimmerli 1993; Johnson et al. 2002). It is not known whether a queen invades a *Formica* nest immediately after a slave raid while the workers are still disorganized, or on subsequent days. The *Polyergus* queen acquires the cuticular hydrocarbon profile of the host queen that she has killed and is subsequently tended by the host workers (Johnson et al. 2001). The *Formica* workers then rear the *Polyergus* queen's brood as their own, giving rise to a mixed colony of workers of the two species.

A preliminary study of sex pheromone-mediated behaviors of *P. breviceps* was initiated after observing that *Polyergus* males were attracted to a vial in which a virgin queen had been inadvertently squashed (Topoff and Greenberg 1988). When the various body parts of a fresh queen were tested, only air flowing over the squashed head elicited a response from males, causing them to rapidly run in circles and to attempt to mate with each other. The same response was observed when only the mandibular glands were tested, whereas a head with the glands removed did not elicit any response.

Methyl 6-methylsalicylate had been reported as the major component of the mandibular glands of *Polyergus rufescens*, the European congener of *P. breviceps* (Castracani et al. 2003; Grasso et al. 2003), and in field trials it was reported to attract male ants (Castracani et al. 2005). However, these authors suggested that a second compound also may be involved in the queen pheromone, possibly as a component of the secretion of the newly described intramandibular gland (Grasso et al. 2004).

In a recent rapid communication (Greenberg et al. 2004), we reported that the queen-produced pheromone of *P. breviceps* consisted of an approximately 3:1 blend of methyl 6-methylsalicylate and racemic 3-ethyl-4-methylpentan-1-ol. We also provided a brief description of the field trials and chemical analyses that resulted in the identification. Here, we report the syntheses of the enantiomers of the chiral component, 3-ethyl-4-methylpentan-1-ol. We further report the determination of the absolute configuration of the 3-ethyl-4-methylpentan-1-ol produced by the queen ants, and comparative bioassays of pheromone blends composed of the racemate or its individual enantiomers, in combination with the second component of the pheromone, methyl 6-methylsalicylate.

Methods and Materials

Insect Samples

Winged (virgin) queen *P. breviceps* were collected at the Southwestern Research Station of the American Museum of Natural History in Portal, Arizona. Queens were collected from raiding columns by aspiration, immediately killed by freezing, and cut into head, thorax,

and abdomen. Frozen body parts in 1.5-ml screw cap glass vials were shipped on dry ice to University of California Riverside for analysis. Voucher specimens of *P. breviceps* and *Formica gnava* are archived at the UC Riverside Entomology Museum (UCRC ENT 131329–131343 and 131328, respectively).

Preparation and Analysis of Extracts

Solid phase microextraction (SPME) collections of volatiles released from virgin queen heads were made by crushing heads in their vials with a glass rod, sealing the vial with aluminum foil, pushing the SPME needle through the foil, and exposing the SPME fiber (100 μm polydimethylsiloxane coating; Supelco, Bellefonte, PA, USA) in the headspace for 30 min. The loaded fibers then were desorbed in the injection port of a coupled gas chromatograph-mass spectrometer (GC-MS) for 30 sec at 250°C, in splitless injection mode. GC-MS analyses of SPME extracts were carried out with a Hewlett-Packard 6890 GC (H-P; Avondale, PA, USA) with liquid CO_2 cryogenic cooling, equipped with a 30 m×0.25 mm HP-5 MS column, interfaced to an HP 5973 mass selective detector (electron impact ionization, 70 eV), using a GC temperature program of 0° for 1 min, then 10° per minute to 250°C.

To determine the absolute configuration of the insect-produced 3-ethyl-4-methylpentanol, SPME-collected volatiles from squashed heads of virgin queens were analyzed on a Cyclodex-B column (J&W Scientific, 30 m×0.25 mm id, 0.25 film; Folsom, CA, USA) with a head pressure of 140 kPa and a temperature program of 50°C for 1 min, then 3° per minute to 240°C. The retention times of synthetic standards of the (3*R*)- and (3*S*)-enantiomers under these conditions were 19.64 and 19.76 min, respectively. The same conditions were used to determine the enantiomeric purity of synthetic compounds.

Syntheses of Pheromone Components

All reactions were carried out at room temperature in oven-dried glassware unless stated otherwise. Methyl 6-methylsalicylate (Seidel et al. 1990) and racemic 3-ethyl-4-methylpentanol standards (Bühring et al. 1976) were synthesized as previously described. The first synthesis of enantiomerically enriched 3-ethyl-4-methylpentanol enantiomers was carried out as described by Nicotra et al. (1986), providing the (*R*)-and (*S*)-enantiomers in 89.0 and 86.4% enantiomeric excess (ee), respectively. This material was used in bioassays in 2004. A second synthesis subsequently was carried out to provide material of higher ee, starting from commercially available (*R*)-(+)-limonene **2**, as follows (Fig. 1).

(2RS,5S)-5-Ethyl-6-methylheptan-2-ol (5) Commercially available (*R*)-(+)-limonene **2** was hydrogenated to (*R*)-(+)-dihydrolimonene **3** as described by White et al. (1981). Alkene **3** was then transformed to (3*R*,6*RS*)-3-(1-methylethyl)heptane-1,6-diol 4 by the method of Nicotra et al. (1986).

Under an atmosphere of dry nitrogen, (3*R*,6*RS*)-3-(1-methylethyl)heptane-1,6-diol **4** (1.29 g, 7.40 mmol) was dissolved in 8 ml dry pyridine and cooled to 0°C. *p*-Toluenesulfonyl chloride (1.72 g, 9.02 mmol) dissolved in 12 ml dry pyridine was added to the stirred solution over 2 hr, and stirring was continued for 24 hr at room temperature. The mixture then was diluted with 40 ml diethyl ether. This mixture and 120 ml dilute hydrochloric acid (3% solution in brine) were added separately to 150 ml ice-cold brine so that the solution was kept at pH 6. After separation of the layers, the aqueous layer was

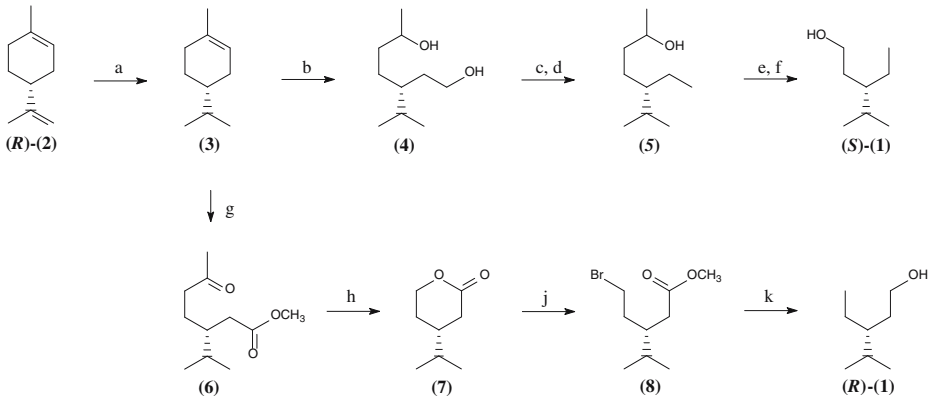

Fig. 1 Syntheses of (*S*)-(-)- and (*R*)-(+)-3-ethyl-4-methylpentan-1-ol. (a) PtO_2, H_2, MeOH; (b) (1) O_3, CH_2Cl_2/MeOH, −70°C; (2) $NaBH_4$ −70°C; (c) *p*-TsCl, pyridine, 0°C; (d) $LiAlH_4/Et_2O$, −30°C; (e) PDC, CH_2Cl_2; (f) H_2O_2, aq. NaOH/MeOH; (g) (1) O_3, CH_2Cl_2/MeOH, −70°C, (2) *p*-TsOH, −70°C to room temp, dimethylsulfide; (h) H_2O_2, aq. NaOH/MeOH; (j) HBr, MeOH, −30°C; (k) $LiAlH_4/Et_2O$, −20°C

extracted five times with 20 ml diethyl ether. The combined organic extracts were washed with 15-ml portions of saturated $NaHCO_3$, brine, aqueous cupric sulfate, and brine. After drying over anhydrous (anhyd.) $MgSO_4$, the solvent was removed *in vacuo* to yield 1.90 g of crude (3*R*,6*RS*)-3-(1-methylethyl)-1-*p*-toluenesulfonyloxyheptan-6-ol, which was used without further purification.

Under an atmosphere of dry nitrogen, $LiAlH_4$ (530 mg, 14 mmol) was suspended in 30 ml dry diethyl ether and cooled to −30°C. Crude (3*R*,6*RS*)-3-(1-methylethyl)-1-*p*-toluenesulfonyloxyheptan-6-ol (1.42 g) in 10 ml diethyl ether was added dropwise over 20 min to the stirred suspension. The mixture was stirred for 2 hr, followed by refluxing for 3 hr. After cooling to 0°C, 2 N aq. NaOH (2.4 ml) was added, and the mixture was stirred for 2 hr. After removal of the aqueous layer and drying of the organic layer with anhyd. $MgSO_4$, the solvent was removed *in vacuo*. Chromatography on silica gel (32–63 μm, 60 Å, ethyl acetate/hexane 1:4) yielded 789 mg (90%) (2*RS*,5*S*)-5-ethyl-6-methylheptan-2-ol **5** as a colorless oil. ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.83/0.84 (2 d, 6 H, J=6.6 Hz, CH(CH_3)$_2$), 0.86 (*t*, 3 H, J=7.4 Hz, CH_2CH_3), 0.98–1.04 (m, 1 H, CH_2CHCH_2), 1.13–1.22/1.30–1.38 (2 m, 2 H, CH(OH)CH_2CH_2), 1.19 (d, 3 H, J=6.1 Hz, CH_3CHOH), 1.23–1.32 (m, 2 H, CH_2CH_3), 1.38–1.44 (m, 2 H, CH_2CHOH), 1.65–1.73 (m, 1 H, $CH(CH_3)_2$), 3.76 (m, 1 H, CHOH). ^{13}C NMR (101 MHz, $CDCl_3$): δ 12.19 (q, C9), 19.31/19.35/19.49/19.51 (2q, C7 and C10), 23.04 (t, C8), 23.60/23.66 (q, C1), 26.11/26.13 (t, C4), 29.09 (d, C6), 37.64 (t, C3), 45.69 (d, C5), 68.82/68.88 (d, C2). MS (70 eV), *m*/*z* (relative abundance): 39 (18), 40 (4), 41 (64), 42 (15), 43 $\left(88, CH_3CHCH_3^+\right)$, 44 (10), 45 (99, CH_3CHOH^+), 53 (6), 55$\left(100, C_4H_7^+\right)$, 56 (16), 57 (17), 58 (4), 59 (7), 67 (3), 69 (37), 70 (18), 71 (9), 81 (4), 83 (9), 84 (12), 85 (6), 97 (26, M^+-iPr, -H_2O), 98 (11), 115 (3), 123 (1), 125 (2, M^+-H_2O, -Me), 140 (2, M^+-H_2O), 141 (2).

(S)-3-Ethyl-4-methylpentan-1-ol, (S)-1 Powdered 4-Å molecular sieve (1.28 g) was added to a solution of (2*RS*,5*S*)-5-ethyl-6-methylheptan-2-ol **5** (638 mg, 4.03 mmol) in 30 ml dry CH_2Cl_2 under nitrogen. The vigorously stirred suspension was cooled to −10°C, and pyridinium dichromate (3.2 g, 8.5 mmol) was added in small portions. Stirring then was continued for 24 hr at room temperature. After addition of 30 ml diethyl ether, the mixture

was filtered through a plug of silica gel. After washing the filter cake with several portions of diethyl ether, drying of the combined ethereal solution with anhyd. $MgSO_4$ and removal of the solvent *in vacuo*, 611 mg of crude (*S*)-5-ethyl-6-methylheptan-2-one were obtained as a colorless oil. The mass spectrum of the compound was in accord with that previously reported (Renold et al. 1974), and the compound was used without further purification.

Aqueous NaOH (20 ml) was added to a stirred solution of 375 mg of crude (*S*)-5-ethyl-6-methylheptan-2-one in 15 ml methanol, followed by 20 ml of 30% aqueous hydrogen peroxide in four portions over 5 d while stirring in the dark. The mixture then was heated to 50°C and small portions of an aqueous solution of sodium sulfite were added until the remaining peroxide was destroyed (no darkening of an acidic solution of potassium iodide). After cooling, the reaction mixture was saturated with sodium chloride and extracted five times with 25 ml diethyl ether. The combined extracts were washed twice with brine, dried over anhyd. $MgSO_4$, and concentrated *in vacuo*. Silica gel chromatography, eluting with ethyl acetate/hexane 1:4 yielded 54.6 mg (0.42 mmol, 17%) of (*S*)-3-ethyl-4-methylpentan-1-ol, (*S*)-**1**, of 98% ee, as a colorless oil. Spectroscopic data matched those of the racemic material and those reported in the literature (Enders and Rendenbach 1986).

(R)-4-(1-Methylethyl)tetrahydropyran-2-one (**7**) (*R*)-(+)-dihydrolimonene **3** (see above) was converted to methyl (*R*)-3-(1-methylethyl)-6-oxoheptanoate **6** as described by Kitahara and Mori (1984). A mixture of methyl (*R*)-3-(1-methylethyl)-6-oxoheptanoate **6** (1.24 g, 6.19 mmol), 60 ml methanol, 24 ml 10% aq. NaOH, and 56 ml of 30% aq. H_2O_2 was stirred for 3 d in the dark. Work-up and purification as described for the synthesis of (*S*)-**1** from (*S*)-5-ethyl-6-methylheptan-2-one (see above) yielded 475 mg (3.34 mmol, 54%) of (*R*)-4-(1-methylethyl) tetrahydropyran-2-one **7**. Analytical data matched literature values (Theisen and Heathcock 1993).

Methyl (S)-5-bromo-3-(1-methylethyl)pentanoate (**8**) A solution of of (*R*)-4-(1-methylethyl)tetrahydropyran-2-one **7** (451 mg, 3.17 mmol) in 35 ml methanol was cooled to −30°C, then a gentle stream of dry HBr gas was passed into the stirred solution. After termination of the reaction (approximately 1 hr), the mixture was added slowly to 50 ml of ice-cold brine. The mixture was extracted with 15 ml diethyl ether, and the layers were separated. The aqueous layer was extracted three more times with 30 ml diethyl ether. The combined organic extracts were washed twice with saturated aq. $NaHCO_3$ and then with 8 ml of brine. The solution was dried over anhyd. $MgSO_4$, and the solvent was removed *in vacuo*. Silica gel chromatography, eluting with ethyl acetate : hexane, 1:6, yielded 623 mg (2.63 mmol, 83%) of bromide **8** as a slightly yellow liquid. ^{1}H NMR (400 MHz, $CDCl_3$): δ 0.87/0.90 (2 d, 6H, J=6.6 Hz, $CH(CH_3)_2$), 1.72–1.77 (m, 1 H, $CH(CH_3)_2$), 1.75–1.82/1.89–1.99 (2 m, 2H, $BrCH_2CH_2$), 1.89–1.99 (m, 1 H, CH_2CHCH_2), 2.18/2.34 (dd, J=15.4/7.4 Hz, dd, J= 15.4/5.9 Hz, 2H, CH_2COO), 3.45–3.67 (m, 2 H, CH_2Br), 3.68 (s, 3 H, $COOCH_3$). ^{13}C NMR (101 MHz, $CDCl_3$): δ 18.60/19.35 (q, C-7 and C-8), 29.94 (d, C-6), 31.77 (t, C-5), 34.81 (t, C-4), 35.47 (t, C-2), 39.93 (d, C-3), 51.77 (q, C-9), 173.89 (s, C-1). MS (70 eV), *m/z* 39 (31), 40 (6), 41 (78), 42 (15), 43 (80), 44 (3), 45 (6), 51 (4), 52 (2), 53 (21), 54 (11), 55 (99), 56 (7), 57 (8), 59 (50), 65 (2), 67 (9), 68 (2), 69 (29), 70 (3), 71 (13), 72 (3), 73 (11), 74 (100), 75 (8), 79 (4), 81 (17), 82 (10), 83 (57), 84 (4), 85 (2), 87 (42), 88 (4), 93 (2), 95 (3), 96 (2), 97 (30), 98 (2), 99 (4), 101 (11), 107 (4), 109 (7), 113 (4), 115 (4), 121 (2), 123 (2), 125 (27, 205-HBr), 126 (2), 129 (4), 135 (2, $C_4H_8Br^+$), 137 (1),141 (3), 143 (1), 157 (12, M^+-Br), 161 (2), 163 (16), 164 (2, M^+-88), 165 (14), 187 (1, 205-H_2O), 189 (1), 193 (27, M^+-iPr), 194 (3), 195 (26), 196 (3), 205 (7, $^{79}M^+$-OMe), 207 (7), 221 (0.6,$^{79}M^+$-Me), 223 (0.6), 236 (0.2, $^{79}M^+$), 237 (0.3, $^{79}M^+$+1), 238 (0.2), 239 (0.3).

(R)-3-Ethyl-4-methylpentan-1-ol, (R)-1 A solution of bromide **8** (103 mg, 0.44 mmol) in 15 ml dry diethyl ether was added dropwise to a stirred suspension of $LiAlH_4$ (35 mg, 0.91 mmol) in 15 ml dry diethyl ether. The mixture was stirred for 2 hr, then refluxed 3 hr. Work-up and purification as described for the syntheses of **5** (see above) yielded 53 mg (0.40 mmol, 92%) of (*R*)-**1**, 97% ee. Spectroscopic data matched those of (*S*)-**1**.

Field bioassays

Field trials were conducted in July of 2004 and 2005. Solutions of test compounds in hexane were loaded onto 11-mm gray rubber septum lures (West Pharmaceutical Services, Lionville, PA, USA). Septa treated only with hexane were used as controls. Lures were placed in the centers of Pherocon® AM sticky traps, and traps were placed on the ground. A replicate consisted of the test treatments plus a control, each on its own sticky trap. The placement of the traps within a replicate was randomized, with the traps spaced 3 m apart. Replicates were spaced ~50 m apart and at least 15 m from the nearest *P. breviceps* nest. Traps were set out at 1600 hour and retrieved 2 hr later. Trap count data were square-root transformed ($X+0.5$) and analyzed by analysis of variance (ANOVA), followed by Student–Newman–Keuls tests to determine differences between means ($\alpha=0.05$).

Results

The syntheses of (*S*)-(-)-3-ethyl-4-methylpentan-1-ol, (*S*)-**1** and its enantiomer started from (*R*)-(+)-limonene **2** (Fig. 1). Commercially available **2** was hydrogenated to (*R*)-(+)-dihydrolimonene **3** as described by White et al. (1981). This was then transformed to either (3*R*,6*RS*)-3-(1-methylethyl)heptan-1,6-diol **4** (Nicotra et al. 1986) or to methyl (*R*)-3-(1-methylethyl)-6-oxoheptanoate **6** (Kitahara and Mori 1984), the respective precursors for each of the two enantiomers.

For the synthesis of (*S*)-**1**, the primary hydroxyl group of diol **4** was selectively tosylated, followed by reduction of the tosylate to (2*RS,5*S)-5-ethyl-6-methylheptan-2-ol **5** with $LiAlH_4$ (analogous to Kishida 1960). Oxidation of **5** to (*S*)-5-ethyl-6-methylheptan-2-one with pyridinium dichromate followed by Baeyer–Villiger oxidation yielded the target compound, (*S*)-**1**, with 98% ee.

For the synthesis of (*R*)-1, ketoester **6** was transformed to (*R*)-4-(1-methylethyl) tetrahydropyran-2-one **7**. Treatment of **7** with dry HBr in methanol (Paquette et al. 1991) yielded methyl (*S*)-5-bromo-3-(1-methylethyl)pentanoate **8**, which was converted to (*R*)-**1** of 97% ee by reduction with $LiAlH_4$ (Jefford et al. 1972).

Analysis of the volatiles from squashed heads of virgin queens on a Cyclodex-B chiral stationary phase GC column showed that queens produced exclusively the (*R*)-enantiomer (Fig. 2). This result was confirmed in field bioassays. In the first field trial in 2004, using blends of methyl 6-methylsalicylate with racemic and enantiomerically enriched (*R*)- and (*S*)-3-ethyl-4-methylpentanol (89 and 86.4% ee, respectively), mixtures of the racemic or the (*R*)-alcohol plus the salicylate were highly attractive to male ants, whereas the (*S*)-enantiomer plus the salicylate blend was much less attractive (Fig. 3A). The weak attraction to the latter blend may have been caused by the small percentage of the contaminating (*R*)-enantiomer in the blend, so the bioassay was repeated in 2005 with newly synthesized compounds of much higher enantiomeric purity ((*R*), 97% ee, (*S*), 98% ee). With these almost pure enantiomers, the results were unequivocal: traps baited with blends of the

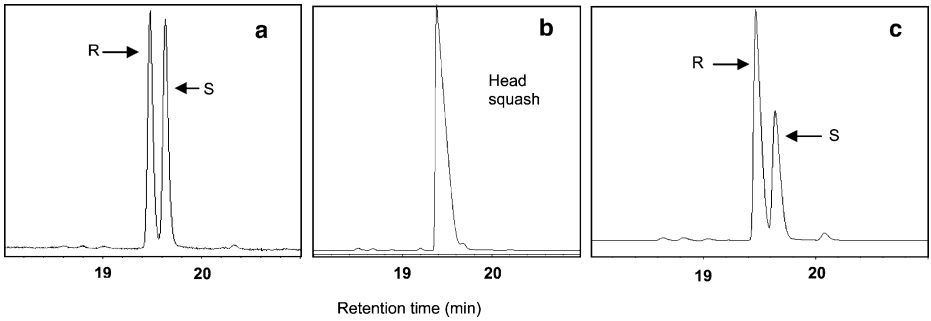

Fig. 2 Gas chromatograms on a Cyclodex B column of: (a) synthetic racemic 3-ethyl-4-methylpentanol; (b) SPME-collected volatiles from a *P. breviceps* queen head squash; c) volatiles from a queen head squash spiked with racemic 3-ethyl-4-methylpentanol, showing the enlargement of the first (3*R*) peak. Chromatography conditions are described in "Methods and Materials"

racemic or (*R*)-alcohol were highly attractive to male ants, whereas the corresponding blend prepared with the (*S*)-enantiomer attracted no male ants at all (Fig. 3B).

Discussion

There are about 190,000 described species within the order Hymenoptera, which includes the ants, bees, wasps, and sawflies (Goulet and Huber 1993). Within this group, numerous researchers have described anecdotal evidence for the use of sex pheromones and attractants, but sex pheromones have been conclusively demonstrated with bioassays in few cases (reviewed in Ayasse et al. 2001). The dearth of data on mating behavior in this group to some extent reflects the difficulty in observing and studying insects that often mate in flight or under circumstances that render detailed observation and manipulation difficult. Among the ants (family Formicidae), which consist of over 10,000 described species in 16 extant subfamilies (Bolton 1995), evidence of sex pheromones or attractants secreted by males or females has been described in three subfamilies: the Ponerinae, Myrmicinae, and Formicinae. For example, *Rhytidoponera* females (Ponerinae) release a sex attractant from their abdominal pygidial glands (Meinwald et al. 1983), whereas *Pogonomyrmex* males (Myrmicinae) release 4-methyl-3-heptanone from their mandibular glands, which attracts both sexes (McGurk et al. 1966). In the subfamily Formicinae, methyl 6-methylsalicylate, the most abundant component we identified in extracts of heads of *P. breviceps* queens, is also found in mandibular glands of males of several *Camponotus* species (Hölldobler and Maschwitz 1965; Torres et al. 2001), and its release has been shown to trigger flight of sexuals from the nest (Hölldobler and Maschwitz 1965). This same compound has also been identified from a ponerine ant, *Gnamptogenys pleurodon* (Duffield and Blum 1975) and as a trail pheromone in the myrmicines *Tetramorium impurum* (Morgan and Ollett 1987) and *Mayriella overbecki* (Kohl et al. 2000). The second component of the sex pheromone of *P. breviceps*, 3-ethyl-4-methylpentanol, has been identified previously from mandibular glands of workers of *Harpegnathos saltator* (do Nascimento et al. 1993) and in heads of *Formica rufa* workers and *Formica polyctena* queens (Francke et al. 1985). However, the biological relevance of this compound for the latter three species has not been reported, nor has the absolute configuration of the compound from these various species been determined.

In *Formica lugubris*, the only other ant for which a sex pheromone has been identified (Walter et al. 1993), males and females fly from their nests to open places in the forest

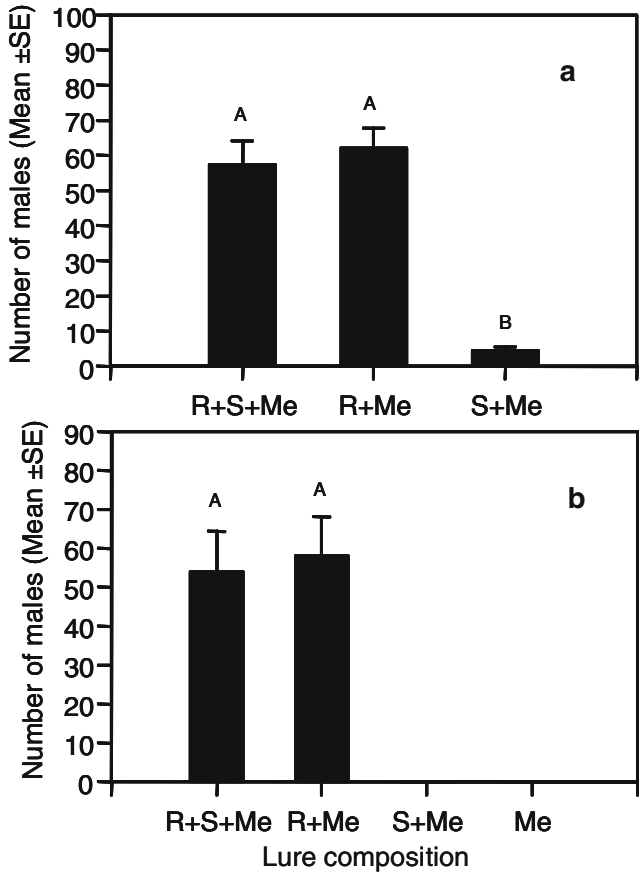

Fig. 3 Mean numbers (± SE) of *P. breviceps* males captured in traps baited with mixtures of racemic or enantiomerically enriched (*R*)- and (*S*)-3-ethyl-4-methylpentanol with 6-methylsalicylate. "R"=(*R*)-enantiomer, "S"=(*S*)-enantiomer, and "Me"=methyl 6-methylsalicylate. Trial 1 with less pure enantiomers (a): blend ratios were racemic (R+S)/Me (25:75), R/Me (15:75), and S/Me (15:75). Trial 2 with high enantiomeric purity materials (b): blend ratios were racemic (R+S)/Me (25:75), R/Me (12.5:75), and S/Me (12.5:75). Means with the same letter are not significantly different (Newman–Keuls test on square root transformed count data)

where they mate on the ground. Extracts of the Dufour's gland were found to contain three volatile compounds (undecane, tridecane, and (*Z*)-4-tridecene, mean ratio 100:5:4), but undecane as a single component was as attractive as the three compounds together. Thus, even within the same ant subfamily, the sex pheromone system in this species bears no relationship to that of *P. breviceps*, with the pheromone being produced from an entirely different gland, and the chemistry of the pheromone components also being entirely different.

The sex pheromone of *P. rufescens*, a European congener of *P. breviceps*, was reported to consist of methyl 6-methylsalicylate as a single component (Castracani et al. 2005). Although it is difficult to directly compare their results with ours because of differences in bioassay designs (e.g., Castracani et al. 2005 placed traps only 2 m from nests, whereas ours were at least 15 m away), the relatively low trap catches they reported compared with ours suggest that the reported pheromone of *P. rufescens* may be incomplete.

Previous reports had suggested that the *P. breviceps* pheromone was produced in the mandibular glands (Topoff and Greenberg 1988; Greenberg et al. 2004). However, the squashes used in those studies did not distinguish between mandibular glands located in the head behind the mandibles and the newly described intramandibular glands (Grasso et al. 2004). Therefore, it is possible that one or both of the two pheromonal components come from the intramandibular glands.

Polyergus breviceps and *P. rufescens* both illustrate the "female calling syndrome" (Hölldobler and Bartz 1985; Ayasse et al. 2001), with queens remaining close to their nest of origin where they emit sex attractant pheromones. This behavior may be adaptive for parasitic ants that are uncommon or that live in patchy environments. This mating strategy assures that queens mate in the habitat that contains the slave species that are essential for starting new colonies. Other ant species such as harvester ants in the genus *Pogonomyrmex* (Hölldobler and Bartz 1985; Ayasse et al. 2001) use a different mating strategy called the "male-aggregation syndrome," whereby unmated female reproductives fly upwind to aggregations of pheromone-producing males.

Pheromones consisting of blends can increase the message specificity created from subsets of a relatively small number of compounds. The examples mentioned above suggest that volatile components used for communication by ants are quite highly conserved, with the same compounds being found repeatedly in even quite distantly related species. Reconstruction of the sex pheromones of other ant species may be facilitated by behavioral bioassays conducted in tandem with gas chromatography-electroantennogram detection (GC-EAD) analysis, as proved to be crucial in the location and identification of the minor component of the *P. breviceps* pheromone (Greenberg et al. 2004). Furthermore, the specificity of a sex pheromone blend is likely to be important in reproductive isolation of closely related sympatric species (Blum 1981). We plan to test this prediction in ongoing research comparing the sex pheromone blend of *P. breviceps* with that of a second slave-making ant, *P. lucidus*, in their areas of sympatry in the United States.

Abstract Pheromone binding proteins (PBP) play an important role in insect pheromone communication. However, the PBP for the beet armyworm, *Spodoptera exigua* Hübner (Lepidoptera: Noctuidae), an important agricultural pest worldwide, remains unaddressed. We report the cloning of two PBP genes, *SexigPBP1* and *SexigPBP2*, from the antennal cDNA of *S. exigua* by reverse transcriptase-polymerase chain reaction (RT-PCR) and rapid amplification of cDNA ends-PCR (RACE-PCR). The deduced PBP amino acid sequences are characteristic of the odorant binding protein (OBP) family, although the two PBPs are only 44% identical. From an analysis of the genomic DNA, two introns and a similar intron/extron structural pattern were identified in each of the two PBP genes. RT-PCR analysis revealed that the two PBP genes are only expressed in antennae. Real-time PCR further indicated that the expression of *SexigPBP1* is much higher than that of *SexigPBP2*, regardless of sex. However, the female expression levels for *SexigPBP1* and *SexigPBP2* are about 39% and 73%, respectively, relative to male levels. Finally, phylogenetic analysis suggested that PBPs from the Noctuidae are divided into three distinct groups based on the primary sequences.

Introduction

Interactions of insects with their surroundings are based primarily on chemical signals. Odor reception in insects involves small (15–17 kDa) soluble proteins, called odorant

binding proteins (OBPs) (Vogt and Riddiford 1981). OBPs are synthesized by accessory cells and accumulated to high concentrations (10 mM) in the sensillar lymph (Steinbrecht et al. 1992). They are postulated to solubilize semiochemicals, to protect the ligands from degradation, and to participate in fast inactivation of chemical signals (Kaissling 1986, 1996; Du and Prestwich 1995; Prestwich et al. 1995; Klusák et al. 2003). Insect OBPs are all α-helical proteins (Sandler et al. 2000), thus, completely different from mammalian OPBs, which belong to the lipocalin superfamily and have a β-barrel fold (Spinelli et al. 1998; Tegoni et al. 2000). OBPs can be further divided into two classes: highly specific and sensitive pheromone binding proteins (PBPs) and less specific general odorant binding proteins GOBP1 and GOBP2 (Vogt and Riddiford 1981; Robertson et al. 1999; Vogt et al. 1999).

In moths, the pheromone communication system is extremely sensitive, enabling the detection of a few molecules, and selective in the discrimination between closely similar compounds or isomers (Hansson 1995). PBPs have been identified from various moth species (Vogt and Riddiford 1981; Maïbèche-Coisné et al. 1998; Robertson et al. 1999; Picimbon and Gadenne 2002), and the proteins display considerable diversity, sharing 32–92% amino acid identity (Abraham et al. 2005). Moreover, there is evidence for multiple PBPs in a single moth species, each encoded by a distinct locus (Bette et al. 2002; Picimbon and Gadenne 2002). Ligand-binding experiments in some moths, especially in the gypsy moth, *Lymantria dispar* (L.) (Lepidoptera: Lymantriidae), have shown that the various PBPs show specificity in binding their respective pheromones (Du and Prestwich 1995; Plettner et al. 2000; Bette et al. 2002; Maida et al. 2003). Therefore, it has been suggested that PBPs in some species may be involved in discriminating between pheromone components.

The beet armyworm, *Spodoptera exigua* Hübner (Lepidoptera: Noctuidae), is a severe pest of various agricultural crops in Asia and North America. The sex pheromone of female *S. exigua* has been identified as a complex blend, and a lure with two components (*Z*9,*E*12–14:Ac and *Z*9–14:OH) has been successfully used in pest population monitoring and management (Wakamura et al. 1989; Mitchell and Tumlinson 1994; Yoshiyasu et al. 1995; Mitchell et al. 1997; Dong and Du 2002). However, the molecular mechanism of the perception of female sex pheromone by the male in *S. exigua* remains unknown. Here, we report the molecular isolation and identification of two genes from *S. exigua* that encode members of the PBP family. In addition, reverse transcriptase-polymerase chain reaction (RT-PCR) was performed to investigate the distribution of PBPs in different tissues, and the mRNA expression levels of both PBPs in antennae were detected in male and female moths by real-time PCR.

Methods and Materials

Collection of Tissues

Spodoptera exigua were reared at 27°C (14:10 L:D) in the laboratory on an artificial diet (Huang et al. 2002) and sexed as pupae. Antennae were collected by excising the tissue at the base from 3-d-old male and female moths and immediately transferring it to Eppendorf tubes immersed in liquid nitrogen. The same procedure was used for collecting the head (without antennae), thorax, abdomen, and legs. All tissues were stored at −75°C until used experimentally.

Nucleic Acid Manipulation

Total RNA was extracted by homogenizing antennae or other tissues of male and female moths in Trizol™ reagent (Invitrogen, Carlsbad, CA, USA) following the manufacturer's

instructions. Total RNA was transcribed into single strand cDNA that served as templates for PCR amplification by extension of an oligo(dT)$_{18}$ primer using MMLV reverse transcriptase (Promega, Madison, WI, USA) at 42°C for 60 min. The reaction was stopped by heating at 95°C for 5 min.

Genomic DNA was prepared from one-fourth instar. Animal tissues were disrupted by grinding in liquid nitrogen and homogenizing with 300 μl DNA extraction buffer (100 mM Tris–HCl, pH 8.0; 50 mM ethylenediaminetetraacetic acid (EDTA); 200 mM NaCl; 1% SDS). The homogenate was transferred to an Eppendorf tube, gently mixed with 20 μl Proteinase K (20 mg/ml), and incubated at 56°C for 3 hr. The tube was centrifuged for 10 min at 12,000×*g*. The supernatant was transferred to a new tube. DNA was extracted with an equal volume of phenol:chloroform:isoamyl alcohol (25:24:1) followed by an equal volume of chloroform:isoamyl alcohol (24:1), each time centrifuging for 5 min at 12,000×*g* to collect the aqueous phases. Two-and-one-half volumes of chilled ethanol were added to the aqueous supernatant for DNA precipitation. The pellets were washed in 70% ethanol, briefly vacuum-dried, and the DNA was redissolved in 50 μl Tris–EDTA (TE) buffer (10 mM Tris–HCl, pH 8.0; 1 mM EDTA, pH 8.0; 100 μg/ml RNase A).

PCR and Sequencing

The cDNAs encoding pheromone binding proteins of *S. exigua* were amplified from antennal cDNA of males. Comparing PBP sequences from *Heliothis virescens* (Krieger et al. 1993, GenBank X96861), *Helicoverpa zea* (Callahan et al. 2000, GenBank AF090191), *Agrotis ipsilon* (Picimbon and Gadenne 2002, GenBank AY301986), *Agrotis segetum* (LaForest et al. 1999, GenBank AF134253), and *Mamestra brassicae* (Maïbèche-Coisné et al. 1998, GenBank AF051142 and AF051143), a pair of degenerate primers (Table 1) was designed to match amino acid regions of FWK(R)EG(E)Y and HE(D)LN(K)WA. Amplification was carried out in a PTC-200 (MJ Research, Waltham, MA, USA) and included negative controls under the following conditions: 94°C for 3 min; 9 cycles at 94°C for 50 sec, 65°C for 1 min, and 72°C for 30 sec, with a decrease of the annealing temperature by 1°C per cycle. This was followed by 25 cycles at 94°C for 50 sec, 55°C for 1 min, and 72°C for 30 sec, and final incubation for 10 min at 72°C. The reaction was performed in 50 μl with 3 μl single-stranded cDNA, 2.0 mM $MgCl_2$, 0.2 mM dNTP, 1.5 μM for each primer and 2.5 U Taq polymerase (Promega).

A RACE procedure was employed to amplify the 5′ and 3′ end of the coding region using SMART RACE cDNA Amplification Kit (Clontech, Mountain View, CA, USA) following the kit instructions. Gene-specific primers (GSP) (Table 1) for 5′-RACE and 3′-RACE were derived from the sequence of PCR products. Amplification conditions were 94°C for 2 min; 28 cycles at 94°C for 30 sec, 68°C for 30 sec, and 72°C for 3 min.

Regions of the PBP gene were amplified from genomic DNA by PCR to ascertain the intron/exon structure of the genes. Specific primer pairs (Table 1) were chosen for the amplification. Primer sequences were designed to include a *Bam*HI restriction site in the sense primers and an *Xho*I restriction site in the antisense primers (underlined). Touchdown PCR reactions were performed as follows: 94°C for 3 min, 5 cycles at 94°C for 50 sec, 61°C for 50 sec, and 72°C for 2 min, with a decrease of the annealing temperature by 1°C per cycle. Subsequently, 35 cycles of 94°C for 50 sec, 55°C for 50 sec, and 72°C for 2 min was followed by incubation for 10 min at 72°C. LA Taq polymerase (LA Taq Polymerase is a thermostable polymerase that possesses a 3′ to 5′ exonuclease activity, allowing amplification of long targets, TaKaRa, Otsu, Shiga, Japan) was used following manufacturer's instructions.

[a] Gene-specific primer

PCR products were analyzed by 1.5% agarose-gel electrophoresis, and DNA purification was performed using Wizard PCR Preps DNA purification kit (Promega). Purified products were subcloned in a T/A cloning plasmid using the pGEM-T easy vector system (Promega) following manufacturer's instructions. The plasmid DNA was transformed into DH5α competent cells. Positive clones on the basis of restriction enzyme cleavage sites and PCR amplification were sequenced using dye-terminator chemistry and reactions on an ABI 377 automatic sequencer (Applied Biosystems, Foster City, CA, USA).

Sequence Analysis

Sequences were identified with the NCBI-BLAST network server (Altschul et al. 1990). The putative signal peptides and their cleavage sites were predicted by using the SignalP V 3.0 program (Bendtsen et al. 2004; http://www.cbs.dtu.dk/services/SignalP/). The hydrophobicity profile was determined by the method of Kyte and Doolittle (1982). The sequence data were aligned and compared by using Clustal X (1.81) (Thompson et al. 1997). The phylogenetic tree was constructed with Neighbor Joining (NJ) by the MEGA2.1 program (Kumar et al. 2001). Bootstrap analysis used 1,000 replications.

Tissue Specificity of SexigPBP

Tissue specificity was assessed by reverse transcription (RT)-PCR. RT-PCR templates were the cDNA from antennae and other tissues of male and female moths, and genomic DNA. Specific primer pairs (Table 1) were derived from the cDNA sequences, spanning at least one predicted intron region, thus, allowing us to distinguish amplification products resulting from cDNAs templates from those amplified from possible genomic contaminants in the cDNA preparation. For testing the integrity of the cDNA templates, a control primer pair (Table 1) from the coding region of the *S. exigua* β-actin gene (*ACTB*) (GenBank AY507963) was used. PCR began at 94°C for 3 min, then 5 cycles at 95°C for 50 sec, 54°C for 50 sec, and 72°C for 2 min (with a decrease of the annealing temperature by 1°C per cycle); followed by 35 cycles at 95°C for 50 sec, 49°C for 50 sec, and 72°C for 2 min; with a final 10-min incubation at 72°C.

Real-time PCR Analysis of SexigPBP Expression

Real-time PCR was performed in an ABI Prism 7000 Sequence Detection System (Applied Biosystems,) by using SYBR green dye bound to double strand DNA at the end of each elongation cycle (SYBR Green Realtime PCR Master Mix; TOYOBO, Osaka, Japan). PCR primers were designed to yield products of 75 to 150 bp; each pair was designed to span a cDNA exon–exon border to avoid amplification of potential traces of genomic DNA (Bohbot and Vogt 2005). SexigPBP1 primers (Table 1) amplified a 130-bp product from cDNA. SexigPBP2 primers (Table 1) amplified a 133-bp fragment from cDNA. As an endogenous control to normalize the results of a variable target gene and to correct for sample-to-sample variation, the amplification size of *ACTB* primers (Table 1) was 107 bp.

Real-time PCR was conducted in 25 μl reactions containing 12.5 μl of 2× SYBR Green PCR Master Mix, 0.5 μl of each primer (10 μM), 2.5 μl of sample cDNA, and 9 μl sterilized ultrapure H_2O (Millipore). To check reproducibility, test samples, endogenous control, and "no sample control" were done in triplicate. Cycling parameters included 94°C for 3 min, 40 cycles at 94°C for 30 sec, and 62°C for 45 sec. The products were analyzed by sequencing, agarose gel electrophoresis, and melting curve, which indicated that each reaction did not produce nonspecific amplification.

Relative quantification was performed by using the comparative $2^{-\Delta\Delta C_T}$ method (Livak and Schmittgen 2001) to identify the amount of PBP mRNA in female antennal tissue relative to the amount in male tissue. All data were normalized to endogenous *ACTB* levels from the same individual sample. In the analysis of the relative fold change, the male sample, which was one of the experimental samples, was taken as the calibrator (Mittapalli et al. 2006). Thus, the relative fold change was assessed by comparing the expression level

of *SexigPBP* in female moths to that in males. Calculations for relative quantification were performed according to the instructions of the User Bulletin #2 from Applied Biosystems (Relative Quantification of Gene Expression; ABI Prism 7700 Sequence Detection System).

An assumption in the $\Delta\Delta C_T$ calculation for the comparative $2^{-\Delta\Delta C_T}$ method for relative quantification is that the amplification efficiencies of the target and reference are approximately equal. To confirm this, a pilot experiment was conducted to examine the variation of ΔC_T ($C_{T,\text{Target}} - C_{T,ACTB}$) with template dilution. Briefly, four serial tenfold dilutions of cDNA from each sample were amplified. For each dilution, amplifications were performed in triplicate by using primers for *PBP* and *ACTB*. Mean C_T was calculated for both *PBP* and *ACTB*, ΔC_T was calculated, and log cDNA dilution vs. ΔC_T was plotted.

Fig. 2 cDNA sequence and predicted amino acid sequence of SexigPBP2. The stop codon is indicated with an *asterisk*. The signal peptide is *underlined*. Sites of intron one and two are marked with >< above the sequence, and the intron sequences are given at the *bottom* of the figure

Results

Identification and Characterization of SexigPBPs

PCR performed with a pair of degenerate primers designed on the conserved amino acid regions of FWK(*R*)EG(*E*)Y and HE(D)LN(K)WA in PBPs of other insects, afforded two

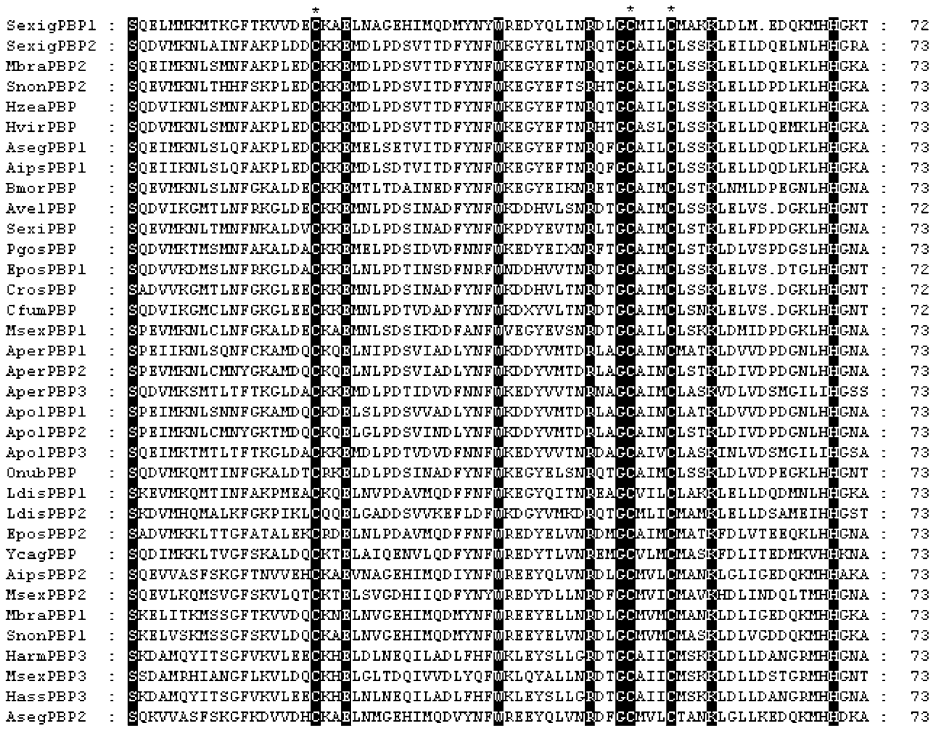

Fig. 3 Alignment of the mature SexigPBP1 and SexigPBP2 from *Spodoptera exigua* with their orthologs from other species of moths: SexigPBP1 and SexigPBP2 are at the top, AipsPBP1 (*Agrotis ipsilon*, AY301985), AipsPBP2 (*A. ipsilon*, AY301986), AperPBP1 (*Antheraea pernyi*, X96773), AperPBP2 (*A. pernyi*, X96860), AperPBP3 (*A. pernyi*, AJ277265), ApolPBP1 (*Antheraea polyphemus*, X17559), ApolPBP2 (*A. polyphemus*, AJ277266), ApolPBP3 (*Antheraea polyphemus*, AJ277267), AsegPBP1 (*Agrotis segetum*, AF134253–AF134294), AsegPBP2 (*A. segetum*, AY301987), AvelPBP (*Argyrotaenia velutinana*, AF177640), BmorPBP (*Bombyx mori*, X94987), CfumPBP (*Choristoneura fumiferana*, AF177644), CrosPBP (*Choristoneura rosaceana*, AF177654), EposPBP1 (*Epiphyas postvittana*, AF416587), EposPBP2 (*E. postvittana*, AF411459), HarmPBP3 (*Helicoverpa armigera*, AF527054), HvirPBP (*Heliothis virescens*, X96861), HassPBP3 (*Helicoverpa assulta*, DQ286414), HzeaPBP (*Helicoverpa zea*, AF090191), LdisPBP1 (*Lymantria dispar*, AF007867), LdisPBP2 (*L. dispar*, AF007868), MbraPBP1 (*Mamestra brassicae*, AF051143), MbraPBP2 (*M. brassicae*, AF051142), MsexPBP1 (*Manduca sexta*, AF323972), MsexPBP2 (*M. sexta*, AF117588), MsexPBP3 (*M. sexta*, AF117581), OnubPBP (*Ostrinia nubilalis*, AF133631), PgosPBP (*Pectinophora gossypiella*, AF177656), SexiPBP (*Synanthedon exitiosa*, AF177657-AF177660), SnonPBP1 (*Sesamia nonagrioides*, AY485219), SnonPBP2 (*S. nonagrioides*, AY485220), and YcagPBP (*Yponomeuta cagnagellus*, AF177661). Conserved amino acids in all PBPs are shown in a *black background*. Positions of six conserved cysteine residues are indicated by *asterisks*

cDNA products of 275 and 281 bp, respectively. They were called SexigPBP1 and SexigPBP2, respectively. A RACE procedure was employed to obtain full-length sequences of PBP1 and PBP2 from *S. exigua*. Gene-specific primers (GSP) for 5′-RACE and 3′-RACE were derived from the sequences of the two cDNA products. The two PBP sequences of SexigPBP1 and SexigPBP2 (Figs. 1 and 2) were deposited in GenBank with the accession numbers AY540316 and AY545636, respectively.

The full-length sequences of *SexigPBP1* and *SexigPBP2* are 1,077 and 819 bp, respectively. *SexigPBP1* cDNA contains a 492-bp open reading frame that encodes a 164 amino acid protein, with a calculated molecular weight of 18.870 kDa and isoelectric point of 5.64. The initial 23 amino acids are predicted as a signal peptide, suggesting that the protein is secreted into the extracellular fluid. The mature SexigPBP1 comprises 141 amino acids, with a molecular weight of 16.413 kDa, and isoelectric point 5.34. *SexigPBP2* cDNA contains a 510-bp open reading frame that encodes a 170 amino acid protein, with

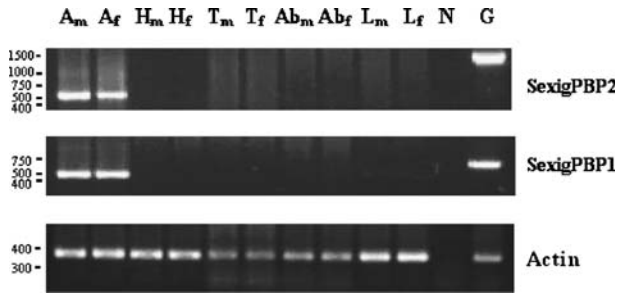

Fig. 4 Tissue-specific expression of *SexigPBP1* and *SexigPBP2*. RT-PCRs were performed using RNAs isolated from the different tissues. Amplification products were analyzed on agarose gels and visualized by UV illumination after ethidium bromide staining. Based on the primer design, the sizes of the expected PCR-products were 496 bp for *SexigPBP1*, 561 bp for *SexigPBP2*, and 377 bp for the control *Actin*. A_m male antenna, A_f female antenna, H_m male head (without antenna), H_f, female head (without antenna), T_m male thorax, T_f female thorax, Ab_m male abdomen, Ab_f female abdomen, L_m male leg, L_f, female leg, *N* no-template negative control ensures the specificity of the amplifications, *G* genomic DNA template reaction indicates the relative position of PCR product derived from genomic DNA contamination in experimental samples. The position of molecular weight markers (bp) is indicated on the *left side*

calculated molecular weight of 18.881 kDa and isoelectric point 5.32. As the fragment of initial 27 amino acids is predicted as the signal peptide, the mature protein SexigPBP2 comprises 143 amino acids, has a calculated mass of 16.088 kDa, and an isoelectric point of 5.01. The two PBPs display similar hydropathy profiles (Supplementary material Fig. S1).

To ascertain the intron/exon structure of the genes, the two PBP genes were further cloned and sequenced from the genomic DNA preparation. Both *SexigPBP1* and *SexigPBP2* genes contain two introns and present a similar intron/exon structure. The two introns in *SexigPBP1* are located between Glu45 and Leu46 (intron1, 87 bp) and inside the codon for Asp105 (intron2, 142 bp). The introns in *SexigPBP2* are located between Glu49 and Met50 (intron1, 295 bp) and inside the codon for Asp110 (intron2, 644 bp). The ends of the introns have a typical GT-AG structure (Figs. 1 and 2).

We aligned the mature amino acid sequences deduced from *SexigPBP1* and *SexigPBP2* with the PBPs of other Lepidoptera (Fig. 3). Both SexigPBP1 and SexigPBP2 have conserved motifs of lepidopteran PBPs, including six cysteine residues forming three disulfide bridges and the position of the hydrophobic domains. The two PBPs from *S. exigua* share low similarity (44% identity), but are similar to PBPs of the same group from other insect species. SexigPBP1 displays a high identity with SnonPBP1 (72%), MbraPBP1 (71%), and AipsPBP2 (69%), whereas SexigPBP2 is more similar to HzeaPBP (86%), MbraPBP2 (85%), and HvirPBP (84%).

Tissue-specificity of PBP Gene Expression

To investigate the presence of PBPs in different tissues of *S. exigua*, RT-PCR experiments were performed with specific primers. Based on detailed genomic information, specific primer pairs were designed to span at least one intron region. This allowed us to distinguish amplification products resulting from cDNA templates from those resulting from possible genomic contamination of the cDNA preparation. Specific expression of the two PBPs in *S. exigua* was observed (Fig. 4). RT-PCR products of the predicted size were observed exclusively in reactions with antennal cDNA. No specific product was observed with head (without antennae), thorax, abdomen, or leg cDNA. The integrity of the cDNA templates prepared from different tissues was verified by primers specific for the actin gene. In all cDNA preparations, an *Actin* amplification product of the correct size was amplified. Larger bands that might have been generated from amplification of genomic DNA were not found. Therefore, *SexigPBP1* and *SexigPBP2* are only expressed in *S. exigua* antennae.

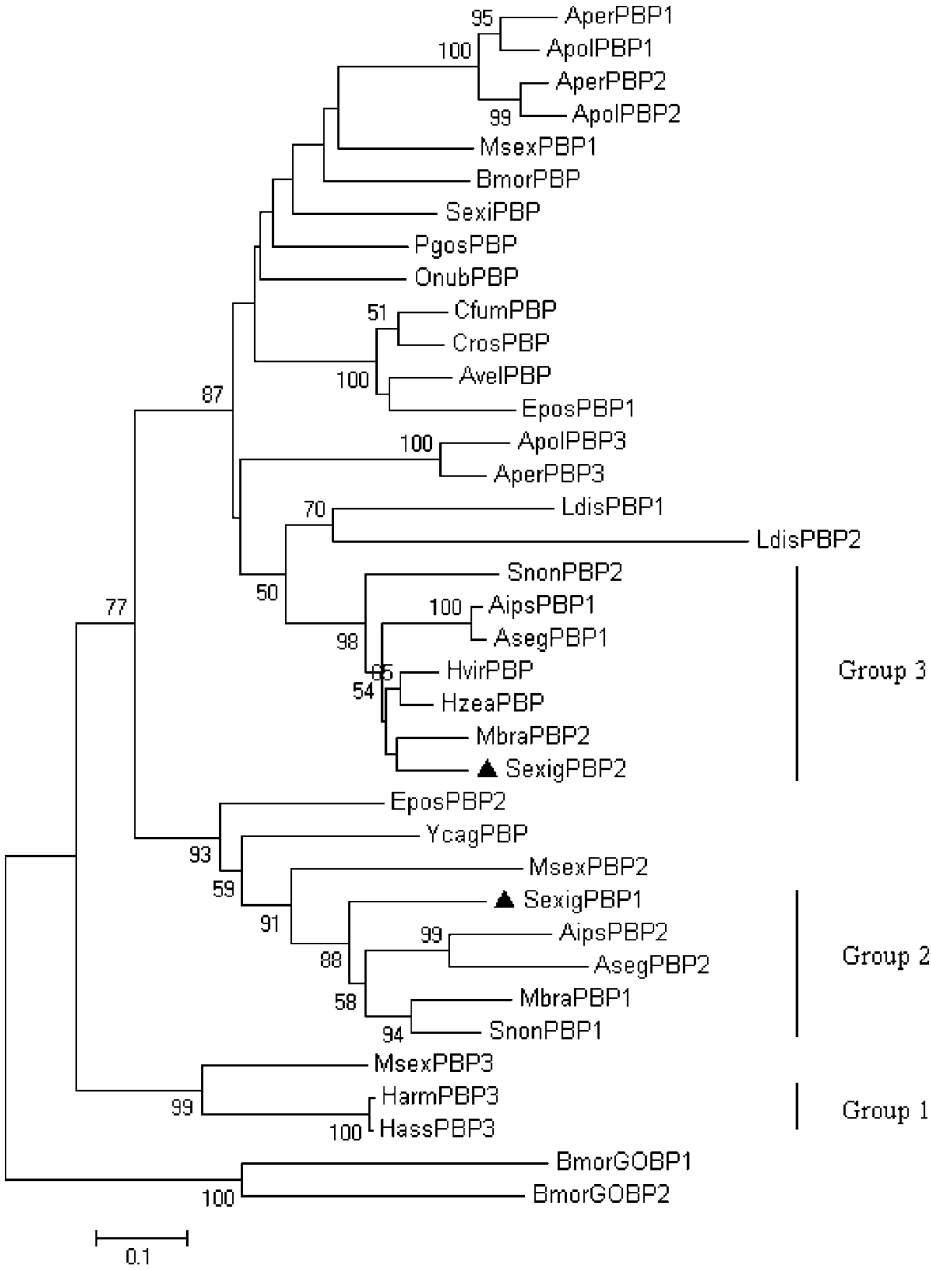

Fig. 5 Phylogenetic analysis based on SexigPBP1 and SexigPBP2 amino acid sequences. The tree was made with the neighbor-joining method using multiple alignments of amino acid sequences from Fig. 3. BmorGOBP1 and BmorGOBP2 from *Bombyx mori* are defined as the outgroup. Bootstrap analysis used 1,000 replications. Bootstrap values >50% are presented. SexigPBP1 and SexigPBP2 are marked with *arrows*. The *bar* indicates phylogenetic distance value

Comparison of PBP Gene Expression between Male and Female Antennae

Real-time PCR was performed to compare the transcript levels of *SexigPBP1* and *SexigPBP2* from antennae of male to female moths. For each sex, cDNA was synthesized from mRNA isolated from pools of 800 antennae. For sample analysis, the comparative $2^{-\Delta\Delta CT}$ method (Livak and Schmittgen 2001) was used to quantify the results obtained for *SexigPBP1* and *SexigPBP2* transcripts by real-time PCR. All samples were normalized with reference to *ACTB*. The absolute values of the slope of all lines from template dilution plots (log cDNA dilution vs. ΔC_T) were close to zero (data not shown). Therefore, the efficiencies of the target and reference genes were similar in our analysis, and the $\Delta\Delta C_T$ calculation method can be used for the relative quantification.

The transcription levels of PBP genes from antennae were higher in male moths than in females (Table 2). The amounts of *SexigPBP1* and *SexigPBP2* mRNA in female antennae were about 39 and 73%, respectively, relative to those in male antennae. It is noteworthy that the transcript level of *SexigPBP1* was much higher when compared to *SexigPBP2* transcript in both sexes. The transcription level of *SexigPBP1* was 50-fold higher than that of *SexigPBP2* in male moths, and *SexigPBP1* was 25-fold higher than *SexigPBP2* in female tissues.

Discussion

In this study, we identified two novel PBPs from antennae of *S. exigua*. The mature proteins contain 141 and 143 amino acids, respectively, and bear all the hallmarks of the PBP family including a signal peptide, a major hydrophobic domain, six conserved cysteine residues, and considerable similarities to other PBPs in amino acid sequence. The identification of the two SexigPBP genes will enable future studies of structure–function and evolutionary relationships of these genes with similar ones in related taxa.

Generally, high similarity in amino acid sequences means the same origin for the genes in question. In addition, if these genes share similar exon/intron structures in genomic DNA, they may have arisen from a shared ancestral gene by gene duplication. Both SexigPBP genes contain two introns with the same pattern reported for two *Agrotis* species, *A. segetum* and *A. ipsilon* (Picimbon and Gadenne 2002; Abraham et al. 2005). These conserved intron/extron structures and the intron positions, and the similar amino acid sequences of the PBPs (Fig. 3) suggest that the two PBP genes originated from duplication of a common PBP ancestral gene. However, the two introns differ in length within and between the PBP genes. The introns of *SexigPBP1* are much shorter than those of *SexigPBP2*, and intron1 is much shorter than intron2 in both PBP genes. It would be interesting to analyze the implication of these differences (particularly between PBP1 and PBP2) for PBP gene evolution and their functional diversification. However, more data are needed from intron/extron structures of PBPs from other insect species to facilitate such an analysis.

Real-time PCR indicated that *SexigPBP1* and *SexigPBP2* are expressed at different levels in both sexes, as is the case with other moths, such as *Bombyx mori* (L.) (Krieger et al. 1996; Maida et al. 2005), *M. brassicae* (Nagnan-Le Meillour et al. 1996), *H. zea* and *Spodoptera frugiperda* (Callahan et al. 2000), *A. ipsilon* (Picimbon and Gadenne 2002), and *Sesamia nonagrioides* (De Santis et al. 2006). The function and behavioral significance of PBPs in female moths still remains unclear. It is possible that female PBPs are involved in pheromone detection, as the autodetection of pheromonal compounds by females has been

demonstrated by electroantennography assay in *S. exigua* (our unpublished data) and in *Spodoptera littoralis* (Ljungberg et al. 1993; Ochieng et al. 1995), *Trichoplusia ni* (Seabrook et al. 1987), and *Helicoverpa armigera* (Fan et al. 2003).

Phylogenetic analysis showed that noctuid PBPs are classified into three distinct groups (Fig. 5), and SexigPBP1 and SexigPBP2 belong to two different groups, respectively. Group 1 contains HarmPBP3 and HassPBP3; group 2 includes SexigPBP1, AipsPBP2, AsegPBP2, MbraPBP1, and SnonPBP1; and group 3 contains SnonPBP2, AipsPBP1, AsegPBP1, HvirPBP, HzeaPBP, MbraPBP2, and SexigPBP2. This phylogenetic tree is somewhat different from that reported by Abraham et al. (2005), where HarmPBP3 and HassPBP3 were included in group 2 (group 1 in their nomenclature). In our analysis, however, HarmPBP3 and HassPBP3, and MsexPBP3 form a distinct group.

Our phylogenetic tree suggests that two duplication events might have occurred during noctuid PBP gene evolution. The first resulted in the divergence of group1/group 2–group 3, and the second gave rise to the divergence of group 2/group 3. Apart from the Noctuidae members, MsexPBP2 from Sphingidae, YcagPBP from Gelechiidae, and EposPBP2 from Tortricidae are closely related to group 2. Therefore, the duplication of group 2/group 3 might have occurred before the differentiation of these families. As for the duplication of group 1/group 2–group 3, it might have occurred even earlier. However, it is curious why PBPs of group 1 have been found just in three species, whereas those of groups 2 and 3 have been found in many species, especially in the Noctuidae. In our experiment with *S. exigua*, we successfully amplified the cDNAs for group 2 and 3 proteins, but using the same degenerate primers, we failed to obtain the cDNA for a hypothetical group 1 protein. We do not know the reasons for the failure to amplify the Group 1 protein cDNA for *S. exigua*. It is possible that PBP genes of group 1 may have been lost during later evolution in *S. exigua*. It is also possible that *S. exigua* possesses one or more group 1 protein PBP genes, but they remain to be cloned. A more meaningful phylogenetic tree of insect PBPs can be constructed when more PBPs become available from a larger number of species.

Abstract Tiglic, 2-methylbutyric, and ethacrylic acids are found in the pygidial gland defensive fluid of many carabid beetles. By injecting a deuterium-labeled precursor into the carabid beetle *Pterostichus* (*Hypherpes*) *californicus*, and analyzing the defensive fluid by gas chromatography/mass spectrometry, we were able to demonstrate that tiglic and ethacrylic acids are biosynthesized from isoleucine via 2-methylbutyric acid. Moreover, we observed that the injection of L-isoleucine induces an increased production of tiglic acid in *P. californicus*. A strong primary kinetic isotope effect was found to operate in the dehydrogenation step of 2-methylbutyric acid to tiglic and ethacrylic acids. Consequently, ethacrylic acid was found to preferentially accumulate the deuterium labeling from [2,3,4,4-$^{2}H_4$]isoleucine during our biosynthetic experiments.

Keywords Biosynthesis · Defensive allomones · Tiglic acid · 2-Methylbutyric acid · Ethacrylic acid · Isoleucine · Carabid beetles · *Pterostichus* (*Hypherpes*) *californicus* · Carabidae

Introduction

Carabid beetles are well known to produce a large variety of defensive allomones. Although information on the defensive chemistry of more than 500 species is now available (Will et al. 2000), little is known about the biosynthetic pathways by which these compounds are produced. Among the compounds characterized, small molecular weight carboxylic acids have been regarded as the most deterrent constituents against vertebrate or invertebrate predators. Tiglic acid is a frequently encountered allomone in the pygidial gland secretion

This paper is dedicated to Prof. Jerrold Meinwald on the occasion of his 80th birthday.

of many carabid beetles. Tiglic acid derivatives are frequently encountered as plant secondary metabolites as well (Leete and Murrill 1967; Leete 1973). The biosynthesis of some tiglic derivatives in plants has been investigated, and isoleucine (**1**) has been shown to be the precursor of the acid moiety (Leete and Murrill 1967; Leete 1973). Presumably, 2-keto-3-methylvaleric acid (**2**) and 2-methylbutyric acid (**3**) are the key intermediates in this transformation, which can lead either to tiglic (**4**) or ethacrylic acid (**5**) (Scheme 1) (Leete 1973; Leete and Murrill 1967; Basey and Woolley 1973).

In beetles, the related biosynthetic origin of methacrylic acid from valine has been investigated (Benn et al. 1973; Attygalle et al. 1991). Benn et al. (1973) speculated that ethacrylic acid (**5**) might be produced from isoleucine in the pygidial gland in a manner similar to that of tiglic acid, perhaps without the intermediacy of tiglic or angelic acids (Scheme 1). However, molecular mechanisms leading to tiglic and ethacrylic acids in insects have not been elucidated, although Adachi et al. (1985) explored the biosynthetic origin of methacrylic and tiglic acids in *Carabus yaconinus* by using universally ^{14}C-labeled amino acids. From their results, L-valine and L-isoleucine were indicated to be the precursors of methacrylic acid and tiglic acid, respectively. However, results from universally labeled precursor experiments rarely provide molecular details of biosynthetic pathways. The availability of *Pterostichus* (*Hypherpes*) *californicus*, a beetle that produces tiglic acid, a minute amount of 2-methylbutyric acid, and traces of ethacrylic acid, gave us a chance to study the biosynthetic pathways of these five-carbon acids in detail.

Scheme 1 Biosynthesis of tiglic and ethacrylic acids

Methods and Materials

Live beetles were collected in the vicinity of Concord, California and transported to laboratory facilities in Berkeley, California. Beetles were kept in an environmental chamber simulating local day length and ambient temperatures and fed commercial dog food before and after injections. Before injection, beetles were agitated to cause them to spray their defensive compounds until no more perceptible liquid was expressed and the characteristic smell of volatile acids diminished. At this point, they were assumed to be nearly exhausted of stored defensive secretions. Beetles were then injected with ~2 µl of the treatment solution through the thin cuticle of the abdominal epipleura near tergum-VII. A solution of DL-[2,3,4,4-$^2H_4$]isoleucine/DL-*allo*-[2,3,4,4-$^2H_4$]isoleucine (Cambridge Isotope Laboratories, 5 mg/100 µl in insect saline) was injected into two adults. Untreated beetles, and those injected with L-isoleucine (Aldrich Chemical Company, 5 mg/100 µl in insect saline) were used as controls. After 2 d, beetles were frozen and the defensive glands were excised according to methods described by Will et al. (2000). Sealed glass ampoules containing excised gland reservoirs were shipped to laboratory facilities in Hoboken, New Jersey, for chemical analysis.

For chemical analysis, gland reservoirs were extracted with dichloromethane (about 20 μl). Extracts were concentrated, and nearly all the sample was injected to a gas chromatograph/mass spectrometer [a Shimadzu QP5050A mass spectrometer linked to a Shimadzu 17A gas chromatograph fitted with an FFAP-coated (0.25 μm film thickness) fused silica capillary column (30 m×0.25 mm)]. The oven temperature was held at 40°C for 3 min and increased at 6°C/min to 240°C. Electron-ionization (70 eV) mass spectra were recorded from *m/z* 35 to 300.

Results and Discussion

Gas chromatography/mass spectrometry analysis of volatile components of the pygidial gland extracts of *P.* (*Hypherpes*) *californicus* showed the presence of undecane, methacrylic acid, tiglic acid, acetic acid, propanoic acid, butanoic acid, isobutyric acid, 2-methylbutyric acid, 3-methybutyric acid, crotonic acid, senecioic acid, myristic acid, palmitic acid, stearic acid, oleic acid, and linoleic acid. Sections of the reconstructed chromatograms depicting peaks for compounds relevant to this biosynthetic investigation are shown in Fig. 1. All identifications were based on comparisons of mass spectra and retention times with those of the authentic samples. Peak 5 shown in Fig. 1b was a composite that represented traces of ethacrylic acid coeluting with crotonic acid.

Both 2-methylbutyric acid and 3-methylbutyric acid are present in the defensive secretion. Although these two acids coelute under the chromatographic conditions used (Fig. 1, peak 2), their mass spectra are distinguishably different, allowing unambiguous identification even when the spectrum recorded is a composite representing both

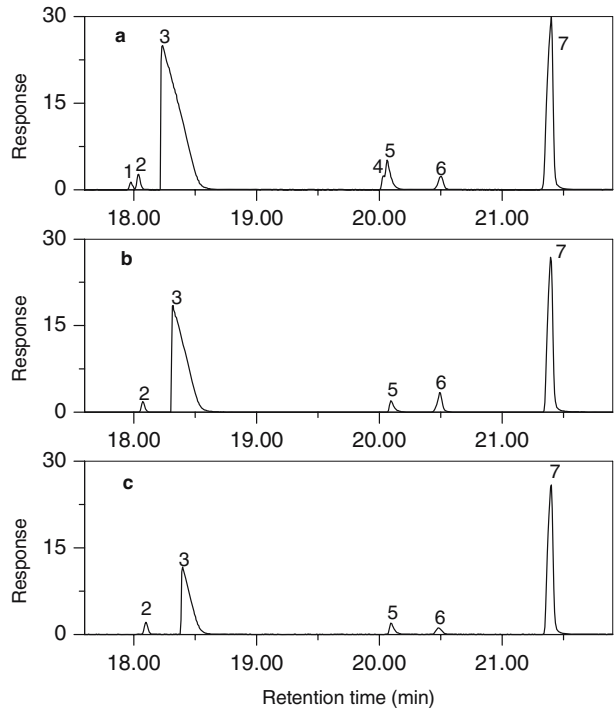

Fig. 1 Relevant sections of the reconstructed chromatograms obtained from the defensive fluid extracts of *P.* (*Hypherpes*) *californicus*: after DL-[2,3,4,4-$^2H_4$] isoleucine/DL-*allo*-[2,3,4,4-$^2H_4$] isoleucine was injected **(a)**; without injection **(b)**; and after L-isoleucine was injected **(c)**. Peak identifications: *1* 2-methyl [2,3,3-$^2H_3$]butyric acid, *2* 2-methylbutyric and 3-methylbutyric acids, *3* methacrylic acid, *4* 2-[1′,1′-$^2H_2$] ethacrylic acid, *5* crotonic acid with traces of ethacrylic acid, *6* solvent impurity with traces of senecioic acid, and *7* tiglic acid

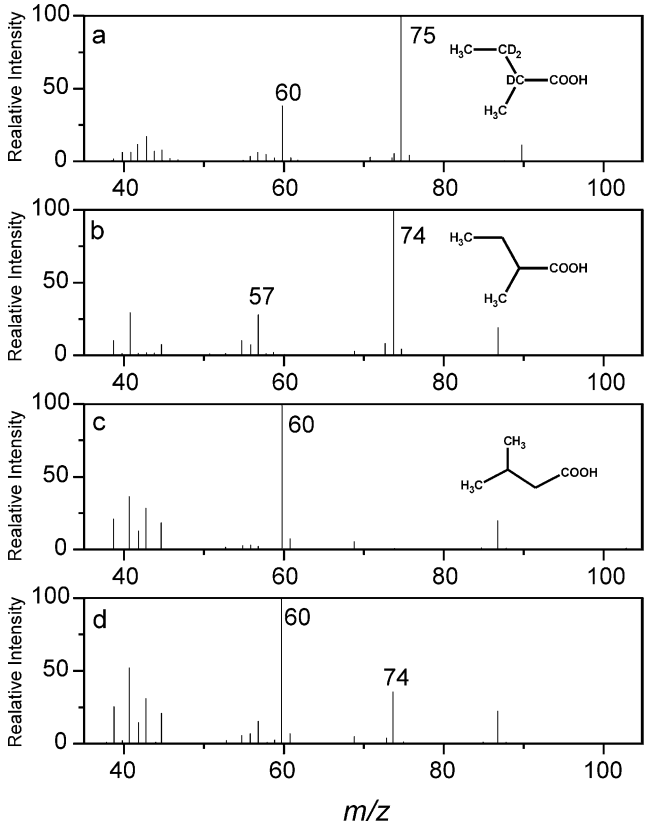
compounds. For example, the mass spectrum of authentic 2-methylbutyric acid shows a peak for the ion *m/z* 74 (McLafferty rearrangement) as the base peak, and a minute peak at *m/z* 60 (Fig. 2b). In contrast, the spectrum of 3-methylbutyric acid shows its most predominant peak at *m/z* 60, and that at *m/z* 74 is negligible (Fig. 2c). Hence, from the peak intensities of *m/z* 60 and 74 observed in the composite mass spectrum (Fig. 2d) corresponding to chromatographic peak number 2 in Fig. 1b, recorded from pygidial gland extracts of untreated *P.* (*Hypherpes*) *californicus*, it was clear that both 2-methylbutyric acid and 3-methylbutyric acid are present in the secretion. This conclusion was further supported by gas chromatography/mass spectrometry analyses of authentic mixtures of 2-methylbutyric acid and 3-methylbutyric acid.

In the chromatogram recorded from glandular extracts of labeled-isoleucine-injected beetles, an additional chromatographic peak was observed immediately before that of 2-methylbutyric acid (peak 1, Fig. 1a). The mass spectrum corresponding to this chromatographic peak showed significant peaks at *m/z* 60, 75, and 90, although a molecular ion peak was absent (Fig. 2a). A comparison of this spectrum with that of authentic 2-methylbutyric acid (Fig. 1b) indicated that the spectrum represented 2-methyl



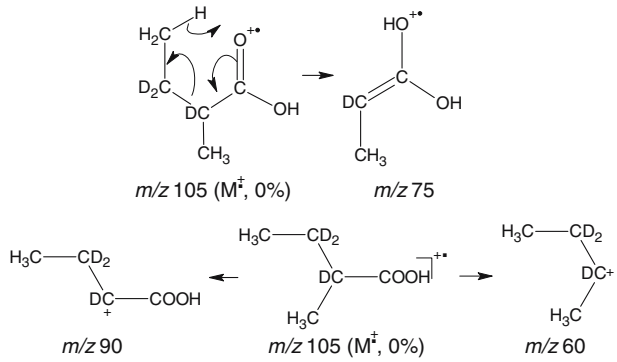


Fig. 2 Electron-ionization mass spectra corresponding to chromatographic peak 1 in Fig. 1a **(a)**, synthetic 2-methylbutyric acid **(b)**, synthetic 3-methylbutyric acid **(c)**, and that corresponding to chromatographic peak 2 of Fig. 1b **(d)**

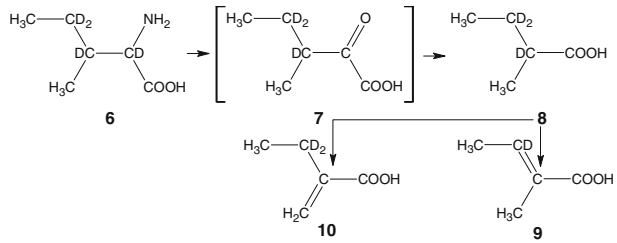
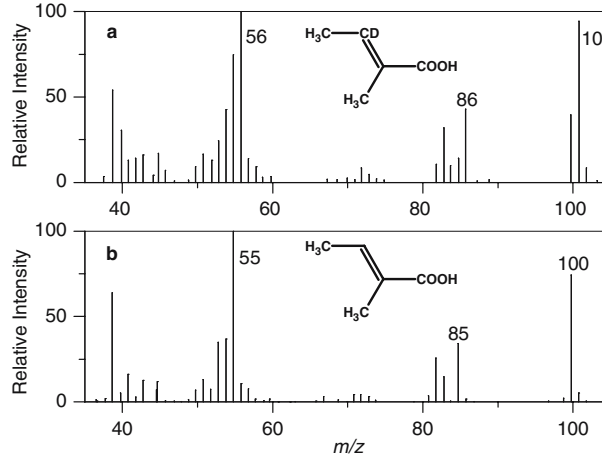


Scheme 2 Mass spectrometric fragmentation mechanisms proposed for 2-methyl [2,3,3-$^2H_3$]butyric acid

[2,3,3-$^2H_3$]butyric acid. Mass spectrometric fragmentation mechanisms, upon which this deduction was made, are illustrated in Scheme 2. A neutral molecule bearing two deuterons is lost during the McLafferty rearrangement to form the fragment ion observed at *m/z* 75. Deuteriated substances are known to elute before the nonlabeled parent compounds (Attygalle et al. 1991). Evidently, deuterium tagging from labeled-isoleucine has been incorporated specifically to 2-methylbutyric acid, and not to 3-methylbutyric acid. Hence, it was conclusive that 3-methylbutyric acid in *P.* (*Hypherpes*) *californicus* does not originate from a biosynthetic transformation of isoleucine. Evidently, [2,3,4,4-$^2H_4$]isoleucine (**6**) undergoes a deamination step, and the putative intermediate formed in this way, which is 2-keto-3-methyl[3,4,4-$^2H_3$]valeric acid (**7**), is converted by an oxidative decarboxylation step to 2-methyl[2,3,3-$^2H_3$]butyric acid (**8**) as postulated in Scheme 3.

The relative amount of tiglic acid present in glandular extracts of unlabeled L-isoleucine-injected beetles was significantly higher than that of untreated beetles (Fig. 1b, c). Apparently, the injection of L-isoleucine induces the production of tiglic acid. A careful mass chromatographic examination of acquired data corresponding to the chromatographic peak 7 in Fig. 1a, obtained from the glandular extracts of labeled-isoleucine-injected beetles, revealed that peak 7 represents both labeled and unlabeled tiglic acid. The ascending side of this chromatographic peak corresponded to a deuteriated tiglic acid bearing one deuterium atom (**9**, Scheme 3). When the background was subtracted from an average mass spectrum corresponding to the ascending side of the chromatographic peak, the resulting spectrum (Fig. 3a) unambiguously showed the labeled acid to be [3-$^2H_1$]tiglic acid (9), although the spectrum still had some contribution from the unlabeled tiglic acid (Fig. 3b). The mass spectral peaks observed at *m/z* 101, 86, and 56 indicated the presence of a deuteron in the labeled compound (Scheme 4, Fig. 3a). In all probability, a dehydrogenation step causes the biotransformation of 2-methylbutyric acid to tiglic acid.

Scheme 3 Biosynthetic transformation of [2,3,4,4-$^2H_4$]isoleucine



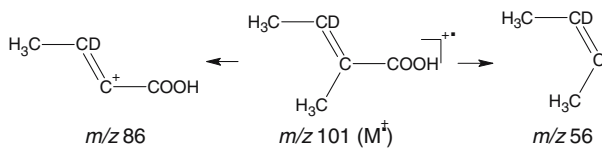


Fig. 3 Electron-ionization mass spectrum derived from the ascending side of chromatographic peak 7 of Fig. 1a (some contribution from unlabeled tiglic acid can still be observed) **(a)**, and that of synthetic tiglic acid **(b)**

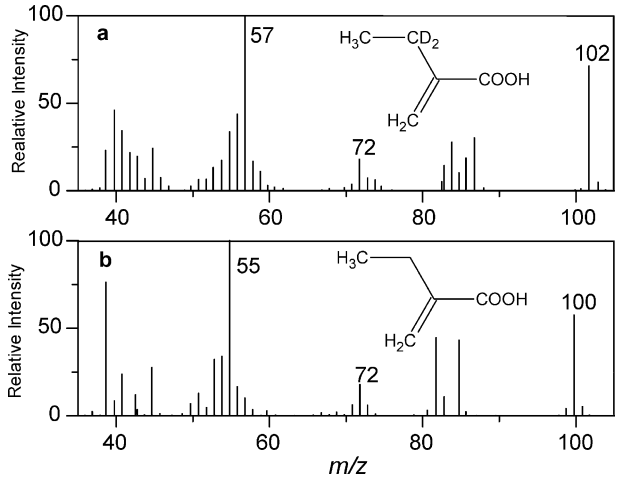
Biosynthesis of Ethacrylic Acid (=2-Ethylacrylic Acid) (5) The chromatographic peak 5 in Fig. 1b is a composite peak that represents crotonic and traces of ethacrylic acids. In some other carabids, such as *Trachypachus gibbsii*, ethacrylic acid is the major constituent in its defensive secretion (Attygalle et al. 2004). The chromatogram recorded from samples obtained from labeling experiments with *P.* (*Hypherpes*) *californicus* showed a new chromatographic peak immediately before the composite peak for crotonic and ethacrylic acids (peak 4, Fig. 1a). The mass spectrum corresponding to this peak (Fig. 4a) was unambiguously that of 2-[1′,1′-$^2H_2$]ethacrylic acid (a.k.a 2-ethyl[1′,1′-$^2H_2$]acrylic acid, **10**) (Scheme 3). The fragment ions observed at *m/z* 102 and 57 indicated the presence of two deuterons in the labeled compound (Scheme 5, Fig. 4a). In other words, 2-methylbutyric acid also serves as the precursor of ethacrylic acid.

Our results indicate that depending on the dehydrogenation mechanism, the intermediate 2-methyl[2,3,3-$^2H_3$]butyric acid can eliminate either two deuterium atoms forming [3-$^2H_1$] tiglic acid, or one deuterium atom and a hydrogen atom forming 2-[1′,1′-$^2H_2$]ethacrylic acid. If the deuteriated ethacrylic acid were generated through the intermediacy of tiglic acid, then the nominal mass of labeled ethacrylic acid should have been 101. In this way, we were able to establish that both tiglic and ethacrylic acids are formed via 2-methylbutyric acid according to mechanisms suggested by Benn et al. (1973) over three decades ago (Scheme 1).

Relative Ratios of Labeled to Unlabeled Compounds An interesting observation was made when the intensity ratios of labeled to unlabeled compounds were estimated by integrating appropriate ion chromatograms. A comparison of chromatographic peak intensities of *m/z* 74 (for unlabeled 2-methylbutyric acid) and 75 (for labeled 2-methylbutyric acid), after relevant compensations were made for the natural isotopic abundances, revealed that about

Scheme 4 Rationalization of mass spectral peaks observed at *m/z* 101, 86, and 56 in the mass spectrum of [3-$^2H_1$]tiglic acid



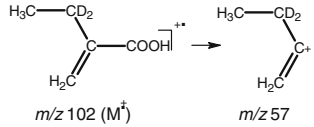


Fig. 4 Electron-ionization mass spectrum corresponding to chromatographic peak 4 of Fig. 1a **(a)**, and that of synthetic ethacrylic acid **(b)**

40% of the 2-methylbutyric acid had acquired the deuterium labeling under our experimental conditions. Similarly, the ion intensities of *m/z* 100 and 101 for unlabeled and labeled tiglic acid, respectively, showed a deuteriation of about 8%. Moreover, the relative amount of the labeled ethacrylic acid (*m/z* 102) was about seven times higher than that of the nonlabeled acid (*m/z* 100) [peaks 4 and 5, Fig. 1a (the major constituent in peak 5 is crotonic acid)]. Similar results were obtained from both beetles used in the labeling experiment. If 2-methybutyric, tiglic acid, and ethacrylic acid all came from the same isoleucine pool, how can these observations be rationalized? We suggest that a strong primary kinetic isotope effect operates in the dehydrogenation of 2-methylbutyric acid to tiglic and ethacrylic acids. For the formation of 2-[1′,1′-$^2H_2$]ethacrylic acid, an elimination of only one deuterium atom from 2-methyl[2,3,3-$^2H_3$]butyric acid is required. The production of [3-$^2H_1$]tiglic acid requires the removal of two deuterium atoms. As a consequence, the relative deuterium enrichment in the ethacrylic acid fraction compared to that in the tiglic acid fraction could be anticipated if 2-methylbutyric acid is the common precursor of these two unsaturated carboxylic acids. However, the unusually large incorporation of the deuterium label on ethacrylic acid cannot be rationalized entirely as a consequence of a kinetic isotope effect. Most likely, two different desaturases are involved in the dehydrogenation. At least to a certain extent, the preferential accumulation of the deuterium label on ethacrylic acid may be because of different enzyme activities and concentrations. No information is currently available on the nature of the desaturase enzymes.

Scheme 5 Formation of *m/z* 57 ion from 2-[1′,1′-$^2H_2$]ethacrylic acid

Abstract Wax constituents produced by worker bees and the chemistry of the nest batumen (mixture of wax, mud, and floral materials) in a *Melipona scutellaris* colony changed when it was invaded by *Melipona rufiventris* workers. Gas chromatography/mass spectrometry analyses showed that after invasion, the *M. scutellaris* workers of the invaded colony produced waxes with higher relative abundance of triacontanyl acetate and decreased the amounts of *n*-alkanes and *n*-9-alkenes. On the other hand, waxes from *M. rufiventris* workers displayed few changes. The change in the composition of the *M. scutellaris* waxes chemically differentiates that species from the *M. rufiventris* invader workers. Comparative analyses of batumens samples from pure and invaded colonies revealed greater amounts of terpenes and phenolic derivatives in the batumen from the invaded colony. This is the first report on the chemical characterization of batumens from stingless bees.

Keywords Meliponinae · *Melipona rufiventris* · *Melipona scutellaris* · Wax · Batumen · Triacontanyl acetate · Alkenes · Alkanes · Apidae

Introduction

Bees are among the world's most important pollinating agents. Their value in terms of the production of honey, wax, propolis, and other products used by humans is trivial when

compared to their central role in pollination (Michener 2000). Stingless bees are responsible for pollinating 40 to 90% of the native flora in tropical regions where they occur, including Brazil, and play a fundamental role in perpetuating ecosystems (Nascimento et al. 2000). The destruction of forests and savannas has threatened the survival of a large number of bee species; thus, preservation of wild bee species is of paramount importance to biodiversity conservation and one of the reasons for the present study.

Among the corbiculate Apidae (Euglossinae, Bombinae, Meliponinae, and the Apinae), only two major groups of highly social bees are found: the stingless honeybees of the tropics and the true honeybees, the Meliponinae and the Apinae, respectively (Winston and Michener 1977). The social organization of the Meliponinae requires complex social interactions inside their nests, as well as in the surrounding environment. Nest construction is of major importance in the integration of the colony, and both the provisions and brood contained in the nest have profound influences on the behavior and caste determination of the bees (Roubik 1989). To construct their nests, the Meliponinae use cerumen, which is a mixture of wax and floral resins (propolis) gathered in large amounts by the forager bees. Cerumen is utilized in different ratios in storage pots, brood cells, entrance openings and tubes, pillars, involucrum layers, and in royal cameras to imprison gynes. The nests of stingless bees are surrounded and protected by a structure called batumen, a wall-like plate made up of a brittle cerumen produced by mixing wax with floral oils and floral resins (propolis), to which is added mud, sometimes even pieces of flowers, and leaves (Roubik 1989; Nogueira-Neto 1997). When excessive mud is added, the mixture is called "geopropolis" (Nogueira-Neto 1997), and this is employed in the peculiar design of the nest entrance and in the batumen of many *Melipona* species, including *Melipona scutellaris* and *Melipona rufiventris*. Pure propolis, pure wax, and cerumen are stored in the nest and used in construction and defense (Roubik 1989).

The ability to recognize nestmates and distinguish them from individuals of other colonies is a key property of social insects (Obin 1986; Gamboa et al. 1991; Billen 2006). After brief antennation, social wasps, bees, and ants typically show an immediate discriminative response toward nestmates compared to others that are not members of the colony. The profiles of cuticular substances, particularly hydrocarbons, are often species- and colony-specific, and the quality of interactions among individuals is correlated with similarities or differences in the hydrocarbon profiles, indicating that cuticular hydrocarbons play a role in nestmate recognition and even reproduction (Bonavita-Cougourdan et al. 1987; Morel and Blum 1988; Nowbahari et al. 1990; Singer 1998; Simmons et al. 2003; Beekman 2004).

Perception of Apidae to substances such as floral odors, bee pheromones, and chemicals is sensitive. Thus, bee behavioral responses can be determined by inter- and intraspecific olfactory stimuli, and a good example is provided by the cleptobiotic bee *Lestrimellita limao*, which uses citral to disrupt the organization inside the *M. rufiventris* colony (Pompeu and Silveira 2005). In *Melipona*, as in other Apidae, wax, mandibular, and Dufour glandular secretions are responsible for intraspecific chemical communication. Glandular secretions determine caste and sexual hierarchy, following a rather specific pattern in each species (Cruz-López et al. 2001, 2002; Patricio et al. 2003).

The temporary host–parasitic interaction between *M. rufiventris* and *M. scutellaris* (Apidae: Meliponinae) is an uncommon phenomenon, where *M. rufiventris* workers invade a *M. scutellaris* colony. Roubik was the first to observe this (Nogueira-Neto 1997) and hypothesized that the invasion can be understood by nest guarding, which is based on the perception of the characteristic scent of each species. At the nest entrance, bees assess the scents of other bees, and a guard bee will not let an individual pass if it lacks the correct smell. This hypothesis, however, has not been proven.

To address whether bees alter their chemistry (waxes) and colony environment (nests) upon the presence of an invader species, two aspects of a *M. scutellaris* colony invaded by *M. rufiventris* workers were studied: (1) the chemical compositions of abdominal waxes of bee workers, and (2) the chemical constituents of the nest batumen, which is composed of bee waxes and external material collected by worker bees, thus reflecting the global activity of the colony. Wax and batumen samples were gathered from pure colonies of each species, and the chemistry was compared to samples collected from a *M. scutellaris* colony invaded by *M. rufiventris* workers.

Methods and Materials

Biological Material Abdominal waxes from worker bees of *M. rufiventris* and *M. scutellaris* and nest batumens were collected at Aretuzina farm in São Simão, São Paulo, Brazil, where colonies of both species have been established for many years. Waxes were collected from worker bees living in three different colonies: colony 1, a pure colony of *M. scutellaris* (N=4), colony 2, a pure colony of *M. rufiventris* (N=4), and colony 3, a *M. scutellaris* colony invaded by *M. rufiventris* (N=4 for each species).

Batumen samples (N=2) were collected from each of the three colonies above.

Reagents *n*-Alkane standards (C_{10}–C_{37}) were obtained from petroleum (100 ml), by silica gel column chromatography using bidistilled hexane as solvent. The distilled and bidistilled solvents (Synth, São Paulo, Brazil) were obtained according to the method described by Perrin et al. (1980). Iodine (Rothyl, New York, USA), dimethyl disulfide (DMDS) (Aldrich, Steinheim, Germany), magnesium sulfate (Nuclear, Brazil), and sodium thiosulfate (Merck, Rio de Janeiro, Brazil) were used.

Wax Sample Preparations Abdomens of *M. rufiventris* (N=4) and *M. scutellaris* (N=4) workers were washed with bidistilled hexane (2 ml). The solvent was evaporated under a nitrogen stream to produce around 0.4 mg of crude extract in the form of a white wax. The wax samples were dissolved in 0.5 ml of ethyl acetate, and analyzed by gas chromatography/mass spectrometry (GC-MS) by injecting 1 μl quantities (Table 1).

Batumen Chromatographic Fractionation Equal amounts of batumens samples (805 mg) from pure colonies and the invaded colony were collected, and their constituents were separated by silica gel 60 (0.035–0.070 mm, Merck, Dannstadt, Germany, 20 g) column chromatography (h=23 cm, id=2.5 cm), eluted with solvents of increasing polarity (500 ml to each fraction) (Table 2). Solvent evaporation furnished five fractions for each batumen: A (hexane), B (hexane/dichloromethane 1:1), C (dichloromethane), D (dichloromethane/ethyl acetate 1:1), and E (ethyl acetate). Each fraction was analyzed by GC-MS by injecting 1 μl (2 mg in 0.5 ml of ethyl acetate) (Table 3). Polar compounds and dirt from batumens remained on the top of the silica column and were not analyzed.

GC-MS Analyses Analyses were carried out by using an HP 6890/5973 system equipped with an HP5 fused silica capillary column (30 m×0.25 mm×0.25 μm). Helium was used as carrier gas at a flow rate of 1 ml/min, splitless mode. The MS were taken at 70 eV, and the scanning speed was 2.89 scans/sec from *m/z* 40 to 550. The interface temperature was maintained at 280°C. Injector temperature was 240°C for the extracts of worker bees and 250°C

t_R Retention times, *RI (calc.)* calculated retention indexes, *RI (lit.)* retention indexes taken from literature (Adams 1995), – not found

[a] Relative abundance (%)

[b] The double bond position was not determined for this alkenes.

fraction D, from 50 to 290°C at 12°C/min with a final hold time of 22 min; and for derivatized samples, from 50 to 290°C at 12°C/min with a final hold time of 50 min.

Retention Indexes Wax samples and fractions of the batumen were coinjected with a hydrocarbon mixture. Retention indexes (RI) were calculated according to the Van den Dool and Kratz equation (Van den Dool and Kratz 1963) and compared with the literature (Adams 1995). Retention indexes for the *n*-alkane standards (C_{10}–C_{37}) were taken as whole numbers from 1,000 to 3,700.

The *Z* and *E* alkenes (C_{25}–C_{31}) were identified by applying the equivalent chain length (ECL), which is 100 times smaller than the retention indexes (ECL=RI/100) (Ashes et al. 1980), and by comparison with literature values (Howard and Baker 2003).

Derivatizations The position of the double bonds in alkenes present in waxes and batumens samples was determined by derivatization with DMDS. The samples (~1 mg) were dissolved in bidistilled hexane (2 ml) and treated with DMDS (200 µl) and 100 µl of iodine solution (32 mg of I_2 in 2 ml of distilled diethyl ether). Reaction mixtures were stirred overnight at 50°C, and quenched with 2 ml of aqueous sodium thiosulfate solution (1 g of $Na_2S_2O_3$ in 10 ml of distilled water). The organic phase was extracted, dried over anhydrous magnesium sulfate, and evaporated to dryness under a nitrogen stream (Buser et al. 1983; Vincenti et al. 1987). The derivatized samples were dissolved in bidistilled hexane and analyzed by GC-MS.

Identification of Chemical Compounds Compounds in wax and batumen were identified by comparing their mass spectra with those in the equipment library (Wiley, 275). Pure substances were further analyzed by NMR.

NMR Analyses The ^{1}H NMR spectrum was recorded with a Varian 300 MHz spectrometer, using $CDCl_3$ as solvent and TMS as internal standard. The residual solvent ($CDCl_3$) signal at δ 77.00 was used as internal reference in ^{13}C NMR analyses at 75.5 MHz. Methyl, methylene, and quaternary carbons were discriminated by using distortionless enhancement by polarization transfer (DEPT) 135° and 90°.

Results

Pure Colonies Gas chromatography/mass spectrometry analyses of abdominal waxes from *M. scutellaris* (Fig. 1a, b) and *M. rufiventris* workers (Fig. 2a, b) living in pure and invaded

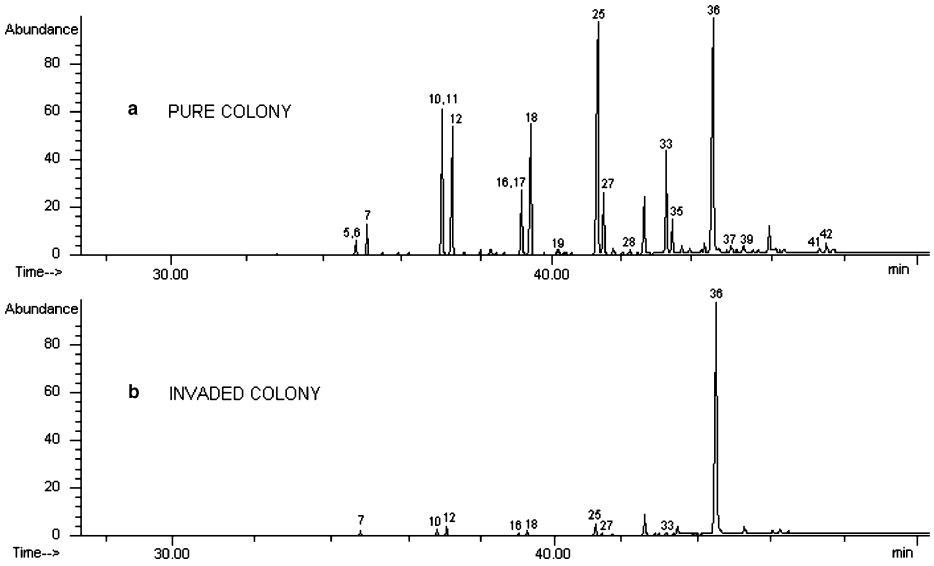

Fig. 1 Total ion current chromatograms of *M. scutellaris* workers' abdominal waxes: **a** pure colony and **b** invaded colony

colonies revealed several substances (Table 1). Wax from *M. scutellaris* workers living in a pure colony was mainly composed of *n*-alkanes (24.99%), *n*-9-alkenes (41.94%), and triacontanyl acetate (21.54%) (Fig. 1a, Table 1). Wax from *M. rufiventris* workers living in a pure colony was mainly composed of *n*-alkanes (49.72%), *n*-9-alkenes (35.45%), and alkadienes (6.86%) (Fig. 2a, Table 1).

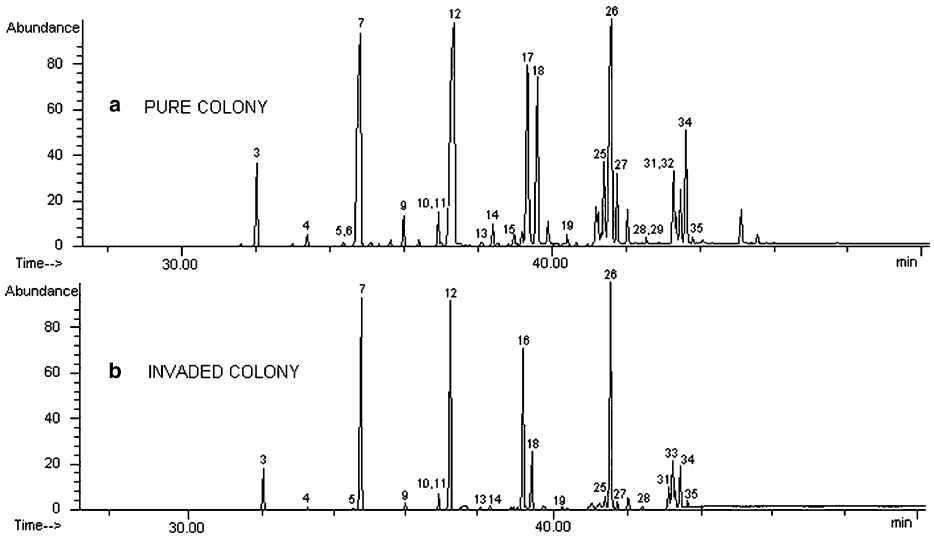

Fig. 2 Total ion current chromatograms of *M. rufiventris* workers' abdominal waxes: **a** pure colony and **b** invaded colony

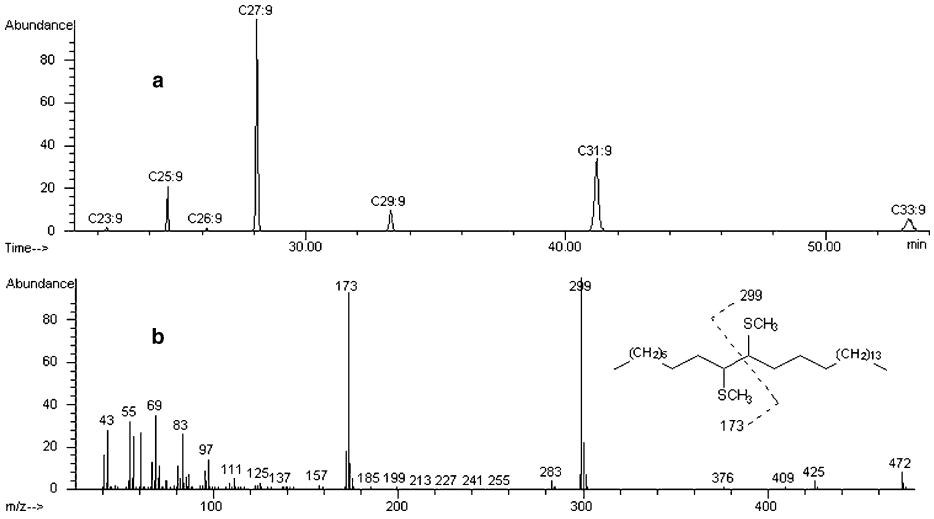

Fig. 3 **a** Ion extraction chromatogram (*m/z* 173) of DMDS derivatives of *n*-9-alkenes from invaded colony batumen and **b** mass spectrum of DMDS derivative of (*Z*)-9-heptacosene

Triacontanyl Acetate This compound is characteristic of *M. scutellaris* wax and it is not found in *M. rufiventris*. Electron impact mass spectrometry (70 eV), *m/z* (%): 480 ($M^{+\cdot}$, 3%), 420 (8%), 392 (7%), 264 (4%), 125 (35%), 111 (58%), 97 (95%), 83 (97%), and 57 (100%). ^{1}H NMR (300.07 MHz, $CDCl_3$): δ 0.90–1.82 ppm (*m*, 59 H), 2.08 (*s*, 3H. characteristic of methyl belonging to an acetyl group), and 4.06 (*t*, 2H, *J*=8 Hz, hydrogens of a methylene linked to oxygen). ^{13}C NMR (DEPT 135° and 90°, 75.5 MHz, $CDCl_3$): δ 14.2 ppm (CH_3), 21.5 (CH_3), 22.0–34.0 (CH_2), and 65.0 (CH_2 linked to an oxygen).

Invaded Colony The wax composition of *M. rufiventris* invader workers [*n*-alkanes (41.18%), *n*-9-alkenes (38.41%), and alkadienes (7.99%)] barely differed from that in the pure colony, with the total alkane/alkene/alkadiene ratio being maintained (Fig. 2a, b, Table 1). However, the relative abundances of some specific hydrocarbons increased after invasion.

In the wax of *M. scutellaris*, the relative abundances of *n*-alkanes and *n*-9-alkenes were substantially affected by the *M. rufiventris* invasion (Table 1). Compared to the pure colony of *M. scutellaris*, there was a decrease in the relative abundances of *n*-alkanes (3.24%) and *n*-9-alkenes (4.20%), and an increase in triacontanyl acetate (82.27%).

The position of the double bond in *n*-alkenes from wax and batumen samples was determined at C-9, by derivatization with DMDS. Their characteristic fragment ion was the *m/z* 173 $[CH_3(CH_2)_7CH{=}SCH_3]^+$ (Fig. 3a, b, Tables 1 and 3) (Buser et al. 1983; Vincenti et al. 1987). The *n*-9-alkenes (C_{25}–C_{31}) present in both batumens and waxes were identified as *Z* isomers by comparing the values of the ECL (ECL=RI/100) with those published in the literature (Howard and Baker 2003).

Nest Batumens Batumens of both pure colonies and the invaded colony had complex mixtures that were separated by silica column chromatography into fractions (A–E) of increasing polarities (from hexane to ethyl acetate) (Table 2). The components of each fraction, as identified by GC-MS, are shown in Table 3.

Fractions A of the batumen samples from pure colonies have similar size and composition (Tables 2 and 3). The main constituents are *n*-alkanes and *n*-alkenes ranging

from C_{14} to C_{30}. However, fraction A from the invaded colony is 30% larger than that of fraction A from pure colonies (Table 2), and is composed of 13.4% nonoxygenated sesquiterpenes, which are almost absent in fraction A from pure colonies (Table 3).

Fractions B, C, D, and E from pure colonies have similar weights (Table 2), whereas in the invaded colony they weigh 2–30 times more.

The *n*-alkanes ranging from C_{14} to C_{29} in fraction B are present only in this fraction from pure colonies (Table 3). In contrast, triterpenes and triacontanyl acetate are present in fraction B from the invaded colony and the pure colony of *M. scutellaris*. The major triterpene was identified as cycloart-24-en-3β-ol; the identity was established by mass spectral comparison and coinjection in the GC-MS with a standard previously isolated from *Maxillaria friedrichsthalii* (Orchidaceae) floral waxes (Flach 2005).

In the pure colonies of *M. scutellaris* and *M. rufiventris*, fraction C is composed of *n*-alkanes ranging from C_{13} to C_{29}, whereas the fraction C from the invaded colony has no *n*-alkane, and its major constituent (80%) is an unknown triterpene that is not present in the pure colonies (Table 3).

Fraction D from the invaded colony contains resorcinol derivatives, but these are not found in pure colonies.

Fraction E shows many unidentified compounds in the pure colony of *M. scutellaris* (Table 3), but in the pure colony of *M. rufiventris* it has long chain fatty acids, and in the invaded colony mainly phenol derivatives.

Discussion

Our data show that the abdominal waxes of both bee species are chemically similar, especially regarding *n*-alkanes and *n*-alkenes. These were possibly responsible for the "pacific" invasion of *M. scutellaris* nest by *M. rufiventris* workers where the invaders lured the *M. scutellaris* nest guard bees. Our chemical findings corroborate the Roubik's hypothesis that scent similarities between the species could be responsible for this invasion (Roubik 1989). However, some differences in wax composition were also evident, as demonstrated by triacontanyl acetate, which is characteristic of *M. scutellaris* wax and was not present in *M. rufiventris* wax (Table 1). Alkadienes are characteristic of *M. rufiventris* wax and were not detected in the wax of *M. scutellaris*.

As chemistry plays an important role in bee behavior, one could predict that nest sharing between *M. rufiventris* and *M. scutellaris* might produce a chemical response. Indeed, the wax composition of *M. scutellaris* workers from the invaded colony showed an increase in the relative abundances of triacontanyl acetate and a decrease of *n*-alkanes and *n*-9-alkenes when sharing the colony with *M. rufiventris* invader workers (Table 1). On the other hand, chemical changes in *M. rufiventris* wax composition were small. Workers from both pure and invaded colonies displayed almost the same amounts of *n*-alkanes, *n*-9-alkenes, and alkadienes. A chemical response of *M. rufiventris* workers to nest invasion, however, is demonstrated by subtle changes in the relative abundance of each alkane, alkene, and alkadiene. The chemical changes in both bee species in the invaded colony are likely connected to the fact that each species needs to distinguish each other to maintain identity. Such chemical alterations confirm that the invasion is not as "friendly" as first assumed by us, and that *M. scutellaris*, the invaded species, responds more dramatically to the invasion.

In this context, Meliponinae nest construction and habits must be understood. Stingless bees prefer cavities in trees for nest construction; nests are found often in small cavities

(Nogueira-Neto 1997). The bees do not enlarge the cavities, they just use them as they are. In the present case, the colonies were established in manmade wooden boxes, and *M. rufiventris* and *M. scutellaris* constructed their nests with batumen, the mixture of wax, mud, and floral materials, that is used to line the nest, leaving a single hole leading into the nest cavity (Roubik 1989; Nogueira-Neto 1997). The batumens of pure colonies of *M. rufiventris* and *M. scutellaris* are composed of similar amounts of secondary metabolites, as demonstrated by the weight similarity of the batumen fractions A–D (Table 2). However, the change observed when *M. scutellaris* is invaded by *M. rufiventris* is significant, as assessed by the 2–30 fold increase in the weights of fractions B–E in the invaded colony. These changes reflect a higher foraging activity in the invaded colony in comparison with the pure ones.

In addition, the chemical composition of the batumen fractions D–E in the invaded colony has substantial amounts of phenolic derivatives not found in batumens from pure colonies (Table 3). Phenol and resorcinol derivatives could be derived from Anacardiaceae plant species (Aguilar-Ortigoza et al. 2003), widely spread around the Aretuzina farm where the nests are located. *Melipona scutellaris* workers probably collect substances from these plants and deposit them in the nest. This may be evidence of a chemical war in which *M. scutellaris* is stimulated to work more intensively in the nest than *M. rufiventris*. First, there is an increased foraging activity in the invaded colony as revealed by the substantial increase in weight of fraction B of the batumen relative to pure colonies (this quantitative change was not accompanied by a qualitative change in the triterpenoid constituents, which remained approximately the same) (Table 3). Second, fraction E indicates that *M. rufiventris* contributes minimally to the batumen of the invaded nest; in the pure colony of *M. rufiventris*, this fraction contains some long-chain fatty acids that are not found in batumens of either pure or invaded colonies of *M. scutellaris*.

In summary, we found that *M. scutellaris* and *M. rufiventris* are chemically distinguished by their wax composition. *Melipona scutellaris* workers are characterized by having triacontanyl acetate as a specific marker in their abdominal waxes, which they deposit in batumen, whereas *M. rufiventris* workers produce a wax characterized by alkadienes. When *M. rufiventris* workers invade a colony of *M. scutellaris*, physiological changes occur in both species, but the most prominent chemical changes are found in the abdominal waxes of *M. scutellaris*. The data support the idea that the invasion is not pacific, but rather that *M. scutellaris* workers are induced to deposit different substances in the batumen, possibly thus deterring the *M. rufiventris* invader workers.

Acknowledgments We thank Fundação de Amparo a Pesquisa do Estado de São Paulo for grants, which made the present contribution possible (Adriana Flach, Proc. no. 02/07029-0, and Adriana Pianaro, Proc. no. 03/09358-3). We also acknowledge Prof. Carol H. Collins (IQ/UNICAMP) for critically revising the manuscript.

A 4-Alkyl-substituted Analogue Of Guaiacol Shows Greater Repellency To Savannah Tsetse (*Glossina* spp.)

Rajindar K. Saini · Ahmed Hassanali

Received: 16 August 2006 / Revised: 27 November 2006 / Accepted: 10 December 2006 /
Published online: 3 April 2007
© Springer Science + Business Media, LLC 2007

Abstract The responses of *Glossina morsitans morsitans* Westwood to guaiacol (2-methoxyphenol), a mild repellent constituent of bovid odors, and seven analogues comprising 2-methoxyfuran, 2,4-dimethylphenol, 2-methoxy-4-methylphenol (4-methylguaiacol), 4-ethyl-2-methoxyphenol (4-ethylguaiacol), 4-allyl-2-methoxyphenol (4-allylguaiacol; eugenol), 3,4-methylenedioxytoluene, and 3,4-dimethoxystyrene were compared in a two-choice wind tunnel. The 4-methyl-substituted derivative (2-methoxy-4-methylphenol) was found to elicit stronger repellent responses from the flies compared with guaiacol. None of the other analogues showed significant repellent effects on flies. 4-Methylguaiacol, guaiacol, and eugenol (which was included because of previous reports of its repellency against a number of arthropods) were further evaluated in the field with wild populations of predominantly *Glossina pallidipes* Austen. The presence of guaiacol or eugenol near odor-baited traps caused some nonsignificant reduction in the number of tsetse catches at relatively high release rates (~50 mg/hr). In contrast, the 4-methyl derivative at three different release rates (2.2, 4.5, and 9.0 mg/hr) reduced trap catches of baited traps in a dose-response manner. At 10 mg/hr release rate, it reduced the catches of baited and unbaited traps by ~80 and ~70%, respectively. In addition, the compound not only reduced the number of tsetse attracted to natural ox odor (~ 80%), but also had an effect on their feeding responses, reducing the proportion that fed on an ox by more than 80%. Our study shows that the presence of a methyl substituent at the 4-position of guaiacol enhances the repellency of the molecule to savannah tsetse and suggests that 4-methylguaiacol may represent a promising additional tool in the arsenal of techniques in trypanosomiasis control.

Introduction

Tsetse-transmitted trypanosomiasis continues to cause morbidity and death in human populations and livestock throughout sub-Saharan Africa. Current intervention options

R. K. Saini (✉) · A. Hassanali
International Centre of Insect Physiology and Ecology, P.O. Box 30772, Nairobi, Kenya
e-mail: rsaini@icipe.org

include parasite control through the use of trypanocidal drugs (Jordan 1986; Holmes, 1997); the promotion of trypanotolerant livestock (FAO 1987a, b; d'Lteren et al. 1999); vector control through the use of visual and odorant baits such as traps (Hassanali et al. 1986; Brightwell et al. 1987, 1991), insecticide-treated targets (Vale et al.1988a), and insecticide-treated animals (Bauer et al. 1995; Hargrove et al. 2000); and sterile insect technique (SIT) (Vreysen et al. 2000).

The potential of repellents to protect cattle and thereby reduce cases of trypanosomiasis has been recognized since the 1970s. Earlier work by Vale (1974a) showed that constituents in human odor reduced the number of tsetse attracted to a host and the number that subsequently fed. The effect was greater on females than on males, and *Glossina pallidipes* was more strongly affected than *Glossina morsitans.* During the process of screening for tsetse attractants, a number of compounds were discovered that had varying levels of repellency against the two savannah tsetse species. These included two synthetic compounds, acetophenone and caproic acid, and two naturally occurring constituents of cattle and human odor, respectively, guaiacol (2-methoxyphenol) and lactic acid (Vale 1977a, 1980; Vale et al. 1988b). Commercially available insect repellents such as N,N-diethyl-meta-toluamide (DEET) and naphthalene were ineffective (Vale 1977a; Torr et al. 1996). Torr et al. (1996) evaluated the effects of controlled release of acetophenone, 2-methoxyphenol, and a series of fatty acids on attractants-baited trap catches of *G. pallidipes* in Zimbabwe. 2-Methoxyphenol reduced the catch by 85%, whereas acetophenone, pentanoic acid, or hexanoic acid halved the respective catches. Further studies on targets baited with a synthetic attractant blend, a source of natural ox odor, and an ox placed at the center of rings of electrified nets showed that whereas 2-methoxyphenol reduced the numbers of tsetse attracted to the attractant sources by ~50% and ~40%, respectively, only pentanoic acid had a small but significant effect on the feeding responses of the flies that arrived closer to the ox. These findings led these authors to conclude that the repellents could not provide any useful degree of protection against trypanosomiasis.

We have explored two approaches to discovering more potent tsetse repellents: (1) by detailed analyses of odors and assays of different blends of candidate semiochemicals of wild animals that are refractory to tsetse (Gikonyo et al. 2000, 2002, 2003); and (2) through structure-activity studies of known natural repellents in the laboratory followed by field evaluations of promising analogues. Herein, we report our discovery of a synthetic analogue of guaiacol (2-methoxyphenol), which has demonstrated greater repellency than the parent compound.

Methods and Materials

Laboratory Bioassays

Wind Tunnel Bioassays Tests were conducted in a two-choice cylindrical plexi-glass tunnel (180 cm long, 24 cm diam) described in detail by Gikonyo et al. (2003). The middle of the tunnel was connected to a PVC pipe in the terminal end of which an air-extracting fan was mounted. The duct in the middle divided the tunnel into two equal arms with a 20-cm wide middle zone where air from both arms mixed. When the fan was switched on, air flowed into the tunnel from both arms, thereby making the middle of the tunnel downwind. The upwind ends of the tunnel were closed with PVC gauze and the down end with a metallic mesh cover. The upwind ends were connected to air filters containing activated charcoal (4-14 mesh, Sigma Chemical Co.) The wind tunnel had three windows, one on each arm (15×10 cm) for

introducing the test odors and one in the middle (4.7 cm diameter) for introducing an insect release cage. Light from fluorescent tubes and bulbs controlled with a dimmer switch was diffused through frosted glass sheeting placed 35 cm above the tunnel, giving about 1,000 lx incident light. A white sheet of paper marked with black stripes about 2 cm apart was placed beneath the tunnel floor to provide contact to a fly during anemotaxis. The wind speed inside the tunnel was maintained at 10 cm/sec. The bioassay room was maintained at 25±2°C and 70± 5% relative humidity (RH).

Test Compounds Guaiacol (2-methoxyphenol) and seven analogues comprising 2-methoxyfuran, 2,4-dimethylphenol, 2-methoxy-4-methylphenol (4-methylguaiacol), 4-ethyl-2-methoxyphenol (4-ethylguaiacol), 4-allyl-2-methoxylphenol (4-allyllguaiacol; eugenol), 3,4-methylenedioxytoluene, and 3,4-dimethoxystyrene (Fig. 1) (each 98–99% pure, obtained from Sigma-Aldrich, Taufkirchen, Germany) were each tested against a control (blank). Eugenol was specifically included in the tests because of previous reports of its repellency against some arthropods (Chogo and Crank 1981; Hassanali et al. 1990; Mwangi

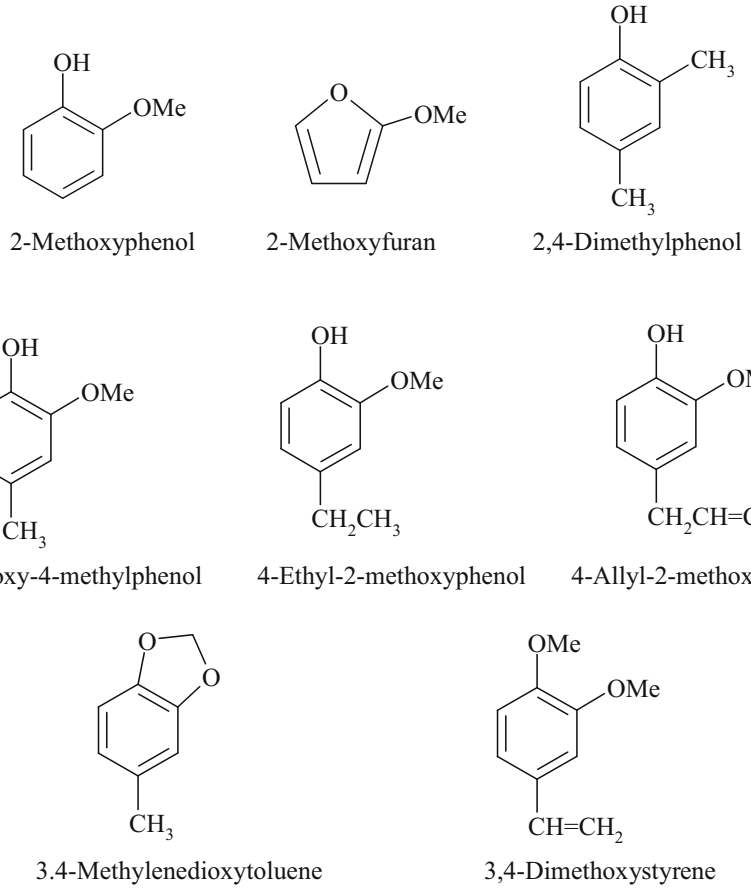

Fig. 1 Structures of 2-methoxyphenol (guaiacol) and analogues screened in the wind tunnel for repellency against *G. m. morsitans*

et al. 1995). A blank test comprising of two blank odor dispensers placed at both upwind ends was also undertaken.

Odor Dispensers The odor dispenser consisted of a black cloth that was secured with Soxhlet-cleaned (dichloromethane) rubber bands placed on one end of an open-ended plexiglass tube (5 cm long and 4.5 cm diam). The dispensers were each placed via the window on the upper side of either arm of the tunnel onto a metallic rack positioned 15 cm from the upwind end such that they were at midheight with the cloth facing downwind. The appropriate dose of the odor was pipetted onto the center of the cloth on one of the dispensers, and air was allowed to flow at 10 cm/sec. A similar dispenser placed in the other arm of the tunnel served as a control. All windows of the tunnel were closed and air allowed to flow for 5 min before the first fly was introduced.

Testing Procedure The procedure detailed in Gikonyo et al. (2003) was followed. One hour before the bioassay, individual flies (3-d-old teneral male tsetse flies) were placed in cylindrical plastic cages (8.0 cm long and 4.5 cm diam) closed on one side with a paper stopper inserted into a semicircular slit. At the start of the bioassay, a release cage containing a quiescent male fly was introduced cautiously through the release hole in the middle of the tunnel (downwind end, middle zone), and the paper plug of the release cage was removed gently so that only air from the charcoal filters carrying odor from the dispensers passed over the release cage. The behavior of each fly was observed and recorded for 3 min, after which the fly was aspirated out with a vacuum pump. The following observations were made: (1) number of flies departing from the midsection; (2) initial direction of flights upwind and any subsequent changes; and (3) return downwind flights and final landing/resting position (middle, control, or treated arms of the tunnel).

In each replicate cycle, involving one dose of a given test odor in 1 day, the above observations on about 10 individual flies were recorded after which the tunnel, the metallic racks, and the release cages were cleaned with water and then with 70% ethanol. With the humidifier switched off, the bioassay room temperature was raised to above 30°C, and air was exhausted from the room for about 6 hr by a powerful extraction fan fixed on the room wall. At the same time, the tunnel was exhausted at maximum wind speed overnight. Blank tests were conducted to confirm no residual effects of previous test materials. Once a week, the tunnel walls were also flushed with hot air from a heat gun. Between three and 10 replicates (corresponding to 30–100 flies observed) were carried out for each treatment. To avoid possible bias, the arms of the tunnel were used alternately for control or test odor in successive replicates. The percent responses were rank-transformed before being subjected to analysis of variance (ANOVA) by using PROC GLM (SAS institute, 2002) with significance level set at 5%.

Insects Newly emerged male *G. morsitans morsitans*, available from the ICIPE colony maintained in a rearing room at 25±2°C, 65±5% RH on a 12:12 (L/D) photocycle, were used as a representative of savannah morsitans species to initially screen the relative repellency of the test compounds in the laboratory.

Field Experiments

Field Site All experiments were carried out at ICIPE's Nguruman field station, southwest of Kenya where *G. pallidipes* Austen are predominantly present.

Traps All catches were made by NG2G traps, baited with acetone at ~500 mg/hr and cow urine aged 1–4 wk at overall (water plus volatiles) release rate of ~1,000 mg/hr, which provide relatively uniform catches (Brightwell et al. 1991). Traps were placed 100 m apart along the forest edge. The odors were placed on the ground 30 cm downwind of the trap.

Effects of Various Candidate Repellents on Trap Catches The effect of 2-methoxyphenol (guaiacol), 4-allyl-2-methoxyphenol (eugenol) and 2-methoxy-4-methylphenol (4-methyl-guaiacol) on trap catches were compared in a series of Latin square design experiments comprising of the following treatments:

(a) Baited trap, baited trap with 1.0 or 10.5 mg/hr eugenol, and baited trap with 1.0 or 9.0 mg/hr guaiacol, respectively. In the second experiment, higher doses (25.0 or 50.0 mg/hr) of the two compounds were evaluated. The repellents were dispensed undiluted from glass vials (1.7 cm wide and 4.3 cm deep) with lids containing 1- or 2-mm-diam holes to give the desired release rates.
(b) Unbaited trap, baited trap, baited trap with 2-methoxy-4-methylphenol at a dose of 10.0 mg/hr. The repellent was dispensed from glass vials, as above.
(c) Baited traps with 2.2, 4.5, or 9.0 mg/hr, 2-methoxy-4-methylphenol. In this set of experiments, the repellent was dispensed from sealed polythene sachets (25–50 cm^2 surface area and 50 μm thickness). The surface area of the sachets was varied to obtain the different release rates.

In all the above experiments, the repellents were incorporated into a series of replicated Latin squares consisting of days × sites × treatments. The catches (n) were normalized by using a $\log_{10}$ (n + 1) transformation and subjected to analysis of variance (ANOVA with PROC GLM, SAS Institute, 2002). The detransformed means are reported accompanied by their transformed means and standard errors.

4-Methylguaiacol Effects on Glossina pallidipes Responses to Natural Attractants This set of experiments was conducted to determine the number of tsetse attracted to a source of ox odor with or without the synthetic repellent. The odor was generated by placing an ox (~250 kg) in a pit (5 m long, 2 m wide, and 2 m deep with iron sheet roofing and entrance door) and exhausting the air from the pit at 2,000 l/min via a ventilation shaft fitted with a 12-V co-axial fan at the end (Vale 1974b). Two such pits were constructed. To estimate the number of tsetse attracted to the odor, an electric net (1.0×1.0 m) was placed 1 m downwind of the odor source (Vale 1974b). Sheets of corrugated fiberglass coated with a thin film of polybutene were placed underneath the screens to collect the electrocuted flies. As tsetse orientate imprecisely to an odor source in the absence of a visual stimulus (Vale 1974b), a visual model (metal drum 50 cm long and 37 cm diam covered with black cloth) was placed between the screen and odor source. A balanced incomplete Latin square design was used for these experiments with the following treatments: (1) ox odor, (2) ox odor + model, (3) ox odor + repellent, (4) ox odor + model + repellent. The repellent (10 mg/hr) was released from a polythene sachet placed near the odor outlet. The experiments were conducted for 3 hr in the morning (0800–1100 hours) and 3 hr in the afternoon (1400–1700 hours).

Effect of 4-Methylguaiacol on Feeding Efficiency of Glossina pallidipes The feeding efficiency of *G. pallidipes* on an ox with or without the repellent was determined by using the method developed by Vale (1977b). In this experiment, an ox was tethered in the middle of an incomplete ring of five electric screens (1.0×1.0 m). The screens covered 20% of the circumference of the circle. These rings were constructed at two different locations. The

experiment was a randomized complete block design and treatments were: (1) ox alone and (2) ox + repellent, which were randomly assigned to the two sites. At the site that received the repellent treatment, sachets containing the repellent (10 mg/hr) were placed on the post to which the animal was tied. The animals were kept stationary, whereas the treatments were rotated after each cycle of the experiment. Because in a preliminary experiment a relatively higher number of flies were caught in the afternoon, all the experiments were run for 3 hr from 1500–1800 hours. At the end of the experiment, the numbers of flies caught inside and outside the ring were recorded. Flies were also classified as fed or unfed based on the presence of fresh blood visible through the abdominal wall. The number of flies approaching the target (animals) with/without a repellent were estimated and statistically analyzed. Following Vale (1977b), feeding efficiency was estimated as a percentage of the fed tsetse relative to the total catch (fed + unfed) inside the ring of nets.

Results

Responses in the Wind Tunnel Equal number of flies flew upwind to the control (44%) or treated (47%) arms of the wind tunnel (N=145) when no odor was dispensed (blanks). Table 1 shows the responses of *G. m. morsitans* to the eight methoxyphenol analogues tested in the two-choice wind tunnel. Only the final resting position was statistically affected by the presence of a candidate repellent (Table 1) as previously shown with waterbuck repellents, a refractory host of savanna tsetse (Gikonyo et al. 2003). Only one 4-substituted methoxyphenol derivative, 2-methoxy-4-methylphenol, elicited consistent and significant repellent responses. The final resting position was dependent on the dose of this phenol: at lower doses (25 and 50 μl), more of the flies flying downwind settled in the midsection of the tunnel; however, at higher doses (100–400 μl) the flies tended to fly further away from the repellent-treated side and landed on the control arm of the wind tunnel (no odor present). Guaiacol (2-methoxyphenol) itself elicited milder responses, and

Table 2 Mean catches (detransformed and transformed ± SE) of *Glossina pallidipes* from NG2G-baited (cow urine + acetone) traps with various doses of eugenol or guaiacol (N=10)

Treatment	Trap catch	
	Detransformed	Transformed (±SE)
Expt 1		
Baited trap (BT)	524.807	2.720±0.138
BT + 1.0±0.18 mg/hr eugenol	644.169	2.809±0.137
BT + 10.5±0.03 mg/hr eugenol	516.416	2.173±0.140

Table 3 The detransformed mean catch (transformed ± SE in brackets) of *Glossina pallidipes* from unbaited or baited (cow urine + acetone) NG2G traps plus 4-methylguaiacol

Treatment	Mean catch	Index	Percent reduction
Unbaited trap	214.2 (2.333±0.070)*	0.29×	71
Baited trap	740.7 (2.870±0.048)	1.0×	
Baited trap + repellent	138.8 (2.146±0.050)*	0.19×	81

The catch index is the detransformed mean catch of tsetse expressed as a proportion of that from a baited trap (N=24)

The asterisk indicates that means are significantly different from baited trap catch (P<0.05, F test)

in one dose (100 μl), the number of flies that flew downwind and settled on the control arm was statistically significant. Contrary to our expectation, eugenol did not elicit any significant repellent responses from *G. m. morsitans*.

Effect of Candidate Repellents on Baited Trap Catches In field experiments, neither 2-methoxyphenol (guaiacol) nor 4-allyl-2-methoxyphenol (eugenol) reduced the trap catches of *G. pallidipes* ($F_{8,41}$=0.13 and $F_{8,41}$=0.43, respectively, Table 2).

The inclusion of 4-methylguaiacol with unbaited and baited (acetone + cow urine) traps reduced trap catches (>70 and 80%, respectively) ($F_{4,67}$ =31.38; P<0.001, Table 3). There was no significant difference in the responses of males and females, and hence the data for the sexes were pooled.

Effect of 4-Methylguaiacol on Attraction to Natural Attractants In both experiments, *G. pallidipes* catches to ox odor (ox placed in a ventilated pit) with 4-methylguaiacol were reduced by ~80% ($F_{3,20}$=18.54, P<0.001 and $F_{3,20}$= 100.77, P<0.001, respectively, Table 4). In the presence of the visual stimulus (metal drum covered with black cloth placed between the screen and odor source), the repellent caused reductions of ~70 and ~80% in the two experiments, respectively.

Table 4 The detransformed mean catch (transformed ± SE in brackets) of *Glossina pallidipes* from a target at a source of natural ox odor with and without 4-methylguaiacol

Treatment	Mean catch	Index	Percent reduction
Expt 1			
Ox odor	25.6 (1.424±0.093)	1.0×	
Ox odor + model	31.8 (1.516±0.092)ns	1.24×	
Ox odor + repellent	5.3 (0.799±0.082)*	0.20×	80
Ox odor + model + repellent	7.9 (0.949±0.085)*	0.31×	69
Expt 2			
Ox odor	358.1 (2.555±0.354)	1.0×	
Ox odor + model	379.3 (2.580±0.036)ns	1.06×	
Ox odor + repellent	66.8 (1.831±0.031)*	0.19×	81
Ox odor + model + repellent	64.7 (1.818±0.062)*	0.1×	82

The catch index is the detransformed mean catch of tsetse expressed as a proportion of that from an ox odor source (N=6)

The asterisk indicates that means are significantly different from ox odor (P<0.05, F test)

Table 5 The detransformed mean catch (transformed ± SE in brackets) of *Glossina pallidipes* from NG2G-baited (cow urine and acetone) traps with various doses of 4-methylguaiacol

Treatment (baited trap + repellent)	Mean catch	Index	Percent reduction
A Trap alone (control)	117.8 (2.075±0.084)[a]	1×	
B Trap + 2.2 mg/hr	41.6 (1.629±0.071)[b]	0.35×	65
C Trap + 4.5 mg/hr	38.6 (1.598±0.068)[b]	0.33×	67
D Trap + 9.0 mg/hr	29.8 (1.489±0.071)[b]	0.25×	75

The catch index is the detransformed mean catch of tsetse expressed as a proportion of that from a baited trap (control) (N=16). Means followed by different letters are significantly different (P<0.05, F test)

Effect of 4-Methylguaiacol on Trap Catches All release rates of 4-methylguaiacol significantly reduced trap catches, with 9.0 mg/hr showing maximum reduction ($F_{3,60}$=12.61, P<0.001, Table 5).

Effect of 4-Methylguaiacol on Feeding Efficiency of Glossina pallidipes on Host The studies on feeding levels of *G. pallidipes* in the field (Table 6) showed that in addition to reducing the proportion of the tsetse attracted to an ox by >80% (Table 4), the candidate repellent also reduced host feeding from 27 to 4.8%, a >80% reduction.

Discussion

In a previous study undertaken in Zimbabwe (Torr et al. 1996), guaiacol at 5–10 mg/hr reduced the numbers of *G. pallidipes* attracted to baited and unbaited Epsilon (Hargrove and Langley 1990) traps (~85 and ~60%, respectively), baited targets (~50%), and a source of natural ox odor (~40%). In the present study, the compound elicited relatively mild repellent responses from *G. m. morsitans* in a two-choice wind tunnel, but no significant reductions in baited trap catches of *G. pallidipes* even at relatively high doses. The difference in the two studies may be due to different efficiency of the two trap designs used and/or some differentiation in the sensory responses of the two *G. pallidipes* populations. Detailed comparison of the electrophysiological and behavioral responses of the two *G. pallidipes* populations and their close-range behaviors to the two traps may shed some light on the question.

Despite the relatively high repellency demonstrated in different experiments in Zimbabwe, guaiacol had no significant effect on the numbers of flies that fed on an ox, which makes it an ineffective tool for protecting cattle against trypanosomosis (Torr et al.

Table 6 Mean catches and percent feeding efficiency of *Glossina pallidipes* on cattle with and without 4-methylguaiacol

Treatment	Total catch (inside the screen)	Total catch (inside and outside the screen)	Total fed (inside the screen)	Feeding efficiency (%)
Ox alone	445±8.5[a]	818±23.5[a]	120±10.3[a]	27
Ox + repellent	83±4.5[b]	154±9.6[b]	4±0.2[b]	4.8

Synthetic repellent reduces the feeding efficiency on treated cattle by 82%. Feeding efficiency is the catch of fed flies from inside the ring of nets expressed as proportion of the total catch (fed + unfed). Number of replicates = 6. Means followed by different letters are significantly different at (P<0.05, F test)

1996). In the present study, the presence of a methyl substituent at the 4-position of guaiacol significantly enhanced the repellency of the molecule to savannah tsetse *G. m. morsitans* in the wind tunnel, and reduced numbers of *G. pallidipes* attracted to baited and unbaited traps and to ox odor. In addition, the compound reduced the number of flies that landed on the ox and those that fed on the host (>80%).

These results suggest that 4-methylguaiacol represents a promising tool for protecting individual cattle against trypanosomiasis (Saini and Hassanali 2004). We are currently exploring two strategies for integrating the repellent with existing tools and tactics. First, we are studying its efficacy in controlled release devices carried by individual cattle owned by nomadic communities who need a mobile technology to protect their cattle and reduce their dependence on trypanocidal drugs. Such devices may also provide an effective means of reducing challenge to trypanotolerant cattle, which succumb to the disease at high infection rates (Jordan 1986). Second, use of the repellent as a "push" component with bait technologies (traps, targets, or live baits with insecticides as "pull") in "push–pull" tactics in areas where cattle are the dominant source of blood meal may provide a more effective way of suppressing tsetse among settled pastoralist and agro-pastoralist communities.

The enhanced repellency of 4-methylguaiacol (and lack of activity of the other analogues tested) against savannah tsetse discovered in the present study raises some interesting questions about the sensory mechanism that underlies its action. This phenol reduced the catch of *G. pallidipes* in unbaited traps that were only visually attractive and thus, according to Dethier et al. (1960) definition, qualifies as a true repellent. This suggests that these phenols probably interact with a specific group of receptors different from those of the two tsetse kairomonal phenols, 4-methylphenol and 3-*n*-propylphenol (Owaga et al. 1988; Saini and Hassanali 1992). They not only inhibit or counter the response of sensory signals from the receptors of these attractants, but also those associated with close-range visual attraction (Davis 1985). However, the close structural relationship between 4-cresol and 4-methylguaiacol and lack or mild activity of the respective parent phenols and those of ethyl analogues (Owaga et al. 1988) suggests a close similarity of the binding sites of their respective receptors. Our current studies on the odor binding proteins of savannah tsetse are expected to provide some insights into the relationship between the two sets of receptors and their relative specificity.

Acknowledgments This study was carried out with funding from the European Union (EU) and the International Fund for Agricultural Development (IFAD) to whom we are grateful. We thank John Andoke, Peter Musa, Melaku Girma, and Caroline Muya for technical assistance and Anthony Wanjoya for assistance in statistical analyses of data.

Abstract Induced plant responses to attack by chewing insects have been intensively studied, but little is known about plant responses to nonchewing insects or to attack by multiple herbivores with different feeding habits. We examined volatile emissions by tobacco, *Nicotiana tabacum*, in response to feeding by the piercing–sucking insect western flower thrips (WFT), *Frankliniella occidentalis*, the chewing herbivore *Heliothis virescens*, and both herbivores simultaneously. In addition, we examined the effects of herbivore-induced plant defenses on host-plant selection by WFT. Plants responded to thrips feeding by consistently releasing five compounds. Simultaneous feeding by WFT and *H. virescens* elicited the same 11 compounds emitted in response to caterpillar feeding alone; however, two compounds, α-humulene and caryophyllene oxide, were produced in greater amounts in response to simultaneous herbivory. In choice tests, thrips consistently preferred uninduced plants over all other treatments and preferred plants damaged by caterpillars and those treated with caterpillar saliva over those treated with caterpillar regurgitant. The results are consistent with a previous finding that caterpillar regurgitant induces the release of significantly more volatile nicotine than plants damaged by caterpillars or plants treated with caterpillar saliva. A repellent effect of nicotine on WFT was confirmed by encircling unwounded plants with septa releasing volatile nicotine. Our results provide the first direct evidence that thrips feeding induces volatile responses and indicates that simultaneous herbivory by insects with different feeding habits can alter volatile emissions. In addition, the findings demonstrate that induced plant responses influence host-plant selection by WFT and suggest that the induction of volatile nicotine may play a role in this process.

Introduction

Herbivory induces plant defense responses including the production of toxic secondary metabolites and the synthesis and release of volatile chemical signals that are attractive to herbivore natural enemies (Turlings et al. 1990, 1995; Karban and Baldwin 1997; De Moraes et al. 1998; Dicke 1999; Pare and Tumlinson 1999). These induced responses can alter host-plant quality and impact the behavior and performance of subsequent herbivores (Karban and Baldwin 1997; Agrawal 1999; De Moraes et al. 2001; Wise and Weinberg 2002; De Moraes and Mescher 2004; Rodriguez-Saona et al. 2005). Interactions between plants and chewing insects (e.g., lepidopteran larvae) are well documented (Karban and Baldwin 1997; Walling 2000). Much less is known about plant responses to insects that employ other feeding modes, such as aphids, whiteflies, and bugs (Du et al. 1998; Turlings et al. 1998; Rodriguez-Saona et al. 2002, 2003; Williams III et al. 2005), although extensive research has been conducted on the spider mite *Tetranychus urticae*, a non-insect arthropod that also feeds in a piercing–sucking manner (Dicke and Sabelis 1988; Dicke et al. 1990a, b). Western flower thrips (WFT), *Frankliniella occidentalis* (Pergande), is a piercing–sucking insect and a major worldwide pest of agriculture and horticulture (Lewis 1997; Kirk and Terry 2003). We are unaware of any previous research that has explicitly examined volatile induction in response to WFT feeding, but WFT infestation is known to influence subsequent insect behavior. For example, the predatory bug *Orius laevigatus* prefers cucumber plants infested with WFT (Venzon et al. 1999), whereas the spider mite *T. urticae* avoids them (Pallini et al. 1997). Thrips themselves may exploit cues from infested plants to avoid intraspecific competition (Agrawal and Colfer 2000).

Plant responses to feeding by multiple herbivore species that employ different feeding modes are also poorly understood, although attack by herbivores with diverse feeding strategies is common in nature (Strauss 1991; Vos et al. 2001). Simultaneous feeding by multiple herbivores may influence plant volatile responses by inducing competing plant defense pathways, with possible implications for interactions with the third trophic level. For example, feeding by two species of Lepidoptera, *Plutella xylostella* and *Pieris rapae*, causes cabbage plants to emit different volatile blends from those emitted in response to feeding by either species alone and alters the response of parasitoids (Shiojiri et al. 2001). Additionally, the mixing of different volatile blends emitted from neighboring plants simultaneously infested with different herbivore species has the potential to influence the foraging success of herbivore natural enemies (Dicke et al. 2003).

This paper explores plant volatile responses to feeding by WFT and to simultaneous feeding by WFT and the chewing insect *Heliothis virescens* (Fabricius) on tobacco, *Nicotiana tabacum* L. In addition, we document the impacts of induced plant responses on host-plant selection by WFT. Prior herbivory can influence the behavior of subsequent herbivores by impacting host-plant quality (Karban and Baldwin 1997), by eliciting volatile responses that serve as cues for foraging insects (e.g., De Moraes et al. 2001), and by inducing other biochemical changes in host plants (e.g., Duffey and Stout 1996). We previously found that tobacco plants treated with *H. virescens* regurgitant release significantly more volatile nicotine than plants treated with *H. virescens* saliva or plants damaged by *H. virescens* caterpillars (Delphia et al. 2006). In the current study, we examine the effects of *H. virescens* saliva- and regurgitant-induced plant responses, as well as other treatments, on the distribution and ovipositional preferences of WFT. Our results offer insight into the dynamics of plant–herbivore interactions when plants are simultaneously attacked by herbivores with different feeding habits, and into the role of induced defenses in influencing host-plant choice by an important insect pest.

Methods and Materials

Plants and Insects

Tobacco seeds (*N. tabacum* strain K326) were germinated in a peat-based, general-purpose potting soil (Pro-Mix, Premier Horticulture Inc., Quakertown, PA, USA) and transplanted as 2-wk-old seedlings into pots (16 cm tall × 16.5 cm diam) with fertilizer (Osmocote/ Hummert International, MO, USA) in a growth chamber [16:8 hr light:dark; 25:22°C day: night; 65% relative humidity (RH)]. Five-wk-old plants with three fully expanded leaves were used for all experiments. Eggs of *H. virescens* were obtained from the USDA/ARS Research Laboratory in Tifton, Georgia, and reared on an artificial casein diet in a growth chamber under the same conditions as above. Adult and larval *F. occidentalis* were obtained from infested greenhouse plants that were virus-free (i.e., plants free of symptoms typical for tomato spotted wilt virus: chlorotic rings, chlorotic mosaic patterns, mottled leaves, reduction of growth or deformation).

Induced Plant Volatiles

Simultaneous Herbivory

To examine induced plant responses to herbivory, we collected volatiles from tobacco plants receiving the following treatments: (1) feeding by adult and larval thrips, (2) mechanical wounding, (3) mechanical wounding plus feeding by adult and larval thrips, (4) feeding by three third-instar *H. virescens*, or (5) feeding by three third-instar *H. virescens* plus adult and larval thrips. Undamaged plants were used as controls. Treatments were applied daily, immediately before volatile collection, and volatiles were collected on d 1–4 to ensure induction in response to herbivory. Plants were mechanically wounded by using a razor blade to scrape an approximately 1 cm^2 area on each of the three leaves per plant. The same three leaves received new mechanical damage each day so that by the end of the 4-d experiment, plants had three leaves with four wounds each. Five adult and five first- or second-instar thrips were added to thrips treatments each day so that by the end of the 4-d experiment, 20 adult and 20 larval thrips had been added to each plant. Thrips were added daily to ensure that a minimum number of thrips were feeding each day, as they tended to escape from the volatile collecting chambers. The level of infestation was chosen based on the levels found in greenhouses that employ conservative action thresholds for monitoring thrips. *Heliothis virescens* were allow to feed continuously throughout the 4-d experiment. For treatments where both herbivores were allowed to feed on plants, the feeding location of each herbivore did not appear to be influenced by the presence of the other, and both thrips and caterpillars fed on the same leaves. This experiment was replicated four times.

Increased Levels of Thrips Feeding Damage

To determine if higher levels of thrips damage would alter emission profiles, we collected volatiles from tobacco plants exposed to two additional levels of thrips feeding. We employed (1) a medium-damage treatment where plants received 20 first- or second-instar thrips and 20 adult thrips on the first day of the experiment, followed by 10 additional adult thrips per day for the following 3 d for a total of 70 thrips added to each plant, and (2) a high-damage treatment where plants received 40 first- or second-instar thrips and 40 adult

thrips on the first day of the experiment, followed by 20 additional adult thrips per day for the following 3 d for a total of 140 thrips added to each plant. Thrips were added immediately before volatile collection, and volatiles were collected on each of the 4 d to ensure induction in response to herbivory. This experiment was replicated three times.

Collection and Analysis of Volatiles

Volatiles were collected from tobacco plants by using a closed push/pull system. A two-piece Teflon® base with a hole for the plant stem rested on the pot. A glass dome chamber (15 cm tall×16 cm diam) enclosed plants and rested on the base. Filtered air was pushed through Teflon® tubing into the top of the chamber (3.0 l/min) and was pulled through side ports (0.8 l/min) across beds of adsorbent Super-Q® (25 mg, Alltech Associates, Deerfield, IL, USA). Plant volatiles were collected between 1000 and 2200 hours (light period: 0600 to 2200 hours). Super-Q® traps were rinsed with 150 μl of dichloromethane; 5 μl of *n*-octane (40 ng/μl) and *n*-nonyl-acetate (80 ng/μl) were added as internal standards. Samples were injected, using a splitless injector held at 220°C, in 1-μl aliquots into an Agilent model 6890 gas chromatograph fitted with a flame ionization detector. The column (15 m× 0.25 mm i.d., 0.1 μm film thickness, HP-1) was maintained at 35°C for 0.5 min and then increased by 12°C per min to 180°C. Quantifications of compounds were made relative to the internal standard using ChemStation software (Agilent Technologies, Wilmington, DE, USA). Samples were also analyzed by gas chromatography mass spectrometry by using electron ionization (6890 gas chromatograph interfaced to a Hewlett-Packard 5973N mass selective detector). The column (30 m×0.25 mm i.d., 0.25 μm film thickness, HP-1MS) was maintained at 35°C for 0.5 min and then increased by 12°C per min to 180°C. Identifications of all volatile compounds were confirmed by comparing retention times and mass spectra to commercial standards.

Leaf Measurements

To determine leaf area for plants used for volatile collections, we removed leaves from plants and photocopied them. Photocopies were digitized, and leaf areas and amount of damage were determined using an imaging program (SigmaScan® Pro, SPSS Inc., Chicago, IL, USA).

Collection of *H. virescens* Salivary Glands and Regurgitant

Labial salivary glands were dissected from artificial-diet-fed *H. virescens* larvae that had been fifth-instars for 48 hr and had been chilled on ice for approximately 5 min. Once removed, the salivary glands were placed into microcentrifuge tubes, kept on ice in groups of 10 pairs, and stored at −80°C until needed. Immediately before use, each 10-gland sample was extracted in 50 μl physiologically buffered saline (pH 7.2) by homogenizing the salivary glands with a hand-held pestle in a microcentrifuge tube kept on ice. This allowed salivary-gland extracts to be applied to mechanically wounded leaves with a pipette. Protein concentrations were determined by using the method of Bradford (1976). Total protein concentrations for our samples of homogenized salivary glands were around 700 μg per 40 μl (i.e., the amount applied to plants in experiments). This amount was based on a previously described method (Delphia et al. 2006).

Before collecting regurgitant, recently molted fifth-instar caterpillars were fed for 48 hr on tobacco leaves from approximately 7-wk-old plants. Regurgitant was collected from these larvae by gently squeezing the caterpillars, collecting the resulting oral secretions with a pipette,

and dispensing them into a microcentrifuge tube on ice. Regurgitant was pooled from approximately 50 larvae and then separated into 50 μl aliquots and stored at −80°C until needed.

Thrips Distribution and Ovipositional Preferences

We conducted a series of choice tests to examine thrips behavior in response to induced and uninduced tobacco plants. Adult thrips were allowed to choose between undamaged control plants and plants that received various treatments including mechanical wounding, wounding plus the application of caterpillar saliva or regurgitant, and caterpillar feeding. We also explored the effects of volatile nicotine on thrips behavior by allowing thrips to choose between undamaged plants surrounded by rubber septa releasing nicotine and those surrounded by blank septa. In all choice tests, adult thrips (20–50 depending on the experiment) were released each day for 2 d then counted every day for 3, 4, or 6 d (depending on the experiment) to determine thrips distributional preferences. At the end of all experiments, the leaves of plants were removed, and the numbers of larvae were counted to determine ovipositional preferences. All choice experiments were conducted under greenhouse conditions except for the nicotine choice experiment that was done in a growth chamber.

Effects of Mechanical Wounding

To determine the effects of mechanical wounding on thrips distribution and oviposition preferences, we allowed thrips to choose between wounded plants and unwounded controls. Two mechanically wounded plants and two control plants were positioned 0.3 m from each other at one end of a greenhouse bench (approximately 1.5×3 m), creating a square with wounded plants on one side and control plants on the other. This design was replicated, with treatments reversed, at the other end of the bench. On the first day of the experiment, the plants were wounded by using a razor blade to damage three leaves (as above). This was repeated on d 2–5, wounding the same three leaves each day. On d 1 and 2, wounding was followed by the release of 20–30 adult WFT from a 150-ml beaker in the center of each set of four plants. On d 3–6, we recorded the number of adult thrips on each plant. On d 8, we removed leaves and counted the larvae. Observations and wounding occurred each morning between 0800 and 1000 hours. This experiment was replicated six times.

Effects of Caterpillar Feeding and Oral Secretions

To determine the effects of caterpillar feeding damage and the application of oral secretions associated with herbivore feeding on thrips distribution and ovipositional preferences, thrips were allowed to choose between tobacco plants receiving the following treatments: (1) prior feeding (~18 hr) by two third-instar *H. virescens* followed by continuous feeding by one third-instar *H. virescens* for 5 d, (2) mechanical wounding, (3) mechanical wounding plus the application of 40 μl of *H. virescens*-homogenized salivary glands distributed among three wounds per day, (4) mechanical wounding plus the application of 40 μl of *H. virescens* regurgitant distributed among three wounds per day, or (5) control (i.e., unwounded) plants. We were unable to include a treatment that examined thrips ovipositional preferences in response to plants induced by thrips infestation because of an inability to exclude or distinguish larvae resulting from prior infestation. The amounts of oral secretions applied to plants were based on a previously described method (Delphia et al. 2006).

Five plants were positioned in a circle equidistant from a central point (0.3 m) on each of the two greenhouse benches (approximately 1.5×3 m). The positions of the treatments on each bench were arranged so that no two treatments were adjacent to one another on both benches. On d 1, the plants were wounded by using a razor blade to damage three leaves (as above). Regurgitant and homogenized salivary glands were applied at this time using a pipette to evenly distribute the compounds among the damaged sites. This procedure was repeated on d 2–5. Also, on d 1, we removed one of the two third-instar *H. virescens*, which had been feeding for the previous 18 hr, from the caterpillar-damaged treatment to limit leaf tissue loss. The remaining caterpillar was allowed to feed continually on d 1–5. On d 1 and 2, wounding and the application of oral secretions were followed by the release of 30–40 adult WFT from a 150-ml beaker in the center of each set of five plants. On d 3–8, we recorded the number of adult thrips on each plant. On d 8, we removed leaves and counted the larvae. All observations and manipulations occurred between 0900 and 1100 hours. This experiment was replicated six times.

Effects of Volatile Nicotine

To determine the effects of volatile nicotine on thrips distribution and ovipositional preferences, thrips were allowed to choose between unwounded tobacco plants encircled by rubber septa that had been treated with either nicotine or left blank (i.e., treated with solvent alone). Two plants were positioned about 1 m from each other in a growth chamber (16:8 light:dark; 25:22°C day:night; 65% RH). Three rubber septa, which were previously conditioned with 150 μl dichloromethane, were positioned on metal stands around each of the two plants. With a pipette, 2 μl of nicotine was added to each of the septa in the nicotine treatment. Control septa were left blank. On the first 2 d of the experiment, 45–55 adult WFT were released from a 150-ml beaker centered between the two plants. On d 2, 3, and 4, we recorded the number of adult thrips per plant. On d 7, we removed leaves and counted the larvae. Observations and thrips release occurred each morning between 1030 and 1130 hours. This experiment was replicated three times.

Statistical Analyses

We analyzed the data collected on d 4 from volatile collection experiments to allow sufficient induction in response to herbivory. We quantified all volatile compounds released in measurable amounts. The data from the simultaneous herbivory experiment were $\log_e(x+1)$-transformed to satisfy the assumptions of normality and homogeneity of variance among treatments and were analyzed by analysis of variance (ANOVA), with trial treated as a random effect. The data from the levels of thrips feeding damage experiment were analyzed by ANOVA. All pairwise comparisons were conducted by using Tukey's honestly significant difference (HSD) test. The data from choice tests were square-root-transformed to homogenize variance among treatments. We analyzed both the mechanical wounding and the caterpillar feeding and oral secretions choice tests for adult thrips distribution over four and six sampling days, respectively, by repeated-measures ANOVA, with day treated as a fixed effect and with trial and bench position within trial treated as random effects. We analyzed the volatile nicotine choice test for adult thrips distribution over three sampling days by repeated-measures ANOVA, with day treated as a fixed effect. We used ANOVA to analyze the number of larvae per plant at the end of all three choice tests. All statistical analyses were conducted by using Minitab v. 14.1 (Minitab Inc., State College, PA, USA).

Results

Induced Plant Volatiles

Thrips Feeding Damage

When we compared volatile emissions in response to low, medium, and high levels of thrips feeding damage, we saw an apparent increase in the total amount of volatiles released, although this difference was not statistically significant (ANOVA: $F_{2,\ 7}=2.86$, $P=0.124$; Fig. 1a; Table 1). Plants responded to low levels of thrips feeding by releasing two compounds consistently ((*E*)-β-ocimene and β-caryophyllene; Table 1). Two additional

Compounds are labeled as follows: *1*, myrcene; *2*, (*E*)-β-ocimene; *3*, linalool; *4*, indole; *5*, nicotine; *6*, β-elemene; *7*, β-caryophyllene; *8*, α-humulene; *9*, unidentified sesquiterpene; *10*, (*E, E*)-α-farnesene; *11*, caryophyllene oxide; *IS* and IS_2, internal standards (*n*-octane and *n*-nonyl-acetate)

Table 1 Amounts (nanogram per day; mean ± SE) of volatiles released on d 4 by tobacco plants receiving varying treatments

Compound	Treatment		
	LT	MT	HT
(*E*)-β-Ocimene	433±259a	494±114a	1100±141a
Linalool	0±0a	26.5±14.2a	46.9±5.78b
Nicotine	0±0a	0±0a	78±50.4a
β-Caryophyllene	100.9±62.8a	125.3±29.3a	195.9±54.4a
Unidentified sesquiterpene	6.8±6.8a	0±0a	5.9±5.9a
(*E,E*)-α-Farnesene	14.7±14.7a	5.11±5.11a	20.4±13.5a
Total volatiles	555±342a	651±157a	1447±232a

Numbers in each row followed by the same letter indicate no significant differences (Tukey's HSD test, $P<0.05$) Low levels of thrips feeding damage (LT), medium levels of thrips feeding damage (MT), and high levels of thrips feeding damage (HT) ($N=3$).

compounds (an unidentified sesquiterpene and (*E*,*E*)-α-farnesene) were also emitted in response to low levels of thrips feeding, but were only observed in one replicate (Table 1). In response to medium and high levels of thrips feeding damage, (*E*)-β-ocimene and β-caryophyllene remained the dominant compounds and were released in increasing amounts, although not significantly so ($P>0.05$; Table 1). In addition to releasing (*E*)-β-ocimene and β-caryophyllene, plants responded to medium and high levels of thrips feeding damage by releasing linalool (Table 1). Significantly more linalool was released by plants receiving high levels of thrips feeding damage compared to those with low levels of thrips damage (ANOVA: $F_{2,\ 7}=9.55$, $P=0.010$; Table 1). Nicotine was also released by plants in response to high levels of thrips damage, although the difference was not significant due to large variance (ANOVA: $F_{2,\ 7}=2.93$, $P=0.119$; Table 1). The compound (*E*,*E*)-α-farnesene was released in response to all three levels of thrips feeding damage, but it was only consistently released by plants receiving high levels of thrips damage (Table 1).

The highest level of thrips feeding induced the consistent release of five compounds (Table 1). In comparison, feeding by *H. virescens* induced the release of 11 compounds (Fig. 2; Table 2). Of the five shared compounds released by plants in response to thrips and caterpillar feeding, (*E*)-β-ocimene, linalool, β-caryophyllene, and (*E*,*E*)-α-farnesene were all released in greater amounts in response to caterpillar feeding ($P<0.05$). Because several of the compounds induced by thrips feeding were also among the most dominant compounds released in response to caterpillar feeding, it is conceivable that the observed differences are due solely to the differences in feeding damage. Additionally, because the feeding habits of thrips and caterpillars are so dissimilar, standardizing the amount of damage among treatments is problematic. However, we did observe consistent differences in plant volatile responses to caterpillars vs thrips that persisted over a range of thrips damage levels. Moreover, when we look at the relative proportions of individual compounds in each of the blends, we see that the ratios of (*E*)-β-ocimene to β-caryophyllene (i.e., the two dominant compounds released in response to thrips and caterpillars) are dissimilar (Fig. 1b). The relative proportion of (*E*)-β-ocimene to β-caryophyllene in the caterpillar blend is almost 1:1 (46 to 39%) vs 4.3:1 (78 to 18%), 4:1 (76 to 19%), and 5.8:1 (76 to 13%) in the low, medium, and high thrips feeding blends, respectively, which suggests that plants are responding differently to the two herbivores irrespective of damage (Fig. 1b).

Conceivably, these differences might still reflect differences in damage levels, as the observable leaf damage caused by caterpillar feeding is considerably more extensive than

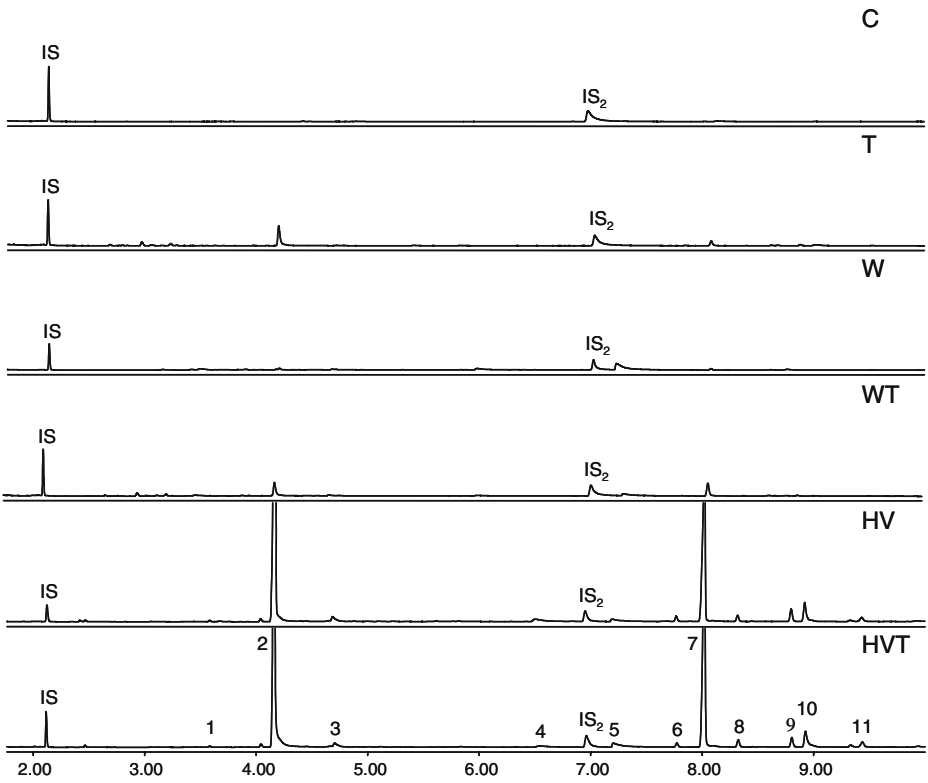

Fig. 2 Chromatograms showing typical daytime emission profiles of volatiles released by tobacco plants receiving the following treatments: unwounded control plants (C), thrips feeding (T), mechanical wounding (W), mechanical wounding plus thrips feeding (WT), *H. virescens* feeding (HV), or *H. virescens* plus thrips feeding (HVT). Compounds are labeled as follows: *1*, myrcene; *2*, (*E*)-β-ocimene; *3*, linalool; *4*, indole; *5*, nicotine; *6*, β-elemene; *7*, β-caryophyllene; *8*, α-humulene; *9*, unidentified sesquiterpene; *10*, (*E,E*)-α-farnesene; *11*, caryophyllene oxide; *IS* and *IS*$_2$, internal standards (*n*-octane and *n*-nonyl-acetate)

that caused by even high levels of thrips feeding ($P<0.001$), although leaf loss is probably a poor indicator of the damage inflicted by thrips feeding. Another approach to standardizing the treatments is to compare overall responses at damage levels where the amounts of the dominant compounds are similar. The level of (*E*)-β-ocimene emitted by plants on the second day of caterpillar feeding (data not shown) was similar to that released in response to high levels of thrips damage on d 4 ($P>0.05$; Table 1). Yet, the overall blends were notably different: all 11 compounds typically released in response to caterpillar feeding were induced by d 2 compared to only five compounds released in response to high levels of thrips feeding. Of the shared compounds, β-caryophyllene and (*E*,*E*)-α-farnesene were released in greater amounts in response to caterpillar feeding ($P<0.05$). There were no significant differences in the amounts of linalool or nicotine released by plants that were damaged by thrips or caterpillars ($P>0.05$). These results suggest that there are differences in plant responses to thrips and caterpillar feeding that cannot be entirely explained by differences in leaf-damage area.

Plants that were mechanically wounded or those that received mechanical wounding plus thrips feeding released three compounds [(*E*)-β-ocimene, nicotine, and β-caryophyllene;

Numbers in each row followed by the same letter indicate no significant differences (Tukey's HSD test on log-transformed data, $P<0.05$).

Unwounded control plants (C), thrips feeding (T), mechanical wounding (W), mechanical wounding plus thrips feeding (WT), *H. virescens* feeding (HV), or *H. virescens* plus thrips feeding (HVT) ($N=4$).

Table 2]. Nicotine was the most abundant compound released by mechanically wounded plants and by mechanically wounded plants that also received thrips feeding (Table 2).

Simultaneous Herbivory

Simultaneous feeding by thrips and *H. virescens* induced the release of the same 11 compounds emitted in response to *H. virescens* feeding alone (Fig. 2; Table 2). However, simultaneous herbivory induced the release of more α-humulene ($P<0.05$) and caryophyllene oxide ($P<0.01$; Table 2). There were no significant differences in the amount of leaf area removed by simultaneous herbivory (1,678±348 mm^2 damage/day) compared to caterpillar feeding alone (1,691±417 mm^2 damage/day), although this measure likely fails to capture the intensity of thrips feeding damage.

Thrips Distribution and Ovipositional Preferences

Effects of Mechanical Wounding

More adult thrips were found on unwounded plants (22.3±2.8 thrips/plant) than wounded plants (4.6±0.7 thrips/plant) over four sampling days (ANOVA: $F_{1,\ 40}=102.12$, $P<0.001$; Fig. 3). Thrips also displayed an apparent ovipositional preference for unwounded plants, with more larvae recovered on control plants (45±11.7 larvae/plant) compared to wounded plants (6.5±2.5 larvae/plant; $P<0.01$).

Effects of Caterpillar Feeding and Oral Secretions

We observed more adult thrips on unwounded plants than on any other treatment over six sampling days (ANOVA: $F_{4,\ 165}=15.74$, $P<0.001$; Fig. 4a). Additionally, more thrips were

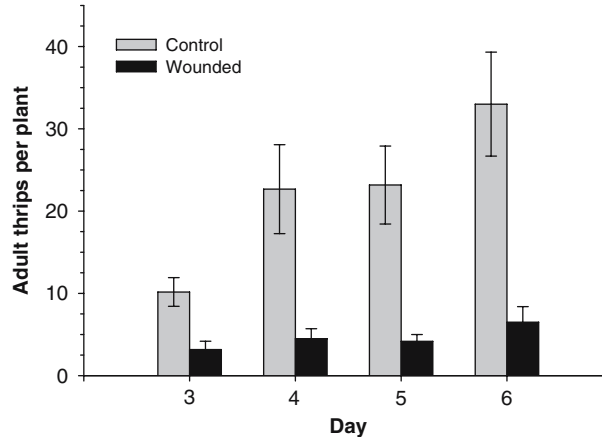

Fig. 3 Mean (±SE) number of adult WFT on control and mechanically wounded plants over four sampling days (N=6)

found on plants damaged by *H. virescens* and plants treated with *H. virescens* saliva than on plants treated with *H. virescens* regurgitant (P<0.01; Fig. 4a). Female thrips preferred to oviposit into unwounded control plants compared to mechanically wounded plants or plants treated with *H. virescens* regurgitant (P<0.05; Fig. 4b). Although there were no statistical differences, thrips appeared to prefer control plants as oviposition sites compared to plants damaged by *H. virescens* and plants treated with *H. virescens* saliva (Fig. 4b). They also appeared to prefer plants damaged by *H. virescens* and plants treated with *H. virescens* saliva compared to mechanically wounded plants and plants treated with *H. virescens* regurgitant, although, again, the observed differences were not statistically significant (Fig. 4b).

Effects of Volatile Nicotine

More adult thrips were found on plants encircled by blank (control) septa (19.78±3.34 thrips/plant) than on plants encircled by septa releasing nicotine (7.56±1.42 thrips/plant) over three sampling days (ANOVA: $F_{1,\ 14}$=33.3, P<0.001; Fig. 5). More larvae were also recovered on plants encircled by control septa (97.7±17 larvae/plant) compared to plants encircled by the nicotine septa (37±8.08 larvae/plant; P=0.032).

Discussion

Induced Plant Volatiles

Simultaneous feeding by multiple herbivores is common in natural ecosystems (Strauss 1991; Vos et al. 2001). Previous research has demonstrated that plant responses to feeding by a single herbivore species differ from response to attack by multiple herbivores (e.g., Shiojiri et al. 2001; Rodriguez-Saona et al. 2003) and that attack by multiple species can have both positive and negative effects on preference and performance of subsequent herbivores and herbivore natural enemies (Cardoza et al. 2002; Shiojiri et al. 2002; Rodriguez-Saona et al. 2005). In our study, simultaneous herbivory by thrips and *H. virescens* induced the same 11 compounds as caterpillar feeding alone, although there were significant differences in the relative amounts of two individual compounds, α-humulene and caryophyllene oxide. Total

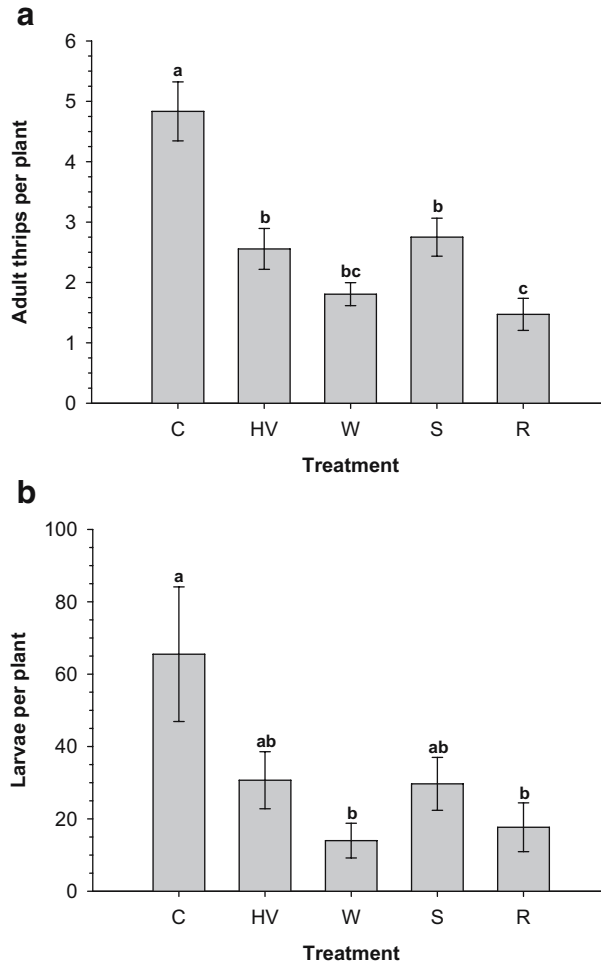

Fig. 4 Mean (±SE) number of adult WFT (**a**) and larvae (**b**) on plants receiving the following treatments: unwounded control plants (C), *H. virescens* feeding (HV), mechanical wounding (W), mechanical wounding plus *H. virescens* saliva (S), or mechanical wounding plus *H. virescens* regurgitant (R) (N=6). Letters above each bar indicate the significant differences as indicated by Tukey's HSD test, $P<0.05$

volatile production in our study was not reduced in response to simultaneous herbivory, in contrast to the 60% reduction observed in cotton plants when exposed to simultaneous feeding by silverleaf whitefly and beet armyworm compared to beet armyworm feeding alone (Rodriguez-Saona et al. 2003). However, our findings are similar to those reported by Cardoza et al. (2002) who found that simultaneous pathogen infection and herbivore feeding in peanut plants, *Arachis hypogaea*, induced the release of some compounds in higher quantities compared to herbivore feeding alone. Dual-damaged plants were also shown to be more attractive to the parasitoid *Cotesia marginiventris* (Cardoza et al. 2003). Similarly, Shiojiri et al. (2002) demonstrated an increase in parasitism by *Cotesia glomerata* on plants infested by two caterpillar species compared to plants infested with their host caterpillar alone. It remains to be determined whether the changes in volatile emissions that we observed in response to simultaneous infestation by thrips and caterpillars similarly alter the behavior of herbivore natural enemies.

Our results provide the first direct evidence that thrips induce volatiles and support previous research that provided evidence for the use of thrips-induced plant volatiles in

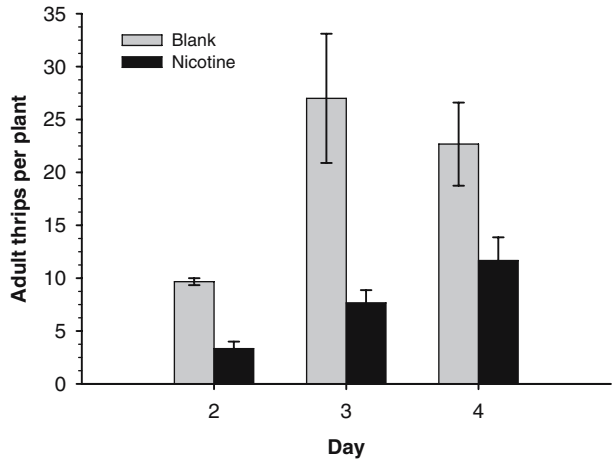

Fig. 5 Mean (±SE) number of adult WFT on unwounded plants encircled by blank rubber septa (control) and rubber septa containing nicotine over three sampling days (N=3)

both avoidance (Pallini et al. 1997) and attraction (Venzon et al. 1999) of heterospecifics to thrips-infested plants. Plants responded to feeding by the piercing–sucking insect WFT by emitting a volatile blend that was qualitatively and quantitatively distinct from that released in response to caterpillar feeding. While the very different feeding modes of these two herbivores make it difficult to standardize damage levels across treatments, the observed differences in volatile blends persisted across a wide range of thrips damage levels. Moreover, the overall volatile responses to thrips vs caterpillar feeding were different at damage levels where the amount of the most dominant compound released was similar. These results suggest that there are systematic differences in the volatile response to thrips vs caterpillar feeding that cannot be wholly explained by differences in the amount of damage inflicted. This contrasts with the previous finding by Turlings et al. (1998) that feeding by the stemborer *Ostrinia nubilalis* on maize induced a volatile blend qualitatively similar to that induced by caterpillar feeding but released in much lower quantities. The phloem-feeding aphid *Rhopalosiphum maidis*, which causes limited cell damage, did not induce measurable volatile emissions at all, although other aphid species elicit plant volatile responses (Du et al. 1996, 1998).

Thrips Distribution and Ovipositional Preferences

The ability of herbivores to distinguish among plants as suitable oviposition sites is important for the fitness of their offspring (e.g., Ohsaki and Sato 1994). Our results indicate that thrips are able to distinguish among plants as suitable hosts and that induced plant responses influence this preference. Thrips exhibited a consistent distributional preference for unwounded plants over all other treatments and preferred plants fed on by *H. virescens* and those treated with *H. virescens* saliva to those treated with *H. virescens* regurgitant (Figs. 3 and 4a). A similar pattern was observed for thrips ovipositional preferences, although significant differences were observed only between unwounded controls and plants that were mechanically wounded or treated with regurgitant (Fig. 4b). However, the fact that control plants had double the number of larvae compared to plants damaged by *H. virescens* and those treated with saliva suggests that adult thrips may be able to distinguish among these treatments as suitable oviposition sites for larval development

(Fig. 4b). While it is possible that poor egg hatch or increased larval mortality may have contributed to the low numbers of larvae recovered on wounded plants, we did not observe any dead adults or larvae throughout the choice experiments. Moreover, Maris et al. (2004) reported a direct correlation between the number of eggs laid and the larvae that emerged even on a resistant pepper variety.

The observed thrips preference for unwounded plants is consistent with the observation that the application of jasmonic acid, a natural elicitor of plant responses similar to those elicited by chewing herbivores, resulted in a decrease in the abundance of thrips on tomato (Thaler et al. 2001). Herbivore-induced plant responses were also found to reduce thrips feeding compared to un-induced control plants in the absence of prey (Agrawal et al. 1999). In contrast, Rodriguez-Saona and Thaler (2005) investigated the effects of herbivore-induced responses on the abundance of arthropods on tomato and found that patch type (i.e., induced vs un-induced) did not affect the abundance of thrips. However, because thrips are omnivores, prey availability may explain why patch type did not affect abundance (Agrawal et al. 1999).

We previously reported that tobacco plants treated with *H. virescens* regurgitant release significantly higher levels of volatile nicotine compared to those treated with *H. virescens* saliva or induced by caterpillar feeding (Delphia et al. 2006). Thus, we suspected that the similar pattern of thrips distribution and ovipositional preferences observed in this study might be explained, in part, by differential nicotine induction in plants treated with *H. virescens* saliva and regurgitant. In our choice assays, thrips preferred plants encircled by blank (control) septa compared to those encircled by septa releasing nicotine (Fig. 5), and more larvae were also found on the control plants, suggesting that nicotine has a significant effect on thrips behavior. This finding is consistent with studies demonstrating that induced plant volatiles can repel herbivores, such as ovipositing moths and aphids (Bernasconi et al. 1998; De Moraes et al. 2001).

Other authors have previously suggested a role for caterpillar saliva in suppressing induced plant defense mechanisms (Musser et al. 2002; Na and Chenzhu 2004; Bede et al. 2006). For example, glucose oxidase, an enzyme first identified from the saliva of the corn earworm, *Helicoverpa zea*, and subsequently found in other caterpillar species, suppresses the wound-inducible production of foliar nicotine in tobacco, *N. tabacum* (Musser et al. 2002). It is possible that foliar nicotine, which increases upon mechanical wounding (McCloud and Baldwin 1997; Musser et al. 2002), as well as other non-volatile metabolites (Duffey and Stout 1996), likely contributed to thrips distribution and ovipositional preferences observed in our experiments.

In summary, our results offer insights into plant responses to feeding by piercing–sucking insects, simultaneous feeding by herbivores with different feeding habits, and the influence of induced plant responses on subsequent herbivore behavior. Tobacco plants responded to all three levels of thrips feeding damage by releasing a volatile blend distinct from that released in response to caterpillar feeding. Simultaneous feeding induced the release of the same 11 compounds as caterpillar feeding alone; however, two compounds were produced in greater quantities. Induction of plant defenses had significant impacts on the distribution and ovipositional preferences of WFT: significantly more adults were found on unwounded control plants in both thrips choice tests, and more thrips were found on plants damaged by caterpillars and plants treated with caterpillar saliva compared to plants treated with caterpillar regurgitant. Furthermore, thrips preferred to oviposit into unwounded control vs wounded plants or plants treated with caterpillar regurgitant. These differences may be explained, at least in part, by the apparent repellant effect of nicotine, as significantly fewer adult and larval thrips were found on plants encircled by septa releasing volatile nicotine compared to those encircled by blank septa.

Foliar Phenolics are Differently Associated with *Epirrita autumnata* Growth and Immunocompetence

Abstract The quality of available food may affect insect herbivores directly (via growth and survivorship) and/or indirectly (by modifying insect vulnerability to parasitoids and pathogens). We examined the relationship between different phenolic compounds, belonging to various phenolic groups, in *Betula pubescens* spp. *czerepanovii* (mountain birch) foliage and the larval performance of the geometrid *Epirrita autumnata* (autumnal moth). Direct effects on insect performance were described by pupal weight, developmental rate, and survivorship; indirect effects were described by the encapsulation rate of an implant inserted into the insect hemocoel, a commonly used way to describe insect immune defense. We found profound differences in the effects of different phenolic categories: several individual hydrolyzable tannins were associated positively with larval performance but negatively with level of immune defense, whereas flavonoid glycosides were inversely related to larval survival but showed no association with the larvae immune defense.

Introduction

Since the classic paper by Feeny (1970), many analyses of the chemical defenses of woody plants have focused on phenolic compounds. The results have been variable; correlations between individual phenolic compounds or groups of compounds and insect performance have often ranged from negative to zero, but positive correlations have also been reported (Karban and Baldwin 1997). Although it is possible, in a single study, to find negative correlations between individual phenolic compounds and insect performance, extensive

studies of foliar chemistry in *Betula pubescens* spp. *czerepanovii* (Orlova) Hämet-Ahti (mountain birch), have not identified any particular compound that would consistently explain the performance of herbivorous insects (reviewed in Haukioja 2003).

This failure to identify defense mechanisms contrasts strongly with the situation in laboratory studies, often using *Arabidopsis* or agricultural plants. These studies have established sophisticated general defense cascades (Karban and Baldwin 1997), which often utilize indirect defenses, i.e., recruiting parasitoids and predators to attack the herbivores (Havill and Raffa 2000), thus protecting the plant (Agrawal 1999).

Outbreaks of herbivorous insects are characteristic of many ecosystems. If the defense mechanisms of a plant play a role in the population dynamics of its herbivores, then the level of defenses should increase at and after peak herbivore density. Attempts to demonstrate this have given indications that the defenses of woody plants indeed function in a delayed density-dependent way (Benz 1974; Kaitaniemi et al. 1998). There is, however, no consensus as to the importance of plant defenses in the population dynamics of the herbivore. Uncertainties as to which plant traits should be measured have made it difficult to find out whether phenolic compounds, or plant defenses in general, are a factor contributing to or driving herbivore population outbreaks and cycles (Haukioja 2005a, b).

Another reason for a skeptical attitude toward the importance of induced plant defenses behind defoliator outbreaks and cycles is that time series models have repeatedly shown that parasitism seems to be sufficient to explain declines in population density (see examples in Berryman 2002). These analyses search for factors with delayed, negative density dependence, implicitly suggesting that the increase phase does not demand any explanation at the chemical level. Kapari et al. (2006), however, have demonstrated that during the early increase phase of the *Epirrita autumnata* (Bkt.) Lep., Geometridae (autumnal moth) cycle, the immune defense of this natural and important defoliator of the *B. pubescens* varies among individual host trees. Interestingly, the index of immune defense was higher in trees with artificially introduced larvae in the previous year than in control trees, many of which still were devoid of larvae. Because the increase phase of the *E. autumnata* cycle is characterized by a low level of parasitism (Klemola et al. 2004), this result suggests an unanticipated connection between induced changes in plant defense and the resistance of defoliators toward their enemies (parasitoids and diseases). It also implies that defoliator outbreaks and cyclic peaks may be facilitated, perhaps even caused, if defoliators benefit from the compounds produced by the plants against them (Haukioja 2005b).

The effects of host plant chemistry in tritrophic interactions have been studied mainly in herbaceous plants and in insect–pathogen systems (reviewed in Cory and Hoover 2006). Often, individual phenolic compounds in food inhibit viral infection (Felton et al. 1987; Keating et al. 1990; Young et al. 1995; Hoover et al. 1998) but not always (Roth et al. 1997; Lindroth et al. 1999). Chlorogenic acid in the diet increases the toxicity of bacteria (Ludlum et al. 1991). Some alkaloids have antifungal effects (Gallardo et al. 1990).

The diet of an herbivore also affects parasitoids (e.g., in *Populus*; Auerbach and Alberts 1992; Holton et al. 2003; Parry et al. 2003), and the effects of individual secondary chemicals on parasitoids are potentially important (Ode et al. 2004; Ojala et al. 2005). Different food-quality-dependent defense mechanisms against predators are common in herbivorous insects: sawflies, for instance, are better at protecting themselves against ants if the food plant contains abundant resin acids (Bjorkman and Larsson 1991), and *Chrysomelidae* larvae are able to secrete a repellent, which contains compounds obtained from the food plant (Hilker and Schulz 1994). In woody plants, the high levels of foliar hydrolyzable tannins made *Lymantria dispar* larvae more resistant against their viral diseases (Hunter and Schultz 1993; Keating et al. 1988, 1990; but see also Lindroth et al.

1999). In contrast, phenolic glycoside salicin increased *L. dispar* larval susceptibility to viral infection (Cook et al. 2003).

To determine how secondary chemicals directly and indirectly affect an insect defoliator, we analyzed ca. 50 phenolic compounds of birch foliage in the early phase of the natural population cycle of the geometrid *E. autumnata*. The compounds covered the main phenolic groups: condensed tannins (proanthocyanidins), hydrolyzable tannins (including ellagitannins and gallotannins [galloylglucoses]), *p*-coumaroylquinic acid derivatives, and flavonoid glycosides. We tested whether phenolics correlate with the indirect and direct resistance of *B. pubescens* during the early increase phase of a defoliator population. We correlated the contents of phenolic compounds with larval survivorship, pupal weight, and duration of the larval period (to detect associations relating to direct defenses), and with insect immune defense, measured as the encapsulation rate (to detect associations relating to indirect defenses). The main results demonstrate that several individual hydrolyzable tannins are associated positively with larval performance but at the same time negatively with level of immune defense.

Methods and Materials

Species Betula pubescens spp. *czerepanovii* (mountain birch) is the dominant tree in Northern Finland, and forms the tree line in NW Europe (Kallio and Mäkinen 1978). The most harmful herbivore of is *Epirrita autumnata*, which has cyclic large-scale outbreaks (Tenow 1972; Ruohomäki et al. 2000). *E. autumnata* has several species of parasitoids (Ruohomäki 1994; Ruohomäki et al. 2000) and pathogens (Bylund 1995).

Setup In the summer of 2002, 100 mature mountain birches were randomly selected from a natural population near the Kevo Subarctic Research Station (Northern Finland, 69°45′N, 27°01′E), as described in Kapari et al. (2006). The birches were mature with at least three ramets (stems). During that field season, we reared *E. autumnata* larvae in half of the trees. Larvae were reared in two mesh bags on different branches of each tree. Control trees had empty mesh bags attached. During the next field season (2003), 60 of these 100 trees (30 control and 30 larval trees) were randomly selected for the experiment.

The experiment was conducted in 2003 by attaching one mesh bag to a branch on the same trunk that was bagged the year before. The branches selected were different from those bagged in 2002. Each bag contained at least 150 leaves (at least 50 short shoots). At the time of leaf flush at the end of May, 10 (in 2002) or 15 (in 2003), newly hatched moth larvae were released into each bag: 20 larvae per tree in 2002, and 15 in 2003. Each bag contained an identical mixture of the *E. autumnata* broods. At the end of the larval period, the bags were checked daily. Larvae were collected when they started to pupate and were placed individually in plastic vials embedded in moist moss. The duration of the larval period was recorded for each larva (N=374). After 7 d as a pupa, the moth pupa was weighed and sexed (N=368) and its encapsulation rate was measured (N=356).

The level of insect immune defense was estimated by a commonly used technique that measures the efficiency with which insect hemocytes encapsulate a foreign object in their hemocoel (see, e.g., Vainio et al. 2004; Rantala and Roff 2005). We inserted an implant (a nylon monofilament, 2 mm long, 0.20 mm in diameter, rubbed with sandpaper) into the hemocoel of 1-wk-old pupae. Pupae were incubated +14°C for 1 hr to allow encapsulation and then frozen in liquid nitrogen (the method is described in detail in Kapari et al. 2006). Later, the implant was removed and photographed from three different angles under a light

microscope with a digital video recorder. As a measure of encapsulation rate, we used the average gray values of three video pictures (the observed gray values were subtracted from the gray value of a clean implant (see details in Kapari et al. 2006). The ability to encapsulate abiotic material is related to the ability to encapsulate a parasite (Paskewitz and Riehle 1994; Gorman et al. 1996). Previous studies with the *E. autumnata* suggest that the encapsulation rate of nylon monofilament is associated with resistance against an entomopathogenic fungus (Rantala and Roff, unpublished data).

Analyses To determine the chemical properties of *B. pubescens*, we measured the concentrations of condensed tannins (proanthocyanidins), 24 hydrolyzable tannins (12 gallotannins [galloylglucoses] and 12 ellagitannins), 15 flavonoid glycosides, 4 *p*-coumaroylquinic acid derivates, and 2 catechins from the leaves (Table 1).

A total of 6–10 leaves from short shoots were sampled randomly throughout the canopy of the experimental trees (within 2 hr on the morning of June 27 2003) when larvae were on average at the beginning of their last (fifth) instar. Leaves were sealed in plastic bags and transported to the laboratory in a cooler; they were weighed and freeze-dried (72 hr). Dried leaves were reweighed, and their initial water content was determined from the fresh and dry weight of the samples. Dry leaf samples from each tree were then homogenized to a powder and stored in plastic vials at −20°C.

A sample of the birch leaf powder (30.0±1.0 mg) was placed in a plastic 1.5-ml Eppendorf tube, and 0.65 ml of 80% aqueous acetone were added. The sample was allowed to stand for 30 min at room temperature with continuous stirring (1.5 U, Vortex, Genie 2). The homogenate was centrifuged for 10 min at 2,500×*g*, and the first portion of extract was transferred into a 2.0-ml plastic Eppendorf tube. The pellet was reextracted with 0.65 ml of 80% acetone, and then twice more with the same volume of 100% acetone. All extracts were combined, and the acetone was removed in a vacuum concentrator (Concentrator 5301, Eppendorf AG, Germany). The resulting aqueous phase was frozen and lyophilized for 24 hr. The insoluble residue, including proteins, starch, cellulose, lignin, etc., was dried under a vacuum for 24 hr and weighed, and the proportion of acetone-insoluble compounds in the sample was determined.

The lyophilized extract was dissolved in 1.0 ml of the chloroform/methanol/water mixture (50/30/20, v/v/v) and vortexed for 25 min. Then 0.5 ml of 20% aqueous methanol was added. The forming biphasic system was vortexed for 10 min and centrifuged for 10 min at 2,900×*g* (+4°C) to separate the two solvent phases (chloroform/methanol and methanol/water). The methanol/water fraction of polar compounds was concentrated in a vacuum concentrator to remove methanol, and the water phase was frozen and lyophilized. The dry residue of polar compounds was dissolved in 0.7 ml of water, centrifuged for 20 min at 2,900×g, and stored at −20°C.

Individual phenolics in the fraction of polar compounds (0.1 ml) were studied by using the high-performance liquid chromatography (HPLC) diode-array detection system as in Salminen et al. (1999), except that the solvents used were (1) 0.05 M of H_3PO_4, and (2) acetonitrile. A selected set of samples was also analyzed with HPLC electrospray ionization mass spectrometry as in Salminen et al. (1999), except that the data system used was Analyst Software 1.1. Phenolics were identified on the basis of their UV, mass spectra, and retention times.

For the quantification of polar phenolics, the HPLC raw data of all samples were exported in COWTool software (COWTool version 1.1., Department of Biotechnology, Technical University of Denmark, Denmark) in text format and subjected to baseline correction to reduce the noise level. To correct retention time differences among different samples, the chromatograms derived from each sample were later aligned against the master

Table 1 Means and standard deviations of concentrations of compounds measured in *B. pubescens* spp. *czerepanovii* (mountain birch) leaves

Name of Compound	Mean	SD	Encapsulation	Weight	Development Rate	Survival
Flavan-3-ols						
Condensed tannins (proanthocyanidins)	98.39	22.73				−0.25
plus-Catechin	23.38	5.8		0.29		−0.36
Catechin derivate	2.96	1.49				
Gallotannins (hydrolyzable tannins)						
1,2,3,4,6-penta-*O*-galloyl-*β*-D-glucose	19.67	10.85		0.34		
1,2,3,6-tetra-*O*-galloyl-*β*-D-glucose	5.58	4.07				
1,2,6-tri-*O*-galloyl-*β*-D-glucose	28.59	19.93				
Digalloylglucose	24.42	15.27	−0.25		0.20	
1-*O*-galloyl-*β*-D-glucose	120.5	76.54	−0.29			
Tetragalloylglucose	37.94	26.99	−0.26

trans-5-*p*-Coumaroylquinic acid	3.83	5.14				

Means and standard deviations were estimated with bootstrap. The correlations between secondary compounds of birch and larval traits (encapsulation rate, pupal weight, and larval development rate, and survival) were calculated with bootstrap. Only those bias-corrected correlation coefficients are shown whose 95% confidence limits do not include zero. Content of low molecular mass phenolics is expressed as a peak height per 1 g of dry mass; condensed tannin content is measured as milligram per 1 g of dry mass.

HHDP = Hexahydroxydiphenoyl

chromatogram of polar phenolics. The processed raw data were exported in Excel software and used to determine the retention times and heights of all phenolic peaks. The relative content of individual phenolics was calculated as peak height per 1 g of dry mass of the leaf sample.

To determine the condensed tannin (proanthocyanidin) content, 0.05–0.1 ml of the polar fraction was used (Ossipova et al. 2001).

Statistical Analyses Phenolic compounds used in the statistical analyses, with means and standard deviations of the concentrations, are shown in Table 1. Four compounds (1-6-di-galloyl-glucose, tetragalloylglucose, pedunculagin, and pedunculagin derivative) had two isomers. We present them as the sum of these two isomers, and used their combined content in statistical analysis.

Tree-specific least square means were calculated for each dependent variable (encapsulation rate, pupal weight, duration of larval period, and larval survival) with ANOVA. For encapsulation rate values (mean=47.6, SD=9.7) and for duration of the larval period (mean=44.8 d, SD=2.2), the tree-specific means were computed including sex as a random factor in the model. The effect of sex on pupal weight (mean=57.4 mg, SD=8.1) was removed by transforming male weights into female weights by using the formula given in Haukioja and Neuvonen (1985). In the original data, mean pupal (female) weight was 57.9 mg (N=368, SD=10.6), mean duration of the larval period was 44.2 d (N=374, SD=3.0), and the mean encapsulation rate was 46.0 (N=356, SD=18.1). Survival was measured as the number of larvae in one tree surviving until pupation. Survival percentages ranged from 0 to 93%, with a mean of 42% (SD=20) (Kapari et al. 2006).

Other things being equal, a short larval period in *E. autumnata* indicates good growth (Kause et al. 1999a, b). To help interpret growth rate, we constructed a new variable, the development rate, defined as the reciprocal of the duration of the larval period (in days). Thus, for each variable (pupal weight, survival rate, and developmental rate), a positive correlation with an individual compound indicates that larvae did well.

Correlations between tree-specific least square means and concentrations of phenolics were calculated as *Spearman's* nonparametric correlations with the PROC CORR (SAS Institute 1990), as the concentrations of compounds were not normally distributed. We used *bootstrap* analysis to estimate the 95% confidence limits for individual correlation coefficients (Dixon 2001). Bootstrap estimates the precision of the correlation coefficient by creating random resamples from the data. With bootstrap, the distribution of the data is better taken into account than by using *Bonferroni* correction. If zero was not included in the 95% confidence limit, we assumed that the correlation coefficient differed from zero. The 95% confidence limit in our data was on average ±0.24. In the bootstrap analysis, we used 200 resamples and the % boot macro. In Fig. 1, we marked every individual correlation into its biochemical group. Larval treatment of the previous year did not affect the concentrations of compounds. The treatment or the sex of the larvae did not significantly affect the correlation coefficients.

Results

The immune response measured by encapsulation rate correlated negatively with 8 (out of 24) individual hydrolyzable tannins in birch foliage (mean correlation coefficient −0.15).

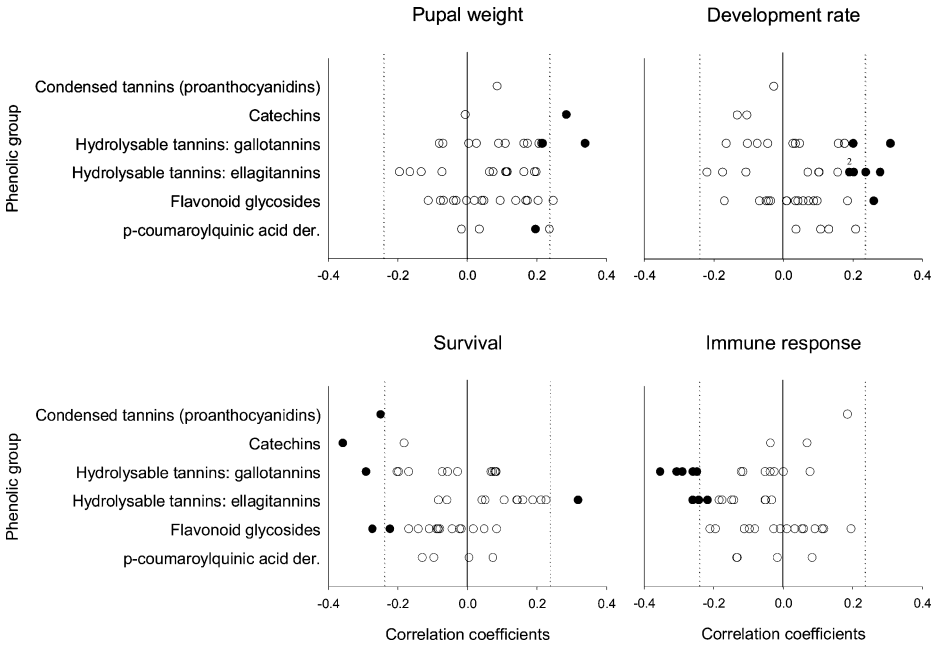

Fig. 1 Overview of correlations between *E. autumnata* (autumnal moth) traits and phenolic contents in *B. pubescens* spp. *czerepanovii* (mountain birch) foliage. The figure shows the correlation coefficients of individual phenolics (belonging to the condensed tannins [proanthocyanidins], catechins, hydrolyzable tannins [gallotannins and ellagitannins], flavonoid glycosides, or *p*-coumaroylquinic acid derivates) with *E. autumnata* traits (pupal weight, larval development rate, larval survival, and pupal encapsulation rate). Filled circles represent correlations significantly different from zero. A number 2 indicates two overlapping filled circles. The dotted line represents the mean 95% confidence limit around zero

Hydrolyzable tannins had mostly positive associations with the other moth traits. There was a positive correlation with pupal mass (0.08) and with larval development rate (0.08). In addition, the survival rate of the larvae was positively correlated with the contents of one type of hydrolyzable tannins, ellagitannins (0.12), but not with the other type, i.e., gallotannins (−0.05) (Fig. 1).

Condensed tannins had a negative association with larval survival (−0.23) but no relationship to larval encapsulation rate (0.19). The correlation coefficients between condensed tannins and pupal weight (0.09) and the larval development rate (−0.03) were close to zero, suggesting that condensed tannins had no direct impact on the growth of the *E. autumnata* (Fig. 1).

Flavonoid glycosides were generally negatively associated with larval survival (−0.08) and positively with pupal weight (0.06) and larval development rate (0.04). In contrast to hydrolyzable tannins, we did not detect any relationship between flavonoid glycosides and the immune response of the *E. autumnata* (−0.01) (Fig. 1).

Discussion

Within all phenolic groups, we found large variation in the correlations of individual compounds with moth traits. Some trends, however, were obvious, the most remarkable being the negative association between hydrolyzable tannins and the immune response measured as the melanotic encapsulation rate. We also noted that hydrolyzable tannins were positively related to pupal weight and larval development rate, and that flavonoid glycosides were negatively related to larval survival.

The phenolics compounds of *B. pubescens* spp. *czerepanovii* leaves often represent more than 20% of leaf dry weight, the bulk of the secondary compounds in leaves. There are dramatic shifts in the proportions of different phenolic groups during leaf growth and maturation. Flavonoid aglycones are a dominant phenolic group in bursting buds (up to 4% leaf dry mass), whereas young leaves are characterized by high levels of hydrolyzable tannins and flavonoid glycosides. Some flavonoid glycosides correlated negatively with larval mortality. In mature leaves, levels of hydrolyzable tannins tend to decrease or stay unchanged (Salminen et al. 2001) whereas levels of condensed tannins increase markedly, reaching in some trees concentrations as high as 15–20% of leaf dry mass (Riipi et al. 2002; Haukioja 2003). In addition, during leaf maturation water and protein concentrations decline and the leaves become tougher (Haukioja et al. 2002). The fact that the chemical composition of mountain birch changes dynamically during the season complicates the interpretation of the correlation results (Riipi et al. 2002). Fortunately, despite the massive changes in the foliar chemistry during the season, individual birches consistently have either a relatively low or high content of phenolics (Riipi et al. 2004).

The levels of condensed tannins, the most abundant foliar phenolics, were negatively related to survival rate of *E. autumnata* larvae. This was unexpected because condensed tannins are sometimes considered to be defenses of mature leaves (but see Ayres et al. 1997). There were no other associations between foliar condensed tannins and moth traits. The negative association between survival and condensed tannins, together with the positive correlations between hydrolyzable tannins and larval performance, may at least partly reflect the dependence of *E. autumnata* larvae on young foliage. However, because most *E. autumnata* mortality occurs during the first instars and we did our chemical sampling at the beginning of the fifth (last) instar, it is difficult to draw explicit conclusions from the correlation results.

Traditionally, hydrolyzable tannins have traditionally been considered to play an important part in a plant's direct resistance against herbivores. In our study, however, the higher the concentration of hydrolyzable tannins (both gallotannins and ellagitannins), the heavier the pupae and the more rapid the larval development. This counterintuitive result has been observed earlier (Kause et al. 1999b). In other studies, however, a negative relationship between hydrolyzable tannins and larval performance has been found (Kause et al. 1999a, Ossipov et al. 2001).

Intriguingly, the relationship of hydrolyzable tannins on the immune response measured as the encapsulation rate was the reverse of the relationship on direct resistance. A possible explanation is that insect melanotic encapsulation is a resource-demanding process and may therefore trade off with insect traits relating to growth (Rantala and Roff 2005). The tannin composition of the larval diet could affect moth investment in growth and immune response.

The negative correlation between immune response and hydrolyzable tannins is interesting for two reasons. First, the direction of the correlation is the opposite of what would be intuitively anticipated and what has been found in a different system, consisting of oaks and gypsy moth and their viruses (Hunter and Schultz 1993; Keating et al. 1988, 1990; but see also Lindroth et al. 1999). Second, unpublished results have demonstrated a significant increase in hydrolyzable tannins in birch foliage during the peak phase of the *E. autumnata* cycle. If the negative within-year correlation between immune response and hydrolyzable tannins, which we found, also holds in among-year comparisons, this would suggest that foliar chemistry promotes escape of the herbivore from its enemies during the increase phase of the population cycle (leaves still relatively low in hydrolyzable tannins), but no longer at later stages of the cycle (high hydrolyzable tannin content).

Acknowledgements We thank the staff of the Kevo Subartic Research Station for making this study possible. Irma Saloniemi and Kari Saikkonen gave helpful comments on the manuscript. Ellen Valle checked the language. The study was supported financially by the Academy of Finland: project 212712 (EH), 206144 (TR), 201073 (VO), and 207294 (MJR). The experiments presented comply with the current laws of Finland.

Abstract Ultraviolet-B (UV-B) radiation has been increasing in temperate latitudes in recent decades and is expected to continue rising for some time. Enhanced UV-B radiation can change plant chemistry, yet the effects of these changes on mammalian herbivores are unknown. To examine the influence of enhanced UV-B radiation on nutrition of a specialist and generalist hindgut fermenter, we measured nutritional and chemical constituents of three common North American range plants, big sagebrush (*Artemisia tridentata*), yarrow (*Achillea millefolium*), and bluebunch wheatgrass (*Pseudoregneria spicata*), and how these changes influenced *in vitro* dry matter digestibility and *in vivo* digestibility by pygmy rabbits (*Brachylagus idahoensis*) and eastern cottontails (*Sylvilagus floridanus*). Forages were irradiated for 3 mo with ambient (1×) or supplemental (1.6×) UV-B radiation representing a 15% ozone depletion for Pullman, WA, USA. Enhanced UV-B radiation had minimal effects on the nutritional content and the tannin-binding capacity of forages. Similarly, the terpene concentration in sagebrush and yarrow was not affected by higher UV-B irradiances. Flavonoid compounds increased in sagebrush but decreased in yarrow. Rabbit preference and intake was not affected by treatment levels for any forage species and no differences were found between treatments for dry matter, fiber, protein digestibility, and apparent digestible energy.

Introduction

Stratospheric ozone (O_3) depletion has led to enhanced surface ultraviolet-B (UV-B; 280–320 nm) radiation at temperate latitudes of both hemispheres in recent decades (McKenzie et al. 1999; UNEP/WMO 2002), and full recovery of the ozone column is not expected before 2050 (Anonymous 2000; Schrope 2000). Enhanced UV-B radiation can reduce growth and yield and alter photosynthesis in terrestrial plants (Reddy et al. 2004), change plant morphology, including height, leaf area, leaf waxes, and epidermal layers (Liakoura et al. 2003), and damage deoxyribonucleic acid (DNA) and photosystem II (PSII) (Keiller et al. 2003). However, the primary effect of enhanced UV-B radiation on plants seems to be changes in carbon partitioning from growth pools to secondary metabolic pathways (Tegelberg et al. 2002; Warren et al. 2002a, b; Bassman 2004).

Changes in plant secondary metabolites have the potential to influence herbivores that eat them, by reducing palatability, causing toxicity, or altering intake and digestibility by either inhibiting rumen bacteria or interfering with the animal's metabolism (Launchbaugh 1996). Behavioral, morphological, and physiological adaptations of herbivores influence their ability to avoid or tolerate plant secondary metabolites. Specialist herbivores are expected to have mechanisms for tolerating large amounts of chemicals produced by plants for which they are specifically adapted, whereas generalists are expected to avoid plant secondary metabolites or mix diets so as to acquire only small amounts of a variety of chemicals (Launchbaugh 1996; McCloud and Berenbaum 1999; Sorensen and Dearing 2003). The response of specialist and generalist herbivores to chemical components of plants altered by enhanced UV-B radiation has been studied in invertebrates (McCloud and Berenbaum 1999; Warren 2002a) but not in mammals.

In this study, we investigated the effects of enhanced UV-B radiation on secondary metabolites of three forage species common to northwestern rangelands (i.e., big sagebrush [*Artemisia tridentata*], yarrow [*Achillea millefolium*], and bluebunch wheatgrass [*Pseudoregneria spicata*]) and the nutritional response of two lagomorphs that occupy these rangelands. The pygmy rabbit (*Brachylagus idahoensis*) is a specialist feeder on terpene-containing sagebrush (Thines et al. 2004), whereas the eastern cottontail (*Sylvilagus floridanus*) is a generalist herbivore that eats a wide variety of grasses, forbs, and shrubs (Warren and Kirkpatrick 1978). Both were used previously in a nutritional diet choice study (Shipley et al. 2006). We expected that enhanced solar UV-B radiation would induce production of secondary plant metabolites and/or changes in nutritional quality that in turn would alter the palatability, intake, and digestibility of the food. Our objectives were to: (1) determine the effects of enhanced solar UV-B radiation on the concentration of predominant secondary compounds in sagebrush, yarrow, and bluebunch wheatgrass; (2) quantify the effects of enhanced UV-B radiation on nutritional quality of these same forage species; and (3) quantify the response for a specialist and generalist mammalian herbivore through preference and digestibility.

Materials and Methods

Plant Material and Growth Conditions The study was conducted both in a glasshouse and the in field at E. H. Steffen Center on the Washington State University campus in Pullman, WA, USA (46°44′N, 117°10′W, elevation 777 m) during the winter and summer of 2004. We selected a native shrub, forb, and grass to cover a range of nutritional qualities and secondary plant compounds. Big sagebrush (*Artemesia tridentata*) produces abundant

terpenes. This plant can comprise up to 98% of the diet of the pygmy rabbit, whereas the cottontail consumes only trace amounts (Thines et al. 2004). Bluebunch wheatgrass (*Pseudoregneria spicata*) contains few plant secondary compounds but has thick cell walls containing cellulose and lignin, and yarrow (*Achillea millefolium*) is a plant known also for its terpene and tannin content (Chandler et al. 1982).

We germinated unstratified seeds of sagebrush and yarrow in pots (Ray Leach container super cell, 164 cm^3, Stuewe and Sons, Corvallis OR, USA), and bluebunch wheatgrass in flats (50.8×35.6×8.9 cm) with a standard nursery-potting medium (Sunshine Mix #4, Sungro Horticulture, Bellevue, WA, USA). Plants were watered and fertilized with a commercial liquid fertilizer containing N, P, and K (20-20-20) and micronutrients. We extended the photoperiod in the glasshouse to 16 hr with high-pressure sodium, high-intensity discharge lamps (HPS/HID, 1000 W).

After seeds germinated, we exposed plants to two UV-B treatments supplied over an 8-hr period centered at solar noon and provided by Q-panel UV-B-313 fluorescent lamps (Q-Panel, Cleveland, OH, USA). Treatment levels included: 1) ambient (1×) biologically effective UV-B radiation at Pullman, WA on the summer solstice (7.5 kJ kJ^{-m} d^{-1}), or 2) 1.6× ambient supplemental UV-B radiation to simulate a 15% ozone depletion over Pullman, WA. We determined biologically effective UV-B radiation based on the new plant action spectrum of Flint and Caldwell (2003).

Sagebrush and yarrow were grown in the glasshouse during late winter and spring of 2004. Four UV-B lamps were mounted in frames (1.25×1.25 m) and suspended over plants. We adjusted the frame distance above the canopies to alter radiation levels by using an Optronics 754 spectroradiometer to measure UV-B radiation (Optronics Laboratories, Orlando, FL, USA). Lamps were filtered with 0.13 mm thick clear cellulose acetate film (transmission ≥292 nm) that were presolarized for 6 hr to stabilize transmission of filters. At 1-wk intervals, we replaced filters, rotated plants around the glasshouse to minimize location effects, and adjusted lamp height to maintain correct UV-B treatment levels.

We also grew bluebunch wheatgrass in flats banked with local soil to maintain root temperatures in an open field adjacent to the glasshouse during the summer of 2004. The same two treatments were examined. In the field, treatments were supplied by a stepped square-wave lamp system with eight UV-B lamps mounted in 1.2×2.4 m metal frames adjusted weekly to maintain the correct UV-B level. For control treatments, we filtered lamps with 0.13 mm polyester film (absorbs ≤320 nm) and plants only received ambient solar UV-B. Enhanced UV-B radiation treatment lamps were filtered with 0.13 mm cellulose acetate. We changed filters weekly and monitored radiation throughout the growing season to match current ambient or ambient plus 1.6× UV-B radiation.

Foliar Sampling and Nutritional Constituents Plants were harvested before the majority of flowering and after 12 wk of treatment. Because rabbits used in this study use all parts of the plants, we harvested both leaves and stems, leaving a 3-cm stubble. We randomly selected one flat (yarrow and bluebunch wheatgrass) or one tray of containers (sagebrush) from each lamp frame (to compose five or six samples from each treatment at the midpoint of animal trials) for analyses of nutritional quality and chemical components. Samples for terpene analysis were collected between 1000 and 1130 hours to avoid diurnal variation in concentration, placed in airtight bags, frozen upon harvest to prevent breakdown of oils (−30°C), and then stored at −40°C. All other samples were lyophilized and stored in a −10°C freezer until analyses.

We evaluated samples for protein, energy, fiber, lignin, and *in vitro* dry matter digestibility (IVDMD). We determined neutral detergent fiber (NDF), acid detergent fiber

(ADF), and acid detergent lignin (ADL) of forages by using sequential detergent analysis (Goering and Van Soest 1970) with filter bags, sodium sulfite, and alpha amylase in an Ankom Fiber Analyzer (Ankom Technology, Macedon, NY, USA). Nitrogen content was determined by the Kjeldahl procedure (Bradstreet 1965), and crude protein (CP) content (%) was estimated as 6.25 times the nitrogen content (Robbins 1993). We used standard procedures for bomb calorimetry to determine gross energy content, and IVDMD was determined by using an Ankom Daisy II Incubator (Ankom Technology, Macedon, NY, USA).

Phytochemical Analyses We analyzed sagebrush and yarrow for tannin-binding capacity and terpenes. Tannin-binding capacity was determined by the bovine serum albumin (BSA) method (Robbins et al. 1987). To determine volatile terpenes, sagebrush (0.08 g) and yarrow (0.1 g) samples were extracted by using solid-phase microextraction (SPME) (Steffen and Pawliszyn 1996) with 4 ml ddH_2O and 0.65 g NaCl in a 25-ml flask. We stirred the solution at a rate of 1,100 rpm on a magnetic plate while a fused silica fiber coated with 65 um poly(dimethylsiloxane)/divinlybezene was exposed to the headspace for 35 min before injection. Splitless injection was completed over 5 min at 200°C into a Hewlett-Packard 5890II/5970 GC/MS equipped with a DB-1 60 m (0.32 mm with 0.25 μm film) column with helium as the carrier gas. Transfer line temperature and ion source was held at 250°C. We maintained column temperature at 33°C for 5 min, increased to 50°C at a rate of 2°C/min, and then to 225°C at a rate of 5°C/min. Initial identification was completed by comparing spectra with those present in the Wiley-NBS library. Further quantification and identification was accomplished by comparing sample retention times and using response factors generated from standards obtained from commercial sources (Fluka Chemicals, Milwaukee, WI, USA; Sigma-Aldrich Corporation, St. Louis, MO, USA; Indofine Chemical Company, Belle Mead, NJ, USA). Several selected compounds had mass spectra and retention data compared to the literature (Buttkus et al. 1977; Pearson 1977; Epstein and Gaudioso 1984; Hofmann et al. 1992; Gunawardena et al. 2002; Adams 2004).

Phenolic and flavonoid purification and quantification of the three forages was completed by using modified procedures of Miller (1995) that have also been utilized on pine and poplar trees (Warren et al. 2002b). We extracted lyophilized and ground plant tissue (0.5 g) with a solution of ethanol (80%) and formic acid (1%). This was then partitioned with ethyl ether to remove carotenoids and chlorophylls. The aqueous fraction was partitioned with ethyl acetate and a phenolic solution (20% ammonium sulfate, 20% ethanol, 2% metaphosphoric acid) into the acetate phase (flavonoids) and the aqueous phase (anthocyanins). We evaporated the ethyl acetate from the flavonoid fraction, and the remaining residue was dissolved in 2 ml of high-performance liquid chromatography (HPLC) grade methanol, filtered, and stored below 0°C.

We injected 10 μl of the extract onto a Dynamax UV-1 HPLC system (Varian, Inc. Walnut Creek, CA, USA) with a 5-μ C-18 column (150×4.6 mm, Varian, Inc. Walnut Creek, CA, USA) with detection at 254 nm. The mobile phase started (1.0 ml min^{-1}) at 80:10:10 (distilled water, 0.5% phosphoric acid, methanol) and was increased to 20:10:70 over 40 min. We maintained the 20:10:70 solution for 5 min. The column was cleaned with 100% methanol for 13 min and then re-equilibrated to the starting solution over 2 min. We quantified flavonoids by using response factors from standards with similar retention times on the same instrument and with the same injection method. External calibration was used, and major flavonoids compounds known to exist in plants (particularly in sagebrush and yarrow), were purchased from Sigma-Aldrich Corporation (St. Louis, MO, USA) and

Indofine Chemical Company (Belle Mead, NJ, USA). Compounds included esculin, chlorogenic acid, esculetin, scopoletin, coumarin, scoparone, luteolin-7-*O*-flucoside, apinegen-7-*O*-glucoside, quercetin, luteolin, 6-methyl luteolin, kaempferol, and apigenin.

For initial quantitative HPLC analysis of standards and samples, we used wavelengths 254, 280, and 320 nm. Final analysis was completed at 254 nm, which has been shown to be the UV-B wavelength useful in analyzing a wide range of phenolics in methanol or acidified methanol (Macheix et al. 1990; Waterman and Mole 1994).

Preference and Digestibility Feeding Trials Pygmy rabbits used for nutrition studies were bred in captivity at Washington State University from animals originally captured in Idaho. Six adult animals (two female, four male) ranging in age from 1 to 2 yr and in weight from 350 to 464 g were available from which 2–4 were used for each trial. Two female and two male eastern cottontails were captured on the grounds at E. H. Steffen Center. All were at least 1-yr old at capture and they ranged in weight from 950 to 1,283 g. When not used in experiments, animals were housed in stainless steel rabbit cages and fed an *ad libitum* (ad lib) maintenance diet, a mix of fresh forbs, tap water, and supplied with a mineral block. All experimental protocol and husbandry practices were approved by the WSU Institutional Animal Use and Care Committee (#3291).

We conducted preference trials to determine whether animals could detect and make decisions based on chemical changes induced by enhanced UV-B radiation. By using standard procedures for cafeteria-style preference tests, we offered foliage produced under ambient and enhanced UV-B regimes (Molloy and Hart 2002). Animals were gradually shifted from their maintenance diet to each experimental diet over 1–2 wk, and during the last 2 d of pretrial, we moved animals into metabolic crates. During trials, we offered equal amounts (dry mass basis) of tissue grown under ambient and enhanced levels of UV-B radiation for each day of 5 d per plant species to 2–3 adult pygmy rabbits and 3–4 adult cottontail rabbits. We offered fresh plant material 2–6 times per day to maintain freshness and to limit the release of volatiles from plants. Orts were dried and weighed to determine dry mass consumed. The software Prefer for Windows based on Johnson's (1980) method with usage and availability, was used to evaluate preference of plants treated with ambient vs. supplemental UV-B grown plants.

Separate total-collection digestion trials were used to determine if chemical changes enhanced by UV-B radiation had physiological effects on the two rabbit species. We gradually shifted animals from their maintenance diet to each experimental diet over 1 to 2 wk and isolated animals in metabolic crates 2 d before the start of trial. For each day of a 4- or 5-d digestion trial, we offered 2–4 adult pygmy rabbits and 3–4 adult cottontail rabbits fresh forage 2–6 times per day. Forages were corrected for dry matter each day, and we collected all urine, feces, and orts, and determined energy balance. During the sagebrush digestion trials, we supplemented both species of rabbits with dry pellets because the cottontails would not eat any sagebrush alone. Animals were offered 5% body weight of pellets, and animals consumed all pellets offered. Using standard procedures (Goering and Van Soest 1970; Robbins 1993), we calculated dry matter, fiber, protein, and apparent energy digestibility, and we compared between plant treatments for each species (ambient vs. enhanced UV-B irradiated plants) and animal species.

Statistical Analyses One-way analysis of variance (PROC GLM, SAS Institute, Inc., 2005) was performed to test for significant treatment effects on plant components as well as the response of animals. We tested for differences between treatments for all nutritional components and for each individual terpene and phenolic. Differences between treatment

Table 1 Mean and standard deviation of neutral detergent fiber (NDF, %), acid detergent fiber (ADF, %), acid detergent lignin (ADL, %), crude protein (CP, %11), energy (kJ/g), tannin-binding capacity (BSA, mg BSA ppt/mg), and *in vitro* dry matter digestibility (IVDMD, %) of sagebrush (*Artemisia tridentate*), yarrow (*Achillea millefolium*), and bluebunch wheatgrass (*Pseudoreogneria spicata*) irradiated with 1× and 1.6× UV-B radiation

An asterisk denotes a significant difference between radiation levels for that plant species (P=0.05).

and animal species were also tested by using treatment*species as the interaction. All percent data were arcsin-transformed before analyses.

Results

Forage Quality In general, the nutritional quality of forages was not affected by supplemental UV-B radiation. Neither yarrow or bluebunch wheatgrass showed any changes in neutral detergent fiber (NDF), acid detergent fiber (ADF), acid detergent lignin (ADL), crude protein (CP), energy, or *in vitro* dry matter digestibility (IVDMD) ($P>0.05$, Table 1). Only sagebrush showed changes with higher UV-B radiation, which caused lignin ($P=0.021$) and IVDMD ($P=0.018$, Table 1) to decrease. Sagebrush and yarrow showed no precipitate in the BSA assay, indicating no biological response to possible tannins in those plants.

Phytochemistry We identified 18 different volatile compounds from sagebrush and yarrow (Table 2). There was no significant change correlated with increased UV-B radiation for the major terpenes in either plant (Fig. 1) with the exception of E-β-santolina epoxide, which decreased ($P=0.002$) from 450 ng/ml to 55 ng/ml in yarrow treated with enhanced (1.6×) UV-B.

An asterisk denotes a significant difference in digestibility between rabbit species for that plant species (P=0.05)

Although found in lower concentration than in the dicots sampled, bluebunch wheatgrass contained a large number of phenolic compounds (Fig. 2), but only one was influenced by enhanced UV-B radiation (P=0.048). Sagebrush and yarrow phenolics, however, did respond to increased UV-B radiation. In sagebrush, eight of the 13 predominant phenolics increased with higher UV-B radiation (all P<0.035, Fig. 2). In contrast, seven of the 14 predominant phenolics decreased in yarrow (all P<0.046, Fig. 2).

Animal Response When simultaneously offered plants from each treatment, neither pygmy rabbits nor cottontails showed a preference for 1× or 1.6× UV-B irradiated plants of sagebrush (pygmy rabbits: F=1.00, P=0.42; cottontails: F=0.25, P=0.67), yarrow (pygmy rabbits: F=1.00, P=0.36; cottontails: F=1.00, P=0.39), or bluebunch wheatgrass (pygmy rabbits: F=1.00, P=0.42; cottontails: F=1.00, P=0.42). Similarly, in digestion trials where treatments were fed separately, rabbits also ate the same amount of treated and untreated plants (all P's>0.05, Table 3). After consuming plants, both rabbits also digested ambient and supplemental UV-B irradiated plants equally for each plant species (all P>0.05, Table 3). However, regardless of treatment, the larger cottontail rabbit was better able to digest yarrow and bluebunch wheatgrass than the pygmy rabbit. The cottontails achieved a higher dry matter (P=0.037) and protein (P=0.003) digestibility than pygmy rabbits fed yarrow (Table 3). During bluebunch wheatgrass trials, cottontails also achieved a higher dry matter digestibility (P=0.018), fiber digestibility (P=0.010), and apparent digestible energy (P=0.011, Table 3).

Discussion

UV-B radiation, artificially enhanced to the levels predicted for temperate North America representing a 15% ozone depletion, influenced flavonoid concentrations of a forb and shrub common to rangelands of North America, but had minimal effects on other aspects of nutritional chemistry. In turn, neither a specialist nor generalist lagomorph consuming these plants showed preference or digestive response to the UV-B treatments.

Phytochemistry In our study, as in previous ones (Tegelberg et al. 2002; Warren et al. 2002b; Ambasht and Agrawal 2003), the accumulation of flavonoids was the most common response to UV-B radiation. In sagebrush, eight of 13 flavonoids detected increased significantly with higher UV-B levels. Increases in flavonoids with UV-B radiation are expected, because they are known to protect plants by attenuating UV-B radiation in the leaf epidermis, thus reducing internal leaf damage (Brandt et al. 1995). Some flavonoids, such as triterpenoids, flavonoid-aglycones, kaempferol-2-0-β-glucuronic acid, and quercetin-3-0-β-glucuronic acid, can deter feeding by mammals (Halaweish et al. 2003; Laitinen et al. 2004), and others can increase fat excretion and reduce *in vitro* fermentation (Bravo et al. 1994). However, flavonoids are a diverse group of 4,500 compounds, and the effects of UV-B radiation on them may not be universal in plants. In our yarrow, seven of 13 flavonoids decreased, and in bluebunch wheatgrass, only one of 12 flavonoids decreased.

Condensed tannins comprise another subclass of phenolics. Condensed tannins are bitter, function as feeding deterrents, and can bind to proteins in plants, making some protein and energy functionally unavailable to herbivores that feed on them (Robbins et al. 1987). Higher UV-B radiation may compound the biological effects of tannins as plants growing in the shade of coniferous trees have shown lower levels of tannins than those growing in full

sun (Hartly et al. 1997). However, we detected no tannin-binding capacity of phenolics in either sagebrush or yarrow.

Terpenes are known to inhibit or destroy gut flora (Burritt et al. 2000), act as a feeding deterrent (Sinclair et al. 1988; Gershenzon and Croteau 1991), cause acidosis (Cork and Foley 1991), or act as a cue for animals to avoid more toxic secondary compounds (Bray et al. 1991; Lawler et al. 1999). Previous studies indicated that when UV-B radiation was filtered out, terpene concentration was altered in *Grindelia chiloensis* (Zavala and Ravetta 2002) and leaves of *Ocimum basilicum* (Johnson et al. 1999). However, in our experiments, enhanced UV-B radiation did not affect overall terpene composition and quantity in sagebrush or yarrow. Similarly, Tegelberg et al. (2002) found that enhanced UV-B radiation did not influence terpenes in *Betula pendula.* Plants may be less responsive to increases when exposed to a relatively high ambient level of UV-B radiation because target compounds and mechanisms may already be saturated at ambient levels of UV-B radiation (Day 2001).

Like flavonoids, lignin forms via the shikimate acid pathway, and gives structural support to plants. Lignin is insoluble and nondigestible by mammals and thus limits their ability to digest the plant cell wall (Van Soest 1994). Although little-studied, lignin in grasses and trees (Rozema et al. 1997; Cybulski et al. 2000) has been shown to increase with UV-B radiation. We expected plants that we irradiated with supplemental UV-B radiation to have more lignin, especially the grass that is not presumably defended by secondary compounds but rather by a thick cell wall. However, enhanced UV-B radiation did not alter any component of the cell wall (NDF, ADF, or lignin), except in sagebrush, where lignin declined by 21%. We harvested all plant tissue as new growth <120 days. At harvest, the stems of sagebrush were still green and nonwoody, and bluebunch wheatgrass was a lush green with only 3% lignin, which was lower than lignin content of bluebunch wheatgrass collected in the field during the spring (4–6%, Thines et al. 2004). Thus, any differences in lignin caused by UV-B in bluebunch wheatgrass might be only detectable at maturity.

When plants allocate resources to producing secondary plant metabolites, protein is sacrificed. A negative relation has been found between phenolics and nitrogen (Price et al. 1989), and protein and nitrogen decrease in various grasses, forbs, and tree species with enhanced UV-B radiation (Zavala and Ravetta 2002; Milchunas et al. 2004). However, although enhanced UV-B radiation altered flavonoids of sagebrush and yarrow, it did not alter protein content of any of the plants in our study.

Animal Response Although terpenes, phenolics, cellulose, and lignin can either be toxic or reduce the nutrients gained from forages by mammalian herbivores, the changes in these in plants exposed to enhanced UV-B radiation in our study were too small and inconsistent to influence the behavior and digestion of pygmy rabbits and eastern cottontails. In fact, the variation in plant chemistry caused by two levels of UV-B radiation was within the range of variation commonly experienced among plants, plant parts, and in different seasons by mammalian herbivores. For example, in a field study assessing pygmy rabbit forages, fiber content ranged from 39% in big sagebrush to 70% in needlegrass (*Stipa* spp.), and protein ranged from 5.4% in bluebunch wheatgrass to 10.9% in big sagebrush (Thines et al. 2004). Likewise, Thines et al. (2004) found that nutritional components differed significantly among seasons for four common pygmy rabbit forages including sagebrush and bluebunch wheatgrass. In fact, the differences found in nutritional components among seasons was greater than differences we detected in our measurements of plants grown under different amounts of UV-B. These data perhaps suggest that alterations in plant chemistry and

nutritional components caused by increasing UV-B levels are not likely to be greater than variations already found in nature.

If our rabbits did detect differences in plant chemistry caused by enhanced UV-B radiation, they may have been able to mitigate chemical effects by selecting plant tissue on a finer scale than measured in our experiment, i.e., subtly avoiding plants and plant parts with higher content of plant secondary metabolites and fiber. For example, other lagomorphs and rodents select plant parts that have higher protein and energy but lower concentrations of terpenes and phenolics (Gershenzon and Croteau 1991; Zhang and States 1991; Palo et al. 1992).

Additionally, mammalian herbivores, such as rabbits, that house microorganisms in their digestive tract, may not respond to changes in plant chemistry as dramatically as do monogastric mammals or insects, because microorganisms may be able to detoxify or ameliorate effects of plant chemistry and can adapt to changes in plant flora (Launchbaugh 1996). For example, monogastric rats demonstrated aversive behavior to kaempferol-2-0-β-glucuronic acid and quercetin-3-0-β-glucuronic acid extracted from leafy spurge (*Euphorbia esula*), whereas foregut-fermenting cattle did not (Halaweish et al. 2003). Although animals often need time to develop conditioned aversions to toxic chemicals through postingestive feedback (Provenza et al. 1992; Launchbaugh 1996), our pretrial period was designed to give the rabbits adequate time to detect and respond to increased levels of toxic plant chemicals.

In summary, responses of plant chemistry to UV-B radiation were neutral to mixed. Although flavonoids were consistently higher in sagebrush and lower in yarrow, such changes did not influence protein-precipitating capacity or *in vitro* dry matter digestibility. Thus, artificial application of UV-B radiation, representing a 15% ozone depletion (1.6×), did not alter the secondary compounds and nutritional components of sagebrush, yarrow, and bluebunch wheatgrass enough to change the behavior or digestion of a generalist and a specialist lagomorph.

Acknowledgments The authors thank Gary Radamaker for assistance with field work and maintenance of greenhouse plants. This project was funded with support of the United States Department of Agriculture's Ultraviolet-B Monitoring and Research Program at Colorado State University.

Inhibition of Proteinase Inhibitor Transcripts by *Leptinotarsa decemlineata* Regurgitant in *Solanum lycopersicum*

Susan D. Lawrence · Nicole G. Novak · Michael B. Blackburn

Received: 28 November 2006 / Revised: 21 February 2007 / Accepted: 14 March 2007 /

Abstract One mechanism by which plants defend themselves against insect herbivores is the production of plant proteinase inhibitors, which can inhibit digestion in the midgut, thus affecting growth and survival. In this work, the effect of Colorado potato beetle (CPB) [*Leptinotarsa decemlineata* (Say)] regurgitant on *Solanum lycopersicum* defenses was investigated. When regurgitant from fourth-instar CPB was applied to wounded *S. lycopersicum* leaves, the wound-induced transcripts for the proteinase inhibitors *pin1* and *pin2* were reduced. Boiling the regurgitant abolished its ability to reduce the *pin* transcripts. Ultrafiltration of the regurgitant demonstrated that it contained a component between 10 and 30 kDa molecular weight that inhibited wound-induced *pin1* and *pin2* expression, suggesting that it may be a protein. This may represent a mechanism that the CPB has evolved to elude the plant's induced response to infestation.

Keywords Herbivore · Colorado potato beetle · Regurgitant · Proteinase inhibitor

Introduction

The Colorado potato beetle [CPB; *Leptinotarsa decemlineata* (Say), Coleoptera: Chrysomelidae] is a serious pest of solanaceous crops in the USA. In *Solanum tuberosum* (potato), volatiles produced in the plant upon attack by CPB result in the attraction of the CPB predator *Perillus bioculatus* (F.) (Heteroptera: Pentatomidae) (Weissbecker et al. 1999). This response appears to be a part of the insect/plant interaction because mechanical wounding alone does not produce the same set of volatiles or attraction of the predator.

Elicitors isolated from the regurgitant of pest insects applied to mechanically wounded leaves often result in a plant response that mimics the response to insect feeding. For example, a β-glucosidase was isolated from *Pieris brassicae* (L.) regurgitant (Mattiacci et al.

1995). Volicitin (Albourn et al. 1997), a fatty acid–amino acid conjugate (FAC), is synthesized by the insect from a plant fatty acid and an amino acid from the insect (Pare et al. 1998). When placed on a wounded leaf, this component of *Spodoptera exigua* (Huber) saliva elicited volatiles similar to those produced by insect infestation rather than by mechanical injury. In addition, glucose oxidase (GO) from the salivary glands of *Helicoverpa zea* (Boddie) (Eichenseer et al. 1999; Musser et al. 2002) and additional FACs from other lepidopteran species (Pohnert et al. 1999; Halitschke et al. 2001) all either enhance or reduce defense responses when applied to a wounded leaf. Thus, it appears that a number of insect-produced secretions may affect plant response to insect attack.

Baldwin's lab (Halitschke et al. 2001; Schittko et al. 2001) has examined the effect of regurgitant from *Manduca sexta* (L.) on *Nicotiana attenuata*. They have isolated FACs that mimic the effect of the regurgitant (Halitschke et al. 2001). One gene coding for threonine deaminase, normally induced by wounding, was inhibited by regurgitant (Schittko et al. 2001). Other genes were amplified by regurgitant, whereas others inhibited by wounding were reduced further. Generally, nicotine expression was inhibited by GO (Musser et al. 2002), whereas FACs induced plant defense genes.

Little is known about the components of CPB regurgitant. Although regurgitant enhances peroxidase and polyphenol oxidase activity, ethylene is also increased in regurgitant-treated wounded leaves of potato (Kruzmane et al. 2002). We have tested the effects of CPB regurgitant on wound-induced genes in *Solanum lycopersicum* and have found that the wound-induced proteinase inhibitor transcripts *pin1* and *pin2* are inhibited by CPB regurgitant. In addition, the inhibitory component in the regurgitant appears to be between 10 and 30 kDa molecular weight (MW).

Methods and Materials

Plant Material Solanum lycopersicum var. Rutgers were germinated from seed and transplanted to individual 4-in pots containing Metromix® (Scotts, Marysville, OH, USA) and osmocote® (Scotts). Plants were grown for approximately 4 weeks in a greenhouse until they had at least eight leaves.

Regurgitant Colorado potato beetle were reared on *S. lycopersicum*. Regurgitant was collected from the oral cavity of fourth-instar CPB with a P200 Pipetteman (Gilson, Middleton, WI, USA). The regurgitant was centrifuged for 5 min at 10,000×*g*, and the supernatant was collected and stored at −80°C.

Wounding, Regurgitant Treatment, and Infestation Mechanical wounding involved crushing a leaf with pliers, while avoiding the major veins, at 1-cm increments. Regurgitant was diluted in water or phosphate-buffered saline at the concentration specified in the figure legends. One hundred microliters of diluted regurgitant per leaf was added within minutes to the wounds, and the plants were incubated for 4 hr unless otherwise noted. To test the activity after boiling, the regurgitant was resuspended at a 1:3 dilution with water and heat inactivated for 5 min at 100°C in a heat block. The boiled regurgitant was centrifuged for 1 min, and the supernatant was collected and applied to a wounded leaf. Regurgitant was centrifuged at 20,000×*g* for 20 min at 8°C, and 250 μl of the supernatant was subjected to ultrafiltration by using Microcon™ centrifugal filtration devices (Millipore, Bedford, MA, USA) with 3, 10, 30, and 100 kDa MW cut-off (MWCO) regenerated cellulose membranes. Samples were centrifuged at 7,000×*g* until sufficient material passed through the membrane

for assay. The filtrate was collected and frozen at −20°C until diluted and applied to wounded leaves.

Five hundred microliters of regurgitant was diluted with 2 ml of water and loaded onto a Sep-Pak Light™ C18 solid phase extraction cartridge (Waters, Milford, MA, USA) equilibrated with 5% acetonitrile (MeCN) in water. After the sample was loaded, the cartridge was washed with 3 ml of 5% MeCN and eluted stepwise with 3 ml each of 40, 80, and 100% MeCN. Each fraction was collected in a polypropylene tube, dried by vacuum centrifugation, dissolved in a small amount of ethanol, and brought up to 500 μl with water prior to assay. To determine the time course of CPB-infested plants, the fifth leaf from the bottom was covered with a fine mesh sleeve and ten third- to fourth-instar CPB larvae that had been starved for 4 hr were added. The insects were allowed to feed for 45 min, at which time they were removed and the plants were held for 0, 1, 2, 4, 7, and 24 hr. Approximately 10% of the leaf area had been eaten after 45 min of infestation.

RNA Isolation and Northern Blots RNA was isolated from treated leaves by rapidly freezing in liquid nitrogen using the methodology of Chang et al. (1993). Plant tissue was ground with a mortar and pestle and extracted with vigorous shaking in a buffer preheated to 65°C containing 2% cetyl hexadecyltrimethylammonium bromide, 2% polyvinylpyrrolidone, 100 mM Tris pH 8.0, 25 mM EDTA, 2 M NaCl, 0.5 g/l spermidine, and 2% β-mercaptoethanol. This mixture was chloroform extracted ×2. The aqueous layer was precipitated overnight at 0°C with 1/4 vol of 10 M LiCl. The pellet was collected by centrifugation at 11,950×*g* for 20 min and resuspended in 1.0 M NaCl, 0.5% sodium dodecyl sulfate, 10 mM Tris pH 8.0 and 1 mM EDTA. The RNA was extracted once with chloroform and precipitated in 2 vol of 95% ethanol.

RNA was run on formaldehyde denaturing agarose gels and transferred onto Hybond N+ (Amersham, Buckinghamshire, England) by using capillary transfer as described in Sambrook et al. (1989). *pin1* and *pin2* were acquired from the Boyce Thompson Institute Tomato EST Distribution Center (Ithaca, NY, USA) as LET41L12 and LET21I5, respectively. These cDNAs were cloned into pBluescript, and were amplified by PCR using the T7 and T3 promoter primers. ^{32}P-labeled *pin1* and *pin2* transcript was produced with an *in vitro* transcription kit from Ambion (Austin, TX, USA), and the unincorporated ^{32}P was removed by using NucAway spin columns (Ambion). Northern hybridization was performed with Expresshyb hybridization solution (Clontech, Palo Alto, CA, USA) and washed as described in the instruction manual. The ribosomal RNA (rRNA) probe came from J. Davis (University of Florida, Gainesville). It was cloned into pGEM-T, prepared as described for the other probes, and used to equalize loading of the lanes. Relative expression of *pin1* and *pin2* was calculated by quantifying volume in the band using Imagequant (Molecular Dynamics, Sunnyvale, CA, USA) and dividing by volume of the rRNA band. Each RNA sample contained material from two plants. For Figs. 2, 3 and 4, the experiments were duplicated, although the results of a single experiment are presented.

Results

Mechanical wounding induced *pin1* and *pin2* (Fig. 1). The samples from different experiments were divided by their control, so the relative expression represents the fold increase in expression. The addition of CPB regurgitant to the wounded leaf resulted in a reduction of the amount of wound-induced transcript present. This is particularly apparent

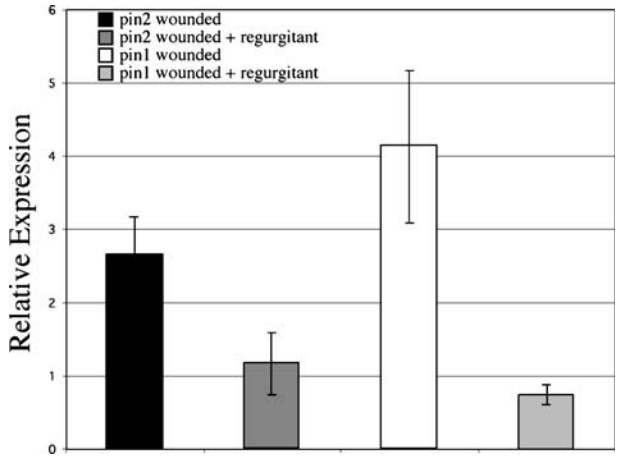

Fig. 1 Wound-induced *pin1* and *pin2* were inhibited by the addition of regurgitant. These data represent five separate experiments. The fifth or sixth leaf was wounded and regurgitant was added. Plants were incubated for 4 hr, at which time the wounded leaf was harvested and frozen in N_2. RNA was isolated and Northern blots were performed. To calculate relative expression between experiments, the wounded sample or the wounded plus regurgitant sample was divided by the control from the appropriate experiment. *Error bars* represent standard error. $N=5$ for wounded and $N=10$ for wounded plus regurgitant treatment

for *pin1*. Because the equal variance test failed for the *pin2* data, the nonparametric Mann–Whitney rank sum test was performed on the raw data with SigmaStat 2.0. This test showed that the addition of regurgitant to mechanically wounded leaves significantly lowered transcript levels for both *pin1* ($P=0.004$) and *pin2* ($P=0.028$) when compared to mechanical wounding alone. Boiling of the regurgitant before application to the wounded leaf inactivated the inhibitory factor (data not shown).

A time course was performed to determine whether the regurgitant is slowing the production of the transcript with time. Fig. 2 shows that the amount of *pin1* and *pin2* that is produced is greatest after 24 hr. Production of *pin1* and *pin2* is appreciably reduced at 8 and 24 hr by the addition of regurgitant.

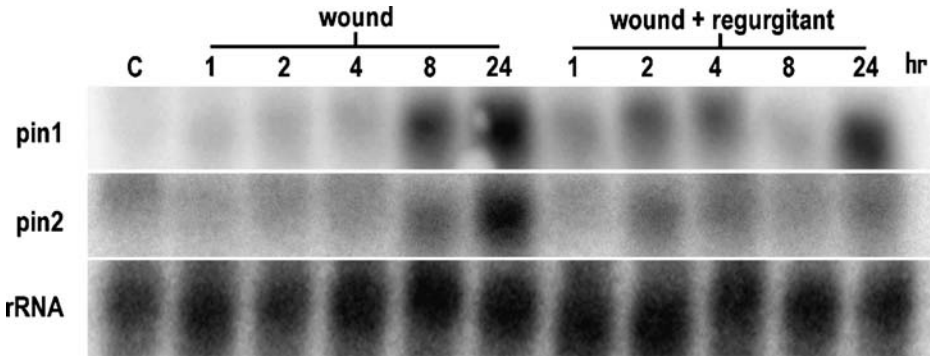

Fig. 2 Wound-induced *pin1* and *pin2* were inhibited by the addition of regurgitant at 8 and 24 hr. The sixth leaf from the bottom was wounded and 100 μl of regurgitant diluted in water 1:3 was or was not added. The plants were incubated for 0, 1, 2, 4, 8, or 24 hr. The wounded leaves were harvested and frozen in N_2. RNA was isolated and Northern blots were performed

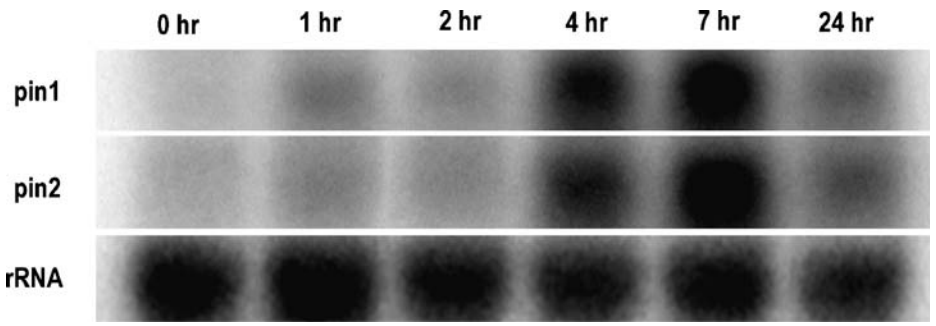

Fig. 3 Infestation of *S. lycopersicum* leaves with CPB resulted in the expression of *pin1* and *pin2* at 4 and 7 hr. The fifth leaf from the bottom was infested with ten third- to fourth-instar CPB for 45 min and held for an additional 0, 1, 2, 4, 7, or 24 hr. The wounded leaves were harvested and frozen in N_2. RNA was isolated and Northern blots were performed

Is the negative effect of the regurgitant apparent in leaves that have been infested by CPB? A time course was performed by using plants that had been infested for 45 min, after which approximately 10% of the leaf area had been eaten. The amount of leaf injured is less than the amount affected by our wounding regime, so it is difficult to compare wounding and infestation. Fig. 3 demonstrates that transcripts were indeed produced in leaves that have been infested with CPB. The amount of transcript for *pin1* and *pin2* peaked at 7 hr.

Finally, two different approaches were made to further characterize the component of the regurgitant responsible for the inhibition of *pin1* and *pin2* transcript. First, regurgitant was loaded onto a C18 solid phase extraction cartridge, and bound material was eluted with increasing concentrations of acetonitrile. No inhibitory activity was recovered using this approach. However, we also subjected regurgitant to ultrafiltration. The results are shown in Fig. 4. The inhibitory activity passed freely through a 30-kDa MWCO membrane, but not through 3- or 10-kD MWCO membranes.

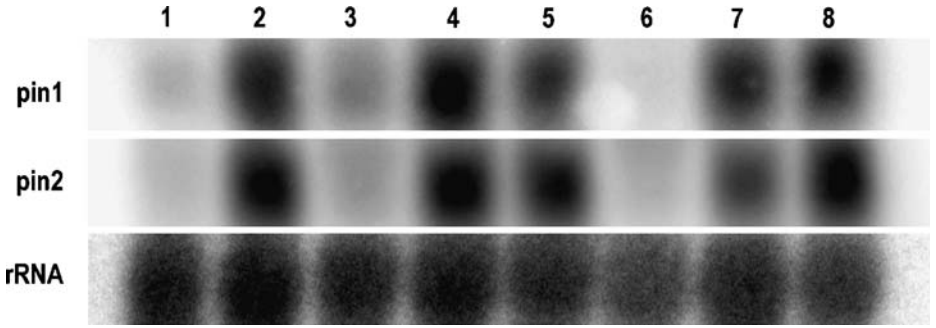

Fig. 4 A component of CPB regurgitant between 10 and 30 kDa MW results in the inhibition of *pin1* and *pin2*. The ninth leaf from the bottom was wounded and regurgitant diluted 1:2 in phosphate-buffered saline (PBS) was or was not added. *Lane 1*, unwounded; *2*, wounded + PBS; *3*, wounded + regurgitant diluted in PBS 1:2; *4*, wounded + filtrate from 3 kDa; *5*, wounded + filtrate from 10 kDa; *6*, wounded + filtrate from 30 kDa; *7*, wounded + filtrate from 100 kDa; and *8*, regurgitant remaining on top of 100-kDa filter. The plants were incubated for 4 hr and the wounded leaf was harvested. RNA was isolated and Northern blots were performed

Discussion

Addition of CPB regurgitant to wounded leaves results in the inhibition of *pin1* and *pin2* wound-induced transcripts. However, although infestation by CPB results in the expression of *pin1* and *pin2*, the addition of regurgitant does not fully mimic the insect/plant interaction. It is difficult to wound tissue in the same manner as insect feeding because the insect feeds at a comparably slower rate and the resulting wounds are different. The Mecworm, a mechanical device developed by Mithofer et al. (2005), mimics the wounding produced by a caterpillar and consequently results in a qualitatively similar volatile mix as produced by the insect. Because that work was done by replicating a single insect species on lima bean, it is not clear how general this result may be. It does suggest that more natural wounding is necessary to tease out the mechanical reaction to insect feeding from any insect-produced compounds. Alternatively, other compounds that allow production of *pin1* and *pin2* may not survive the isolation and storage of the regurgitant, in which case the regurgitant may contain a complex mix of plant reactive components. Finally, CPB were starved for 4 hr before they were used for infestation. This is necessary to entice the insects to feed quickly on the plant, but it may affect the contents of the CPB digestive system, altering components of the regurgitant and affecting the inhibition of *pin1* and *pin2*.

The size of the inhibitory compound appears to be between 10 and 30 kDa MW; given the size and also that it is inactivated by boiling suggests that it is a protein. One perplexing question is why the inhibitory factor was not present in the 100-kDa MW filtrate? We speculate that the factor is somewhat labile and that perhaps a protease copurifies with the factor in the 100-kDa MW filtrate but that the factor is protected by other proteins in the unfractionated sample.

The enzyme GO is present in salivary extracts from the caterpillar of *H. zea*, and this enzyme inhibits the defense compound nicotine in tobacco (Musser et al. 2002). However, the MW of GO is greater than 60 kDa (Eichenseer et al. 1999), so perhaps the component of CPB is a different protein. Interestingly, salivary gland extract from *H. zea* moderately inhibits trypsin inhibitor in *S. lycopersicum*, whereas GO does not (Musser et al. 2005). Perhaps additional components are present in *H. zea* that have not been identified.

Colorado potato beetle larval midgut contains cysteine and aspartate proteinases (Wolfson and Murdock 1987). However, a serine proteinase has also been detected in CPB (Novillo et al. 1997). Wounded *S. lycopersicum* induce serine proteinase inhibitors Pin1 and Pin2 (Plunkett et al. 1982), and the wound signaling molecule methyl jasmonate also induces a cysteine proteinase inhibitor in *S. lycopersicum* (Bolter 1993). Colorado potato beetles exposed to induced potatoes develop proteases with insensitivity to cysteine inhibitors (Bolter and Jongsma 1995). Perhaps the inhibition of transcription of *pin1* and *pin2* is an alternative mechanism to developing new proteases insensitive to constitutively expressed midgut proteases.

We have begun a characterization of a component of CPB regurgitant that is inhibitory to two defense genes in *S. lycopersicum*. It is unclear whether this is similar to the compound that enhances the defensive enzymes peroxidase and polyphenol oxidase in potato (Kruzmane et al. 2002) because it was not characterized. Further work is required to elucidate the components of CPB regurgitant that are involved in the plant/insect interaction.

pin1 and *pin2* have been used extensively as marker genes for the examination of wound-induced signal transduction. In tomato, systemin is induced by wounding, leading to the biosynthesis and then perception of jasmonic acid, and results in the expression of *pin1* and *pin2* (Schilmiller and Howe 2005). Wound-induced genes have been subdivided into early- and late-expressed genes, with both *pin1* and *pin2* categorized as late wound-induced

genes (Ryan 2000). It would be valuable to determine where the regurgitant interacts with this signaling cascade. Is the down-regulation specific to *pin1* and *pin2* or are all late-induced genes also repressed? When regurgitant from *M. sexta* was added to wounded leaves of *N. attenuata*, jasmonic acid was induced to higher levels than in "control" wounded leaves (Halitscke et al. 2001). In addition, regurgitant up regulated 51 genes, whereas 66 genes were down regulated when compared to leaves exposed only to wounding (Halitschke et al. 2003). If regurgitant affects tomato in a similar manner, then it acts early in the signal transduction pathway before jasmonic acid is induced. In addition, it would not just down-regulate wound-induced genes in the signal transduction pathway, but it would enhance other wound responsive genes. Experiments sorting out these questions in tomato and potato are underway.

Abstract The consequences of interactions among genetic, ontogenetic, and environmental factors for the quality of winter-dormant tissues as food for browsing herbivores is poorly understood. We conducted two sequential common garden studies to assess the impacts of intraspecific genetic variation, nutrient availability, prior defoliation, and ontogenetic stage on the chemical quality of winter-dormant tissue in quaking aspen (*Populus tremuloides* Michx.). In the first study, saplings of 12 aspen genotypes were grown under low and high soil nutrient conditions, with or without two successive seasons of defoliation. Quantity and quality of current year's twig growth were assessed. Twig production varied among genotypes and declined under low nutrient availability, but showed little response to prior defoliation. Chemical quality of sapling twigs varied substantially among genotypes, and in response to nutrient availability and prior defoliation. Overall, browse quality improved (nitrogen levels increased while phenolic glycoside and condensed tannin levels decreased) after defoliation. Growth and chemical variables exhibited low to moderate clonal repeatability (broad sense heritability) values. Our second study employed the same 12 genotypes, grown under high-nutrient conditions and with or without two seasons of defoliation. The trees were coppiced to produce root sprouts, which were chemically assessed 1 yr later. Rejuvenation via coppicing

led to increased levels of nitrogen, phenolic glycosides (salicortin), and tannins in root sprouts, and the magnitude of change varied among aspen genotypes. Signatures of defoliation nearly 2 yr earlier persisted in terms of elevated levels of phenolic glycosides in root sprouts of previously defoliated trees. Aspen forests likely present browsing herbivores with chemically heterogeneous environments because of the interactions of genetic, ontogenetic, and environmental factors that vary over space and time.

Introduction

The quality of plant tissues as food for herbivores is determined by the complex interplay of plant genetics, ontogenetics, biotic factors such as prior feeding damage, and abiotic factors such as resource availability. The independent and interactive effects of these factors on the quality of foliage for herbivorous insects have been assessed in numerous studies (reviewed by Berenbaum and Zangerl 1992; Fritz and Simms 1992; Karban and Baldwin 1997; Agrawal et al. 1999; Nykanen and Koricheva 2004). Much less is known, however, about how these factors influence the quality of woody tissues for browsing mammals.

During winter periods in north temperate and boreal forests, herbaceous vegetation is of low nutritional quality because of senescence and is often inaccessible because of snow. Mammalian herbivores rely heavily on dormant woody plants for food (Bryant and Kuropat 1980). Browsing mammals typically feed on the current year's growth (CYG), including woody stems and buds. Such damage alters the quantity and quality of foliage produced in the following growing season, with attendant impacts on the performance of folivorous insects (Danell and Huss-Danell 1985; Den Herder et al. 2004; Hochwender et al. 2005; Valkama et al. 2005). The reciprocal interaction, i.e., the effects of defoliation on the subsequent quantity and quality of woody browse, has rarely been investigated.

Quaking aspen (*Populus tremuloides*) and European aspen (*Populus tremula*) are circumpolar in distribution, and are a major food source for browsing mammals in boreal, north temperate, and montane regions. In North America, aspen provides winter food for browsing mammals such as hare, beaver, deer, elk, and moose (Bryant 1981; Perala 1990; Romme et al. 1995). Aspen is also subject to regular and expansive insect outbreaks by species such as forest tent caterpillars, gypsy moths, and large aspen tortrix (Mattson et al. 1991). In the Great Lakes Region, for example, forest tent caterpillars defoliated nearly seven million hectares of forest in 2001. Much of this was aspen forest, where early summer defoliation rates averaged nearly 100% (Donaldson 2005). Quaking aspen thus provides an ideal experimental organism for addressing how winter browse quality is influenced by defoliation in preceding summers.

A characteristic form of asexual reproduction in aspens is the production of new sprouts from adventitious buds of roots, after death of the primary stem. "Coppicing" of aspen trees by natural agents (e.g., browsing mammals or fire) or by timber harvest typically causes prolific suckering, with densities of ramets reaching 30,000–100,000/ha (Zasada et al. 2001). Loss of competing apices in the crown and access to nutrients and growth-promoting cytokinins in the remaining roots leads to "rejuvenation" and rapid growth of root sprouts (Dickmann et al. 2001). In essence, coppicing restarts the ontogenetic clock of sprouts. The juvenile sprouts typically express high levels of chemical defenses, ostensibly as protection

against browsing mammals (Bryant 1981; Bryant et al. 1991; Bryant and Julkunen-Tiitto 1995; Boege and Marquis 2005). Then, as trees grow beyond the reach of mammalian herbivores, levels of chemical defenses typically decline. The effects of prior defoliation on the quality of winter-dormant sprouts and how these may vary among plant genotypes are unknown.

Two of the major determinants of tissue quality for browsing herbivores are nutrients (e.g., protein) and secondary metabolites (Lindroth 1989; Iason 2005). In aspen, the major secondary compounds are phenolics, including salicylate phenolic glycosides and condensed tannins (Lindroth and Hwang 1996). Concentrations of these compounds in aspen foliage are highly genetically variable, as well as differentially responsive to resource availability and prior feeding damage (Osier and Lindroth 2004, 2006; Stevens and Lindroth 2005). These compounds strongly influence interactions of *Populus* species with herbivores (Hemming and Lindroth 1995; Bailey et al. 2004, 2007; Donaldson and Lindroth 2007) and mediate ecosystem processes such as litter decomposition and nitrogen mineralization (Schweitzer et al. 2004; Madritch et al. 2006). Levels of these compounds also exhibit striking ontogenetic variation in aspen foliage, with high levels of phenolic glycosides and relatively low levels of tannins in young ramets, and the reverse in mature trees (Donaldson et al. 2006).

The research reported here had several objectives. First, we were interested in evaluating how aspen genetic variation, soil nutrient availability, prior defoliation, and interactions among those factors influence the quantity and quality of dormant winter browse in aspen. Plant defense theory suggests that levels of carbon-based secondary metabolites should increase in response to both relatively low soil nutrient availability (Herms and Mattson 1992) and prior defoliation (Bryant et al. 1991). Moreover, phenotypic plasticity in response to resource availability and defoliation is likely to vary among plant genotypes, especially in highly genetically variable species such as aspen (Perala 1990; Mitton and Grant 1996). We predicted that (1) current year's twig growth would be reduced under conditions of low nutrient availability or prior defoliation; (2) levels of nitrogen (an index of protein) would decline in twigs in response to low soil fertility or prior defoliation; (3) levels of phenolic glycosides, which are relatively nonplastic in response to environment (Osier and Lindroth 2004, 2006), would change little in response to experimental treatments; (4) levels of condensed tannins, which are highly plastic in response to environment (Osier and Lindroth 2004, 2006), would increase under low soil nutrients and prior defoliation; and (5) aspen genotypes would vary in response to nutrient availability and prior defoliation (significant gene × environment interactions).

Our second objective was to assess genetic variation in tissue quality of dormant juvenile sprouts after coppicing of saplings, and whether chemical profiles of the sprouts retain a signature of prior defoliation of the original (parent) ramet. No soil nutrient treatment was included in this study. We predicted that (1) sprouts would exhibit strong genetic variation in expression of chemical traits; (2) chemical profiles of sprouts would differ from those of parent ramets because of rejuvenation (increased concentrations of phenolic glycosides and decreased concentrations of tannins); and (3) prior defoliation to parent ramets would have no influence on chemical profiles of sprouts a year after removal of all aboveground biomass.

Methods and Materials

Experimental Design

We established a common garden of potted trees on the campus of the University of Wisconsin, Madison. The split-plot experimental design consisted of two soil nutrient

environments, two levels of defoliation (0% and 75%), and 12 aspen genotypes (details below). The defoliation rate of 75% corresponds to rates experienced by natural stands of aspen during outbreaks by forest tent caterpillars (Donaldson 2005). The soil nutrient and defoliation treatments were crossed at the whole plot level, with genotype incorporated at the subplot level. The 48 treatment combinations were replicated across 5 blocks for a total of 240 trees.

Genotypes

We micropropagated root material originally collected from 12 wild aspen genotypes growing in south-central Wisconsin. Micropropagation allows for the replication of many ramets from a single root source and decreases nongenetic effects (analogous to maternal effects) from source tissues (Wright 1976). Microsatellite DNA markers were used to verify that each genotype was unique (Cole and Lindroth, unpublished data).

Propagation

The micropropagates were planted outside into 5-l pots containing a 40:40:20 mix of sand/silt loam field soil/perlite in spring of 2001. All pots received Osmocote 3–4 mo slow release fertilizer (14:14:14 N/P/K + micronutrients) at a rate of 4.5 g/l of soil. In spring 2002, saplings (average height=1.1 m) were transplanted into the experimental garden comprised of 80-l pots. Each pot contained a 70:30 mixture of sand and silt loam field soil. High-nutrient pots received Osmocote 8–9 mo slow release fertilizer (18:6:12 N/P/K + micronutrients; 4.5 g/l) in the spring of both 2002 and 2003. Low-nutrient pots received no fertilizer.

Defoliation

Our defoliation treatment modeled an insect outbreak in both duration and intensity (Mattson et al. 1991; Parry et al. 2003). We severely defoliated experimental trees in two successive summers using both forest tent caterpillars and scissors. Insects were employed to provide natural cues (e.g., frass and saliva) that may be important to trigger tree responses to defoliation (Karban and Baldwin 1997; Havill and Raffa 1999), whereas scissors were used to ensure that all genotypes were damaged similarly regardless of their chemical quality (Stowe et al. 2000; Siemens et al. 2003). In early June of both 2002 and 2003, we exposed a subset of branches on each sapling in the defoliation treatment to forest tent caterpillar herbivory for 10 d. Scissors were then used to remove 75% of each leaf (for details see Stevens et al. 2007). Background levels of natural herbivory at our common garden were low.

Dormant Twig Collection

In March 2004, 9 mo after the second defoliation, we collected winter-dormant twig samples from 4 of the 5 experimental blocks (192 trees). We haphazardly selected five branches from each tree, and ensured that our sample included branches from lower, middle, and upper portions of the crown. The terminal leader was avoided. We measured the length and diameter of the CYG on each selected branch. Diameter was measured at the proximal end of the CYG using calipers. For chemical analyses, we collected the most distal 10-cm portion of each of the five branches per tree. For branches with less than 10 cm

of growth, the entire CYG was collected. If branches had dead tips, those portions were removed and discarded. In the few cases where the entire CYG was dead, length and diameter were measured but chemical analyses were not done.

Coppicing and Dormant Root Sprout Collection

In May 2004, 3 yr after the trees were planted outside, all of the high-nutrient trees were coppiced (severed at the soil surface with loppers). The coppiced trees were allowed to regenerate via root sprouting. In March 2005, we collected the terminal 10 cm of winter-dormant CYG from 3–4 sprouts per pot (1–2 sprouts per pot for 6 trees with little regeneration). Trees from all five experimental blocks of the high-nutrient treatment were sampled.

Phytochemical Analyses

Aspen samples consisting of multiple twigs or spouts per pot were freeze-dried and ground through a Wiley mill (no. 20 mesh). To improve homogeneity of samples, highly fibrous woody particles were removed via sifting through a no. 25 mesh screen. Samples were stored frozen (−20°C) until chemically analyzed.

We analyzed the tissue samples for chemical constituents likely to influence the feeding preferences of browsing mammals. These included nitrogen (an index of protein), phenolic glycosides (salicortin and tremulacin, which typically comprise >95% of the phenolic glycoside pool; Lindroth and Hwang 1996), and condensed tannins. Total nitrogen concentrations were determined with an FP452 LECO (St. Joseph, MI, USA) elemental analyzer. Glycine *p*-toluenesulfonic acid was used as a standard. Phenolic glycosides were quantified by high-performance thin layer chromatography using salicortin and tremulacin purified from aspen as standards (Lindroth et al. 1993). Quantification was effected on the basis of peak heights, and peak identity was confirmed via UV spectral scanning. Condensed tannins were extracted from tissues in 70% acetone (with 10 mM ascorbic acid, 4°C) and quantified by the butanol–HCl assay (Porter et al. 1986). Purified aspen condensed tannins (Hagerman and Butler 1980) served as the standard.

Statistical Analyses

Differences in sapling growth and in concentrations of chemical constituents in CYG among aspen genotypes, and between nutrient and defoliation treatments, were assessed in a three-factor split-plot analysis of variance, using JMP version 5.0.1a. Defoliation and nutrient treatments were whole plots (crossed), and sapling genotype was analyzed as a subplot effect nested within whole plots. In separate analyses, the effects of "ontogenetic stage" (i.e., sapling vs. postcoppice root sprouts), genotype, and defoliation on chemical constituents were assessed using PROC MIXED in SAS. The statistical model was similar to that described above, except that there was no nutrient treatment, and ontogenetic stage was analyzed as a repeated measure. Pairwise relationships among phytochemical variables (among saplings), as well as correlations between sapling and root sprout chemical composition, were assessed using simple correlation analyses performed with JMP. For the sapling–sprout correlations, we used data from the four experimental blocks for which we had paired measurements from "parent" and "offspring" (root sprout) plants.

In studies with multiple ramets of different genotypes, variance component analysis can be used to partition the variance in traits of interest into within- and between-genet

components (Falconer 1989). Because clonally derived plants of a single genotype have identical genetic material, differences among them can be attributed to environmental variation or sampling error. Differences among genets estimate V_G (total genetic variance), which is the sum of V_A (additive genetic variance, the component of genetic variance that responds to selection), nonadditive sources of genetic variance such as dominance and epistasis, and maternal effects. The proportion of total phenotypic variance (V_P) that is genetically based is known as broad-sense heritability ($H^2 = V_G/V_P$). When clonally derived plants are the subject of research, the term "clonal repeatability" is preferred in lieu of "broad-sense heritability" (Falconer 1989). Clonal repeatability is an indirect index (and upper bound) of V_A (Mitchell 2004). We calculated clonal repeatabilities as described by Falconer (1989). Standard errors for repeatability values were estimated following Becker (1984).

Results

Growth indices differed among aspen genotypes and in relation to environmental factors. Similarly, chemical constituents differed among aspen genotypes, and in relation to both environmental and ontogenetic factors. In the following text, descriptions of changes among treatment factors are provided in relative, not absolute, terms, unless noted otherwise.

Genetic and Environmental Effects on Winter-dormant, Sapling Twigs

Current year growth (i.e., twig production) varied among aspen genotypes and in response to nutrient availability, but only weakly in response to prior defoliation. The length of CYG twigs varied by 2.6-fold among genotypes (averaged across nutrient and defoliation treatments; Fig. 1). Twig length increased an average of 76% in high-nutrient trees relative to low-nutrient trees, and genotypes responded differently to changes in nutrient availability (significant genotype × nutrient effect). Twig length did not change significantly, however, in response to defoliation. The diameter of CYG twigs varied by 2.1-fold among genotypes and increased 58% in high-nutrient relative to low-nutrient trees (Fig. 1). Twig diameter declined by 10% in defoliated trees (a marginally significant response). When we incorporated both twig length and diameter into a metric of total twig production (calculated as diameter^2 × length), we found strong effects of genotype, nutrient availability, and genotype × nutrients, but no significant effect of defoliation (data not shown).

Chemical composition of CYG twigs also varied among genotypes and in response to nutrient and defoliation treatments. Nitrogen levels differed among genotypes, especially under high-nutrient conditions (Fig. 2; significant genotype × nutrient interaction). Nitrogen levels averaged 73% higher in aspen twigs under high-nutrient, relative to low-nutrient conditions. Prior defoliation influenced twig nitrogen concentrations, but differently so for the two nutrient treatments (significant nutrient × defoliation effect). Under low-nutrient conditions, defoliation led to a similar increase (29%) in nitrogen levels across genotypes. Under high-nutrient conditions, however, defoliation slightly increased, slightly decreased, or did not alter nitrogen concentrations in aspen genotypes.

Phenolic glycoside concentrations varied markedly among genotypes, but responded less strongly to environmental factors. Levels of salicortin in twig tissues increased slightly (8%) in high-nutrient relative to low-nutrient conditions, with some genotypes responding more strongly than others (Fig. 2; marginally significant genotype × nutrient interaction). Responses to defoliation also varied among genotypes, and included increases, decreases,

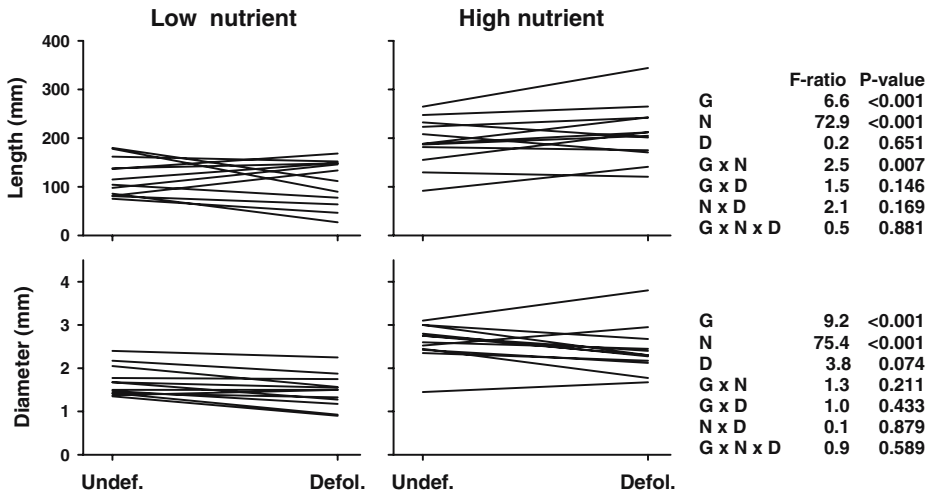

Fig. 1 Genetic and environmental effects on CYG of terminal branches (twigs) in quaking aspen saplings. Norm of reaction plots reveal responses for branch length and diameter after two successive seasons of 75% defoliation. Each line represents the mean response (N=4 replicate trees) of a single aspen genotype in the undefoliated vs. defoliated condition, under low and high soil nutrient availability. Summary statistics are provided to the right of the figure; G = genotype, N = nutrient treatment, D = defoliation treatment

and no change in concentrations (significant genotype × defoliation interaction). Levels of tremulacin showed a more pronounced increase (19%) under high-nutrient conditions, and again some genotypes responded more strongly than others (Fig. 2; significant genotype × nutrient interaction). With the exception of one genotype, tremulacin concentrations declined (an average of 15%) in response to prior defoliation.

As was the case for phenolic glycosides, condensed tannin concentrations varied most among genotypes and less in response to environment (Fig. 2). Levels varied an average of 1.6-fold among genotypes, and this variance was greater under high-nutrient than low-nutrient conditions (significant genotype × nutrient interaction). The marginally significant genotype × defoliation interaction reflects the fact that most genotypes exhibited slight declines in tannin levels in response to defoliation, whereas a few showed small increases or no change.

Genetic and environmental factors influenced sapling tissue quality in a similar manner for several chemical constituents (Table 1). Concentrations of both salicortin and tremulacin were positively correlated with concentrations of nitrogen. As expected, levels of the two phenolic glycosides were strongly and positively correlated with each other. Concentrations of condensed tannins were weakly and positively correlated with concentrations of tremulacin.

Clonal Repeatability of Sapling Twig Growth and Chemistry Variables

Both twig length and diameter exhibited moderately high clonal repeatabilities (Table 2), indicating a substantial genetic component in expression of those traits. The genetic component of variance in twig chemical characteristics varied from low to moderately high, even between structurally similar constituents (i.e., salicortin and tremulacin).

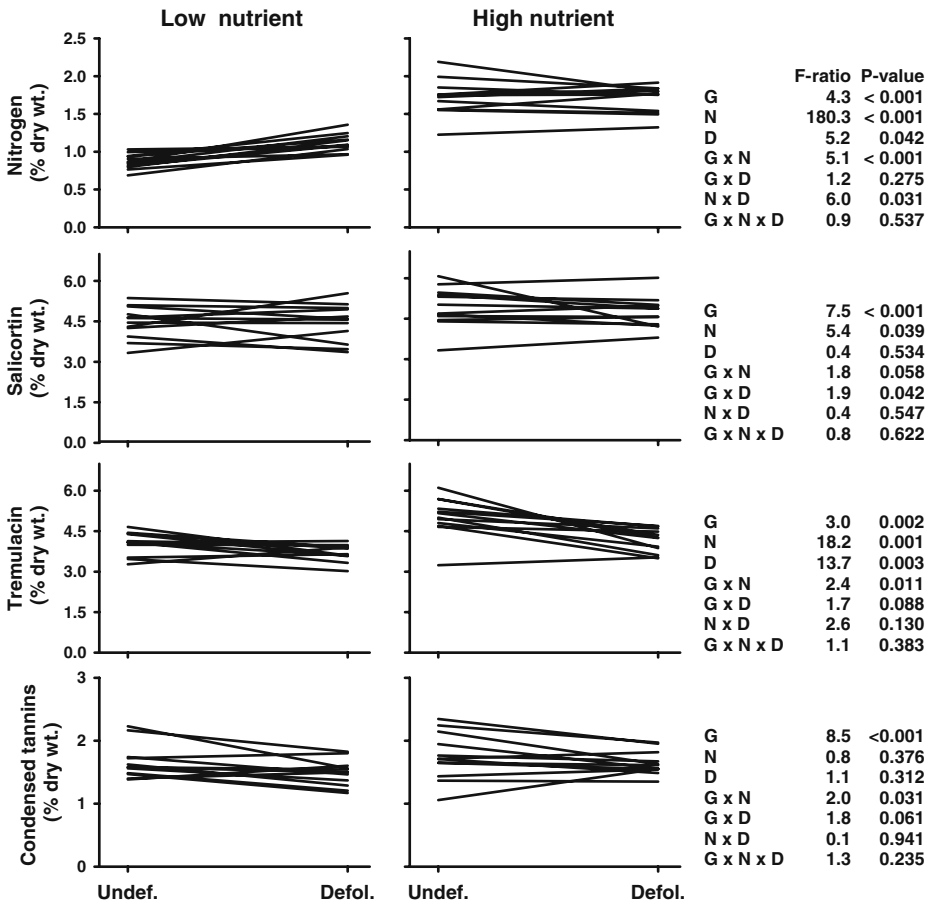

Fig. 2 Genetic and environmental effects on chemical composition of winter-dormant twigs in quaking aspen saplings. Norm of reaction plots reveal responses for nitrogen, salicortin, tremulacin, and condensed tannin concentrations after two successive seasons of 75% defoliation. Each line represents the mean response (N=4 replicate trees) of a single aspen genotype in the undefoliated vs. defoliated condition, under low and high soil nutrient availability. Summary statistics are provided to the right of the figure; G = genotype, N = nutrient treatment, D = defoliation treatment

Condensed tannins	0.386	0.044

Genetic, Ontogenetic, and Defoliation Effects on Winter-dormant Root Sprouts

The chemical composition of dormant root sprouts shifted from that of parent saplings (i.e., as a function of ontogenetic stage), and differed both among genotypes and in response to defoliation history of the saplings. Nitrogen levels increased slightly (7%) in root sprouts, relative to sapling twigs, and genotypes varied in their magnitude of response (significant genotype × ontogenetic stage interaction; Fig. 3). Prior defoliation of aspen saplings did not significantly alter nitrogen levels in root sprouts. In general, nitrogen levels varied more among genotypes than in response to either coppicing or prior defoliation.

Phenolic glycoside concentrations exhibited strong genetic and ontogenetic effects, as well as interactions between those factors and defoliation (Fig. 3). Rejuvenation increased salicortin concentrations by 49 to 153% among aspen genotypes (significant genotype × stage interaction). Prior defoliation affected salicortin levels differently among genotypes (significant genotype × defoliation interaction). Defoliation had little effect on salicortin levels in saplings, but slightly increased (8%) levels in root sprouts (significant stage × defoliation effect). Similar to salicortin, tremulacin levels varied among genotypes, and differently so for the two ontogenetic stages (significant genotype × stage effect; Fig. 3). Contrary to the pattern exhibited by salicortin, however, average tremulacin levels were similar between rejuvenated root sprouts and saplings. Moreover, in response to prior defoliation, levels of tremulacin decreased (an average of 18%) in saplings, but increased slightly (an average of 5%) in root sprouts (significant stage × defoliation effect).

Condensed tannin concentrations varied among genotypes and ontogenetic stages, but not in response to prior defoliation, and showed relatively few interactive effects (Fig. 3). Rejuvenation stimulated an increase in tannin concentrations, ranging from 5 to 72% among genotypes (significant genotype × stage interaction).

Correlation analyses revealed surprisingly few significant relationships between parent sapling and root sprout chemical constituents (Table 3). We found positive correlations between parents and sprouts for nitrogen (marginally significant) and salicortin, but only in trees that had previously been defoliated.

Discussion

Although much research has addressed the interactive effects of genetics, ontogenetics, resource availability, and herbivore damage on the quality of foliar tissues, remarkably little work has evaluated the consequences of such interactions for the quality of winter-dormant woody tissues. To our knowledge, this is the first attempt to address all of those factors in a

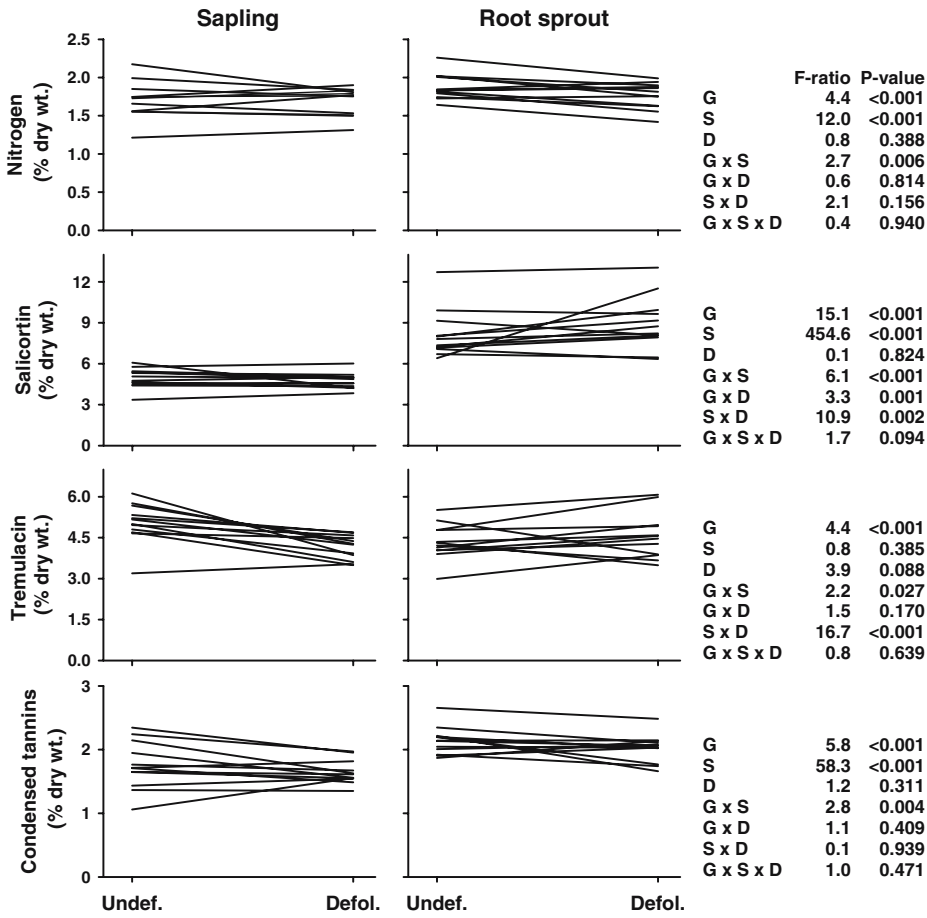

Fig. 3 Genetic, ontogenetic, and environmental effects on chemical composition of winter-dormant twigs in quaking aspen saplings and root sprouts. Norm of reaction plots reveal responses for nitrogen, salicortin, tremulacin, and condensed tannin concentrations after two successive seasons of 75% defoliation. Note the difference in scale for salicortin in Fig. 3 vs. Fig. 2. Each line represents the mean response of a single aspen genotype, as either saplings (N=4) or root sprouts (N=5), in the undefoliated vs. defoliated condition. Summary statistics are provided to the right of the figure; G = genotype, S = ontogenetic stage, D = defoliation treatment

Table 3 Correlations (Pearson) between sapling and root sprout chemistry

Variable	Undefoliated Trees		Defoliated Trees	
	r	*P*	*r*	*P*
Nitrogen	0.212	0.201	0.317	0.052
Salicortin	−0.095	0.570	0.399	0.013
Tremulacin	0.218	0.189	−0.070	0.678
Condensed tannins	0.036	0.828	0.089	0.605

single study. Here we document that for aspen, the production and chemical composition of dormant woody tissue is strongly influenced by a complex of independent and interacting genetic, ontogenetic, and environmental factors. The resulting temporal and spatial variation in food quality likely holds implications for the ecology and evolution of plant–mammal interactions.

Total current year twig production declined substantially under low-nutrient conditions, but weakly if at all in response to two successive seasons of heavy defoliation. This finding suggests that the availability of winter-dormant browse to vertebrate herbivores may not be significantly reduced in years after extensive defoliation by outbreak species such as forest tent caterpillars and large aspen tortrix. Moreover, growth responses to defoliation did not differ among aspen genotypes. This result is similar to those of a larger study (of which these trees were a part), which documented little genotypic variation in allocation of biomass to stem (aboveground woody) tissues, in response to defoliation of high-nutrient trees (Stevens and Lindroth, unpublished data). Finally, moderately high clonal repeatability values indicate that CYG twig production may show a strong response to selection, assuming no constraints beause of genetic correlations with other factors influencing fitness.

Nitrogen concentrations of dormant twigs increased in response to high-nutrient conditions and in response to prior defoliation in low-nutrient trees. The latter increase was contrary to our expectations; heavy defoliation typically causes fine root mortality and reductions in plant nitrogen concentrations (Bryant et al. 1991). These results suggest that defoliation may elicit changes in the sites of overwinter storage of nitrogen-containing compounds. The primary form of reduced nitrogen storage in perennating tissues of plants is vegetative storage proteins. In *Populus*, the major form of storage proteins is bark storage proteins, which accumulate during autumn senescence in tissues such as bark, wood, and roots (Cooke and Weih 2005). Extensive defoliation may shift allocation of bark storage proteins from roots and primary stems to CYG tissues, thereby elevating concentrations of nitrogen.

Levels of phenolic glycosides varied substantially among aspen genotypes, increased slightly to moderately under high-nutrient conditions, and exhibited mixed responses (salicortin) or declines (tremulacin) after defoliation. This pattern of substantial variation among genotypes, coupled with relatively small responses to resource availability and prior damage, is similar to that observed in previous studies of both rapid and delayed induced resistance in aspen foliage (Osier and Lindroth 2001, 2004). Overall, concentrations of phenolic glycosides in winter-dormant twigs were similar to those in leaf tissues of trees growing in the same common garden (Stevens et al. 2007) and in comparably aged trees (Donaldson and Lindroth 2007).

Condensed tannin concentrations also showed substantial genotypic variation, coupled with minimal and genotype-dependent responses to nutrient availability and defoliation. These latter, environmentally mediated changes were different from what we had predicted. Previous studies of aspen foliage have consistently demonstrated both substantial decreases in tannin concentrations when plants are grown in nutrient-rich environments (Bryant et al. 1987; Osier and Lindroth 2001, 2004, 2006; Stevens and Lindroth 2005; Donaldson and Lindroth 2007) and strong short- and long-term induction in response to defoliation (Osier and Lindroth 2001, 2004; Stevens and Lindroth 2005). This disparity in expression profiles between winter-dormant wood and summer leaf tissues may indicate differences in both the cost of metabolite production and the risk of tissue damage between the two seasons. Finally, overall levels of tannins in winter-dormant twigs were low in comparison with levels in foliage of comparably aged trees (Donaldson and Lindroth 2007; Stevens et al. 2007).

Although sapling aspen showed substantial genetic variation in terms of current year twig production and tissue chemistry, the genotypes tended to respond similarly to the

defoliation treatment imposed (i.e., relatively few genotype × defoliation interactions). Thus, phenotypic plasticity of woody tissue response to foliar damage may be constrained in aspen, and expressed more strongly in response to other environmental factors, such as resource availability. Such patterns have been observed for both short- and long-term induction responses in foliage (Osier and Lindroth 2001, 2004).

In summary, the general effect of prior, extensive defoliation was to not alter the quantity, but increase the quality, of winter-dormant twigs in sapling aspen. In this unique case of induced susceptibility, damage to one form of tissues (leaves), by one set of herbivores (outbreak insects), during the growing season, is likely to influence susceptibility of another set of tissues (CYG twigs), to another set of herbivores (browsing mammals), during winter dormancy. Whether preferences of and damage imposed by browsing herbivores in the field actually do change after major summer defoliation events remains unknown. We are aware of only one study that evaluated the impact of defoliation on subsequent mammal browsing. Hjältén et al. (1994) found that voles preferred previously defoliated birch seedlings over controls, despite the fact that defoliation did not significantly affect phenolic concentrations in birch shoots.

Estimates of heritability for quantitative traits indicate the proportion of phenotypic variance that is genetically determined. Heritability values calculated for concentrations of secondary metabolites in other experimental systems are highly variable, spanning the range from 0 to 1 (Berenbaum and Zangerl 1992; Laitinen et al. 2005). In this study, broad-sense heritability (clonal repeatability) values for secondary metabolites were low to moderate. Particularly low values (e.g., as for tremulacin) may reflect previous strong selection for the trait, and subsequent loss of genetic variation (Falconer 1989). Our value for tannins was similar to that reported by Laitinen et al. (2005) for birch condensed tannins, whereas our value for salicortin was similar to that reported by Orians et al. (1993) for the same compound in *Salix*. In contrast, Stevens and Lindroth (2005) and Donaldson and Lindroth (2007) reported high values (>0.70) of clonal repeatability for foliar concentrations of tannins and phenolic glycosides in aspen. This disparity may reflect a difference in the heritability of woody vs. foliar chemical constituents. Or, it may simply highlight the fact that estimates of heritability can vary greatly among habitats and studies. Because no general rules exist for extrapolating among environments (Pigliucci 2005), comparisons among studies must be interpreted cautiously.

During plant development, both the risks of herbivore damage and the costs of antiherbivore defenses are likely to change, leading to ontogenetic variation in the expression of defense traits (Boege and Marquis 2005). In general, levels of secondary metabolites tend to be higher in juvenile than in adult tissues (Bryant, 1981; Bryant and Julkunen-Tiitto 1995; Laitinen et al. 2005). Few studies, however, have evaluated genetic variation in defense traits across multiple developmental stages for plants growing in standardized environments (e.g., common gardens). Rejuvenation of biochemical and physiological characteristics in plant tissues is of particular ecological and evolutionary relevance in aspen, where damage to individual trees (ramets) because of browsing, logging, or fire typically elicits a dense flush of root sprout production.

We observed strong ontogenetic shifts in the chemistry of dormant root sprouts. Juvenile sprouts contained elevated levels of nitrogen, salicortin, and tannins, relative to the saplings from which they derived. Genotype × stage interactions were significant for all chemical variables, revealing that expression of genetic variation in defense differs among ontogenetic stages. That genotypes exhibit different ontogenetic trajectories (*sensu* Boege and Marquis 2005) explains why we observed few significant correlations in chemical traits between precoppice trees and their root sprouts. Somewhat surprisingly, signatures of

defoliation carried through to affect several chemical traits of sprouts, despite the facts that defoliation had occurred nearly 2 yr previously, and that all aboveground biomass had been removed 10 mo earlier. For nitrogen, the effects of prior defoliation on root sprouts mirrored those on saplings. For phenolic glycosides, however, concentrations generally increased in response to prior defoliation for root sprouts, but not for saplings.

Striking ontogenetic variation in biochemical and physiological function is a hallmark characteristic of *Populus* (Dickmann et al. 2001; Donaldson et al. 2006). Numerous studies relating the ontogeny of individual leaf development (within a season) to the biosynthesis, transport, and accumulation of secondary metabolites have employed *Populus* as a model system (e.g., Arnold and Schultz 2002; Kleiner et al. 2003; Orians 2005; Donaldson et al. 2006; Rehill et al. 2006). Additional studies have linked ontogenetic shifts in resistance (whole plant development) to variation in the distribution and abundance of herbivorous insects on poplars (Kearsley and Whitham 1989; Martinsen et al. 1998). Little research, however, has addressed ontogenetic variation in the chemical quality of woody tissues in *Populus*. Bryant (1981) showed that adventitious shoots of aspen produce increased amounts of extractable "resin" (chemical composition unknown), which deters feeding by snowshoe hares. Our results are consistent with that finding, and suggest that elevated levels of tannins and phenolic glycosides (salicortin) in dormant root sprouts may serve as deterrents to mammalian browsers. Indeed, consumption of aspen summer foliage and twigs by elk and porcupine is negatively related to concentrations of phenolic glycosides (Bailey et al. 2007; Diner et al., unpublished data; Wooley and Lindroth, unpublished data), and selection of *Populus* branches by beaver is inversely correlated with bark tannin levels (Bailey et al. 2004).

Given that levels of phenolic glycosides and tannins are strongly genetically determined in aspen, and confer defense against a variety of biotic and abiotic agents (Lindroth 2001), the question arises as to why genetic variation for these traits persists in natural populations. The conventional explanation is that the costs and benefits of chemical defense vary over time and space. Such appears to be the case with aspen. In young aspen, production of phenolic glycosides exacts a cost in terms of growth, particularly in resource-limited habitats (Osier and Lindroth 2006), whereas in older saplings, costs of chemical defense are greatest under favorable growing conditions (Stevens et al. 2007). How cost–benefit relationships are shaped by extensive root systems and clonal integration, particularly among aspen root sprouts after coppicing, is unknown.

In conclusion, aspen exhibits substantial genetic variation in expression of woody tissue chemistry, as has been established previously for aspen foliage. Browse quality is further influenced by ontogenetic stage, as well as by environmental factors such as soil nutrient availability and prior defoliation. Winter browsers, like summer defoliators, are likely to encounter a chemically heterogeneous environment because of the complex interplay of genetic, ontogenetic, and environmental factors that vary spatially and temporally in aspen forests.

Abstract Trees of the genus *Glochidion* (Phyllanthaceae) are pollinated by females of *Epicephala* moths (Gracillariidae) whose larvae consume the seeds of the flowers that they pollinate. Each *Epicephala* moth species is specific locally to a single host species, although two to four *Glochidion* hosts often cooccur. To investigate the role of olfactory signals in maintaining the plant–moth specificity, we analyzed floral scent composition of five *Glochidion* species by using gas chromatography–mass spectrometry (GC-MS) and conducted Y-tube olfactometer bioassays with *Epicephala* moths and their host flowers. The GC-MS analysis showed that the floral scents of the five *Glochidion* species are dominated by (*R*)-(−)- and (*S*)-(+)-linalool, and (*E*)- and (*Z*)-β-ocimene, and that each species produces 6–20 compounds. Transformation of scent profiles by using chord-normalized expected species shared distances and analysis of the data with nonmetric multidimensional scaling showed that floral volatiles of cooccurring *Glochidion* species can be distinguished by relative chemical composition, especially that of minor compounds. The bioassay with pollinators of *Glochidion lanceolatum* and *Glochidion ruburm* further indicated that *Epicephala* moths are capable of discriminating their hosts by using floral odor. The results suggest that the floral scent of *Glochidion* is one of the important key signals that mediate the encounters of the species-specific partners in the *Glochidion–Epicephala* mutualism.

Keywords Bioassay · *Epicephala* · Floral scent · *Glochidion* · Obligate pollination mutualism · Species specificity

Introduction

Glochidion, a monoecious tree genus of the family Phyllanthaceae, consists of more than 300 species ranging from tropical Asia to Australia and Polynesia (Govaerts et al. 2000).

All members of the genus have minute apetalous flowers that are pollinated at night exclusively by locally species-specific moths of the genus *Epicephala* (Fig. 1; Kato et al. 2003; Kawakita and Kato 2006). Each female moth lays an egg in the ovary after pollinating the flower with pollen carried on her proboscis. The hatched larva consumes some of the developing seeds while leaving others intact. Because *Glochidion* tree serves as the only larval host of the pollinator moth, neither partner can successfully reproduce in the absence of the other. Similar examples of obligate mutualisms between flowering plants and their seed-parasitic pollinators are classically known in the fig–fig wasp and yucca–yucca

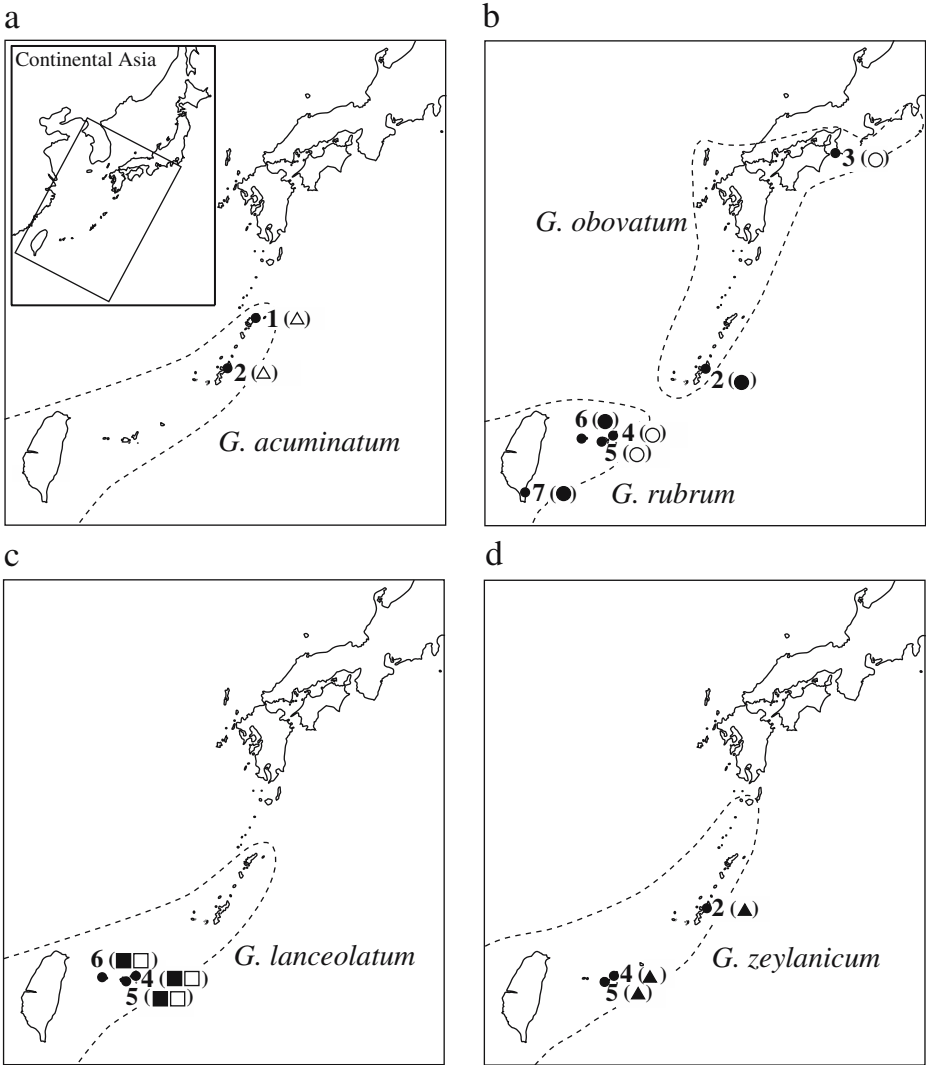

Fig. 1 Distribution of the five studied *Glochidion* species in western Japan and Taiwan. All but one (*G. obovatum*) species are widely distributed throughout Southeast Asia. Numbers indicate sampling localities corresponding to those in Table 1. Symbol(s) in parentheses indicate *Epicephala* moth species present at each host population, with different symbols representing different pollinator species

moth associations (Janzen 1979; Weiblen 2002; Pellmyr 2003). These mutualisms share various characteristics that are thought to have coevolved in the host and the pollinator, such as highly specialized floral structures and active pollinating behavior, which make them model systems for various studies of coevolutionary processes (Weiblen 2002; Cook and Rasplus 2003; Pellmyr 2003).

Among the most intriguing characteristics of these mutualisms are the high species diversity and species specificity of the lineages involved. For example, the figs comprise more than 750 species, and as many as 18 species occur sympatrically in the tropics (Corner 1965; Herre 1996). Meanwhile, the extremely high specificity of the pollinator to a single host suggests that a comparable number of wasp species also exists (Lopez-Vaamonde et al. 2002; Weiblen 2002; Molbo et al. 2003). Although less diverse, the Indo-Pacific genus *Glochidion* consists of more than 300 species, and up to 10 are known to grow sympatrically on the islands of Polynesia (e.g., Fiji Islands; Govaerts et al. 2000). Similarly, host specialization by the pollinators suggests that the pollinator moths are also highly diverse in this system (Kato et al. 2003; Kawakita and Kato 2006). The remarkable diversity and host-specificity of these interactions have sparked several analyses of the evolutionary dynamics of the interaction (Machado et al. 2001; Weiblen and Bush 2002; Kawakita et al. 2004; Weiblen 2004) and have provided opportunities for comparative studies on the ecological outcomes of mutualism (Herre 1989; Nefdt and Compton 1996; Herre and West 1997; Weiblen et al. 2001).

In cases where multiple plant species coexist in an obligate pollination mutualism, the maintenance of host specificity may be important in facilitating pollination by conspecific pollen and simultaneously allowing the pollinators to ensure larval nourishment by avoiding pollen incompatibility. Alternatively, the pollinators may be loyal to their hosts simply because their larvae suffer higher mortality on alternative hosts because of nutritional constraints, as is often observed in herbivorous insects (Via 1986; Singer et al. 1988; Traxler and Joern 1999; Bossart 2003; Forister 2004). Thus, understanding the mechanism by which the plant-pollinator specificity is maintained has important general implications for the role of specificity in these specialized pollination interactions, as well as the effects the mechanism may have on the evolutionary and ecological dynamics of mutualism.

In the fig–fig wasp mutualism, species specificity is maintained by responses of the pollinating wasps to specific fig volatile cues (Hossaert-McKey et al. 1994; Ware and Compton 1994; Song et al. 2001; Grison-Pigé et al. 2002a, b; Yokoyama 2003). For example, Grison-Pigé et al. (2002a) analyzed floral volatiles of four *Ficus* species and conducted biological tests of wasp stimulation by volatile samples to show that olfactory cues, especially floral volatiles, are often important signals that ensure the encounter of the two partners in this association. Because *Glochidion* flowers are small and inconspicuous (Fig. 2) compared with generally white or pale yellow flowers of most moth-pollinated plants (Proctor et al. 1996), it is unlikely that the nocturnal *Epicephala* moths detect the host plants by using only visual cues. Thus, olfactory cues are likely the predominant signal used by the moths to locate their hosts in the *Glochidion–Epicephala* mutualism.

In this study, we tested the following two hypotheses. If floral scents of *Glochidion* are used to detect host plants by moths, then (1) variations in floral scent composition should reflect differences in *Epicephala* moth species with which the plants are associated, and (2) *Epicephala* moth should be attracted to the floral scents of its host plant. We conducted two experiments to test these hypotheses. First, we identified the composition of the floral volatiles in five *Glochidion* species by using gas chromatography–mass spectrometry (GC-MS), and carried out a nonmetric multidimensional scaling (NMDS) analysis by using distance matrix obtained from floral scent profiles to investigate the differences in floral scents among the five

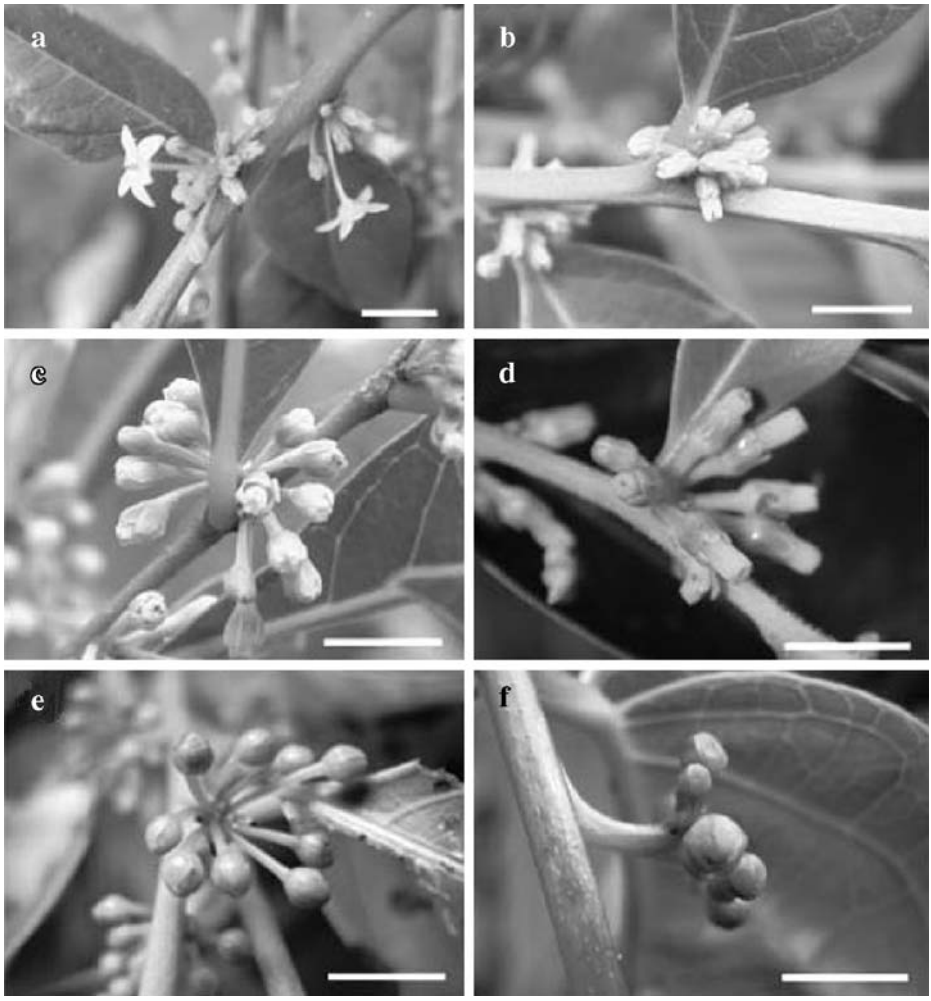

Fig. 2 Flowers of the five studied *Glochidion* species. **a** Male and female flowers of *G. acuminatum* aggregated at the axil. Female flowers of **b** *G. acuminatum*, **c** *G. obovatum*, **d** *G. rubrum*, **e** *G. lanceolatum*, and **f** *G. zeylanicum*. Bars=1 cm

Glochidion species. Second, we carried out a bioassay with a Y-tube olfactometer to determine whether *Epicephala* moths can detect their host plants by using floral scents.

Methods and Materials

Plants We studied five *Glochidion* species, *Glochidion acuminatum*, *Glochidion lanceolatum*, *Glochidion obovatum*, *Glochidion rubrum*, and *Glochidion zeylanicum*, that commonly occur in western Japan and Taiwan. *Glochidion obovatum* is distributed from temperate to subtropical regions of western mainland Japan and the Ryukyu Archipelago, whereas the other four species are more or less widely distributed throughout tropical Southeast Asia and as far north as the Ryukyu Archipelago (Fig. 1). They are common on forest edges, and two

to four species occur sympatrically at many of our study sites. *Glochidion* trees are monoecious and have male and female flowers aggregated on the axils (Fig. 2), the latter usually situated more proximally than the former. They have yellow male flowers with six perianths and less conspicuous female flowers that are more or less bud-like (Fig. 2). Flowers are open throughout the day and night and normally last about 1 wk. Flowers do not produce detectable nectar but are fragrant to the human nose during the evening, especially around 2000 hours. Although thrips are infrequently observed on male flowers during the day, insects other than *Epicephala* moths have rarely been observed on male or female flowers.

Among the five studied species, *G. lanceolatum* and *G. zeylanicum* are closely related (Kawakita et al. 2004) and share similar female flower morphologies (ovoid flower with styles almost completely covered with perianths; Fig. 2e, f). They are sympatric in the southern islands of Japan (Fig. 1). Similarly, *G. obovatum* and *G. rubrum* form another pair of closely related species (Kawakita et al. 2004), but their distributions are allopatric (Fig. 1). *Glochidion acuminatum* belongs to a distinct lineage and is equally related to the other four species.

Moths Six *Epicephala* moth species are associated with the five *Glochidion* species in our study region (Fig. 1; Kawakita and Kato 2006). *Glochidion acuminatum* and *G. zeylanicum* are each pollinated by a specie-specific *Epicephala* throughout its range in southern Japan. *G. obovatum* and *G. rubrum* are associated with two *Epicephala* species that are allopatric in distribution and pollinate the two *Glochidion* species at different parts of their ranges. Lastly, *G. lanceolatum* is pollinated by two *Epicephala* species that occur sympatrically in the southern Ryukyu Archipelago. Overall, each *Epicephala* pollinator is locally specific to a single host species, although each *Glochidion* species is pollinated by more than one moth species either in sympatry (*G. lanceolatum*) or in different parts of its range (*G. obovatum* and *G. rubrum*).

Collection and Identification of Floral Volatiles To test if the compositions of floral volatiles differs among *Glochidion* species, we collected floral volatiles by the headspace adsorption technique (Raguso and Pellmyr 1998) in the five *Glochidion* species. Study sites, dates, and sample sizes of the flowers used for headspace collection are shown in Fig. 1 and Table 1.

We used branches bearing both flowers and leaves for the collection of floral scents. For background, we used branches on the same plant bearing only the leaves. Branches were enclosed in low-density polyethylene bags. Air was purified by active charcoal and introduced into the bag through Tygon tubes with a minipump (flow rate, 300 ml/min; MP-2N, SIBATA, Tokyo, Japan). Volatiles in the bag were adsorbed by Tenax TA (50 mg; mesh 80–100; GL Sciences, Tokyo, Japan) stuffed into a glass tube (inner diam., 3 mm; length, 15 cm). We collected the volatiles for 120–200 min between 1900 and 2400 hours. The glass tube containing captured flower volatiles was sealed with glass beads, wrapped with aluminum foil, and stored at −30°C until used for analysis.

We eluted volatiles from the adsorbent with 2 ml of diethyl ether and added 5 μl of *n*-eicosane (1 mg/ml) as an internal standard. The eluate was carefully concentrated by N_2 flow to 25 μl and topped up with 25 μl of hexane. An aliquot (1 μl) of each sample was used for GC-MS (GC: GC-17A, MS: QP5050A; Shimadzu Inc., Tokyo, Japan). For GC, we used a DB-WAX capillary column (30 m×0.25 mm; film thickness, 250 μm; J&W Scientific, USA) and helium as the carrier gas. The injector was operated in the splitless mode for 1 min. Electron ionization mass spectra were obtained at an ionization voltage of 70 eV and a source temperature of 240°C. The oven temperature was programmed at 40°C

Table 1 Study sites, dates, and sample sizes of the headspace collection

Species	Study Sites[a]	Dates	Individuals[b]	No. of Flowers

[a] Numbers in parentheses indicate locality numbers shown in Fig. 1.

[b] Numbers in parentheses indicate individuals resampled in 2006 for enantiomeric determination of linalool.

for 5 min, followed by an increase by 3°C/min to 100°C and 10°C/min to 200°C where it was held for 10 min. By comparing the volatiles emitted by branches with and without flowers, we isolated the volatiles emitted only from flowering branches and considered them the floral volatiles. For a preliminary identification of the compounds, we compared the fragments to those contained in the NIST 05 and NIST 05s libraries. We also calculated retention indices for all compounds by using *n*-alkane standards and compared them with those reported in previous studies (Davies 1990; Sagrero-Nieves et al. 1997; Gancel et al. 2002; Minh Tu et al. 2003). The identification of a subset of the compounds was further verified by using the retention indices and MS fragments of authentic compounds whenever possible. The percentage composition of each volatile compound was obtained by calculating its peak area as a percentage of the total peak area on gas chromatograms.

Determination of Linalool Enantiomers Because the above analysis indicated that the floral odor of *Glochidion* is often dominated by linalool, we performed an additional analysis by using a chiral column to discriminate the two enantiomers, (*R*)-(−)-linalool and (*S*)-(+)-linalool. We resampled floral scents from five trees for each of the five *Glochidion* species, which consisted of the same trees as used for the above analysis of floral scent profiles. Floral samples of *G. acuminatum* and *G. zeylanicum* were collected by headspace adsorption as described. For *G. lanceolatum*, *G. obovatum*, and *G. rubrum*; however, we sampled odor by removing the flowers from the branches in a 10-ml glass vial and pumping the air inside via a glass tube containing the Tenax TA adsorbent. This method does not allow for discriminating floral bouquet from background noise, but enables floral compounds to be adsorbed in a higher concentration, which facilitated enantiomeric determination and identification of other floral compounds produced in small amounts.

The volatiles were eluted and concentrated as described above except that 2 μl of *n*-hexadecane (1 mg/ml) were used as internal standard. The samples were analyzed with GC (GC-2010; Shimadzu Inc.) equipped with InertCap CHIRAMIX capillary column (30 m× 0.25 mm; film thickness 250 μm; GL Sciences). We used helium as the carrier gas. The

injector was operated in the splitless mode for 1 min. The oven temperature was programmed at 30°C for 5 min, followed by an increase by 1°C/min to 180°C, where it was held for 30 min. Before analyzing the floral samples, we analyzed authentic compounds of racemic linalool, (*R*)-(−)-linalool and (*S*)-(+)-linalool, including the *n*-hexadecane standard. Identification of the enantiomer was then conducted by comparing the retention time (standardized with *n*-hexadecane) of floral linalool with that of authentic compounds.

Statistical Analyses To examine differences of floral scents among the five *Glochidion* species, we performed a NMDS analysis based on relative GC peak area of floral compounds in each sample. For the NMDS, we used chord-normalized expected species shared (CNESS) distances to convert similarity between samples into metric indices. Chord-normalized expected species shared was originally designed to analyze faunistic or floristic similarity among biogeographic areas, and has been successfully incorporated in studies of floral volatiles (Jürgens and Dötterl 2004). Chord-normalized expected species shared distance is a dissimilarity index that reflects the expected number of species shared between a pair of samples in a random draw of *m* individuals, and ranges between zero and the square root of two. The advantage of CNESS is that sensitivity to changes in the abundance of dominant species (or dominant compounds in case of a floral bouquet) can be adjusted by altering the *m* parameter (CNESS*m*), thus emphasizing the importance of minor species (or compounds). Chord-normalized expected species shared distances were calculated by using the COMPAH program (Gallagher 1999). We rounded off percent value of each compound to two decimal points so that all detected compounds have nonzero values and multiplied them by 100 to convert to integers, as COMPAH does not appropriately handle decimals.

We determined the CNESS*m* having balanced influence to abundant and trace compounds in the floral samples by using the method described in Trueblood et al. (1994). We also used minimum and maximum CNESS*m* (m=1 and 9,999, respectively) that are most sensitive to dominant and minor compounds, respectively. NMDS analysis was performed with the SPSS 10.0J program to visualize the similarity between floral samples. When converting the distance matrix to a two-dimensional scatterplot in NMDS, a stress value is output, which represents how well or poorly a particular configuration fits the given data. The smaller the stress value, the better is the fit of the reproduced diagram to the distance matrix (Clarke 1993).

Bioassay To test whether *Epicephala* moths can detect their host plants by olfactory cues, we carried out a bioassay with a Y-tube olfactometer and the male and female moths reared from wild fruits of *G. lanceolatum* and *G. rubrum* that widely cooccur at our study sites (Fig. 1). We randomly collected fruits from 10 *G. lanceolatum* trees in September 2005 and October 2006 in Ishigaki Island, and 10 *G. rubrum* trees in October 2006 in Hateruma Island. They were kept in plastic containers under laboratory conditions (temperature 28.0°C, humidity 66.0–78.0%) until *Epicephala* larvae emerged from the fruits, at which point larval development is complete. After emergence, we removed the fruits from the containers to prevent possible negative effect of plant degradation on moth survival. Adult moths were used for the bioassay within 24 hr after eclosion. Intensive observation of adult moths behavior within the rearing containers indicated that the moths do not mate under such conditions (T. Okamoto, personal observations). Thus, the moths used for the test are most likely unmated individuals. Overall, we obtained 255 and 11 moths from *G. lanceolatum* and *G. rubrum* fruits, respectively.

For the bioassay, we connected the two arms of a Y-shaped glass tube (stem 13.5 cm, arm 11.0 cm, inner diam. 20.0 mm) via plastic tubes to polyethylene bags (48.0×34.0 cm), active charcoal, and mini pumps. Unidirectional airflow from the arms to the stem of the Y-tube was

purified by active charcoal and pumped into each bag, respectively (flow rate 20 ml/min). The experiment was done by using the following three pairs of odor bags: (1) a bag containing a flowering branch of a host (100–150 male and 500–550 female flowers) and an empty bag containing only air; (2) bags containing host branches with and without flowers; and (3) bags containing flowering branches of a host and a cooccurring nonhost. The first two experiments test for the roles of overall host fragrance and floral volatiles, respectively. The third experiment examines whether *Epicephala* moths can discriminate between a cooccurring pair of *Glochidion* using olfactory cues. *Epicephala* pollinators of *G. lanceolatum* were used in all three experiments. However, those of *G. rubrum* were used only in the third experiment because of low availability of moth specimens at our study populations.

Each moth was allowed 10 min to select either arm of the Y-tube in a dark condition. When the moth moved into an arm within 10 min and stayed for at least 30 sec, we considered the arm to have been selected. When a moth did not select either arm within a given time, we removed it and recorded that the moth had made no response. The bags connected to the two arms were randomly alternated in each test. After the experiments, moths were dried in silica gels for sex determination and species identification.

Identification of Epicephala Moths The *Epicephala* moths parasitizing *G. lanceolatum* fruits comprise two distinct, undescribed species (Kawakita and Kato 2006). Although male *Epicephala* can be determined by distinct genital morphology, there is subtle difference in female morphological characters. For this reason, we amplified a fragment of the mitochondrial cytochrome oxidase subunit I (COI) gene by using polymerase chain reaction (PCR) and species-specific primers to identify adult female moths used in the Y-tube test. We extracted genomic DNA from thoracic muscles with a standard phenol–chloroform method. We used the primers lanceolatum F (forward: 5′-CCC CCA CTT TCA TCA TTA ATA TTG CCC ATG CAG G-3′), lanceolatum R1 (reverse: 5′-TCC TCC TCC TGC AGG ATC AAA AAA T-3′), and lanceolatum R2 (reverse: 5′-ACC TCC ACC TGC TGG GTC AAA GAA G-3′). The two reverse primers were designed to amplify specifically either one of the two *Epicephala* species (A. Kawakita and T. Okamoto, unpublished data). Polymerase chain reaction conditions for amplifying the fragment containing the COI region were as follows: initial denaturation step at 94°C for 5 min; 30 cycles for 30 sec at 94°C, 30 sec at 55°C, and 1 min at 70°C; and final extension at 70°C for 7 min. All PCR amplifications were aided by Ex *Taq* DNA polymerase (TaKaRa, Otsu, Japan) and carried out on GeneAmp PCR System 9700 (PerkinElmer, Foster City, CA, USA). Presence/absence of successful PCR product was checked by electrophoresis on agarose gel.

Male moths pollinating *G. lanceolatum* used in the Y-tube bioassay were identified by examination of genitalia under a light microscope. For specimen preparation, we took off the apical end of the abdomen and boiled it in 10.0% potassium hydroxide for 5 min to remove abdominal tissue. We then washed it with distilled water and subsequently 100.0% ethanol to remove residual tissue fragments. After isolation of the genitalia, the specimen was mounted in Euparal (Waldeck, Münster, Germany) on a glass slide and observed under a microscope.

Results

Composition of Floral Volatiles Overall, we detected a total of 42 compounds in the headspace collections of the five *Glochidion* species. In each sample, 2 to 20 compounds

were found. We identified 69.0% of all compounds, whereas the remaining trace compounds had less than 1.0% peak area compared to that of the internal standard on GC-MS, and thus could not be identified. Most identified compounds were monoterpene and sesquiterpene compounds (Table 2). In all five species, floral samples were dominated by monoterpenes: (*R*)-(−)-linalool in *G. lanceolatum* (0.6–95.4% relative peak area) and *G. obovatum* (13.6–88.6%); (*E*)-β-ocimene in *G. acuminatum* (82.8–98.3%); (*E*)-β-ocimene and (*R*)-(−)-linalool in *G. rubrum* (0–71.3% and 0–90.7%, respectively); and (*Z*)-β-ocimene and (*S*)-(+)-linalool in *G. zeylanicum* (0.5–78.6% and 1.4–99.0%, respectively). Of the 42 compounds detected, 50.0% were shared by at least two species. Each *Glochidion* species had one to eight compounds that were unique. For example, *G. acuminatum* had β-myrcene and seven unidentified compounds that were not emitted by any other species. Most compounds unique to single species, except benzenoids, were produced in relatively small amounts, occupying 0.3–2.2% of the total peak area in each sample. A benzenoid, 2-phenoxyethanol, included in the *G. lanceolatum* samples occupied 3.9–71.9%, and phenylacetaldehyde and benzyl alcohol produced by *G. zeylanicum* occupied 0.0–87.0% and 0.0–53.8% of the total peak area, respectively.

Similarity of floral volatile profiles among individual samples was transformed by using CNESS distances and also subjected to the NMDS analysis. Scatterplots resulting from NMDS are shown (Fig. 3). The result of NMDS using CNESSm=1 (stress 0.17) indicates that floral samples were divided into three main species groups: (1) *G. acuminatum*; (2) *G. zeylanicum*; and (3) *G. lanceolatum*, *G. obovatum*, and *G. rubrum* (Fig. 3). These separations were likely caused by differences in the principal compounds included in floral scents of the three groups; *G. acuminatum* mainly contain (*E*)-β-ocimene, *G. zeylanicum* has (*S*)-(+)-linalool and/or (*Z*)-β-ocimene, and the other three *Glochidion* species have (*E*)-β-ocimene or (*R*)-(−)-linalool. The samples of *G. lanceolatum*, *G. obovatum*, and *G. rubrum* could not be distinguished from each other. When CNESSm=39 (stress 0.17) that is equally sensitive to dominant and trace compounds, the floral samples were divided into three main species groups as in CNESSm=1. In addition, the differences among the samples of *G. lanceolatum*, *G. obovatum*, and *G. rubrum* became more or less pronounced in this scatterplot. When trace compounds were maximally emphasized in the CNESS distance transformation (CNESSm=9,999, stress 0.18), the floral scents of the five species roughly grouped by species, although there were slight overlaps between the ranges of variation in the *G. lanceolatum*, *G. obovatum*, and *G. rubrum* samples. However, when only the samples of the above three species were included in the analysis, there was a clear separation between *G. lanceolatum* and the other two species, although the floral samples of *G. obovatum* and *G. rubrum* remained indistinguishable (results not shown).

Bioassay In the first two experiments that used the *Epicephala* pollinators of *G. lanceolatum*, the moths selected the odor of the flowering branch significantly more often than blank air or nonflowering branch (Table 3). In the third experiment, both the *Epicephala* pollinators of *G. lanceolatum* and *G. rubrum* selected the odor of their respective host significantly more often than that of the nonhost (Table 3). Overall, 5.0–10.0% of the moths tested did not make choices within the given 10 min in each experiment, and thus were excluded from the analysis. The tested moths consisted of 116 males and 139 females in *G. lanceolatum*, and 4 males and 7 females in *G. rubrum*. Inspection of male genital morphology and PCR amplification of the female moths indicated that all *G. lanceolatum* pollinators used in the bioassay belong to one of the two species that cooccur at our study sites.

[e] Detected only by GC (undetectable peak in GC-MS).

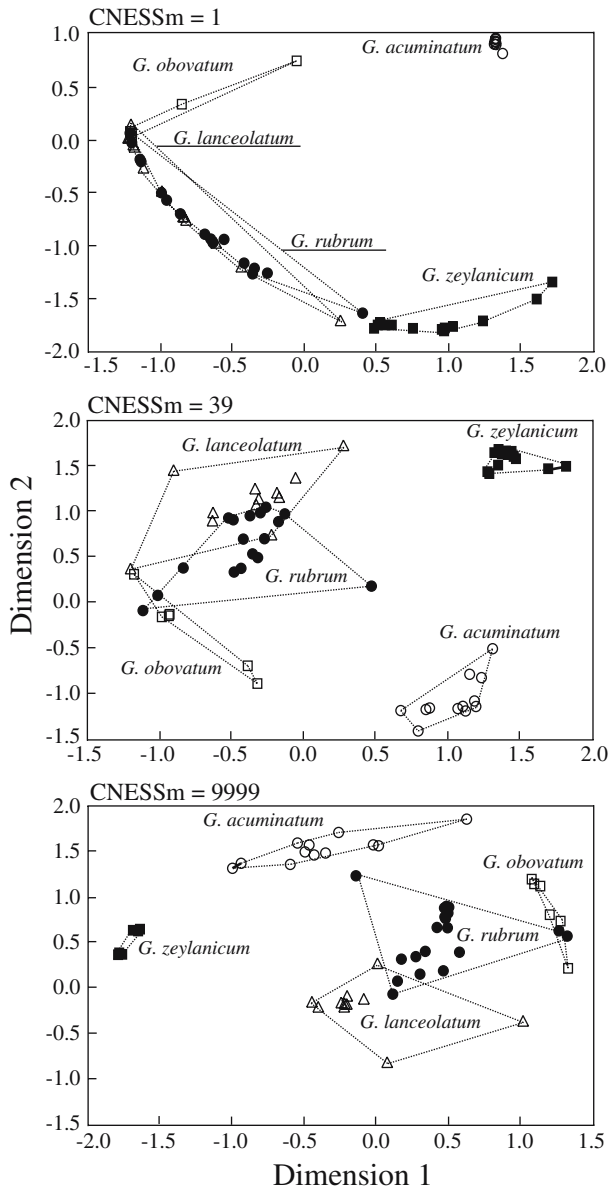

Fig. 3 Scatterplots resulting from the NMDS analysis of floral scents of the five *Glochidion* species

Discussion

Overall, 2 to 20 compounds were detected in each floral sample of *Glochidion*, and in total, 42 compounds were found. The 30 identified compounds are common to floral scents of many flowering plants (Knudsen et al. 1993). For example, monoterpenes, such as (*E*)- and (*Z*)-β-ocimene, (±)-linalool, linalool oxide, and eugenol are emitted by a wide range of flowering plants that are pollinated by various animals, such as moths (Knudsen and

Table 3 Results of Y-tube bioassay by using *Epicephala* moths pollinating *G. lanceolatum* and *G. rubrum*

Pollinator	Test Performed	Number of Moths	Host or Flower Selected	Otherwise Selected	Significance[a]
G. lanceolatum	Host vs. air	83	68	15	$P<0.001$
	Host vs. nonhost	76	59	17	$P<0.001$
	Flower vs. leaf	62	49	13	$P<0.001$
G. rubrum	Host vs. nonhost	10	8	2	$P<0.05$

[a] Binomial test

Tollsten 1993; Miyake et al. 1998; Raguso et al. 2003; Makholela and Manning 2006), butterflies (Andersson et al. 2002), beetles (Pellmyr et al. 1991; Jürgens and Dötterl 2004), bees (Gerlach and Schill 1991; Borg-Karlson et al. 1994), and bats (Pettersson et al. 2004). In addition, (±)-linalool, linalool oxide, and (*E*)-α-farnesene are attractive or at least shown to be electroantennographically positive to lepidopterans (Raguso et al. 1996; Hern and Dorn 1999; Bäckmann et al. 2001; Andersson and Dobson 2003). Most of these compounds were shared by the five *Glochidion* species, and floral scent of each species was not dominated by any compound unique to one species.

The result of CNESS-NMDS analysis based on CNESSm=1 indicated that the floral samples of the five *Glochidion* species can be grouped into three distinct types based on relative proportion of the dominant compounds, such as (*E*)-β-ocimene, (*Z*)-β-ocimene, and (±)-linalool (Fig. 3). This indicates that, at least for some species pairs, floral odors can be clearly discriminated based solely on dominant compounds. When principal and trace compounds were equally weighted in the CNESS distance calculation (CNESSm=39), the distinction between species became evident, although there were still overlaps among the samples of *G. lanceolatum*, *G. obovatum*, and *G. rubrum* (Fig. 3). Finally, when trace compounds were maximally emphasized in the analysis, the floral scents of *Glochidion* roughly grouped by species (Fig. 3). The floral samples of the two cooccurring species, *G. lanceolatum* and *G. rubrum*, were clearly separated when only the samples of these two species were included in the analysis (results not shown), indicating that the distinction between them was masked in the scatterplot shown in Fig. 3 because of inclusion of more dissimilar samples in the NMDS configuration. These results suggest the possibility that the presence of minor compounds and/or their amount relative to other compounds are also important in attracting specific *Epicephala* pollinators. However, a further study that uses electroantennographic detection analysis and field trapping with authentic chemicals is needed to test which compounds have the actual physiological activity to the specific pollinator of each species.

The floral scent of *G. acuminatum* was easily distinguished from that of the other four *Glochidion* species, as it was dominated by (*E*)-β-ocimene and contained a few minor compounds that were not emitted from the other four species, such as β-myrcene and an unidentified monoterpene (Table 2). *Glochidion obovatum* and *G. rubrum* had similar compositions of floral scent and did not have distinct proportions of either the principal or minor compounds (Table 2; Fig. 3), which possibly reflects phylogenetic relatedness (Kawakita et al. 2004). Although their floral scents could not be distinguished from each other (Fig. 3), they do not need to be distinct because their distributions do not overlap (Fig. 1) and the two hosts share the same two pollinators (Kawakita and Kato 2006). *Glochidion lanceolatum* and *G. zeylanicum* are also closely related; however, the results of CNESS-NMDS

indicated that floral scents of these could be distinguished based on both principal and trace compounds (Fig. 3). Such dissimilarity may be particularly important ecologically as the two *Glochidion* species have distinct pollinators and commonly occur in sympatry.

The Y-tube bioassay indicated that male and female pollinator *Epicephala* moths are attracted to the scents released from the host *Glochidion* trees, particularly those produced from the flowers (Table 3). These results are consistent with our prediction that olfactory cue is a key stimulus used by *Epicephala* moths to locate their host plants. Furthermore, the *Epicephala* pollinators of *G. lanceolatum* and *G. rubrum* were attracted to the odor of their respective host plants, indicating that *Epicephala* moths can discriminate between odors of the host and cooccurring nonhosts. Because the CNESS-NMDS analysis indicated that the floral scents of the two species were distinguishable based on minor compounds, the presence/absence of compounds unique to each species or characteristic proportions of relatively minor compounds may be the key decisive signal for moths to locate their host plants. The fact that both sexes of the pollinator were attracted further points to the possibility that host plants are used as mating sites because the males do not engage in pollination or oviposition, and the moths used in the test were unmated. Ideally, more *Epicephala* moths that pollinate *G. rubrum* need to be tested in the Y-tube bioassay, but these *Epicephala* moths occur at a very low density throughout our study range in the southern islands of Japan.

The differences in floral scents among *Glochidion* species that were found in this study may have resulted from a nonadaptive process but they can also have resulted from coevolution with *Epicephala* pollinators. Exploration of the extent to which floral scent of *Glochidion* is shaped by odor preferences in *Epicephala* pollinator needs further exploration by using dense sampling of plant and moth species and a robust phylogenetic hypotheses for the two groups. However, our results have implications for understanding the evolution of floral scent in the *Glochidion–Epicephala* mutualism. Within our study range, *G. obovatum* and *G. rubrum* share a pair of allopatric, phylogenetically distant *Epicephala* species that pollinate the two different *Glochidion* species within different populations (Fig. 1). The result of CNESS-NMDS analysis indicated that floral scents of *G. obovatum* and *G. rubrum* remain indistinguishable when blocked by the *Epicephala* species with which they interact (results not shown), indicating the absence of floral scent differentiation based on pollinator species. Furthermore, in several populations of *G. lanceolatum* in our study range, the plants host two divergent pollinator species, although only one of them was sampled in the present bioassay perhaps because of phenological difference between the two species. These observations suggest that floral scent differentiation does not necessarily occur when two pollinator species interact with a single host species. A similar lack of variation based on pollinator species is found in an ecologically similar yucca–yucca moth interaction (Svensson et al. 2005).

Overall, our study provides supportive evidence that floral scent of *Glochidion* is used as a signal by *Epicephala* moths to locate their specific host plants. The results provide a baseline for elucidating the mechanism that underlies the unusually high species specificity in the pollination mutualism between *Glochidion* and *Epicephala*. Furthermore, the *Glochidion–Epicephala* mutualism is a unique situation among other obligate pollination mutualisms in that the plant has separate male and female flowers, which may produce different odor blends to induce complex pollination behavior in the moths. Further study of the floral scents in *Glochidion–Epicephala* mutualism may provide additional insight into evolutionary and ecological aspects of the mutualisms between plants and their obligate seed-parasitic pollinators.

Acknowledgements We appreciate Y. Inui for providing the opportunity to conduct this study; T. Y. Chiang, T. W. Hsu, and S. C. Liu for assistance in the field in Taiwan; Y. Yamaoka and I. Shimizu for allowing us to use the GC and GC-MS; Y. Kumano and N. Fujiwara-Tsujii for technical advice in collecting and analyzing the floral scents; and the subject editor and anonymous reviewers for valuable comments on the manuscript. RAPID COMMUNICATION

The Influence of Tissue Handling on the Flavonoid Content of the Aquatic Plant *Posidonia oceanica*

Abstract In recent times, more and more studies have focused on flavonoids as biomarkers of environmental quality in aquatic plants, in particular, *Posidonia oceanica* (Linnaeus) Delile. It is therefore of interest to determine how different prehandling methods can affect flavonoid concentrations. The methods tested were (1) immediate extraction of fresh samples, (2) extraction after 48 hr chilling, (3) freeze-drying, and (4) oven drying. Chilling and freeze-drying considerably altered the quantity of flavonoids measured, but not their profile. The effect of oven drying was not significant. Chilling led to a loss of 57% of total (pro)anthocyanidins, 39% of total flavonols, and 48% of all simple flavonols (myricetin, quercetin, isorhamnetin, and kaempferol). Freeze-drying caused a loss of 71% of total (pro) anthocyanidins, 87% of total flavonols, and 95% of all simple flavonols.

Keywords Prehandling methods · Chilling · Freeze-drying · Oven-drying · *Posidonia oceanica* · Flavonoids · (pro)Anthocyanidins · Flavonols

Introduction

Marine Magnoliophyta are of increasing interest as bioindicators because of their worldwide distribution in the littoral zone, their longevity, and their potential to provide useful information on the evolution of environmental quality (Cannac et al. 2006). Many studies of phenolics have been carried out, in particular of flavonoids (Kaundun et al. 1998), as they have the potential to be reliable biomarkers of environmental quality (Cannac et al. 2006). Flavonoids are divided into 12 classes, according to the oxidation level of their central pyran ring. The most important and widespread are flavonols and (pro)anthocyanidins.

Flavonoids have mostly been studied in terrestrial plants (Kaundun et al. 1998), whereas only a few studies have been performed on aquatic plants (Cannac et al. 2006).

Most studies indicate that, whenever possible, intact fresh plant material should be used in the analysis of secondary plant metabolites (Julkunen-Tiitto and Tahvanainen 1989). However, the high moisture content and increased enzymatic activity of fresh samples and the difficulty of repeating experiments may often invalidate and restrict the use of such material. When working on a large number of field samples collected from distant locations, it is necessary to prepare the material so that it can be stored for some time before analysis (Julkunen-Tiitto and Tahvanainen 1989).

Given the importance of secondary metabolites in plant defense, and because individual flavonoids exhibit different biological activities, proper methods for preservation of foliar material prior to chemical analysis are important (Orians 1995). Inappropriate methodologies may cause substantial changes in concentration that can lead to false interpretations. Many studies have highlighted the damages provoked by freeze-drying and oven drying on phenolic content in terrestrial plants (Julkunen-Tiitto and Tahvanainen 1989; Orians 1995; Lindroth and Koss 1996; Julkunen-Tiitto and Sorsa 2001). In these studies, the appropriate prehandling method depends upon the chemical species (Orians 1995), the part of the plant, and the plant considered (Julkunen-Tiitto and Tahvanainen 1989). Concerning aquatic plants, Steinberg (1986) demonstrated that freezing seems to cause changes in total phenolic compounds for *Sargassum* sp. (phaophyceae), but otherwise, no other prehandling study has been carried out.

Our purpose here was to verify to what extent different prehandling methods can alter flavonoid concentrations [total (pro)anthocyanidins and total and simple flavonols] for *Posidonia oceanica* (Linnaeus) Delile, the most widely studied species of marine Magnoliophyta in the Mediterranean (Cannac et al. 2006).

Methods and Materials

Plant Material *Posidonia oceanica* is organized into roots, rhizomes, and leaves, differentiated as follows (Cannac et al. 2006): (1) adult leaves consisting of a blade and a sheath, (2) intermediate leaves (length more than 50 mm without sheath), and (3) juveniles leaves (length less than 50 mm without sheath). Eighty *P. oceanica* foliar shoots were sampled by SCUBA diving on July 2006, in the Gulf of Calvi, Corsica (France, N 42° 34.811′, E 008°43.479′) at a depth of 15 m. Only blades were studied because phenolic concentrations are higher than in sheaths (Cannac et al. 2006).

Prehandling After sampling, shoots were kept cool in an icebox until their return to the laboratory (1-hr drive). All work was carried out in the dark. Blades were cleared of their epiphytes by gentle scratching with a glass blade, to alter the plant surface as little as possible and on a cool pack to avoid variations in temperature and to minimize chemical changes.

Samples were divided into four batches of 20 shoots, each of which underwent a different prehandling process, and within each batch, shoots were grouped in fours to obtain five replicates. The treatments were as follows: (1) immediate extraction of fresh samples, (2) chilling samples for 48 hr before extraction, (3) freeze-drying samples (FD 4-85, HETO ®) with prefreezing (−26°C) for 48 hr, and (4) oven-drying samples in a steam room (D-6450 Hanau, Heraeus) for 48 hr at 40°C.

Extraction Extraction and quantification of flavonoids [total (pro)anthocyanidins and total and simple flavonols] was based on the work of Kaundun et al. (1998). Thus, 1.6 g (dry weight) of *P. oceanica* was suspended in 100 ml of 2 M HCl. The solution was heated to 80°C in a water bath with reflux for 50 min with influxes of air every 10 min. The solution was left to cool for 30 min (solution A) and then, apart from 2 ml removed for measurement of (pro)anthocyanidins, was filtered through a no. 28 porosity filter. Flavonols were extracted from the filtered solution and from the filter wash liquid with 60 ml (twice) and then 40 ml (once) of diethyl ether. These different fractions were remixed and evaporated. The residue was kept in the freezer in the dark and then mixed with 5 ml of methanol (solution B) before analysis of the simple and total flavonols. A volume of 2 ml taken from solution A was adjusted to 3 ml with 2 M HCl. The total (pro)anthocyanidins were measured by using an absorption spectrophotometer (UV-1201, Shimadzu) at 530 nm wavelength. The results were indicated as measurements of optical density because there were no standards. A volume of 100 µl of solution B was left to react for 20 min in 5 ml of a 1% AICl3 (w/w) methanol solution. Total flavonols were measured by absorption spectrophotometry at a wavelength of 435 nm (measurement of the formation of a colored complex in the presence of Al^{3+} ions). Quantitative results were expressed with reference to a standard set carried out by using quercetin.

Identification and Quantification of Simple Flavonols Extracts were analyzed by high-performance liquid chromatography with a UV detector (UVD170, Dionex) set at wavelength 370 nm and a Nucleosil 100 C18 column (4.6×250 mm) fitted with a stationary same-phase precolumn. The eluent composition was 1, water; 2, methanol; 3, tetrahydrofuran; and 4, acetic acid. The elution profile was from 57:20:17:6 (1/2/3/4) to 20:60:17:3 for 35 min with a constant flow rate of 1 ml min^{-1}. The injection volume was 20 µl. Identification of compounds was based on the comparison of their retention times and their UV spectra (250–400 nm) with those of commercial standards (Roth-Sochiel®). External calibration was performed with a mixture of four flavonoids: myricetin, quercetin, isorhamnetin, and kaempferol. These simple flavonols are the most used, according to the literature, for their response to variations in environmental conditions (Waterman and Mole 1994).

Statistical Analyses For each analysis, three replicates were made. The two-way ANOVA, a nonparametric test of median comparisons, Kruskall–Wallis, and Tukey tests were performed by using the "Statgraphics for Windows" software produced by Statistical Graphics®.

Results

Total (pro)Anthocyanidins and Total Flavonols Average concentrations of total (pro) anthocyanidins (Fig. 1a) are significantly lower in chilled (57% loss) and freeze-dried (71% loss) blades than in fresh and oven-dried ones (only 3% loss; Kruskal–Wallis, $P<0.05$) in *P. oceanica*. Average concentrations of total flavonols (Fig. 1b) are lower in freeze-dried samples (87% loss) compared to the other prehandling methods (39 and 2% losses for chilled and oven-dried samples, respectively; Kruskal–Wallis, $P<0.05$). No significant differences were found between fresh and oven-dried samples (Kruskal–Wallis, $P>0.05$) for (pro)anthocyanidins and total flavonols.

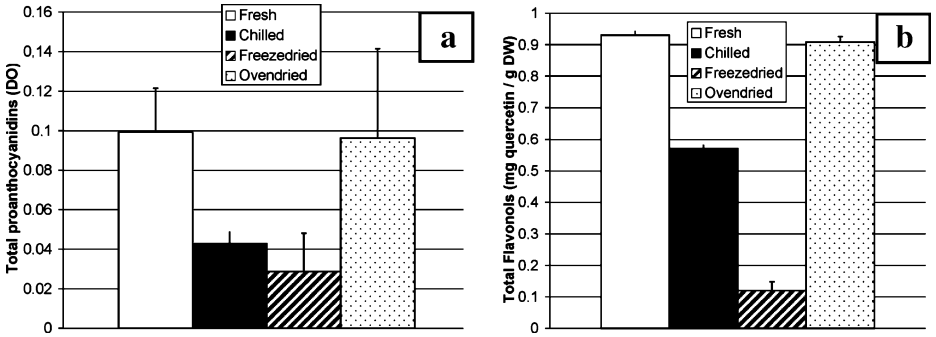

Fig. 1 Average concentrations of total flavonoids in fresh, chilled, freeze-dried, and oven-dried blades of *P. oceanica*. **a** Total proanthocyanidins [in optical density (*OD*) ± standard error]; **b** total flavonols (mg of quercetin g^{-1} of dry matter ± standard error)

Simple Flavonols All simple flavonols measured in *P. oceanica* samples were identified and classified according to their retention time: myricetin, quercetin, isorhamnetin, and kaempferol. Average concentrations of simple flavonols (Table 1) were lower in freeze-dried samples compared to the other prehandling methods (Kruskal–Wallis, $P<0.05$). No significant differences were found between fresh and oven-dried samples (Kruskal–Wallis, $P>0.05$) for any simple flavonols. Compared to fresh samples, for all simple flavonols, chilling led to a loss of 48%, freeze-drying to a loss of 95–98%, and oven drying to a loss of only 4–7% (two-way ANOVA, $P<0.05$).

Discussion

Concentrations of total and simple flavonols measured in *P. oceanica* are of the same order as those found in terrestrial species such as *Pinus halepensis* Mill. (Kaundun et al. 1998). Those identified in *P. oceanica* have been observed previously (Kaundun et al. 1998). Total and simple flavonols in *P. oceanica* are quantitatively influenced by the prehandling method, but their profiles are not. Concentrations of total and simple flavonols are considerably reduced by chilling or freeze-drying, but remain relatively unchanged by oven drying, compared to fresh samples.

Table 1 Mean concentrations in simple flavonols (μg g^{-1} of dry matter ± standard error) and rapport between fresh, chilled, freeze-dried, and oven-dried samples in the blades of *P. oceanica*

Simple Flavonols	Myricetin	Quercetin	Isorhamnetin	Kaempferol
Fresh	19.790±2.102 (c)	2.702±0.301 (c)	3.341±0.335 (c)	1.057±0.097 (c)
Chilled	10.292±0.989 (b)	1.405±0.137 (b)	1.737±0.198 (b)	0.55±0.057 (b)
Freeze-dried	0.382±0.031 (a)	0.066±0.006 (a)	0.160±0.011 (a)	0.046±0.004 (a)
Oven-dried	18.299±1.598 (c)	2.505±0.142 (c)	3.220±0.235 (c)	0.979±0.084 (c)
ANOVA results	$F=219.57$ $P<0.001$	$F=71.28$ $P<0.001$	$F=137.67$ $P<0.001$	$F=42.54$ $P<0.001$

Results of statistical analysis are also done for each flavonol type (F and p value). Tukey's tests with regard to treatment effects are also presented for each flavonol: values not different at $\alpha=5\%$ are denoted with the same letter.

Waterman and Mole (1994) explained that, after collection of plant material, enzymatic activity may quickly lead to irreversible changes in phenolic compounds, such as oxidation and subsequent polymerization or decomposition. After 48 hr of chilling, we saw the color of *P. oceanica* leaves becoming brownish, which indicated that chemical and enzymatic reactions were occurring (Julkunen-Tiitto and Tahvanainen 1989). This result emphasizes the importance of treating leaves immediately after sampling. The time spent in the fridge and/or icebox must be as short as possible and must always be the same from one sampling to another.

Freeze-drying drastically altered the quantity of measured flavonoids. There was a loss of 71% of total (pro)anthocyanidins, 87% of total flavonols, and 95% of all simple flavonols (myricetin, quercetin, isorhamnetin, and kaempferol). The impact of freeze-drying on phenolic compounds has been much debated. It seems to vary according to the chemical species, the part of the plant, and the plant considered. For example, Julkunen-Tiitto and Sorsa (2001) did not show any significant impact of freeze-drying on flavonoid glycosides in *Salix purpurea*, but Orians (1995) demonstrated a loss of 70% for some *Salix* sp. phenolic glycosides. The results observed by Steinberg (1986) seem to vary with the species, as freezing led to an 11% decrease in total phenolic compounds in *Sargassum globulariaefolium* but a 4–5% increase in *Sargassum* sp.

Chalker-Scott et al. (1989) observed a loss of phenolics of more of 40%, when Rhododendron leaves were frozen to −15°C and showed that losses are caused by temperatures lower than −5°C, the phenomenon being aggravated at lower temperatures. In our study, samples were frozen to −26°C, which may partly explain the significant losses. Freezing would break the membranes, simultaneously releasing compartmentalized phenolics and proteins into the cell (Chalker-Scott and Fuchigami 1989). Phenolics, once free in the cell, are likely to form hydrogen bonds with proteins to form insoluble complexes, by means of their hydroxyl groups (Chalker-Scott and Fuchigami 1989; Waterman and Mole 1994). Such modifications can lead to phenolic variation. Such changes may result in higher or lower concentrations, depending on the formula of the compound considered. Beyond the presence of hydroxyl groups, their particular disposition on the carbon skeleton and the molecular weight may also be important in how specific phenolic molecules interact with proteins (Waterman and Mole 1994).

Lindroth and Koss (1996) have explained the reduction in phenolic concentrations by hydrolytic degradation during thawing of frozen leaf tissue. This may occur during freeze-drying and not by freeze-drying *per se*, thus emphasizing the importance of using a temperature-regulated drying chamber (Orians 1995). This thawing phenomenon cannot alone be responsible for the decrease in flavonoid concentrations because the decreases are higher than those observed with chilling (when enzymatic decomposition is assumed to be maximal). The problem of thawing may be aggravated by the fact that, in parallel, the drying process slowly continues, leading to the concentration of enzymes and substrates, which would likely facilitate such reactions (Waterman and Mole 1994). Some phenolics might also be lost during freeze-drying under high-vacuum conditions by their being concentrated in the ice trap (Van Sumere et al. 1983 in Orians 1995).

Oven-drying seems to be an appropriate method for preserving flavonoids from *P. oceanica*, as the concentrations remain similar to those of fresh samples. Our results are in accordance with those reported by Julkunen-Tiitto and Tahvanainen (1989), who underline the importance of oven-drying intact leaves to minimize enzymatic decomposition that occurs when samples are stirred into a homogeneous mixture before drying. During oven drying, the disappearance of moisture is rapid in *P. oceanica*, even in entire leaves, because the species has very thin leaves (its growing cycle occurs entirely in submerged meadow, so

it is highly subject to desiccation). This is not systematically the case for most terrestrial species, which need to be cut into small pieces to accelerate the elimination of moisture. Rapid drying shortens the time that compounds are subject to enzyme action because the reactions require water (Julkunen-Tiitto and Tahvanainen 1989). The use of high temperatures (60 to 80°C) for drying, however, has been shown to reduce the amount of extractable total phenolics and (pro)anthocyanidins in the leaves of *Salix* sp. (Julkunen-Tiitto 1985 in Julkunen-Tiitto and Tahvanainen 1989).

Our results indicate that, when treating fresh samples immediately is not possible, oven drying for 48 hr at 40°C is preferable to freeze-drying for *P. oceanica*. Although there were significant differences among the different methods regarding flavonoid concentrations, none altered the flavonoid profile.

Acknowledgments This work was carried out and funded in the framework of the Interreg III European Programs. The authors thank C. Lafabrie and B. Mimault for participation in field missions.

Abstract Methyl jasmonate (MeJA) and methyl salicylate (MeSA) are important signaling molecules that induce plant defense against insect herbivores and microbial pathogens. We tested the hypothesis that allelopathy is an inducible defense mechanism, and that the JA and SA signaling pathways may activate allelochemicals release. Exogenous application of MeJA and MeSA to rice (*Oryza sativa* L.) enhanced rice allelopathic potential and led to accumulation of phenolics, an increase in enzymatic activities, and gene transcription of phenylalanine ammonia-lyase (*PAL*) and cinnamate 4-hydroxylase (*C4H*), two key enzymes in the phenylpropanoid pathway. Aqueous extracts of the leaves of rice IAC165, a putative allelopathic variety, treated with MeSA (5 mM) or MeJA (0.05 mM), showed increased inhibitory effects (25 and 21%, respectively) on root growth of barnyardgrass (*Echinochloa crus-galli* L.), and increased inhibitory effects (18 and 23%, respectively) on shoot growth. Aqueous extracts from leaves of Huajingxian 1 rice, a putative nonallelopathic variety treated with MeJA and MeSA, caused 63 and 24% inhibition of root growth in barnyardgrass seedlings. The root exudates of both IAC165 and Huajingxian 1 plants treated with MeJA and MeSA for 48 hr also showed significant increases in their inhibitory effects on root growth of barnyardgrass seedlings. At the four-leaf stage, levels of 3,4-hydroxybenzoic acid, vanillic acid, coumaric acid, and ferulic acid that accumulated in the

leaves were 5.3-, 31.3-, 2.2-, and 1.7-fold higher in response to MeJA exposure, and 3.3-, 13.1-, 2.0-, and 2.2-fold higher in response to MeSA. Treatments of MeSA and MeJA enhanced the PAL activity in the rice leaves up to 52.3 and 80.1%, respectively, whereas C4H activity was increased by 40.2 and 67%. Gene transcription of *PAL* and *C4H* in rice leaves significantly increased after the plants were subjected to treatment with MeJA and MeSA. These results suggest that allelopathy may be an active defense mechanism, and that plant signaling compounds are potentially valuable in its regulation.

Keywords Methyl salicylate · Methyl jasmonate · Rice · Allelopathy · Inducible · Phenolic acid · Phenylalanine ammonia-lyase · Cinnamate 4-hydroxylase

Abbreviations

MeSA	methyl salicylate
MeJA	methyl jasmonate
VA	vanillic acid
CA	caffeic acid
FA	ferulic acid
CMA	coumaric acid
HBA	3,4-hydroxybenzoic acid
PAL	phenylalanine ammonia-lyase
C4H	cinnamate 4-hydroxylase

Introduction

Allelopathy provides an alternative for weed management in sustainable agriculture. Rice (*Oryza sativa* L.) is one of the most important crops in the world, and its allelopathy has attracted great attention since Dilday et al. (1989) demonstrated that some varieties have allelopathic potential against one or more paddy weeds. Rice allelopathy has been extensively studied with respect to screening allelopathic rice germplasm (Dilday et al. 1994; Olofsdotter et al. 1995, 1999), the allelochemicals produced (Mattice et al. 1998; Kato-Noguchi 2004; Seal et al. 2004a, b), and genetic control (Ebana et al. 2001; Jensen et al. 2001; Zeng et al. 2003; He et al. 2004). More than 12,000 rice accessions have been evaluated in the United States for their allelopathic potential of weed control in paddy fields (Dilday et al. 1994, 1998). Selection of allelopathic rice germplasm has been conducted in many countries (Fujii 1992; Garrity et al. 1992; Dilday et al. 1994; Olofsdotter et al. 1995; Chung et al. 1997, 2000, 2001a, b; Chou 1999; Ahn and Chung 2000). Work by Seal et al. (2005) has shown the correlation between the allelopathic potential of rice, as measured in the laboratory, and weed inhibition in the field. Several putative allelochemicals have been identified, including simple phenolic acids such as *p*-hydroxybenzoic (Chou and Lin 1976), ferulic (Chung et al. 2000, 2001a), syringic, caffeic, sinapic, and *o*-coumaric acids (Olofsdotter et al. 1995). Recent studies have indicated that momilactone A and B may play an important role in rice allelopathy (Kato-Noguchi et al. 2002; Kato-Noguchi 2004; Chung et al. 2006). Kato-Noguchi and Ino (2003) found that momilactone B from rice seedlings could accumulate to levels high enough to inhibit growth of cress seedlings. 3-Isopropyl-5-acetoxycyclohexene-2-one-1, momilactone B, and 5,7,4′-trihydroxy-3′,5′-dimethoxyflavone were also identified as putative allelochemicals in the rice accession PI312777 (Kong et al. 2004).

The genetic control of allelopathy in rice has been assessed. Jensen et al. (2001) identified four main-effect quantitative trait locus (QTL) genes located on three chromosomes (2, 3, and 8), which collectively explained 35% of the total phenotypic variation of the allelopathic activity in the population. Ebana et al. (2001) also identified QTL genes associated with the effect by using restriction fragment length polymorphism markers. One of the QTLs on chromosome 6 had the largest effect, explaining 16.1% of the phenotypic variation. He et al. (2005) employed proteomic methods to study the molecular mechanism of crop allelopathy and identified four proteins involved in the production of allelochemicals: peroxidase precursor, thioredoxin M-type, 3-hydroxy-3-methylglutaryl-coenzyme A reductase 3, and phenylalanine ammonia-lyase (PAL). The genes encoding these four allelopathy-related proteins are located on chromosomes 4, 7, 8, and 12.

Upon attack by herbivores and pathogens, plants may produce chemicals that combat their enemies. Chemical defense of plants is ubiquitous, often inducible, and activated through a complex network of signaling cascades involving jasmonate and salicylate pathways. Jasmonates and salicylates function as key signal molecules in plant defense (Kessler and Baldwin 2002) and modulate plant resistance to insects and pathogens (Creelman and Mullet 1997). Many defense-related genes require jasmonic acid (JA) and salicylic acid (SA) for activation (Reinbothe et al. 1994; Thomma et al. 1998; Turner et al. 2002). Exogenously applied JA induces the production of momilactone A, a major phytoalexin and possible allelochemicals in rice (Nojiri et al. 1996), and increases resistance of wild plants to insects in the field (Baldwin 1998). Poplar leaves increase phenolic acids when exogenously treated with methyl salicylate (MeSA) and methyl jasmonate (MeJA) (An et al. 2006). Sakuranetin, a flavonoid phytoalexin, is also induced by amino acid conjugates of JA (Shigeru et al. 1997). Two acyclic homoterpenes 4,8-dimethyl-1,3*E*,7-dimethylnonatriene (homoterpene I) and 4,8,12-trimethyl-1,3*E*,7*E*,11-tridecatetraene (homoterpene II), which are of sesquiterpenoid and diterpenoid origin, can be induced by 0.1 to10 mM of JA on leaves of *Phaseolus lunatus* and *Zea mays* (Jörn et al. 1994). Methyl salicylate treatment increased concentrations of *u*-tropine, and tropine in jimsonweed (*Datura stramonium*) seedlings (Fan 2005) and induced triterpenoid synthesis in both *Centella asiatica* and *Galphimia glauca* plantlets (Mangas et al. 2006). MeJA also induced indole glucosinolate biosynthesis in *Arabidopsis* (Brader et al. 2001) and oilseed rape (Loivamaki et al. 2004). Salicylic acid is a well-known inducer of plant systematically acquired resistance in plant–pathogen interactions, which results in resistance to pathogens and is characterized by the induction of defense-related gene expression and synthesis of phenylpropanoids, phytoalexins, and pathogenesis-related proteins (Métraux 2001; Durrant and Dong 2004; De Vos et al. 2005). Salicylic acid also induces the biosynthesis of secondary metabolites in plants (Taguchi et al. 2001).

Secondary compounds can enhance the survival of a plant, allowing greater reproduction in stressful environments. It is still unclear, however, whether the release of allelochemicals into the environment is passive or active. It is hypothesized that allelopathy is an actively inducible defense mechanism, and that the JA and SA signaling pathways may activate chemical release. In this study, we tested the above hypothesis by applying MeJA and MeSA to rice exogenously and by examining changes in the allelopathic potential of rice exudates and aqueous extracts, as well as in gene expression and in enzymatic activities of PAL, which catalyzes the first step in the biosynthesis of phenylpropanoids and cinnamate 4-hydroxylase (C4H). The latter catalyzes the conversion of cinnamate into 4-hydroxy-cinnamate, a key reaction in the phenylpropanoid pathway.

Methods and Materials

Plant and Chemical Materials

Two rice varieties were used: IAC165, a standard cultivar with known allelopathic potential (Kim et al. 2005) was provided by the International Rice Research Institute, and Huajingxian 1, a nonallelopathic cultivar (Bi 2004), was provided by Prof. Zhi-qiang Chen at the South China Agricultural University. Vanillic acid (VA), caffeic acid (CA), 3,4-hydroxybenzoic acid (HBA), ferulic acid (FA), coumaric acid (CMA), MeJA, and MeSA were purchased from Sigma (St. Louis, MO, USA). The concentrations of MeJA and MeSA used were 0.05 and 5 mM, respectively. These two were chosen because they are well-established signal molecules belonging to an integral part of a general signal transduction system in plant defense responses, and they are volatile signals whose potential phytotoxicity could be avoided (Preston et al. 2002). TRIzol reagent, AMV reverse transcriptase, *Taq* polymerase, and deoxynucleotide triphosphates were purchased from TaKaRa (Shuzo Co. Ltd., Shiga, Japan). MOPS and DEPC were purchased from AMRESCO (Solon, OH, USA). All solvents used were high-performance liquid chromatography (HPLC) grades.

Bioassays

Rice seeds were surface-sterilized with 1% NaClO for 30 min, rinsed with distilled water, and pregerminated in petri dishes for 3 d. Twenty germinated seeds were transplanted to a plastic pot (10×15 cm) and raised in a growth chamber kept at 24–26°C with 150 μMd m^{-2} sec^{-1} light and a photoperiod of 12-hr light/12-hr darkness. The pots were watered and fertilized with Hoagland nutrient solution every 2 d.

Rice seedlings at the two-, four-, and six-leaf stages were sprayed with 0.05 mM of MeJA or 5 mM of MeSA and kept in the growth chamber for 48 hr. Aqueous extracts were prepared by extracting 8 g of plant leaves and stems with 100 ml of distilled water for 24 hr. Extracts were filtered through filter paper and stored at 4°C until used.

Barnyardgrass (*Echinochloa crus-galli*) seeds were used to bioassay the aqueous extracts of rice leaves and stems, as described by Zeng et al. (2001). Root and shoot lengths of the *E. crus-galli* seedlings were determined 7 d after treatment.

Root Exudates

Pregerminated seeds of rice (10 seeds per beaker) and barnyardgrass (20 seeds per beaker) were planted in a 1,000-ml beaker with 300 ml of 1% agar culture media. The agar medium was divided into two equal compartments by using a membrane with a pore size of 35 μm. The membrane prevented root contact between the plants but allowed root exudates to pass through. Rice and barnyardgrass seedlings were grown in the growth chamber as described above. Leaves were painted with 0.05 mM of MeJA or 5 mM of MeSA three times with a brush pen—at the two-, four-, and six-leaf stages. The barnyardgrass seedlings and culture medium were wrapped in aluminum foil to prevent contact with signaling compounds as the compounds were applied. Seedlings were watered and fertilized with Hoagland nutrient

solution every 2 d. Root and shoot lengths of the *E. crus-galli* seedlings were measured 7 d after the rice plants received the final application of signaling compounds.

Chemical Analysis

Plants treated with MeJA or MeSA at the four-leaf stage were kept in the growth chamber for another 48 hr before sampling. One gram of rice leaves and stems was collected from the different treatments and extracted in 12.5 ml of distilled water for 24 hr. Water extracts were partitioned against an equal volume of ethyl acetate three times. The ethyl acetate extracts were combined and concentrated to dryness at 40°C under reduced pressure, then dissolved in 1.25 ml of methanol. Methanol extracts were passed through sterilized filter paper in a syringe. Phenolic compounds in the filtrate were analyzed by using an Agilent Technologies HP1100 series HPLC system equipped with an ODS reverse phase C18 column (250×4 mm, 5 μm) and diode array detector (G1315 B) monitoring the absorbance of the elution at 280 and 268 nm. The solvent system was 75% methanol and 25% water with pH adjusted to 2.6 with acetic acid. Five microliters of each extracted sample were injected, flow rate was 1.0 ml/min, and temperature was 30°C. Pure compounds were used as standards, and phenolic acids were identified by comparison of retention times and UV spectrum.

Enzymatic Activities

Rice plants were treated with signal compounds at the four-leaf stage for the C4H assay, and at the two-, four-, and six-leaf stages for the PAL assay. Before the enzymatic activity analysis, the plants were sprayed with MeJA (0.05 mM) or MeSA (5 mM) and kept in different growth chambers for another 48 hr. Phenylalanine ammonia-lyase activity was assayed based on the method described by Ramamoorthy et al. (2002) with slight modification. Root samples (1 g) were ground with liquid nitrogen and homogenized in 1 ml of ice-cold 0.1 M Tris–H_2SO_4 buffer, pH 8.8, containing 7 mM of 2-mercaptoethanol and 1 mM EDTA–Na, 7% glycerin. The homogenate was centrifuged (10,000×*g* for 15 min). The supernatant was used for enzyme analysis.

PAL activity was determined based on the rate of the conversion of L-phenylalanine to *trans*-cinnamic acid, as measured by absorbance at 290 nm. The absorbance (OD1) of 0.5 ml of enzyme extract, 2 ml of 50 mM Tris–H_2SO_4 buffer (pH 8.8), and 1 ml of 20 mM L-phenylalanine was measured before and after incubation in hot water for 15 min at 40°C. Enzyme activity was stopped after incubation with the addition of 6 M HCl. Phenylalanine ammonia-lyase activity was determined spectrophotometrically as described by Edwards and Kessmann (1992) and was expressed in units per gram per hour.

The C4H activity was assayed by using the method described by Lamb and Rubery 1975 with slight modification. Cinnamate 4-hydroxylase was extracted from fresh rice leaves (1 g), then homogenized in 2 ml of potassium phosphate buffer (200 mM, pH 7.5, containing 2 mM of 2-mercaptoethanol). After filtration and centrifugation (15 min at 10,000×*g*), the supernatant was diluted 20 times, and used for enzymatic analysis. The extract (0.2 ml) was added to 2 ml of reaction buffer (50 mM phosphate buffer containing 2 mM of 2-mercaptoethanol, 2 mM *trans*-cinnamic acid, and 0.5 mM NADPH), which was incubated for 1 hr at 37°C. Absorbance values were measured at 290 nm after the reaction

was stopped with 6 M of HCl and readjusted to pH 11 with 6 M of NaOH. The C4H activity was expressed in units per gram per hour.

Reverse Transcription Polymerase Chain Reaction

Rice plants at the four-leaf stage were sprayed with MeJA and MeSA and kept in growth chambers for 48 hr before sampling. The total RNA was extracted and isolated according to the method described by Kiefer et al. (2000) with slight modification. Fresh plant tissue (0.2 g) was ground with a mortar and pestle under liquid nitrogen, and the powdered tissue was transferred to a 2-ml Eppendorf tube, then 1,000 μl of TRIzol reagent was added and mixed. After incubation for 8–10 min on ice, 200 μl of chloroform were added and mixed. After 5 min of incubation at room temperature, the mixture was centrifuged for 15 min at 4°C and 12,000×*g*. The supernatant was transferred to a 1.5-ml Eppendorf tube, and 500 μl of isoamyl alcohol was added, followed by vortexing at room temperature for 10 min and centrifugation for another 10 min at 4°C and 13,000×*g*. The supernatant was discarded, and the pellet washed with 1 ml of 75% ethanol (v/v) and kept at −20°C until used.

The expression patterns of defense-related genes in rice leaves after treatment with signaling compounds were analyzed by using reverse transcription polymerase chain reaction (RT-PCR). The degenerate primers used for amplification of the putative genes are described in Table 1. Actin was used as a reference. Reverse transcription polymerase chain reactions were initiated with first strand cDNA synthesis at 42°C for 60 min. After denaturation of the RNA–cDNA hybrid at 94°C for 2 min, 40 PCR amplification cycles (94°C for 1 min, 56°C for 1 min, and 72°C for 1 min) were run and followed by a final extension for 7 min. Two microliters of concentrated (×10) loading dye were added to each reaction, and 5 μl of each sample were run on a 1.2% agarose gel in 1×Tris–acetate–EDTA buffer.

Table 1 Specific primers for RT-PCR

Gene	Accession Number	Gene Function	Specific Primer
*Os*PAL	X16099	The first enzyme of the phenylpropanoid pathway catalyzing the deamination of phenylalanine to produce *trans*-cinnamic acid	F: 5′-CACAAGCTGAAGCACCACCC-3′ R: 5′-GAGTTCACGTCCTGGTTGTG-3′

Actin	X15865	Constitutive actin gene and internal standard of RT-PCR	F: 5′-ACTGTCCCCATCTATGAAGGA-3′ R: 5′-CTGCTGGAATGTGCTGAGAGA-3′

Actin, internal standard of RT-PCR

C4H=Cinnamate 4-hydroxylase, PAL=phenylalanine ammonia-lyase

Statistical Analyses

All data were evaluated by one-way analysis of variance with treatment differences among means being tested at $P=0.05$ with Duncan's multiple range test. The root and shoot growth results as well as the content of phenolic acids and the enzymatic activities of PAL and C4H were means from three replicates.

Results

Aqueous Extract

The aqueous extracts of the stems and leaves of rice IAC165, a putative allelopathic variety, had much stronger phytotoxic effects on the root and shoot growth of barnyardgrass after being treated with MeSA (5 mM) or MeJA (0.05 mM) than the control, i.e., aqueous extracts from rice not receiving treatment with signaling compounds (Table 2). Aqueous extracts of the stems increased inhibition of the root growth in barnyardgrass by 24 and 32% and shoot growth by 38 and 27%, respectively. Aqueous extracts of the leaves increased inhibition of the root growth by 25 and 21% and the shoot growth by 18 and 23% (Table 2).

After treatment with signaling compounds, aqueous extracts of both leaves and stems of rice Huajingxian 1, a putative nonallelopathic variety, also showed stronger inhibition of the root growth in barnyardgrass compared with aqueous extracts from plants not receiving treatment (Table 2). Aqueous extracts from stems of Huajingxian 1 plants treated with MeJA (0.05 mM) or MeSA (5 mM) for 48 hr showed 63 and 36% higher inhibition of root growth compared with the control. Similarly, the aqueous extracts of leaves from Huajingxian 1 plants exposed to MeJA or MeSA also displayed higher inhibition of root growth by 63 and 24% compared with the control (Table 2), but the shoot length of barnyardgrass seedlings did not differ from the controls (Table 2). Bioassay results showed that both the allelopathic and nonallelopathic rice varieties enhanced their phytotoxicity against barnyardgrass after being treated with the signaling compounds MeSA and MeJA.

Table 2 Effects of the aqueous extracts from Huajingxian 1 and IAC165 rice treated with MeJA (0.05 mM) or MeSA (5 mM) on root length and shoot length of barnyardgrass

Extraction Organ	Treatments	Huajingxian 1		IAC165	
		Root Length (cm)	Shoot Length (cm)	Root Length (cm)	Shoot Length (cm)
Stems	Control	7.0±0.49a	6.0±0.18a	6.3±0.27a	6.0±0.49a
	MeJA	2.6±0.21c	5.9±0.42a	4.2±0.47b	4.4±0.42b
	MeSA	4.5±0.51b	5.6±0.23a	4.8±0.4b	3.7±0.39b
Leaves	Control	4.8±0.37a	5.5±0.25a	6.3±0.32a	5.6±0.34a
	MeJA	1.8±0.37c	5.2±0.25a	5.0±0.35b	4.3±0.28b
	MeSA	3.6±0.14b	6.0±0.31a	4.7±0.49b	4.5±0.32b

Rice plants were treated externally at the four-leaf stage for 48 hr. Values are mean±standard error. Significant difference ($P<0.05$) among treatments in each group are indicated by different letters.

Table 3 Effect of the root exudates of Huajingxian 1 and IAC165 rice treated with MeJA (0.05 mM) or MeSA (5 mM) on root length and shoot length of barnyardgrass grown in agar

Rice Cultivars	Treatments	Root Length (cm)	Shoot Length (cm)
Huajingxian 1	Control	10.9±0.44a	22.3±0.55a
	MeJA	8.4±0.44b	21.4±0.76a
	MeSA	8.8±0.36b	21.2±0.77a
IAC165	Control	10.4±0.74a	20.6±0.54a
	MeJA	8.6±0.56b	20.9±0.80a
	MeSA	8.4±0.55b	18.8±1.33a

Rice plants were treated externally at the four-leaf stage for 48 hr. Values are mean±standard error. Significant difference ($P<0.05$) among treatments in each group are indicated by different letters.

Root Exudates

The root exudates of rice plants treated with MeJA (0.05 mM) or MeSA (5 mM) for 48 hr significantly increased their inhibitory effects on root growth of barnyardgrass seedlings compared with the control, i.e., the root exudates of plants not treated with a signaling compound (Table 3). Application of MeJA increased inhibitory effects of Huajingxian 1 and IAC165 by 24 and 17%, respectively, and MeSA application increased it by 20 and 19%, respectively. Thus, application of signaling compounds increased the toxicity and allelopathic potential of root exudates for both allelopathic and nonallelopathic rice plants.

Phenolic Acids

Phenolic acids in the leaves and stems of rice IAC165 were analyzed with HPLC after plants were treated with MeSA (5 mM) or MeJA (0.05 mM) for 48 hr at the four-leaf stage. An accumulation of HBA, VA, CMA, and FA was observed in the treated plants (Fig. 1). Coumaric acid and FA accumulated in the stems (Fig. 2), whereas HBA, VA, CMA, and FA in the leaves accumulated to levels of 5.3-, 31.3-, 2.2-, and 1.7-fold higher after MeJA treatment, and accumulated to levels of 3.3-, 13.1-, 2.0-, and 2.2-fold higher in response to MeSA (Fig. 1).

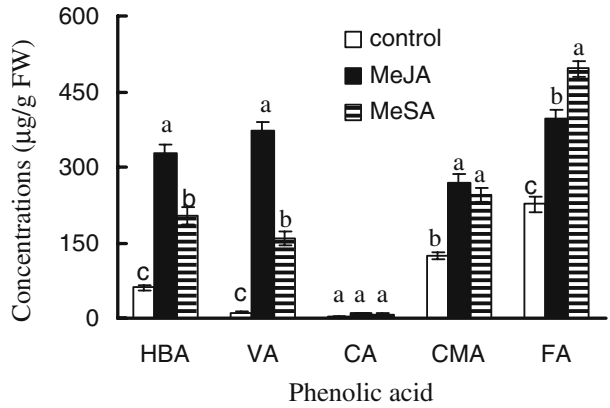

Fig. 1 Concentration of phenolic acids in aqueous leaf extracts of rice IAC165 after treatment with MeSA (5 mM) or MeJA (0.05 mM) for 48 hr at the four-leaf stage. Values are means±SE from three replicates. Significant differences ($P<0.05$) among treatments in each group are indicated by different letters above bars. VA=Vanillic acid, CA=caffeic acid, FA=ferulic acid, CMA=coumaric acid; HBA=3, 4-hydroxybenzoic acid

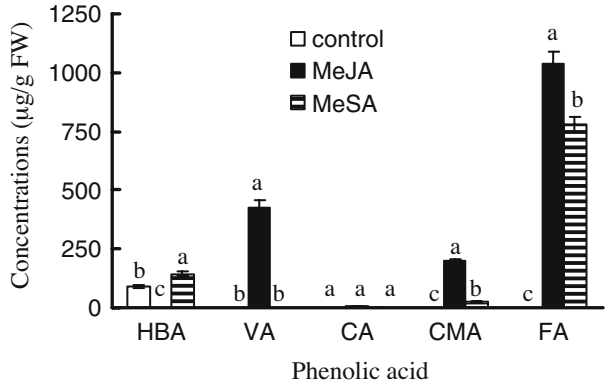

Fig. 2 Concentrations of phenolic acids in aqueous stem extracts of rice IAC165 after treatment with MeSA (5 mM) or MeJA (0.05 mM) for 48 hr at the four-leaf stage. Values are means±SE from three replicates. Significant differences ($P<0.05$) among treatments in each group are indicated by different letters above bars. VA=Vanillic acid, CA=caffeic acid, FA=ferulic acid, CMA=coumaric acid; HBA=3, 4-hydroxybenzoic acid

Vanillic acid, CMA, and FA were not detected in the untreated rice stems, whereas MeJA induced high accumulation of VA, CMA, and FA in the stems of treated plants, and MeSA induced accumulation of CMA and FA in the stems (Fig. 2).

Phenylalanine Ammonia-lyase and Cinnamate 4-Hydroxylase Activity

Phenylalanine ammonia-lyase catalyzed the first step in the biosynthesis of phenylpropanoids. The activities of PAL in the leaves treated with MeSA (5 mM) or MeJA (0.05 mM) significantly increased compared with the control. Phenylalanine ammonia-lyase activities in the leaves treated with MeSA or MeJA at the two-leaf stage increased by 56 and 32%, respectively, compared with the control. At the four-leaf stage, MeSA and MeJA enhanced PAL activity by to 52 and 80%. Phenylalanine ammonia-lyase activity increased by 62.5 and 62.7%, respectively, when leaves were treated with MeSA or MeJA at the six-leaf stage (Fig. 3).

Forty-eight hours after treatment with MeSA or MeJA at the four-leaf stage, C4H activity in the rice IAC165 leaves increased by 40 and 67%, respectively, compared to leaves without a signaling treatment (Fig. 4).

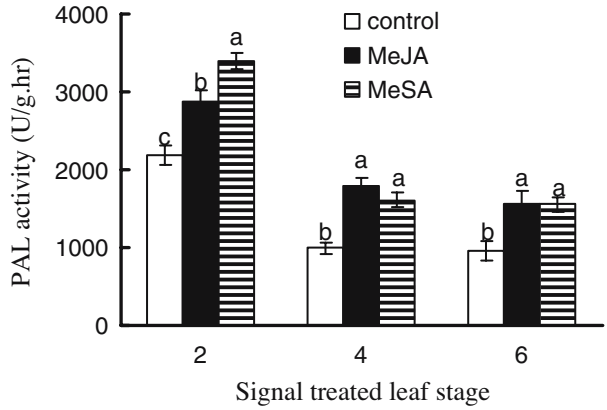

Fig. 3 Enzymatic activity of PAL in the leaves of rice IAC165 after treatment with MeSA (5 mM) or MeJA (0.05 mM) for 48 hr at the two-, four-, and six-leaf stages. Values are means±SE from three replicates. Significant differences ($P<0.05$) among treatments in each group are indicated by different letters above the bars

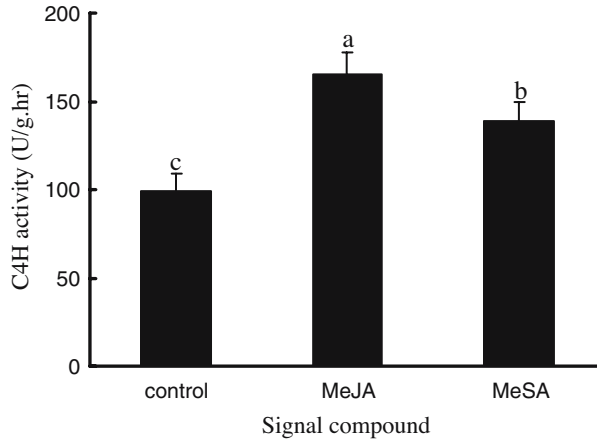

Fig. 4 Enzymatic activity of C4H in the leaves of the IAC165 after treatment with MeSA (5 mM) or MeJA (0.05 mM) for 48 hr at the four-leaf stages. Values are means±SE from three replicates. Significant differences ($P<0.05$) among treatments are indicated by different letters above bars

Induction of Phenylalanine Ammonia-lyase and Cinnamate 4-Hydroxylase Transcripts

To determine whether MeJA and MeSA enhance the production of phenolic acids by inducing transcription of the genes encoding PAL and C4H, enzymes responsible for biosynthesis of phenylpropanoids, the expression patterns of PAL and C4H genes, were analyzed in the leaves of rice IAC165 after being treated with MeSA (5 mM) or MeJA (0.05 mM) for 48 hr at the four-leaf stage. Both MeJA and MeSA induced accumulation of PAL and C4H transcripts over basal levels present in the control leaves (Fig. 5).

Discussion

Plants are frequently subjected to insect herbivory attack, pathogen infection, and competition from surrounding plants. In response, plants have evolved a diversity of chemicals that defend against herbivores and pathogens, and produce allelopathic effects on their neighboring competitors. Plant chemical defense against herbivores and pathogens are inducible and regulated by both the JA and SA signaling pathways. Exogenous addition of JA increases the resistance of wild plants to insects in the field (Baldwin 1998). Whereas many studies have shown that signal compounds can induce such defense against insect herbivores and microbial pathogens, rarely have experiments been conducted to demonstrate that signaling pathways are involved in allelopathy.

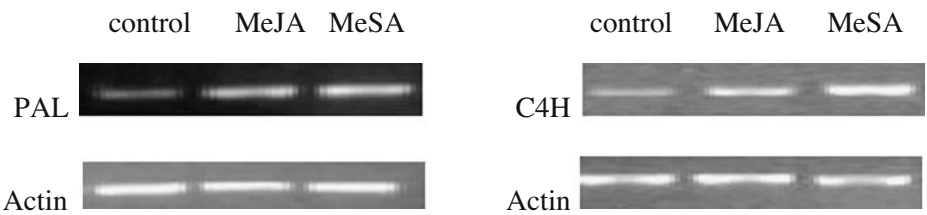

Fig. 5 Gene expression of *PAL* and *C4H* in the leaves of rice IAC165 in response to treatment with MeSA (5 mM) or MeJA (0.05 mM) for 48 hr at the four-leaf stage. Actin was used as internal standard of RT-PCR

This study found that rice allelochemicals could be induced by exogenous application of the signaling compounds MeJA and MeSA. The allelopathic potential of the root exudates of rice thus increased after treatment with MeJA and MeSA (Table 3). Aqueous extracts of both leaves and stems of MeSA- and MeJA-treated Huajingxian 1 and IAC165 rice cultivars showed enhanced inhibitory effects on barnyardgrass root growth (Table 2).

High-performance liquid chromatography analysis showed that phenolic acids VA, CA, CMA, FA, and HBA accumulated in rice leaves after being treated with MeJA and MeSA for 48 hr (Fig. 1). Caffeic acid, CMA, and FA were detected in the stems of rice plants treated with MeJA and MeSA, but not in the stems of untreated control plants (Fig. 2). Vanillic acid was also detected in the stem after treatment with MeJA. This increase in phenolic acids after application of signaling compounds may be a factor in the corresponding increase in the phytotoxicity of root exudates and aqueous extracts of induced rice plants. Similar changes in the production of several phenolic acids have been observed in poplar plants treated with MeJA (An et al. 2006).

Phenolics have been well documented in rice allelopathy (Chung et al. 2000, 2001a; Olofsdotter et al. 1995; Seal et al. 2004b). Greater quantities of *trans*-ferulic acid, *p*-hydroxybenzoic acid, and caffeic acid were detected in the exudates of allelopathic cultivars (Seal et al. 2004b). Five phenolics, caffeic, *p*-hydroxybenzoic, vanillic, syringic, and *p*-coumaric acids, that were found in rice exudates have been correlated with the observed allelopathic effects of rice on arrowhead (*Sagittaria montevidensis*) root growth (Seal et al. 2004b). Methyl jasmonate induced multiple biosynthetic pathways that included the shikimic acid pathway (producing MeSA), the octadecanoid pathway (producing *cis*-jasmone), as well as the mevalonate-dependent and mevalonate-independent terpenoid pathways (producing mono- and sesquiterpenes) (Gundlach et al. 1992; Thaler et al. 1996; Martin et al. 2002). The induction of these pathways has been demonstrated in agricultural plants, such as tomato (*Lycopersicon esculentum*), lima bean (*P. lunatus*), and corn (*Z. mays*) (Thaler et al. 1996; Dicke et al. 1999; Schmelz et al. 2003). Martin et al. (2003) recently demonstrated that application of MeJA induced the activity of both constitutive and novel terpene syntheses in Norway spruce (*Picea abies*).

Exogenous application of MeJA (0.05 mM) or MeSA (5 mM) increased PAL activity in rice at all three ages (two-, four-, and six-leaf stages) tested (Fig. 3), and also increased C4H activity in leaves at the four-leaf stage (Fig. 4). The genes coding for PAL and C4H that are constituents in the phenylpropanoid biosynthetic pathways leading to phenolic acid production were induced by exogenous application of MeJA and MeSA. Reverse transcriptase polymerase chain reaction showed that PAL and C4H mRNA level in the induced groups was greater than that in untreated plants (Fig. 5).

These results suggest that signaling compounds upregulate gene transcription of PAL and C4H, resulting in increased biosynthetic activities and accumulation of phenolic acids, which likely lead to enhanced allelopathic potential. The findings are ecologically significant in a sense that JA and SA signaling pathways may control the production and release of phytotoxins. Thus, plants may respond to competition or stress by activating signaling systems that release chemicals that interfere with a neighbor's growth. Wang et al. (2005) reported that rice plants showed increased allelopathic potential when in competition with barnyardgrass, flatsedge (*Cyperus difformis*), and ducksalad (*Monochoria vaginalis*). *Bidens pilosa* plants showed increased phytotoxicity in seasons of drought (Zeng and Luo 1995). Sorgoleone, the major phytotoxin in the root exudates of sorghum (*Sorghum bicolor*), was released in greater quantities in the presence of a crude extract of velvetleaf (*Abutilon theophrasti*) root, suggesting that seedling may increase their phytotoxicity and thus their allelopathic potential in the presence of other plants (Dayan 2006).

These findings also suggest that plant chemical defenses against herbivores, microbial pathogens, and other plants may share a common mechanism in which signal transduction plays a vital role. Cross resistance may occur. *Centaurea maculosa*, one of the most destructive invasive plants in North America, exuded higher amounts of (±)-catechin, a compound known to have inhibitory effects on native plants, when attacked by larvae of two different root boring biocontrol insects and a parasitic fungus (Thelen et al. 2005). Plant signals are potentially valuable for the regulation of allelopathy in competition with other plants. Understanding the signaling pathways involved will provide insight into plant chemical defense and help in the optimization of chemically based pest management programs.

Although recent experiments shed doubt on the importance of phenolic acids in rice allelopathy (Kato-Noguchi 2005), the correlation observed between the increase in rice inhibitory effects and the elevated production of phenolic acids in response to MeJA and MeSA exposure suggests the complexity of this issue. Plants produce an array of chemicals with different bioactivities, and a single compound is rarely responsible for a complicated biological process (Inderjit et al. 2006). More in-depth studies are required to determine the collective roles of phenolic acids and other putative allelochemicals in the overall allelopathic phenomenon of rice.

Acknowledgments This research was supported by the National 973 project of China (2006CB100200), Natural Science Foundation of China (30370246, 30670331), and Natural Science Foundation of Guangdong Province (group project 039254, 04105977), Guangdong Science and Technology Plan Program (2004B20501010, 2002C20506) and the Program for New Century Excellent Talents in University (NCET-04-0830) to R. S. Z. We thank three anonymous reviewers for helpful comments. We also thank Reed Johnson at University of Illinois at Urbana-Champaign for language revision.

RAPID COMMUNICATION

Chemical Composition of Inks of Diverse Marine Molluscs Suggests Convergent Chemical Defenses

Charles D. Derby · Cynthia E. Kicklighter · P. M. Johnson · Xu Zhang

Abstract Some marine molluscs, notably sea hares, cuttlefish, squid, and octopus, release ink when attacked by predators. The sea hare *Aplysia californica* releases secretions from the ink gland and opaline gland that protect individuals from injury or death from predatory spiny lobsters through a combination of mechanisms that include chemical deterrence, sensory disruption, and phagomimicry. The latter two mechanisms are facilitated by millimolar concentrations of free amino acids (FAA) in sea hare ink and opaline, which stimulate the chemosensory systems of predators, ultimately leading to escape by sea hares. We hypothesize that other inking molluscs use sensory disruption and/or phagomimicry as a chemical defense. To investigate this, we examined concentrations of 21 FAA and ammonium in the defensive secretions of nine species of inking molluscs: three sea hares (*Aplysia californica*, *Aplysia dactylomela*, *Aplysia juliana*) and six cephalopods (cuttlefish: *Sepia officinalis*; squid: *Loligo pealei*, *Lolliguncula brevis*, *Dosidicus gigas*; octopus: *Octopus vulgaris*, *Octopus bimaculoides*). We found millimolar levels of total FAA and ammonium in these secretions, and the FAA in highest concentration were taurine, aspartic acid, glutamic acid, alanine, and lysine. Crustaceans and fish, which are major predators of these molluscs, have specific receptor systems for these FAA. Our chemical analysis supports the hypothesis that inking molluscs have the potential to use sensory disruption and/or phagomimicry as a chemical defense.

Introduction

Animals use a variety of defenses against predators, among them chemical defenses. Marine molluscs, including sea hares, squid, octopus, and cuttlefish, have a striking defensive behavior—releasing ink when attacked. Unlike cephalopods, sea hares often simultaneously release secretions from two glands, the ink and opaline glands (Johnson and Willows 1999). As the cephalopod ink sac is not homologous with the sea hare secretory glands, any functional similarities in the secretions would be the result of convergent evolution.

Sea hare secretions function against predators in at least three ways: chemical deterrence, sensory disruption, and phagomimicry. Chemical deterrents, which are typically unpalatable or toxic, inhibit feeding of predators on sea hares (Johnson and Willows 1999; Kicklighter and Derby 2006). Sensory disruption results from secretions massively stimulating the predator's chemosensory systems, preventing normal function, which leads to confusion and cessation of attack by the predator (Kicklighter et al. 2005). Phagomimicry results from secretions stimulating the predator's sensory pathways involved in feeding, thus causing the predator to attend to the secretions as if they were food and thus affording the sea hare an opportunity to escape (Johnson 2002; Kicklighter et al. 2005). The active compounds involved in sensory disruption and phagomimicry include free amino acids (FAA) and ammonium, which are extraordinarily concentrated in ink and opaline of the sea hare *Aplysia californica* and are powerful stimulants of the chemosensory neurons and feeding behavior of the spiny lobster *Panulirus interruptus*, a sympatric predator (Kicklighter et al. 2005).

Cephalopod inks function as anti-predatory visual stimuli, either as "smoke screens" or distracting decoys (Caldwell 2005). Some have proposed that cephalopod inks may contain compounds that disrupt a predator's chemical senses, but evidence is fragmentary or anecdotal (Caldwell 2005).

Our hypothesis is that inks from diverse cephalopods serve not only as visual defenses but also as chemical defenses against a diversity of predators, through sensory disruption, phagomimicry, or other mechanisms similar to those elucidated for *A. californica* against *P. interruptus*. As a first test, we analyzed FAA composition of the inks of three species of sea hares and six species of cephalopods, and compared these with FAA in typical food of predators of molluscs.

Methods and Materials

Aplysia californica individuals were field-collected in California (Marinus Scientific Inc., Garden Grove, CA, USA). Secretions from the ink and opaline glands were collected and pooled from one set of 15 individuals, and from a second set of 10 animals. Hemolymph from *A. californica* was collected from five animals. Mucus was collected from the skin of five animals. Ink and opaline glands were also collected from five *A. californica* raised in the NIH/University of Miami National Resource for *Aplysia* Facility and fed the red alga

Gracilaria ferox. The ink and opaline glands were taken from 10 *Aplysia dactylomela* collected in the Florida Keys. The opaline glands were taken from eight *Aplysia juliana* collected in waters off New Zealand.

Ink collected from the ink sacs of the following squid species were analyzed: three *Lolliguncula brevis* (collected near Galveston, TX, USA); three *Loligo pealei* (collected near Woods Hole, MA, USA); and one *Dosidicus gigas* (collected in California). In addition, ink was collected from the ink sacs of two *Octopus bimaculoides* (National Resource Center for Cephalopods) and one *Octopus vulgaris* (collected in waters near St. Augustine, FL, USA). Ink from three cuttlefish *Sepia officinalis* (collected near Galveston, TX) was also analyzed.

All species were collected in the field, except for the one group of *A. californica* raised in the NIH *Aplysia* facility, and *S. officinalis* cultured at the National Resource Center for Cephalopods. All animals, except for *L. brevis*, were adults and were alive until immediately before collection of the tissue or secretions. Sea hares were cooled until immobilized and then injected with isotonic magnesium chloride. Cephalopods were anesthetized by cooling on ice. Animals were dissected to remove the tissues of interest, which were frozen until used. Frozen samples were thawed, and secretions were collected. Ink and opaline were collected as previously described (Kicklighter et al. 2005; Kicklighter and Derby 2006). Hemolymph was collected from sea hares by first de-inking the animals to avoid contamination of hemolymph with ink and opaline, cold anesthetizing them, washing an area of skin between the rhinophores with 70% ethanol, making a small incision in that region, and collecting the released hemolymph into a sterile tube. Mucus was collected from sea hares by gently scraping the surface of the skin with a blunt probe. Secretions or tissue collected from multiple animals were pooled. Frozen samples were lyophilized and stored until used, at which time they were diluted in deionized water. Proteins were removed from the samples by dialysis. Concentrations of FAA and ammonium in the samples were analyzed by using a Beckman Model 6300/7300 amino acid analyzer by Scientific Research Consortium, Inc. (http://www.aminoacids.com). This system uses an ion exchange column, post-column ninhydrin reaction at 131°C, followed by absorbance measurements at 440 and 570 nm. (*S*)-2-Aminoethyl-1-cysteine and glucosaminic acid were used as internal standards. Data were acquired and managed with Beckman System Gold 8.10 chromatography software.

Multidimensional scaling (MDS) was used to examine the degree of similarity in the FAA composition of molluscan secretions and fluids, and food tissues. Our analysis used the proportional (%) compositions of the 20 secretions in Table 1 plus an equidose mixture (E). E, which contains the same 21 FAA as the mixtures in Table 1 but has all FAA at the same relative concentration (4.76), was included in this analysis for comparison. MDS was performed by using SPSS-X software and Euclidean values as a distance measure. The dimensionality of an acceptable MDS solution is the minimum that produces a stress value <0.10 (Kruskal and Wish 1978). In our analysis, a 3-dimensional solution produced a stress value of 0.072 and was thus accepted.

Results and Discussion

Sensory disruption requires that a secretion has the type and amount of FAA sufficient to strongly stimulate the sensory pathways of predators, although not necessarily mimicking the composition of food. Phagomimicry requires that a secretion's absolute and relative

concentrations of FAA adequately mimic that of the predators' food. Both mechanisms are supported by our chemical data.

The concentrations of FAA in ink and opaline of wild-caught sea hares are in the high millimolar range (Table 1). Opalines of wild-caught *A. californica* and *A. dactylomela* have the highest concentrations, 310–448 mM total FAA (TFAA), and opaline of *A. juliana* has 3.2 mM TFAA. Inks of wild-caught *A. californica* and *A. dactylomela* have 12–15 mM TFAA. Ink of maricultured *A. californica* contains about 15% of the TFAA in wild-caught animals, but the relative amounts of FAA acids are similar. Ink or opaline from two groups

of 10–15 wild/caught *A. californica* collected at different times and places had similar TFAA, demonstrating a relative constancy at the population level.

Taurine, a sulfonic amino acid, is the major component in most secretions, constituting 41–86% of the TFAA. A few other FAA are in relatively high concentration, notably aspartic acid, glutamic acid, alanine, and lysine. Ammonium levels in *A. californica* and *A. dactylomela* ink or opaline are also high, 5–36 mM.

Cephalopod ink has lower millimolar levels of TFAA: 132 mM in *Octopus vulgaris*, 14.4 mM in *O. bimaculoides*, 2.5 mM in *Sepia officinalis*, 2.1 mM in *Dosidicus gigas*, 1.7 mM in *Loligo pealei*, and 0.5 mM in *Lolliguncula brevis* (Table 1). Taurine is typically

[c]Not measured

the most abundant FAA in cephalopod inks. *O. bimaculoides* is unusual in that its taurine content is low and no single FAA dominates. Ammonium levels in cephalopod inks are also in the low millimolar range.

The major FAA in molluscan inks are those to which their major predators—crustaceans and fish—are sensitive, and their concentrations are well above response threshold, in many cases higher than response saturation. This is true of both the antennular (olfactory) and mouthpart (gustatory) chemoreceptor neurons of crustaceans (Voigt and Atema 1992; Derby 2000). Taurine and ammonium are noteworthy, as they are in such high concentrations in all of the molluscan secretions, and crustaceans have specialized receptor systems for them and are sensitive to submicromolar concentrations. Fish olfactory and gustatory systems are likewise highly sensitive to the FAA in these secretions, and have specialized receptors for several of them (Caprio 1988). These observations are consistent with the potential function of these secretions as sensory disruptors of molluscan predators. Furthermore, *A. californica* ink and opaline have much higher levels of TFAA (310–404 and 12–15 mM, respectively) compared to *A. californica* hemolymph and mucus (0.7 and

0.6 mM FAA, respectively). This finding is consistent with the idea that the FAA of sea hare ink and opaline are not reflective of the composition of other fluids or secretions of sea hares, but are more concentrated by up to several orders of magnitude, thus further supporting the idea that ink and opaline have evolved as a chemical defense.

Phagomimicry requires that the secretions contain chemicals in absolute and relative concentrations sufficient to mimic the food of predators. The molluscan secretions contain the same FAA as food, and they are generally present at similar absolute concentrations. TFAA in ink and opaline of *A. californica* and *A. dactylomela* (12–448 mM) and the inks of cephalopods (0.5–132 mM TFAA) are within or close to the range of TFAA in tissues of typical food of fish and crustacean predators (crab, shrimp, oyster, and mullet: 29–290 mM). This comparison of the FAA compositions of molluscan secretions and food tissues, together with behavioral results showing that an artificial mixture of *A. californica* ink or opaline with the FAA composition shown in Table 1 evokes feeding behaviors of the predatory spiny lobster *Panulirus interruptus* (Kicklighter et al. 2005), shows that molluscan secretions can be food-like in their TFAA.

Multidimensional scaling (MDS) was used to compare the relative FAA compositions of molluscan secretions with each other and with the prey species (Fig. 1). This analysis reveals several features of these secretions and tissues. First, different batches of the same secretion have similar proportions of FAA. *A. californica* ink samples Si1 and Si2, each representing samples pooled from 10–15 wild-caught animals, are similar to each other. A similar trend is seen for *A. californica* opaline samples So1 and So2. This shows relative constancy in the proportion of FAA for groups of animals collected at a different time and place. Second, secretions of a particular type (e.g., sea hare opaline, sea hare ink, or cephalopod ink) tend to be more closely grouped to each other, and thus have FAA composition more similar to each other than to those in a different type of secretion or tissue. The sea hare opalines (especially So2/So4) are clustered close to each other, the ink of three species of wild-caught sea hares (Si1, Si2, Si4) are clustered, and five of the six cephalopod inks (C1–C4, C6) are clustered. This supports the idea that although molluscan defensive secretions have quantitative and qualitative compositional similarities to food, the different molluscan secretions (molluscan opaline vs. molluscan ink, sea hare ink vs. cephalopod ink) have some differences in their FAA compositions. Third, whereas all of these molluscan secretions are similar to food in having high absolute concentrations of TFAA, the relative compositions (i.e., FAA proportions) of some molluscan secretions are more similar than others to food of their predators. All of the sea hare inks (Si1–Si4) and five of the cephalopod inks (*S. officinalis* C1, *L. pealei* C2, *L. brevis* C3, *D. gigas* C4, *O. vulgaris* C6) group close to each other and to oyster *Crassostrea virginica* (T3) and mullet *Mugil cephalus* (T4), indicating their FAA proportions are most similar. Sea hare inks and tissues from oyster and mullet also have some compositional similarity to the sea hare opalines, although less so than to each other. Relatively different in composition from all of these are sea hare hemolymph (Sf1), *Callinectes sapidus* muscle (T1), *Penaeus duorarum* muscle (T2), and *O. bimaculoides* ink (C5), and the equidose mixture (E). Thus, this MDS analysis, together with the absolute concentrations of FAA, shows that all molluscan secretions have FAA compositions highly similar to that of food, with some molluscan inks being more similar to food than are others.

Taurine, lysine, alanine, glycine, and glutamine contribute most to the compositional differences in the secretions and tissues in Fig. 1, as indicated by a linear multiple regression model of the MDS data ($P<0.001$) (Kruskal and Wish 1978). The concentration of taurine is relatively high in sea hare ink and opaline and in cephalopod inks, and relatively low in sea hare mucus and hemolymph and the crustacean muscle tissues. (The

exception is *O. bimaculoides*, which is not dominated by any component and thus is compositionally similar to the equidose mixture, E.) Regarding the other FAA in relatively high concentrations, lysine is high in sea hare opaline compared to all the other secretions and tissues. Alanine is relatively high in sea hare ink and cephalopod ink but not in sea hare opaline. Glutamine is absent in sea hare opaline but present in other secretions and food tissues. Glycine is relatively high in sea hare mucus and in the four food tissues.

The FAA composition of the molluscan defensive secretions and the sensory abilities of predators of these molluscs suggest that these secretions have the potential to function as chemical defenses through mechanisms that may include sensory disruption and/or phagomimicry. The focus of our paper is FAA and ammonium, but other chemicals in these secretions may also have defensive properties. A combination of mechanisms may enhance the effectiveness of the secretions (Kicklighter et al. 2005). For example, ammonium can be an inhibitor of feeding behavior of crustaceans (Zimmer-Faust 1987) and thus might also function as a deterrent in addition to its role as a sensory disruptor. Our demonstration of the presence in cephalopod ink of millimolar concentrations of feeding

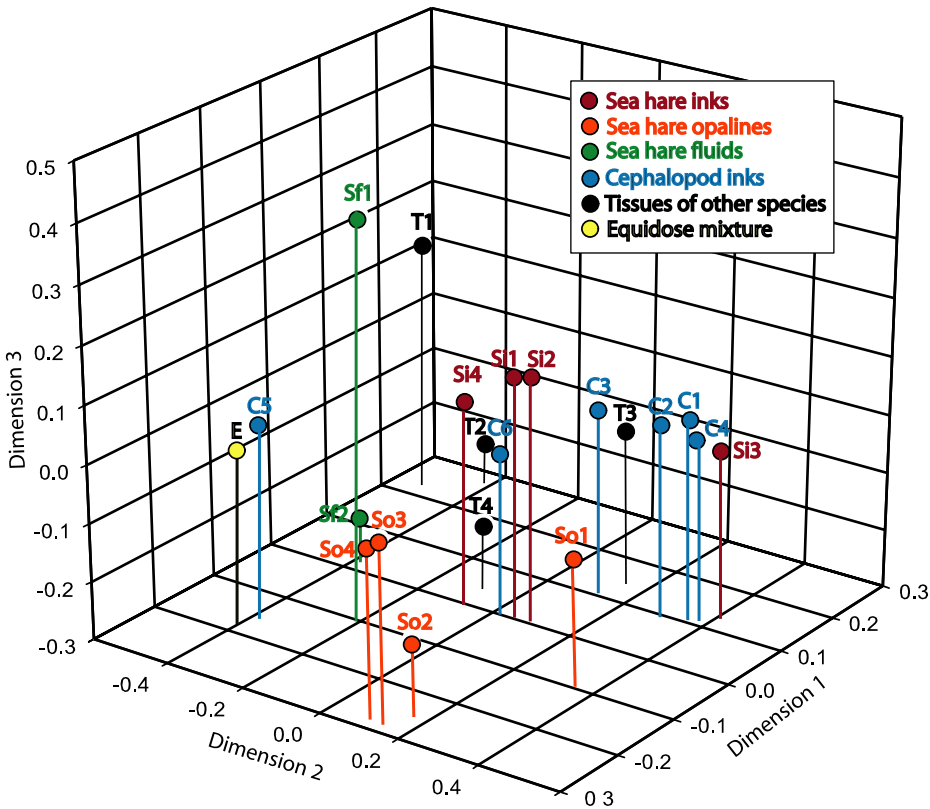

Fig. 1 Degree of similarity in the chemical composition of molluscan secretions and fluids, and food of predators of molluscs, based on multidimensional scaling. The identities of the secretions and tissues associated with the labels in this figure are coded according to type (e.g., Si=sea hare inks, So=sea hare opalines, C=cephalopod inks, T=food items), and the identity of each of the individual secretions and tissues (e.g., Si1, C4) are given in Table 1 and Methods and Materials. The values on the dimensions are derived from the analysis and are not strictly FAA concentration. See text for an explanation of the MDS analysis and results

chemostimulants of fish raises the possibility that cephalopod ink might have convergently evolved antipredatory effects through a combination of chemical mechanisms that may include sensory disruption or phagomimicry. Confirmation awaits behavioral testing.

Abstract This study investigated metabolites with activities against plant parasite nematodes from the fresh-water fungus *Caryospora callicarpa* YMF1.01026. We obtained three novel tetradecalactone metabolites, caryospomycins **A**–**C**, with such activities. The chemical structures of these were determined through NMR spectroscopic analysis and were found to belong to the 14-membered macrolides with a fused 1,2-dimethoxy-4-hydroxybenzene ring, a rare structure among the resorcylides. In the *in vitro* tests, all three compounds exhibited moderate killing activity against the nematode *Bursaphelenchus xylophilus*. To our knowledge, this is the first report of secondary metabolites in the aquatic fungal genus *Caryospora*.

Keywords *Caryospora carllicarpa* · Freshwater fungi · Nematicidal · Resorcylide

Introduction

The annual global loss in agriculture due to damages by plant-parasitic nematodes has been estimated as US $100 billion worldwide (Sasser and Freckman 1987). To reduce economic loss, several procedures for nematode control have been developed that use biological control agents and organic amendments. However, none of the procedures is ideal, and

there is an urgent need for alternative, environmentally friendly measures, including natural nematocidal compounds (Noling and Becker 1994). One way to search for such compounds is to screen naturally occurring fungi. Fungi are important sources of naturally occurring antibiotics and pesticides. In addition, fungal secondary metabolites often have low plant and human toxicity and can be easily biodegraded (Siddiqui and Mahmood 1996). Compounds with nematicidal activity include alkaloids, peptides, terpenes, and fatty acids (Anke and Sterner 1997; Dong et al. 2005a, b, 2006). Omphalotin A, a cyclic dodecapeptide isolated from *Omphalotus olearius* (Mayer et al. 1997; Sterner et al. 1997), under *in vitro* conditions, out-performs known nematicides such as ivermectin in both potency and selectivity (Mayer et al. 1999).

These findings prompted us to conduct an evaluation of other little characterized members of freshwater fungi. Specifically, we were interested in the extracts of strain YMF1.01026 that belongs to species *Caryospora callicarpa* (Cai et al. 2002). This strain has shown high nematicidal activities towards the pine wood nematode, *Bursaphelenchus xylophilus* (Dong et al. 2004). In addition, there is so far no record of any previous investigation of the chemistry of this genus. The genus belongs to subfamily Zopfiaceae of the Dothideomycetidae and includes 15 species (*Caryospora australiensis*, *C. callicarpa*, *Caryospora cariosa*, *Caryospora coffeae*, *Caryospora langloisii*, *Caryospora lichenopsis*, *Caryospora mangrovei*, *Caryospora masonii*, *Caryospora minima*, *Caryospora minor*, *Caryospora nuclearia*, *Caryospora olearum*, *Caryospora phyllostachydis*, *Caryospora putaminum*, and *Caryospora striata*). In ths study, we report the bioassay-guided fractionation of extracts of *C. carllicarpa* YMF1.01026 that were tested against pine wood nematode, *B. xylophilus*.

Methods and Materials

Culture and Fermentation of C. callicarpa YMF1.01026 The fungal strain *C. callicarpa* YMF1.01026 was initially isolated from a submerged woody substrate collected from a freshwater habitat in Yunnan Province, China. This strain is deposited in the Laboratory for Conservation and Utilization of Bio-resources, Yunnan University, Yunnan Province, the People's Republic of China (culture collection number YMF1.01026). The strain was maintained on PDA medium (potato 200 g, sucrose 20 g, agar 18 g, and water 1,000 ml) and was grown on wheat at 26°C for a period of 30 d before being processed for extracts.

Extraction and Isolation of Compounds Mycelial cultures were lyophilized and extracted with CH_3OH. The CH_3OH solution, after concentrated through vacuuming, was sequentially extracted ×3, each with petroleum ether and EtOAc. The combined EtOAc solution, upon evaporation, yielded a deep-brown syrup (~3.2 g). The syrup had *in vitro* nematicidal activity against pine wood nematodes *B. xylophilus*. This syrup was loaded onto a silica gel column [200 g Silica gel G (200–300 mesh), 3.6 cm i.d.×150 cm] and eluted by using solvent mixtures containing petroleum ether (bp 60–90°C)-EtOAc with increasing polarities (95:5 to 10:90). The resulting fractions were monitored by TLC (Silica gel G, 0.25-mm film thickness; Qingdao Marine Chemical Ltd., Qingdao, China) and reduced to one active fraction, **FV** (430 mg). The **FV** fraction, obtained on elution with petroleum (bp 60–90°C)-EtOAc (30:37), was further separated on a Sephadex LH-20 gel column and eluted with CH_3COCH_3 to yield pure **1** (16 mg), **2** (11 mg), and **3** (8 mg), respectively (Fig. 1).

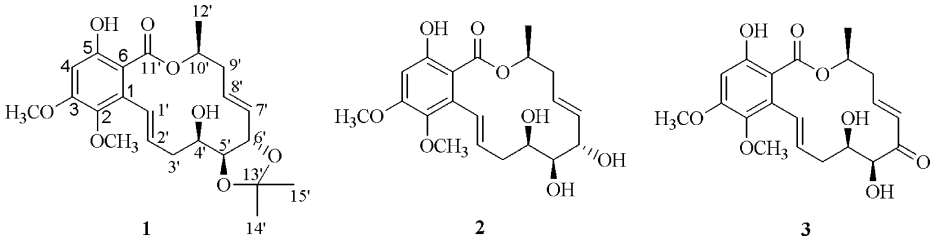

Fig. 1 Structures of caryospomycin **A**–**C** (**1**–**3**)

Identification of Compounds The structures of caryospomycins isolated from the cultures of *C. carllicarpa* YMF1.01026 were determined by spectroscopic analysis. Infrared (IR) spectra were obtained in KBr pellets with a Bio-Rad FTS-135 spectrophotometer (Bio-Rad, Richmond, CA, USA). UV spectra were taken on a Shimadzu double-beam 210A spectrophotometer (Shimadzu, Kyoto, Japan). Optical rotations were measured with a Horiba SEPA-300 polarimeter (Horiba, Tokyo, Japan). MS was performed on an Autospec-3000 spectrometer (VG, Manchester, England). Nuclear magnetic resonance (NMR) spectra were recorded on DRX-500 NMR (Bruker, Karlsruhe, Germany) spectrometers, with TMS as an internal standard and coupling constants were represented in Hertz.

Caryospomycin A (**1**): white amorphous powder (CH_3COCH_3); [α]+ 62.1° (CH_3OH; *c* 0.31); UV (CH_3OH) λ_{max} (log ε) 320.2 (4.01), 267.0 (4.22), 229.8 (4.70), 204.4 (4.71) nm; IR (film) ν_{max} 3,441, 2,959, 2,931, 2,875, 1,728, 1,648, 1,598, 1,472, 1,448, 1,381, 1,360, 1,316, 1,246, 1,224, 1,169, 1,126, 1,057, 1,041, 1,018, 969, 834, 743, 606; FABMS *m/z* (rel. int) 433$[M\text{-}H]^+$(3), 339 (40), 325 (100), 311 (60), 281 (42), 255 (5); EIMS *m/z* (rel. int) 434 $[M]^+$ (58), 416 $[M\text{-}18]^+$ (1), 372 (10), 296 (14), 267 (15), 249 (38), 223 (60), 221 (88), 219 (100), 205 (98), 195 (45), 193 (42), 167 (25), 109 (50), 95(58), 55(42); HRMS (ESI-TOF) *m/z*: 457.1844 $[M+Na]^+$ (calcd for $C_{23}H_{30}O_8Na$, 457.1838).

Caryospomycin B (**2**): white amorphous powder (CH_3COCH_3); [α]+ 30.0° (CH_3OH; *c* 0.76); UV (CH_3OH) λ_{max} (log ε) 319.0 (3.83), 267.2 (4.01), 225.4 (4.54) nm; IR (film) ν_{max} 3,424, 2,929, 2,856, 1,726, 1,648, 1,597, 1,474, 1,447, 1,383, 1,358, 1,308, 1,248, 1,226, 1,202, 1,169, 1,136, 1,063, 1,021, 965, 887, 610; FABMS *m/z* (rel. int) 393$[M\text{-}H]^+$(100); HRMS (ESI-TOF) *m/z*: 393.1554 $[M\text{-}H]^-$ (calcd for $C_{20}H_{25}O_8$, 393.1549).

Caryospomycin A (**3**): white amorphous powder (CH_3COCH_3); [α]+ 58.1° (CH_3OH; *c* 0.54); UV (CH_3OH) λ_{max} (log ε) 320.3 (3.97), 267.0 (4.07), 225.3 (4.60) nm; IR (film) ν_{max} 3,431, 2,939, 2,865, 1,728, 1,648, 1,598, 1,472, 1,448, 1,381, 1,360, 1,306, 1,245, 1,225, 1,200, 1,166, 1,059, 1,021, 969, 854, 609; FABMS *m/z* (rel. int) 391$[M\text{-}H]^+$(100); HRMS (ESI-TOF) *m/z*: 391.1403 $[M\text{-}H]^-$ (calcd for $C_{20}H_{23}O_8$, 391.1393).

Nematode Culture and Nematicidal Study Nematicidal activity was determined by using a microtiter plate assay as described previously (Dong et al. 2004). The test organism was the pine wood nematode *B. xylophilus*. This species has been maintained in our laboratory and used as a model target for *in vivo* nematocidal assays. For this assay, *B. xylophilus* was first grown on PDB agar media containing a strain of the fungus *Botrytis cinerea* in disposable Petri dishes prewetted with 2–4 ml of physiological saline. Cultures were then stored at room temperature and subcultured before assay. The assay was conducted in Corning polystyrene 96-well plates. Nematodes were added to 1 ml physiological saline in a scintillation vial and diluted until the nematode counts were 20–25 in a 48-μl aliquot. A solution (48 μl) containing nematodes was delivered to each of three wells for each

treatment. Two microliters of DMSO (5%) or DMSO (5%) plus the test compounds were added to each well. Plates were covered, parafilmed, and kept in a humid chamber. The numbers of live and dead nematodes were counted under a binocular microscope after various incubation times. Toxicity was inferred by using the mean percentage of dead organisms. Nematodes were considered dead if they gave no response to physical stimuli such as mechanical stirring or pricking with a pointed needle.

Statistical Analysis To evaluate nematicidal activity of compounds at different concentrations of 50, 80, 100, and 200 ppm, and different exposure times of 12, 24, and 36 hr, data were subjected to independent sample *F* test using ANALYZE (SPSS/version11.0 software, USA). Data on proof mortality were changed to $\sin^{1/2}$(M) before analysis.

To describe nematicidal effects of compound against *B. xylophilus*, LC_{50} was calculated according to probit analysis (Sporleder et al. 2005). Regression analyses were also conducted by SPSS for linear model. Data on proof mortality of nematodes were transformed into probit value, and concentrations (C) of compound were also changed to $\log_{10}$ (C) before analysis.

Results and Discussion

The molecular formula of caryospomycin A (**1**) was determined as $C_{23}H_{30}O_8$ by HRMS (ESI-TOF) and ^{13}C NMR data, indicating the presence of nine unsaturated bonds in the molecule. The IR (KBr) spectrum showed absorptions at 3,441, 1,728, 1,648, 1,598, 1,472, 1,448, 1,381, 1,360, 1,316, 1,246, 1,224, 1,169, 1,126, 1,057, 1,041, 1,018, 969, 834, 743, and 606 cm^{-1} that were attributable to hydroxyl, ester carbonyl, olefin, ether functions, and the aromatic ring. The UV spectrum maxima near 305, 265, and 220 were typical of the 4-methoxy resorcylic acid lactone macrolide chromophore present in the radicicol derivatives (Mirrington et al. 1964; Nair et al. 1981). The ^1H NMR spectrum (Table 1) showed signals attributable to the presence of one secondary methyl [δ_H 1.44 (3H, d, J=6.4 Hz)], two tertiary methyls [δ_H 1.34 (3H, s, acetonide), 1.28 (3H, s, acetonide)], and two oxymethyls [δ_H 3.88 (3H, s), and 3.56 (3H, s)]. An exchangeable 1H singlet at δ_H 11.1 was assigned to the chelated phenolic hydrogen (Nair et al. 1981; Isaka et al. 2002). Additional resonances were observed in the ^1H and ^{13}C NMR spectra for two *trans* 1,1-disubstituted double bonds [δ_H 6.75 (1H, d, J=15.9 Hz), 5.96 (1H, dt, J=15.6, 5.7, 3.5 Hz), 5.55 (1H, dd, J=8.6, 15.4 Hz), and 5.99 (1H, dt, J=15.4, 5.3, 3.5 Hz); δ_C 127.2 (d), 131.5 (d), 133.9 (d), and 129.4 (d)], and four oxymethine carbons [δ_H 3.86 (1H, dd, J=8.0, 2.0 Hz), 4.15 (1H, m), 4.58 (1H, t, J=8.3 Hz), 5.41 (1H, m); δ_C 69.2 (d), 72.0 (d), 76.1 (d), 82.3 (d)]. The ^{13}C NMR spectra also revealed resonances consistent with one lactone carbonyl [δ_C 171.7 (s)], one acetonic carbon [δ_C 108.7 (s)], and one penta-substituted benzene ring [δ_H 6.46 (1H, s); δ_C 100.2 (d), 105.1 (s), 133.6 (s), 141.4 (s), 159.5 (s), 160.8 (s)]. From this analysis, coupled with the degrees of unsaturations (9), it became clear that **1** was a resorcylic macrolide with two *trans*-disubstituted olefins.

The HMQC analysis revealed the assignment of each direct C–H bonding in **1** as summarized in Table 1. The ^1H–^1H correlations obtained from the ^1H–^1H COSY exhibited one big spin system, substructure **1a**, as depicted in Figs. 2 and 3. The HMBC correlations from O**H** at C-5 (δ_H 11.1, s) to C-6 (δ_C 105.1), C-5 (δ_C 160.8), C-4 (δ_C 100.2), from the aromatic proton H-4 (δ_H 6.46, s) to C-6 (δ_C 105.1), C-5 (δ_C 160.8), C-3 (δ_C 159.5), C-2 (δ_C 141.4), and C-11′ (δ_C 171.1), from one oxymethyl OC**H**$_3$-3 (δ_H 3.88, s) to C-4 (δ_C 100.2), C-3 (δ_C 159.5), and from the second oxymethyl OC**H**$_3$-2 (δ_H 3.56, s) to C-2

[a] Assignments of the ^{13}C and ^{1}H signals were made on the basis of HMQC.

(δ_C 141.4) established one penta-substituted benzene ring, substructure **1b**, as depicted in Fig. 3. Furthermore, HMBC cross peaks of the olefinic proton at H-1′ (δ_H 6.75, d) with C-6 (δ_C 105.1), C-1 (δ_C 133.6), C-2 (δ_C 141.4), C-2′ (δ_C 131.5), and C-3′ (δ_C 38.0), the olefinic proton H-2′ (δ_H 5.96, dt) with C-3′ (δ_C 38.0), C-4′ (δ_C 69.2), C-1′ (δ_C 127.2), and C-1 (δ_C 133.6), the oxymethine proton H-10′ (δ5.41, m) with C-11′ (δ_C 171.7), C-12′ (δ_C 19.3), C-8′ (δ_C 129.4), and C-7′ (δ_C 133.9) established the reasonable connection patterns of C-1 with C-1′ and C-10′ with C-11′ through an oxygen atom, and permitted fragments **1a** and **1b** to be joined together. Finally, the HMBC correlations of two geminal methyl groups, C**H**$_3$-14′ and C**H**$_3$-15′ to C-13′ identified the occurrence of the acetonide moiety **1c**. Based on the ^{13}C NMR chemical shifts values (δ_C 27.1 and δ_C 27.4) of two geminal methyl

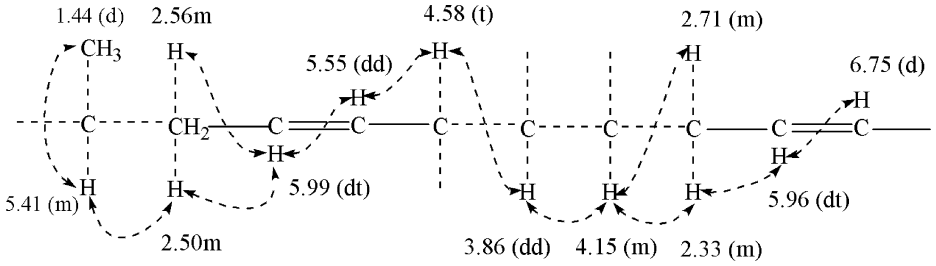

Fig. 2 Substructure **1a**, ^{1}H NMR data, and ^{1}H–^{1}H correlations (dashed arrows) of caryospomycin **A** (**1**)

groups, and the strong cross peak at H-5′ (δ_H 3.86, dd) with C**H**$_3$-15′ (δ_H 1.28, s) and the weak cross peak at H-6′ (δ_H 4.58, t) with C**H**$_3$-14′ (δ_H 1.34, s) in the NOESY spectrum, the acetonide carbon (C-13′, δ_C 108.7, s) was connected to C-5′ (δ_C 82.3) and C-6′ (δ_C 76.1) with *trans* stereochemistry (Adamczeski et al. 1988; Rychnovsky and Skalitzky 1990). Thus, the structure of caryospomycin **A** was established as **1**.

Both coupling constants between H-1′ (δ_H 6.75) and H-2′ (δ_H 5.96), H-7′ (δ_H 5.55) and H-8′ (δ_H 5.99) olefinic protons were measured as near 15 Hz, indicating the *E* geometry of the carbon–carbon double bonds in the diene at C-1′(2′) and C-7′(8′), because the *cis* coupling constant in comparable hypothemycin is 11 Hz (Nair and Carey 1980; Nair et al. 1981). The relative stereochemistries of C-10′ (δ_C 72.0), C-6′ (δ_C 76.1), C-5′ (δ_C 82.3), and C-4′ (δ_C 69.2) in **1** was deduced from the analysis of NOESY correlations with supporting information from vicinal coupling constants (Table 1). A NOESY experiment on **1** showed cross-peaks between H-1′ (δ_H 6.75)/$H_\beta-3'$(δ_H 2.33), $H_\beta-3'$(δ_H 2.33)/H-6′ (δ_H 4.58), H-6′ (δ_H 4.58)/C**H**$_3$-14′ (δ_H 1.34), H-4′(δ_H 4.12)/$H_\alpha-3'$(δ_H 2.33), H-4′(δ_H 4.12)/H-5′(δ_H 3.86), H-5′(δ_H 3.86)/C**H**$_3$-15′ (δ_H 1.28), H-7′ (δ_H 5.55)/$H_\beta-9'$(δ_H 2.50), H-7′ (δ_H 5.55)/$H_\alpha-9'$(δ_H 2.56), H-8′(δ_H 5.99)/$H_\alpha-9'$(δ_H 2.56), and $H_\alpha-9'$(δ_H 2.56)/H-10′(δ_H 5.41) (Fig. 4). This result demonstrated that $H_\alpha-3'$, H-4′, H-5′, $H_\alpha-9'$, C**H**$_3$-15′, and H-10′ were α-oriented, while $H_\beta-3'$, H-6′, C**H**$_3$-14′, $H_\beta-9'$, and C**H**$_3$-12′ possessed β-orientation. The 2.0 H-4′/H-5′ coupling constant and the almost 8 Hz H-5′/H-6′ coupling constant further supported the axial configurations for H-4′ and H-5′, as well as the equatorial configuration for H-6′. From the ^{1}H NMR, COSY, and NOESY spectra, a

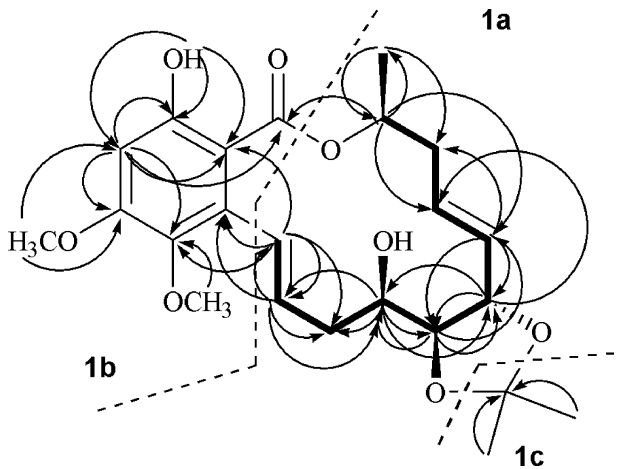

Fig. 3 Gross structure, ^{1}H–^{1}H correlations (bold lines), key HMBC correlations (plain arrows) of caryospomycin **A** (**1**)

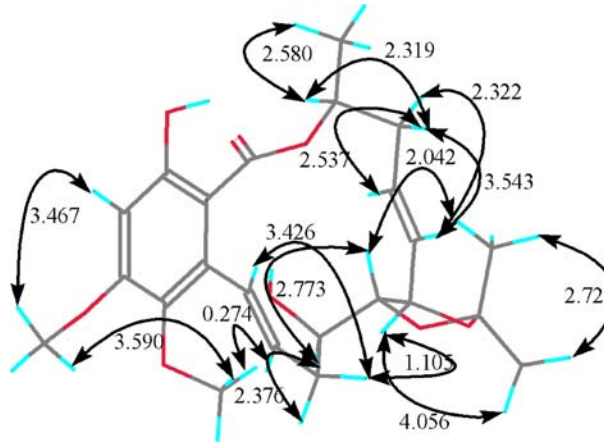

Fig. 4 Key NOESY correlations of **1** and corresponding interatomic distance (A), and some protons hidden for concision of the picture

computer-generated 3D structure of **1** was obtained by using the molecular modeling program, CS CHEM 3D V 4.0, with MM2 force-field calculations for energy minimization (Fig. 4). The calculated distances between $H-1'/H_\beta-3'$, $H_\beta-3'/H-6'$, $H-4'/H_\alpha-3'$, H-4′/H-5′, H-5′/C**H**$_3$-15′, $H-7'/H_\beta-9'$, $H-7'/H_\alpha-9'$, $H-8'/H_\alpha-9'$, and $H_\alpha-9'/H-10'$ were all less than 4.00 Å, except that the calculated distance between H-6′ and C**H**$_3$-14′ was slightly higher, at 4.056 Å. This high value is consistent with the observed weak cross peak at H-6′ with C**H**$_3$-14′ and the observed strong cross peaks from each of these proton pairs. Thus, the relative overall stereochemistry for compound **1** was deduced as 1′*E*, 4′*R**, 5′*S**, 6′*S**, 7′*E*, 10′*R**.

The molecular formula of caryospomycin B (**2**), $C_{20}H_{26}O_8$, was established from a high-resolution MS (ESI-TOF) measurement of the $[M-H]^-$ peak at *m/z* 393.1554, indicating the presence of eight unsaturated bonds in the molecule. The UV, IR, and NMR spectra were similar to those obtained for **1**, indicating that they were structurally related. The most striking differences in the NMR data between **1** and **2** compared were the disappearance of the acetonide moiety signals (δ_C 108.7, 27.1 q, and 27.4 q; δ_H 1.34 s and 1.28 s) in **2** but their presence in **1**. In the ^{13}C NMR data, signals of the C-5′ and C-6′ oxymethine carbons were noticeably shifted upfield from δ_C 82.3 and 76.1 in **1** to δ_C 78.6 and 73.9 in **2**, while the C-4′ oxymethine carbon signal was noticeably shifted downfield from δ_C 69.2 in **1** to δ_C 73.5 in **2** (Table 1). Corresponding differences were observed in the ^1H NMR data, in which signals of the oxymethine protons were shifted upfield from δ_H 4.15 (1H, m, H-4′), 3.86 (1H, dd, *J*= 8.0, 2.0 Hz, H-5′), and 4.58 (1H, t, *J*=8.3 Hz, H-6′) in **1** to δ_H 3.73 (1H, m, H-4′), 3.53 (1H, dd, *J*=8.2, 2.0 Hz, H-5′), and 4.13 (1H, t, *J*=7.8 Hz, H-6′) in **2**. These spectral changes were consistent with the absence of the acetonide moiety from C-13′ to C-15′ in **2**. Despite the spectral differences, however, the combined 2D NMR experiments showed that **2** had the same proton-proton and proton-carbon correlations as **1** throughout the entire molecule. Thus, the structure of **2** was determined to be a deacetonided derivative of **1**.

The molecular ion $[M]^+$ of caryospomycin C (**3**) is 2 mass units lower than compound **2**, and its molecular formula was determined as $C_{20}H_{24}O_8$ by HRMS (ESI-TOF) and NMR data. One noticeable difference in the ^{13}C NMR data between **2** and **3** was the addition of a ketone functionality at δ_C 198.0 in **3**, and the absence of an oxymethine carbon at this position, an observation suggesting that the oxymethine carbon of **2** was replaced by the ketone functionality in **3**. In addition, the ^{13}C chemical shifts of the C-7′/C-8′ double band and the C-4′, C-5′ oxymethines were also changed from δ_C 134.2 (CH, C-7′), 128.4 (CH,

C-8′), 73.5 (CH, C-4′), and 78.6 (CH, C-4′) in **2** to δ_C 132.3 (CH, C-7′), 142.6 (CH, C-8′), 75.0 (CH, C-4′), and 79.8 (CH, C-4′), respectively, in **3**. Corresponding differences were observed in the ^{1}H NMR data, in which signals of the olefinic and oxymethine protons were shifted downfield from δ_H 5.94 (dt, J=14.2, 5.5, 3.9 Hz, H-8′), 5.65 (dd, J=7.6, 15.5 Hz, H-7′), 3.53 (dd, J=8.2, 2.0 Hz, H-5′), 3.73 (m, H-4′) in **2** to 7.00 (dt, J=15.5, 6.0, 3.5 Hz, H-8′), 6.43 (d, J=15.4 Hz, H-7′), 4.52 (d, J=3.5 Hz, H-5′), 3.87 (m, H-4′) in **3**. Based on these spectral changes, the newly appearing ketone carbonyl was placed in between C-5′ and C-7′ neighboring the C-7′/C-8′ double band. This was confirmed by HMBC correlations between the protons at δ_H 6.43 (H-7′), 7.00 (H-8′), and 3.87 (H-4′), and the ketone carbonyl signal at δ_C 198.0. Thus, the structure of caryospomycin **C** was determined to be an analogue of **2** but with a different oxidation state at C-6′, as shown in Fig. 1.

Nematicidal Activity The nematicidal activities of caryospomycin **A**–**C** are shown in Table 2. Caryospomycin **A**–**C** displayed moderate nematicidal activities against *B. xylophilus*. Nematicidal effects varied with concentration and exposure time. Activity differed significantly between different exposure times of 12, 24, and 36 h at the same concentration (Table 3), and different concentration of 50, 80, 100, and 200 ppm at the same exposure time (Table 4). Probit value of proof mortality showed linear type of increase with increasing Log_{10} (concentrations). The LC_{50} values of compounds **1**-**3** against *B. xylophilus* were 103.1, 105.8, and 105.1 ppm, at 36 hr, respectively.

The study demonstrated the presence in *C. carllicarpa* YMF1.01026 of three new nematicidal metabolites, all of which belonged to the resorcylic 14-membered macrolide family. This family of compounds includes many well-characterized chemicals such as zearalenone isolated from *Gibberella zeae* and *Fusarium culmorum* (Stob et al. 1962; Richardson et al. 1985); radicicol (also named monorden) from *Chaetomium chiversii* (Turbyville et al. 2006), *Cylindrocarpon radicicola* (Evans and White 1966), *Monocillium nordinii* (Ayer et al. 1980), *Penicillium luteo-aurantium* (Nozawa and Nakafima 1979), *Neocosmospora tenuicristata* (Cutler et al. 1987), *Verticillim chlamydosporium* (Khambay et al. 2000), and *Humicola* sp. F02942 (Wicklow et al. 1998; Arai et al. 2003); monorcillins from *Monocillium nordinii* (Ayer and Pena-Rodriguez 1987; Ayer et al. 1980), *Diheterosporia chlamydosporia* (Espenshade and Calton 1979), *Humicola fuscoatra* NRRL22980 (Wicklow et al. 1998), *Humicola* sp. (Arai et al. 2003; Yamamoto

[b] Values were *f* values from independent sample ANOVA

et al. 2003), and *Paraphaeosphaeria quadriseptata* (Wijeratne et al. 2004); pochonins from *Pochonia chlamidospora* (Hellwig et al. 2003); hypothemycin from *Hypomyces trichothecoides* (Nair and Carey 1980; Nair et al. 1981; Agatsuma et al. 1993); and aigialomycins from *Aigialus parvus* (Isaka et al. 2002). All of these compounds have been reported to have a wide range of biological activities such as antifungal, antitumor, antiprotozoan, antimalarial, antiviral, and antiparasitic functions. Among them, zearalenone and radicicol are probably the two most noteworthy. Specifically, zearalenone possesses anabolic, estrogenic, and antibacterial activities. Compounds exhibiting anabolic activities can be employed as cattle-growth stimulants (Lone 1997) as well as in treatments of menopausal and postmenopausal syndromes (Utian 1973). The compound radicicol exhibits various biological activities including antifungal, antibiotic, and antimalarial functions (with *in vivo* efficacy). In addition, radicicol inhibits various kinases and the Heat-shock protein Hsp 90 (Janin 2005). There have been over 200 publications and patents associated with this compound (Jayasuriya et al. 2005). Among its various activities, the inhibition against Hsp90 has attracted significant attention in recent years. Specifically, this compound is capable of suppressing the transformed phenotype caused by various oncogenes such as *src*, *ras*, and *raf*. These suppressive functions are linked to radicicol's high-affinity binding (20 nM) and inhibition of the Hsp90 molecular chaperone. This "antichaperone" activity might help reduce the level of oncogenic proteins, and could thus be of clinical interest. Consequently, the resorcylic 14-membered macrolides have been the subject of many preparative and biosynthetic studies (Nicolaou et al. 1998; Furstner et al. 2000; Burckhardt and Ley 2002; Yang and Danishefsky 2003; Moulin et al. 2005). Our finding that the widely distributed fresh water fungus *C. carllicarp* YMF1.01026 can

also produce resorcylic 14-membered macrolides may be of significant biomedical importance. Further studies are required to examine the resorcylide biosynthetic capacities of this fungus and to obtain sufficient quantities of caryospomycins **A**–**C** as well as their analogues to fully evaluate their biological activities.

The present study demonstrated that fungi inhabiting freshwater environments can produce nematicidal metabolites. The occurrence of nematicidal substance in freshwater fungi might be linked to their survival strategies. For example, nematicidal compounds could help fungi obtain nutrients (e.g., organic nitrogen compounds) from dead nematodes, similar to the proposed functions of these groups of compounds in some wood-inhabiting Basidiomycetes like *Pleurotus* species (Thorn and Barron 1984; Barron 1992). In freshwater ecosystems, submerged woody substrata constitute the main energy input source (Wong et al. 1998). Wood is, however, a substrate notably deficient in nitrogen, and thus the nitrogen utilized by freshwater fungi might need to come from other sources. Nematodes are cosmopolitan organisms and are adapted to live in both terrestrial and aquatic environments. They have been shown to be an integral part of various ecosystems, providing food and energy for small invertebrates or fungi (Dropkin 1980). With their high nitrogen contents, nematodes are considered to play an important role in providing nitrogen to other organisms in freshwater ecosystems. Several nematophagous fungi have previously shown to be associated with nematodes found in wood that was submerged in freshwater. These fungal species included *Dactylella ellipsospora* Grove (Hyde and Goh 1998) and *Dactylella aquatica* (Ingold) Ranzoni (Kane et al. 2002). Similarly, freshwater fungi producing nematicidal compounds might also obtain their nitrogenous nutrients from nematodes living in submerged wood. The ability for these fungi to produce nematicides that can kill nematodes and release nutrients could be highly advantageous for these fungi in their natural environments.

LETTER FROM THE EDITOR-IN-CHIEF

John T. Romeo (For the Associate Editors and Editorial Board)

All of us are saddened by the passing of R. Milton Silverstein, one of the founding editors of the *Journal of Chemical Ecology*. Coming just a little over 2 years after the death of his friend and co-founder John Simeone, this is truly the end of an era. The following tribute by those who knew him well reminds us of the legacy he left, as well as his warmth, wit, and humility.

We commemorate his vision and accomplishments as a scientist, which will long inspire us. The Silverstein/Simeone award, which is awarded annually by the International Society of Chemical Ecology and funded by Springer Publishing, will continue to recognize scientists who are advancing the discipline of Chemical Ecology with innovative research.

Milt was also, and above all, a humanist, and we are forever grateful for the privilege of knowing him. It is with gratitude, respect, and affection that we dedicate this issue of the Journal to Milt.

On February 26, 2007, Robert Milton Silverstein died peacefully, surrounded by his family, at the age of 90. He was an internationally recognized expert on the chemistry of insect communication. His pioneering studies led to the development of the field of chemical ecology. Born in Baltimore, MD, he grew up in Tottenville, Staten Island. He earned a B.S. in Chemistry at the University of Pennsylvania and an M.S. and a Ph.D. at New York University. During WWII, Milt served in the Army Medical Corps and was sent to the Pacific Theater, where he rose to the rank of Captain. He married Olive Jorgenson in 1943. They began a family and, in 1948, moved to California. Milt worked for 21 years at the Stanford Research Institute (SRI), where he made significant contributions in analytical methods, chemical synthesis, and flavor and fragrance chemistry. While at SRI, he began his ground-breaking studies in chemical ecology and wrote the first edition of his textbook,

Spectrometric Identification of Organic Compounds. This enduring textbook is now in its seventh edition and has been translated into five languages.

In 1962, Milt phoned the Department of Entomology and Parasitology at the University of California, Berkeley (UCB), to inquire about entomologists working on insect behavior. What motivated him to make that phone call to UCB and other universities? He was ahead of the times. He recognized the significance of Butenandt's landmark identification of the silkworm moth sex attractant in 1959. At that time, synthetic organic pesticides were being used indiscriminately against insects, mites, and nematodes in the US and throughout the world. As a consequence, pest resistance, resurgence, and replacement with new pests became a central theme in pest control. In those early days, Milt had concluded that, through the application of their newly developing techniques in microchemistry, naturally occurring compounds that control insect behavior and development could be identified and thus be made available to reduce pest-caused damage in an environmentally friendly way. He vigorously pursued this objective throughout his career, as can be seen from the long list of invertebrate pests that he investigated. His great versatility and wide-ranging interests are further highlighted by his collaborative investigations of vertebrate behavior.

He collaborated with David Wood to isolate and identify the first beetle pheromone. This was also the first multicomponent pheromone to be identified, and they were the first to demonstrate the importance of using a complete blend of pheromone components. Simultaneously, they had discovered synergism among the three active terpene alcohols isolated from the attractive substrate (frass or fecal material). None of the compounds were active alone! They rushed to the field to test two of these compounds that together elicited an attractive response in the lab. Milt could be seen picking the little (3–4-mm) beetles out of the talcum powder-like dust around the trap and tossing them onto the trap. He was convinced that they were "near misses" and were, in fact, responding to that treatment. With or without the near misses, the differences were obvious. But, they had trapped a different species from the one producing the compounds that were being tested! When all three compounds were released the next day, they trapped the species that produced these compounds, but not the other species. They were amazed by these unexpected results! Milt published one of his favorite quotes a few years later: "To him who in the love of Nature holds Communion with her visible forms, she speaks A various language..." *Thanatopsis*.

During experiments in 1965 near Yosemite National Park, Milt learned the rigors of field research. When the team arrived in the field site they soon realized that they had forgotten the release devices. Milt offered to stay behind and watch over the traps. He lay down in the tall grass to take a nap, as he was also recovering from a small dose of the "killer grape" that had been enjoyed the previous evening. Suddenly, he was awakened by an order to stand up slowly and identify himself. As he opened his eyes, he stared up at the barrel of a sawed-off shotgun aimed at his head by a deputy sheriff from Madera County. He said that what went through his head was, "I am a chemist employed by the SRI in Menlo Park, California, and that I am in this brush field testing bark beetle pheromones...No!...He will never believe this story!" Milt's employee card saved the day.

Milt was invited to lecture in France, but his hosts asked if he would be willing to deliver it in French! Always rising to the challenge, Milt sat in his office for weeks memorizing his speech. When asked questions after his talk, his French colleagues quickly realized what an accomplishment he had made to accommodate their request. He disdained paperwork. On one occasion when he was out of town, a secretary tried to find a portion of a research proposal in his files. She returned empty-handed, exclaiming: "He keeps nothing in his file cabinets. They are empty!" Besides being an outstanding scientist, Milt also

relaxed in nature. He and Olive shared many memorable hours in the woods with friends, watching beavers, skiing, hiking, and gathering wild apples.

Milt wrote the definitive papers on the role of chirality in insect pheromones. He and his colleagues demonstrated the importance of host tree compounds in synergizing bark beetle pheromones and identified and synthesized the pheromones of over 20 species of beetles, several ticks, moths, and ants, as well as mammals like the deer and pronghorn antelope. His pioneering work on pheromones provided the knowledge and the tools for successful monitoring and control programs for insect pests of forests, stored products, and agricultural crops. As an example, the pink bollworm moth sex pheromone, which he played a critical role in identifying, is used successfully for control of this important pest of cotton, thus avoiding the use of pesticides on thousands of acres.

In 1969, Milt and his family moved to Syracuse, NY, where he was appointed Professor of Chemical Ecology at the State University of New York College of Environmental Science and Forestry (ESF), the first position of its kind in the world. At ESF, he focused on developing the field of chemical ecology, publishing more than 200 research papers and seven books over his career. He was a founding member of the International Society of Chemical Ecology and helped to establish its Journal. He served, along with John Simeone, as editor until 1994. Milt is honored by the society with its annual presentation of the Silverstein–Simeone Award, which is given to a scientist for outstanding lifetime contributions. He also received many other scientific honors, including the Bussart Memorial Award from the Entomological Society of America and the first Silver Medal of the International Society for Chemical Ecology, culminating in his election to the National Academy of Sciences. He was predeceased by his son, Roy; his daughter, Amy; and his brother, Fred. He is survived by his wife, Olive; son Paul and his wife, Elizabeth; grandchildren Brian, Ilana, and Nava; great-grandson Matthias; several nieces and nephews; and other close family and friends. A memorial service was held March 17, 2 to 4 P.M. at the First Unitarian Universalist Society of Syracuse, 250 Waring Road, Syracuse. Memorial contributions may be made to the Alzheimer's Association, 441 W. Kirkpatrick St., Syracuse, NY, 13204, and Greenleaf Funeral Home, Inc.

We are fortunate to have traveled on life's path together. Thank you Milt, and, in his understated words of praise, "good show."

Determining Larval Host Plant Use by a Polyphagous Lepidopteran Through Analysis of Adult Moths for Plant Secondary Metabolites

Abstract Many polyphagous insect species are important economic pests on one or more of their crop hosts. For most important insect pests, the common crop hosts are well-known, but knowledge of weedy and unmanaged hosts is limited. Furthermore, the relative contribution of different hosts to local and regional populations has rarely been ascertained because this requires having some way to determine which plant hosts are the source of the adult moths observed ovipositing in a crop field at a given place and time. One way of determining the larval host of polyphagous pest species is to analyze for several plant-derived chemicals that are each specific to a different small set of related plant species and are preserved in detectable amounts in adult moths. In this paper, we describe novel methods for analyzing adults of the polyphagous lepidopteran, the tobacco budworm (TBW) *Heliothis virescens* (F.), for plant secondary metabolites, specifically cotinine and gossypol, which are diagnostic for larval feeding on tobacco and cotton, respectively. Cotinine was extracted from individual TBW moths with acetic acid and methanol, then concentrated and analyzed directly by gas chromatography/mass spectrometry (GC/MS). The same moths then were analyzed for bound gossypol by creating a Schiff's base that used aniline, and the resulting dianilino–gossypol complex was quantified using high pressure chromatography coupled with a triple quadrupole mass spectrometer (MS) as the detector. Based on analysis of standards, the detection limit for the cotinine was less than 1.5 ppb by dry weight. Comparable standards were not available for the gossypol derivative so a quantitative limit of detection could not be calculated. When TBW moths reared on known hosts were analyzed for gossypol and/or cotinine, all of the moths reared on tobacco or cotton were correctly identified, although some false positives were recorded with the gossypol method. Analysis of TBW moths of various ages and at various lengths of time after death determined that a significant gossypol signal was detectable in all moths reared on cotton. TBW moths collected from the vicinity of cotton fields in July and August in North Carolina also were analyzed. A much larger portion of the moths were derived from tobacco (6.7–46.4%) than from cotton (0–3.6%) in both months. Thus, these methods can be reliably used to estimate the proportion of TBW derived from noncotton host plants in

Introduction

Many insect species are highly polyphagous, and many are important economic pests on one or more crop hosts. Understanding patterns of host use is a prerequisite to understanding population dynamics, which, in turn, is necessary for designing appropriate management programs for these pest species. Knowing which host plant species are most responsible for sustaining pest populations and causing pest outbreaks, and when these hosts are used, enables pest monitoring and control programs to be targeted appropriately.

For most important insect pests, the common crop hosts are well-known precisely because that is where these pests cause the most economic impact, but knowledge of weedy and unmanaged hosts is more limited. Furthermore, even where the host range of a pest has been carefully documented, the relative contribution of different hosts to regional metapopulations has rarely been determined because of significant technical barriers. In particular, although larval pest populations are relatively easy to estimate, these populations are highly variable over space and time even on a given host plant species, and thus it is difficult to determine how larval populations on different hosts translate into regional populations.

Armyworms (*Spodoptera* spp.) and heliothines (particularly *Helicoverpa* spp. and *Heliothis* spp.) are important larval pests of cotton, corn, sorghum, and numerous other monocotyledonous and dicotyledonous crops in the Old and New World (Fitt 1989). Adults of these lepidopteran species feed only on nectar and other sugar and moisture sources. To understand the population dynamics of these species, one must determine which plant hosts are the source of the adult moths observed ovipositing in a crop field at a given place and time.

Stable isotope analysis has been used successfully to qualitatively (Gould et al. 2002) and quantitatively (Head et al., unpublished data) infer host use by the important corn, cotton, and vegetable pest *Helicoverpa zea* Boddie. This analysis is based on the principle that the isotopic composition of the wings of adult moths is determined by the physiology of the larval host plant. However, the stable carbon isotope analysis used in these studies could only distinguish whether adults came from larvae that had fed on C3-type hosts (broad-leaved plant species such as cotton, soybean, peanuts, or tobacco) or C4-type hosts (grass-like plant species such as corn, sorghum, or weedy, warm-season grasses). With highly polyphagous pest species like these noctuids, more specific methods are needed to determine the larval host plants from which individual moths originated.

Conceptually, it should be possible to design analyses comparable to stable isotope approaches but focused on plant-derived chemicals that are specific to one or a small set of related plant species. If these analyses are to provide accurate and useful data, the plant-derived analytes need to be preserved in significant (detectable) amounts in adult moths, and they should be unique to the plant species of interest or cause a unique change in the biochemical makeup of the adult moth. Plant secondary metabolites, particularly those involved in plant defense against herbivores, are a promising target for such analyses because many are relatively limited in their taxonomic distribution, and insect herbivores tend to sequester such compounds because of their toxicity.

An example of such a compound is gossypol, which is uniquely related to the lysigenous glands of cotton (*Gossypium* spp.) and closely related species. Work by Rojas et al. (1992) demonstrated that adults of the important cotton pest species, the tobacco budworm (TBW) *Heliothis virescens* (F.), contained gossypol from cotton consumed as larvae. The gossypol was in a bound form; no free gossypol was found. However, the method used pooled samples, and the mass analyzed ranged from hundreds of milligrams to grams.

For an analytical method to be useful for population dynamic and host use studies, it must be suitable for use with large numbers of individual moths, and its selectivity needs to be demonstrated. In addition, having appropriate analyses for several different analytes, each largely or wholly specific to one particular important host plant species, would be particularly useful for gaining an understanding of host use patterns by polyphagous pest species. In the case of *H. virescens*, this would mean having analytical techniques for a cotton-specific compound such as gossypol to determine cotton-derived moths and for a comparable tobacco-specific compound such as nicotine because tobacco (*Nicotiana* spp.) also is a major crop host of this pest.

This paper describes and characterizes novel methods for the analysis of adult moths for both gossypol and cotinine, a metabolite of nicotine. The methods are applied to TBW moths reared on known host plant species and to a set of field-collected TBW moths.

Methods and Materials

Moths For development and characterization of the cotinine and gossypol analyses, TBW larvae were reared individually on leaves of cotton (*Gossypium hirsutum*), tobacco (*Nicotiana spp.*), peanut (*Arachis hypogea*), soybeans (*Glycine max*), and the weedy host, velvetleaf (*Abutilon theophrasti*). Larvae were allowed to pupate, and the resulting adults were freeze-dried for 48 hr. Wings were removed, and the thorax and abdomen of the adults were weighed and frozen for further analysis. The dry weight of the moth bodies ranged from 0.020 to 0.040 g.

Adult male TBW also were collected for cotinine and gossypol analyses adjacent to cotton fields in two North Carolina counties (Lenoir and Wilson) in July and August of 2004. These moths were collected in pheromone traps baited with Zealure (Hercon® Luretape® Insect Attractant Dispenser, Hercon Environmental Company, Emigsville, PA, USA), and pheromone was replaced on a weekly basis. The collected moths were processed as described for laboratory-reared moths.

Chemicals for Cotinine Analysis Chemicals were obtained from the following sources: glacial acetic acid (J.T. Baker ,VWR International, West Chester, PA, USA); ACS-grade methanol (EMD, VWR International); deionized water (Milli-Q Gradient A10 system, Millipore, Billerica, MA, USA); anhydrous diethyl ether (J.T. Baker, VWR International); ethanol (AAPER Alcohol and Chemical Co); 50% solution of sodium hydroxide (J.T. Baker, VWR International). The internal standard d_4 cotinine (98.2% D) was from CDN isotopes (C/D/N ISOTOPES INC., Pointe-Claire, Quebec, Canada), and the cotinine standard from (Sigma-Aldrich, St. Louis, MO, USA).

Chemicals for Gossypol Analysis Chemicals were obtained from the following sources: glacial acetic acid (J.T. Baker,VWR International); gossypol acetic acid standard (95% pure) (Sigma-Aldrich); ACS-grade methanol (EMD, VWR International); HPLC methanol (Burdick & Jackson, Sigma-Aldrich); deionized water (Milli-Q Gradient A10 system

(Millipore); ACS Grade dimethylformamide (DMF) (EMD, VWR International); aniline (99.5% pure) (Sigma-Aldrich); d_5-aniline (98% D) (Sigma-Aldrich); high purity acetonitrile (Burdick & Jackson,WR International); acetone for sample processing (Fisher Certified ACS, Fisher Scientific, Houston, TX, USA); HPLC acetone (Burdick & Jackson, VWR International); ammonium hydroxide (28–30%) (J.T. Baker, VWR International).

Equipment Grinding of moths and extractions were carried out in 96-well polypropylene plates (2.0 ml) (Microliter Analytical Supplies, Suwanee, GA, USA). For grinding, 1- to 6-mm glass balls were used (VWR International). Divinyl benzene (DVB) solid-phase microextraction was carried out by using 96-well SPE Plates (50 or 100 mg DVB, 2 ml capacity), (Supelco [Sigma-Aldrich] and P. J. Cobert, St. Louis, MO, USA). For standards and individual samples, 100-mg DVB 3-ml capacity columns were used (Alltech Associates, Deerfield, IL, USA). The HPLC column was an Agilent Eclipse XDB-C8 (2.1×12.5, 5 μ) guard column. Autosampler 96-well plates (0.5 ml) (Agilent Technologies) were capped with Agilent Technologies 96-well Plate Piercible Cap Mats (P. J. Cobert Associates). The gas chromatograph was an Agilent 6890 (Agilent Technologies, Santa Clara, CA, USA) equipped with a Leap autosampler (Leap Technologies, Carrboro, NC, USA). The detector was a Leco® Pegasus III time of flight mass spectrometer (Leco Corporation, St. Joseph, MI, USA). The capillary column was a 15-m DB5 column with an inside diameter of 0.250 mm and a phase thickness of 0.25 μm (P. J. Cobert Associates).

Analytical Determination of Cotinine To analyze for cotinine and gossypol in the same adult moth requires two different but complementary methods. The extraction of cotinine is carried out first because the gossypol analysis involves a derivatization method. The cotinine determination is accomplished by using d_4 cotinine as an internal standard. The selectivity is achieved by combining a solid-phase extraction (SPE) cleanup procedure with gas chromatography coupled with a mass spectrometer (GC/MS) as the detector . To obtain the requisite selectivity for gossypol, a SPE procedure, followed by electrospray ionization with tandem mass spectrometry, is used. The use of the tandem mass spectrometer gives a high degree of selectivity and minimizes the need for high-resolution, high-pressure liquid chromatography techniques (HPLC). The methods are adapted to a 96-well format, allowing several hundred samples to be processed per day.

The procedure for determination of cotinine was adapted from Kim et al. (2005) and is summarized in Fig. 1a. This involved extraction and a cleanup with a DVB SPE column. Stable isotope-labeled cotinine was added at the beginning of the extraction so that matrix effects could be minimized. The extracted cotinine was concentrated and analyzed directly by GC/MS. The calibration curve for cotinine was obtained by running standards that ranged from 20 to 600 ng. The quantification was carried out by measuring the ratio of the area of *m*/*z* 176 to the area of 180 *m*/*z* where 180 *m*/*z* was the d_4 cotinine internal standard.

To prepare the extraction solution, 50 ml of acetic acid and 200 ml methanol were added to a 1,000-ml volumetric flask, and the volume was brought up to the mark with deionized water. A 20% by volume methanol ether solution was prepared by mixing 20 ml of methanol with 80 ml of ether. A solution of d_4 cotinine was used as an internal standard by dissolving d_4 cotinine in the extraction solution to give a concentration of 100 ng/20 μl.

Individual freeze-dried TBW moths were placed into the wells of a 2-ml 96-well plate. A glass bead was added to each well, and the plate was capped and placed onto a mega grinder and shaken at 1,100 rpm for 45 sec to grind up the moths (Deppermann 2005). One milliliter of cotinine extraction solution, followed by 20 μl of deuterated cotinine internal standard solution, was added to each of the wells. Parafilm was placed over the top of the

plate, and a cap was pressed onto the plate. The moth mixture was vortexed for 15 min, then centrifuged, and the liquid layer removed and added to an 8-ml vial. A second 1 ml of extract solution was added to the moth residue, and the solution was vortexed again for 5 min, centrifuged, and as much liquid removed as possible and combined with the previous extract. One hundred fifty microliters of 40% NaOH, followed by 4 ml of deionized (DI) water, were added to the 8-ml vial containing the extraction solution. The solution was mixed and put through a solid-phase extraction (SPE) DVB column. The 96-well plate containing the moth residue was dried under dry nitrogen and stored at −20°C until needed for the gossypol analysis. An SPE DVB 100 mg (SPE) was used to remove the cotinine from the extraction solution. The DVB solid-phase extraction was prepared by first washing with 2 ml of ethanol, followed by 2 ml of DI water. The cotinine was removed from the extraction solution by passing it through the column. The column was washed with 1 ml of DI water and allowed to dry for 5 to 30 min by drawing or forcing air through the column. The cotinine was eluted with 3.0 ml of 20% methanol/ether. The methanol/ether was removed by using a stream of dry nitrogen. Methanol (150 μl) was added and the sides were carefully washed. The solution was placed into an autosampler vial and injected into a GC/MS.

Gas Chromatography and Mass Spectrometry Conditions for Cotinine The gas chromatography column was a DB-5 column with a length of 15 m, an inner diameter of 0.25 mm, and a film thickness of 0.25 μm. The inlet temperature was 285°C with the injection set for a splitless injection. One microliter was injected. The carrier gas was He, with a flow rate of 2.1 ml/min. The column was held at 100°C for 0.1 min, after which it was ramped to 175°C at a rate of 40°C/min, then to 300°C at 30°C/min. The mass spectrometer was a Leco Pegasus III time of flight. The ionization was through electron impact at 70 eV. The solvent delay was 50 sec. The scan range was from 50 to 210 *m*/*z*. The number of scans was 15 per sec. The ion source temperature was 200°C.

The quantification was carried out by measuring the ratio of the area of *m*/*z* 176 to the area of *m*/*z* 180, where 180 was the d_4 cotinine internal standard. The retention time varied during the running of sets of samples so the retention time was set using the internal standard as a reference. The results for detected cotinine are reported in nanograms.

Analytical Determination of Gossypol The overall method for gossypol analysis of *H. virescens* tissues is summarized in Fig. 1b. The method involved the formation of a Schiff base with aniline, which permits the total amount of gossypol present (bound and unbound) to be determined (Pons et al. 1958; Rojas et al. 1992; Kim et al. 1996). The resulting dianiline complex was further isolated from the moth matrix with divinyl benzene solid-phase extraction, and then was quantified by using high-pressure chromatography coupled with a triple quadrupole mass spectrometer (MS) as the detector. Electrospray ionization (ESI) was used with post addition of ammonia after the LC column. The ESI was operated in negative ionization mode. Because the matrix is complex and the HPLC method was not set for optimum selectivity, the triple quadrupole was operated in reaction monitoring mode. In this mode, the pseudomolecular ion representing the dianiline–gossypol (667 *m*/*z*) was selected by the first quadrupole, followed by collision-induced dissociation in the second quadrupole region. The collision resulted in the loss of one aniline (574 *m*/*z*) and, to a lesser degree, the loss of a second aniline (481 *m*/*z*). These fragments were monitored in the third quadrupole. Deuterated aniline complexed with gossypol was used as an internal standard for the HPLC/MS/MS determination.

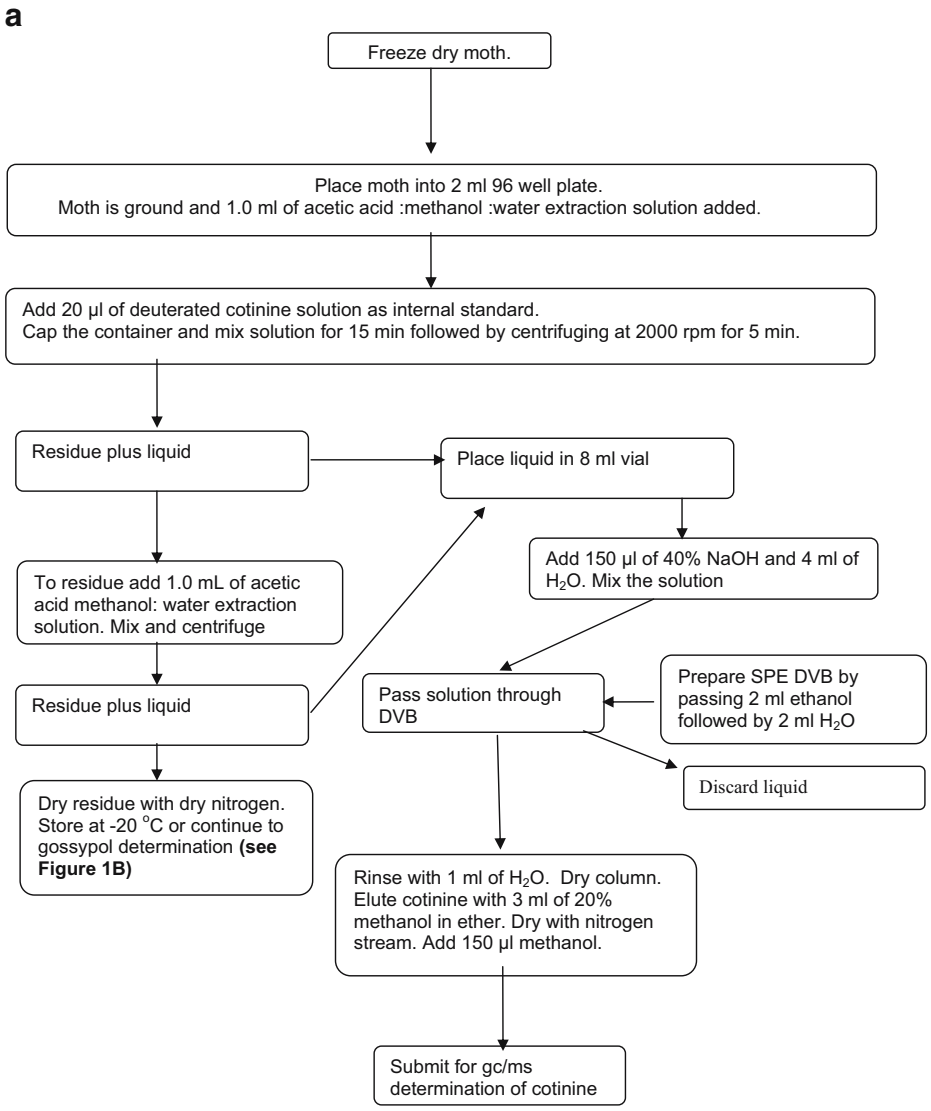

Fig. 1 **(a)** Scheme for cotinine determination in moths. **(b)** Scheme for gossypol determination in moths

The derivatizing reagent was prepared by mixing 1 ml aniline, 5 ml glacial acetic acid, and 44 ml dimethylformamide. This reagent lasted for up to 1 wk if refrigerated at 4°C. The deuterated derivatizing reagent was prepared by mixing 0.1 ml d_5-aniline, 0.5 ml acetic acid, and 4.4 ml dimethylformamide. This was used within 24 hr for preparing the deuterated internal standard. The other necessary solutions were, by volume, 20% water/methanol, 10% water/methanol, 5% acetone/methanol, 50% DMF/water, 0.6% NH_4OH, wash solvent of 100% methanol, acetonitrile/1% acetic acid, and 2:1 acetonitrile/acetone.

The standard stock solution of gossypol was prepared by weighing approximately 10 mg gossypol-acetic acid into a 100-ml volumetric flask, which was filled to the mark with

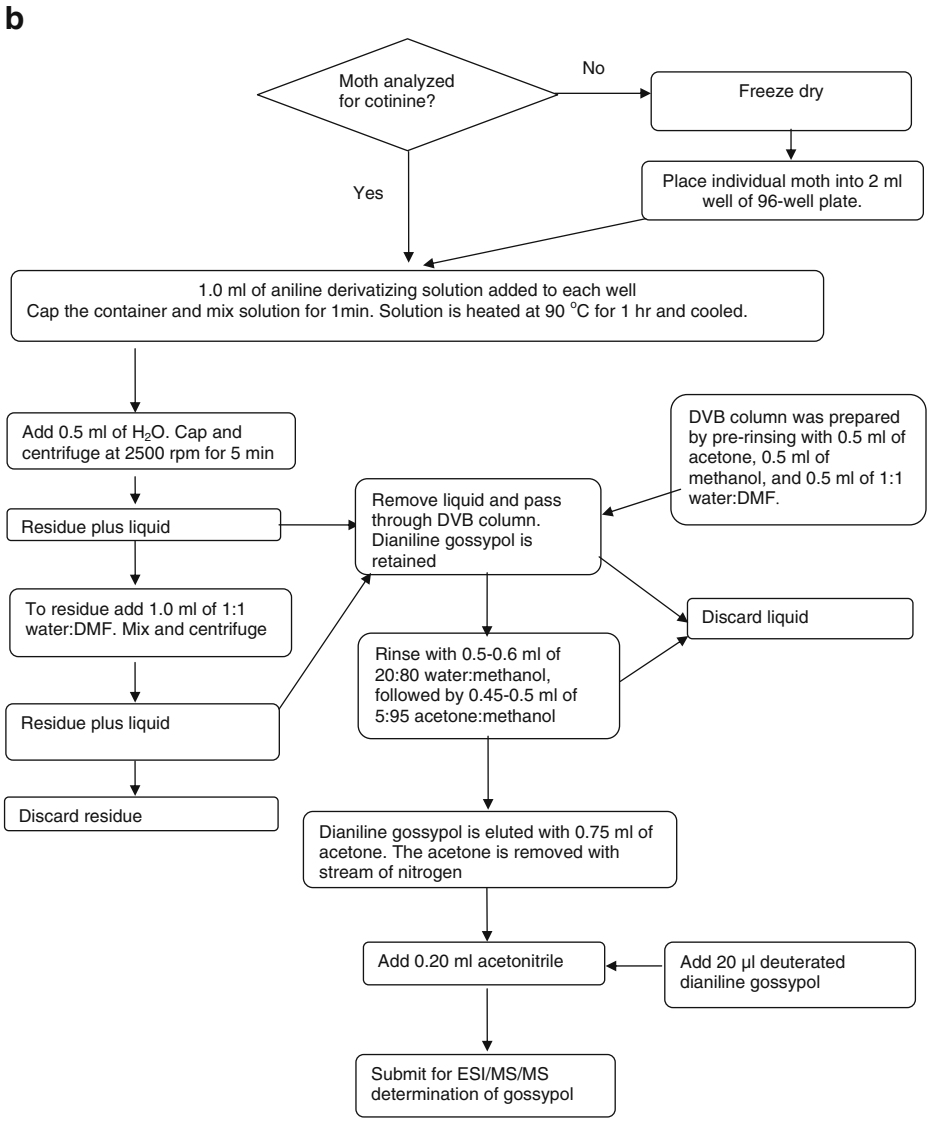

Fig. 1 (Continued)

acetonitrile/1% acetic acid. This solution was stored in an amber glass bottle at 4°C and used within 3 mo. The gossypol-acetic acid standard stock solution was used to prepare a 10 μg/ml standard solution of the dianilino–gossypol by taking 500 μl of the gossypol-acetic acid standard stock solution and removing the solvent under a dry nitrogen stream. To this, 1.0 ml of the aniline derivatizing reagent was added, and the solution was heated at 90°C for 30 min. The excess aniline was removed with a 100 mg DVB SPE column that had been prerinsed with 1.0 ml of acetone, 1.0 ml of methanol, and 1.0 ml of 1:1 water/DMF. The column beds were wetted with the 1:1 water/DMF. One milliliter of DI water was added to the 1.0 ml of dianiline–gossypol solution. This solution was put through the

column, which retained the dianiline–gossypol. The column was rinsed with 0.8 ml of 20:80 water/methanol. The gossypol derivative was eluted from the column with 2 ml of acetone into an amber vial, and the acetone was removed with dry nitrogen. This yielded 50 μg of dianiline–gossypol, which was used with acetonitrile to prepare standards ranging from 25 to 75 ng/ml. These standards were prepared on a daily basis because the dianiline–gossypol was not stable once diluted with acetonitrile.

The deuterated dianiline–gossypol internal standard also was prepared on a daily basis. The 1.0 ml of the standard gossypol stock solution was blown dry, and 1.0 ml of the d_5-aniline derivatizing reagent solution was added to the dry residue. The solution was capped and heated for 30 min at 90°C. To use this d_{10}-dianiline-gossypol as an internal standard, it was necessary to remove the excess d_5-aniline. This was accomplished by using a 100-mg DVB SPE column, which was prerinsed with 1.0 ml of acetone, 1.0 ml of methanol, and 1.0 ml of 1:1 water/DMF. The column beds were wetted with the 1:1 water/DMF, and 1.0 ml of DI water was added to the 1.0 ml of d_{10}-dianiline–gossypol solution. This solution was passed through the column, which retained the d_{10}-dianiline–gossypol. The column was rinsed with 0.5 ml of 20:80 water/methanol, and the d_{10}-dianiline–gossypol was eluted from the column with 2 ml acetone into an amber vial. The acetone was removed with dry nitrogen, yielding 100 μg of d_{10}-dianiline–gossypol. This was used to prepare a 5 μg/ml solution by using acetonitrile.

The individual freeze-dried moths were placed into a 2-ml 96-well plate. For routine analysis, five method blanks, two positive control moths reared on cotton, and two negative control moths reared on plants other than cotton were included. These controls were placed at random in the plate by using a pseudorandom number generator. A glass bead was added to each well, and the plate was capped and placed onto a mega grinder and shaken at 1,100 rpm for 45 sec to grind up the moths (Deppermann 2005). If the moths had been through the cotinine determination, the grinding steps had already occurred. The aniline derivatizing solution (1.0 ml) was added to each well. The plate was sealed by placing a sheet of Parafilm over the top, a new cap was added, and the cap was pressed into place. The plate was vortexed at a low setting for 1 min. The Parafilm and cap were removed, and the plate was covered with aluminum foil and placed in a well heater set at 80–90°C. The solution was heated for 1 hr and then allowed to cool. The samples were cleaned up by using a 96-well DVB plate containing 50 mg of DVB and a positive pressure apparatus (SpeedDisk 96 Pressure Processor from Mallinckrodt Baker, Inc., Phillipsburg, NJ, USA). The 50-mg SPE DVB 2-ml 96-well plate was prerinsed with 0.5 ml of acetone, 0.5 ml of methanol, and 0.5 ml of 1:1 water/DMF. Column beds were wetted with 1:1 water/DMF. Water (0.5 ml) was added to each well of the 96-well plate. The plate was resealed with a clean sheet of Parafilm, capped, and the cap was pressed into place. The plate was centrifuged at 2,500 to 3,000 rpm for 5 min. With a multipipetter, the solution was transferred to the DVB 96-well plate, taking care to leave solid residue behind. The residue was washed with 1.0 ml of 1:1 water/DMF, and this was passed through the DVB 96-well plate. The dianiline–gossypol was retained in the DVB. The DVB column was washed with 0.5–0.6 ml of 20:80 water/methanol, followed by 0.45–0.5 ml of 5:95 acetone/methanol. A clean 96-well plate was placed under the DVB 96-well plate, and the dianiline–gossypol was eluted with 0.75 ml of acetone. The acetone was removed under a dry stream of nitrogen. It was found, at this point, that the samples could be stored for 48 hr without loss of signal. For HPLC/MS/MS determination, 200 μl of acetonitrile were added to each well, along with 20 μl of 5 μg/ml d_{10}-dianiline–gossypol internal standard. The autosampler was equipped for 0.5 ml 96-well plates so it was necessary to transfer the solution to such a plate. The plate was capped and the autosampler was set for less than 18°C.

If only a few samples were to be analyzed, then individual SPE DVB 3-ml columns were used in place of the DVB 96-well plate. The same procedure as for the 96-well DVB plates was followed, except that the volumes were doubled.

HPLC/MS/MS Solvent A was 10% water/methanol and solvent B was acetonitrile/acetone 2:1. The flow rate through the Agilent Eclipse XDB-C8 (2.1×12.5, 5 μ) guard column was set for 0.250 ml/min. The gradient was 0% B for 2.1 min, which then was brought to 60% B in 4 min. Post column, a 0.6% ammonium hydroxide modifier was added at a flow rate of 0.050 ml/min to enhance the negative ion signal. The volume of the sample extract injected was 5 μl. The 0.3 ml/min output of the HPLC system was put directly through the electrospray ionization source of a Micromass Quattro Ultima LC/MS/MS system (Waters, Milford, MA, USA). The electrospray source was operated in negative ion mode. The process forms $M–H^-$ pseudomolecular ions (667 *m*/*z*), which undergo collision activation to form a rearrangement fragment at 574 *m*/*z* reflecting the loss of one aniline. For further confirmation, the loss of a second aniline at 481 *m*/*z* also was monitored. The sensitivity of the loss of the second aniline was relatively low so it was used only for confirmation.

Characterization of the Cotinine and Gossypol Analyses Two methods were used to characterize the accuracy and sensitivity of both analytical methods. First, recovery experiments were conducted with both methods. For the cotinine analysis, cotinine was spiked into samples of TBW adult moths that had not been reared on tobacco. For the gossypol analysis, gossypol was spiked into samples of adult moths that had not been reared on cotton. The spike levels ranged from 5 to 20 ng per moth, and the recovery experiment was replicated over a number of days. The percent recovery was calculated as the ratio of the measured response for the spiked moth to the measured response for the standard. In each case, the response was a ratio of the peak area measured for the analyte to the peak area measured for the internal standard. Because the cotinine method provides an absolute measurement, absolute recoveries could be obtained for the cotinine analysis as compared to relative values for the gossypol analysis.

The second approach for estimating bias was to estimate positive and negative error rates by analyzing adult moths that were reared on known hosts. The gossypol analysis was characterized with a set of 193 TBW moths reared on different known host plants: cotton (118), soybean (7), peanut (5), velvet leaf (30), and an artificial laboratory diet with no cotton content (33). The moths were submitted for analysis with labels that did not indicate on which plant they were reared. Based on the chromatograms for individual moths, Tukey's honestly significantly different (HSD) multiple comparison procedure was used to conduct all possible pair-wise comparisons of the average response ratio and signal-to-noise ratio for the different larval host plants. The statistical analyses were carried out by using SAS Version 8.2 (SAS 2001). A set of criteria for determining if gossypol were present (whether the test was positive) was determined by using a set of cotton reared moths and noncotton reared moths. The criteria were based on the response ratio and the signal-to-noise ratio for the chromatogram signal.

The characterization of the cotinine analysis was carried out in the same fashion but on a smaller scale so that estimates of positive and negative error rates could not be determined. In addition, to determine if the cotinine method and the gossypol method could be used on the same moths, a set of moths reared on different plants were analyzed for both cotinine and gossypol: soybean (3), peanut (3), tobacco (3), and cotton (3).

An additional experiment was conducted to determine if the gossypol signal in adult TBW reared on cotton is sufficiently stable to be detectable under a reasonable range of

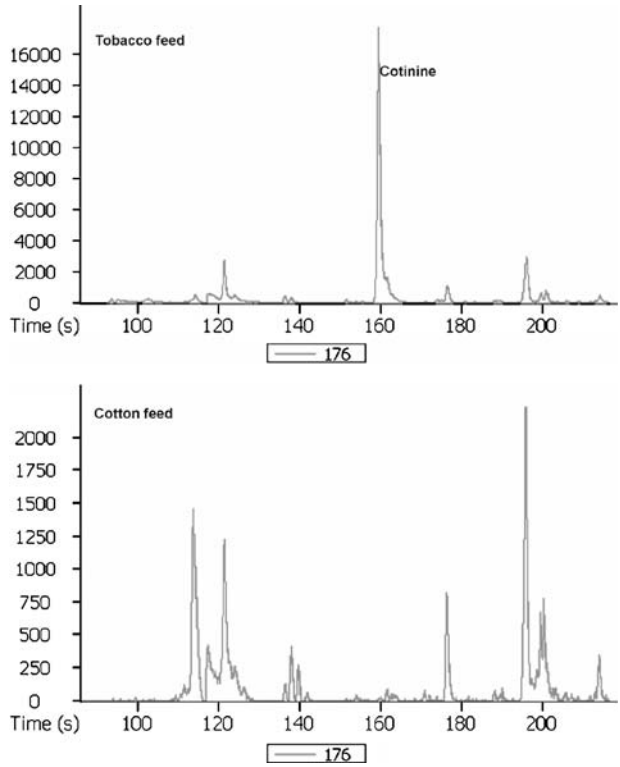

Fig. 2 Ion chromatogram for 176 *m/z* for adult moths reared on tobacco (top) and cotton (bottom). The bottom figure is the ion chromatogram for 176 *m/z* for an adult moth with cotton as the host plant. The peak in the top figure at 159 sec is cotinine. The detection limit represented by the lack of a peak at 159 sec in the bottom figure is 1.5 ppb by dry weight

field conditions. TBW were reared in cages on cotton or chickpea plants in the field. After larvae pupated and emerged as adults, a total of 73 cotton-reared adult TBW were held alive for various lengths of time (0–11 d), then sacrificed and left exposed to the elements for different lengths of time (0–7 d) before being frozen. These treatments were chosen to cover the range of conditions that might occur in collecting moths in the field. Eleven days represents the upper end of the TBW adult lifespan and, therefore, is as long as an adult would be expected to live before being captured in the field. Similarly, moths might remain in a trap for several days after dying and before collection. The 73 cotton-reared moths,

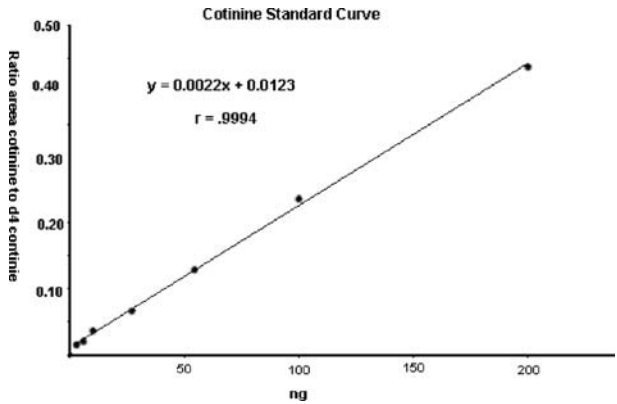

Fig. 3 Calibration curve for cotinine with standards ranging from 2.6 to 200 ng. The detection limit per moth was 0.037 ng

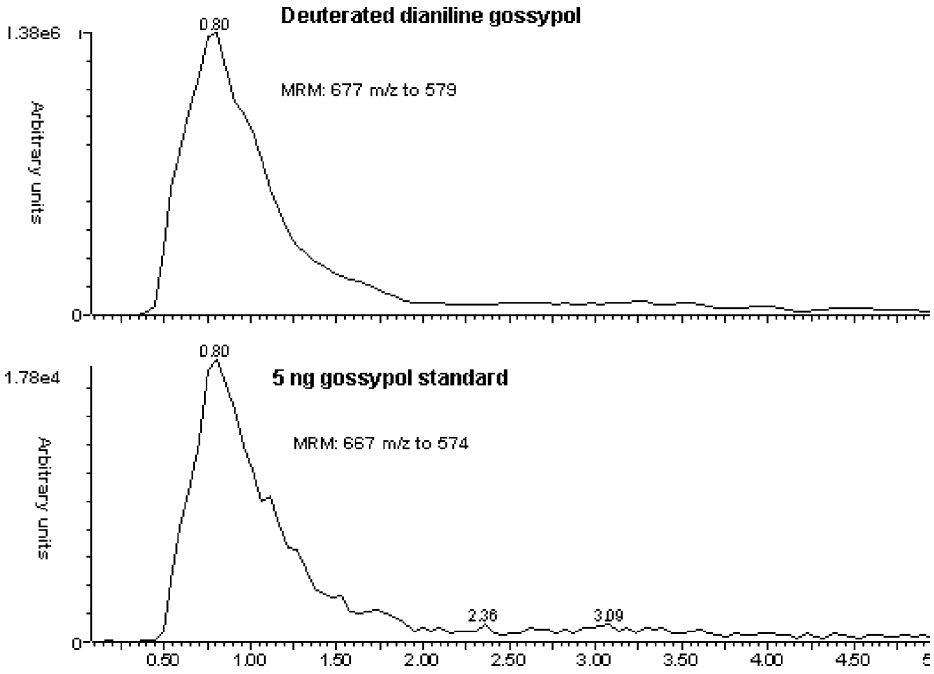

Fig. 4 Reaction monitoring chromatogram for a 5-ng gossypol standard (bottom), and the corresponding chromatogram for a d_{10}-dianiline–gossypol internal standard (top)

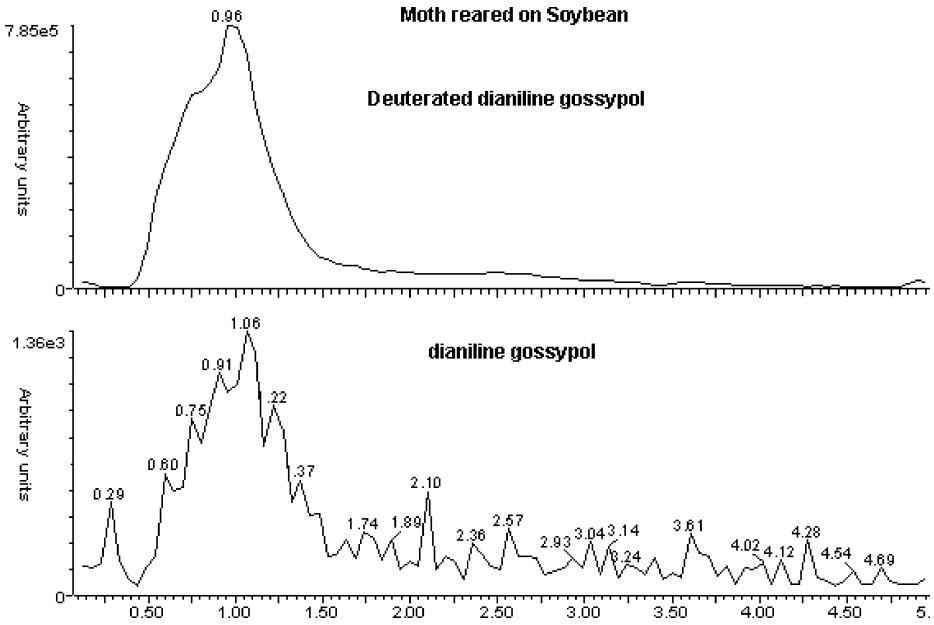

Fig. 5 Reaction monitoring chromatogram for an adult moth reared on soybeans (bottom), and the corresponding chromatogram for an internal d_{10}-dianiline–gossypol standard (top)

together with 19 TBW moths reared on chickpea, were coded and run through a blind analysis for gossypol. Tukey's HSD multiple comparison procedure was used to conduct all possible pair-wise comparisons of the average response ratio and signal-to-noise ratio for the different treatment combinations. The statistical analyses were carried out by using SAS Version 8.2 (SAS 2001).

Application of the Cotinine and Gossypol Analyses to Field-collected TBW Moths To demonstrate the suitability of the cotinine and gossypol analyses for the study of field-collected moths, a small set of moths collected in North Carolina was first analyzed for cotinine and then for gossypol. In total, 30 moths from Lenoir County and 78 moths from Wilson County were analyzed individually as described above.

Results

Cotinine Analysis Figure 2 shows the ion chromatogram for cotinine for a moth reared on cotton and a moth reared on tobacco. The signal for cotinine in the tobacco-reared moth represents 115 ng. The cotinine ion chromatogram for the cotton-reared moth (the bottom chromatogram) represents a detection limit of less than 1.5 ppb by dry weight (Fig. 2). Figure 3 shows the calibration curve for cotinine over the range of 200 to 2.6 ng. The method for cotinine also can provide estimates for nicotine.

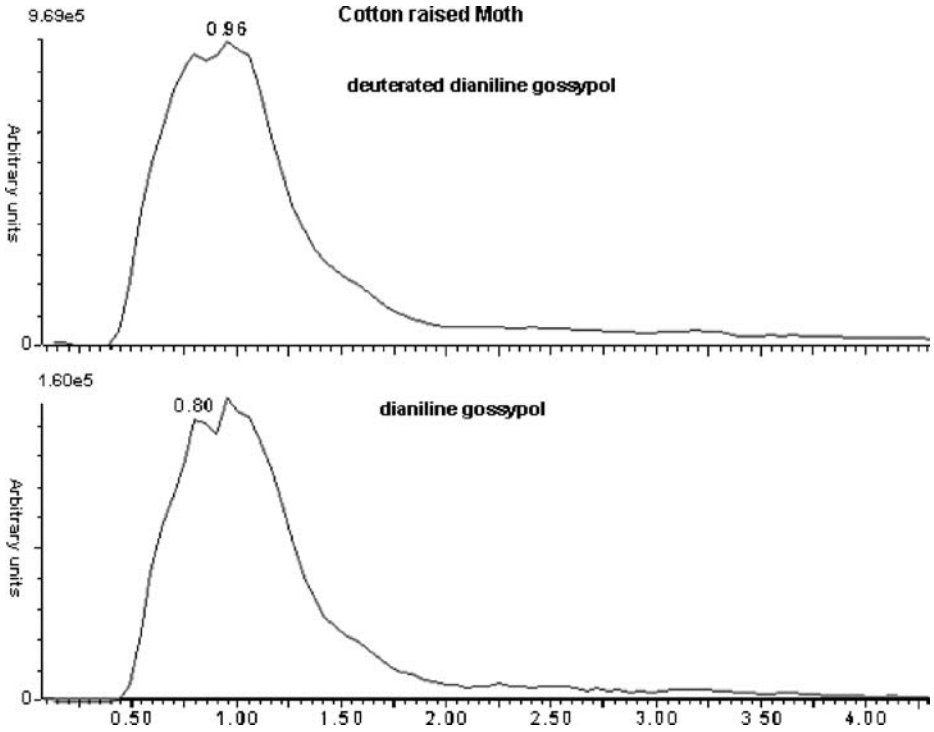

Fig. 6 Reaction monitoring chromatogram for an adult moth reared on cotton (bottom), and the corresponding chromatogram for an internal d_{10}-dianiline–gossypol standard (top)

Table 1 Mean (+ SE) relative response and signal-to-noise ratio from gossypol analyses of TBW moths reared on different hosts, and the percentage of moths judged positive for gossypol

Larval host plant	Cotton (N=118)	Soybean (N=7)	Peanut (N=5)	Velvet leaf (N=30)	Artificial diet (N=33)
Relative response[a]	0.77±0.14a	0.008±0.003ab	0.002±0.002ab	0.03±0.02b	0.01±0.001b
Signal-to-noise ratio[a]	114±8a	8.4±3.6b	0.6±0.6b	6.2±1.2b	9.4±1.1b
Percent positive[b]	100	29	0	13	24

[a] Values in a row followed by the same letter are not significantly different (Tukey's HSD, $P<0.05$).

[b] The following criteria were applied, in order, to determine if a given moth was positive or negative for gossypol: (1) negative if signal to noise ratio <6; (2) positive if response ratio >0.05; (3) negative if response ratio <0.005; (4) positive if signal to noise ratio >10; (5) otherwise negative

Gossypol Analysis Figure 4 shows the reaction ion monitoring chromatogram for a gossypol standard (5 ng in 200 μl). The bottom figure shows the pseudomolecular ion of the dianiline–gossypol 667 *m*/*z* losing an aniline to give 574 *m*/*z*. This represents 125 pg injected. The top portion of Fig. 4 is the corresponding chromatogram for d_{10}-dianiline–gossypol (677 *m*/*z* with loss of one aniline to give 579 *m*/*z*). This represented 2.2 ng that was injected. The chromatograms were normalized to 100. The peak intensity is shown in the upper-right-hand corner and was 1.38×10^6 for the internal standard and 1.78×10^4 for the 5-ng standard. The internal standard was for use with the HPLC/MS/MS system only and did not correct for incomplete conversion to the dianiline–gossypol complex or for recovery.

Figure 5 shows the reaction monitoring chromatogram for an adult moth reared on soybeans; the bottom chromatogram is the response for the dianiline–gossypol and the top is the internal d_{10}-dianiline–gossypol standard as in Fig. 4. The d_{10}-dianiline–gossypol internal standard is not pure and has a small contribution to the dianiline–gossypol signal but the level of d_{10}-dianiline–gossypol was selected so that the contribution would be below detection limits.

Table 2 Results for cotinine analyses followed by gossypol analyses of TBW moths reared on different plant hosts

Larval host	Cotinine[a]	Gossypol[a]
Soy	ND	ND
Soy	ND	ND
Soy	ND	ND
Peanut	ND	ND
Peanut	ND	ND
Peanut	ND	ND
Tobacco	48 ng	ND
Tobacco	21 ng	ND
Tobacco	115 ng	ND
Cotton	ND	+
Cotton	ND	+
Cotton	ND	+

[a] ND, no response detected (for cotinine <1.5 ppb by dry weight and for gossypol based on criteria described in the "Methods and Materials"); +, response detected based on criteria described in Table 1

Table 3 Results of gossypol analysis of TBW moths reared on a noncotton host or on cotton and then sacrificed at various ages and held for various lengths of time after death

Host plant	Moth age (days)	Time in trap after death (days)	Signal-to-noise ratio[a,b]	Relative response[a,b]	Percent positive[c]
Chickpea	NA[d]	NA[d] (*N*=19)	2.7 (1–4) c	0.004 (0.002–0.010) b	0
Cotton	0–5	0-3 (*N*=20)	50 (12–188) b	0.29 (0.024–2.83) a	100
		4-7 (*N*=13)	75 (11–190) ab	0.33 (0.013–1.19) a	100
	6–11	0-3 (*N*=26)	99 (31–228) a	0.58 (0.022–3.48) a	100
		4-7 (*N*=14)	51 (23–139) b	0.18 (0.040–0.49) a	100

[a] Results are expressed as the average signal-to-noise ratio and response for each treatment combination, with the range in parentheses.

[b] Values in a column followed by the same letter are not significantly different (Tukey's HSD, $P<0.05$).

[c] The following criteria were applied, in order, to determine if a given moth was positive or negative for gossypol: (1) negative if signal-to-noise ratio <6; (2) positive if response ratio >0.05; (3) negative if response ratio <0.005; (4) positive if signal-to-noise ratio >10; (5) otherwise negative

[d] NA, not applicable

Figure 6 shows the results for an adult moth that was reared on cotton. The comparison of the adult moth reared on soybean and the cotton-reared adult moth show that the two can be readily distinguished.

Recovery Experiments for Gossypol The recovery experiments were carried out on 16 different days over the course of a 37-d period. The average over all of runs was 111% (SE=10%). If one extreme outlier (240%) is excluded, the average recovery was 102% (SE=5%). The outlier probably resulted from excess aniline remaining in the extraction solution.

Estimation of Positive and Negative Error Rates for Gossypol Method Table 1 shows the results for the analysis of 193 moths reared on known plant hosts. All of the cotton-reared moths were classified as positive for gossypol, indicating that the method has a low rate of false negatives. However, for the criteria used, 14 of the 75 moths reared on noncotton hosts were incorrectly judged as positive for gossypol, indicating that the method yields some false positive results, at least with the decision criteria used in this case. The rate of false positives tended to be higher for moths reared on artificial diet than for moths reared on noncotton plant hosts (25% vs. 16%). However, all of the false positives had relatively low response ratios and signal-to-noise ratios (see Table 2) indicating that it should be possible to adjust the decision criteria to reduce these error rates. This was accomplished in subsequent testing, in which false positive rates were consistently <10% (data not shown).

Table 4 Percentage of TBW moths collected adjacent to cotton fields that were positive for cotinine or gossypol in North Carolina in 2004

County	Month	Number tested	Percent cotinine positive[a]	Percent gossypol positive[a]
Lenoir	July	15	13.3	0
	August	15	6.7	0
Wilson	July	28	46.4	3.6
	August	50	32.0	2.0

[a] Response detection was based on the criteria described in Tables 1 and 2.

Accuracy of Cotinine and Gossypol Analyses When Performed on the Same Insects Table 2 shows the results of cotinine analysis followed by gossypol analysis for a set of moths reared on known plant hosts. All moths reared on tobacco were correctly identified with no errors. Likewise, the moths that were reared on cotton and had gone through the determination for cotinine followed by the gossypol determination were correctly identified as cotton-reared moths.

Stability and Detection of Gossypol in Older and Deceased Moths The results of the gossypol analysis on aged moths are presented in Table 3. The blind analysis correctly identified all moths; 100% of the cotton-reared moths were determined to be positive for gossypol, and none of the moths reared on noncotton plants was determined positive for gossypol. Therefore, a significant gossypol signal was detected in all cotton-reared moths regardless of the age of the moth and/or the length of time the moth was held in a trap after death. The strength of the gossypol signal (measured as either signal-to-noise ratio or as relative response) for cotton-reared moths was always greater than the highest signal observed for moths reared on noncotton plants.

Cotinine and Gossypol Analyses of Field-collected TBW Moths The results of the analyses of the field-collected moths are shown in Table 4. In both counties (Lenoir and Wilson), and in both months (July and August), a higher proportion of the moths was positive for cotinine than for gossypol, indicating that more of the moths developed on tobacco than on cotton. In all cases, the percentage of cotton-derived TBW was less than 4%. The percentage of tobacco-derived moths was higher in the samples from Wilson County than those from Lenoir County, and was higher in the samples from July than in the samples from August.

Discussion

Characteristics and Limitations of the Analyses The prerequisites for the gossypol and cotinine analyses included high selectivity, low detection limits, and the capability to analyze hundreds of samples (insects) per day. The selectivity and high throughput for the gossypol analyses were accomplished by using a combination of analyte isolation followed by the use of tandem mass spectrometry. The gossypol extraction involves the formation of a Schiff base with aniline. The formation of an amine Schiff base is a common approach to determining the total amount of gossypol in a variety of different matrices including cotton (Smith 1967; Stipanovic et al. 1985; Benson et al. 2001), ovine tissues (Kim et al. 1996), blood plasma (Dabrowski et al. 2001), and oils. Bound gossypol is believed to form a Schiff base with proteins (Dabrowski et al. 2001). The addition of excess aniline removes the gossypol from the protein forming an extractable dianilino–gossypol Schiff base.

The sample preparation before determination of gossypol by the HPLC ESI/MS/MS was complicated. When performed by using a single SPE column, no cross-contamination of samples was observed. To accommodate 200 or more analyses per day, the sample processing was adapted to a 96-well plate format. The lyophilized moths were ground with glass beads that could remain in the well and not interfere with the extraction solution. Metal ball bearings were tried initially but interfered with the extraction. Attempts to remove the metal ball bearings caused cross-contamination between wells. Cross-contamination between wells was believed to be the main source of false positives in this approach. Attempts to minimize this included the use of Parafilm between the 96-well cap

and the plate to provide a tight seal during the extraction step. The routine use of blanks and other negative and positive controls were necessary because of the potential for cross-contamination of wells. The blanks were method blanks with no moth present and were placed at random throughout the plate by using a pseudorandom number generator.

As shown in Figs. 4, 5, 6, the dianilino–gossypol detection was complete after 2.5 min. The top of the peak occurred at approximately 1 min. The C8 guard column used in the introduction of the sample to the ESI source helped remove material that diminished the electrospray ionization process, but did not provide the selectivity of a high-resolution analytical column. The best conditions for separation were at low pH. However, these conditions provide poor ionization. The best ionization was observed under neutral or basic conditions. Several other columns were examined with the best separation occurring with a polydivinyl column (PRP-1). However, the solvents used for this column were not conducive to the ESI process. In addition, the time for each analysis was over 12 min. This limited the number of samples that could be analyzed per day. In Figs. 4, 5, 6, the time period after 2.5 min was used for washing the guard column. The total cycle time for each sample injection was 5 min. Thus, over a 20-hr period, 240 samples could be processed through the HPLC ESI/MS/MS system.

The internal standard for the ESI/MS/MS had two main purposes: first, to verify that injection had occurred, and second, to correct for matrix effects that occurred because of the electrospray ionization process. Variation in the mass of the moth caused variation in the electrospray ionization process, leading to similar spike levels producing different peak areas. The lower peak areas appeared to occur with larger moths. The use of the d_{10}-dianiline–gossypol corrected for this variation because the ratio of dianiline–gossypol to d_{10}-dianiline–gossypol remained constant throughout.

The ideal internal standard would be a stable isotope of gossypol. Because this was not available at the time, deuterated aniline was used to generate a stable isotope, which led to some methodological challenges. First, if excess aniline or deuterated aniline remained in solution with the dianiline–gossypol and the d_{10} dianiline, this would lead to exchange of the complexed aniline with the free aniline. If excess aniline were present in the extraction solution, this would have exchanged with the deuterium-labeled aniline of the internal standard, giving rise to aniline-d_5 anilino gossypol and dianiline gossypol, which would have been seen as false positives. If there is no desire to estimate the amount of gossypol present in a sample, the d_{10}-aniline-gossypol could be eliminated and an internal standard for injection such as butylanthraquinone could be used (Benson et al. 2001). This would not correct for matrix effects on the ionization but would provide confirmation of sample injection.

The cotinine determination has all of the components for a highly selective and accurate method. The method uses a stable isotope internal d_4 cotinine standard. The d_4 cotinine is added at the beginning of the extraction procedure for cotinine compensating for recovery losses through all of the steps of the procedure. The high selectivity of the method yields detection limits that are less than 0.037 ng per moth or for a 30-mg moth, a detection limit of less than 1.5 ppb by dry weight. This detection limit is based on a signal-to-noise in the cotinine response of three to one. Therefore, recovery is assumed to be 100% for this level of detection. A nicotine stable isotope can be used in this analysis. However, environmental contamination apparently led to low levels of nicotine being detected in moths reared on host plants other than tobacco. The levels were low compared to moths on which the host was tobacco (data not shown). The likely source of the nicotine contamination was handling of the moths by people using tobacco products.

Applications of the Method One way to slow the rate at which insects evolve resistance to insecticides is to ensure the presence of a refuge where susceptible pest insects are not

exposed to the insecticide. This strategy has been widely used in managing transgenic corn and cotton containing insecticidal proteins derived from the bacterium *Bacillus thuringiensis* (so-called Bt crops). The refuge acts as a source of susceptible pest insects that are available to mate with any resistant insects emerging from the Bt crop fields, thereby "diluting" any resistance present and increasing the durability of the Bt crop.

The refuge may consist of portions of the crop of interest that are untreated, like structured conventional cotton refuges for transgenic Bt cotton. The refuge also may include other suitable crop and weedy hosts of the insect pest (natural or alternative host refuge). Evaluating the refuge available for an insect that is capable of developing on multiple host plant species requires some means of evaluating the portion of the insect population that exists on the different potential hosts. For example, studies of larval host use by the important cotton pest, *Helicoverpa armigera*, in India (Ravi et al. 2005) and China (Wu et al. 2002) demonstrated that many commonly planted crops supported larger larval populations than cotton at the same time that this pest is found feeding on cotton. However, larval surveys of this sort are labor intensive and provide only inferential information on the composition of adult populations. Trapping adults and using suitable diagnostic tools to deduce the host on which a given insect has completed larval development can provide more accurate and comprehensive information about the relative contribution of different plant hosts to regional pest population dynamics.

The method described in this paper has been used for this purpose; the proportion of TBW moths derived from alternative noncotton hosts (the natural refuge) was estimated for populations trapped around Bt cotton fields using the gossypol assay on thousands of individual moths collected in pheromone traps (Head et al., unpublished data). When these assays were run at a large scale, no false negatives were observed with the positive controls, and a rate of <5% of false positives was observed with the negative controls (moths reared on noncotton hosts and method blanks). Therefore, analytical methods that detect the presence of host plant-specific chemicals such as those described in this paper have the ability to quantify accurately host use patterns in polyphagous agricultural pests.

Acknowledgments We thank Ryan Jackson (USDA-ARS, Stoneville, MS) for providing the TBW moths reared on known hosts and for coding samples for the blind experiment on gossypol signal stability. James Jennings, Melinda McCann, and Eric Sachs (Monsanto Company) provided helpful comments on the manuscript. Sharon Alexander and Mary Anderson (Monsanto Company) contributed tireless technical assistance with the gossypol assays.

Isolation, Identification, and Quantification of Potential Defensive Compounds in the Viceroy Butterfly and its Larval Host–Plant, Carolina Willow

Kathleen L. Prudic · Smriti Khera · Anikó Sólyom · Barbara N. Timmermann

Received: 4 October 2006 / Revised: 26 January 2007 / Accepted: 27 February 2007 /
Published online: 13 April 2007

Abstract The viceroy–monarch and viceroy–queen butterfly associations are classic examples of mimicry. These relationships were originally classified as Batesian, or parasitic, but were later reclassified as Müllerian, or mutalistic, based on predator bioassays. The Müllerian reclassification implies that viceroy is unpalatable because it too is chemically defended like the queen and the monarch. However, unlike the queen and the monarch, the viceroy defensive chemistry has remained uncharacterized. We demonstrate that the viceroy butterfly (*Limenitis archippus*, Nymphalidae) not only sequesters nonvolatile defensive compounds from its larval host–plant, the Carolina willow (*Salix caroliniana*, Salicaceae), but also secretes volatile defensive compounds when disturbed. We developed liquid chromatography–mass spectrometry–mass spectrometry methods to identify a set of phenolic glycosides shared between the adult viceroy butterfly and the Carolina willow, and solid phase microextraction and gas chromatography–mass spectrometry methods to identify volatile phenolic compounds released from stressed viceroy butterflies. In both approaches, all structures were characterized based on their mass spectral fragmentation patterns and confirmed with authentic standards. The phenolics we found are known to deter predator attack in other prey systems, including other willow-feeding insect species. Because these compounds have a generalized defensive function at

the concentrations we described, our results are consistent with the Müllerian reclassification put forth by other researchers based on bioassay results. It seems that the viceroy butterfly possesses chemical defenses different from its monarch and queen butterfly counterparts (phenolic glycosides vs. cardiac glycosides, respectively), an unusual phenomenon in mimicry warranting future study.

Introduction

Visual defensive mimicry, defined as close physical resemblance between unrelated species (Bates 1862), is an enduring example of adaptation by natural selection (Fisher 1958; Charlesworth and Charlesworth 1975; Ruxton et al. 2004; Thompson 2005). Mimicry is generally classified as either Batesian or Müllerian. In Batesian mimicry, a rewarding (i.e., palatable) species evolves a physical resemblance to the warning phenotype of a nonrewarding (i.e., unpalatable) species. This relationship is considered parasitic because the palatable species undermines the effectiveness of the warning signal. In contrast, Müllerian mimicry involves two unpalatable species with both participants sharing a common physical appearance. In a Müllerian system, both species benefit by distributing the mortality costs of predator education, and thus the relationship is generally considered mutualistic (Mallet 1999). Therefore, correctly classifying the mimicry system has important ramifications regarding the ecology and evolution of the involved participants.

The monarch (*Danaus plexippus*) and queen (*Danaus gilippus*) butterflies (Nymphalidae: Danainae) arrived at the forefront of biological interest as Batesian models of the viceroy butterfly (*Limenitis archippus*) (Nymphalidae: Limenitinae) based on predator bioassays (Brower 1958a, b). In these behavioral experiments, monarch and queen butterflies were more unpalatable than viceroy butterflies to avian predators. Furthermore, monarch and queen larvae feed on milkweeds (Asclepiadaceae), and both insect species are able to sequester and retain bitter and toxic cardenolides present in milkweeds into their adult stage (reviewed in Ackery and Vane-Wright 1984; Brower et al. 1984). Cardenolides are known to contribute to prey unpalatability, resulting in avoidance learning by both vertebrate (Glendinning 1992) and invertebrate (Berenbaum and Miliczky 1984; Prudic et al. 2007) predators. Conversely, viceroys were originally shown to be relatively palatable (Brower 1958a, b), and were not known to sequester noxious compounds from their larval host–plants, willows and poplars (Nishida 2002). However, subsequent behavioral bioassays led to a re-evaluation of these relationships. In those assays, viceroys were equally or more unpalatable to avian predators than their monarch and queen counterparts, and this shared unpalatability increased the rate of predator aversion learning (Ritland and Brower 1991). These results led the authors to conclude that viceroy butterflies were Müllerian, not Batesian, mimics with queens and monarchs.

Ritland and Brower's conclusions imply that viceroy butterflies, like monarch and queen butterflies, are protected by chemical compounds that render them unpalatable to predators; however, these putative defensive compounds were not known. This absence of knowledge about underlying defensive mechanism provoked criticisms of the predator bioassay results and interpretations (Guilford 1991). In light of these criticisms, a chemical explanation for viceroy unpalatability would go far in deciding whether viceroys are Müllerian or Batesian mimics and understanding their ecological interactions and evolutionary trajectories. If the

viceroy is a Batesian mimic, it should not possess chemical defenses. However, if the viceroy is a Müllerian mimic, then it should have chemical defenses (Rothschild 1991). We sought to determine if the viceroy was indeed chemically defended and is thus consistent with the Müllerian classification.

A critical first step in such chemical characterization was determining candidate compounds associated with unpalatability. Many different chemical classes contribute to the unpalatability of Lepidoptera, including aristolochic acids, cardenolides, cyanogenic glycosides, iridoid glycosides, and pyrrolizidine alkaloids (Nishida 2002). Although they have not previously been identified in any butterfly species, we considered phenolic glycosides and their chemical relatives as the most likely candidate compounds for viceroy butterfly unpalatability because (1) these compounds are ubiquitous antiherbivore compounds of the Salicaceae (willows and poplars), the larval host–plants of the viceroy butterfly (Palo 1984; Tahvanainen et al. 1985; Lindroth et al. 1988b); (2) these compounds are sequestered by other insects of the willow-feeding guild, such as the beetles *Phratora vitellinae* and *Chrysomela* spp. (Coleoptera: Chrysomelidae) (Pasteels et al. 1988; Köpf et al. 1998); and (3) these compounds when present in insects deter attack by generalist predators (Pasteels et al. 1986; Rank et al. 1996; Müller et al. 2006). By using high-performance liquid chromatography–mass spectrometry (LC/MS), and gas chromatography–mass spectrometry (GC/MS), we investigated whether (1) viceroy butterflies sequester nonvolatile defensive phenolic glycosides from their larval host–plants; (2) viceroy butterflies emit volatile defensive phenolic compounds when disturbed; and (3) both the identity and the concentrations of the compounds we found have been shown to be predator deterrents in other bioassay experiments.

Methods and Materials

Natural History

The viceroy butterfly is a member of *Limenitis* (Nymphalidae, Limenitidinae). Three of the four members of this genus in North America are involved in some type of mimicry relationship with vastly different butterfly species (Prudic et al. 2002 and references therein). According to phylogenetic analysis, the ancestral phenotype for all North American *Limenitis* is a black ground color with a white dorsal band (Mullen 2006). The viceroy adult phenotype is diverged from this ancestral pattern with an orange or brown ground color with black markings. Viceroy butterflies (*Limenitis archippus*) are widely distributed over North America, and they exhibit regional variation in adult color pattern (Scott 1986) that correlates with geographic distribution of their models (Ritland and Brower 2002). In areas where the monarch is prevalent, the viceroy exhibits a tawny orange ground color with black markings (*Limenitis archippus archippus, Limenitis archippus lahontani*), like the monarch. Conversely, viceroy butterflies in areas where the queen butterfly is more frequent exhibit a color pattern similar to the queen, which is a more brownish-orange ground color with black markings (*Limenitis archippus floridensis* and *Limenitis archippus obsoleta*). Viceroy larvae primarily feed on *Salix* and *Populus* (Salicaceae), unlike monarch and queen larvae that feed on members of the Asclepiadaceae (Scott 1986). In Florida, where the biological collections for this study were done, the viceroy butterfly (*L. archippus floridensis*) is believed to mimic the queen, not the monarch butterfly, and the viceroy larvae feed almost exclusively on the Carolina willow, *Salix caroliniana* (Ritland and Brower 1991).

Butterfly and Host–Plant Collections

Adult viceroy butterflies and their larval host–plants were collected between July 20–21, 2004 from two locations in Florida, USA: Green Meadow Road, Lehigh Acres, Lee County, N26°31.69′, W−81°40.67′ and Newnan's Lake, Gainesville, Alachua County, N29°38.19′, W−82°12.00′. These sites are close to the viceroy collection sites used in previous predator bioassays (Brower 1958b; Ritland and Brower 1991). For the LC/MS analysis, four samples each of butterflies and willow were collected from both locations. A butterfly sample consisted of 10 adults (either all male or all female) (~1 g dry weight), whereas a willow sample consisted of 16 young leaves, 2 leaves from 8 different plants (~10 g dry weight). All samples were weighed, then air-dried at room temperature for 1 wk, and re-weighed. For the GC/MS analysis, live butterflies were individually sampled by using both solid phase microextraction (SPME) and direct sampling of the putative defensive secretion in the laboratory. Butterflies were caught in the field and analyzed the next day before being fed. There were five males and five females per site, and each individual butterfly secretion was analyzed separately.

Authentic Standards

Benzoic acid, benzaldehyde, salicylaldehyde, and salicin standards were purchased from Sigma Chemical Co. (USA). A salicortin standard was provided by C. Orians (Tufts University, USA), and a tremulacin standard was purchased from Apin Chemical Ltd. (Abingdon, Oxon, UK).

High-performance Liquid Chromatography–Mass Spectrometry

Sample Extraction and Preparation The Green Meadow Road samples had the following dry weight: willow 1, 11.11 g; willow 2, 10.90 g; male viceroy 1, 0.89 g; and female viceroy 1, 0.91 g. The Newnan's Lake samples weighed the following: willow 3, 9.24 g; willow 4, 10.88 g; male viceroy 2, 0.99 g; and female viceroy 2, 1.17 g. Whole butterflies including their wings were used in the extraction. Dried samples were ground to a fine powder before methanol extraction. Methanol (50 ml viceroy, 200 ml willow) was added to each sample, sonicated for 30 min, and then allowed to soak overnight. The mixture was partitioned with an equal volume of hexane, ×3. The methanol fraction was concentrated to dryness, weighed, and 1 mg samples were resuspended in 1 ml of high-performance liquid chromatography (HPLC) grade methanol, then filtered through a 0.45-μm PTFE filter (Whatman) for analysis.

Identification of Nonvolatile Defensive Compounds Chromatograms were obtained by using an Agilent 1100 HPLC system (quaternary gradient pump, diode array detector, thermostated column compartment, and autosampler) with a 4-μm Waters Nova Pack Sentry guard column (3.9×20 mm) and Waters Nova Pak reverse phase C18 column (4.6×150 mm). Each sample (20 μl) was injected into a methanol–water gradient flowing at 1 ml/min (N=8) (solvent gradient described in Table 1). UV signals were observed at 200, 230, 277, and 300 nm. For LC/MS, analyses of each sample were obtained with an Agilent 1100 HPLC system tandem with Agilent MSD-Trap-SL ion trap mass spectrometer. LC parameters were the same as above. The MS acquisition parameters were positive electrospray ionization mode, drying gas temperature 350°C, drying gas flow rate 10 l/min, nebulizer pressure 35 psi, HV capillary 3500 V, HV end plate offset −500 V, capillary current 24.4 nA, current end plate 1,138.6 nA, RF amplitude capillary exit 158.5 V, and skimmer 40.0 V.

Table 1 LC solvent gradient with flow rate of 1.00 ml/min

Time (min)	% Water+0.05% Acetic Acid	% Methanol+0.05% Acetic Acid
0.00	100	0
3.50	80	20
7.00	55	45
15.00	50	50
19.00	5	95
20.00	0	100
26.00	0	100
29.00	85	15

Compounds were identified by comparing their retention times and mass spectra (MS and MS/MS) with those of authentic standards.

Quantification of Nonvolatile Defensive Compounds Quantification was done by external standard method using a six-point standard curve with standards ranging from 0 to 2.0 mg/ml. Calibration curves were constructed for the three phenolic compounds by using LC/MS protocol described above. For each compound, a characteristic product ion was chosen from its MS/MS as its quantification ion (Table 2). Peak integration and quantification were performed automatically with Agilent ChemStation software (version A.10.01). The same samples used in identification analyses were re-run twice for quantification to ensure consistency within a sample. Concentrations were considered consistent if run 1 and run 2 were within 10% of each other. If not, then the sample was reinjected until the two runs reached the consistency criteria. However, only the concentration of the first run was used for reporting and statistical analyses (N=4 willow samples; N=4 viceroy samples). All statistical analyses were performed in JMP-IN software (SAS Institute Inc. 2002) with one-way ANOVAs.

Gas Chromatography–Mass Spectrometry

Identification of Defensive Volatiles The viceroy butterfly secretes a malodorous fluid from its abdomen when disturbed. To characterize the volatile compounds that a predator would encounter when it disturbs a viceroy, StableFlex PDMS/DVB-coated SPME fibers (Supelco, USA) were used to sample the volatiles in the headspace above the abdomen

Table 2 Compound-specific LC/MS and LC/MS/MS identification and quantification results of viceroy butterfly and its larval host–plant

Compound	Retention Time (min)	Diagnostic Ions (m/z) Parent/Daughters	Willow Conc.±SD (mg/g dry wt.) (N=4)	Viceroy Conc.±SD (mg/g dry wt.) (N=4)
Salicin	6.8	309:185,[a] 277	3.55±0.91	3.04±2.02
Salicortin	8.9	442:263,[a] 268, 245	25.36±2.93	6.56±3.74
Tremulacin	18.6	546:267,[a] 373	34.90±3.54	26.69±15.91

For salicin the extracted ion was 309 m/z [M+Na] from 5.0–7.0 min; for salicortin the extracted ion was 442 m/z [M+H_2O] from 8.0–10 min; and for tremulacin 546 m/z [M+H_2O] from 18.0–20.0 min.

LC–MS–MS = liquid chromatography–mass spectrometry–mass spectrometry

[a] Quantification ion

of both stressed and normal butterflies (Borg-Karlson and Mozuraitis 1996). To simulate a predatory event, a butterfly was pinned horizontally by the wings between a glass plate and a glass cylinder with one small opening (400 ml beaker) (Supplemental Material Fig. 1). This arrangement positioned the butterfly legs parallel to the glass plate without any surface for the butterfly to perch on. A SPME fiber holder with an averted fiber was placed in the small opening for 1 hr of sampling of the area directly above the struggling butterfly and its secretion. To collect the volatile compounds emitted by an unstressed butterfly, the same individuals were placed in the same container and sampled as described; however, the butterfly was not pinned down to simulate a predation event. The butterfly was able to wander, or more often perch, on the glass plate. Separate SPME fibers were used for stressed and normal sampling events. The glassware was cleaned between sampling bouts with methanol. Each butterfly was sampled twice for each treatment to ensure consistency of the results (N=20).

Data were collected with a Varian Saturn 2100T GC/MS and a Chrompack capillary column (CP Sil 8 CB; 30 m×0.25 mm; 0.5 μm film thickness). The initial column oven temperature was set for 80°C, increasing to 210°C at 10°C/min; the injector, transfer line, and trap temperatures were 230, 250, 200°C, respectively, and the electron voltage was set at 70 eV. Ultra high purity helium was used as the carrier gas at a flow rate of 1.0 ml/min. Each volatile sample was injected directly into the chromatograph after desorbing from the SPME fiber for 15 sec in the GC injector (230°C). Compounds were identified by comparison of retention times and mass spectra to authentic standards and the NIST 02 MS library.

Quantification of Defensive Volatiles Volatile compounds were quantified by the external standard method using a six-point standard curve with standards ranging from 0.005–5.0 μl/ml. Calibration curves from triplicate injections of 2.0 μl were obtained by using the GC/MS protocol above. Peak integration and quantification were performed automatically with Saturn 2100 Workstation software. The same insects used for compound identification were reanalyzed for compound quantification; however, for this analysis, the secretion was sampled directly from the abdomen of the butterfly with a glass capillary (Supplemental Material Fig. 2). Two microliters of the secretion were collected from a disturbed butterfly and dissolved in 2.0 μl of ethyl acetate with 1.0 μl of 0.25 M *p*-chlorotoluene as the internal standard. Then, 2.0 μl of this solution were injected directly into the GC column. Each butterfly sample was run twice on the GC for consistency. The concentrations were considered consistent if run 1 and run 2 were within 5% of each other. If not, then the individual butterfly was resampled until the two runs reached the consistency criteria. However, only the concentration of the first run was used for reporting and statistical analyses (N=20). All statistical analyses were performed in JMP-IN software (SAS Institute Inc. 2002) using one-way ANOVAs.

Results

In the LC/MS assays, we characterized the tissue chemical profiles of the Florida viceroy (*L. archippus floridensis*) and its larval host–plant Carolina willow (*S. caroliniana*). Of the five peaks shared between the viceroy and willow extracts, three corresponded to phenolic glycosides known to be unpalatable to either herbivores or their predators: salicin, salicortin, and tremulacin (Fig. 1; Table 2). These compounds were found in both the willows and butterflies across sites and between sexes. Geographic location and butterfly sex did not significantly affect the concentration levels of any of the three phenolic glycosides (one-way ANOVAs, P>0.05) (Table 3).

In the GC/MS assays, we characterized and quantified the volatile chemical profile of a viceroy during a predation simulation and compared it to the volatile profile of a viceroy at rest. During these collection bouts, an unstressed viceroy never emitted a secretion, but the stressed butterflies always did. By using SPME in the stressed butterfly, we identified four compounds not found in the unstressed butterfly: benzaldehyde, benzoic acid, methyl salicylate, and salicylaldehyde (Table 3). These were identified both in the headspace surrounding the provoked butterfly and in its secretion. Again, all four compounds were found in butterflies across geographic location and between butterfly sexes. There were significant differences in geographic concentrations in benzaldehyde ($F_{1,19}$=10.24, P=0.001), benzoic acid ($F_{1,19}$=12.35, P<0.001), and salicylaldehyde ($F_{1,19}$=11.91, P<0.001) (Table 3). Butterflies from the northern Florida site, Newnan's Lake, had higher concentrations than butterflies from the southern Florida, Green Meadow Road.

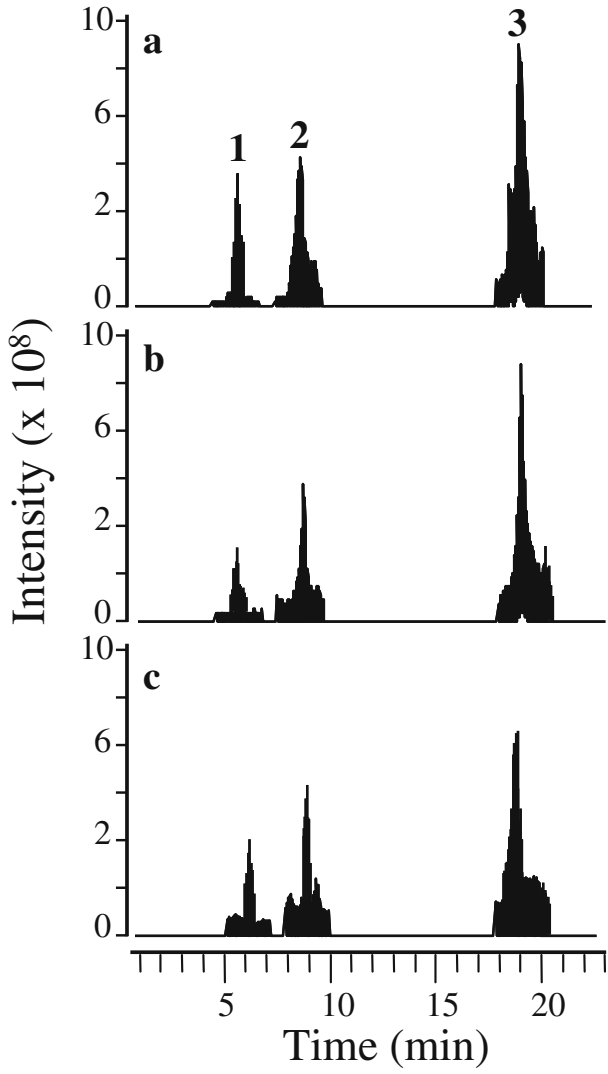

Fig. 1 Extracted ion chromatograms of shared phenolic glycosides of Carolina willow and viceroy butterfly compared to authentic standard mixture. **(a)** Standard solution containing three phenolic glycosides: salicin (peak 1), salicortin (peak 2), and tremulacin (peak 3). **(b)** Carolina willow sample 1 from Green Meadow Road site. **(c)** Adult viceroy butterfly sample 1 (10 males) from Green Meadow Road site. Specific site information is provided in the methods and materials section

Discussion

Originally, the viceroy butterfly was widely regarded as a palatable, Batesian mimic without any form of chemical defense (Brower 1958a, b). However, subsequent predator bioassays suggest that it is unpalatable and chemically defended against predation. These results led to a re-classification of the system as Müllerian (Ritland and Brower 1991). Our results are consistent with the Müllerian, not the Batesian, classification. We have shown that adult viceroys possess compounds that function as defensive compounds in other willow-feeding insects. We found three phenolic glycosides (salicin, salicortin, and tremulacin) in the larval host–plant, the Carolina willow, and the adult viceroy (Fig. 1; Table 2). It is known that salicin can be a sample preparation artifact; however, our sample preparation protocol limited this possible bias (Julkunen-Tiitto and Sorsa 2001). All three phenolic glycosides were found in the butterflies and the willows from both populations and in both sexes of butterflies, but there were no statistical differences in compound concentration between either geographic location or butterfly sex (Table 3). We also found the viceroy emitted four volatile compounds (benzaldehyde, benzoic acid, methyl salicylate, and salicylaldehyde) when disturbed in a simulated predation event. All these compounds were found in

butterflies from both locations and in both sexes, although concentrations of benzaldehyde, benzoic acid, and salicylaldehyde were statistically higher in butterflies from northern Florida compared to butterflies from southern Florida (Table 3). Future sampling that focuses on more populations is needed to verify these preliminary patterns of geography and sex on viceroy chemical defense profiles and concentrations.

This is the first time that Carolina willow (*S. caroliniana*) has been chemically characterized for phenolic glycosides, and the three phenolic glycosides we documented resemble the chemical profiles of other willow species (Palo 1984; Nyman and Julkunen-Tiitto 2005) and other members of the Salicaceae in general (Lindroth et al. 1988a; Lindroth and Hemming 1990). Typically, when tremulacin is found in willows, it is accompanied by salicortin and salicin (Julkunen-Tiitto 1989). The Carolina willow had average levels of salicin, salicortin, and tremulacin compared to other *Salix* spp. (Soetens et al. 1998), and these quantities have been shown to deter generalist herbivores (Palo 1984; Tahvanainen et al. 1985).

This is also the first example of adult butterflies containing phenolic glycosides (compare with Nishida 2002). In this case, they are probably derived via sequestration from the larval host–plant. Although our study did not address if these compounds deter predation on viceroys, the results from other bioassay experiments suggest this is a likely function. Willow-derived phenolic glycosides, including the compounds we found, are known for their deterrent and toxic effects on a variety of insect predators (reviewed in Bairlein 1997). Salicin, when present in leaf beetles at concentrations similar to those found in the viceroy butterflies, deters predators (Pasteels et al. 1986). Salicortin and tremulacin have been evaluated together, not individually, for their defensive properties against predators. When these two compounds are present in gypsy moth caterpillars at concentrations similar to the viceroy, they are deterrent and toxic, and they also negatively affect diet choice in insectivorous songbirds (Müller et al. 2006).

The volatile compounds, benzaldehyde, benzoic acid, and salicylaldehyde, are well-documented chemical defenses of willow-feeding leaf beetles against a variety of generalist predators (Smiley et al. 1985; Pasteels et al. 1988; Denno et al. 1990). The concentrations of these that we documented were lower than in some other studies; however, they are within the range of concentrations that are effective in conferring resistance to predation (Pasteels et al. 1988; Denno et al. 1990). Methyl salicylate (wintergreen oil) has not been evaluated as a deterrent to avian or invertebrate predators. However, it is described as the most poisonous of the salicylates; doses less than 1 g have killed small children weighing 10 kg (Michael and Sztajnkrycer 2004). Concentrations as low as 2 mg/ml also induce nausea and vomiting when ingested by mice (Davidson et al. 1961). It is not presently known how viceroys acquire these volatile compounds. Some are known to occur in the foliar scent of willows (Dötterl et al. 2005), and thus may be sequestered from the larval host plant or acquired through adult nectar feeding. Regardless of the exact mechanism, our data demonstrate that viceroy butterflies contain known toxic and deterrent phenolic compounds.

Our chemical results are consistent with other researchers' reclassification of the viceroy–queen and viceroy–monarch butterfly mimicry as Müllerian. Viceroys likely share the costs of predator education with their co-mimics. Unlike other Müllerian mimicry systems such as the one involving *Heliconius* butterflies, the shared appearance and unpalatability between the viceroy and the monarch and queen did not arise through either common ancestry or shared host–plant use. Thus, a comparison of these two types of Müllerian systems will provide a framework for understanding the relative roles of host–plant use, sequestration, and genetic architecture of wing coloration in Müllerian mimicry and aposematic coloration. This system is also one of the few Müllerian examples where

the participants unmistakably vary in defensive chemistry: the adult viceroy sequesters defensive phenolic glycosides from its larval host–plant, whereas the queen and monarch butterflies sequester defensive cardiac glycosides from their larval host–plant (Brower et al. 1984). Although these compound classes differ structurally and functionally, recent experimental evidence indicates that such differences could actually facilitate Müllerian mimicry evolution by increasing rates of predator aversion learning and remembering (Skelhorn and Rowe 2005). Our findings provide a likely mechanism that explains previously reported viceroy unpalatability. These results are consistent with the Müllerian reclassification of this classic mimicry system.

Acknowledgments We thank J. Oliver for assistance in collecting the specimen; J. Gu, B. Jackson, R. Lindroth, C. Orians, and V. Rodriguez for assistance in chemistry; D. Bowers, D. Papaj, and D. Ritland for discussion; and the late Hon. M. Rothschild for enthusiasm and insight. Abstract Plants have been suggested to have an immunological memory comparable to animals. The evidence for this, however, is scarce. In our study with the mountain birch—*Epirrita autumnata* system, we demonstrated that birches exposed as long as 5 yr to feeding of *E. autumnata* larvae (delayed induced resistance, DIR), responded more strongly to a new challenge than trees without an herbivory history. Pupal weights remained lower, and the duration of the larval period was prolonged in the DIR trees, although immunity, measured as an encapsulation rate, was not affected. We further demonstrated that the effects of birch phenolics on performance of *E. autumnata* were different in the exposed (DIR) trees from naive control trees, although we found only one significant change in chemistry. The quercetin:kaemferol ratio was increased in DIR trees, suggesting that herbivory caused oxidative stress in birches. In DIR trees, phenolics, especially hydrolyzable tannins (HTs), affected pupal weights negatively, whereas in control trees, the effects were either nonsignificant or positive. HTs also prolonged the duration of the larval period of females, whereas peroxidase (POD) activity prolonged that of males. We suggest that the causal explanation for the induced resistance was an enhanced oxidation of phenolic compounds from the DIR trees in the larval digestive tract. Phenolic oxidation produces semiquinones, quinones, free radicals, and ROS, which may have toxic, antinutritive, and/or repellent properties against herbivores.

Introduction

Herbivory-induced changes in plants have been intensively studied. These physiological and biochemical changes may increase (Danell et al. 1997; Karban and Baldwin 1997; Lempa et al. 2004) or decrease (Haukioja 1982; Karban and Myers 1989; Tallamy and Raupp 1991; Karban and Baldwin 1997) the palatability of plants and also their nutritive value for plant-eating animals. Induced resistance can be divided into rapidly induced resistance (RIR) that appears within the same season and delayed induced resistance (DIR) that affects herbivores in subsequent seasons (Haukioja 1982).

Herbivory triggers a sensitive signal cascade, which may lead to an increase in plant defense at the vicinity of wound sites and at distal, unwounded parts of plants (Ryan 2000). In plants, wounding may also trigger the production of reactive oxygen species (ROS), such as hydrogen peroxide (H_2O_2), superoxide (O_2^-), hydroxyl radicals (·OH), and singlet oxygen. H_2O_2 acts as a signal molecule, which activates defense-related genes like the ones encoding phenoloxidases (Levine et al. 1994; Orozco-Cárdenas et al. 2001; Gatehouse 2002). As ROS are highly reactive molecules capable of oxidizing membrane lipids, DNA, and proteins (Chan et al. 1999; Schweigert et al. 2001; Heim et al. 2002; Pourcel et al. 2006), they may also have direct defensive properties against plant-eating animals (Bi and Felton 1995).

The leaves of deciduous trees often contain a high diversity of phenolic compounds, some of which are defensive against plant-eating animals. Despite intensive research, the mechanisms behind defensive activity of phenolics have remained poorly understood. For example, the principal role of tannins traditionally has been thought to be the precipitation of proteins via hydrogen bonding. Although this might occur under certain conditions, such a mechanism is ineffective against some insect herbivores, many of which have alkaline midgut and/or surfactants in their gut fluid; these prevent the formation of insoluble protein–tannin complexes (Martin et al. 1987, Appel 1993). However, at high pH (e.g. in the midgut of caterpillars), some phenolics, such as ellagitannins, auto-oxidize into quinones that are highly reactive and also toxic compounds (Barbehenn et al. 2006). Quinones form covalent bonds with nucleophilic moieties of biomolecules, such as the functional groups of amino acids and proteins, making them indigestible (Felton et al. 1989). The oxidation of phenolics may also occur by enzymatic reactions catalyzed by plant polyphenol oxidases (PPOs) and peroxidases (PODs) (Felton et al. 1989; Felton and Duffey 1991; Bi and Felton 1995).

The population cycle of many northern Lepidopteran species is characterized by regular fluctuations, and populations may reach outbreak densities at certain intervals (Tenow 1972; Myers 1998). The driving forces behind these cycles are likely predation, parasitism, and the induced resistance of plants (Ruohomäki et al. 2000). The delayed induced resistance (DIR) that occurs after peak years might explain why population density remains low after the collapse of a population (Haukioja 1982; Haukioja et al. 1988). In contrast, induced amelioration may act as a positive regulator of population density in the increasing phase of the cycle (Ruohomäki et al. 2000). In a recent study with the mountain birch—autumnal moth system, RIR retarded growth of the autumnal moth (*Epirrita autumnata* Borkhausen) larvae, whereas DIR had no effect on growth parameters, but instead, increased the immunity measured as an encapsulation rate (Kapari et al. 2006), i.e., induced resistance may have enhanced the growth of a population by decreasing infection and parasitism.

In mountain birch (*Betula pubescens* ssp. *czerepanovii* (Orlova) Hämet-Ahti)), total phenolics have been shown to increase and total nitrogen to decrease due to herbivory

(Haukioja et al. 1985; Ruohomäki et al. 1996; Kaitaniemi et al. 1998; Ossipov et al. 2001). However, no single phenolic or group of compounds has been found unequivocally to be behind the induced resistance (Haukioja 2005). We have demonstrated that birch PPOs that oxidize phenols might contribute to the RIR of birches (Ruuhola et al., unpublished results).

Plants are suggested to have an immunological memory comparable to animals: repeated challenges by herbivores induce a more effective defense response than one-season challenges (Karban and Niiho 1995). Our purpose here was to test, whether a challenge conducted as long as 5 yr earlier still had an effect on the resistance response of mountain birches. This might explain why population density remains low after a population collapse. We utilized the same trees as Lempa et al. (2004) used 5 years earlier. We reared bagged larvae in both control and larval trees until they pupated and measured the immune defense and other life history traits of *E. autumnata*. To characterize the factors that are behind the resistance of trees against moth larvae, we determined phenolic contents and oxidase activities in birch leaves and correlated these with larval performance on control and DIR-trees.

Methods and Materials

Experimental Organisms The mountain birch inhabits subarctic and arctic areas in northern Fennoscandia, where it forms both the northern and upper tree lines. The economic value of mountain birches has not been acknowledged, whereas it has significant ecological value in subarctic systems (Wiegolaski 2005). The phenotype is highly variable from small persuading shrubs to large monocormic trees, probably due to the hybrid nature of the species (Vaarama and Valanne 1973). In our study area, the prevailing growth form is a low (ca 2 to 5 m) polycormic tree, whose canopy consists of multiple clonal ramets of both short and long shoots; the major part of the canopy is built from short shoots whose leaves flush simultaneously in early spring.

The autumnal moth, *E. autumnata*, is a univoltine, generalist capital feeder, whose larvae hatch synchronously with the bud burst of mountain birch (Kaitaniemi et al. 1997). Despite its generalist nature, the larvae feed mainly on leaves of mountain birches in northern latitudes, apparently due to the abundance (Seppänen 1970). Moth larvae get through five distinct instars before they pupate in the litter from the end of June to early July. Adult moths fly in autumn, and females lay either single eggs or small patches of eggs onto the lichen cover of trees. Autumnal moths are the worst pest species of mountain birches, and outbreaks occur periodically with 10- to 11-yr intervals in the Scandinavian mountain chain (Tenow 1972; Haukioja et al. 1988).

Experimental Design The experiment was conducted at Kevo Subarctic Research Station in the summer of 2005. We used the same trees that were exploited in an induction experiment 5 yr earlier (Lempa et al. 2004). In the summer of 2000, 24 trees growing in a river valley close to Kevo Subarctic Research Station (69° 45′ N, 27° 01′ E) were haphazardly selected for experimental trees (Lempa et al. 2004). Twelve trees were randomly selected for larval treatment trees, and the other 12 were left as unmanipulated control trees. Five ramets and two branches from each ramet were selected from each experimental tree. The selected branches were covered with large nylon mesh bags (ten bags/tree). We introduced 20 larvae onto one bagged branch, i.e., altogether 200 larvae per a larval treatment tree. In the summer of 2005, we randomly selected three ramets from each control and larval treatment tree. One large branch per each ramet was bagged (three bags/tree), and 12 newly hatched

first instar *E. autumnata* larvae were introduced into the bags at the time of the bud burst (36 larvae/tree). For practical reasons, we collected all larvae from mesh bags at the end of the last instar stage and reared them with the leaves of the experimental trees in a laboratory for a short period until they pupated (the pupation day was recorded for each pupa). One week after pupation, each pupae (7-d-old) was weighed, sexed, and the encapsulation rate was determined as described below.

Leaf phenology was recorded twice early in the season by using a classification based on bud morphology and leaf elongation (Alanen, unpublished results). Leaf samples for chemical analyses were collected when the bagged larvae were at their third and fifth instar stages (12th of June and 21st of June, respectively). On the first sampling day, leaves were young and rapidly expanding, and on the latter day, they were fully expanded. Leaf samples were collected from the three ramets with introduced larvae, and the leaves of one tree were pooled. Leaves were put into plastic bags on an ice bath and carried into a laboratory in a closed ice box for freeze drying. Leaf samples for enzymatic assays were collected on the latter day (21st of June) throughout the canopy, and ca 10 g (fresh weight) leaf material were collected. Samples were frozen immediately in liquid nitrogen and stored in −80°C before analysis.

Encapsulation Rate Assay The melanotic encapsulation depends on the activation of phenoloxidases (POs), which convert *o*-diphenols into quinones that subsequently polymerize to melanin (Söderhäll and Cerenius 1998). The encapsulation kills an intruder either by suffocation or through the production of necrotizing compounds (Nappi et al. 1995). In our study, the strength of insect immune defense was determined by measuring the melanotic degree of an encapsule formed around a foreign object (Kapari et al. 2006; Klemola et al. 2007). In the autumnal moth, the encapsulation rate correlates with the resistance against entomopathogenic fungi, which are known to cause substantial mortality in *E. autumnata* (Rantala and Roff 2007). In other species, the ability to encapsulate abiotic material strongly relates to the ability to encapsulate parasites (Paskewitz and Riehle 1994; Gorman et al. 1996).

A sterile nylon filament (2 mm long, 0.20 mm diameter rubbed with sandpaper) was inserted into the pupal hemocoel (Kapari et al. 2006). The pupae were incubated at + 14°C for 1 hr, after which the reaction was stopped by freezing the pupae in −80°C. The implant was photographed from three angles with a digital video recorder under a light microscope. The pictures were analyzed with Image Pro program with methods presented in Rantala et al., 2002.

Chemical Analyses Dried and ground birch leaves (20 mg material per sample) were extracted three times (3×1 hr) with 500 µl acetone/water (7/3, *v*/*v*) on a planary shaker. After extraction, acetone was evaporated from the combined extract *in vacuo* with an Eppendorf concentrator. The freeze–dried aqueous phase of the extract was dissolved in 1 ml water. The supernatant of the centrifuged (10 min at 2,500×*g*) sample was filtered through a 0.45-µm polytetrafluoroethylene (PTFE) filter and kept frozen at −20°C until analyzed with high-performance liquid chromatography with photodiode-array detection (HPLC-DAD).

HPLC-DAD analysis of birch leaf extracts was performed at 280 and 349 nm with Merck-Hitachi's LaChrom HPLC system (Merck-Hitachi, Tokyo, Japan). Column and chromatographic conditions were as described earlier (Salminen et al. 1999), except that 0.1 M H_3PO_4 was replaced with 0.05 M H_3PO_4. Phenolics were identified by comparing their retention times and ultraviolet (UV) spectra to those earlier reported by Salminen et al.

(1999, 2001). Phenolic compounds were quantified by using pedunculagin, pentagalloylglucose, catechin, coumaric acid, chlorogenic acid, and quercetin as external standards.

Enzymatic Assays Frozen birch leaves were ground with a cooled mortar and pestle, and 1.5 g leaf powder were immersed in 20 ml of cold extraction buffer containing 1 mM phenylmethanesulphonylfluoride (PMSF) (Sigma-Aldrich), 1 mM dithiothreitol(DTT) (Sigma), and 1% TritonX-100 (Acros) in 0.2 M potassium buffer, pH 7.5. We used 4.7% (*w*/*v*) of polyvinylpolypyrrolidone (PVPP) (Sigma) and 2.5% (*w*/*v*) of an anion exchange resin (AG® 1-X8 resin, 200–400 mesh chloride form, BioRad) in the extraction buffer to remove endogenous phenolic compounds. Leaf powder was homogenized in an Ultra Turrax homogenizer for 2×30 sec in a cold room (+8°C). Homogenates were incubated by shaking on an ice bath for 1 hr. Samples were centrifuged at 17,000×*g* for 20 min at +4°C. The supernatant was filtered through a cheesecloth.

Total POD activity was measured with 60 mM guaiacol (90%, Sigma) as a substrate and 20 mM H_2O_2 as a co-substrate, and the rate of change at A_{470} was followed (Ruuhola and Yang 2006).The increase in absorbance was followed for 3.5 min (initial reaction velocity) with a spectrophotometer with an external water bath to control the reaction temperature.

Combined PPO/POD activity was measured with 80 mM catechol (Sigma) as a substrate. The increase in absorbance during 10 min was read at 414 nm on a temperature controlled 96-well plate reader (Multiscan Ascent, Thermo Electron, Shanghai, China). The reaction was started by an addition of 10 μl of the enzyme extract. Pure PPO activity was measured similarly as combined PPO/POD activity but in the presence of a commercial catalase (Sigma, 280 U ml^{-1}), which removes H_2O_2 and inhibits POD activity. All enzymatic measurements were performed in triplicate at +25°C. The amount of protein in the samples was measured in triplicate by using the BioRad protein assay method, which is based on the Bradford method (Bradford 1976). Absorbance was measured with the plate reader at 595 nm. All enzyme activities were expressed as units per mg protein (U mg^{-1} protein), one unit being the amount of enzyme required to increase absorbance by 0.001 min^{-1}.

Statistical Analysis The effects of a previous defoliation treatment (conducted 5 yr earlier) on the pupal weight and the encapsulation rate of *E. autumnata* were tested with the mixed model analysis (SPSS 11.5.1.). The normality of the distribution and the equality of variances were tested with the *Kolmogorov–Smirnov's* and *Levene's* tests, respectively (SPSS 11.5.1.). The treatment and sex were set as fixed factors and the tree and ramet as random factors in the analysis; the tree was also set as a subject. There was no significant sex * treatment interaction, so it was removed from the final model. The effects of the treatment and sex on the length of the larval period were analyzed with the *Kruskall–Wallis's nonparametric* test, as the data was not normally distributed (SPSS 11.5.1.).

The effects of the treatment and leaf age (third or fifth instar leaves) on the contents of phenolic compounds were tested with the mixed model analysis (SPSS 11.5.1.). The treatment and leaf age (third or fifth instar leaves) were set as fixed factors, and the tree was set as a subject. There was no significant interaction between the treatment and leaf age, and it was removed from the final model. The normality of the distribution and the equality of variances were tested with the *Kolmogorov–Smirnov's* and *Levene's* tests, respectively (SPSS 11.5.1.). The contents of phenolics that were not normally distributed were *ln*-transformed to meet the assumptions of parametric tests. The effect of treatment on the activity of foliar oxidases (PPO, PPO/POD, and POD) was tested with one-way analysis of variance (ANOVA) (SPSS 11.5.1.).

Correlations between larval and leaf traits were tested with the *Pearson's two-tailed correlation* test (SPSS 11.5.1). The main idea was to test and present the differences in correlation coefficients between the control and the DIR treatments, not to present individual correlations (thus, *Bonferron* correction was not used). These differences were statistically tested by two independent analyses. First, the correlation coefficients were analyzed with the univariate analysis of ANOVA with the model, wherein the treatment, sex, leaf age (third or fifth instar leaves), and treatment * sex and treatment * leaf age were set as fixed factors. The dependent variables were correlation coefficients (calculated by correlating the pupal weight, development time, and encapsulation rate with phenolic compounds). In the analysis of the correlation coefficients of pupal weight and development time, the two way interactions were nonsignificant and were removed from the final model, but kept in the analysis of the correlation coefficients of the encapsulation rate. Second, we tested the differences in each correlation coefficient between the control and defoliation treatments by using the *Tukey's* type test presented in Zar (1999) (in chapter: "19.8 Multiple comparisons among correlation efficiencies").

Results

Effects of Previous Defoliation on Larval and Tree Traits Final pupal weights of *E. autumnata* remained lower in DIR trees that were exposed 5 yr earlier to the defoliation of *E. autumnata* larvae than in control trees (F=7.67, P=0.011) (Fig. 1a). In females, difference in pupal weights between control and DIR-trees was 9.5%, and in males, 6%. Development time of larvae was also longer (χ^2=10.93, P=0.001) in DIR trees than in controls (Fig. 1b). In contrast, encapsulation rate of pupae did not differ between control and DIR trees (Fig. 1c; F=0.08, P=0.783). Female pupae were heavier than male pupae (F=22.81, P<0.001), and the larval period of females was longer than that of males (χ^2= 28.84, P<0.001), whereas there were no sex differences in the encapsulation rate (F=0.40, P=0.530).

The activities of PPO, combined PPO/POD, or total POD did not differ significantly between treatments (Fig. 2a). Combined PPO/POD activity was higher than pure PPO activity (measured in the presence of commercial catalase), which suggests that the enzyme extract contained endogenous H_2O_2 (which PODs need as a co-substrate). In DIR trees, PPO/POD activity (and guaiacol POD activity) showed a slight (but nonsignificant) increasing tendency, whereas pure PPO activity showed a decreasing tendency, suggesting an increased endogenous level of H_2O_2 in DIR trees.

Neither did the contents of any individual phenolic compound nor the total contents of galloylglucoses, ellagitannins, hydrolyzable tannins, flavonoid glycosides, or total HPLC-phenolics differ significantly between control and DIR trees (data not shown). However, the quercetin:kaemferol ratio increased in DIR trees, although the change in the levels of quercetin or kaemferol were not statistically significant.

The contents of phenolic compounds varied significantly between sampling dates; generally the contents were markedly higher in young leaves of the third instar than in mature leaves of the fifth instar (Fig. 3). The contents of di- and trigalloylglucose (Fig. 3a), casuarictin, trigalloyl-HHDP-glucose, and galloyl-*bis*-HHDP-glucose, gallic acid, catechin (Fig. 3b), myricetin, quercetin, and kaempferol glycosides (Fig. 3c) decreased significantly during leaf development. In addition, the total contents of galloylglucoses, flavonoid glycosides, and HPLC-phenolics decreased toward leaf maturation (Fig. 3d). In contrast, the contents of

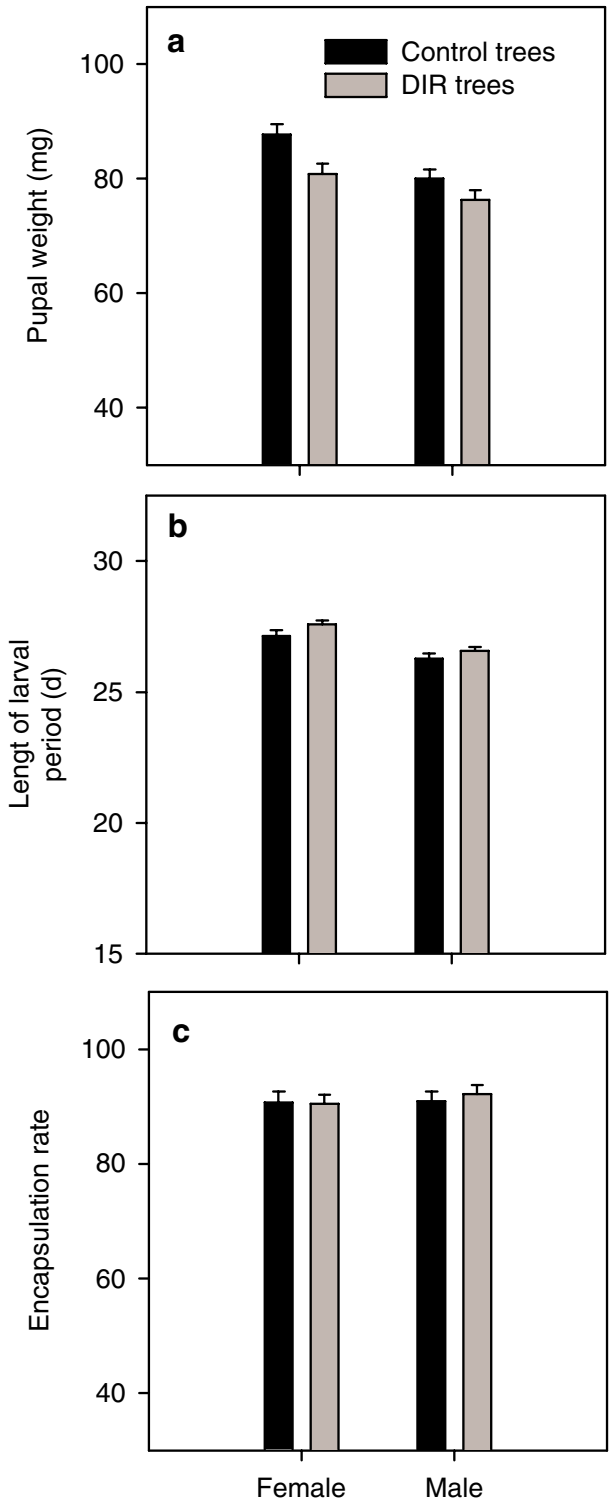

Fig. 1 Pupal weights (**a**), development time (**b**), and encapsulation rate (**c**) of *Epirrita autumnata* on control and DIR trees

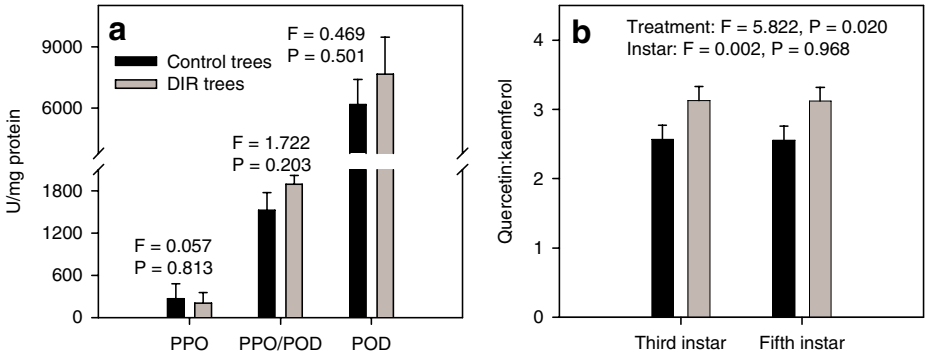

Fig. 2 Phenoloxidase activities (**a**) and the quercetin:kaemferol ratio (**b**) in the control and DIR trees. Pure PPO activity was measured by using catechol as a substrate, and POD activity was inhibited with commercial catalase. Combined PPO/POD activity was measured in the absence of catalase. Pure POD activity was measured with guaiacol and H_2O_2 as substrates

pedunculagin derivative, chlorogenic acids, and coumaroylquinic acids increased from young to mature leaves (Figs. 3a and c).

Relations of Tree Traits and Larval Traits between Treatments Although the contents of phenolic compounds did not differ between control and DIR trees, the correlation coefficients (calculated from correlations between larval parameters and the contents of phenolic compounds) differed significantly between the treatments (Table 1). The sexes did not differ in their correlation coefficients (Table 1). In the DIR treatment, correlations between pupal weight and contents of hydrolyzable tannins (HTs) were strongly negative, whereas in the control treatment these correlations were nonsignificant or positive (Table 2).

Correlations calculated between the length of larval period and contents of phenolics also differed; and sexes as well differed in their coefficients (Table 1). The length of the larval period of females correlated positively with the contents of tannic compounds in DIR trees, but the correlations were mostly nonsignificant or negative in control trees (Table 3). In other words, hydrolyzable tannins decreased the development rate of female larvae in DIR trees but had small effect in control trees and male larvae.

The correlation coefficients, calculated between the encapsulation rates of *E. autumnata* pupae and the contents of phenolic compounds in leaves, showed interesting features. The encapsulation rate of males was positively related to the contents of phenolics in the DIR treatment but negative in the control treatment (Table 4). The encapsulation rate of females, however, showed a positive relation to phenolic content in the control treatment, whereas correlations were negative in the defoliation treatment. Indeed, there was a significant treatment * sex interaction in the correlation coefficients (Table 1).

POD activities seemed to have differing effects on the performance of males (but not females) in DIR trees: the correlation between male pupal weight and POD activities was positive in the control (r=0.531, P=0.076) but nonsignificant in the larval treatment (r=−0.390, P=0.210). However, POD activity correlated positively with the length of male larval period in the DIR treatment (r=0.576, P=0.050), wherein the relation between male pupal weight and length of larval period was strongly negative (r=−0.845, P=0.001). In the control, both of these correlations were nonsignificant (data not shown). In addition, the correlations with other oxidase activities were nonsignificant.

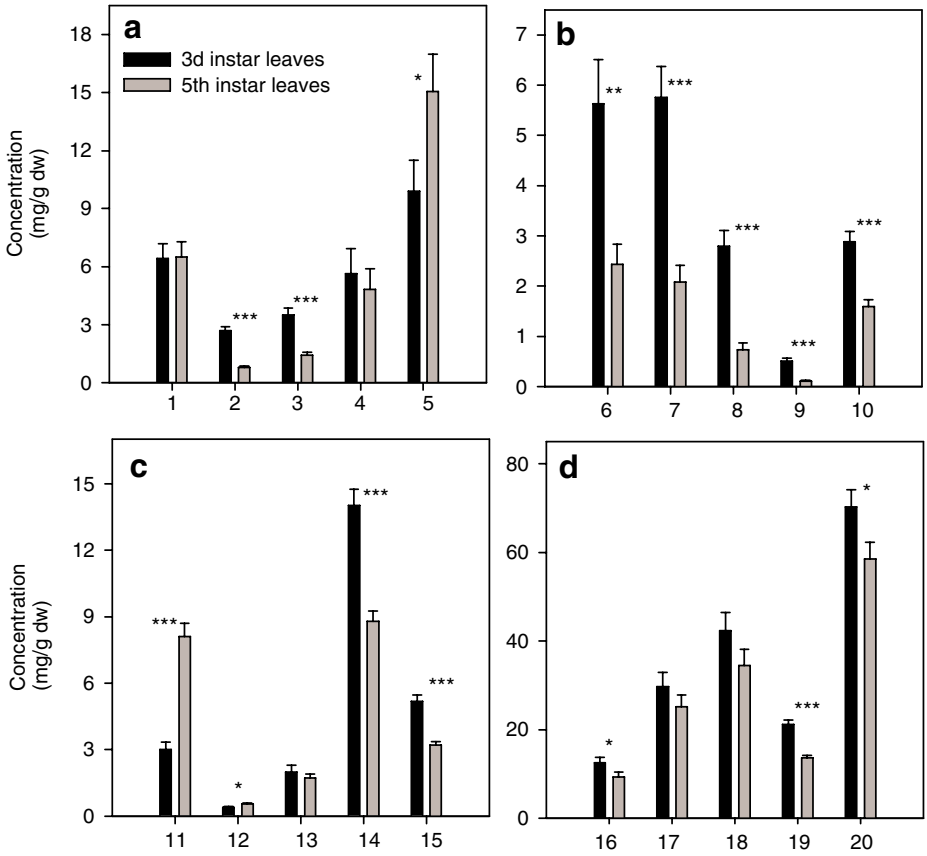

Fig. 3 Phenolic compounds in mountain birch leaves at the time of third instar (expanding leaves) and fifth instar (fully expanded leaves) of *E. autumnata*. **a** The contents of mono-, di- and trigalloylglucose (1-3), pedunculagin (4) and pedunculagin derivative (5). **b** The contents of casuarictin (6), trigalloyl-HHDP-glucose (7), galloyl-*bis*-HHDP-glucose (8), gallic acid (9), and catechin (10). **c** The contents of chlorogenic acids (11), coumaroylquinic acids (12), and myricetin, quercetin, and kaempferol glycosides (13-15). **d** The total contents of galloylglucoses (16), ellagitannins (17), hydrolyzable tannins (18), flavonoid glycosides (19), and HPLC-phenolics (20). The compounds whose contents differ significantly between these sampling points are marked with *asterisks* (*$P \leq 0.05$; **$P \leq 0.01$; ***$P \leq 0.001$)

POD activity correlated negatively with the encapsulation rate of males in control trees ($r=-0.611$, $P=0.035$) but not in DIR trees ($r=0.495$, $P=0.102$), whereas the combined PPO/POD activity correlated positively in control trees ($r=-0.598$, $P=0.040$). The encapsulation rate of males (but not females) was negatively associated to pupal weight both in the control ($r=-0.538$, $P=0.071$) and DIR trees ($r=-0.661$, $P=0.019$). The correlations between female fitness traits and phenoloxidase activities were nonsignificant in either treatment (data not shown).

Leaf phenology was negatively related to male pupal weight in control trees ($r=-0.592$, $P=0.043$), but not in DIR trees ($r=0.123$, $P=0.703$) and did not affect the traits of the females (data not shown). In addition, leaf water contents (determined both from the third

[1] Leaf age=third or fifth instar leaf

and fifth instar leaves) showed no significant association to pupal weight or other traits (data not shown).

Discussion

This is the first study where the DIR has been shown to last as long as 5 yr, although it is a well-characterized phenomenon in the mountain birch (Haukioja and Neuvonen 1985; Ruohomäki et al. 1996; Kaitaniemi et al. 1998). In addition, our results suggest that the DIR is a specific process, not a passive response that results in the exhaustion of nutrients due to herbivory. Mild damages that occurred 5 yr earlier were not likely to have affected the reservoirs of trees in the present experiment. The definition of immunological memory of plants means that induced resistance should be stronger and more rapid in plants that are challenged a second time to an herbivore attack than in plants that encounter the challenge the first time (Karban and Niiho 1995; Baldwin and Schmelz 1996). Our results satisfy this definition as trees that were earlier exposed to herbivory reacted more strongly to a new challenge than trees without a marked herbivory history. We found that larval treatment, which was conducted as long as 5 yr earlier, still affected the performance of moth larvae: pupal weights remained significantly lower in DIR trees than in control trees, and also the length of larval period was prolonged on previously damaged foliage.

In a study that was conducted previously in the beginning of the increase phase of moth cycle, DIR did not affect growth rate or pupal mass of the autumnal moth; whereas the encapsulation rate of pupae was enhanced in DIR trees (Kapari et al. 2006). The present study, however, was conducted in the later stage of the cycle, and the results are opposite: DIR retarded pupal weight and prolonged the larval stage, whereas encapsulation rate was not affected. One explanation is the different timing of the second challenge: in the former study, the experiment was conducted 1 yr after the previous defoliation, whereas in the latter study, the experiment was conducted 5 yr after the first challenge. This may partly explain the discrepancies. Both birches and larvae may respond differently depending on the phase of the cycle. This hypothesis awaits confirmation.

The nature of the mountain birch–autumnal moth interaction is complex (see Haukioja 2005): we did not find any individual inducible factor that alone could explain the retarded pupal weights on the induced trees. No individual phenolic compound was significantly affected by the treatment, nor did we find a significant increase in foliar enzyme activities. The only significant difference in the chemistry of control and DIR trees was the enhanced quercetin:kaemferol ratio in DIR trees. In addition, we found that correlations between phenolic compounds and larval traits differed significantly between the treatments. Correlations between the contents of phenolics (especially HTs) and pupal weights were negative in the DIR treatment and nonsignificant or positive in the control treatment, and the larval period of females was prolonged by phenolics, whereas those of males were

prolonged by POD activity in DIR trees. Similar results where the negative correlations were found in larval treated trees but not in control trees have been reported in other studies with mountain birch (Lempa et al. 2004; Ruuhola et al. unpublished results) and its parental species *Betula nana* (Ruuhola et al. unpublished results).

Both the antioxidative and prooxidative capacity of flavonoids is proportional to the number of OH-groups in the B-ring (Heim et al. 2002), and quercetin has two, but kaemferol has only one. The ratio of dihydroxylated:monohydroxylated flavonoids has been shown to increase as a response to UV-B radiation in many plant species (Liu et al. 1995; Markham et al. 1998a, b; Ryan et al. 1998; Olsson et al. 1999), but this is possibly the first study wherein herbivory has been shown to affect the ratio. Artificial acid rain and heavy metal pollution also increase this ratio in the mountain birch (van Ooik et al., unpublished results).

The increase in the quercetin:kaemferol ratio in the leaves of DIR trees suggests an increased oxidative stress due to herbivory. Enzymatic data also indicate an increase in the endogenous level of H_2O_2. In an earlier study with mountain birch, we found that herbivory

caused oxidative stress in birch leaves: H_2O_2 accumulated in the vicinity of the wound sites, POD and PPO activities increased, and the activity of the antioxidative catalases that remove H_2O_2 decreased concomitantly (Ruuhola and Yang 2006). In other plant species, wounding also has been shown to increase the production of ROS (Levine et al. 1994; Bi and Felton 1995; Orozco-Cárdenas et al. 2001; Gatehouse 2002).

Despite the antioxidative and health-promoting effects of flavonoids and other phenolics, they may actually be prooxidative agents, e.g., in the presence of transition metals, NADH, ROS, oxygen, and oxidases (Hoover et al. 1998a, b; Chan et al. 1999; Schweigert et al. 2001; Heim et al. 2002; Pourcel et al. 2006). Oxidation of phenols, like flavonoids, by PPOs and PODs, produces quinones and semiquinones, which can, through coupled oxidation reactions, oxidize other polyphenols that cannot be directly oxidized by oxidases (Pourcel et al. 2006), i.e., quinones formed by oxidation of flavonoids may also activate the oxidation of HTs.

The toxicity of catecholic compounds containing two hydroxyl groups in the *ortho*-position is most often linked to the generation of ROS and damages in DNA and proteins (Schweigert et al. 2001). Differences in the oxidative status of leaf cells may explain the

observed phenomenon in birch: phenolics and phenoloxidases produce ROS and reactive radicals in larval trees, which are quenched in control trees. Which factors quench the oxidative stress in control trees is not yet known, but ascorbate is a good candidate, as a high level of ascorbate attenuates generation of ROS by phenolics and would regulate the prooxidant activity of phenolics *in vivo* (Heim et al. 2002).

Autumnal moth sexes did not differ in the strength of their immune defense, which is common in insects (Rantala et al. 2007 and references therein), although the components that affected the encapsulation rate differed between sexes. We know that in males, the genetic variation of immune response is largely additive or nondirectional with respect to dominance, whereas in females, variation is reduced and consists of a directional dominance variance (Rantala and Roff 2007). In addition, sexes differed in their correlations between life history traits: in females, the strength of immunity correlated positively with body size, whereas males' immune response increased with a reduction in development time (Rantala and Roff 2007). Thus, the genetic differences between males and females may cause differences in the effects of phenolic compounds on the immunity of males and females.

Interestingly, the chemicals (HTs, catechin, kaempferol glycosides) that had a negative effect on male pupal weight in larval trees affected encapsulation rate positively. There may be a trade off between body size and strength of immunity (Rantala and Roff 2005). Hoover et al. (1998a, b) found that bacoluviral infections of noctuid larvae *Heliotis virescens* and *Helicoverpa zea* were decreased by the phenolics' redox cycling catalyzed by PODs, a process that also involved the generation of H_2O_2. They did not, however, study whether immunity of larvae was affected by phytochemicals and/or the activity of foliar oxidases.

Rapid developmental changes, together with high among and within tree variation in both secondary and primary compounds in mountain birch leaves, have complicated the search of induced defensive factors (Haukioja et al. 1988; Kause et al. 1999; Haukioja et al. 2002). Condensed tannins increase with leaf maturation, whereas flavonoids and hydrolyzable tannins decrease (Salminen et al. 2001, 2002; Riipi et al. 2002). In this study, we found that the contents of several individual HTs, flavonoids, and total HPLC-phenolics similarly decreased during leaf maturation, whereas chlorogenic acid, coumaroylquinic acids, and pedunculagin derivative increased.

Haukioja et al. (2002) found that specific defensive leaf traits are sensitive to simultaneous variation in other leaf components and that different instars might be vulnerable and affected by different factors. Here, the contents of HTs determined from young third instar leaves negatively correlated with final pupal weight in the DIR trees, suggesting that early phases in larval development are critical for final pupal weights, although most of the weight gain is attained during the last fifth instar (see also Tammaru 1998). In third instar leaves, the contents of HTs were significantly higher than in the fifth, further indicating a defensive role of HTs against early instars (see also Kaitaniemi et al. 1998). The leaf maturing index is an important determinant of tree suitability for autumnal moth larvae (Haukioja et al. 2002), and fast larval development is possible only in young leaves (Kause et al. 1999). In our study, the phenological index of trees was negatively related to male pupal weight in control trees but not in DIR trees, indicating that other leaf traits were more important determinants for the growth of larvae on induced foliage than the leaf maturation index.

In summary, our results show that mountain birches possess a long-term memory: trees that are exposed to herbivory 5 yr earlier are more strongly defended than control trees without an herbivory history. How the immunological memory functions in the molecular level, needs to be investigated. The causal mechanism behind the induced resistance is

suggested to be an enhanced oxidation of phenolic compounds in larval trees due to increased oxidative stress. In our proposed model, herbivory enhances the accumulation of ROS, activates foliar phenoloxidases, and exhausts the antioxidants. These oxidation products, quinones, semiquinones, and ROS may have toxic, antinutritive, and repellent properties against herbivores.

Acknowledgements The research was conducted in Kevo Subarctic Research Station, and we thank the staff for help and co-work. We also thank the department of Physiology and Genetics for providing the facilities for the enzymatic assays. We also thank our field assistants Ulla Anttila, Tia Lampela, Liisa Rantala and Mikko Oikamo, and Piia Saarinen for doing the phenolic analyses. Salla-Riikka Vesterlund kindly checked the English language. The study was supported financially by the Academy of Finland, Kone and Emil Aaltonen Foundation.

Abstract To examine how plant allelochemicals in prey affect foraging choices made by generalist predator paper wasps, *Polistes dominulus* (Vespidae), we compared predation on *Pieris napi* (Pieridae) caterpillars reared on host plants with different allelochemicals. In naturalistic behavioral choice experiments, free-flying wasps chose between living pierids reared on cabbage (*Brassica oleracea*), which lacks deterrent allelochemicals, or alternate host plants with potentially deterrent allelochemicals. The alternative host plants were: wormwood mustard, (*Erysimum cheiranthoides*: Brassicaceae), which contains cardenolides; nasturtium (*Tropaeolum majus*: Tropaeolaceae) with high concentrations of chlorogenic acid; and black mustard (*Brassica nigra*: Brassicaceae) with high concentrations of the aliphatic glucosinolate, sinigrin. Although wasps captured equal numbers of caterpillars reared on cabbage and each alternate host plant, they spent significantly longer handling prey from the alternate host plants as they selectively removed the caterpillar's gut, which contained the plant material. This was true even if the caterpillar did not sequester toxins in its tissues, as revealed by high performance liquid chromatography (HPLC) analysis of *Erysimum*-reared pierids. Because handling time is longer, predators that capture pierids containing non-sequestered allelochemicals experience an overall reduction in foraging rate that may translate into a fitness cost.

Introduction

Plants have evolved a wide variety of chemical defenses against herbivory. Although plant allelochemicals may effectively deter herbivory by most insect species, in many cases, insect specialists are able to consume the plants, and subsequently use the acquired allelochemicals as defense against predators (Price et al. 1980; Brower 1984). The literature on the effectiveness of allelochemicals acquired from host plants in reducing predation on insect prey has focused on vertebrate predators of adult insect herbivores (see Brower 1984), or effects of allelochemicals on parasitoids (Duffey et al. 1986; Barbosa 1988; Gauld and Gaston 1994). The effects of acquired allelochemicals in prey on generalist invertebrate predators have also received attention, although generalist predators are major selective forces on immature insect herbivores (Brower 1984; Stamp and Bowers 1988; Dyer 1995; Müller and Brakefield 2003; Boeve and Müller 2005). Generalist predators are proposed to play a significant role in restricting host-plant range of insect herbivores by selectively predating more on polyphagous generalists than on specialists (Bernays 1988; Bernays and Graham 1988). Relatively little is known, however, about the dynamics of how generalist invertebrate predators deal with potentially toxic allelochemicals in insect herbivores.

We developed a predator–herbivore–plant system to examine how generalist paper wasp predators respond to herbivorous caterpillars raised on host plants with different types of defensive chemistry (Eigenbrode, et al. 2000; Rayor and Munson 2002; Rayor 2004). The relatively large, social paper wasps, (Vespidae: *Polistes* spp.), are major generalist predators on lepidopteran larvae that they capture to feed to their carnivorous larvae (Raveret Richter 2000; Rayor 2004). Because the adults feed solely on nectar, their foraging behavior is dictated by the nutritional requirements of their developing larvae (Raveret Richter 2000). We have previously demonstrated that *Polistes dominulus* prefer prey with lower concentrations of allelochemicals (Danaidae: *Danaus plexippus*: Rayor and Munson 2002; Rayor 2004) and that larval development is slower when reared on caterpillars raised on host plants with high cardenolide concentrations (Rayor, unpublished data). While palatability may be a key factor affecting prey capture, the wasps also must locate prey on host plants that may differ considerably in leaf structure or density. Plant architecture has been shown to affect the ability of wasps to locate or capture caterpillars (Cornelius 1993; Geitzenauer and Bernays 1996. Eigenbrode et al. 2000).

In this study, we used a behavioral choice test to determine whether the predatory behavior of *P. dominulus* is affected by allelochemicals found in pierid caterpillars' host plants. We hypothesized that wasps would discriminate against conspecific *Pieris napi* (Pieridae) caterpillars that had been reared on host plants that differed in their defensive compounds. The oligophagous feeding habits of *P. napi* permit a comparison of wasp predation on caterpillars reared on host plants with and without cardenolides or on host plants with different glucosinolate profiles, such as cabbage, nasturtium, and black mustard. The use of a single caterpillar species in these tests minimized behavioral or morphological factors that could affect predation risk by wasps. Most pierids readily consume cabbage (*Brassica oleracea*) that contains indole glucosinolates, but *P. napi* also eats the crucifer, *Erysimum cheiranthoides*, which contains cardenolides that deter other *Pieris* species (Sachdev-Gupta et al. 1993; Renwick 2002). Nasturtium (*Tropaeolum majus*: Tropaeolaceae) contains a benzylic glucosinolate attractive to many cruciferous herbivores, but also contains high concentrations of chlorogenic acid unpalatable to some pierid species (Renwick and Huang 1995). Black mustard (*Brassica nigra*) contains high concentrations of the aliphatic glucosinolate, sinigrin (Fenwick et al. 1983).

Our goals were: (1) to examine how plant allelochemicals in prey affect foraging choices made by generalist paper wasps; and (2) to determine if the wasps use behavioral strategies to effectively overcome protection that caterpillars derive from the host plants allelochemicals.

Methods and Materials

Subjects Queens of the invasive European paper wasp, *P. dominulus* (Vespidae) with their six to ten cell nests were collected in early June 1995 and 1996 in Ithaca, New York. Nests were hung in a 5.8 by 2.7 m room in the Entomology Insectary Greenhouse on the Cornell University campus. As nests were captured at the single foundress stage with eggs and a few larvae, all workers that emerged from each nest were raised entirely in the experimental environment of the greenhouse and had foraging experience only with prey species provided to them. The first cohort of wasp larvae was fed highly palatable cabbage loopers (Noctuidae: *Trichoplusia ni*) raised on artificial wheat germ diet. Experiments started upon the emergence of the first cohort of adult foragers on 4 July 1995 and 3 July 1996. Each adult wasp was individually marked with enamel paint. Each summer, the *P. dominulus* wasps came from four nests. The number of developing larvae increased over the summer, from approximately 6 to 30 larvae per nest with 11 to 20 active foragers at a time. The exact number of foragers is provided in the results for each experiment. Experiments I, III, and IV were done in 1995, Experiment II in 1996. Individual foragers were active for several weeks before retiring, and a few were active foragers during two experiments in 1995.

Caterpillars and their host plants were raised in the greenhouse. Depending on the particular experiment, *P. napi* oleracea larvae were raised on cabbage (*B. oleracea capitata*, wormseed mustard (*E. cheiranthoides*), black mustard (*B. nigra*), or nasturtium (*T. majus*). Conspecific caterpillars raised on different host plants are referred to as different "types".

Behavioral Experiments Predatory bouts in *Polistes* involve prey detection, attack (initial contact), capture (subduing and killing), handling (cutting it into two or more pieces small enough to be carried in flight), departure (flying to the nest with prey pieces to be fed to the developing wasp larvae), and rapidly returning (to the site where "remains" of the prey have been left behind or where hunting has been successful) (Rabb and Lawson 1957; Raveret Richter 2000). Wasps accept or reject the prey during the attack, capture, and return phases. This study focused on the number of predation events ("captures"), duration from the initial attack until an individual wasp departed ("handling time"), and her return for prey remains ("remains"). "Total prey captured" reflects the number of prey pieces returned to the nest (all prey pieces taken from the initial capture and remains, minus the number of prey that were rejected during handling; see Rayor and Munson, 2002 for details). All prey used were sufficiently large that they needed to be cut into smaller pieces to be flown to the nest. Detailed behavioral data were recorded for 1-h sessions using the Noldus Observer 3.0 software on Psion hand-held computers. Focal observations were simultaneously recorded for five to ten individual wasps.

To compare wasp predatory behavior and prey preferences, free-flying wasps were given a choice between two types of caterpillars reared on different host plants for 1-h sessions. Approximately six size-matched live caterpillars of each type were widely distributed on six to eight presentation plants placed within 1 m of each other. Caterpillar numbers were held constant, by adding new caterpillars after others were killed but by placing them on different presentation plants and changing the location of presentation plants every half-hour. Care was taken not to attract the attention of foraging wasps when caterpillars were replaced. To control

for differences in plant architecture, the caterpillar's host plant ("own host") and cabbage were used as presentation plants in experiments I and II, but only cabbage in experiments III and IV. Presentation plants were replaced between sessions to minimize visual or olfactory cues from caterpillar hemolymph or leaf damage. Herbivory on presentation plants was minimal.

Behavioral choice experiments:

Experiment I: *P. napi* raised on *Erysimum* vs *P. napi* raised on cabbage, presented to wasps on their "own host" plants or on cabbage;

Experiment II: *P. napi* raised on cabbage and painted on the epidermis with 0.5 mg digitoxin/ml in methanol vs *P. napi* painted on the epidermis with methanol alone, presented to wasps on cabbage. Digitoxin is a representative cardenolide;

Experiment III: *P. napi* raised on nasturtium vs *P. napi* raised on cabbage, presented to wasps on their "own host" plants or on cabbage;

Experiment VI: *P. napi* raised on black mustard vs *P. napi* raised on cabbage, presented to wasps on cabbage.

Data Analysis As in nature, individual foragers made repeated prey captures. To avoid pseudoreplication issues, nonparametric Wilcoxon-signed rank tests were used to determine the direction of preferences by individual wasps for one prey type over the other in total prey returned to the nest (Seigel and Castellan 1988). The Wilcoxon-signed rank test evaluates the relative magnitude and direction of difference within paired samples for an individual wasp. Wilcoxon Signed Rank T values were reported for small sample sizes ($N<15$), Z values for large sample sizes ($N>15$).

Mean handling time for each prey type for individual wasps was compared with the nonparametric Wilcoxon Signed Rank Test (Seigel and Castellan 1988). Variation in intra- and interindividual handling time was large. We attribute the large variation in processing to differences in individual experience, motivation relative to the number of feeding larvae at the nest, or event-specific circumstances. Such circumstances include an unstable location on the plant where the prey is killed, necessitating dragging of the prey to a more stable location or the influence of other foraging wasps in the vicinity (which increases the speed of handling). Only predatory bouts greater than 30 s (from initial attack of live prey to departure for the nest with the prey ball) were used. Predatory bouts where wasps were interrupted by another wasp were omitted from handling time comparisons and inexperienced wasps that attacked fewer than four caterpillars were also omitted. Handling data were pooled for presentation plants in experiments I and II.

Overall differences in handling time for caterpillars raised on *Erysimum*, nasturtium, and black mustard compared to those raised on cabbage were calculated as follows: For each prey type, the mean difference between handling times was calculated for each individual wasp and transformed into a percentage. A grand mean of the individual percentages was subsequently calculated and is plotted in Fig. 2 along with 1 SD. The handling times for cabbage caterpillars were calculated only from those captured in each separate experiment and were not combined between experiments.

Chemical Analysis To determine whether *P. napi* sequestered cardenolides from *Erysimum*, HPLC was used and the cardenolide content examined from 1.97 g fresh *Erysimum* leaves, 0.184 g frass from *P. napi* raised on *Erysimum*, 0.33 g starved *P. napi* larvae raised on *Erysimum*, and 0.38 g *P. napi* pupae raised on *Erysimum* using the methodology of Sachdev-Gupta et al. (1993).

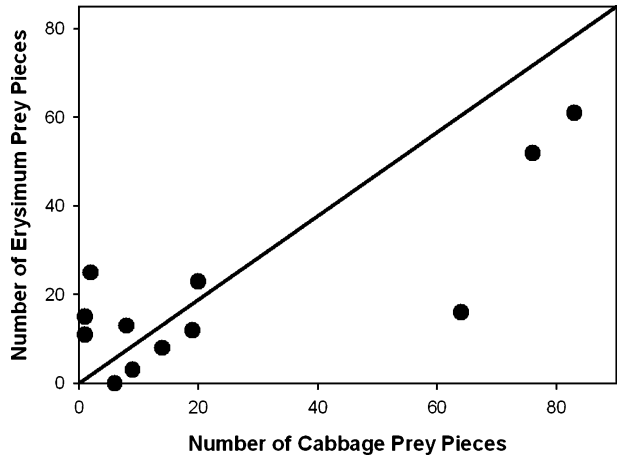

Fig. 1 Types of prey returned to nests by wasps. Individual foraging wasps took similar numbers of prey pieces of *Erysimum*-reared and cabbage-reared *Pieris napi* back to their nest. The *diagonal line* indicates equal numbers of each prey type. *Data above the line* indicate that an individual wasp captured more *Erysimum*-reared prey; *data below the line* indicate that the wasp captured more cabbage-reared prey. Data were pooled from both sets of presentation plants

Results

Behavioral choice: *P. napi* raised on *Erysimum* vs *P. napi* raised on cabbage

Equal numbers of *P. napi* raised on cabbage or on *Erysimum* were captured by individual wasps when presented on their own host plants [total prey captured: *Erysimum*-reared (N=84) and cabbage-reared (N=107); Fig. 1, T=10, foraging wasps N=5, P=0.31]. Similarly, when both types of caterpillars were simultaneously presented on cabbage presentation plants, there was no significant difference in number of captures [total prey captured: *Erysimum*-reared (N=159) and cabbage-reared (N=180); Fig. 1, T=42, foraging wasps N=11, P=0.23]. Only three wasps were active foragers during experiments on both sets of presentation plants.

Wasps meticulously removed the guts of *Erysimum*-reared caterpillars when processing prey; they did not remove guts of caterpillars raised on cabbage. This activity increased individual forager's handling time of *Erysimum*-reared caterpillars over cabbage-reared caterpillars (T=38.5, foraging wasps N=9, P=0.04, pooled presentation plant data). The

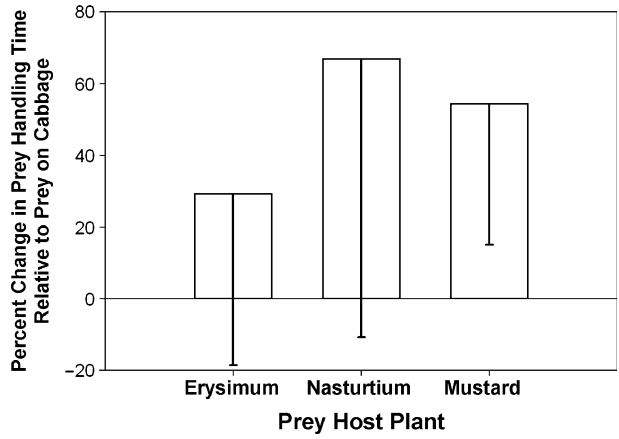

Fig. 2 Handling time by wasps as a function of prey host plant. Wasps spent more time handling *Pieris napi* prey raised on *Erysimum*, nasturtium, or black mustard host plants than on cabbage-reared prey, as indicated by the overall mean percent difference in time spent on each type of prey. *Each bar* represents separate experiments where the cabbage-reared prey was paired with an alternate host plant-reared prey. *Error bars* indicate standard deviation

overall mean handling time for all wasps was 29.3% longer on *Erysimum*-reared caterpillars than on cabbage-reared caterpillars (Fig. 2).

Chemical Analysis HPLC revealed peaks that were characteristic of cardenolides (Dimock et al. 1991) in the *Erysimum* leaf control sample and in the sample of frass from *Erysimum*-raised *P. napi*. Retention times and the total ultraviolet (UV) spectra were consistent with *Erysimum* cardenolide samples run under the same conditions (Sachdev-Gupta et al. 1993). Although starved before analysis, samples of larvae gave small peaks with absorption maxima at 221 and 222 nm, indicating the presence of traces of cardenolides. Pupae did not contain detectable cardenolides. Because the gut content of caterpillars is completely voided before pupation, the lack of cardenolides after pupation demonstrates that no sequestration occurred.

Behavioral Choice: *P. napi* with Digitoxin vs untreated *P. napi*

Prey pieces from pierids with the cardenolide standard digitoxin on their epidermis were returned to the nest far less (N=65) than pierids without the cardenolide (N=116). Wasps captured fewer caterpillars with digitoxin (Fig. 3, Z=2.66, foraging wasps N=18, P=0.004). Pierids with digitoxin were 3.6 times more likely to be rejected once bitten, and prey remains without digitoxin were handled 1.9 times more often. The time wasps spent handling pierids with digitoxin did not differ significantly from the time spent handling pierids without digitoxin (T=25, foraging wasps N=8, P=0.19).

Behavioral choice: *P. napi* raised on nasturtium vs *P. napi* raised on cabbage

Nasturtium contains the aromatic benzylic glucosinolate (glucotropaeolin) and high levels of chlorogenic acid. There was no significant difference, however, in the number of prey pieces taken by individual wasps from nasturtium- or cabbage-reared *P. napi* when caterpillars were presented on their own host plant [total prey captured: nasturtium-reared (N=56) and cabbage-reared (N=71); Z=1.17, foraging wasps N=16, P=0.12] or when they were presented on cabbage [total prey captured: nasturtium-reared (N=52) and cabbage-

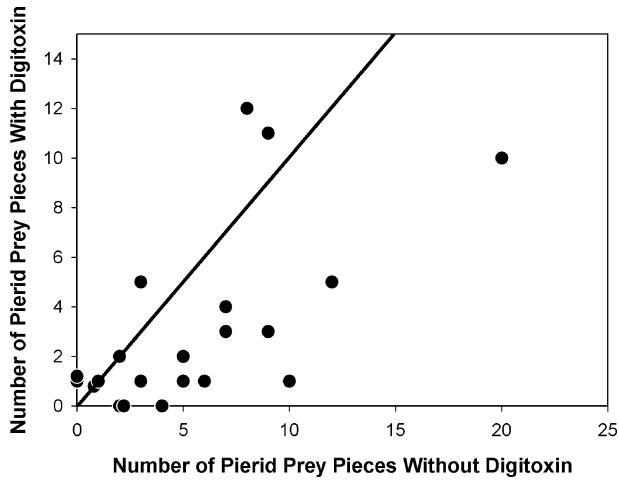

Fig. 3 Prey species taken by wasps with or without digitoxin. Individual wasps took significantly fewer *P. napi* caterpillars painted with digitoxin than those without digitoxin, as indicated by the data points below the diagonal line

reared (N=63); Z=0.84, foraging wasps N=20, P=0.20]. However, the time individual foragers spent handling caterpillars raised on nasturtium was greater than for caterpillars raised on cabbage (Z=2.72, N=17, P=0.02, pooled data). On average, wasp handling time on nasturtium-reared caterpillars was 66.8% longer than for those raised on cabbage due to time spent removing caterpillar guts (Fig. 2).

Behavioral choice: *P. napi* raised on black mustard vs *P. napi* raised on cabbage

Wasps found pierids raised on black mustard, which contains high concentrations of sinigrin, to be equally palatable to pierids raised on cabbage. There was no significant difference in the number of captures by individual wasps when these caterpillars were presented on cabbage (total prey captured: mustard-reared N=57, cabbage-reared N=50; Z=−0.933, foraging wasps N=16, P=0.17). Although relatively few wasps handled both caterpillar types more than once without interruption, handling time was longer on black mustard (T=21, foraging wasps N=6, P<0.015). Overall, wasps took 54.3% longer processing mustard-reared caterpillars than cabbage-reared caterpillars due to gut removal (Fig. 2).

Discussion

The results of the study indicate that *Polistes* wasps are not deterred from capturing *P. napi* that have consumed host plants containing cardenolides and glucosinolates in *Erysimum*, glucotropaeolin and chlorogenic acid in nasturtium, or sinigrin in black mustard. However, sensitivity to these allelochemicals is indicated by the wasps' significantly longer handling time of *P. napi* that had fed on these plants. The behavioral strategy of removing guts containing plant material from caterpillars that have not sequestered the allelochemicals effectively removed toxins that might affect larval development. Costs are likely incurred by this behavioral strategy. In the field, fewer prey items would be brought back to the nest because it takes more time to handle prey containing potentially toxic allelochemicals than prey without the compounds. Similarly, a wasp that spends longer time with prey at the host plant is more likely to attract other foragers' attention and risks fighting over the prey and possibly having wasps from other nests steal it (Raveret Richter 1990, personal observation). This could lead to a slower growth rate for developing wasp larvae, and fewer workers and reproductives produced over the course of a summer. Locating prey in the field is difficult and time-consuming, and rapid prey handling helps to maximize foraging success over the course of a day. Thus, a cost in slower prey handling due to plant allelochemicals may translate into an overall cost in fitness for a wasp colony.

P. dominulus were strongly deterred in this study by digitoxin that was painted on the epidermis of pierids. Most insect herbivores are strongly deterred from consuming *Erysimum* due to its high cardenolide content (Dimock et al. 1991; Sachdev-Gupta et al. 1993). The cardenolide concentrations are as high as those documented for milkweed (*Asclepias*) species (Rodman et al. 1982). We predict that if *P. napi* were able to sequester cardenolides from the *Erysimum* host plant in their tissues, the allelochemicals could function as a more effective antipredator defense. Based on our HPLC analysis, traces of cardenolides may be retained by *P. napi* larvae, but the allelochemicals are not stored or accumulated, so that none is detected in the pupae. *P. rapae* and *Pieris brassicae* have been shown not to sequester sinigrin (aliphatic glucosinolate) or several other benzylic or indole-glucosinolates (Müller et al. 2003). Pierids are not unique among lepidopteran larvae that feed on host plants containing potent allelochemicals in their lack of sequestration of the

chemicals (Bowers and Stamp 1997; Müller and Brakefield 2003). In contrast, lepidopteran larvae that do sequester a variety of allelochemicals from their host plants successfully reduce predation risk from generalist predators, including predatory wasps (Bernays 1988; Bernays and Cornelius 1989; Montllor et al. 1991; Stamp 1992; Dyer and Bowers 1996; Müller and Brakefield 2003). *P. dominulus* discriminates against high cardenolide levels in monarch caterpillars (Rayor 2004). Because the monarchs accumulate cardenolides in their hemolymph and epidermis (Duffey 1980), wasps are unable to avoid cardenolides by removing the guts alone. Monarch caterpillars were never gutted nor were their epidermis or other tissues selectively removed during processing (Rayor, unpublished data).

This study demonstrates that predatory wasps may use behavioral strategies to overcome potentially toxic host plant allelochemicals in prey.

Acknowledgments The work was supported by NSF DEB - 97 27547 to LSR and by NSF DEB- 9419797 to JAR. We thank Laurel Southard and the Cornell Howard Hughes Scholars Program for two summers of financial support for LJM. K. Campbell helped with 1996 data collection. Kimberly Lopez's assistance to LJM with chemical analyses was indispensable. The project and manuscript were improved by suggestions from Nancy Stamp, Lincoln Brower, Paul Feeny, Caroline Müller, Connie Rayor, and an anonymous reviewer. Particular thanks go to Elizabeth Bernays, University of Arizona, for initially encouraging LSR's approach to wasp predatory behavior. Patrick Hughes provided cabbage loopers. Brian Traw helped collect black mustards. Andrew Scherrer, Biostatistical Consultant, Biometrics Unit, Cornell University contributed statistical advice.

Feeding Selectivity by Mantled Howler Monkeys (*Alouatta palliata*) in Relation to Leaf Secondary Chemistry in *Hymenaea courbaril*

B. J. Welker · W. König · M. Pietsch · R. P. Adams

Received: 22 November 2006 / Revised: 9 March 2007 / Accepted: 20 March 2007 /
Published online: 14 April 2007

Abstract This study is a quantitative examination of primate feeding selectivity in relation to secondary chemistry within a single plant species, *Hymenaea courbaril*. It provides the first evidence that sesquiterpenes may act as feeding deterrents in mantled howler monkeys. A free-ranging group of mantled howler monkeys at the study site of Sector Santa Rosa, Area de Conservacion Guanacaste, Costa Rica were observed for the 2-month period of *H. courbaril* leaf flush in 1999. Tree characteristic data and leaf specimens were collected from 22 focal trees. Gas chromatography and mass spectrometry were used to estimate relative percentages of sesquiterpenes in leaf specimens. The monkeys fed only on the youngest leaves and only from particular trees. Whereas leaf stage selectivity was likely governed by tannin content and structural carbohydrates in younger and older leaf stages, respectively, differential tree use may be related to variability in sesquiterpene content. There is evidence that α-copaene may have played a role in interindividual tree use, and that cyperene may also be implicated. However, there is no reported evidence of antiherbivore activity for cyperene.

Introduction

Much research has been conducted in the area of primate feeding selectivity in relation to plant primary and secondary chemistry (see Milton 1998 for an overview). However, in relation to secondary chemistry, research has not advanced much beyond the role of phenolics and alkaloids, and analyses have often been qualitative rather than quantitative (see Calvert 1985 and Berry 1998 for exceptions). The limited focus on these two groups of compounds is puzzling because (1) plants produce a vast array of secondary compounds; (2) many families of secondary compounds have suspected or demonstrated antiherbivore functions; and (3) herbivorous primates feed from a variety of different plant families, many of which differ greatly in their chemistry.

This research is an examination of feeding selectivity in relation to secondary chemistry within a single plant species, *Hymenaea courbaril*, by mantled howler monkeys. The study was not confounded by the many differences between plant species or by other factors involved in primate dietary selection, e.g., food availability and preferences; plant density, location, phenology, production, and abundance; learned local traditions, etc. It is the first time that sesquiterpenes have been considered to play a role in primate dietary choice.

Mantled howler monkeys are generalist herbivores that exhibit pronounced inter- and intraspecific dietary selectivity for plant parts and stages (Milton 1998). They are thought to choose plant parts in a way that maximizes/balances nutritional intake, whereas minimizing intake of secondary compounds (Glander 1978, 1981; Milton 1978; Estrada 1984). In terms of leaf choice, Milton (1979) reports that the protein-to-fiber ratio is the most important determinant. Glander (1981, 1982) has provided evidence that some differential species/tree/leaf stage selectivity is related to the secondary chemistry of leaves (especially the presence/absence of condensed tannins and alkaloids). Milton (1998) suggests that whereas there is little evidence that secondary chemistry plays a role in primate dietary selectivity, detoxification is energetically demanding and animals might be expected to avoid foods that are relatively costly.

Mantled howler monkeys feed on leaves from some trees and not others within particular food species (Milton 1980; Glander 1981; Welker 2004). Glander (1981) demonstrated that leaves from unused trees contained condensed tannins. Welker (2004) reported pronounced differential tree use within the tree species, *H. courbaril*, by a group of mantled howler monkeys (the same group used in the present study). Her subjects fed exclusively on the first two to three pairs of young leaves, fresh out of the terminal bud, and only from particular trees during the 1997 and 1998 periods of leaf flush. Observed differential tree use was not related to tree size, degree of accessibility from surrounding trees, phenology (in terms of possessing the utilized plant part), leaf crop size, primary chemistry, and/or tree location in relation to group movements.

Here, we examined whether the previously observed differential tree and leaf stage use in Welker's study group was in response to differences in secondary chemistry and leaf stages within trees. Of interest was not whether the animals completely avoided particular compounds, because *H. courbaril* leaves are fed on, but whether there are maximum tolerance thresholds, either physiological or gustatory, that might explain selectivity within the species. Trees chosen for analysis were (1) differentially fed from during the previous two field seasons (Welker 2004), (2) located in a fairly continuous grove, and (3) predictable in terms of the period of leaf drop and flush with many trees reported to simultaneously possess young leaves during this time (Welker 2004).

Leaves of *H. courbaril* contain three types of secondary compounds, sesquiterpenes (Martin et al. 1972), tannins (Crankshaw and Langenheim 1981; McCloskey 1984), and flavonoids (Lopez 1976; McCloskey 1984; Artavia et al. 1995). Sesquiterpenes are the

primary component of the leaf resin (Martin et al. 1972). Langenheim (1981) believes that the resins/sesquiterpenes are an evolved defense mechanism. Several constituent sesquiterpenes, β-caryophyllene, caryophyllene oxide, α-humulene, humulene epoxide, α-selinene, and β-selinene, in *H. courbaril* have demonstrated herbivore deterrent capabilities (Langenheim et al. 1980; Barnola et al. 1994). Several others, β-cadinene, α-copaene, α-cubebene, and germacrene D, are inducible in response to herbivore damage (Barnola et al. 1994; Agelopoulos et al. 1999; Vrkočová et al. 2000). One of those, α-copaene, plus a variant isomer, δ-cadinene, may play a deterrent role in oviposition rates by two butterfly species (Ling et al. 2003), and δ- and γ-cadinene have suspected bactericidal capabilities (Haznedaroglu et al. 2001). Differential herbivore damage in a congener, *Hymenaea stigonocarpa*, has been attributed to variation in the concentrations of several sesquiterpenes, caryophyllene, humulene, selinenes, γ-cadinene, α-copaene, and α-cubebene (Langenheim et al. 1986). γ-Cadinene is one of the primary components of the defensive secretions of soldier termites of the species, *Constrictotermes cyphergaster* (de Asevedo et al. 2006; Quintana et al. 2003).

Whereas Glander (1981) reported that mantled howler monkeys, at his site of Hacienda La Pacifica, Costa Rica, chose foods that are low in tannins; he believes they are avoiding condensed vs. hydrolyzable tannins. Whereas *H. courbaril* leaves contain condensed tannins (Crankshaw and Langenheim 1981; McCloskey 1984), they are primarily found in the terminal bud where they account for more than 16% dry weight (DW). They decrease rapidly so that by the second pair of young leaves, they account for less than 1% DW (Crankshaw and Langenheim 1981). Glander (1981) states that young *H. courbaril* leaves at his study site, which is in the same region of Costa Rica and also classified as dry forest, do not contain condensed tannins. Langenheim (personal communication) claims that there is little variability in tannin content among trees within a microhabitat. Whereas monkeys may have been avoiding condensed tannins by not consuming the terminal buds, it appears unlikely that condensed tannins played an important role in the observed differential tree use because they occur at such low concentrations in the youngest leaves. Because tannins have not been suspected to play a role in differential tree use, and because there is no research to indicate that those flavonoid compounds found in *H. courbaril* act as feeding deterrents, we examined only sesquiterpene content of leaves in the present study.

Methods and Materials

Study Site The site is characterized as dry tropical deciduous forest (Janzen 1983) and is located in the Santa Rosa Sector of the Area de Conservacion Guanacaste, Costa Rica. Santa Rosa is located 35 km northwest of the town of Liberia, Guanacaste Province, in northwest Costa Rica.

Subjects The focal group was a free-ranging group of mantled howler monkeys. Animals included one male, three females, and one juvenile. All animals were recognizable as individuals in that they were collared or exhibited unique throat morphology or genital pigmentation.

Data Collection Two-minute point time samples (Altmann 1974) were used to record all instances of individual animals feeding on *H. courbaril* leaves. Data were collected during the 1999 period of leaf flush (14/I/99–22/II/99), yielding 136 observations (scans) of *H. courbaril* consumption.

Trees All 22 trees (1) possessed young leaves during the period of data collection, (2) were accessible from surrounding trees (as per Welker 2004), and (3) were located within a fairly

continuous grove that the monkeys passed through every few days during 3 yr of data collection (Welker 2004 and current study). During the 2 yr before the current study, Welker observed the monkeys' differential use of grove trees (Welker 2004). Whereas no data are available for which trees were fed from in 1997, in 1998 the monkeys fed from 9 of the aforementioned 22 trees (Welker 2004). The decision to use only grove trees eliminated the possible confound of the few nongrove trees being located in different microhabitats and thus possibly being exposed to different abiotic conditions.

Weekly phenological data were collected from all focal trees before, during, and after the period of leaf flush. Binoculars were used to estimate the volume of the crown (in 10% increments) made up of (1) leaves at the stage of development that the monkeys were observed to eat, and (2) mature leaves beyond the stage at which the monkeys fed. These two stages will hereafter be referred to as "young" vs. "mature" leaves. These data were used to determine whether trees possessed young leaves and hence were hypothetically "available" to the animals for consumption. Weekly estimates of herbivore damage by insects were collected. These were represented as the total percentage of leaf blade missing (0, <25, 25–50, 50–75, and >75%). Binoculars were used to scan the tree crown for evidence of missing leaf blade area, as evidenced by holes in the leaves. No tree exhibited more than 25% leaf blade loss. Equal numbers of trees exhibited either no damage or less than 25% damage and were thus categorized as "undamaged" ($N=11$) and "damaged" ($N=11$), respectively.

Leaf Specimens Young leaf specimens (3 g/tree) were collected. Specimens approximated the stage of development the animals were observed to eat, i.e., the first, second, and/or third pairs of leaves out of the terminal leaf bud that were ~2 cm in length and very tender. In addition, for six trees that the monkeys fed from, one specimen each of a younger and older leaf stage were collected. The younger stage consisted of 1 g of terminal leaf buds, and the older stage consisted of 1 g of the sixth or seventh pair of leaves out of the leaf bud. The monkeys were not observed to feed on either of these two stages.

All leaf specimens were field-dried in a dry-box by using a light bulb to reduce humidity. Langenheim (personal communication) and Adams (personal communication) recommended the air-drying procedure for field-processing *H. courbaril* samples for subsequent sesquiterpene extraction and analyses. Because sesquiterpenes exhibit only moderate volatility among the terpenoids, Langenheim and Adams have determined that they do not degrade with this technique. Samples were weighed before and after drying.

Laboratory Analyses The sesquiterpenes under examination are contained in the essential oils of the leaf resin. These essential oils were extracted at the Institut für Organische Chemie, Universität Hamburg, Germany. Samples were finely ground in a mortar and pestle with liquid N_2. One gram of ground young leaves was used for each individual tree analysis. Leaf samples were weighed with an Ohaus Analytical Standard Scale, accurate to 0.001 g. Samples were placed in 100 ml of deionized water and hydrodistilled for 3 hr in a Likens–Nickerson apparatus, from boiling point to heat source removal, using *n*-hexane as a collection solvent. Extracts were reduced to uniform volumes under a nitrogen gas jet.

Extracts were analyzed for sesquiterpene content with a Carlo Erba Strumentazione HRGC equipped with a Chrompak CPSil 5 fused silica capillary column (25 m×0.25 mm with a film thickness of 0.25 μm). The oven began at 50°C, after which temperature increased by 3°C/min until 230°C was reached. Hydrogen, with an inlet pressure of 70 kPa, was used as the carrier gas. Chromatograms were recorded with a Merck Hitachi model 2500 with FID electronic integrator. Some compounds were not detected in some specimens, either because they occurred at extremely low concentrations or because they lacked an individual peak.

Because of the resulting truncated data sets (values were missing for some compounds for some specimens), a maximum likelihood estimate (MLE) was substituted at the advice of Dr. Paul Kostyniak (toxicology consultant, SUNY Buffalo, Buffalo, NY, USA).

Mass spectrometric analyses (EI 70 ev) were conducted on a sample of specimens to ensure accurate identification of the gas chromatography peaks. Equipment consisted of a Hewlett-Packard HP 5890 gas chromatograph (CPSil 5 fused silica capillary column, 25 m × 0.25 mm, 0.25 μm film thickness) coupled to a VG Analytical 70-250S mass spectrometer.

All mass spectra were cross-referenced with the sesquiterpene mass spectral library (Joulain and König 1998). In addition, two samples were analyzed independently by Adams by using a Hewlett Packard MSD and his library of essential oils.

Gas chromatography results yielded the relative percentages of component sesquiterpenes in a given sample of essential oil, collectively summing to 100%. Values for individual compounds are relative to one another and not translatable into actual concentrations.

Data Analyses Some sesquiterpenes were combined for data analysis purposes as follows. Each of three oxidized analogs of caryophyllene, i.e., caryophyllene oxides 1, 2, and 3, were examined individually and in combination. In addition, the oxidized analogs were also included with β-caryophyllene, under the heading "total caryophyllene". Whereas caryophyllene oxide occurs naturally in *H. courbaril*, β-caryophyllene is readily converted into these oxidized analogs upon exposure to air (König, personal communication). Thus, some portion of the oxidized forms may have resulted from the rearrangement of β-caryophyllene. Langenheim et al. (1986) grouped caryophyllene and caryophyllene oxide together. α-Humulene and its oxidized analog, humulene epoxide, were also examined separately and together as "total humulene". Finally, α- and β-selinene were examined individually and in combination because Martin et al. (1974) reported that there does not appear to be any significance as to the relative concentrations of the two isomers and there is high variability within *Hymenaea*.

Results

Used vs. Unused Trees Table 1 shows mean relative percentages of the various sesquiterpenes identified in leaf specimens from used and unused trees along with *t*-test results. Specimens from unused trees contained significantly higher values for α-copaene and cyperene. For those trees that were fed from, frequency of use was not correlated with relative percentages of α-copaene ($R=-0.341$, $P=0.304$, $N=11$) or cyperene ($R=0.113$, $P=0.741$, $N=11$). However, when all trees were divided into three categories of use/nonuse (Fig. 1), there were significant or near significant differences between the groups for both α-copaene ($F=3.406$, $df=2$, $P=.054$, $N=22$) and cyperene ($F=3.826$, $df=2$, $P=.040$, $N=22$). Whereas there is an obvious pattern of use associated with α-copaene that may be indicative of a maximum consumption threshold (Fig. 1), cyperene shows no such pattern. The range of values for α-copaene were 0.31–4.16. No feeding scans were recorded for any tree whose leaves had >3% of the compound, and only four scans with >2.5% (three scans for one tree with a value of 2.53% and one scan with 2.98%). Only four unused trees had values of <2.5% vs. seven with values of >2.5%. In the case of cyperene, in all but four trees, values for cyperene were lower in used than unused trees. However, 11 feeding scans were recorded for the tree with the overall second highest relative percentage of cyperene, i.e., 1.74%.

Leaf Stage in Relation to Sesquiterpene Chemistry Young leaves were compared with buds and a more mature stage of development. No significant differences were found between

Selena 3,7-diene	6	0.16±0.0	0.02–0.29	0.22±0.0	0.02–0.38	1.14	0.266

df=20, significant values are in boldface and numbers of substituted MLE values for missing values are indicated

young and older leaves. However, values for cyperene (t=2.496, df=10, P=0.032) and selena 3,7-diene (t=3.034, df=9, P=0.014) were greater in buds relative to young leaves and those for γ-cadinene were near significant (t=2.348, df=10, P=0.056).

Leaf Damage in Relation to Sesquiterpene Chemistry and Tree Use Undamaged trees contained higher relative percentages of α-copaene, δ-cadinene, and γ-cadinene, and results for α-cubebene are nearly significant (Table 2). Whereas a chi-square test indicated that monkeys did not preferentially feed from undamaged trees (χ^2=1.636, df=1, P=0.201), only four trees categorized as undamaged were fed from vs. seven damaged trees.

Sesquiterpenes with Suspected Deterrent Function A discriminant function analysis was conducted to determine how well relative percentages of α-copaene and cyperene predicted tree

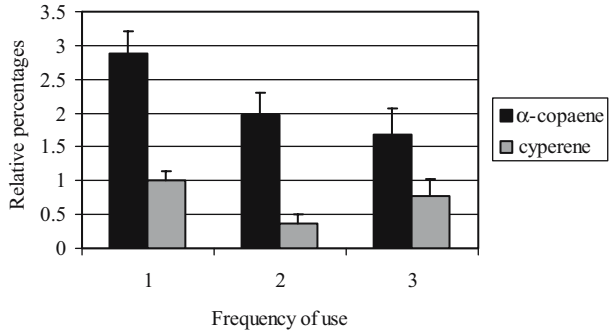

Fig. 1 Relative percentages of α-copaene and cyperene in three categories of use: 1=no scans, 2=1–5 scans, 3=>5 scans

use. Results were significant (Wilks Λ=0.642, χ^2=8.434, *df*=2, *P*=0.015). The discriminant function coefficients were 0.729 for α-copaene and 0.627 for cyperene based upon their degree of correlation with the discriminant function (0.781 and 0.687, respectively). The frequency distribution of the canonical variable for used and unused trees is presented in Fig. 2.

With the exception of α-copaene and γ-cadinene, all compounds implicated in differential insect leaf predation in *H. stigonocarpa* (Langenheim et al. 1986) are intercorrelated in leaf samples from used and unused trees in the present study (see Table 3). As noted, β-cadinene, α-copaene, and α-cubebene have been shown to be inducible in response to herbivorous damage (Barnola et al. 1994). Cyperene was not correlated with any of those compounds.

Discussion

Seventeen sesquiterpenes and several oxidized analogs were identified in young leaf specimens from the 22 study trees. Many are widespread in plant essential oils (δ-cadinene, γ-cadinene, β-caryophyllene, α-copaene, β-copaene, α-cubebene, β-elemene, germacrene D, α-guaiene, α-humulene, α-selinene, and β-selinene) whereas some are known from only one or two genera (cyperene) (Joulain and König 1998). Unused trees contained higher

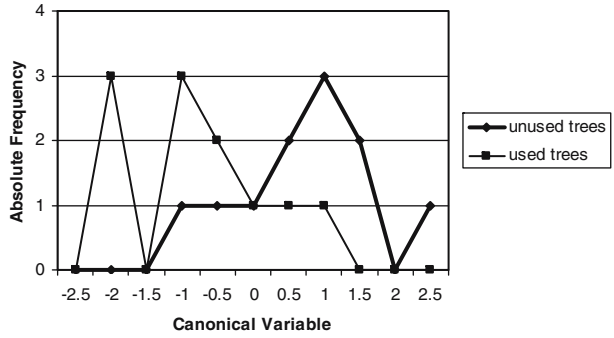

Fig. 2 Absolute frequency distribution of the canonical variable in the discriminant function analysis to determine how well relative percentages of α-copaene and cyperene predicted tree use

relative percentages of α-copaene and cyperene. For those trees that were fed from, no pattern was discernable between relative percentages of cyperene and frequency of tree use. However, in the case of α-copaene, those trees for which few feeding scans were observed (N=1–5 scans/tree) yielded intermediate values when compared with unused trees and more frequently used (N=6–44 scans) trees. These results, along with the relative percentage above which no consumption was observed, suggest the possibility of a dose-dependent effect on tree choice and frequency/duration of use. Whereas young leaves had significantly lower values for cyperene and selena 3,7-diene, when compared with terminal buds, it is difficult to ascertain whether those compounds played a role in bud avoidance as buds contain high concentrations of condensed tannins, and there is evidence of their avoidance by howler monkeys. As mentioned, the occurrence of cyperene is rare relative to other sesquiterpenes, and there are no known reports of a deterrent function. Selena 3,7-diene has not been reported to occur naturally but rather is the result of a rearrangement of β-selinene (Joulain and König 1998). Undamaged trees yielded higher values for α-copaene, δ-cadinene, and γ-cadinene. Finally, α-copaene and cyperene values were found to be predictive of tree use with α-copaene being the strongest predictor.

Langenheim and colleagues have established that populations and subpopulations within *Hymenaea* congeners can be categorized as different chemical "types" based upon the profile of their sesquiterpenes (see, for example, Crankshaw and Langenheim 1981, for a discussion of types). Little intrapopulational variation in sesquiterpene composition, in terms of being classified as one type or another, has been observed in Central American and dry forest *Hymenaea* populations (Martin et al. 1974). Whereas the amount of chemical variation observed in the present study may not be sufficient to qualify them as different

* P<.01

**P<.001

types, between-tree differences could render leaves from some trees more palatable to the monkeys than others.

There are three reported lines of evidence in support of an antiherbivore function for α-copaene: (1) the facultative production of α-copaene in response to defoliation (Barnola et al. 1994; Vrkočová et al. 2000), (2) differential insect predation in *H. stigonocarpa* trees (Langenheim et al. 1986), and (3) differential oviposition rates by two butterfly species (Ling et al. 2003). Whereas a facultative response is not conclusive evidence of a deterrent function, in that levels of α-copaene likely covary with other compounds that may play a deterrent or maintenance function, the differential leaf consumption by insects and monkeys and differential oviposition rates by butterflies lend support to a possible antiherbivore function for this compound. Interestingly, other compounds that were also implicated in the aforementioned inducibility experiments and differential insect predation and ovaposition rates (i.e., α-cubebene, δ-cadinene, and γ-cadinene) covaried in the present study. Whereas these other compounds did not appear to influence leaf choice by the monkeys, relative percentages were greater in undamaged trees, reinforcing a possible deterrent role for insects.

These results must be treated with caution. Observed differences between young leaf specimens and leaf stages were the result of comparing the relative percentages of compounds in essential oil extracts. Nothing can be concluded about the actual concentrations of those compounds in a given area of leaf blade. A second potential problem arises from the fact that Glander (unpublished data in Glander 1982) reports within-tree variability in leaf quality in relation to location within the canopy for some tree species. Thus, one leaf specimen per tree may not be representative of the average sesquiterpene chemistry of all young leaves in the crown. Whereas, Langenheim and colleagues found little experimental evidence of phenotypic plasticity in resin composition in response to variable abiotic conditions, e.g., light, photoperiod, temperature, and moisture (Stubblebine, unpub.; Langenheim et al. 1975, 1979), there were quantitative differences in resin production and hence the possibility of differing concentrations of the constituent sesquiterpenes.

Results for β-caryophyllene, α-humulene, and α-selinene are of interest in that they have known insect deterrent qualities and yet did not deter the monkeys. Mantled howler monkeys are of moderate size, and considering the relatively high proportion of leaves and flowers in their diet, it seems likely they possess the ability to detoxify a variety of plant secondary compounds.

With regard to leaf stage selectivity, the high concentration of condensed tannins in leaf buds likely precluded their consumption, regardless of sesquiterpene content. Total phenolics and condensed tannins drop from 16% DW to less than 1% DW by the second leaf pair, whereas individual sesquiterpenes may increase or decrease (Crankshaw and Langenheim 1981). Resin yield decreases as leaves become more mature and sesquiterpene and phenolic compounds level off. Mature leaves are tough and, other than some saturniid moth larvae, no herbivores have been observed to feed on them (Janzen 1983). They do not appear to be better defended chemically relative to young leaves. Crankshaw and Langenheim (1981) report that leaf toughness increases between the third leaf pair and the fourth to sixth pairs. Monkeys were not observed to eat leaves beyond the third pair. Whereas Welker (2004) concluded that leaf toughness did not play a role in differential tree use in *H. courbaril*, she considered only toughness of young leaves. Thus, toughness of mature leaves may have played a role in leaf stage selectivity.

In summary, results for α-copaene suggest it as a possible factor affecting palatability and consumption in monkeys. Once the range of concentrations of this compound is determined for this tree species, it must be determined if there is a maximum acceptance

threshold for α-copaene and whether this threshold approximates levels in the leaves of unused trees. With reference to plant part selectivity, the youngest leaves contain lesser amounts of total phenolics, condensed tannins, and certain sequiterpene compounds, relative to the terminal leaf buds. In addition, they are less tough and contain more protein and moisture than mature leaves (Crankshaw and Langenheim 1981). Thus, the animals were feeding on the leaf stage that was of high nutritional value, low in chemical defenses relative to buds, and low in mechanical defenses relative to mature leaves, and appeared to be choosing between individual plants and parts/stages in relation to their primary and secondary chemistry.

Acknowledgement BJW thanks the administration and staff of Sector Santa Rosa for their assistance and permission to conduct fieldwork. Assistance with plant specimen analyses was provided by Paul Kostyniak, Jean Langenheim, Claudia Paul, and Annagret Meiners. Ken Glander and Linda Fedigan provided advice, guidance, and animal tagging. Special thanks to the following field assistants: Bertha Fearon, Graeme Hunt, Alex Perez, and Tanya Smith. Carol Berman provided guidance in the preparation of Welker's dissertation of which this study is a part. Financial support was received from NSF, Sigma Xi, Graduate Student Association of SUNY Buffalo, the Trimble Corp., and various grants from SUNY Geneseo.

Relative Availability of Tannin- and Terpene-containing Foods Affects Food Intake and Preference by Lambs

Abstract The availability of different forages varies across landscapes, but little is known about how proportional consumption of different foods affects food intake and the use of landscapes. The relative amounts of nutrients and plant secondary metabolites (PSM) consumed by herbivores may influence forage intake and animal fitness in landscapes dominated by plants with PSM. Our objective was to determine if the relative availability of nutritious foods that contain PSM affected food preference and intake by lambs. Lambs in three treatments (eight lambs/treatment) were offered two PSM-containing foods at different relative availabilities: treatment 1—*ad libitum* terpene- and 100-g tannin-containing food, treatment 2—*ad libitum* tannin- and 100-g terpene-containing food, and treatment 3—*ad libitum* access to both tannin- and terpene-containing foods. We measured intake of individual foods and total intake of PSM-containing foods during conditioning and a preference test, where animals were offered both PSM-containing foods *ad libitum*. When lambs were fed 100 g of the tannin-containing food, they ingested more terpene and total PSM ($P<0.05$) than when both PSM were offered *ad libitum*, but limiting terpenes did not affect intake of tannin or total intake of PSM ($P>0.10$). During preference tests, all groups preferred tannins over terpenes, but lambs in the treatment fed 100 g of tannin had a higher preference for terpenes than did lambs in the other two treatments ($P<0.10$). These results support the notion that the relative amounts of PSM consumed affects intake and preference for PSM-containing foods by herbivores.

Introduction

All plant species contain plant secondary metabolites (PSM) that limit herbivory and can be toxic at high doses (Cheeke and Schull 1985; Foley et al. 1999). To maintain health, grazing animals must regulate intake of PSM. The variable degree to which herbivores cope with PSM creates differential use of plant species, potentially shifting the balance of competition among plant species in ways that can change ecosystem structure (Council for Agriculture Science and Technology 2002; Villalba et al. 2004). As ecosystems become dominated by invasive plants high in PSM, alternative forages decline because of increased competition and grazing pressure. Ever-decreasing plant diversity further compromises the ability of animals to regulate intake of PSM and meet demands for nutrients (Dearing and Cork 1999; Burritt and Provenza 2000; Villalba et al. 2004), which further increases grazing pressure on palatable plants (Provenza et al. 2003a).

Liver biotransformation and rumen degradation both help herbivores ingest plants with terpenes and tannins. In the liver, PSM are processed through two different detoxification pathways (Freeland and Janzen 1974; Dearing and Cork 1999; Burritt and Provenza 2000; Villalba et al. 2004). In mammals, biotransformation of PSM is carried out in the liver and usually occurs in two steps. The first step (phase I) introduces a reactive group—such as OH, NH_2, COOH, or SH—into the structure of the PSM such that the PSM is made more hydrophilic and polar. During the second step (phase II), the newly formed compound is conjugated with endogenous molecules or groups—glucuronic acid, amino acids, sulphates, or methyl groups—that are hydrophilic (Osweiler et al. 1985). PSM such as terpenes are processed primarily via the phase I pathway, whereas tannins are processed by the phase II pathway (Sipes and Gandolfi 1986). Condensed tannins are large molecules normally not absorbed in the gastrointestinal tract; some are degraded and absorbed to a degree, yielding postabsorptive (potentially toxic) effects (Mehansho et al. 1987; Clausen et al. 1990). Finally, diverse microbial populations in the foregut also are important for PSM biotransformation in ruminants. Terpenes (Johnson et al. 1976; Dizba et al. 2006) and tannins (Foley et al. 1999) both are detoxified by microbes in the rumen.

Previous research suggests that total intake of PSM is higher when tannins and terpenes are fed together rather than when fed in isolation (Villalba et al. 2004; Mote et al. 2007), which suggests that the relative amounts of PSM in a landscape play a key role in how herbivores use forages. Postingestive feedback responses likely are sensitive enough to regulate proportional intake of different PSM (Marsh et al. 2006), as they do with protein and energy (Villalba and Provenza 1999; Provenza and Villalba 2006).

Multiple food alternatives increase sheep intake of foods that contain PSM (Burritt and Provenza 2000; Villalba et al. 2004), perhaps because PSM have different effects in the body and are detoxified by different mechanisms (Freeland and Janzen 1974). Most PSM satiate herbivores (Provenza et al. 2003b); once a threshold of PSM intake is reached, an animal will stop eating the food with that PSM until detoxification is achieved (Foley et al. 1999; Wiggins et al. 2006a, b, c). Satiation on specific PSM in foods may create mild to strong food aversions that decrease subsequent intake and preference for those foods (Provenza 1996). Thus, animals exposed too frequently or to too large a quantity of a specific PSM will satiate on food with that PSM, decreasing their preference relative to an alternative PSM-containing food.

We compared consumption of two PSM-containing foods that varied in availability. We hypothesized that the relative abundance of the two PSM-containing foods—tannins and terpenes—would influence the total amount of food consumed as well as preference for each food. We predicted lambs would decrease their preference for the PSM available

ad libitum and that PSM consumed below satiation thresholds would be preferred, as they were not eaten in amounts high enough to promote aversions.

Methods and Materials

The experiment was conducted with weaned commercial crossbred lambs, averaging 35 kg (SEM=1.09), at the Mote Farm in Willard, UT (NAD 83 UTM 12 T 0413040 4583816). Lambs were individually penned with free access to trace mineralized salt blocks and fresh water. All procedures were approved by the Utah State University Institutional Animal Care and Use Committee.

Test Foods Test foods were formulated to be similar in PSM and nutrient contents to plants found in the sagebrush steppe ecosystem. We used two isocaloric (2.9 Mcal digestible energy/kg dry matter [DM]) and isonitrogenous (126 g crude protein/kg DM; NRC 1985) test foods that contained either tannins or terpenes, similar to those described by Villalba et al. (2004). The tannin-containing food (dry weight) was 76% beet pulp, 9% soybean meal, and 15% quebracho tannin powder. The terpene-containing food (dry weight) was 52.8% beet pulp, 26% grape pomace, 14% soybean meal, and 7.2% of a terpene solution where camphor (18.2 mg/g diet), 1–8 cineole (12.0 mg/g diet), and *p*-cymene (0.7 mg/g diet) were dissolved in 4.1% of vegetable oil. Terpene volatilization was reduced by mixing terpenes with vegetable oil, which also improved terpene homogeneity in the diet (Kimball et al. 1998). All ingredients were ground to 2- to 3-mm particle sizes to facilitate mixing.

Conditioning Twenty-four lambs were stratified by weight and randomly assigned to three treatments (eight lambs/treatment) that differed in the amounts of the tannin- and terpene-containing foods they received: treatment 1—terpene food *ad libitum*, 100 g of the tannin food; treatment 2—tannin food *ad libitum*, 100 g of the terpene food; treatment 3—tannin and terpene foods *ad libitum*. One lamb in treatment 1 was removed from the study because it consistently refused to eat any of the test foods. All lambs were offered both foods simultaneously for 4 hr, beginning at 06:00 each morning, for 12 d. Alfalfa pellets were offered at 10:00 for the first 3 d, at 500, 300, and 150 g $lamb^{-1}$ d^{-1}, respectively, to ensure lambs maintained ruminal health while being introduced to the novel foods. After day 3, all lambs were fed only their respective diets.

Preference Tests After conditioning, all animals were fed alfalfa pellets *ad libitum* from 06:00 to 10:00 for five consecutive days to allow for toxin elimination. The retention time of quebracho tannin in the gastrointestinal tract ranges from 48 (free and soluble) to 72 hr (bound to protein and fiber; Silanikove et al. 1994, 1996). The average primary and terminal elimination half-lives of plasma terpene concentrations is on the order of minutes after terpenes are infused into the rumen or blood stream (Dizba et al. 2006).

We wanted to determine lambs' preferences for tannin- and terpene-containing foods as a function of their prior experience during conditioning, so we offered all lambs a choice between the terpene- and tannin-containing foods for 30 min/d on three consecutive days immediately after the 5-d toxin elimination period. The diet fed during preference tests was the same diet lambs in treatment 3 were fed during conditioning. After preference tests, lambs were fed alfalfa pellets until 10:00, when refusals were collected and no other food was offered until the next day.

Statistical Analyses Data were analyzed as a split-plot design with three treatments (*ad libitum* terpenes, restricted tannins; *ad libitum* tannins, restricted terpenes; *ad libitum* tannins and terpenes) as the whole-plot factor; lambs were nested within treatments. Day was the subplot. Intake of individual foods and total intake of PSM-containing foods were the response variables for both the conditioning and preference trials. Refusals were subtracted from the amount of food offered to calculate grams of food ingested per kilogram body weight (BW). Preference was computed as: [intake of a single-toxin containing food/total intake of toxin-containing foods]×100. Analyses of variance (ANOVAs) were completed by using the MIXED procedure in SAS 9.1 for Windows (SAS, Littell et al. 1996). Data were analyzed with standard procedures for unbalanced ANOVA because of the removal of a lamb from treatment 1. Assumptions of normality and homogeneity of variance were met in normal probability plots and plots of residuals against predicted values.

Results

Conditioning Averaged across the 12 d of conditioning, lambs in treatment 1 that were offered a restricted amount of tannins and *ad libitum* amounts of terpenes ate more terpene-containing food (17.4 g/kg BW; SEM=2.1) than lambs in treatment 3 that were offered both the tannin- and the terpene-containing foods *ad libitum* (5.3 g/kg BW; SEM=2.0; $P<0.05$, Fig. 1). Intake of tannins by lambs in treatment 2 fed *ad libitum* amounts of tannins and restricted amounts of terpenes (8.7 g/kg BW; SEM=1.14) did not differ from that of lambs in treatment 3 (9.4 g/kg BW; SEM=1.14; $P>0.05$, Fig. 1). Averaged across days, lambs in treatment 1 ate more total PSM-containing food (20.2 g/kg BW; SEM=1.7) than lambs in treatments 2 (10.6 g/kg BW; SEM=1.6) or 3 (14.7 g/kg BW; SEM=1.6; treatment effect $P<0.001$; Fig. 1). By day 9, ten lambs had diarrhea—five each in treatments 2 and 3. After lambs were offered alfalfa pellets for 5 d, all signs of diarrhea disappeared.

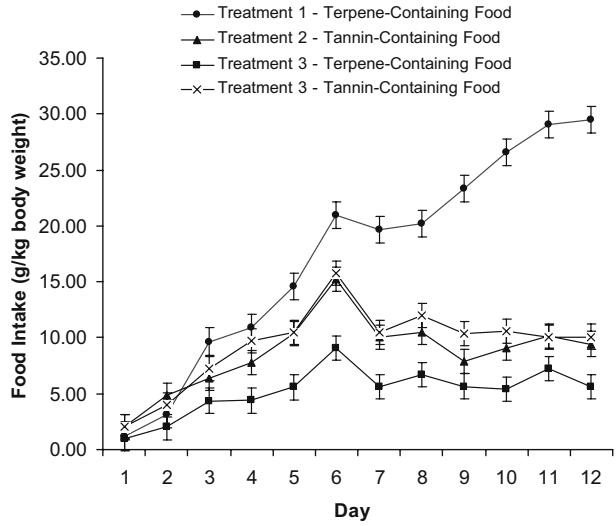

Fig. 1 Daily intake of terpene- and tannin-containing foods by three groups of lambs during 12 d of conditioning. Lambs in treatment 1 (*ad libitum* terpenes, restricted tannins), were offered the terpene-containing food *ad libitum* and only 100 g of tannin-containing food. Lambs in treatment 2 (*ad libitum* tannins, restricted terpenes) were offered the tannin-containing food *ad libitum* and only 100 g of the terpene-containing food. Lambs in treatment 3 were offered both the tannin- and the terpene-containing foods *ad libitum*

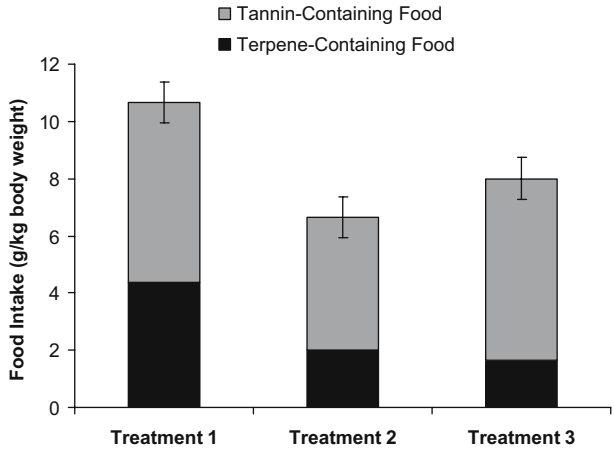

Fig. 2 Intake of terpene- and tannin-containing foods by three groups of lambs during preference tests. During conditioning, lambs in treatment 1 (*ad libitum* terpenes, restricted tannins) were fed the terpene-containing food *ad libitum* and only 100 g of tannin-containing food. Lambs in treatment 2 (*ad libitum* tannins, restricted terpenes) were offered the tannin-containing food *ad libitum* and only 100 g of the terpene-containing food. Lambs in treatment 3 were offered both the tannin- and the terpene-containing foods *ad libitum*

Preference Tests When offered a choice, lambs in all treatments preferred the tannin- to the terpene-containing food, but the differences were less pronounced for treatment 1 (*ad libitum* terpenes, restricted tannins: 59%, $P<0.15$) than for treatments 2 (*ad libitum* tannins, restricted terpenes: 70%, $P<0.10$) and 3 (*ad libitum* tannins and terpenes: 79%, $P<0.05$). Although all lambs preferred tannins to terpenes, lambs in treatment 1 ate more terpene food than lambs in treatments 2 or 3 ($P<0.10$; Fig. 2). Lambs in the three treatments did not differ in intake of the tannin food ($P=0.22$), nor did intake of the terpene food differ for lambs in treatments 2 and 3. Total daily consumption of food with PSM was greater for lambs in treatment 1 (10.7 g/kg BW) than for lambs in treatments 2 (6.7 g/kg BW) or 3 (8.0 g/kg BW; $P=0.002$; Fig. 2).

Discussion

We determined whether the availability of two foods with different PSM affected total food intake and the food preferences of sheep. We hypothesized that the relative amount of tannins and terpenes ingested would influence the amount of food consumed as well as preference for each food. We predicted that lambs would decrease their preference for the PSM available *ad libitum* and that the PSM available in restricted amounts would be more preferred than the PSM available *ad libitum*, as the former were not eaten in amounts high enough to promote satiety and ensuing food aversions (Provenza 1996).

We found that lambs in all treatments preferred the tannin- to the terpene-containing food, but the preference was less pronounced for treatment 1 (restricted tannin, *ad libitum* terpenes) than for treatment 2 (*ad libitum* tannins, restricted terpenes) than for treatment 3 (*ad libitum* tannins and terpenes). The combination of restricted tannins/*ad libitum* terpenes enhanced overall food intake to a greater extent than *ad libitum* tannins/restricted terpenes or *ad libitum* tannins and terpenes. Our results suggest specific flavor-feedback characteristics of the foods, as well as the amount and possibly the order in which they were ingested, influenced intake by lambs of foods that contained tannins and terpenes.

During conditioning, the tannin-containing food induced satiety at a lower level of intake than did the terpene-containing food (Fig. 1). As tannin intake increased relative to

terpene intake, total food consumption decreased indicating an antagonistic relationship between the tannin- and terpene-containing foods. While high intake of tannins (or terpenes) may cause rumen stasis and a general state of anorexia, this was not the case in this study, as lambs in all treatments ate alfalfa pellets readily after conditioning, nor was this the case in previous studies when lambs fed tannin- and terpene-containing foods ate comparable amounts to lambs fed the same nutritious basal foods without these PSM (Villalba et al. 2002a; Shaw et al. 2006a). Rather, Villalba et al. (2004) found that total intake of PSM was higher when tannin- and terpene-containing foods were fed in combination rather than alone. In that study (Villalba et al. 2004), intake of food with terpenes was similar whether terpenes were fed alone or fed with tannins, but the amount of tannin-containing food offered was not restricted; thus, higher tannin intake likely prevented further consumption of terpenes.

In the current study, intake of the terpene-containing food was three times higher when lambs were fed limited tannin and *ad libitum* terpene (treatment 1) than when they were fed *ad libitum* tannin and terpene (treatment 3). Conversely, when terpene was limited and tannin was fed *ad libitum* (treatment 2), tannin consumption was not enhanced relative to *ad libitum* tannin and terpene (treatment 3). Thus, by limiting the availability of the tannin-containing food, tannins were no longer the intake-limiting agent, and the high intake of the terpene-containing food likely was due to a neutralizing effect of a small amount of tannins on the negative effects of terpenes.

Lambs preferred tannins to terpenes, so they likely consumed tannins before terpenes in a meal. If so, tannins in the rumen may have ameliorated the negative effects of terpenes. This hypothesis, while requiring further testing, is consistent with findings of Mote et al. (2007), where tannins and terpenes were fed in different sequences. In that study, the highest PSM consumption occurred with the meal sequence tannin-containing food→ terpene-containing food→nutritious food. Tannins likely bind to small amounts of terpenes reducing their effective concentration or increasing their rate of elimination, allowing sheep to eat more terpene-containing foods. Animals in treatment 3, fed *ad libitum* tannin, likely ingested more tannin than necessary to enhance terpene intake, explaining their lower total intake of PSM-containing food compared with lambs in treatment 1 fed with restricted tannin and *ad libitum* terpene.

Tannins are large molecules (molecular weights from 2,000 to 4,000) that remain in the rumen for many hours (Kumar and Singh 1984; Min and Hart 2003), whereas terpenes are small fat-soluble molecules (Foley and McArthur 1994) absorbed within minutes through the rumen epithelium (Dizba et al. 2006). Tannins are highly reactive molecules that once in the gut are likely to interact with terpenes. Tannins form complexes, mainly through hydrophobic/hydrogen interactions, with a wide variety of compounds including polysaccharides, nucleic acids, alkaloids, and minerals (Okuda et al. 1982; Min and Hart 2003). They also bind to and denature proteins (Jones and Mangan 1977; Burrows and Tyrl 2001). In so doing, they can reduce the production of volatile fatty acids (energy) and the supply of nitrogen (protein) adversely affecting the nutrition of herbivores (Foley et al. 1999).

At appropriate doses, however, tannins can improve the protein status of herbivores, thereby enhancing their ability to consume foods with PSM (Foley and McArthur 1994; Foley et al. 1999; Provenza et al. 2003b). Sheep and goats provided foods high in protein or given a choice between foods high in protein or energy, consume more tannins and terpenes than those fed only with high-energy foods (Villalba et al. 2002a, b). Moderate levels of tannins protect proteins from degrading in the rumen (Barry et al. 2001), which can improve the supply of high-quality amino acids to the abomasum and small intestines (Min and Hart 2003). In our study, tannin- and terpene-containing foods had soybean meal, a rich

source of protein extensively degraded in the rumen (Nocek and Russell 1988). Rumen degradation of protein results in ammonia formation with subsequent loss of nitrogen in the urine (Satter et al. 1999). By binding to the protein in soybean meal, tannins may have protected proteins from degrading in the rumen and improved the supply of high-quality amino acids to the abomasum and small intestines, thus enhancing protein status and increasing terpene consumption by lambs in treatment 1.

Tannins were preferred to terpenes by all groups, but the differences were less pronounced for treatment 1 (59%) than for treatment 2 (70%) than for treatment 3 (79%). Flavor-feedback interactions likely initiated and then maintained the stronger preferences of lambs in treatments 2 and 3 for tannins over terpenes. The flavor of terpenes likely was sufficiently strong to cause lambs to prefer tannins over terpenes in treatments 2 and 3 where lambs were offered tannins *ad libitum*. Conversely, lambs in treatment 1 that were fed limited tannin and *ad libitum* terpene experienced greater exposure to the salient flavor of the terpenes in addition to the postingestive benefit from tannin–terpene interactions. These experiences collectively caused their higher preference for terpenes. This interpretation is consistent with two observations: (1) Several weeks are required for sheep to adapt to the flavor/postingestive consequences of eating foods high in terpenes (Banner et al. 2000) and (2) intake of foods with terpenes increases when alternative foods are restricted (Villalba et al. 2004; Shaw et al. 2006a, b).

Conversely, preference for tannins and avoidance of terpenes during conditioning reduced the ability of lambs in treatments 2 and 3 to maximize food intake. Indeed, their preference for tannins over terpenes caused diarrhea in over half of the lambs in those treatments, whereas no signs of diarrhea were observed in lambs under treatment 1. Fiber digestion in the rumen of sheep is depressed when condensed tannin concentrations reach 4% of DM intake (Roberts and Olson 1999), and tannins (Foley et al. 1999) and terpenes (Nagy and Tengerdy 1968) likely affect rumen bacteria selectively, influencing the ability of herbivores to consume the alternative PSM.

Our present and previous findings (Mote et al. 2007), and those of others (Wiggins et al. 2006a, b, c), suggest that the patchiness of plants with different secondary compounds is important in the foraging behavior of herbivores. Landscapes are mosaics of plant species with varied densities, diversities, and chemistries. Herbivores must move from patch to patch to maintain a balance of macro- and micronutrients. Meanwhile, they must cope with potentially toxic PSM. Preferences for various PSM can change dramatically when PSM are eaten in the right proportions and at the right times. Understanding both the spatial and the temporal contexts that lead to synergy may enable managers of ecological systems to create and maintain mixtures of plant species in a more even manner, creating greater biochemical diversity and reducing the competitive advantage of less-palatable plants that contain high concentrations of toxins.

There is growing appreciation of the importance of interactions between ecosystem chemistry and herbivores (Provenza et al. 2003a). Functional response models predict that food intake is a monotonically increasing function of plant density that asymptotes at maximum intake (Holling 1959). Thus, as the density of a chemotype in a plant community increases, the relative consumption of that chemotype decreases and vice-versa. The proportional disappearance of a plant species through herbivory is inversely related to its density (Provenza et al. 2003a). When the biomass of a chemotype reaches a certain critical amount (escape threshold), that species is increasingly protected from deleterious herbivory, leading to relatively high and ever-increasing use of less-abundant species (Provenza et al. 2003a). Herbivores become quickly satiated on the abundant chemotype and depend upon other complementary chemotypes to maintain appropriate nutrition (Provenza et al. 2003a, b).

The preference for rare species does not necessarily increase, yet they may still be driven to extinction because of their rarity (Provenza et al. 2003a). These processes affect the structure and function of ecosystems (CAST 2002; Villalba et al. 2004), which in turn affect the ability of herbivores to meet their nutritional requirements.

Our study suggests that landscapes high in terpene-containing plants and low in tannin-containing plants may be used differently from ones high in tannins and low in terpenes. Herbivory in a high-terpene/low-tannin system would exert extreme pressure on the tannin components, perhaps to the point of extinction. Assuming plants are equally tolerant of herbivory, at some threshold of plant abundance for tannins and terpenes, as tannins become increasingly rare, the likelihood of tannin-containing plants disappearing from the system increases. A possible synergistic combination could be created in this situation such that herbivores offered limited amounts of tannin could increase pressure on terpene-containing plants helping maintain system stability. The alternative situation (high tannins/low terpenes) would be much more difficult to manage, as terpenes would likely have little influence on the use of tannin-containing plants, and terpene-containing plants may be used to the point of extinction. Thus, extinction rates for terpene-containing plants may be lower than for tannin-containing plants. This hypothesis could be tested with shrubs high in tannins (e.g., bitterbrush, *Purshia tridentata*, and oakbrush *Quercus* spp.) and high in terpenes (e.g., sagebrush, *Artemisia tridentata*). These shrubs codominate much of the sagebrush steppe ecosystem, which occupies nearly 1.1 million km^2 of the western USA and Canada (Meyer and Karasov 1991). Consistent with the proposed interaction between terpenes and tannins, a previous study has shown that sheep manifesting a high preference for sagebrush (terpenes) consume more bitterbrush (tannins) than sheep manifesting a low preferences for sagebrush (Seefeldt 2005).

Finally, our results suggest that tannin-containing plants, such as bitterbrush and oakbrush, may be valuable components of landscapes in the development of grazing systems in the sagebrush steppe ecosystem. By combining the proper proportions of PSM and nutrients, in the right sequence, mangers can potentially optimize the use of dominant plant species with PSM. In our study, a small amount of tannins increased the ability of lambs to consume terpenes, whereas a small amount of terpenes had no such beneficial affect on tannin consumption. Therefore, some dietary mixtures, amounts, and sequences are likely to be more favorable than others nutritionally and physiologically. Thus, we hypothesize that grazing systems that combine limited tannins and large meals of terpenes will more evenly use landscapes high in terpene-containing plants, reducing their competitive advantage and increasing the plant diversity of those landscapes.

Abstract The pinewood nematode (PWN), *Bursaphelenchus xylophilus*, the most important invasive species in pine forests of Asia, is transported to new pine hosts by beetles of the genus *Monochamus*. Third-stage dispersal juveniles (J_{III}) aggregate in pupal chambers around the vector as it matures. We demonstrated that the ratio of three terpenes (α-pinene, β-pinene, and longifolene at 1:2.7:1.1) released by larval *Monochamus alternatus* strongly attract J_{III}, whereas the different ratio (1:0.1:0.01) of these three terpenes found in healthy xylem of *Pinus massoniana* attracts only the propagative stage (J_n) of the nematode. We suggest that the volatiles produced by the host plants could be the basis of a chemoecological relationship between plant parasitic nematodes and their vector insects. Capture of J_{III} with terpene-baited trap tubes deployed for 2 hr in the field was demonstrated. This technique may lead to the development of rapid sampling methodologies for use at either ports-of-entry or in the field.

Introduction

The pinewood nematode (PWN), *Bursaphelenchus xylophilus*(Steiner and Buhrer) Nickle (Tylenchida: Aphenlenchoididae), the causal agent of the destructive pine wilt disease, is native to North America but was introduced to Japan, South Korea, and China, where it has caused irreparable damage to forested ecosystems (Kiyohara and Tokushige 1971; Sun 1982, 2005). It is the most important invasive species in the pine forests of Asia and is

listed as a quarantine pest in more than 40 countries (Rautapaa 1986; Dwinell 1997; Mota et al. 1999; Schrader and Unger 2003; Yang et al. 2003).

There is no cure for pine wilt disease once a susceptible tree becomes infested with the pinewood nematode. Management of the disease is primarily limited to preventing the introduction and spread of the nematode. The PWN is dispersed to uninfested host pines by its vectors, longhorned beetles in the genus *Monochamus* (Coleoptera: Cerambycidae) (Kobayashi et al. 1984; Linit 1988; Necibi and Linit 1998; Yang et al. 2003; Sun 2005). In Japan and China, *Monochamus alternatus* Hope is the most important vector of *B. xylophilus* (Kobayashi et al. 1984; Sun 2005). Mortality of pine trees caused by the propagative stage (J_n) provides oviposition resources for *Monochamus* (Kobayashi et al. 1984; Linit 1988). As an infested pine dies, the availability and quality of both food and moisture decline, and PWN third-stage juveniles (J_{III}), adapted for dispersal, are produced. These J_{III} aggregate in *Monochamus* pupal chambers as the chambers are formed in the outer xylem by mature *Monochamus* larvae (Mamiya 1972; Linit 1988). In synchrony with beetle eclosion, PWN (J_{III}) molt to the dauer larval stage (J_{IV}) and enter the tracheae of the beetle to be carried to other pine trees (Linit 1988; Necibi and Linit 1998; Yang et al. 2003). The species of *Pinus* attacked, as well as the *Monochamus* spp. utilized as vectors by PWN across its native and invasive ranges, differ (Dwinell 1997; Sousa et al. 2001; Yang et al. 2003). To date, the chemical ecology of *B. xylophilus* in the areas it has invaded has not been studied in detail.

Chemotaxis plays an important role in host location by nematodes during certain phases of their life cycles (Zuckerman and Jansson 1984; Perry 1996). The primary mechanism involves response to chemotactic factors emanating from the host (Zuckerman and Jansson 1984; Grewal et al. 1994; Perry 1996; Zhao et al. 2000). Futai (1980) reported that the J_n of PWN were attracted by the sap of healthy host pines, but they did not identify the chemical basis of the attraction. Chemotaxis by predatory nematodes can occur across a tri-trophic level, through orientation to metabolites given off by plants fed upon by host insects (van Tol et al. 2001; Boff et al. 2002). Maize roots damaged by weevil larvae, *Diabrotica virgifera virgifera* LeConte, release (*E*)-β-caryophyllene, which attracts the animal-parasitic nematode *Heterorhabditis megidis*, thereby bringing the nematodes in close proximity to their prey weevil larvae (Rasmann et al. 2005). In a similar fashion, PWN is transported to new host pines by exploiting chemicals from vector beetles (Miyazaki et al. 1977; Bolla et al. 1989; Necibi and Linit 1998; Stamps and Linit 2001). Effective location of *Monochamus* pupal chambers by third-stage dispersal juveniles (J_{III}) is of primary importance in maintaining the host–vector relationship and allowing exploitation of new host pines (Miyazaki et al. 1977; Bolla et al. 1989). However, species-specific volatile attractants of J_{III} have not yet been identified (Mamiya 1972; Miyazaki et al. 1977; Linit 1988; Bolla et al. 1989; Stamps and Linit 2001).

The objectives of this study were to identify volatiles released by larvae of the vector *M. alternatus* and xylem of the host pine *Pinus massoniana* Lambert, and to determine the effects of these compounds on the chemotaxis of J_{III} and J_n PWN.

Methods and Materials

Insects, Nematodes, and Host Materials In April 2005, fifth instars of *M. alternatus* were obtained from Anhui Province of China. PWNs were obtained from Zhejiang, China. J_{III} were extracted from *M. alternatus* pupal chambers. J_n were cultured with the fungus *Diplodia* sp.

Wood samples of *P. massoniana* were obtained from Anhui, China. Xylem from the walls of *M. alternatus* pupal chambers was collected by drilling to a depth of 10 mm around pupal chambers. Xylem samples containing unidentified species of blue-stain fungi were also collected from regions of dead logs lacking *Monochamus* pupal chambers. Healthy xylem samples were collected from uninfected trees at roughly the same depth as the pupal chambers.

Artificial pupal chambers containing J_{III} were constructed and used for bioassays (Aikawa and Togashi 1997; Jikumaru and Togashi 2003). A hole (4 cm deep and 1-cm diameter) was drilled in the center of the cut ends of healthy *P. massoniana* bolts (5 cm long, 2.5-cm mean diam). The bolts were autoclaved at 121°C for 30 min, then inoculated with *Diplodia* sp. Two weeks later, 3,000 J_n were inoculated into each chamber and the bolts kept at 25°C in the dark for 2 mo.

Chemicals The chemicals used in gas chromatography-mass spectroscopy (GC-MS) analyses and bioassays included various alkanes (Beijing Chemical Plant, >95%), α-pinene (Acros Organics, 98%), β-pinene (Fluka Chemie AG, 80%), longifolene (Acros Organics, 99%), butylated hydroxytoluene (Acros Organics, 99%), and camphor (Acros Organics, 97%). Brilliant Blue R (2%) used to stain the nematode secretions was obtained from Sigma-Aldrich.

Volatile Collection and Analyses To investigate the chemotaxis of J_{III} PWN, we collected volatile samples from both fifth instars of *M. alternatus* and empty *M. alternatus* pupal chambers, as well as from blue-stained and healthy xylem samples of *P. massoniana*, by the Super Q method. Individual *M. alternatus* larvae used for the collection were removed from wood over 2 d. Fresh *P. massoniana* wood samples were harvested immediately before aeration. Samples were aerated in glass vacuum traps (9-cm diam., 100 cm long). A glass pipette containing Super Q (Alltech Associates Inc., Deerfield, IL, USA) was attached to the outlet of the trap. Air, filtered through activated charcoal, was drawn through the apparatus with a QC-1 gas sampler (Beijing Municipal Institute of Labor Protection, Beijing, China) at a rate of 500 ml/min. Samples were aerated for 3 hr. The Super Q cartridges were eluted with *n*-hexane (Fisher Chemicals, 99%), and the resulting extracts stored at −20°C until needed (Lacey et al. 2004).

Volatile collections from either 10 insects or 10 pine samples were combined, dehydrated and concentrated to 250 μl. One microliter of each extract was analyzed by GC-MS with an Agilent 6890N GC coupled to a 5973 mass selective detector. The GC was fitted with a DB5-MS capillary column (0.25 mm i.d.×60 m; Agilent Technologies Inc. Palo Alto, CA, USA), and the column temperature was programmed from an initial temperature of 50°C for 2 min, then increased by 5°C/min to 220°C. Injections were run in the splitless mode. Components of the extracts were identified by comparing retention times and mass spectra with those of authentic standards. Quantification was performed using an internal standard (*cis*-9-hexadecenal) added to each sample (Lacey et al. 2004).

Behavioral Bioassays Two bioassays were used to test the behavioral responses of J_{III} or J_n to volatile chemicals.

Pupal Chamber Bioassay Individual *M. alternatus* larvae, samples of the volatile blend collected from *M. alternatus* larvae by aeration (natural blend), or a synthetic blend of volatiles with the same ratio of terpenes as that collected from the larval aerations, were assayed in artificial pupal chambers. Ten larval equivalents, in 100-μl *n*-hexane, of the

natural or synthetic volatile blends were pipetted onto rubber septa (Tongzhou Shunyi Rubber Co., Beijing, China). Individual larvae, or septa with the natural or synthetic blend, were inserted into the artificial pupal chambers and held at 25°C in the dark for 1 wk. After this, wood chips were collected from walls of each chamber (to about 0.7 cm depth) and from the exterior of each bolt (to a depth of 0.7 cm), and the nematodes present were extracted by using the Baermann funnel technique. The chips were dried to a constant weight for determination of dry weight. An Aggregation Index (AI) was calculated and a one-way ANOVA (using SPSS 11.0 for Windows) used to analyze differences in the AI across treatments.

$$\text{Aggregation Index (AI)} = \frac{\text{Nematodes per g dry} - \text{chips in the interior of chamber}}{\text{Nematodes per g dry} - \text{chips in the exterior of chamber}}$$

Ethylene Sheet-Agar Bioassay The aggregation responses of J_{III} or J_n to volatile collections and blends of monoterpenes were also assayed in Petri dishes (Miyazaki et al. 1977). A volume of warm agar (0.8%, 10 ml) containing 500 nematodes was spread evenly over each plate (9 cm diam.) and allowed to solidify. Ethylene sheets (0.5-cm diam., Reynolds Metals Ltd., Shanghai, China), treated with either single larval equivalents (in 10 µl *n*-hexane) or 10 µl of *n*-hexane alone (control), were used as odor sources. After the solvent had evaporated, one test and one control sheet were placed at opposite ends of each plate with the treated face of the sheet in contact with the agar. The plates were kept in the dark for 24 hr at 25°C. Nematodes aggregating on and under sheets were counted (Miyazaki et al. 1977; Bolla et al. 1989; Stamps and Linit 2001). Differences in the mean numbers of nematodes between treatment and control were compared by Independent-Samples *t* tests.

Field Assays In the field, 50 *P. massoniana* (10–20 cm in diameter) dying from pine wilt disease were sampled from Zhejiang, China, in April 2006. Sampling holes (2 cm deep and 1-cm diam.) were drilled through the entrance holes of *M. alternatus* larvae connected to pupal chambers. Trap tubes were constructed from 2-ml centrifuge tubes (Beijing Zohonice Science & Technology Development Co., Beijing, China) containing a rubber septum inserted into the bottom of the tube. Agar (0.8%) was allowed to solidify around the tube walls and the septa. Volatile blends to be tested were pipetted onto the septa, with control tubes receiving an equivalent volume of *n*-hexane. After the solvent had evaporated, the lids were removed, and the tubes inserted into the sampling holes. Differences in the number of nematodes captured in the treatment and control trap tubes were compared by Independent-Samples *t* test at different times (0.5–48 hr) after commencement of the test.

Effects of Ratios of Three Terpenes on Secretions from J_{III} and J_n The primary chemosensory organs of the nematode are the amphids, which secrete proteins when simulated by molecules of some chemical substances (Perry 1996; Zhao et al. 2000). Secretions of J_{III} and J_n can be detected by staining (Premachandran et al. 1988; Zhao et al. 2000). The respective ratios of the three terpenes found in healthy pines (H3R) and larvae (L3R), were dissolved in dimethyl sulfoxide (DMSO) and distilled water to a concentration of one larval equivalent/10 ul. A 10-µl sample of J_{III} (containing 100 J_{III}) was mixed with 10 µl of 0.2% brilliant blue (in 20% methanol) and 10 µl of one of the terpene solutions or distilled water (control) on top of a microscope slide. The cover slip was sealed with clear nail polish and slides were incubated overnight at ambient temperature in the dark.

Results

In the pupal chamber bioassay, for both the solvent and blank controls (Fig. 1a [S and CK]), more PWN J_{III} were recovered from the wood beyond the walls of the artificial pupal chambers than in the artificial pupal chambers themselves (AI±SE=0.73±0.090). However, the addition of *M. alternatus* larvae to the artificial chamber resulted in the AI increasing to 1.94±0.433 (P=0.048), indicating that nematodes moved into the wood adjacent to the chamber wall. A similar result was also obtained with the volatile extracts from *M. alternatus* larvae (LVE), indicating that the larval volatile extracts contained the components attractive to PWN J_{III} (Fig. 1a). Similarly, in the Petri dish bioassay, the number of J_{III} aggregating on sheets treated with volatile extracts of larvae was significantly higher (P=0.020) than for the control (Fig. 1b). There were no significant differences in the number of J_{III} nematodes on the respective control sheets and on sheets treated with host volatiles collected from healthy, blue-stained, or chamber wood samples of *P. massoniana* (Fig. 1b).

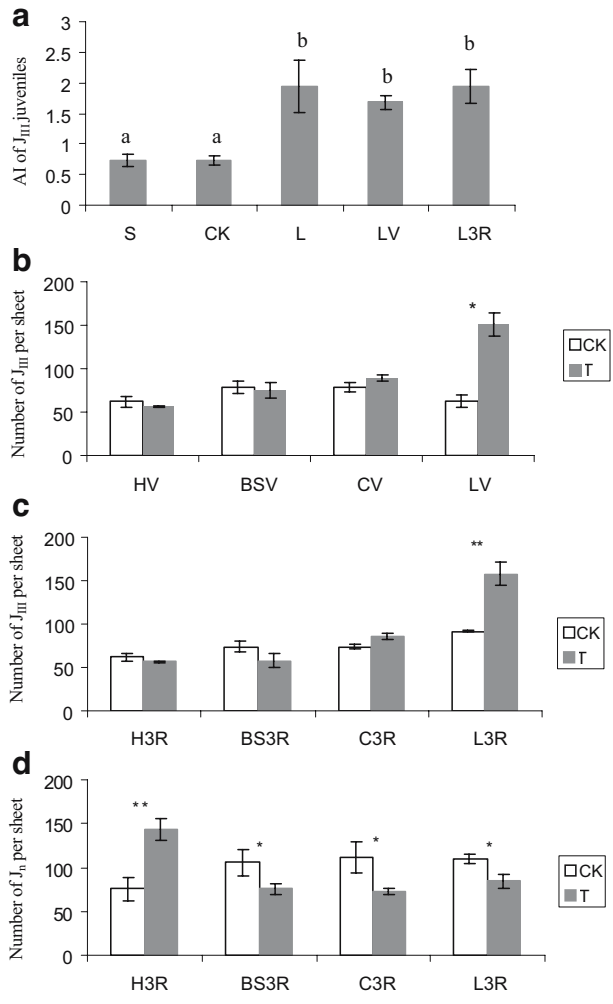

Fig. 1 Aggregation responses of J_{III} and J_n PWN to host and vector volatiles, and blends of terpenes. (**a**) Responses of J_{III} to vector larvae (L), vector larval volatiles (LV) and synthetic terpene blend (L3R) within artificial pupal chambers. AI, Aggregation Index (see text); S, surveyed chambers; CK, control. (**b**) Responses of J_{III} to various volatile collections in Petri dish bioassay. HV, volatiles from healthy pines; BSV, volatiles from blue-stained wood; CV, volatiles from natural pupal chambers. (**c**) Responses of J_{III} to ratios of terpenes in Petri dish bioassay. (**d**) Responses of J_n to ratios of terpenes in Petri dish bioassay. H3R, ratio approximating that of HV=1:0.1:0.01 (1,314 ng/μl); BS3R, ratio approximating that of BSV=1:0.8:0.06 (680 ng/μl); C3R, ratio approximating that of CV=1:0.7:0.08 (242 ng/μl); L3R, the ratio in LV at 1:2.7:1.1 (7.3 ng/μl). Concentrations are expressed for the total amount of the three terpenes. Values indicate the means and standard errors of 10 replicates for each treatment. Bars with the same letters are not significantly different at P>0.05. Asterisks indicate a significant difference from control (*P<0.05; **P<0.01)

The GC-MS traces for the volatile extracts are shown in Fig. 2.Various alkanes (ranging in chain length from C12 to C16) and butylated hydroxytoluene were present only in larval samples, whereas α-pinene, β-pinene, longifolene, camphene, limonene, undecane, and camphor were found in all samples analyzed. Camphor was present in substantially greater amounts in larval samples than in xylem samples. The ratio of α-pinene to β-pinene and longifolene, respectively, varied markedly across the samples. The ratios collected from larvae were lower (1:2.7 and 1:1.1, respectively) than those collected from wood tissue surrounding the pupal chambers or wood from healthy pines (1:0.7 and 1:0.08; 1:0.1 and 1:0.01, respectively).

In Petri dish bioassays, J_{III} of the PWN were not attracted by alkanes, butylated hydroxytoluene, or camphor (data not shown). Differences in the aggregation of J_{III} were noted with four different ratios of three terpenes, α-pinene, β-pinene, and longifolene. Aggregation of J_{III} to sheets treated with a ratio of these terpenes specific to larvae (L3R, 1:2.7:1.1) was significant (P=0.008), whereas ratios of the terpenes matching healthy pines

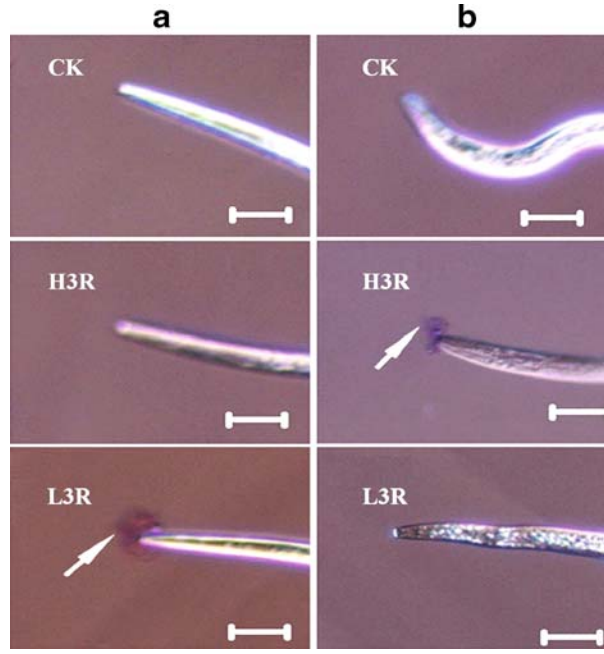

Fig. 3 Stimulation of J_{III} and J_n PWN secretions by different ratios of α-pinene, β-pinene and longifolene. (**a**) J_{III} secretion. (**b**) Stimulation of J_n secretion. Treatments are: H3R, ratio of three terpenes in healthy pine samples at a concentration of 1,314 ng/μl; L3R, ratio of three terpenes released by *M. alternatus* larvae at a concentration of 73 ng/μl. Bar=30 μm. Concentrations are expressed for the total amount of the three terpenes. Arrows point to the stained secretions of nematodes

(H3R, 1:0.1:0.01), blue-stain samples (BS3R, 1:0.8:0.06), and empty pupal chambers (C3R, 1:0.7:0.08) elicited no significant aggregation of J_{III} (Fig. 1c). We also tested the responses of J_n to various ratios of the three terpenes (Fig. 1d). J_n were attracted to the ratio found in natural healthy pine volatiles (H3R, 1:0.1:0.01; P=0.003), but were repelled by BS3R, C3R, and L3R.

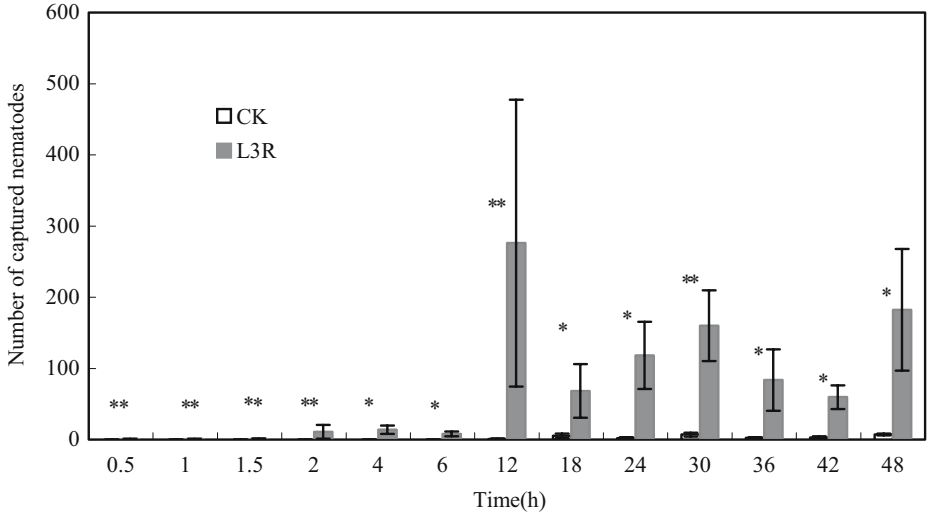

Fig. 4 Catches of PWN in trap tubes, containing different volatile treatments, in the field. Traps were sampled at different times after deployment. L3R, ratio of three terpenes released by *M. alternatus* larvae at a concentration of 7 mg/40 μl. Concentration is for the total amount of the three terpenes. Trial was conducted April 11–15, 2006. Asterisks indicate a significant difference from control (*P<0.05; **P<0.01)

To simulate natural conditions, L3R was also tested in the artificial pupal chamber bioassay. The AI of L3R (1.952±0.277) was significantly (P=0.001) different from that of the control and similar to those of the larvae and larval volatiles (Fig. 1a). This result demonstrates that L3R (1:2.7:1.1) is attractive to J_{III} under natural conditions and that this ratio of the three terpenes is likely the aggregation signal used by the J_{III} juveniles of the PWN.

In the staining assay, for detection of secretions from amphids of PWN, secretions of PWN J_{III} were only detected in response to L3R (Fig. 3a), whereas secretions of J_n were only detected in response to H3R (Fig. 3b). These results demonstrate that the different life stages of PWN distinguish different ratios of terpenes.

In dying *P. massoniana*, significantly greater numbers of nematodes were captured in the L3R-containing traps than in the control traps at all times tested (0.5–48 hr). The greatest number of nematodes was obtained after 12 hr of trapping, with >200 per trap tube baited with L3R (Fig. 4).

Discussion

Animals develop the ability to exploit cues in their habitat during their evolution. We demonstrated that two forms of PWN (reproductive and dispersal) distinguish specific ratios of terpenes produced by their host and vector (Fig. 1; Fig. 3). The reproductive form (J_n) was attracted to the ratio produced by the host tree, but not to the ratio produced by the vector beetle, whereas the dispersal form (J_{III}) was attracted to the ratio produced by the vector, but not to the ratio produced by the host. This attraction demonstrates how J_{III} PWN are able to utilize their vector by moving toward volatile terpenes released by mature *M. alternatus* larvae, allowing the nematodes to aggregate at the site of pupation and adult eclosion of the vector. Subsequent dispersal of the adult beetle allows the nematode access to healthy host pines. Although the specificity and sensitivity of insects to specific ratios of multicomponent pheromones is well established (Monti et al. 1995; Bruce et al. 2005), this is the first report of such a phenomenon in nematodes.

With globalization, biological invasions are a significant environmental threat to the maintenance of natural forest ecosystems (Liebhold et al. 1995). An invasive species must adapt to its new environment. For such a species as PWN, whose life cycle involves multi-trophic interactions, adaptation to its environment can be precarious unless it can utilize both new hosts and new vectors. Our work demonstrates how the alien PWN is able to adapt, by utilizing a common chemoecological relationship between both host and vector, in a new environment.

The PWN is listed as a quarantine target or as a dangerous pest in many countries including those in the European Union (Rautapaa 1986; Dwinell 1997). It has recently been detected in Portugal (Mota et al. 1999). Currently, there is no simple, effective and rapid sampling method available for this pest for use in quarantine monitoring. Our demonstration of chemo-attraction of J_{III} PWN to a specific ratio of terpenes, combined with the successful trapping of PWN, suggests that this approach could be developed into an effective detection method, for use at ports-of-entry and in field detection.

Acknowledgments We thank Daniel Miller, David Kulhavy, Marc Linit, and two anonymous reviewers for critical comments on the manuscript, and Prof. Xingzhong Liu for his technical assistance. We are especially grateful to Leland Humble for his review and editing of the revised manuscript. This study was funded by the CAS Knowledge Innovation Program (KSCX2-YW-N-006), National Natural Science Foundation of China

(30621003, 30525009) and a grant (Chinese IPM0502) from the State Key Laboratory of Integrated Management of Pest Insects and Rodents, IOZ. The publication of this work is also supported by the EU ALARM project. All experiments described in this paper were done according to the rules of the ethical board for animal experiments complying with the current laws of China.

Abstract Many species of insects are known to produce and secrete benzoquinone derivatives. These compounds are usually defined as "defense chemicals." However, in many cases, it has not been determined what the chemicals are meant to defend against. Tribolium beetles produce up to three benzoquinones, but their specific function is not known. In this experiment, one of the derivatives, methyl-1,4-benzoquinone (MBQ) was tested for its effectiveness for one of its purported functions as an antimicrobial. Methyl-1,4-benzoquinone was added in three concentrations (0.3, 30, and 150 μg/ml) to the liquid media of three species of *Bacillus* bacteria and eight species from four genera of yeasts, and the effect on their growth was monitored. The presence of MBQ altered growth in all species. The bacteria responded more negatively than the yeasts. All bacteria species showed reduced growth at all levels of MBQ. Yeasts were more tolerant to the presence of the chemical, and two species, *Saccharomyces microellipsoides* and *Pichia burtonii*, actually showed increased growth at the lowest level of MBQ.

Introduction

Over 100 species of arthropods synthesize benzoquinone derivatives (Blum 1981). Tribolium flour beetles produce up to three benzoquinone derivatives: methyl-1, 4-benzoquinone (MBQ), ethyl-1,4-benzoquinone, and methoxybenzoquinone (Weatherston 1967; Blum 1981). Although often termed "defense chemicals," it is not clear what these compounds actually defend against. Based on potential organismal interactions in their

stored grain environment, one theory has suggested that the compounds prevent rodents from becoming potential predators on flour beetles (El-Mofty et al. 1992; Dettner 1993; Bouchard et al. 1997). Other hypotheses suggest that the compounds act as antimicrobials (Geiger 1946; Engelhardt et al. 1965; Prendeville and Stevens 2002; Yezerski et al. 2005).

Williams (1966) established a list of criteria for a trait to be considered adaptive. These included widespread examples across species, complexity of the trait, cost of the trait to the organisms, and a well-defined genetic basis. The production of benzoquinones by Tribolium beetles fits these criteria. Benzoquinone derivatives are found in many genera of insects (Blum 1981). There is great complexity in the creation and storage of the compounds, as well as metabolic costs to the organisms. In flour beetles, the compounds are derived from an ill defined, but apparently intricate, mechanism in specialized prothoracic and postabdominal glands (Happ 1968). In addition to the metabolic costs, the substances are known to be harmful to the beetles themselves and thus pose a survival cost (Chapman 1926; Roth and Howland 1941). Further supporting the fact that benzoquinone production is an adaptation, the storage of the benzoquinone derivatives has been shown to have a strong and quantitative genetic background (Yezerski et al. 2000, 2004). However, the exact functions of these chemicals for these beetles has not been clearly defined.

In this research, we explored the hypothesis that the benzoquinone trait is an adaptation in the stored grain pest, *Tribolium confusum*, that controls microbial growth in their flour environment. To this end, we obtained type species of bacteria and yeasts known to be associated with stored flours, and we subjected them to an environment containing varying levels of the benzoquinone derivative, MBQ. The effect of the compound on the growth of the microbial species was monitored via turbidity.

Methods and Materials

Source of Microbial Specimens The three species of bacteria are known to inhabit flour and other stored grain products (Norris et al. 1981). These species were provided in both type strain and flour isolate forms by L. K. Nakamura of the USDA in lyophilized preparations. The species included *Bacillus circulans* [NRRL B-380 (type) and B-393 (isolate)], *Bacillus subtilis* [NRRL NRS-744 (type) and B-571 (isolate)], and *Bacillus licheniformis* [NRRL NRS-1264 (type) and NRS-766 (isolate)]. Specimens were grown and maintained in TGY media containing tryptone, glucose, and yeast extract.

Yeasts were provided in lyophilized form by C. P. Kurtzman of the USDA and included the following species known to inhabit wheat flour (Kurtzman et al. 1970): *Pichia fermentans* (NRRL Y-7138), *Pichia anomala* (NRRL Y-7081), *Pichia burtonii* (NRRL Y-7082), *Pichia farinosa* (NRRL Y-7084), *Saccharomyces microellipsoides* (NRRL Y-6524), *Cryptococcus albidus* (NRRL Y-7079), *Cryptococcus laurentii* (NRRL Y-7139), and *Rhodotorula glutinis* (NRRL Y-7140). Specimens were grown and maintained in YM-2 media containing yeast extract, malt extract, peptone, and glucose.

Inoculation Procedure Measurement of the growth of each species began with inoculation of 1 ml of the microbe that had reached maximum turbidity for the species into 100 ml of the appropriate media in a sidearm flask containing one of three concentrations of MBQ: 0.3, 30, or 150 μg/ml. These values were based on the average amount of MBQ found to be on the external surface of a typical beetle and equated to 1, 100, and 500 beetles, respectively (Yezerski et al. 2000, 2004). A control was simultaneously inoculated similarly into a flask containing no MBQ. All measurements were taken in triplicate. Prior testing by plating

found no inherent microbial growth in the purchased MBQ. Methyl-1, 4-benzoquinone has a strong orange to red color in microbial media, and therefore, "color blanks" were needed that contained the same concentrations as the experimental flasks. However, the presence of the microbes themselves also altered the color of the media as growth occurred and, thus, interfered with the accuracy of the readings. Therefore, blanks were created identical to the control, but cells were centrifuged to the bottom of the tube, removing turbidity, before being used to zero the machine. These blank cultures were then resuspended until the next measurement was taken to allow growth to continue as seen in the controls.

Growth Measurements Turbidity of the inoculations was determined by using a manostat colorimeter. Readings began 6–8 hr after inoculation depending on the previously determined lag time for each species. After the colorimeter was zeroed by using the blanks, readings were taken on the experimental cultures to obtain turbidity in Klett units. This procedure was repeated for each inoculation every hour until the control flasks approached a stationary phase. Notable events between and within species and concentrations were compared via a repeated-measures analysis that used the JMP™ Statistical Program (Sall et al. 2006).

Results

Growth curves for the bacteria species are shown in Fig. 1 and growth curves for the yeast species in Figs. 2 and 3. A summary of a statistical comparison of growth in each condition vs. the control flask is shown in Table 1. The control flasks for all species indicated successful and consistent growth under these conditions. The yeasts tended to reach higher turbidities (around 300 Klett units) than the bacteria, which tended to plateau at levels around 200 Klett units. However, the bacteria reached their stationary phases much sooner than the yeasts under the same conditions.

Compared to the controls, the MBQ-treated flasks showed significantly reduced growth rates in most species (Table 1). The equivalent of the presence of 500 beetles, 150 μg/ml MBQ, appears to have eliminated growth altogether in all of the bacterial species and in three of the eight yeast species. However, considering that 30 μg/ml MBQ was not tolerated by any bacterial species, it is notable that the majority of yeast species was somewhat resistant to the effects of the presence of MBQ even at this highest level. *Pichia anomali* demonstrated little reduction in growth with any level of MBQ, while *B. circulans*' growth was completely eliminated by even 0.3 μg/ml MBQ.

Several of the yeasts appeared unaffected by the compound at the two lowest levels, but their growth was strongly suppressed at the highest level. This is not unexpected because the dilutions were serial and not parallel in nature. However, there is a surprising result for three yeasts, *Rhodotorula glutinus*, *P. burtonii*, and *S. microellipsoides*, where growth increased at the lowest level of 0.3 μg/ml MBQ (Figs. 2 and 3). *Saccharomyces microellipsoides* and *P. burtonii* have significantly higher turbidity than the controls in the second half of their growth curves (Table 1; indicated by Xs rather than asterisks).

In general, the microbial growth was consistently decreased during the measurement time, but bacterial species were more greatly affected than yeast species. There is some indication that low levels of MBQ may actually encourage growth in certain species of yeast.

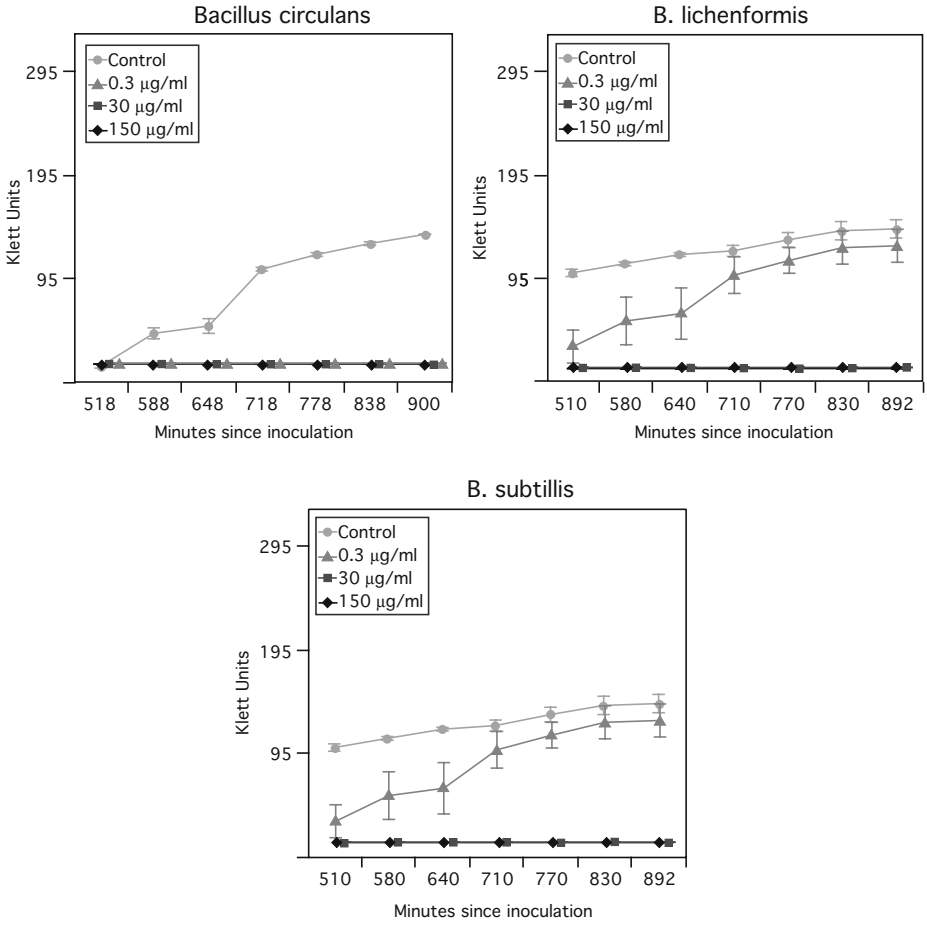

Fig. 1 Growth of three Bacillus species in the presence of MBQ in Klett units + SEM. As indicated in the *legends*, *symbols* represent growth in media without MBQ (*circles*) or with 0.3 µg/ml (*triangles*), 30 µg/ml (*squares*), or 150 µg/ml of MBQ (*diamonds*) measured at the indicated minutes after initial inoculation

Discussion

Our results indicate that MBQ has an effect on microbial growth. However, the compound is more of a deterrent to bacteria than yeast. From an evolutionary standpoint, these results are expected. Bacteria species, especially members of the *Bacillus* genus, can be harmful to insect species by causing numerous diseases and developmental difficulties (Faust 1974; Kreig 1981; Kumari and Neelgund 1985; Abdel-Razek et al. 1999; Abdel-Razek 2002).

Microbes might also compete with beetles for nutritional resources. However, it has been shown that yeast species associated with flour obtain distinct nutritional benefits for the beetles. The beetles do poorly in flour that does not contain sufficient levels of yeast (Offhaus 1952; Charbonneau and Lemonde 1962; Via and Conner 1995). In fact, a veritable symbiosis has been noted (Dunkel 1988). Therefore, the complete elimination of yeast species from the environment would be detrimental to beetle survival.

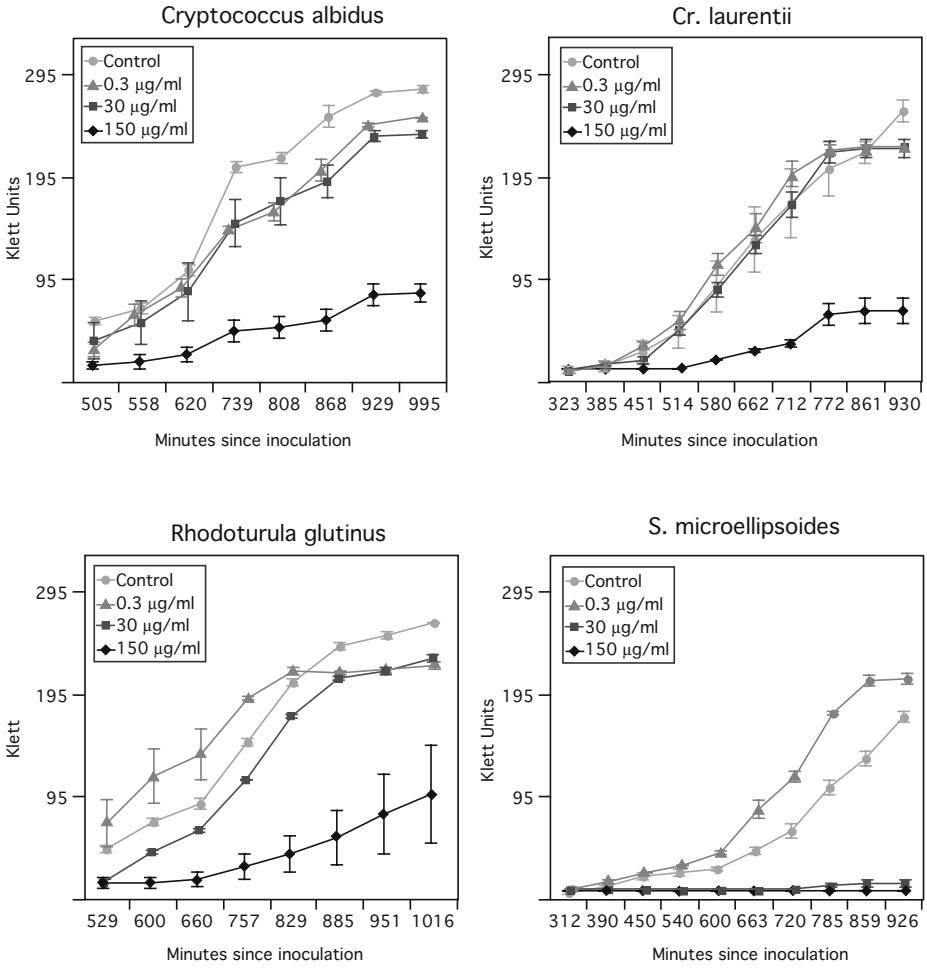

Fig. 2 Growth of four yeast species in the presence of MBQ in Klett units + SEM. As indicated in the *legends*, *symbols* represent growth in media without MBQ (*circles*) or with 0.3 µg/ml (*triangles*), 30 µg/ml (*squares*), or 150 µg/ml of MBQ (*diamonds*) measured at the indicated minutes after initial inoculation

The choice of the bacterial species for this study was based on data for species commonly found in flour according to USDA experts. Species were selected based on previous work specifically with flour isolates. Other sources, however, indicate that, whereas the presence of *Bacillus* species is quite usual, other genera such as *Salmonella* and *Escherichia* should also be considered for future investigation (Farmiloe et al. 1954; Rogers 1978; Okagbue 1990; Richter et al. 1993; Sorokulova et al. 2003). Additionally, our selection of species did not include those that might have been already associated with the beetles themselves because the flour isolates were not from stores containing insects. Recent studies have suggested that insect flour pests introduce members of the Enterococcidae and Enterobacter families into their flour environment, but Tribolium species that produce high levels of benzoquinones generally lack these bacteria species in their stocks (Yezerski et al. 2005). Therefore, although these bacterial species may be

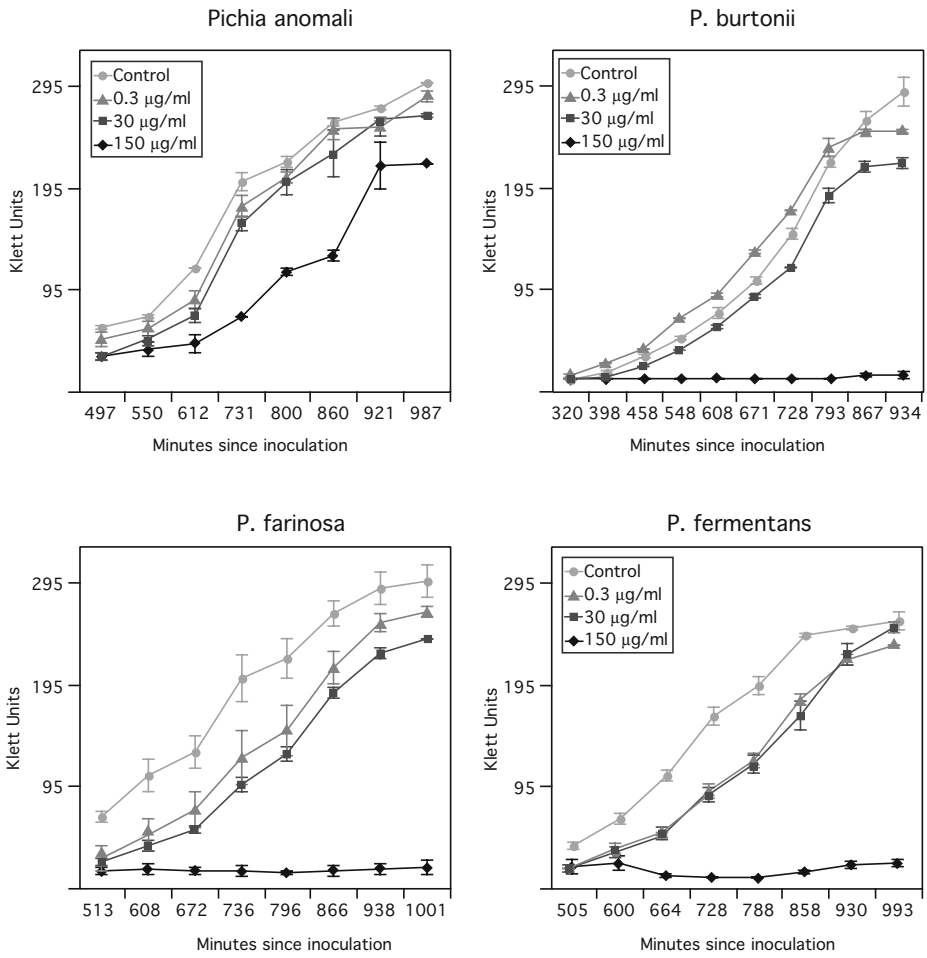

Fig. 3 Growth of four yeast species from the *Pichia* genus in the presence of MBQ in Klett units + SEM. As indicated in the *legends*, *symbols* represent growth in media without MBQ (*circles*) or with 0.3 µg/ml (*triangles*), 30 µg/ml (*squares*), or 150 µg/ml of MBQ (*diamonds*) measured at the indicated minutes after initial inoculation

present in the guts of flour pests, previous work, along with these present data, suggests that the beetles are curtailing their presence.

It is well known that yeasts are associated with flour, but the species varies. The species that we used based on the USDA's flour isolates were not in complete congruence with those suggested by the literature (Kurtzman et al. 1970; Okagbue 1990). However, the species used represent common species. Regardless, the conclusion that yeast species generally grow better in the presence of MBQ than bacterial species is supported.

The levels of MBQ chosen for this study were based on previously determined levels on the external surface of a *T. confusum* beetle (about 0.3 µg per beetle at any given time) (Yezerski et al. 2000, 2004). However, amounts of MBQ on the beetles themselves may differ from amounts present in their flour environment. Other work has shown that beetles secrete approximately 7 µg MBQ over 72 hr, but that much of this degrades into methyl-1,

Blank cells indicate no measurement was taken in this time interval.

ND=no difference

[a] Measurements were taken in 1-hr intervals. The first measurement time from inoculation (1) varied for each species. Actual time in minutes from inoculation can be seen in detail in the accompanying figures. Statistical significance of the comparison of the turbidity in Klett units between indicated culture and respective control. Asterisks represent Klett units significantly lower than control (* $P<0.05$, ** $P<0.01$, and *** $P<0.001$). Xs represent Klett units significantly higher than control (x $P<0.05$, xx $P<0.01$, and xxx $P<0.001$).

4-hydroquinone (MHQ) (Yezerski, unpublished data). It can be assumed that the highly reactive MBQ naturally degrades into MHQ in the flour environment. Therefore, by introducing a reasonable amount of MBQ into the environment and allowing it to degrade normally, one realistically replicates a natural situation. The reactivity of MBQ may be part of the effectiveness of the antimicrobial activity, but this has not been tested directly here.

In this study, we also did not test the chemically related ethyl-1,4-benzoquinone that is also produced by many insect species (Weatherston 1967; Blum 1981). This compound is actually the more abundant compound in the beetle excretion, being produced at a ratio of almost 2:1 in *T. confusum* (Pappas and Morrison 1995; Pappas and Wardrop 1996; Yezerski et al. 2000, 2004). This compound is not commercially available and is also extremely susceptible to light and temperature, making work with it exceedingly difficult (Yamada and Hosaka 1977). The slight structural difference in this substance vs. MBQ perhaps suggests a similar result. The purpose of producing twice as much may be related to ease of natural synthesis.

Although benzoquinone derivatives are a common part of many organisms' physiology, Tribolium beetles and several other insect species incur a metabolic cost that produces a substance that may be harmful to their own survival and development. The results of this experiment indicate that one of these compounds, MBQ, is an effective antimicrobial that is selective to species that are potentially harmful or beneficial. It effectively reduces the growth of bacterial species known to cause harm while controlling and even encouraging the growth of yeast species that are an important food source. Another suggested function may be an antipredatory defense against rats that cohabitate grain storage with flour beetles. We are currently conducting research to determine the efficacy of this alternative hypothesis.

Abstract Chemical investigations of five species of molluscan nudibranchs, *Halgerda*, collected from Australia and Japan were carried out. We identified a novel tryptophan derivative halgerdamine (**1**) along with the known compounds trigonellin (**3**), esmodil (**4**), zooanemonin (**5**), and C2-α-*D*-mannosylpyranosyl-*L*-tryptophan (**2**) from *Halgerda aurantiomaculata*. C2-α-*D*-mannosylpyranosyl-*L*-tryptophan (**2**) was previously thought to be a by-product of tryptophan metabolism exclusive to humans. The only other chordates reported to contain this compound are a number of ascidian species from New Caledonia and Australia including *Atriolum robustum* and *Leptoclinides dubius*. The occurrence of **2** in a mollusc has not been previously reported. Structure elucidation of **1** was achieved by using high-field 2D NMR spectroscopy. No secondary metabolites were detected in extracts from five of the six other species studied, whereas *Halgerda gunnessi* contained mixtures of acylated tetrasaccharides. The compounds isolated from *Halgerda* are different from those found in the close sister taxon, *Asteronotus*. Specifically, species of *Halgerda* contain no terpenes, spirodysin, or bromophenols, as does *Asteronotus*. Furthermore, in contrast to other members of the Nudibranchia such as *Chromodoris* and *Phyllidia*, in which compound yields are quite high, several cryptic species of *Halgerda* seem to lack secondary metabolites, whereas the two highly conspicuous species yield mildly cytotoxic MeOH extracts. Our findings support recent hypotheses regarding progressive evolution of opisthobranchs. In particular, opisthobranchs have evolved to exploit a wider range of

food and metabolites than did their ancestors, a demonstration of physiological innovation. Some species of *Halgerda* may not be chemically protected either via *de novo* synthesis or by sequestering particularly toxic compounds.

Keywords Halgerda · Asteronotus · Nudibranch defense · Trigonellin · Esmodil · Zooanemonin · Amino acids · Halgerdamine · Tryptophan conjugates · C2-α-*D*-mannosylpyranosyl-*L*-tryptophan · Tryptophan metabolism · Muscarinic agonist · Cytotoxicity · Marine sponges · Evolutionary relationships

Introduction

Nudibranchs have long been recognized as producers of biologically active secondary metabolites. The metabolites are either sequestered from food sources (Cimino et al. 2001) or biosynthesized *de novo* (Cimino et al. 2004). For example, nudibranchs from the family Phyllididae contain sesquiterpenes, isocyanides, and isothiocyanates obtained from the marine sponge *Acanthella* (Dumdei et al. 1997). *Aegires* (= *Notodoris*) *gardeneri* from the family Aegiridae sequesters Clathridine-C, Naamidines E and F that are obtained from *Leucetta* sponges (Carroll et al. 1993). Marine sponge (*Ircinia*) compounds, fasciculatin, variabilin, and palinurin have all been isolated from a member of the family Discodorididae, *Discodoris indecora* (Marin et al. 1997).

The nudibranch family Discodorididae contains 24 genera. Chemical investigations within the family have been rare. Two major clades have been proposed based on morphology (Valdés 2002). Within one clade, only *Asteronotus* and *Peltodoris* have been investigated chemically. *Asteronotus cespitosus* contains brominated phenyl ethers that have been isolated from the sponge *Dysidea herbacea* (Fahey and Garson 2002; Fahey 2003), whereas *Peltodoris atromaculata* contains polyacetylenic compounds isolated from the sponge *Petrosia ficiformis* (Castiello et al. 1980). Within the other major clade, only two genera have been chemically investigated. *Dialula sandiegensis* contains polyacetylenes and isoguanasine (Walker and Faulkner 1981), whereas *Jorunna funebris* contains an isoquinoline alkaloid with antitumor activity (Fontana et al. 2000).

The Doridiidae are the most closely related clade to the Discodorididae (but not one of the two clades that comprise the Discodorididae), and these nudibranchs also have species that sequester compounds such as sterols, nucleosides, alkaloids, unusual and toxic diacylglycerols, and polyacetylenes from their sponge diet (Karuso 1987; Avila 1995; Cimino and Ghiselin 1999; Cimino et al. 1993). The Chromodoridae, a group of cryptobranch dorids that is basally situated to both the Doridiidae and Discodorididae (Valdés 2002), contain mainly terpenes (Karuso 1987). These terpenes are largely the result of a diet of sponges from the Dictyoceratida and Dendroceratida, and notably, the genus *Dysidea*. Members of the Chromodoridae contain isothiocyanates and isocyanides derived from *Axinella* spp., Halichondriidae (Cimino et al. 1999).

Based on these publications, particularly the report that extracts from *Asteronotus* contain sponge compounds (Fahey and Garson 2002), it was of interest to investigate species from other taxa within the clade. *Halgerda*, a sister taxon to *Asteronotus*, has a well-resolved phylogeny (Fahey and Gosliner 2001) but has not been investigated chemically. The genus contains 35 recognized species and represents a major genus within the family Discodorididae. Initial studies with two species (*Halgerda aurantiomaculata* and *Halgerda gunnessi*) indicated that MeOH extract and/or MeOH fractions from C_{18} silica gel separations exhibit weak cytotoxic activity (Fahey 2003). These and other studies have

demonstrated that extracts are antibacterial, cytotoxic, ichthyotoxic, and antifungal (Gunthorpe and Cameron 1987; Avila 1995). The present paper reports on the chemical investigations of five species of *Halgerda* collected from Queensland, Western Australia, and Okinawa, Japan.

Methods and Materials

General Procedures All solvents used were Omnisolv high-performance liquid chromatography (HPLC) grade. High-performance liquid chromatography purification was performed on a Waters Associates model 600 pump with a Waters 996 photodiode array detector with a Betasil C_{18} semipreparative (150×10 mm, 5 μm) column and Betasil C_{18} preparative (150×21.5 mm, 5 μm) column. Optical rotations were measured on a JASCO P-1020 polarimeter (23°C, 10 cm cell). UV spectra were recorded on a CAMSPEC M501 and GBC 916 UV/Vis spectrophotometer and IR spectra were recorded on Nicolet NEXUS FT IR spectrometer. One- and two-dimensional nuclear magnetic resonance (NMR) spectra were recorded on Varian Inova 600- and 500-MHz NMR spectrometers. Samples were dissolved in deuterated dimethylsulfoxide (d_6-DMSO), and chemical shifts were calculated relative to the DMSO solvent peak (^{1}H δ 2.49 and ^{13}C δ 39.5 ppm). Electrospray ionization mass spectra (ESIMS) and high-resolution ESIMS were measured on a Mariner Biospectrometry TOF workstation with positive electrospray ionization, mobile phase 1:1 methanol (MeOH)–water (H_2O) containing 0.1% formic acid.

Collection of Samples Three adult specimens of *H. gunnessi* Fahey and Gosliner (Mollusca: Gastropoda: Opisthobranchia) were collected from one location by using SCUBA on the north side of Rottnest Island, Western Australia (Table 1). Two specimens of *Halgerda theobroma* Fahey & Gosliner were also collected by SCUBA on the north side of Rottnest Island, Western Australia. Five adult specimens of *H. aurantiomaculata* Allan were collected from Heron Island and from Mooloolaba, southeast Queensland; six were collected at Heron Island, Great Barrier Reef; and four were collected at Lady Musgrave Island, Great Barrier Reef. All specimens from Mooloolaba were found on sandy substrate,

Species	Coloration	Locality[a]	Specimen Storage
H. aurantiomaculata	White ground color, yellow or orange markings	Mooloolaba, SE Queensland	Frozen
		Heron Island, GBR	Frozen
		Lady Musgrave Island, GBR	Frozen
H. gunnessi	Brown ground color, yellow and white markings	Perth, Western Australia	MeOH
H. rubicunda	Red ground color, deep red markings	Zamami Islands, Japan	MeOH
H. theobroma	Brown ground color, yellow markings	Perth, Western Australia	MeOH
H. willeyi	White, pale gray or yellow ground color, brown, yellow, orange markings	Zamami Islands, Japan	MeOH

GBR = Great Barrier Reef

[a] All species were collected either on rubble from coral reefs or sponge gardens or sandy substrate

and not on a sponge. One specimen of each *Halgerda rubicunda* Baba and *Halgerda willeyi* Eliot was collected from the Zamami Islands, Japan.

Extraction and Processing The nudibranch specimens (*H. aurantiomaculata*, *H. willeyi*, *H. gunnessi*, *H. rubicunda*, and *H. theobroma*) were either stored in MeOH or frozen prior to chemical analysis. Specimens of *H. aurantiomaculata* (collected at Mooloolaba) [556 mg dry weight after extraction (DW)], *H. aurantiomaculata* (collected at Heron Island) (2,680 mg DW), *H. aurantiomaculata* (collected at Lady Musgrave Island) (1,360 mg DW), *H. gunnessi* (1,350 mg DW), *H. rubicunda* (60.2 mg DW), *H theobroma* (312.0 mg DW), and *H. willeyi* (210.0 mg DW) were each macerated in MeOH and exhaustively extracted with MeOH, and the extracts evaporated to dryness. Extract masses were: *H. aurantiomaculata* (collected at Mooloolaba), 655 mg; *H. aurantiomaculata* (collected at Heron Island), 1,203 mg; *H. aurantiomaculata* (collected at Lady Musgrave Island), 1,174 mg; *H. gunnessi*, 896 mg; *H. rubicunda*, 22.2 mg; *H theobroma*, 69.6 mg; and *H. willeyi*, 12.7 mg. These extracts were separated by semipreparative C_{18} silica gel HPLC using a gradient from 1% aqueous trifluoroacetic acid (TFA) and MeOH containing 1% TFA over 22 min. One-minute fractions were collected, and fractions were analyzed by (+) ESIMS and ^{1}H NMR. The structures of compounds were assigned based upon 2D NMR analysis or by comparison with literature data.

Results

The weights of nudibranch and yields of extract from *H. rubicunda*, *H. theobroma*, and *H. willeyi* were low, and as a consequence, the NMR analysis of the HPLC fractions was not sensitive enough to detect anything apart from fatty acids and triacyl glycerides (Table 2). The weight of the specimens of *H. gunnessi* (1,350 mg DW) was significantly higher than for the previous three mollusc species, and the MeOH extract and HPLC fractions from this nudibranch were richer in organic components. Fraction 18 from the

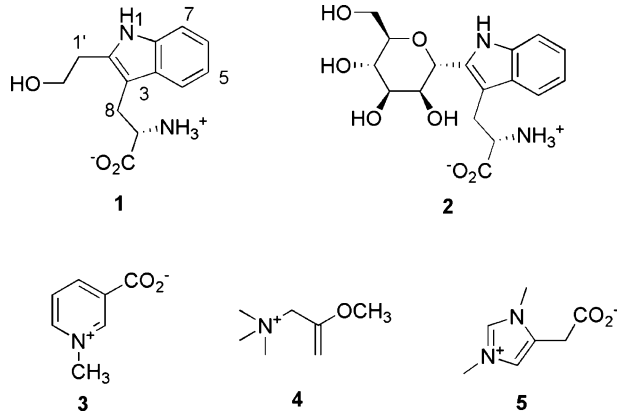

Fig. 1 Compounds isolated from *H. aurantiomaculata* **1** (halgerdamine), **2** (C2-α-*D*-mannosylpyranosyl-*L*-tryptophan), **3** (trigonellin), **4** (esmodil), and **5** (zooanemonin)

HPLC separation contained a mixture of two compounds, which by (+) ESIMS, had molecular weights of 1,455 and 1,469 Da. Further purification by C_{18} silica gel HPLC, isocratic elution with 4:1 MeOH–H_2O did not separate this mixture further, and the yield of compound precluded full structural elucidation. Analysis of gCOSY, gHSQC, and gHMBC spectra suggested that the molecules were long-chain fatty acid esters of acetylated tetra saccharides that also contained an alanine residue. Full structure elucidation will require additional collections of the nudibranchs. High-performance liquid chromatography separation of the MeOH extracts from three different collections of *H. aurantiomaculata* at Heron Island, Mooloolaba, and Lady Musgrave Island yielded the novel tryptophan derivative, halgerdamine (**1**) from the Heron Island collection and the known compounds C2-α-*D*-mannosylpyranosyl-*L*-tryptophan (**2**), trigonellin (**3**), esmodil (**4**), zooanemonin (**5**), and tryptophan from all three collections (Fig. 1, Table 3). These compounds were identified by 2D NMR analysis or comparison with literature data. *Halgerda aurantiomaculata* also contained high concentrations of the amino acids, leucine, isoleucine, and valine.

Halgerdamine (**1**), a novel tryptophan conjugate, was isolated as a colorless gum; $[\alpha]_D^{23}$ + 12.2° (*c* 0.09, MeOH); UV (MeOH) λ_{max} (log ε) 295 (2.8) nm; and IR (KBr) ν_{max} 1,728, 1,667, 1,590, 1,415, and 1,355 cm^{-1}. Accurate mass measurement of the pseudomolecular ion in the positive HRESIMS at *m/z* 249.1225 (Δ 3.6 ppm) allowed a molecular formula, $C_{13}H_{17}N_2O_3$, to be assigned. The ^1H NMR spectrum of halgerdamine (Table 4) contained signals which could be assigned to a 1,2 disubstituted aromatic ring, a sharp downfield exchangeable proton at δ 10.86, which was either a phenol or an indole proton, a broad

three proton exchangeable signal at δ 8.14, and five multiplets between 2.84 and 3.99 ppm, two of which integrated to two protons. Analysis of correlations observed in the gCOSY spectrum indicated that the molecule contained an ethyl group and a methylene vicinal to a methine. Halgerdamine was not isolated in sufficient quantity to obtain a ^{13}C NMR spectrum; however, the chemical shifts of all 13 carbons were established from analysis of data obtained from gHSQC and gHMBC spectra. Correlations observed in the gHSQC spectrum suggested that one of the methylenes, C-2' (δ 3.70/60.0 ppm), in the ethyl group was oxygenated, whereas the methine, C-8, was probably attached to an amino group. Correlations from the sharp exchangeable proton at δ 10.86 to four aromatic quaternary carbons, C-2 (136.0 ppm), C-3 (104.0 ppm), C-3a (127.2 ppm), and C-7a (135.6 ppm), supported the presence of an indole. Two of these carbons, C-3a and C-7a, were also long range coupled to the aromatic protons H-4–H-7. The methylene protons H-8a and H-8b also correlated to three of these four aromatic quaternary carbons, C-2, C-3, and C-3a, as well as to a carboxylic acid carbonyl carbon C-10 (170.9 ppm). This indicated that halgerdamine was a tryptophan derivative, which was alkylated at C-2. HMBC correlations from the methylene protons H-1' (δ 2.84) to the quaternary aromatic carbons, C-2 and C-3, and from the oxygenated methylene H-2′ to only C-2 indicated that an ethoxyl group was attached to C-2 of the tryptophan. Although halgerdamine is a simple analog of tryptophan, it has not previously been reported as either a natural product or a synthetic derivative.

Discussion

The observation that *H. aurantiomaculata* contained many polar metabolites and no lipophilic ones is surprising. Most of the compounds previously isolated from nudibranchs have been lipophilic in character. This difference may reflect the isolation techniques used in the past or maybe that *H. aurantiomaculata* is unique in its ability to manufacture or use polar metabolites. Trigonelline (**3**) has previously been isolated from many sources, both

plant and marine. The antibacterial and antineoplastic compound zooanemonin (**5**) has been isolated previously from the marine sponges *Hippospongia equina* (Ackermann and Menssen 1960), *Protophlitaspongtia aga* (Hattori et al. 2001), *Agelas dispar* (Cafieri et al. 1998), *Axinella carteri*, and *Phakellia flabellate* (Carroll, personal communication) and the sea anemone *Anemonia sulcate* (Ackermann and Janka 1953; Ackermann 1954; Ackermann and List 1960). Esmodil (**4**), a muscarinic agonist, has recently been reported from the sponge *Raspailia* sp. (Capon et al. 2004). C2-α-*D*-mannosylpyranosyl-*L*-tryptophan (**2**) was previously thought to be exclusive to humans. Two papers by Garcia et al. (1996) and Kehraus et al. (2004), however, have subsequently shown that this compound is also present in a number of ascidian species from New Caledonia and Australia. The occurrence of **2** in a mollusc has not been previously reported. Compound **2** is known to be a product of tryptophan metabolism in humans. Enzymatic C-mannosylation of tryptophan leads to its detoxification and excretion. The identification of **2** in the tissues of *H. aurantiomaculata* raises the question does *H. aurantiomaculata* feed on an animal that has high levels of C2-α-*D*-mannosylpyranosyl-*L*-tryptophan (**2**) in its tissues, or does the nudibranch have similar enzymatic machinery to humans to detoxify tryptophan by *C*-mannosylation? Furthermore, is C2-α-*D*-mannosylpyranosyl-*L*-tryptophan (**2**) more widely distributed within other phyla and is *C*-mannosylation of tryptophan a ubiquitous detoxification process? The co-isolation of halgerdamine (**1**), a novel tryptophan conjugate, from the Heron Island collection of *H. aurantiomaculata* suggests that the nudibranch possesses enzymes capable of tryptophan metabolism.

A striking finding was the lack of secondary metabolites present in many of the animals studied. This is in contrast to other members of the Nudibranchia such as *Chromodoris* and *Phyllidia* for which compound yields are quite high. For *H. theobroma*, *H. rubicunda*, and *H. willeyi*, no compounds other than fatty acids and triglycerides were observed in yields down to 0.01%. *Halgerda gunnessi* and *H. aurantiomaculata* both gave higher yields of secondary metabolites. It is interesting that low yields of secondary metabolites have been reported from *Asteronotus*. (Fahey and Garson 2002). The presence of secondary metabolites in extracts from *H. aurantiomaculata* and *H. gunnessi* is compatible with the observation that MeOH extracts from *H. aurantiomaculata* and *H. gunnessi* show cytotoxicity (Fahey 2003). Because esmodil (**4**) has previously been isolated from an Australian sponge *Raspailia* (*Raspailia*) sp., *H. aurantiomaculata* may sequester this compound from a dietary source. Furthermore, the observation that *H. aurantiomaculata* contains high concentrations of zooanemonin (**5**), a compound previously isolated from several different sponge sources (*H. equina*, *P. aga*, *A. dispar*, *Phakelia flabellata*, *A. carteri*) suggests that *H. aurantiomaculata* sequesters compounds from a varied sponge diet.

The compounds isolated from species of *Halgerda* are different from those found in the close sister taxon, *Asteronotus*. *Halgerda* spp. contain none of the terpenes, spirodysin, or bromophenols found in *Asteronotus* (Fahey and Garson 2002). Of the species studied, only extracts from *A. cespitosus*, *H. gunnessi*, and *H. aurantiomaculata* were found cytotoxic against P388 cell lines (Fahey 2003). The cytotoxicity of the extracts from the two *Halgerda* species was less pronounced than that of the extracts and compounds isolated from *Asteronotus*. The isolation of high concentrations of esmodil from *H. aurantiomaculata* raises another possible means of protection from predation. Because esmodil is a muscarinic agonist (an acetylcholine mimic), it possesses properties that could cause reactions in predators, such as cardiovascular effects and respiratory depression. Further studies to determine the localization of esmodil and other compounds from *H. aurantiomaculata* within the nudibranch's tissues (in particular the mantle tissue) may identify a defensive role for these compounds.

A question remains regarding the lack of secondary metabolites found in extracts of the three additional species of *Halgerda* examined in the present study. *Halgerda rubicunda*, *H. theobroma*, and *H. willeyi* may prey only upon nontoxic sponge species. Another possibility is that these nudibranchs ingest toxic sponges but have the ability to excrete all toxins before any are sequestered. A third possibility is that these species have evolved the ability to detoxify other compounds that are ingested, similar to the enzymatic machinery noted above for *H. aurantiomaculata*.

Our findings support Cimino and Ghiselin (2001) with regard to the progressive evolution of opisthobranchs. Their discussion suggests that opisthobranchs have evolved to exploit a wider range of food and metabolites, a demonstration of physiological innovation. Basal taxa to the Cryptobranchia (i.e., *Hexabranchus*) appear to consume a rather specific range of food (*Halichondria* sp.), and the more derived clades (i.e., *Hypselodoris* and *Cadlina*) are able to biotransform or biosynthesize selected metabolites for defensive purposes (Cimino and Ghiselin 2001). This study examined one of the most highly derived clades of cryptobranch nudibranchs consisting of *Asteronotus* and *Halgerda*, and our findings suggest that some species of *Halgerda* may not be chemically protected either via *de novo* synthesis or by sequestering particularly toxic compounds. Rather, this group of nudibranchs exploits a wider range of food, including nontoxic sponges, than did its ancestors.

It is interesting to note that MeOH extracts from the two species that are predominantly white in color are toxic and display "warning coloration." The other three species are predominantly dark (brown or dark red) and more camouflaged in their environment and so potentially have less need of chemical protection. Further studies are needed to test this hypothesis.

Abstract The male-produced sex pheromone of the neotropical redbanded stink bug, *Piezodorus guildinii* (W.) (Hemiptera: Pentatomidae), a serious pest of soybean in Central and South America, was identified as the sesquiterpene hydrocarbon β-sesquiphellandrene by coupled gas chromatography–mass spectrometry and laboratory bioassays. The identity was confirmed by comparison with an authentic standard, and its absolute configuration was determined to be (7*R*)-(+)-β-sesquiphellandrene. The mean rate of release was approximately 40 ng d^{-1} $male^{-1}$. The compound was found only in extracts from sexually mature males. Laboratory olfactometer bioassays showed that 200 ng of the synthetic compound applied to a filter paper strip was as attractive to female bugs as odors from five 15-d-old live males, an airborne extract from males, or the fraction of the extract that contained (7*R*)-(+)-β-sesquiphellandrene.

Keywords Soybean pest · Sex pheromone · β-Sesquiphellandrene · Olfactometer bioassay

Introduction

The neotropical redbanded stink bug, *Piezodorus guildinii* (W.) (Hemiptera: Pentatomidae), is one of the complex of stink bugs that are serious pests of soybean, *Glycine max* (L.) Merryl, in Central and South America, especially in Brazil (Panizzi and Rossi 1991). More than four million liters of chemical insecticides are used in Brazil each year to control these pests (Corrêa-Ferreira and Moscardi 1996). The use of semiochemical-based methods for control, such as pheromone-based mass trapping or attract-and-kill, would be a more ecologically benign approach to management of these stink bugs.

The first study of semiochemicals in the genus *Piezodorus* was carried out by Leal et al. (1998). These authors, working with *Piezodorus hybneri* (Gmelin), found in Thailand, Korea, Taiwan, Japan, and some regions of India and Australia (Shepard et al. 1983; Singh et al. 1989), reported that the male-produced pheromone consisted of three compounds, β-sesquiphellandrene, (*R*)-15-hexadecanolide, and methyl (*Z*)-8-hexadecenoate, in the ratio 10:4:1. In laboratory bioassays, both sexes were attracted to this blend.

More recently, Borges et al. (1999) reported the preliminary identification of two possible components of the pheromone blend of *P. guildinii*. Confirmation of these components in the *P. guildinii* pheromone blend and identification of any additional components could provide a species-specific attractant for this species. Thus, the objectives of the study reported here were (1) to collect and analyze the volatiles produced by sexually mature, virgin adults of both sexes of *P. guildinii*; (2) to compare the extracts, looking specifically for sex-specific compounds that might be pheromone components; and (3) to identify, synthesize, and test the biological activity of any such sex-specific compounds.

Methods and Materials

Insects Piezodorus guildinii were obtained from a laboratory colony started from adults collected from soybean fields between 2003 and 2005 near the EMBRAPA Genetic Resources and Biotechnology Laboratory, Brasília, DF, Brazil (15°47′S and 47°55′W). Bugs were reared on raw peanuts (*Arachis hypogaea*), soybeans (*Glycine max*), fresh green beans (*Phaseolus vulgaris*), and water at 26±1°C and 65% relative humidity under a 14:10 light and dark photoperiod (light 06:00 to 20:00 hours). Insects were reared in 8-l plastic containers (100–150/container) with the food supply being renewed three times per week. A 15-cm^2 plastic mesh (~40 mesh) was placed against the inner wall of each container as an oviposition substrate and shelter for the bugs. Egg masses were collected daily and incubated in 9-cm-inner-diameter (ID) plastic petri dishes until they hatched. After the resulting nymphs molted into second instars, they were transferred to plastic containers and reared as above. To prevent interactions between the sexes, males were separated from females after the imaginal molt and cuticular hardening (ca. 24 hr after molting). Sexually mature adults, ≥8 d after the final molt, were used for all bioassays.

Collection of Volatiles Volatiles were collected (N=150 extracts) from groups of 20 male or female *P. guildinii*. The insects were carefully introduced into 1-l glass containers to minimize emission of defensive secretions (Zhang et al. 2003). A vacuum was used to draw air (~1 l/min) into the container through a bed of 4–12 mesh-activated charcoal (Fisher Scientific, Pittsburgh, PA, USA), and out of the container through two traps (15×1.5 cm outer diameter) containing Super Q (200 mg each; Alltech Associates, Inc., Deerfield, IL, USA).

Collection of volatiles commenced 5 d after the final molt. Insects were fed with fresh green beans (replaced three times a week) and aerated continuously for 15 d, changing the adsorbent traps daily. The traps were eluted with hexane (4×0.5 ml) and the combined eluates stored at −30°C until used for chemical analysis or behavioral bioassay. To check for background volatiles, the volatiles from green beans alone were collected as described above, over four consecutive days (N=12).

Extracts were concentrated under a gentle stream of N_2 to yield a solution of approximately 0.1 bug-equivalent (BE)/μl, where 1 BE was the amount produced by one male bug in 1 d. For quantitative analysis, an internal standard [25 μg (*E*)-2-octen-1-ol in 50 μl of hexane] was added to the solution.

To evaluate the circadian rhythm of pheromone release, volatiles were collected and quantified during three different periods: morning, from 07:00 hours to noon (N=7); afternoon, noon to 17:00 hours (N=5); and evening, 17:00 to 22:00 hours (N=5).

Analysis and Fractionation of Extracts Crude extracts and fractions thereof were analyzed on a PerkinElmer gas chromatograph (GC; DB-1 column, 30 m×0.25 mm ID, 0.25 μm film; J&W Scientific, Folsom, CA, USA) equipped with a flame ionization detector (FID), using a temperature program of 50°C (for 2 min) increased by 15°C/min to 250°C. Crude extracts were also analyzed at the University of California, Riverside, with a Hewlett-Packard 6890 GC interfaced to an HP-5973 mass selective detector, with electron impact ionization (70 eV). A DB-5 MS column was used (30 m×0.25 mm ID, 0.25 μm film thickness; J&W Scientific), with a temperature program of 40°C (for 1 min), 10°C/min to 250°C, injector 250°C, and transfer line 280°C. Injections were made in splitless mode.

An extract was fractionated as described by Leal et al. (1998). A column (6.0 cm× 0.5 cm ID) containing 500 mg of silica gel (80/100 mesh), impregnated by 10% with weight $AgNO_3$ (Merck, Darmstadt, Germany), was conditioned by eluting with 6 ml of 25% ether in hexane, followed by 6 ml of hexane. Three 24-hr aeration extracts from 20 mature males in ~1 ml pentane were loaded onto the column, and eluted sequentially with 3×1 ml pentane, 3×1 ml 5% ether in pentane, 3×1 ml 10% ether in pentane, and 3×1 ml 100% ether, collecting each aliquot as a separate fraction. The first two fractions of 10% ether in pentane, containing primarily β-sesquiphellandrene, were combined (fraction A). All the remaining fractions were recombined into one solution (fraction B) for bioassay.

Components in extracts from both sexes of *P. guildinii* were tentatively identified by comparison of mass spectral data with library data (NIST-Wiley database, 2000). Identifications were confirmed by comparison of retention times and mass spectra of insect-produced compounds with those of authentic standards.

Determination of the Absolute Configuration of β-Sesquiphellandrene The determination of the absolute configuration of the *P. guildinii* male-specific sesquiterpene, β-sesquiphellandrene, was carried out as described by McBrien et al. (2002) (Fig. 1). The enantiomers of β-sesquiphellandrene were not resolved on a Cyclodex B chiral stationary phase GC column (J&W Scientific), but the column did resolve the enantiomers of the related compound, α-curcumene. Consequently, an aliquot of extract (containing β-sesquiphellandrene) was dehydrogenated to α-curcumene (Jackman 1960) by treatment with 100 μl of a benzene solution of 1,2,3,4-tetrachlorobenzoquinone (20 mg/ml) in a sealed vial at 80°C for 1 hr. The cooled reaction mixture was filtered through a 1-cm plug of silica gel, eluted with pentane, and the eluate analyzed with a Cyclodex B column (30 m×0.25 mm ID) operated isothermally at 90°C (140 kPa helium head pressure). Authentic samples of (+)- and (-)-β-sesquiphellandrene (see below) were dehydrogenated in identical fashion to provide standards for comparison.

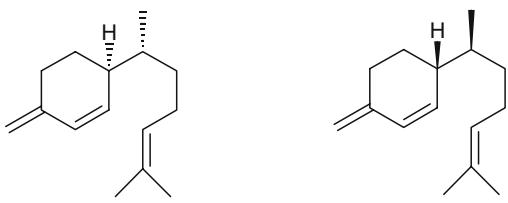

Fig. 1 Enantiomers of sesquiphellandrene. (7*R*)-(+)-β-Sesquiphellandrene is produced by male *P. guildinii*

A second aliquot of the insect-produced β-sesquiphellandrene was hydrogenated by stirring it with 5% Pd on carbon catalyst under H_2 for 1 hr. This produced two diastereomers in a ratio of ~2.5:1. Samples of synthetic β-sesquiphellandrene enantiomers (see below) and a sample of (*S*)-β-sesquiphellandrene isolated from ginger oil (McBrien et al. 2002) were hydrogenated in identical fashion to provide standards. All samples were analyzed isothermally (75°C) on the Cyclodex B column.

Olfactometer Bioassays A two-choice olfactometer modified from Borges and Aldrich (1994) was used to test the biological activity of odors from live insects, aeration extracts of male *P. guildinii*, and fractions thereof. The olfactometer consisted of a 500-ml three-neck, round-bottom flask (24/40 joints, Kontes, Vineland, NJ, USA). Two 250-ml rotary evaporator trap adapters (24/40 joints) were attached to the two outside arms to provide treatment and control chambers. A charcoal filter (20/40 mesh, 130×10-mm ID), connected in series to a water bubbler to humidify the incoming air, was attached to the inlets of the two chambers with silicon rubber tubing (Silastic, 4.8 mm ID; VWR Scientific, Darmstadt, Germany). Air was pulled through the system (400 ml/min) by connecting the middle neck of the flask to a regulated vacuum source, with the flow measured with a Clear Flow Rotameter (Accura Flow Products, Warminster, PA, USA). The olfactometer was positioned horizontally on a countertop in a room with fluorescent lighting (4×40 W). Temperature in the room was maintained at 26.0± 1.0°C. Positions of control and treatment arms were alternated between replicates to avoid any positional bias. The apparatus was cleaned after each five replicates with fragrance-free liquid soap, rinsed thoroughly with water, and dried in a convection oven at 80°C.

To begin an assay, a single *P. guildinii* was gently introduced into the release chamber with an artist's paint brush (Camel Hair, number 1), and allowed to acclimate for 3 min while the remainder of the apparatus was assembled. After attaching the treatment and control chambers and starting the airflow, the test bug's behavior was recorded over 15 min. We recorded the first arm of the olfactometer that each insect chose and subsequently remained in for at least 100 sec. Insects that did not leave the release chamber of the olfactometer during the first 10 min were considered "nonresponders," and were not included in the data analyses.

To determine which sex produced pheromone, we tested the attraction of insects of both sexes to odor from males (N=51 for females and N=30 for males) or females (N=54 for females and N=32 for males). Test individuals were offered a choice between odor from five live, sexually mature virgin insects or a clean air control. The five live insects used as odor sources were changed after 10 replicates.

Bioassays using crude extracts from males were performed with females (N=74) or males (N=30). Five microliters (0.5 BE) of crude hexane extract of the volatiles produced by 20 *P. guildinii* males aerated for 24 hr were spotted on a strip of filter paper, and the paper was placed in one of arm of the olfactometer. Extracts used in these tests contained 800±300 (N=8) ng/μl of β-sesquiphellandrene (ca. 40 ng μl^{-1} $insect^{-1}$ day^{-1}). A control, consisting of a filter paper treated with hexane was placed in the other arm.

To determine when females were most active and responsive to pheromone, bioassays were performed during three periods: morning (07:00 hours to noon) (N=23), afternoon (noon to 17:00 hours) (N=36), and evening (17:00 hours to 22:00 hours) (N=64). For these bioassays the methodology described above was followed.

To test the biological activity of crude extracts of males, fractions of extracts, and synthetic standards, and solutions of test stimuli (1 BE) were spotted on a strip of filter paper (1.5 cm long, 0.5 cm wide), and placed in one of the arms of the bioassay apparatus. Controls, consisting of filter papers treated with hexane, were placed in the other arm. Two

hundred nanograms of each synthetic standard were used in the bioassays. Bioassays were carried out during the evening period, using virgin, sexually mature females.

Fraction A, containing primarily β-sesquiphellandrene (N=70), and fraction B, containing the other volatiles released by male *P. guildinii* (N=34), were tested against hexane controls. Fractions A and B were also directly compared (N=30), as was fraction A against crude extract (N=30) or (7*S*)-(−)-β-sesquiphellandrene (N=30) isolated from ginger oil. Synthetic (7*R*)-(+) and (7*S*)-(−)-β-sesquiphellandrenes were tested against *n*-hexane controls (N=55 and N=54, respectively). In further tests, females were tested with the following comparisons: fraction A vs. synthetic (7*R*)-(+)-β-sesquiphellandrene (N=39) or synthetic (7*S*)-(−)-β-sesquiphellandrene (N=40); (7*R*)-(+) vs. (7*S*)-(−)-β-sesquiphellandrene (N=80); and a 1:1 mixture of synthetic (7*R*)-(+) and (7*S*)-(−)-β-sesquiphellandrenes vs. each enantiomer individually [N=72 for (*R*) and N=65 for (*S*)]. In addition, the biological activities of the last treatments were evaluated in bioassays with males (N=27 and N=34, respectively).

Data on the responses of males and females to different treatments (live insects, aeration extracts and fractions thereof, and synthetic standards vs. controls) were analyzed with chi-square tests. Statistical analyses were carried out by using MathCAD 2001 (MathSoft). Data on the production of pheromone during different periods of the day were analyzed with repeated measures ANOVA (Sigma Stat 3.1 Systat Software Inc.).

Chemicals The synthetic sesquiphellandrenes were synthesized from (*R*)-(+)-citronellal and (*S*)-(−)-citronellal, respectively (Aldrich Chemical, Co., Milwaukee, WI, USA), by the method of Chavan et al. (1997). Each consisted of an inseparable, ~1:1 mixture of the resulting sesquiphellandrene enantiomer with its C6 ring-junction epimer. The enantiomeric purity of the (7*R*)-isomer was 84% enantiomeric excess (ee) (reflecting the enantiomeric purity of the citronellal starting material), whereas the (7*S*)-enantiomer had an optical purity of >98%. In addition, enantiomerically pure (7*S*)-sesquiphellandrene was isolated from ginger oil as previously described (Millar 1998). β-Bisabolene and α-curcumene were available from previous studies (McBrien et al. 2002), (*E*)-β-farnesene was purchased from Bedoukian Research (Danbury, CT, USA), and nonanal was obtained from Avocado Research (Heysham, UK). Samples of *cis*- and *trans*-β-ocimene were kindly provided by Peter Landolt (US Department of Agriculture, Yakima, WA, USA). All other authentic standards were purchased from Aldrich.

Results

Analyses of Extracts of Volatiles Comparison of gas chromatograms and mass spectra of volatile compounds collected from sexually mature virgin males and females showed a number of compounds in common (Table 1). Most compounds had been reported previously from other stink bug species (Borges and Aldrich 1992; Zarbin et al. 2000), including (*E*)-2-hexenal, (*E*)- and (*Z*)-β-ocimene, 2-ethylhexanol, (*E*)-2-hexenyl acetate, undecane, nonanal, dodecane, tridecene, and tridecane. In addition, the extracts contained variable amounts of a group of compounds that were tentatively identified as sesquiterpenes, based on their molecular ions (*m/z* 204 or 202); the general profiles of their mass spectra, which contained patterns of ions typical of sesquiterpene hydrocarbons (Joulain and Konig 1998); and their GC retention times on a nonpolar DB5-MS column, which fell between those of tetradecane and hexadecane. These compounds were tentatively identified as (*E*)-β-farnesene, α-curcumene, zingiberene, β-bisabolene, and the male specific compound β-sesquiphellandrene by mass spectral matches with database spectra.

Table 1 Compounds identified in volatiles collected from sexually mature virgin adult *P. guildinii*

Compound	Amount (%, Mean±SE) Extract from Volatile Collections[a]	
	Male (*N*=4)	Female (*N*=3)
(*E*)-2-Hexenal	13.0±5.3	1.9±0.8
α-Pinene	20.6±6.3	5.9±1.2
Ocimene	0.6±0.3	4.8±1.8
(*E*)-2-Hexenyl acetate	1.4±0.7	15.1±1.5
2-Ethylhexanol	0.3±0.1	3.6±2.2
Undecane	2.6±0.5	4.4±1.9
Nonanal	0.7±0.4	3.8±2.3
Dodecane	2.2±1.5	39.4±13.8
Indole	0.3±0.2	6.2±1.4
Tridecene	0.7±0.1	13.5±6.8
Tridecane	100	100
(*E*)-β-farnesene	29.9±11.9	6.2±5.9
α-Curcumene	3.5±2.4	0.10±0.05
Zingiberene	3.3±3.1	0.10±0.03
β-Bisabolene	5.4±3.5	0.20±0.01
β-Sesquiphellandrene	94.3±46.3	0±0

[a] The mean percentages of compounds relative to tridecane, individually produced by each sex, were obtained from volatiles collection from the first day of collection, where the insects were stressed by manipulation.

The identifications were confirmed by mass spectral and retention time matches with those of authentic standards. All these compounds were of insect origin because they were not present in control aerations of the green beans used as food during aerations (Borges et al. 2006).

Despite the care taken in loading stink bugs into aeration chambers, defensive compounds were still obtained in large quantities on the first day of extraction (Table 1 and Fig. 2). Thus, these extracts were not used for bioassays or for fractionation. Extracts obtained from the second day onward contained low levels of defensive compounds (Fig. 2), and thus were used for analyses and bioassays.

The sesquiterpenes were seen in all extracts (*N*=150) collected from males, whereas these compounds were seen only in trace quantities in a small proportion (15 of 150) of female extracts (Table 1). β-Sesquiphellandrene was never seen in any of the 150 extracts from females that were analyzed. Furthermore, β-sesquiphellandrene was detected only in extracts from sexually mature males (>8 d old) (Fig. 2).

The absolute configuration of β-sesquiphellandrene was determined by two indirect routes because its enantiomers were not resolved on the Cyclodex B GC column. First, the insect-produced β-sesquiphellandrene was dehydrogenated with 3,4,5,6-tetrachloro-1,2-benzoquinone to produce the aromatic analog, α-curcumene, which was resolved on the chiral column, with the (7*S*)-enantiomer eluting first (McBrien et al. 2002). The α-curcumene derived from β-sesquiphellandrene produced by male *P. guildinii* proved to be the (7*R*)-enantiomer. However, because the dehydrogenation reaction gave a poor yield of α-curcumene, a second method was developed to confirm the absolute configuration of the insect-produced β-sesquiphellandrene. Thus, standards of stereoisomerically pure (7*S*)-β-sesquiphellandrene isolated from ginger oil, synthetic (7*R*)- and (7*S*)-sesquiphellandrenes, and the insect-produced β-sesquiphellandrene were hydrogenated, producing a ~2.5:1 mixture of diastereomers. On the Cyclodex B column, the more abundant, earlier-eluting

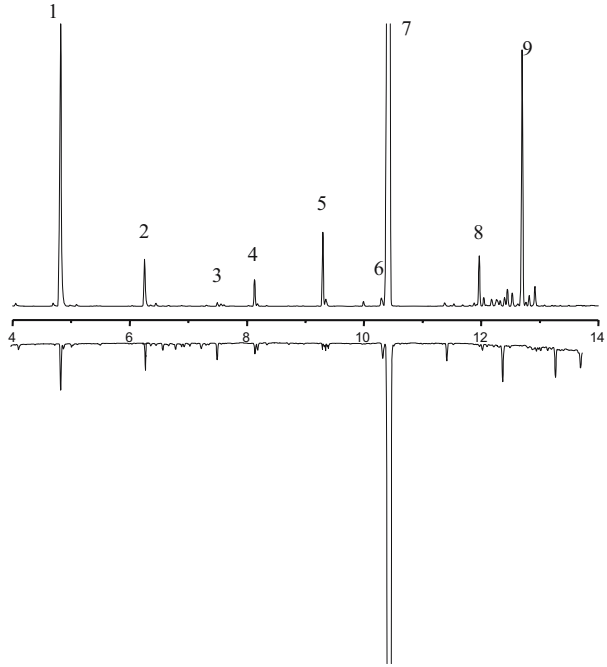

Fig. 2 Typical gas chromatograms of volatiles collected from male (top) and female (bottom, inverted) *P. guildinii* when the insects are not stressed: 1=(*E*)-2-hexenal, 2=ocimene isomer, 3=2-ethylhexanol, 4=undecane, 5=nonanal, 6=tridecene, 7=tridecane, 8=α-farnesene, 9=β-sesquiphellandrene

diastereomer was not resolved into its enantiomers. However, the minor diastereomer derived from each enantiomer was partially resolved [derivative from (*S*)-enantiomer, 133.13 min; from (*R*)-enantiomer, 134.01 min]. Coinjection of the reduced β-sesquiphellandrene collected from the insects with the reduced (7*S*)-β-sesquiphellandrene standard confirmed that the insect-produced material had the (7*R*)-configuration.

Analysis of 10 extracts obtained from groups of 20 males aerated for 24 hr determined that males released approximately 40 ng of sesquiphellandrene per bug per day. There was no clear cycle of production, with males producing similar amounts during morning, afternoon, and evening (Fig. 3, repeated measures ANOVA, $F_{2,8}$=0.21, P=0.81).

Bioassays with Live Insects Female bugs were attracted to odors of live males (χ^2_1 =10.76, N=41, P=0.001; Fig. 4) but not to odors of live females (χ^2_1 =0.13, N=32, P=0.72; Fig. 4). Males were not attracted to odors of females (χ^2_1 =0.28, N=14, P=0.59; Fig. 4) or of males. In the latter case, most of the males tested (24/30) did not leave the release chamber of the olfactometer, and so statistical analysis was not performed for the six individuals that made a choice (four to control, two to treatment; Fig. 4). When female and male *P. guildinii* were tested with the crude extract of males, female bugs were attracted to the extract of male odor (χ^2_1 =18.06, N=64, P<0.001; Fig. 5a), whereas males were not (Fig. 5a). These results indicated that males produced a sex-specific pheromone that attracted only females, and so all further bioassays were done only with females as test individuals, with the exception that males were also bioassayed to the synthetic standards to double-check that the compound was a sex pheromone rather than an aggregation pheromone.

Females' Responses to Crude Extract of Males at Different Times of the Day When females were tested during three different periods of the day (morning, afternoon, and evening), they responded to crude extracts of male-produced volatiles only in the evening. During the

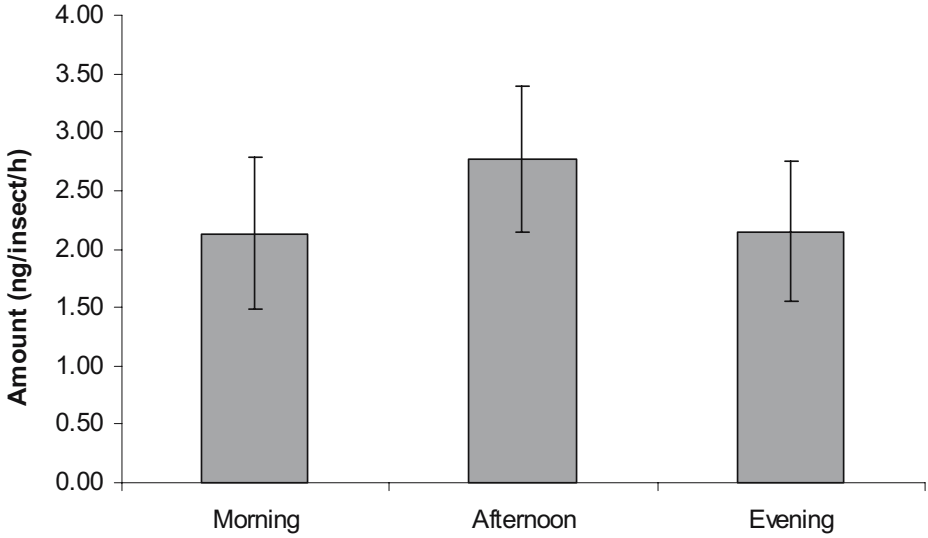

Fig. 3 Mean amount (ng insect^{-1} h^{-1}±SD) of pheromone released by male *P. guildinii* during different periods of the day. Collections lasted 5 hr for each period. The amounts collected during the three periods were not significantly different (repeated measures ANOVA, $F_{2,8}$=0.35, P=0.72)

evening, 70.3% of the females tested chose the treatment chamber (χ^2_1 =25.83, N=53, P<0.001; Fig. 5b), whereas for the morning only 4.3% (1/23) of females tested left the release chamber of the olfactometer (Fig. 5b). In the afternoon, the test insects were more active (69.5% moving out of the release chamber) but their responses were not oriented toward the treatment chamber

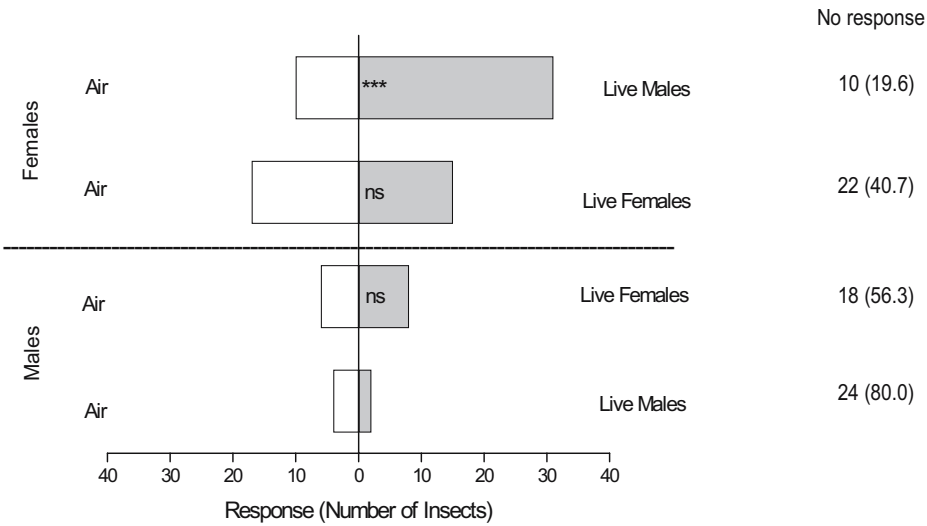

Fig. 4 Responses of male and female *P. guildinii* to odor of conspecifics of each sex vs. blank controls, in a two-choice olfactometer bioassay. Data were analyzed by chi-square tests (ns P>0.05, ***P<0.001). Data for males responding to odor of live males were not analyzed because of the low number of responders (6/30 insects tested). The numbers of nonresponders are to the right of the figure. Numbers in parentheses represent the percentage of nonresponders out of the total number of insects tested

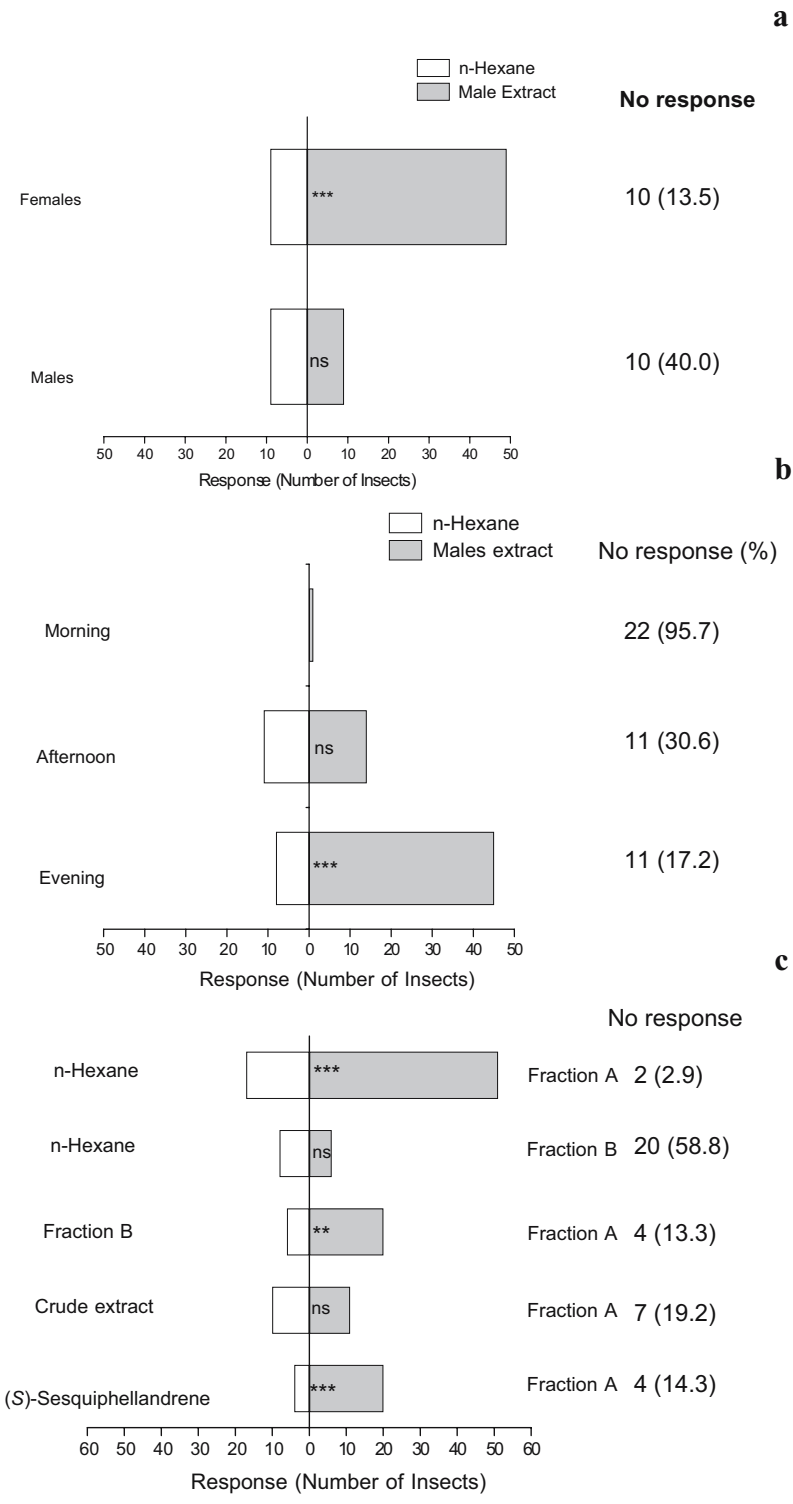

(χ^2_1 =0.36, N=25, P=0.55; Fig. 5B). Thus, during this period the females did not appear to be responsive to male pheromone. In light of these results, all further bioassays were performed from 17:00 to 22:00 hours.

Bioassays with Fractions of Insect Extracts and Synthetic Standards When the two fractions of crude extract were bioassayed against the hexane control, female *P. guildinii* responded to fraction A, which contained primarily (7*R*)-β-sesquiphellandrene (χ^2_1 =17.0, N=68, P<0.001; Fig. 5c). Females did not respond to fraction B, which contained primarily saturated hydrocarbons and several sesquiterpenes (χ^2_1=0.28, N=14, P=0.59; Fig. 5c). Females also preferred fraction A when it was evaluated directly vs. fraction B (χ^2_1 =7.54, N=26, P=0.006; Fig. 5c). There were no differences in the responses of female bugs to fraction A in bioassays against the crude extract (χ^2_1 =0.05, N=21, P=0.83; Fig. 5c), indicating that fraction A was responsible for the attractiveness of the crude extracts. Furthermore, when fraction A, containing (7*R*)-β-sesquiphellandrene, was tested against an equal amount of the pure (7*S*)-enantiomer isolated from ginger oil, fraction A was more attractive (χ^2_1 =10.67, N=24, P=0.001; Fig. 5c). In addition, when synthetic (7*R*)- and (7*S*)-β-sesquiphellandrenes were tested individually against hexane controls, the (7*R*)-β-sesquiphellandrene was attractive to females, whereas the (7*S*)-enantiomer was not (χ^2_1 = 4.83, N=35, P=0.03; Fig. 6a). In contrast, male bugs showed no response to either enantiomer of the synthetic sesquiphellandrene against hexane controls (Fig. 6a). When a 1:1 mixture of synthetic (7*R*)- and (7*S*)-β-sesquiphellandrenes was tested against each enantiomer individually, only the (7*R*)-β-sesquiphellandrene was as attractive as the 1:1 mixture (χ^2_1 = 0.33, N=48, P=0.56; Fig. 6b). However, when synthetic (7*R*)-β-sesquiphellandrene was tested vs. synthetic (7*S*)-β-sesquiphellandrene, females responded equally to both treatments (χ^2_1 =0.09, N=46, P=0.77; Fig. 6b). There was no difference in the response of female bugs to fraction A in bioassays vs. synthetic (7*R*)-β-sesquiphellandrene (Fig. 6b), indicating that fraction A, containing male-produced (7*R*)-β-sesquiphellandrene, was as attractive as synthetic (7*R*)-β-sesquiphellandrene to females. Furthermore, when fraction A was tested against the synthetic (7*S*)-enantiomer, fraction A was more attractive than the (7*S*)-enantiomer (χ^2_1 =10.67, N=24, P=0.001; Fig. 6b).

Discussion

Daily collections of volatiles (N=150) from groups of 20 *P. guildinii* males, starting 5 d after the final molt, and continuing for 15 consecutive days, showed that young males did not produce detectable levels of male-specific compounds. Male-specific compounds were first detected in extracts of males 8 d after the molt to adulthood. Although the pheromone was collected from male *P. guildinii* throughout the day, female bugs were only attracted to volatiles from males during the evening, suggesting that females are only responsive during this period. These results are analogous to previous reports of mating behavior of the stink bugs *Euschistus heros* and *Thyanta perditor* in which the strongest responses to pheromone occurred during late afternoon to early evening (Borges et al. 1998a,b; Moraes et al. 2005b).

Most of the putative defensive compounds identified in the headspace volatiles of *P. guildinii* adults consisted of compounds that have been reported previously from other neotropical stink bug species (Borges and Aldrich 1992; Moraes et al. 2005b; Borges et al. 2006). However, we found that, in addition to β-sesquiphellandrene, males consistently released several sesquiterpenes. In contrast, sesquiterpenes were only seen in trace amounts

in a small percentage of extracts from females. The function of these sesquiterpenes, and why their production is strongly male-biased, is unknown. They did not appear to have a role in sexual attraction because (7*R*)-β-sesquiphellandrene alone was as attractive as crude extracts. They also do not appear to be artifacts from the green beans provided as food because they were not detected in extracts of volatiles from the green beans.

The first study of pheromones within the genus *Piezodorus* was carried out by Leal et al. (1998) with *P. hybneri*. The pheromone blend of *P. hybneri*, which attracted both sexes in laboratory bioassays, consisted of β-sesquiphellandrene (absolute configuration not determined), (*R*)-15-hexadecanolide, and methyl (*Z*)-8-hexadecenoate (ratio 10:4:1). The responses of females to subsets of the blend or individual compounds were not investigated (Leal et al. 1998). Thus, it remains unclear whether the full three-component blend is required to attract females, or whether the attraction observed in bioassays was actually because of only one or two components of the blend.

In contrast, the pheromone of congeneric *P. guildinii* appears to consist of a single component, (7*R*)-β-sesquiphellandrene, which attracts only females. Furthermore, examination of the percentage of nonresponders in bioassays (Figs. 4, 5, and 6b) showed that in all bioassays in which the natural compound (7*R*)-β-sesquiphellandrene was present (live males, airborne extracts, fraction A from airborne extracts), the percentages of females that did not respond were lower than those in bioassays in which the treatments did not include this compound (Figs. 4, 5, and 6b). It is also interesting to note that β-sesquiphellandrene produced by *P. guildinii* has the opposite configuration to the (7*S*)-β-sesquiphellandrene produced as a pheromone component by two other stink bug species, *Thyanta pallidovirens* and *Thyanta custator accerra* (McBrien et al. 2002).

Although the results from most of our bioassays indicated that the insect-produced (7*R*)-enantiomer of β-sesquiphellandrene was the active antipode, in one test similar numbers of bugs responded to both synthetic enantiomers (Fig. 6b). In addition, in some bioassays testing synthetic compounds, there were more nonresponding test bugs than in bioassays with the insect-produced material (Fig. 6). The cause of these anomalies is not clear. It may have been because of the fact that the synthetic compounds were both mixtures of epimers, rather then pure compounds, thereby distorting the olfactory signal. It was not because of large amounts of the (7*R*)-enantiomer in the synthetic (7*S*)-enantiomer because the latter compound was highly enantiomerically pure (>98% ee).

In a preliminary report, Borges et al. (1999) reported the identification of methyl 2,6,10-trimethyltridecanoate and methyl 2,6,10-trimethlyldodecanoate in extracts of field-collected *P. guildinii*. They (Borges et al. 1999) reported that these compounds appeared to be attractive to *P. guildinii*, based on catches in traps, that were deployed to catch *E. heros*. For *E. heros*, these two esters have been identified in volatiles collected from male bugs, and the biological activities of the esters verified in both laboratory bioassays and field tests (Borges and Aldrich 1994; Borges et al. 1998a,b; Costa et al. 2000; Zhang et al. 2003). In contrast, these compounds were not found in any of the samples analyzed in the current

study. It should be pointed out that the previous identifications were based only on GC retention time matches to the two esters, which on more detailed investigation by gas chromatography–mass spectrometry appear to be coincidental. The basis for the attraction of *P. guildinii* to the esters (Borges et al. 1999; Aldrich et al. 1993) is unclear. However, a similar phenomenon has been observed for other stink bug species in which bugs appear to be attracted to the pheromone components of other bug species. For example, the Asian species *Halyomorpha halys* (Stål) is attracted to ester pheromone components of *Plautia stali* (Scott) and of *Thyanta* spp., although the esters have not been found in *Halyomorpha* bugs (J. R. Aldrich, personal communication). In addition, Endo et al. (2007) reported cross attraction of *P. hybneri* to the aggregation pheromone of *Riptortus clavatus* (Thunberg).

The role of (7*R*)-β-sesquiphellandrene as a mediator of *P. guildinii* reproductive behavior under field conditions still remains to be determined. It is likely that the pheromone may act in concert with the substrate-borne vibrational signals that this insect uses for communication over shorter ranges (Moraes et al. 2005a). It may be possible to develop pheromone-based monitoring systems for this insect, particularly if vibrational signals could also be incorporated into the trap design. Such monitoring systems, when used in conjunction with strategies such as trap cropping, may provide an integrated pest management solution for control of this important pest.

A Male Sex Pheromone in a Scorpionfly

Dagmar Kock · Joachim Ruther · Klaus Peter Sauer

Received: 1 December 2006 / Revised: 22 March 2007 / Accepted: 30 April 2007 /
Published online: 12 May 2007

Abstract It has been postulated that males of a number of scorpionfly species produce sex pheromones. This is based on the observation that females often respond only to conspecific males when they evert their genital pouch, the proposed site of pheromone release. In this study, we prove that in *Panorpa germanica* (Mecoptera, Panorpidae), the eversion of a male's genital pouch is associated with the release of a volatile sex pheromone. In dual choice situations, females showed a high preference for 'calling' (males with everted genital pouch) over noncalling individuals. Volatiles emitted by males and females were collected and identified by coupled gas chromatography–mass spectrometry. Two aldehydes [(2*E*,6*Z*)-nona-2,6-dienal and (*E*)-non-2-enal] were characteristic of calling males but not of non-calling or immature males or females. Bioassays with synthetic compounds confirmed that the identified substances are attractive to females. To the best of our knowledge, this is the first identification of a sex pheromone in scorpionflies.

Keywords Sex attraction · (2*E*,6*Z*)-Nona-2,6-dienal · (*E*)-Non-2-enal · Male pheromone · Female mate choice · Scorpionflies · Mecoptera · *Panorpa germanica*

Introduction

In insects, sex attraction and pair formation is often mediated by the release of volatile sex pheromones by the female or, less commonly, the male (Wyatt 2003). Based on behavioral studies, the existence of male-derived sex attractants has long been suggested for Bittacidae (Bornemissza 1964, 1966a, b) and Panorpidae (Thornhill 1973, 1979, 1992) within the

scorpionflies (Mecoptera). However, the chemicals involved in the sexual communication of scorpionflies have not been identified.

Felt (1895) and Grell (1942) suggested that chemical communication existed in *Panorpa* scorpionflies. Felt (1895) first speculated that a 'peculiar organ' formed by two processes at the dorsum of the third and the fourth segment of the male abdomen was the source of a volatile oil that attracts females. However, four decades passed before Grell (1942), in his detailed study on the morphology of the genital bulb of *P. communis*, described a layer of glandular epithelium in the outward septum of the male genital pouch and concluded this was the possible source of substances that sexually stimulate females during courtship. Thornhill (1979) found that females of nine different North American *Panorpa* species responded only olfactorily to conspecific males if the male's genital pouch were everted, confirming this structure to be linked to pheromone release.

Males of several Central European species extend their genital pouch to varying degrees during courtship, being most evident in *P. germanica* (Fig. 1), prominent in *P. alpina* and *P. cognata*, but less noticeable in *P. vulgaris* and *P. communis* (Sauer, personal observation). The 'calling' behavior of *P. germanica* is conspicuous as the male raises his abdomen and extrudes the genital pouch between the two separated ventral parameres of its genital segment (Fig. 1). At the same time, the male spreads and regularly flutters his wings—potentially helping to spread the emitted volatiles. These substances are detectable by humans, having a scent somewhat reminiscent of freshly cut cucumber. Male 'calling' and initiation of mating occurs only over a rather narrow time frame in the last 5 hr of the day and in the hour after sunset (Gerhards 1999). Females approaching a calling male will show interest by wing flapping and gentle nodding of the abdomen, but for mating to occur, the male must present the female a salivary secretion as a nuptial gift (Gerhards 1999). While males of *P. germanica* are polygynous, females usually mate only once or twice during their lifetime (Gerhards 1999). Consequently, male mating success (number of copulations obtained during life) is highly variable (Gerhards 1999), and we assume female choice to be a strong selective force in this system. Conceivably, female mate choice in this species could take place before copulation, based on the males' pheromone bouquets.

The aim of the present study was to investigate whether presentation of the eversible pouch by male *P. germanica* is correlated with the release of a volatile sex pheromone and to identify the involved chemicals.

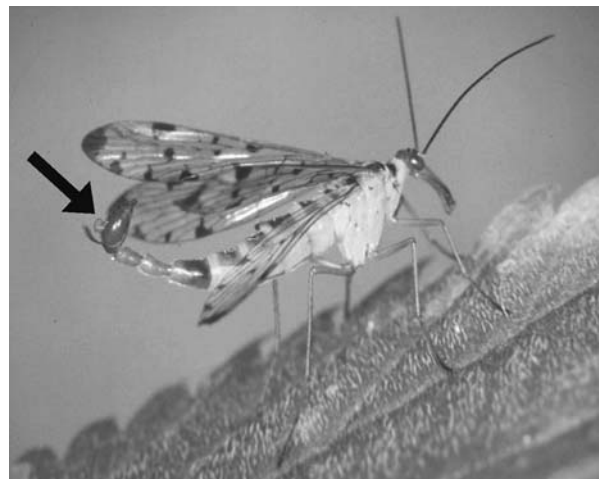

Fig. 1 A 'calling' *Panorpa germanica* male with everted genital pouch (indicated by the *arrow*)

Methods and Materials

Breeding and Keeping of P. germanica Adult *P. germanica* males and females collected in the field near Freiburg i. Br., southern Germany, were used to establish a colony under established rearing procedures (see Sauer 1970, 1977; Kock et al. 2006). The F1 imagoes were kept separately in plastic cylinders (diameter=3.5 cm, height=8 cm) containing moist tissue paper as a water supply under a 18:6 hr light/dark cycle at 18°C. All adult scorpionflies were fed with one segment of a last larval instar of mealworm (*Tenebrio molitor*) at the day of hatching and subsequently every fourth day. Under these conditions, *P. germanica* adults take about 8 d after emergence to reach sexual maturity. As *P. germanica* exhibits courtship display only at the end of the photophase and beginning of the scotophase, we reared some individuals under the same photoperiodic conditions but with lights off occurring 5 hr earlier so that we had both calling and noncalling males available during the normal mating window.

Volatile Sampling An apparatus designed for closed-loop stripping analysis (CLSA; Grob and Zürcher 1976) was used to prepare headspace extracts from (a) greater than 10-d-old mature calling (N=10) and (b) mature noncalling males (N=11), as well as (c) less than 6-d-old immature males (N=7) and (d) mature females (N=9). Individuals were placed in an Erlenmeyer flask (100 ml) equipped with a wash bottle insert that was connected to a mini-vacuum pump (Neolab, Heidelberg, Germany) by Teflon tubing. Volatile laden air (80 ml/min) was sucked for 1 hr through a CLSA adsorption tube (Gränicher & Quartero, Daumazan, France) containing a 1-mm charcoal layer (5 mg). The adsorbed substances were eluted with 25 µl dichloromethane containing 20 ng/µl of methyl nonanoate as an internal standard for approximate quantification of the collected volatiles. For males, it was recorded if the genital pouch was everted during volatile sampling.

Gas Chromatography–Mass Spectrometry Volatile extracts were analyzed by gas chromatography–mass spectrometry (GC-MS) on a Fisons 8060 GC (Fisons Instruments) equipped with a 30 m×0.32 mm inner diameter×0.25 µm film thickness DB-5 ms column (J&W Scientific, Folsom, CA) operated in splitless mode (injector temperature=240°C) and coupled to a Fisons MD800 quadrupole MS running in the electron impact (EI) mode at 70 eV. Helium was used as carrier gas at a head pressure of 5 kPa (flow rate, 1.0 ml/min). Initial oven temperature was 80°C, increased at 5°C/min to 280°C, and held for 30 min. Chemicals were identified by comparison of retention times and mass spectra with those of authentic reference compounds (Sigma-Aldrich, Steinheim, Germany). An approximate quantification of identified compounds was obtained by comparison of peak areas with the internal standard and between treatment values compared using a one-way analysis of variance (ANOVA) and subsequent least significant difference test (LSD).

Bioassays Bioassays on preferences for 'genuine' male odors, as well as for synthetic chemicals, were done by exposing females of *P. germanica* to different dual choice situations (see below) in Y-tube olfactometers constructed entirely from acrylic glass (each arm 50 cm in length and an inner diameter of 5 cm). To eliminate visual cues, targets were placed in opaque chambers at the end of two arms, and the female was then placed at the end of the third. A constant airflow of 50 l/hr was generated in both test and control arms. To eliminate possible positional bias, test and control arms were altered after every individual assay. Y-Tubes were cleaned regularly with 70% ethanol.

In experiment 1, females (N=68) were given the choice between a synthetic blend of (2*E*,6*Z*)-nona-2,6-dienal (17 mg) and (*E*)-non-2-enal (170 mg; Sigma-Aldrich) dissolved in

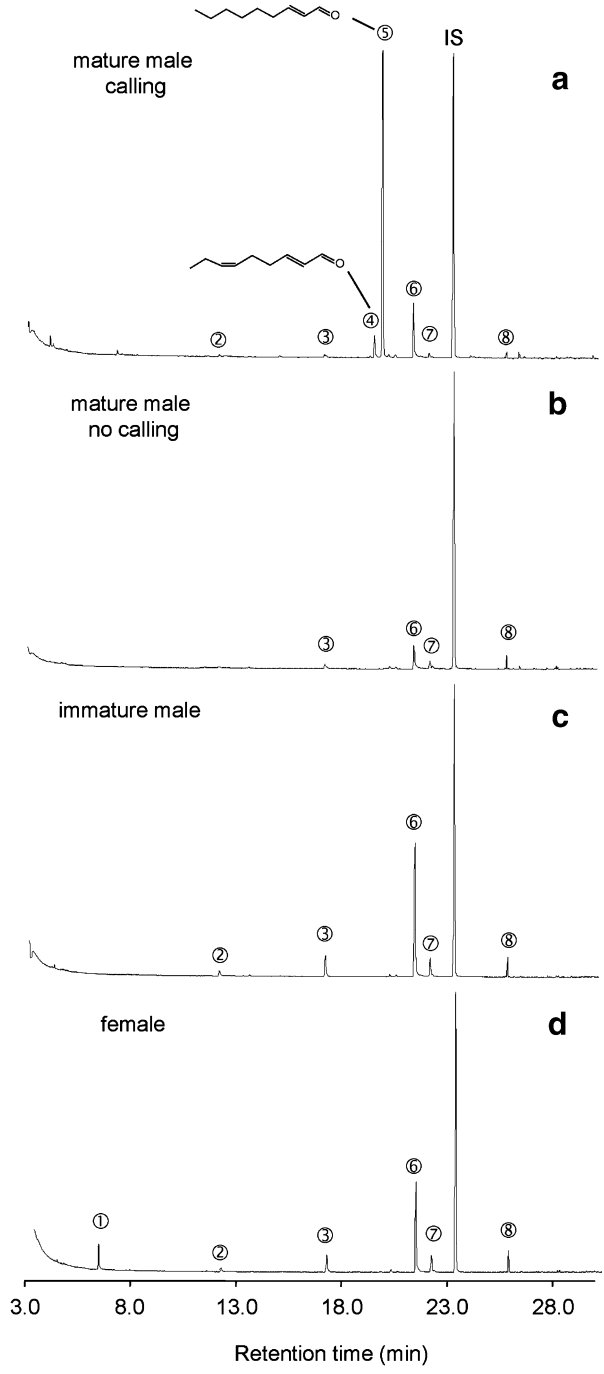

Fig. 2 Total ion current chromatograms obtained by GC-MS analysis of headspace extracts of **a** calling mature males, **b** non-calling mature males, **c** immature males, and **d** mature females. Numbered compounds were identified as butane-1,3-diol (*1*), decane (*2*), undecane (*3*), (2*E*,6*Z*)-nona-2,6-dienal (*4*), (*E*)-non-2-enal (*5*), 2-(2-butoxyethoxy)-ethanol (*6*), dodecane (*7*), tridecane (*8*); *IS* internal standard (20 ng methyl nonanoate). The remaining trace components are unknown

10 ml of polyethylene glycol (PEG) and the pure solvent as control. The selected ratio of the two aldehydes was based on the chemical analyses of headspace collections from calling males (see below). Five hundred microliters of the solutions were transferred into a commercially available membrane dispenser (Langlock® Do 120, Wilhelm Biological Plant Protection, Sachsenheim, Germany) that releases even highly volatile semiochemicals at constant emission rates (Ruther and Mayer 2005). The permeable membrane top cover, the volatile release site, was initially dampened with the PEG solution and then kept moist by gently and regularly shaking the flask. The estimated amounts of synthetic chemicals released from the dispensers was determined by sampling for 1 hr using the same procedure as described above for the volatile collections from insects (N=5).

In experiment 2, females (N=57) were given the choice between a calling (everted genital pouch) and a noncalling mature male (genital pouch not everted). In these trials, females were transferred into the Y-tube olfactometer when one male started calling and the other male exhibited no courtship display.

In both treatments, the behavior of each female was observed for up to 30 min, recording if the female moved into one of the two target sides of the Y-tube olfactometer. If a female showed courtship behavior (wing flapping) and, in addition, passed at least two thirds of the length of one of the target sides, the according target (calling male, noncalling male, synthetic aldehydes, control solution) was noted as the female's decision. If no such behavior occurred within 30 min, 'no decision' was recorded as the female's response to the dual choice situation.

Possible preferences of females that made a choice were analyzed by a binominal test.

Results

Chemical Analyses GC-MS analyses of headspace extracts from (a) mature calling males, (b) mature noncalling males, (c) immature males, and (d) mature females revealed two compounds characteristic of mature calling males (Fig. 2, Table 1) that were identified as (2*E*,6*Z*)-nona-2,6-dienal and (*E*)-non-2-enal (Fig. 3). Trace amounts of both compounds were detectable in volatile extracts from mature females, whereas noncalling mature males only emitted minute amounts of (*E*)-non-2-enal, and immature males released neither. Butane-1,3-diol, *n*-alkanes with chain lengths between 10 and 13 carbon units, and 2-(2-butoxyethoxy)-ethanol (probably a contamination from the insect container) were also

Table 1 Amounts of (2*E*,6*Z*)-nona-2,6-dienal and (*E*)-non-2-fenal collected from mature calling males, mature noncalling males, immature males, and mature females within 1 hr CLSA sampling

Gender	Condition	Number	mean amount±SE (ng/hr)	
			(2*E*,6*Z*)-nona-2,6-dienal[a]	(*E*)-non-2-enal[b]
Male	Mature, calling	10	21±6a	240±60a
Male	Mature, no calling	11	0.0±0.0b	1±1b
Male	Immature	7	0.0±0.0b	0.0±0.0b

[b] ANOVA (df=3): F=14.21, P<0.001.

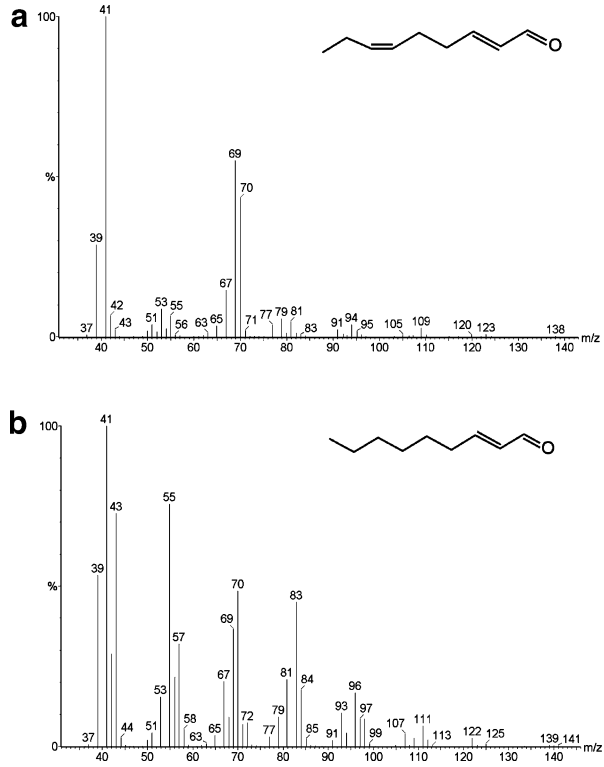

Fig. 3 Mass spectra (EI, 70 eV) of volatiles released by calling *P. germanica* males **a** (2*E*,6*Z*)-nona-2,6-dienal and **b** (*E*)-non-2-enal

detected, but none of these volatiles was specific for any group of insects. The two nine-carbon aldehydes were released by calling males at a ratio of approximately 1:10 in favor of (*E*)-non-2-enal. The membrane dispenser used for the bioassays released 570±60 ng/hr of (2*E*,6*Z*)-nona-2,6-dienal and 5,800±700 ng/hr of (*E*)-non-2-enal. Thus, the dispensing system released amounts equivalent to approx. 24 calling males at a ratio comparable to the natural male odor.

Bioassays Thirty-two out of 68 females (47%) made a choice in the Y-tube olfactometer that tested synthetic aldehydes vs. the solvent control, and 31 chose the arm with the synthetic chemicals ($P<0.001$, binomial test, Fig. 4). In experiment 2, 37 of 57 (65%) females tested made a choice between the calling vs. noncalling male, with 36 preferring the arm containing the calling male ($P<0.001$, binominal test, Fig. 4). By comparing the

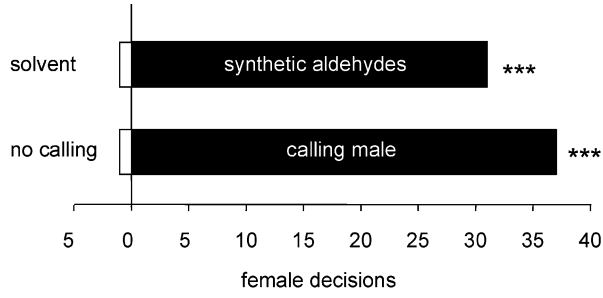

Fig. 4 Female decisions in Y-tube olfactometer preference tests. Females were given the choice between synthetic (2*E*,6*Z*)-nona-2,6-dienal and (*E*)-non-2-enal (1:10) dissolved in PEG and the pure solvent (*top*) or a calling and a noncalling mature male (*bottom*)

two treatments, we found that the number of nonresponders was significantly higher in the experiment that used the synthetic aldehydes (G test, G=3.88, P<0.05).

Discussion

Our results demonstrate that the calling behavior (eversion of the genital pouch) of mature *P. germanica* males is associated with the release of (2*E*,6*Z*)-nona-2,6-dienal and (*E*)-non-2-enal at a ratio of approximately 1:10. Calling males, as well as a mixture of the synthetic aldehydes, are highly attractive to unmated females in the Y-tube olfactometer, so we conclude that the two substances are male sex attractants for this species. To the best of our knowledge, this is the first identification of a sex pheromone in a scorpionfly.

Interestingly, the two aldehydes are major constituents of the odor bouquet of freshly cut cucumber, and they contribute significantly to the characteristic aroma of this vegetable (e.g., Forss et al. 1962; Kemp et al. 1974; Whitfield and Last 1991). Preliminary tests show freshly cut cucumber is attractive to *P. germanica* females in the Y-tube olfactometer. When cucumber fruits are damaged, these aldehydes are formed by enzymatic degradation of unsaturated fatty acids (Galliard and Matthew 1976), but it remains to be determined if the synthesis of pheromone compounds in insects follows the same pathway.

The responsiveness of females in the olfactometer tests was relatively low to both calling males and synthetic lures. In the latter case, the release rates from the dispensers were much higher than from calling males, so the low responses observed may be related to the concentration of the signal. In the case of virgin males, it could be related to mate choice. Unlike many other *Panorpa* species, such as *P. vulgaris* (Sauer et al. 1998, 1999), *P. communis* (Aumann 2000), and *P. cognata* (Engqvist and Sauer 2001, 2003) that are polyandrous, *P. germanica* females are generally monandrous (Kock and Sauer, unpublished data). In the case of the polyandrous *P. vulgaris*, there is no precopulatory mate choice, although females adjust the duration of copulation based on male quality, thereby receiving greater numbers of sperm from high-quality males (Sauer et al. 1997, 1998, 1999). In contrast, monandrous *P. germanica* females may exhibit precopulatory mate choice based on their ability to detect and evaluate the pheromone composition of potential mates. Thus, they will respond only to better quality males. This idea is supported by the fact that *P. germanica* females often refuse to mate if offered only a single male (Kock, personal observation). Additional research is required to determine if there is intermale variability in the ratio of the pheromone blend and whether females can detect and use such differences. We will also investigate whether less volatile substances, which act only at close range, play a role in precopulatory mate choice by this species.

Abstract Perception of the female sex pheromone in *Utetheisa ornatrix* (Lepidoptera: Arctiidae) is responsible for induction and adjustment of calling by females and the collective phenomenon termed "female pheromonal chorusing". We found five olfactory-active compounds in the *U. ornatrix* female gland. When females were exposed to the entire pheromone or to two of its (synthetically prepared) components, (*Z*,*Z*,*Z*)-3,6,9-eicosatriene and (*Z*,*Z*,*Z*)-3,6,9-heneicosatriene, they were more likely to call during a given night, begin calling earlier, and briefly increase signal frequency with which they extrude their abdomen, an observable indication of calling in this species. Some females even initiated calling during photophase when exposed to the pheromone components. In general, female *U. ornatrix* are more sensitive to the complete blend of pheromone than to its individual compounds. We also tested the hypotheses: 1) that abdominal extrusion *per se* increases the rate of pheromone release; and 2) that greater abdominal pumping rhythm increases pheromone release rate. Contrary to our expectations: 1) females did not respond more strongly to a pulsed pheromone stimulus than to the constant release of pheromone at

the same average release rate; and 2) we did not find a relationship between the frequency of abdominal pumping and pheromone release rate. Possible explanations for these unexpected findings are discussed.

Keywords Arctiid moth · Chemical communication · Olfactory response · Sex pheromone · Signal perception

Introduction

In lepidopteran communication, females are typically regarded as non-interactive advertisers before courtship and pair formation. They are believed to signal their receptivity and location to males via long-distance pheromones. Potential responses to the sex pheromones of neighboring females are generally overlooked. However, some neurophysiological and behavioral evidence suggests that the latter may not be accurate for some moth species, and that communication by females may be more interactive and complex than previously considered. Researchers have found electrophysiological responses of female antennal neurons to conspecific female sex pheromone components in several lepidopteran families: Arctiidae (*Panaxia quadripunctaria*, Schneider et al. 1998; *Utetheisa ornatrix*, Grant and O'Connell 2000), Noctuidae (*Heliothis virescens* and *H. subflexa*, Groot et al. 2005; Hillier et al. 2006; *Spodoptera littoralis*, Ljungberg et al. 1993), and Sphingidae (*Manduca sexta*, Kalinová et al. 2001). Conspecific females and/or their sex pheromone are also known to induce calling in females in Tortricidae (*Choristoneura fumiferana*, Palaniswamy and Seabrook 1978, 1985; *Cydia fagiglandana* and *C. splendana*, Den Otter et al. 1996), and to attract (Tortricidae; *C. fagiglandana* and *C. splendana*; Den Otter et al. 1996) or repel other females (Noctuidae; *H. armigera* and *H. zea*, Saad and Scott 1981).

At a basic level, pair formation in the arctiid moth *U. ornatrix* conforms to the general feature of female-emitted pheromones eliciting upwind flight in conspecific males. Female *U. ornatrix* begin calling at dusk and normally continue for several hours. As in various arctiid moths, calling behavior is highly apparent and entails pumping of the abdomen, i.e., rhythmically extruding the terminal segments that bear the pheromone glands, at a rate of 1.5–3.0 sec^{-1} (Conner et al. 1980, 1985). Three active components of the *U. ornatrix* female pheromone have been identified: (*Z*,*Z*,*Z*)-1,3,6,9-heneicosatetraene (1,*Z*3,*Z*6,*Z*9-21Hy), (*Z*,*Z*,*Z*)-3,6,9-heneicosatriene (*Z*3,*Z*6,*Z*9-21Hy), and (*Z*,*Z*)-6,9-heneicosadiene (*Z*6,*Z*9-21Hy) (Conner et al. 1980; Jain et al. 1983). Importantly, electroantennogram (EAG) responses to one of the components, *Z*3,*Z*6,*Z*9-21Hy, occur in females (Grant and O'Connell 2000) and in males (Conner et al. 1980; Jain et al. 1983).

A recent study reported that female *U. ornatrix* within olfactory range of neighboring females synchronize the onset of their daily calling periods and exhibit a higher abdominal pumping rate than isolated individuals (Lim and Greenfield 2007). Grouped females were also more likely to call on a given night, and to call without interruption and for a longer duration than females that were olfactorally isolated from neighbors (Lim and Greenfield 2007). These data show that females modify the timing and intensity of calling in the presence of neighboring females, a phenomenon termed "female pheromonal chorusing" (Lim and Greenfield 2007). Evidence that females respond specifically to conspecific sex pheromone is circumstantial, although as pointed out by Grant and O'Connell (2000), "gender-specific body odors" may conceivably play a role in generating the interactive behavior. In the present study, we examine the specific responses in calling of *U. ornatrix*

females to conspecific female sex pheromone, and its separate components, to understand the mechanisms and evolution of this communal sexual display.

In a previous study, Lim and Greenfield (2007) reported that calling females increased abdominal extrusion rates in response to the presence of calling neighbors. We propose that the extrusion rate indicates the "vigor" with which calling is performed, and is related to energetic expenditure during calling, and pheromone release rate. The latter is based on the hypothesis that rhythmic abdominal pumping serves to increase peak pheromone release rate, thereby maximizing potential attraction of males (Schal and Cardé 1985; Dusenbery 1989). Alternative adaptive hypotheses for abdominal pumping include the creation of an additional axis of the pheromone signal, temporal modulation, along which species specificity may be encoded, and the reduction of sensory adaptation in the male receiver (Conner et al. 1980). Therefore, we examined two additional questions concerning the potential response of female *U. ornatrix* to the conspecific female pheromone: Do females exhibit a heightened response to a pulsed pheromone signal, and does the abdomen extrusion rate relate to the pheromone release rate?

Methods and Materials

Study Population A laboratory population of *U. ornatrix* was bred from moths collected in Highlands County, Florida, USA. Larvae were maintained on a standard pinto-bean diet (Shorey and Hale 1965), supplemented with 20% (*w*/*w*) of seeds of *Crotalaria mucronata*, the host plant of *U. ornatrix* at the collection site (Dussourd et al. 1991), in an environmental chamber at 26°C and 14L:10D photoperiod. Moths from the sixth through ninth generations, from the time of collection from the field, were used for the experiments. Inbreeding was minimized by establishing 10 maternal lines from the original field collection (ca. 300 caterpillars) and out-crossing them. To ensure standard physiological and behavioral states among experimental animals, we only used virgin individuals and tested them once on the second or third day after eclosion, i.e., adult individuals aged 24–48 hr.

Pheromone Gland Extraction Pheromone gland extracts were prepared from individual *U. ornatrix* female moths and analyzed at different times of the diel period, by gas chromatography (GC) and gas chromatography-mass spectrometry (GC-MS). For preparation of the extracts, the terminal 3 or 4 abdominal segments (bearing the pheromone gland) of a female were dissected with microscissors, and placed individually in a vial containing 100 µl of hexane and a mixture of 100 ng each of (*Z*)-5-tridecene and (*Z*)-7-tetradecene as internal standards. Dissection of the pheromone glands was performed 2 hr before (N= 8 females) and 2 hr after (N=40 females) the onset of scotophase. These times were chosen because females rarely call during photophase and mostly attain peak abdominal extrusion rate ca. 2 hr after the onset of scotophase (Lim and Greenfield 2007). Of the 40 individuals tested during scotophase, 26 were calling at the time of gland dissection. The glands were removed from the vial after 30 min and the extracts stored at −20°C until GC analysis and behavioral bioassay.

Gas Chromatography and Electroantennographic Detection A Hewlett-Packard (HP) 5890 Series II gas chromatograph, equipped with either a DB-5 or DB-225 column (30 m× 0.25 mm ID, J & W Scientific, Folsom, CA, USA) and a 50:50 effluent split, was used for gas chromatography-electroantennographic detection (GC-EAD) analysis. Helium was the carrier gas, with a flow rate of ca. 30 ml min^{-1} for both FID and EAD. Before GC analysis,

the gland extracts were concentrated to 10–20 μl, by using a gentle stream of nitrogen, and 1 μl injected into the GC in splitless mode. Initial oven temperature was 60°C, held for 1 min, then increased to 250°C for DB-5 and 200°C for DB-225 at 10°C min^{-1}. The outlet for the EAD had a purified and humidified air stream flowing over the antennal preparation at 600 ml/min.

Gas chromatography-mass spectrometry (GC-MS) analyses of gland extracts were performed with an HP 5890 Series II GC interfaced to an HP 5972 Mass Selective Detector. The GC-MS was equipped with a DB-5 column (identical to that used in the GC-EAD system), which was temperature-programmed as for the GC-EAD analyses. Electron ionization mass spectra were recorded from 30 to 550 amu at 70 eV. Chemicals were identified by comparison of retention indices and mass spectra with those of authentic standards. Two synthetic compounds, (*Z*,*Z*,*Z*)-3,6,9-eicosatriene (*Z*3,*Z*6,*Z*9-20Hy) and *Z*3,*Z*6,*Z*9-21Hy, were provided by Russell Jurenka (Iowa State University, Ames, IA, USA). Isomeric and chemical purity of these two compounds were >99.5%, as determined by GC.

Whole-body preparations were used for EAD experiments. A virgin male or female moth was immobilized on a plasticine block with small U-shaped copper wires, and its antennae were further restrained with thinner copper wires. A glass microelectrode (tip diameter≈ 1 mm, 0.86 mm I.D., A-M Systems Inc., Washington, USA) filled with 0.1 M KCl solution was introduced through the cuticle of the distal part of the antenna and served as a recording electrode; another glass microelectrode penetrated a compound eye to serve as a reference electrode. Silver–silver chloride junctions were used to maintain electrical contact between the electrodes and amplifier. The EAD signal was first amplified with a high-input impedance (>10^{12} Ω) headstage preamplifier (Syntech®, Hilversum, The Netherlands), and further processed with a PC-based signal processing system (Syntech®, Hilversum, The Netherlands).

Bioassay of Calling To test the influences of female pheromone on calling behavior, we presented females with filter paper discs (2 cm diam., Whatman® no. 1) impregnated with *U. ornatrix* female pheromone gland extract or synthetic compounds, *Z*3,*Z*6,*Z*9-20Hy and *Z*3,*Z*6,*Z*9-21Hy. *Z*3,*Z*6,*Z*9-20 Hy was a newly identified olfactory-active compound for both sexes of *U. ornatrix* (see "Results"); therefore, we tested it to evaluate its function in female–female pheromonal interaction. We could not test synthetic 1,*Z*3,*Z*6,*Z*9-21Hy because of its chemical instability (Huang et al. 1983), but we tested the responses of females to synthetic *Z*3,*Z*6,*Z*9-21Hy.

One equivalent of gland extract (IE), the mean amount of pheromone extracted from a naturally calling female during scotophase, was used as a standard unit throughout the experiments. Preliminary GC-EAD and behavioral assays showed that *U. ornatrix* females are sensitive to hexane (personal observation). Therefore, each filter paper disc was dried in an airflow for 30 sec before presentation in our behavioral bioassays.

We monitored the behavior of each of the test females during 15-sec observations made every 5–15 min throughout a 60- to 120-min period during early scotophase at 25±1°C. During these observations, we noted: (1) whether or not the female was calling and, if yes, (2) the number of abdominal extrusions per 15 sec. To avoid observer bias, a double-blinded observer was randomly assigned for each test. From these data, we determined the following three indices of each individual female's calling: (1) the time each individual was first observed calling, with scotophase onset designated as 0 min; (2) the mean signal frequency, measured in abdominal extrusions per minute, of each individual showing calling behavior during at least one observation; (3) the total time that an individual spent

calling, inferred from the number of observations when she was observed calling (Lim and Greenfield 2007). For all data, we listed the time of a reported event as the midpoint of the 5- to 15-min cycle of observations during which it was seen.

Call Induction During Photophase We evaluated whether pheromone could induce females to call by testing its effect during mid-photophase, when *U. ornatrix* ordinarily do not call. Single females were placed in individual glass cells ($d \times l$ = 1 cm×5 cm), connected by tubing to a chemical source at one end and to an exhaust at the other (flow rate <10 cm/sec). Test individuals were placed in cells at least 6 hr before the onset of scotophase, and their behavior observed every 15 min over the following 5 hr at 25°C. We initiated observations 6 hr before scotophase onset to avoid the possibility that the circadian rhythms of some females might trigger calling near the end of photophase (Silvegren et al. 2005).

No behavioral responses were observed from females to 1 IE during photophase. Therefore, we repeated the trials using higher quantities of gland extracts (5 IE, N=50; 10 IE, N=19; 15 IE, N=15) and synthetic *Z*3,*Z*6,*Z*9-21Hy (100 ng, N=16; 200 ng, N=18; 400 ng, N=10; Conner et al. 1980). A *post hoc* analysis indicated that 100 ng of *Z*3,*Z*6,*Z*9-21Hy was approximately equivalent to the mean quantity found in 1 IE (see "Results "). As a control, we tested 48 individuals with filter paper discs containing hexane only.

Call Stimulation During Scotophase Using the apparatus described earlier, we tested the influence of both pheromone gland extracts and synthetic pheromone components on calling behavior of female *U. ornatrix* during scotophase. Ten (N=17) or 20 ng (N=15) of *Z*3,*Z*6,*Z*9-20Hy (N=32 sets of six females), equivalent to the mean quantity in 1 IE and 2 IE, respectively, 50 (N=24 sets) or 100 ng (N=10 sets) of *Z*3,*Z*6,*Z*9-21Hy (N=34 sets), equivalent to the mean quantity in 0.5 IE and 1 IE, respectively, or 1 IE (N=11 sets), 2 IE (N=13 sets), 4 IE (N=15 sets), 6 IE (N=15 sets), and 10 IE (N=20 sets) of gland extract (N=74 sets), were tested. We also tested additional sets (N=54) of six individuals with the control stimulus. We made 15-sec observations for each individual every 5 min for 1 hr after odor presentation. For a given set of six females tested together in the apparatus, we recorded: (1) time of calling first observed for each individual, (2) proportion of individuals calling, and (3) mean signal frequency, expressed as the average of the maximum signal frequencies of individual moths showing calling behavior.

Calling Acceleration During Scotophase We tested whether signal frequency of calling females increased after exposure to pheromone. As described in the previous section, we monitored signal frequencies of 42 individual females and recorded the frequency during and after exposure to 0.05 IE of gland extract. We used the low quantity of 0.05 IE to test only the immediate behavioral response to the pheromone. Because signal frequency usually reaches its peak between 50 and 90 min after the onset of calling (Lim and Greenfield 2007), we presented the pheromone 20 min after the onset of calling to avoid coinciding with the natural increase in signal frequency. We observed and recorded the signal frequency of each individual during three consecutive 5-min observation periods: 5 min before and 5 min after pheromone presentation, and 5 min thereafter. During the observation, signal frequencies of individual moths were counted each and every minute. Filter paper discs containing only hexane were tested as control (N=17).

Calling Stimulation by Pheromone Pulsing Because calling in *U. ornatrix* females entails a rhythmic pulsing of pheromone release, we tested whether females responded to temporal

modulation of pheromone concentration *per se*. Specifically, we examined whether calling females were more likely to accelerate their signal frequency to higher values when exposed to pulsed pheromone than to a steady stream of pheromone, the release rate of which was identical to the mean value of the pulsed one. To pulse the pheromone stream, we punctured a small hole in the tube upstream from the chemical stimulus (filter paper disc) and tapped a finger on the hole at a rate of 3 sec^{-1}, the maximum signal frequency observed in *U. ornatrix* females (Conner et al. 1980, 1985; Lim and Greenfield 2007). We first presented the odor 15 min after scotophase onset and then began tapping 10 min later and continued for 5 min. The 10-min delay between odor presentation and the onset of tapping allowed us to measure the signal frequency after exposure to both continuous and pulsed stimuli. We used 0.05 IE as the stimulus in 18 trials of six individuals each. We confirmed that the finger tapping generated a puff at the location of the test individuals by simulating it with a visible marker (incense smoke). A control volatile (filter paper disc with hexane only) was tested in 15 parallel trials of six individuals each. We recorded the signal frequency of each individual during three 5-min periods as follows: 5 min before the tapping during tapping, and during the 5 min after tapping. During each period, we measured the signal frequency of each individual five times, each measurement being the number of abdominal extrusions in 15 sec. To test whether the pheromone puff *per se* influenced female calling, we also compared the signal frequencies of the females exposed to the pulsed pheromone with the group tested with a steady stream of pheromone in the previous test.

Signal Frequency and Pheromone Release Rate We tested the hypothesis that the signal frequency is positively related to pheromone release rate during calling and that grouped females, who generally call at elevated signal frequencies during the beginning of the scotophase, are releasing pheromone at higher rates. We established two different airborne pheromone collection apparatus, one for "solitary" and one for "grouped" females. In each apparatus, we placed females singly in individual cells, observed their calling behavior and signal frequency, and collected and quantified pheromone released. Solitary females were held in individual glass cells such that they were not exposed to the pheromone of neighbors, whereas grouped females were held in individual screen cells that exposed them to other females' pheromone.

We conducted 12 solitary female trials, in which 10 individual females were held singly within 15-ml glass tubes that were all connected to a Tenax odor trap. To prevent the solitary females from perceiving their neighbors' pheromone accumulating in the collection apparatus, and to enhance collection efficiency, air was exhausted from the apparatus through the odor trapper at a flow rate of 30 cm/sec. We also conducted 12 grouped female trials, in which eight individual females were held singly within screen cells placed in a 12-cm diam Petri dish connected to a Tenax odor trapper. We used different numbers of test individuals in the solitary (10 females for each collection) and grouped trials (eight females for each collection) so that the total number of calling individuals in a trial would be equivalent; typically, in previous tests, we had observed that 50% and 70% of solitary and grouped individuals, respectively, called (Lim and Greenfield 2007). Each of the screen cages holding the grouped females were separated by at least 0.5 cm to prevent direct physical contact between the moths. As in the solitary female trials, air was exhausted from the apparatus through the odor trap at a rate of 30 cm sec^{-1}. The Tenax odor trap consisted of a glass Pasteur pipette ($l \times d = 5 \times 0.5$ cm) packed with 300 mg of pre-cleaned Tenax (35/60 mesh, Alltech®, Deerfield, IL, USA) held in place by glass wool plugs.

In both solitary and grouped female trials, volatile chemicals were collected for 5 hr after onset of scotophase. While collecting pheromone, we observed calling behavior by each

female every 10 min. We estimated pheromone release rates of individual females by dividing the total amount of pheromone collected by the total signaling time in a trial (equal to the sum of total signaling durations of each of the 10 solitary or eight grouped females in the trial). Three grouped females and 10 solitary females that either died before or oviposited while in the apparatus for the 5-hr trial were not included in the analyses. After collection, 100 ng each of (*Z*)-5-tridecene and (*Z*)-7-tetradecene were added to the Tenax trap as internal standards, and the Tenax rinsed four times with 400 μl of hexane. The solution was concentrated under a gentle stream of nitrogen to a final volume <50 μl and analyzed by GC. Unless otherwise noted, variation in all analyses is reported as mean± standard deviation.

Results

Pheromone Components Gas chromatography-electroantennographic detection (GC-EAD) and GC-MS analyses confirmed the presence of the three previously identified pheromone compounds, *Z*6,*Z*9-21Hy (Retention time=8.88 min), *Z*3,*Z*6,*Z*9-21Hy (Rt=9.25 min), and 1,*Z*3,*Z*6,*Z*9-21Hy (Rt=9.43 min) in our *U. ornatrix* population. Both males and females showed strong antennal responses to all three compounds. Besides these compounds, the analyses revealed two additional GC-EAD-active compounds. One was identified as *Z*3,*Z*6, *Z*9-20Hy by comparison of retention time (8.6 min) and mass spectrum with the synthetic compound (Lim, unpublished data). This compound elicited EAD responses from both male and female antennae. The other compound, which had a shorter retention time (8.52 min), elicited responses from male, but not female, antennae. Its identity was not determined in the present study. We also found two distinct profiles of gland extracts from females. In one profile, *Z*3,*Z*6,*Z*9-21Hy was the major component, whereas in the other 1, *Z*3,*Z*6,*Z*9-21Hy was the major component; there was no detectable amount of *Z*3,*Z*6,*Z*9-21Hy in females of the latter profile type. For this study, we did not discriminate these two profiles in our bioassays.

During photophase, only 1,*Z*3,*Z*6,*Z*9-21Hy was found in gland extracts (N=8, 44.76± 54.09 ng/individual). In scotophase, 1,*Z*3,*Z*6,*Z*9-21Hy remained as the major component in general (Fig. 1), although the quantities of all the components varied greatly. The total quantity of the five compounds in gland extracts (354.20±286.47 ng/individual, N=26 calling individuals) prepared during scotophase was approximately eight times greater than that in photophase females (Mann–Whitney U test, W=52.0, P<0.001). There was a general difference in pheromone quantity between calling and non-calling females during scotophase (Fig. 1). The mean quantity of *Z*3,*Z*6,*Z*9-21Hy in calling females (98.72±170.11 ng/individual) was significantly greater than that in non-calling females (1.95±3.14 ng/ individual, Mann–Whitney U test, W=607.0, P=0.03), as was the mean quantity of the unidentified compound (12.41±12.16 ng/individual in calling, vs. 0.98±1.18 ng per individual in non-calling, females; Mann–Whitney U test, W=109.0, P=0.04). The quantity of 1,*Z*3,*Z*6,*Z*9-21Hy in gland extracts did not differ between calling (239.03±288.20 ng/ individual; N=26) and non-calling females (N=14, 80.71±122.49 g/individual, Mann–Whitney U test, W=587.5, P=0.13), although it was the major component. Similarly, the mean quantities of *Z*3,*Z*6,*Z*9-20Hy and *Z*6,*Z*9-21Hy in calling females (11.79±22.91 and 1.50±2.17 ng/individual, respectively) were not significantly different than those in non-calling ones (3.85±7.95 and 2.16±1.69 ng/individual, Mann–Whitney U test, W=588.5, and 75.0, P=0.09 and 0.37, respectively).

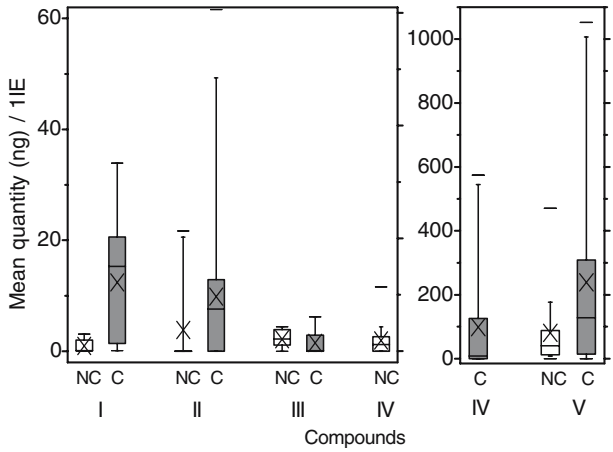

Fig. 1 Mean quantity (ng) of each pheromone component extracted from gland extract of individual females that were not calling (NC: open boxes) or calling (C: solid boxes) 2 hr after onset of scotophase. (I) unknown, (II) *Z*3,*Z*6,*Z*9-20Hy, (III) *Z*6,*Z*9-21Hy, (IV) *Z*3,*Z*6,*Z*9-21Hy, and (V) 1,*Z*3,*Z*6,*Z*9-21Hy. Box plots show means (X), medians (horizontal line), 25–75% ranges (rectangle), 5–95% ranges (inner horizontal bar), and minimum/maximum values (outer horizontal bar) of quantities

Call Induction During Photophase Both gland extract and synthetic *Z*3,*Z*6,*Z*9-21Hy induced calling from solitary females during photophase. No females tested began calling in response to the control discs or discs containing 5 IE, but 6 of 19 females responded to 10 IE, a significantly higher proportion than responding to the control (Fisher's exact test, $P<0.001$). Only 1 of 15 females responded to 15 IE (not different from the control, Fisher's exact test, $P=0.24$). Two of three quantities of *Z*3,*Z*6,*Z*9-21Hy elicited a calling response from significantly more test females compared with responses to the control disc: 5 of 16 to 100 ng (Fisher's exact test, $P<0.001$), 4 of 18 to 200 ng (Fisher's exact test, $P=0.004$), and 1 of 10 females to 400 ng (Fisher's exact test, $P=0.19$). Calling induced during photophase was generally brief, lasting only 3.02±2.78 min on average. The latency of call induction during photophase was generally shorter in response to gland extract (30.44±25.24 min; $N=9$) than to *Z*3,*Z*6,*Z*9-21Hy (92.5±70.67 min; $N=10$; Mann–Whitney *U* test, $W=124.0$, $P=0.05$). Mean signal frequencies of calling stimulated by *Z*3,*Z*6,*Z*9-21Hy (75.46±21.42 extrusions · min^{-1}, $N=9$) were lower than those stimulated by gland extract (138.89±29.33, $N=3$, Mann–Whitney *U* test, $W=45.0$, $P=0.02$).

Call Stimulation During Scotophase The bioassays indicated that both gland extract and individual pheromone components elicited significantly different calling responses during scotophase compared with the control. For each treatment, there was no significant difference in calling pattern in response to different concentrations (Kruskal–Wallis tests for gland extract and Mann–Whitney *U* tests for individual compounds, *ns*); therefore, calling responses were pooled. Females presented with gland extract or *Z*3,*Z*6,*Z*9-20Hy (1) were more likely to call (Kruskal–Wallis test, $H=20.80$, $df=3$, $P<0.001$; Dunn's pairwise comparison, $P<0.01$; but this effect was not found in response to *Z*3,*Z*6,*Z*9-21Hy, Dunn's pair-wise comparison, $P>0.05$; Fig. 2a); (2) started calling sooner (Kruskal–Wallis test, $H=19.92$, $df=3$, $P<0.001$; Dunn's pairwise comparison, $P<0.01$ and $P<0.05$, respectively; but this effect was not found in response to *Z*3,*Z*6,*Z*9-21Hy, Dunn's pairwise comparison, $P>0.05$; Fig. 2b); and (3) called with a higher signal frequency only in response to *Z*3,*Z*6,*Z*9-21Hy (Kruskal–Wallis test, $H=22.76$, $df=3$, $P<0.001$; Dunn's pairwise comparison, $P<0.01$; Fig. 2c), compared to females presented with the control stimulus.

Call Acceleration During Scotophase Exposure to 0.05 IE of gland extract elicited a brief increase (37%) in signal frequency from 106.43±46.29 to 145.36±31.91 extrusions min^{-1}

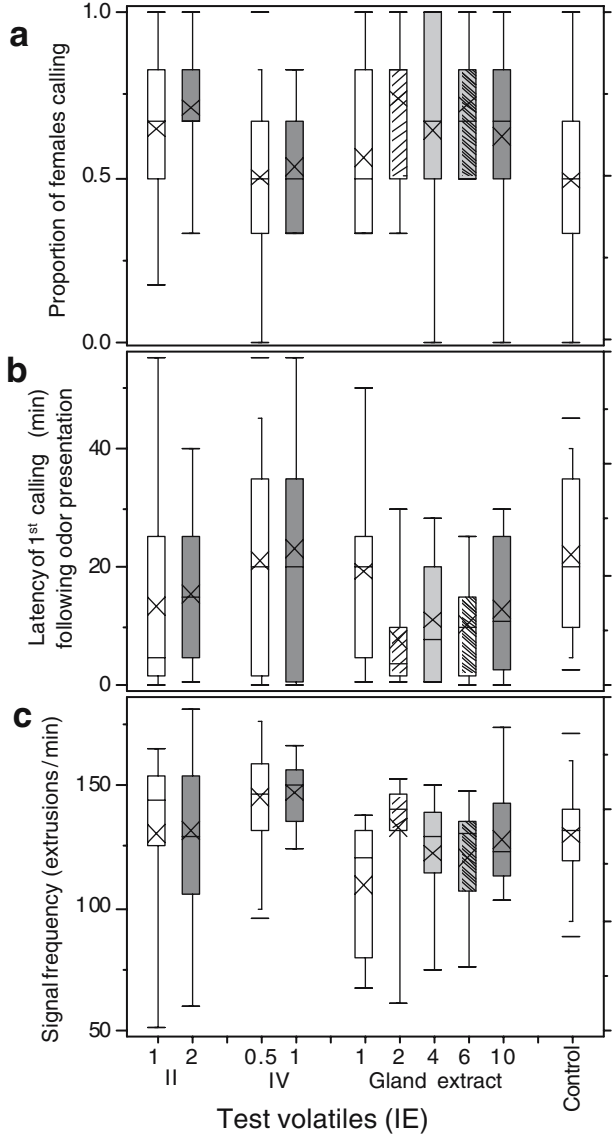

Fig. 2 Behavioral responses and temporal aspects of calling in individual females influenced by three different test volatiles and control. (II) *Z*3,*Z*6,*Z*9-20Hy and (IV) *Z*3,*Z*6,*Z*9-21Hy; 10 and 20 ng of II were equivalent to the quantity of the compound found in one and two female equivalents of gland extract, respectively; 50 ng and 100 ng of IV to 0.5 and 1 equivalents, respectively. (a) Proportion of calling individuals in a trial. (b) Latency (min) of first calling. (c) Signal frequency of calling individuals in each trial. Box plots show means (X), medians (horizontal line), 25–75% ranges (rectangle), 5–95% ranges (inner horizontal bar), and minimum/maximum values (outer horizontal bar) of values

during the 5-min presentation of the chemical stimulus. This increase was short-lived and females returned to values equivalent to pre-stimulus frequencies (119.40±47.26 extrusions · min^{-1}) shortly after removal of the stimulus (Repeated Measures ANOVA based on normally distributed data, N=42, F=25.24, df=2, 41, P<0.001; Fig. 3a). Control females tested in parallel did not show any evidence of change (signal frequencies=114.06±44.15, 119.88±45.15, and 118.18±40.40 extrusions · min^{-1}; N=17; Friedman's test, χ^2=1.20, df=2, P=0.55; Fig. 3a, open boxes).

Call Stimulation by Pheromone Pulsing Females increased their signal frequency from 117.75±30.04 to 147.54±25.06 extrusions · min^{-1} during the 5-min period when a

chemical stimulus (0.05 IE) was pulsed, and then returned to 122.81±28.70 after the cessation of pulsing (Friedman's test, N=67, χ^2=95.74, df=2, P<0.001). There was no change when clean air was pulsed (parallel values 108.55±27.55, 113.28±29.87, and 111.31±28.06 extrusions · min^{-1}; Friedman's test, N=58, χ^2=3.41 df=2, P=0.18).

When we compared peak signal frequencies of females exposed to, pulsed chemical stimulus, continuous chemical stimulus, pulsed clean air, and continuous clean air, we found that groups stimulated by either pulsed or continuous pheromone attained higher signal frequencies than groups stimulated by pulsed clean air (Kruskal–Wallis test, H= 39.83, df=3, P<0.001; Dunn's pairwise comparison, P<0.01; Fig. 4). However, we found no significant difference between signal frequencies of groups stimulated either by pulsed pheromone and continuous pheromone (Dunn's pairwise comparison, P>0.05) or by continuous pheromone and continuous clean air (Dunn's pair-wise comparison, P>0.05). Thus, the increase noted above and shown in Fig. 3b probably did not result from pulsed airflow *per se*, but rather was a short-term response to the onset of the chemical stimulus.

Signal Frequency and Pheromone Release Rate Our 5-hr collections showed that grouped and solitary females released comparable amounts of pheromone. *Z*3,*Z*6,*Z*9-20Hy was the

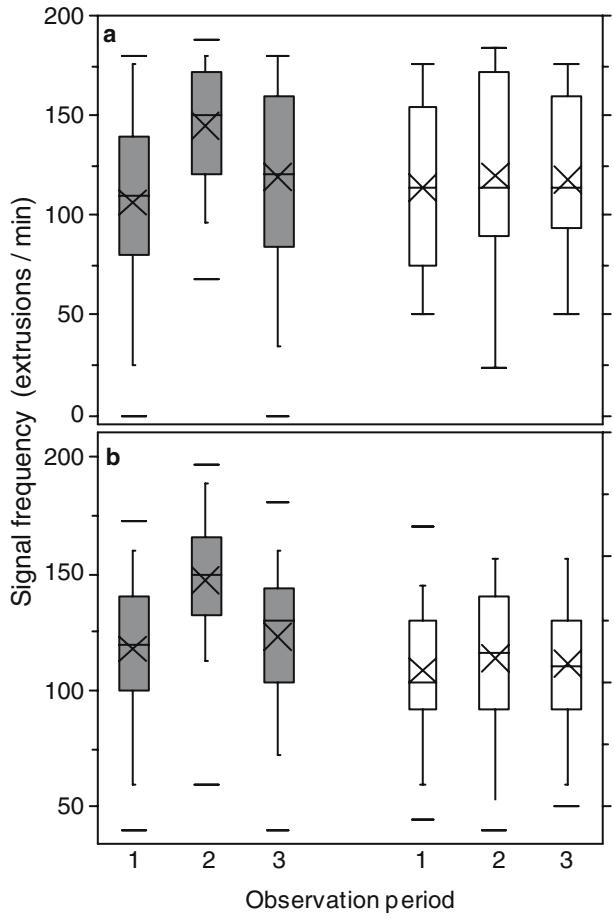

Fig. 3 (a) Mean signal frequency exhibited by females in response to gland extract (solid boxes) or control stimulus (open boxes). Observation periods: (1) 5-min before the odor presentation, (2) 5-min period after odor presentation, and (3) 5-min period after period 2. Data are taken from 42 test females and 17 control females. (b) Mean signal frequency exhibited by females in response to pulsed pheromone stimulus (solid boxes) or control stimulus (open boxes). Observation periods: (1) 5-min period with steady air stream containing pheromone before pulsing, (2) 5-min period of pulsing, and (3) 5-min period with steady air stream after period 2, respectively. Data are taken from 67 test females and 58 control females. Box plots show means (X), medians (horizontal line), 25–75% ranges (rectangle), 5–95% ranges (inner horizontal bar), and minimum/maximum values (outer horizontal bar) of frequencies

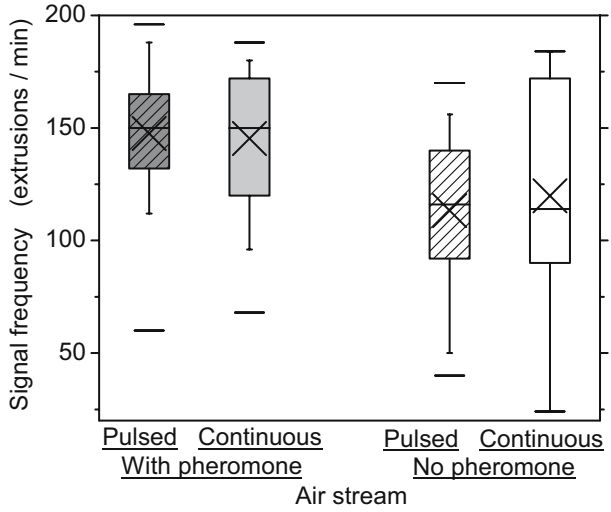

Fig. 4 Mean signal frequency exhibited by females in response to pulsed or continuous air with or without pheromone stimulus. Box plots show means (X), medians (horizontal line), 25–75% ranges (rectangle), 5–95% ranges (inner horizontal bar), and minimum/maximum values (outer horizontal bar) of frequencies

most abundant component released (7.90±7.87 ng/individual for solitary and 7.91±5.27 ng/individual for grouped females; sign test, $n+=7$, $n-=5$, ties=0, $P=0.39$). The amounts of *Z*3,*Z*6,*Z*9-21Hy (0.45±0.93 ng/individual for solitary and 0.08±0.27 ng/individual for grouped females; sign test, $n+=4$, $n-=1$, ties=7, $P=0.19$) and 1,*Z*3,*Z*6,*Z*9-21Hy (3.87±2.50 ng/individual for solitary and 4.22±4.26 ng/individual for grouped females; sign test, $n+=8$, $n-=4$, ties=0, $P=0.19$) also did not differ between solitary and grouped females. The mean pheromone release rates of grouped and solitary females were 0.98±0.92 and 1.03±0.71 ng · individual^{-1} · hr^{-1}, respectively (sign test, $n+=7$, $n-=5$, ties=0, $P=0.39$; Fig. 5).

Most grouped females in our test called at some time during the pheromone collection periods (mean proportion=0.85±0.14, $N=12$ trials), whereas a lower proportion of solitary females did (0.61±0.19, $N=12$ trials; sign test, $n+=10$, $n-=2$, ties=0, $P=0.02$). However, grouped and solitary females spent comparable amounts of time calling (129.90±27.47 min vs. 136.40±29.83 min, respectively; sign test, $n+=6$, $n-=6$, ties=0, $P=0.61$), and also

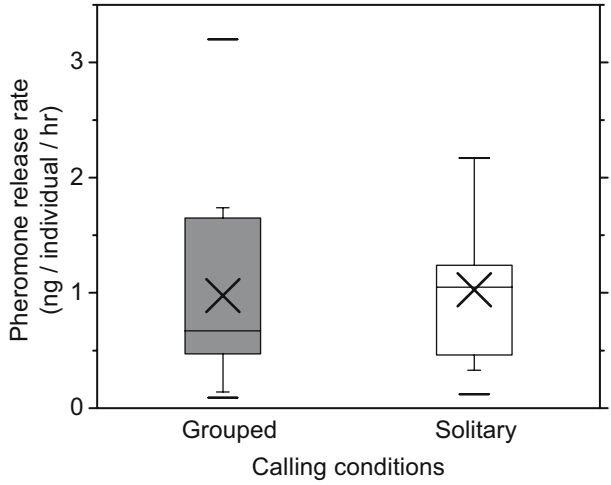

Fig. 5 Mean pheromone release rate (ng individual^{-1} hr^{-1}) of grouped and solitary calling females. Pheromone release rate is the total five compounds. Data are from 78 grouped females (solid box) and 66 solitary females (open box) that called during the collection period. Box plots show means (X), medians (horizontal line), 25–75% ranges (rectangle), 5–95% ranges (inner horizontal bar), and minimum/maximum values (outer horizontal bar) of quantities

exhibited comparable mean signal frequencies (117.48±12.75 extrusions · min^{-1} vs. 116.03± 16.66, respectively; sign test, $n+=7$, $n-=5$, ties=0, $P=0.39$) as well as peak signal frequencies (162.45±5.28 extrusions · min^{-1} vs. 156.91±12.97, respectively; sign test, $n+=6$, $n-=6$, ties=0, $P=0.61$).

Discussion

The chemical analyses and behavioral assays indicate that perception of the female advertisement pheromone is directly responsible for induction and modification of calling by *U. ornatrix* females. When *U. ornatrix* females perceive conspecific female pheromone, they (1) are more likely to call during that night, (2) begin calling earlier, and (3) accelerate their signal frequency to a higher rate during at least a brief interval. Some females even initiate calling during photophase, when such activity normally does not occur, in response to the pheromone or its individual components if presented in high enough concentration. In a previous study (Lim and Greenfield 2007), it was noted that females also increase the total amount of time spent calling during a night in response to the presence of neighboring females. However, the inability to present chemical stimuli in a controlled manner over a prolonged interval prevented us from evaluating the direct effect of sex pheromone on this aspect of calling in *U. ornatrix*.

Entire Pheromone Bouquet vs. Individual Components In general, we found that *U. ornatrix* females are as, or more, sensitive to the entire pheromone blend than to its individual components. During scotophase, both gland extract and *Z*3,*Z*6,*Z*9-20Hy elicited calling from more females and more quickly than did *Z*3,*Z*6,*Z*9-21Hy; the gland extract also elicited calling more quickly during photophase than did *Z*3,*Z*6,*Z*9-21Hy. However, during scotophase, *Z*3,*Z*6,*Z*9-21Hy increased signal frequency in calling females more than either the gland extract or *Z*3,*Z*6,*Z*9-20Hy. The results with *Z*3,*Z*6,*Z*9-20Hy should be viewed with caution, though, as the influence of this compound on orientation of males has yet to be tested either in the laboratory or the field; therefore, its role as a component of the female sex pheromone is not established (see Wyatt 2003).

In many moth species, the male is more sensitive to the entire pheromone bouquet than to its individual components (Cardé and Haynes 2004). In these cases, the sensitivity of males to the specific "blend ratio" of the components may reflect the importance of the ratio in species recognition and in the enhancement of "signal-to-noise ratio" for eliciting a behavioral response from the males. In other species, however, one (major) component may play a more important role throughout the full course of sexual communication and orientation than other (minor) components. Here, males may have an elevated neural sensitivity to the major component (e.g., Baker et al. 2004), and the minor components of the pheromone may function only during limited and specific parts of the pair-forming sequence (e.g., Vickers 2002).

Although many environmental and developmental factors including prior exposure to the female pheromone (Stelinski et al. 2005), prior exposure to host plant volatiles (Ochieng et al. 2002), rearing temperature (Linn et al. 1988), ambient temperature during sexual activity (Ono 1993), age (Greiner et al. 2002), hormonal status (Anton and Gadenne 1999), and circadian rhythm (Silvegren et al. 2005) may affect the sensitivity of pheromone processing in males, males of most moth species generally respond rapidly and selectively to minute changes in blend ratio and quantities of female pheromone components (Cardé

and Haynes 2004). This processing is necessary for locating a signaling female before other males do (Greenfield 2002). Female moths, on the other hand, may not be subject to similar selection pressures. Although females may perceive the conspecific female sex pheromone, it is not clear that they would be selected to discern the composition with the same degree of precision and speed as males. That is, females need only detect the presence of conspecific female pheromone within their vicinity and respond appropriately (Lim and Greenfield 2007). This may explain the comparable effects of the gland extract and some of the individual components in our study.

Influence of Pulsed Chemical Stimuli Contrary to our initial expectation, females did not respond more strongly to the pulsed pheromone stimulus than to the constant release of pheromone at the same average rate. This finding indicates that females may not respond to peak-to-peak changes in pheromone concentration but rather to time-averaged levels. However, the influence of pheromone pulsing on enhancing male responses has yet to be tested.

Signal Frequency and Pheromone Release Rates Along with a previous study (Lim and Greenfield 2007), our present study indicates increases in female signal frequency, the abdominal extrusion rate, in response to neighboring females and to pheromone. Earlier, we had proposed that this increased signal frequency yields a higher pheromone release rate. Contrary to this prediction, we found no difference between the pheromone release rates of solitary and grouped females. This lack of difference may reflect several factors. First, the low amounts of pheromone released, <1 ng $\cdot$ individual$^{-1} \cdot$ hr^{-1} (see "Results"), may have prevented us from resolving differences in release rates should they have occurred. Second, the 5-hr collection period (necessary to collect detectable amounts of pheromone; Jia et al. 2001; Lim and Greenfield 2007) may have masked any transitory changes in pheromone release rates caused by the abdominal pumping. Third, total calling times by solitary and grouped females may have also confounded our attempt to examine the relationship between signal frequency and pheromone release rate. Thus, at this time our data neither support nor unequivocally refute the hypothesis that the elevated signal frequency displayed by grouped females causes an increased pheromone release rate and a more intense signal to neighboring female signalers.

Acknowledgments We thank M. Deyrup of the Archbold Biological Station, Highlands County, Florida, for helping us collect *U. ornatrix* and its host plants. We also thank M. -Y. Choi, W. E. Conner, T. Eisner, V. Iyengar, and C. W. LaMunyon for providing critical information on *U. ornatrix* biology and pheromone analyses during various stages of the project and R. Jurenka for providing us with synthetic pheromone components. J. Kelly and two anonymous reviewers offered valuable critiques of earlier versions of the manuscript. K. M. Nus and J. A. Campbell of the Division of Biological Sciences at the University of Kansas took care of the host plants and provided test facilities. A. M. Swatek served as an invaluable laboratory assistant. The Hungerford Fund and the Entomology Graduate Student Summer Scholarship at the University of Kansas, Department of Ecology & Evolutionary Biology provided financial support.

Introduction

Methyl eugenol (ME) is present as a component of leaf and floral essential oils from many plant species (Tan 2000; Tan et al. 2002, 2006). The strong affinity and voracious feeding behavior of some male tephritids exposed to ME has been a puzzling mystery since 1915 (Howlett 1915), and while the biological basis of this sex-specific attraction has not been fully understood, it has helped to eradicate the oriental fruit fly, *Bactrocera dorsalis*, in the islands of western Pacific by the "male annihilation technique" (Steiner and Lee 1955; Steiner et al. 1970; Koyama et al. 1984). Recent evidence has supported the role of ME as a pheromonal precursor in the mating ecology of *B. dorsalis* (Nishida et al. 1988; Shelly and Dewire 1994; Tan and Nishida 1996, 1998; Hee and Tan 1998; Shelly 2000a, 2001a). The fact that ME metabolites also act interspecifically as allomones against vertebrate predators (Tan and Nishida 1998; Wee and Tan 2001) has sparked the involvement of fruit fly attractants in a tritrophic level in the plant–fruit fly–predator relationship, apart from intraspecific (pheromone) and plant–fruit fly relationships (synomones) (Tan and Nishida 2000, 2005; Tan et al. 2002, 2006). Hence, ME, as a potent male attractant, has evolutionary and ecological significance in the life history of fruit fly.

B. dorsalis males produce (*E*)-coniferyl alcohol (CF) and 2-allyl-4,5-dimethoxyphenol and are sexually more competitive and successful in mating than ME-deprived males 1 d after ME consumption (Tan and Nishida 1996, 1998). Males of *Bactrocera carambolae* Drew and Hancock (a sibling species of *B. dorsalis*) are also attracted to ME, but sensitivity and attraction are significantly lower than that of *B. dorsalis* (Wee and Tan 2000; Wee et al. 2002). Furthermore, *B. carambolae* after ME consumption produced only CF along with its endogenous pheromonal components 6-oxo-1-nonanol (major component), *N*-(3-methylbutyl) acetamide, 1,6-nonanediol and ethyl 3-methyl-2-hydroxybutanoate (Tan and Nishida 1996; Wee and Tan 2005a). *B. carambolae* consumed a significantly lower quantity than *B. dorsalis* (189 vs. 735 μg) when given unlimited access to ME (Wee et al. 2002). We wondered, therefore, whether ME-fed *B. carambolae* males could gain a level of significant sexual advantage similar to that of its sibling species, *B. dorsalis*.

Here, we investigate the role of ME in sexual communication of *B. carambolae* by examining the volatile emissions from ME-fed males before and after courtship and by establishing the relationship between ME-feeding and male sexual advancement in courtship compared to ME-deprived males. Results were compared to those previously obtained for the sympatric and sibling species, *B. dorsalis* (=*Bactrocera papayae*).

Methods and Materials

Insects Laboratory strains of *B. carambolae* were pure-breeding lines for more than 30 generations. Larvae were cultured on a semi-artificial diet containing star fruit, yeast, protein, wheat bran, sugar, sweet potatoes, and water (Wee and Tan 2000).Flies were segregated by sex within 5 d after emergence. Virgin males and females were maintained separately at 30±2°C and relative humidity of 73±5% with a 12 L:12 D photoperiod. Adult food mixture, comprised of protein, yeast, sugar, and sodium benzoate, and water, was provided. Sexually mature 25- to 35-d-old (Wee and Tan 2000) virgin males and females were used.

Chemicals Methyl eugenol (1,2-dimethoxy-4-[2-propenyl]benzene; >99.8% purity) was obtained from Agrisense-BCS Ltd. (UK). (*E*)-Coniferyl alcohol (CF) (> 96% *trans*) and *N*-

(3-methylbutyl)acetamide (>95% purity) were previously synthesized (Nishida et al. 1990). 6-Oxo-1-nonanol was synthesized by reacting propyl magnesium iodide with a large excess of ε-caprolactone (Aldrich Chemical Co. Inc.) in ether, followed by chromatographic purification with a silica gel column and elution with 40% methyl acetate in hexane (>95% purity). Compounds were diluted to appropriate concentrations for chemical identification and internal standards in gas chromatographic (GC) analyses.

Methyl Eugenol Consumption by Males To differentiate between ME-fed and ME-deprived males in a field cage mating competition experiment, 15-d-old male fruit flies were divided into two cohorts (individuals of one cohort were marked with green or white nontoxic paint on the thorax by using a fine-headed pin) and maintained separately until required for the experiment. Color assignment was random for the first replicate and reversed for each subsequent replicate to eliminate any possible effect of color preferences by females, even though color was unlikely to affect mate choice.

To prepare ME-fed flies, groups of ten specific color-marked male flies were allowed to feed on 0.1 μl ME dispensed on a small piece of filter paper (3×3 cm^2; Whatman® No.1), placed in a disposable Petri dish, for 10 min during their peak response to ME (10:00–11:00 hours) (Wee and Tan 2000). Treated males used were either at 1, 2, or 3 d posttreatment (DPT) of ME, depending on experimental design.

Collection of Male Volatile Emissions B. carambolae is a dusk-mating species (Wee and Tan 2000). Therefore, volatiles emitted by live males were collected from (1) 16:00–18:00 hours (before sunset), (2) 18:00–20:00 hours (dusk), and (3) 20:00–22:00 hours (after sunset) by using a simple aeration setup.

Analytical grade compressed air was passed through a dryer (20×3 cm diameter) containing silica gel followed by a Tenax filter, to adsorb excessive moisture and possible organic impurities, before reaching a 3-l airtight glass chamber containing 100–150 virgin ME-fed males. Airflow was maintained at 40–60 ml/min. At the outlet end, the emission was trapped by an adsorbent trap, Tenax TA (5 mg, 50–80 mesh), held between plugs of silanized glass wool in a Pasteur pipette. The Tenax trap was purged with a continuous flow of helium gas (20–40 ml/min) and baked overnight at 270°C before use. The trap was replaced with a newly activated one every 2 hr, and then, eluted with 10-ml redistilled ethanol. The eluate was concentrated to ca 100 μl with a rotary evaporator under partial pressure. One microliter aliquots were subjected to gas chromatographic (GC) and GC-mass spectrometric (GC-MS) analyses, respectively.

Chemical Analyses GC analysis was conducted with a Shimadzu GC-14A gas chromatograph, equipped with a fused silica column (25 m×0.25 mm i.d.×0.33 μm) coated with nonpolar, cross-linked bonded dimethylpolysiloxane (HP Ultra-1). The carrier gas was helium, and the oven temperature was held at 80°C for 1 min then programmed at 10°C/min to 240°C. Injection mode was splitless, and detection was by a flame ionization detector (FID). Data were captured with a Shimadzu C-R6A integrator. Chemical identification was performed by comparing the retention time of authentic standards and co-elution of internal standards on GC.

GC-MS analysis was performed on an HP 5989B mass spectrometer (electron impact at 70 eV) connected to a fused silica column (30 m×0.25 mm i.d.×0.33 μm) coated with nonpolar, cross-linked 5% phenyl-methylpolysiloxane (HP-5MS) under the same conditions as above.

Chemical identity of rectal volatiles was confirmed by comparing the retention time and mass fragment pattern with those of synthetic samples or reported data on GC-MS: *N*-

(3-methylbutyl)acetamide (I): MS, *m/z* (%): M^+ 129 (15), 114 (13), 86 (28), 73 (85), 72 (68), 70 (13), 60 (33), 55 (21), 44 (81), 43 (100); ethyl benzoate (II): MS, *m/z* (%): M^+ 150 (28), 122 (29), 105 (100), 77 (47), 51 (20), 44 (14); benzamide (III): MS, *m/z* (%): M^+121 (76), 105 (100), 77 (95), 76 (12), 51 (44), 44 (30); 6-oxo-1-nonanol (IV): MS, *m/z* (%): M^+ 158 (6), 140 (7), 115 (23), 97 (48), 86 (58), 79 (15), 73 (19), 71 (100), 69 (87), 58 (65), 55 (29), 43 (81), 41 (51); 1,6-nonanediol (V): MS, *m/z* (%): M^+ 160 (0), 142 (18), 99 (46), 81 (89), 73 (58), 71 (13), 70 (27), 57 (31), 55 (100), 43 (48); (*E*)-coniferyl alcohol (VI): MS, *m/z* (%): M^+ 180 (86), 152 (12), 147 (15), 137 (100), 131 (15), 124 (47), 119 (28), 109 (13), 91 (33), 77 (25), 65 (12), 55 (17), 44 (17).

Wind Tunnel Experiment The effect of ME-feeding by *B. carambolae* males in the sexual attraction of conspecific females and males was assayed in a wind tunnel as described by Hee and Tan (1998). A wire mesh cage (15×9 cm diameter) containing 15 sexually mature ME-fed males was used as an attractant source and was placed at the upwind end of the tunnel. Fifteen sexually mature females (or males) were released from the downwind end and assayed for their behavioral response to the attractant. The numbers of respondents performing zigzag anemotactic flight over at least 50 cm to the source of attraction, as defined by Kennedy and Marsh (1974), were noted. Light intensity (average of up-, middle-, and downwind sections) inside the plastic tunnel was measured with a Lutron LX-101 lux meter at the beginning of each 10-min assay. The experiment was conducted from 18:00 to 20:00 hours or until the light intensity approximated 0 lx. Air flow in the wind tunnel was regulated at 15–17 cm/sec. The wind tunnel received natural daylight from the north.

To ascertain the effect of ME feeding by males in the attraction of *B. carambolae*, females were assayed to the ME-fed male source at 1 and 3 DPT, while the ME-deprived male source was used as control. To study the effect of ME feeding in the male-to-male interaction, untreated males were assayed to the ME-fed male source, while the attraction of untreated males to the untreated male source and ME-fed males to the untreated male source were used as negative and positive controls, respectively. Each treatment was replicated between four and ten times with different cohorts on different days. The proportion of responding flies over the total number tested (N=15) was transformed to a modified arcsine square root (Anscombe 1948) before being subjected to one-way variance analysis. Mean responses of females and males at each time interval to various male sources were separated by using least significant difference (LSD) test at P=0.05.

Field Cage Mating Experiment To determine the time lapsed between ME-feeding and heightened mating success against ME-deprived males, ME-fed males of 1, 2, and 3 DPT were used. A major host tree, starfruit (*Averrhoa carambola* L.) (canopy: 2.0 m height and 0.5 m width), was placed in the center of the field cage (2.1×2.1×2.1 m) to provide shade and resting sites for the flies upon release. A hundred and fifty each of ME-fed and ME-deprived males and females were released into the field cage at least 4 hr before courtship began to enable acclimatization. Males were released approximately 1 hr earlier than females to allow time for territorial establishment (McInnis et al. 1999).

Approximately 2 hr after dusk (sunset at ca 19:30 hours), by using red light, mating pairs were individually collected into separate specimen vials, and each male was visually inspected for color mark on the thorax to confirm if it was a ME-fed or -deprived individual. Results were subjected to Student *t*-test for paired samples at P=0.05.

Results

Collection of Male Volatile Emission In the aeration chamber, the male flies mostly rested with minimal locomotive activity during the pre-courtship period (16:00–18:00 hours). At dusk, a decrease in the light intensity to below 1,000 lx stimulated the initiation of excited locomotive activities, i.e., rapid walking and erratic flying by males. When the light intensity decreased to below 600 lx, males were observed to exhibit more erratic flying with intermittent wing fanning and anal-beating behavior (a means of pheromone dispersal in most *Bactrocera* spp.) (Kuba and Sokei 1988). This was followed by mounting attempts on other males in close proximity. As time elapsed and with a further decrease in light intensity, more males engaged in wing fanning, resulting in a visible whitish pheromone smoke within the enclosed glass chamber. As soon as the sun set and the light intensity decreased to below 2 lx, most males became inactive by resuming the resting posture.

Gas chromatographic analysis on the eluate from the Tenax TA traps revealed the presence of a ME-derived compound, CF (VI), along with five endogenous pheromonal compounds [*N*-(3-methylbutyl) acetamide (I), ethyl benzoate (II), benzamide (III), 6-oxo-1-nonanol (IV), and 1,6-nonanediol (V)] during the courtship period (18:00–20:00 hours, 2–2,000 lx; Fig. 1b) (a broad peak at a retention time of 6.30 min, which appeared in varying quantities, is unknown). These compounds were absent before the courtship period (16:00–18:00 hours, >2,000 lx; Fig. 1a) and after sunset (20:00–22:00 hours, <2 lx; Fig. 1c).

Wind Tunnel Experiment In the wind tunnel, the attraction of *B. carambolae* females and males to the conspecific males generally increased concomitant to decreasing light intensity (Figs. 2 and 3). In the female-to-male attraction, females' attraction to the untreated control males increased gradually and peaked (33%) at 19:30 hr (ca 18 lx), followed by a drastic decrease (4%) at 19:45 hours, when the light intensity dropped to ca 3 lx ($F_{7,72}$=2.47, P=0.025) (Fig. 2). ME feeding by males, both at 1 and 3 DPT, increased the overall attraction of females ($F_{7,40}$=18.23, P=1.25×10^{-10}; $F_{7,48}$=36.76, P=3.40×10^{-17}) (Fig. 2). However, peak attraction was observed at least 1/2 hr earlier at 3 DPT (18:45–19:00 hr) compared to 1 DPT (19:15–19:30 hours) (Fig. 2).

When compared across treatments, there was no significant difference in the female attraction to various male sources from 18:00 to 18:15 hours (Fig. 2). However, males of 3 DPT attracted more females than the other two treatments beginning from 18:30 to 18:45 hours (P<0.05) (Fig. 2). At 19:00 hours, males of 1 DPT attracted more females than untreated males, but the attraction was lower than that of the 3 DPT males (P<0.05) (Fig. 2). While the attraction of females to the 3 DPT males seemed to decline at 19:15 hours, it was not significantly different from that of the 1 DPT males (P=0.05), which began to attract more females from 19:30 to 19:45 hours than the other two treatments (P<0.05) (Fig. 2).

In general, even though there was a temporal effect on the male-to-male interaction, the average response of untreated males to the untreated male source (=negative control) was low (ca 7%), with a 12% peak at 19:30 hours ($F_{7,32}$=2.51, P=0.036) (Fig. 3). Males fed with ME were still responding to the untreated male source (=positive control) ($F_{7,24}$=3.16, P=0.016) with the peak of attraction (12%) similar to that of the untreated males, but the average response was also low (ca 3%). There was no significant difference between these two controls throughout the assay time except at 19:00 hours (P<0.05) (Fig. 3). However, when the ME-fed males were used as an attraction source, there was an increase in the

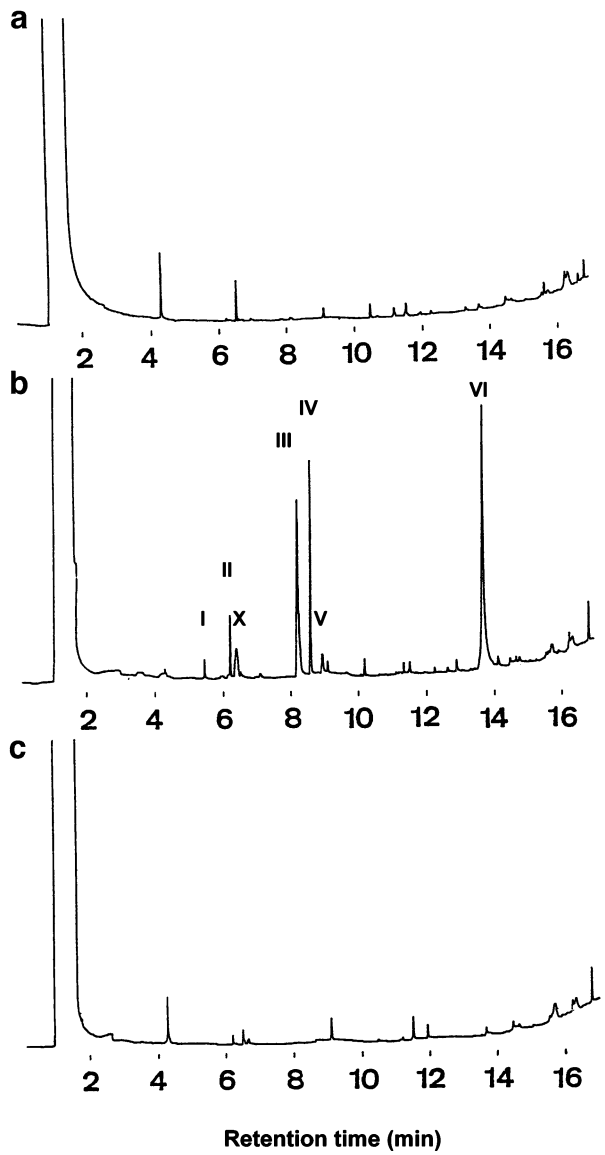

Fig. 1 Gas chromatograms of volatile emission of methyl eugenol-fed *Bactrocera carambolae* males, aerated at **a** 16:00–18:00 hours (before sunset), **b** 18:00–20:00 hours (during sunset), and **c** 20:00–22:00 hours (after sunset). Compound I = *N*-(3-methylbutyl) acetamide, II = ethyl benzoate, III = benzamide, IV = 6-oxo-1-nonanol, V = 1,6-nonanediol, and VI = (*E*)-coniferyl alcohol. Compound X, eluted immediately after compound II, is unknown

overall male-to-male attraction ($F_{7,24}$=6.49, P<0.001), with a peak of 68.3% at 19:15 hours (Fig. 3). When each of the time components was analyzed, males' response to the ME-fed male source was always higher than to the other two treatments (P<0.05), except at the beginning (18:15 hours) and at the end (19:45 hours) of the bioassay (P>0.05) (Fig. 3).

Field Cage Mating Experiment In the field cage, there were no significant differences in male mating success between the ME-fed and the ME-deprived males at 1 DPT (t=0.82, df=11) and 2 DPT(t=1.64, df=4) (P>0.05; Table 1). However, ME-fed males at 3 DPT were more competitive than ME-deprived males in mating (t=7.26, df=8; P<0.001).

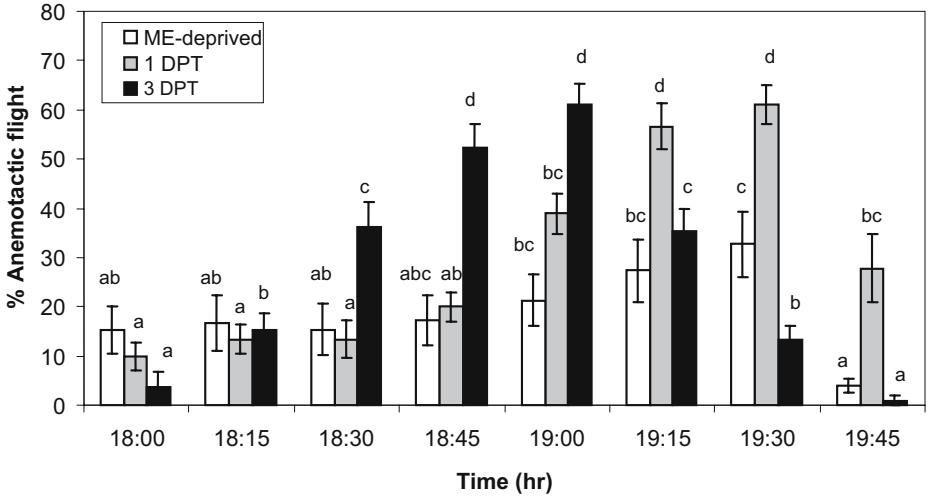

Fig. 2 The attraction of *Bactrocera carambolae* virgin females to various live male sources: (*a*) methyl eugenol (ME)-deprived, (*b*) 1-d posttreatment of ME (1 DPT), and (*c*) 3-d posttreatment of ME (3 DPT), during courtship period in wind tunnel assays. *Bars* (=standard errors) followed by *different alphabets* within the same treatment are significantly different at $P=0.05$ (LSD test)

ME-fed males initiated courtship behavior earlier than the ME-deprived males, consistent with the observation in the wind tunnel assays. The ME-fed males were evidently more attractive to females—in that a female would extrude her ovipositor toward a ME-fed male, a sexual acceptance stance in the tephritids, even though the male was still *in copula*. ME-deprived males were often seen aggregated around a ME-fed male, who was either calling (Fig. 4a) or mating (Fig. 4b), and they fed on the anal region of the ME-fed

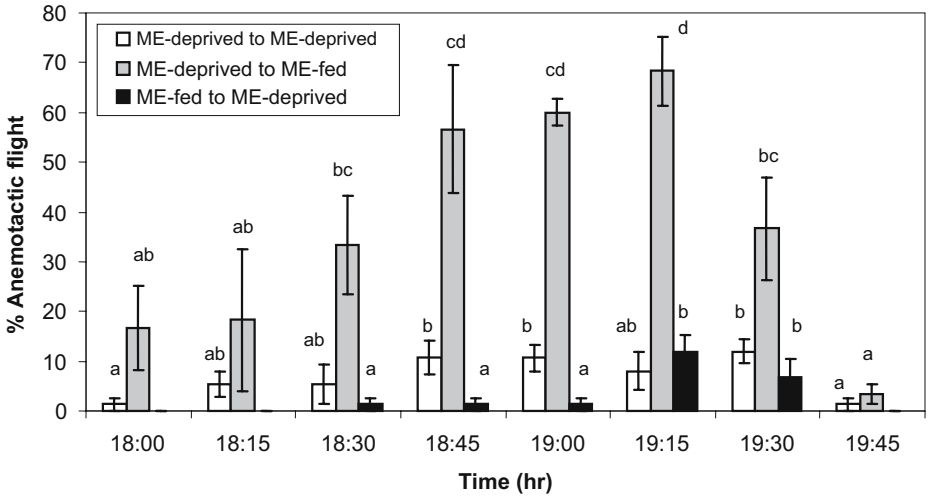

Fig. 3 The attraction of *Bactrocera carambolae* virgin males to various live male sources: (*a*) methyl eugenol (ME)-deprived to ME-deprived, (*b*) ME-deprived to ME-fed, and (*c*) ME-fed to ME-deprived males during courtship period in wind tunnel assays. ME-fed males used were at 3-d posttreatment of ME. *Bars* (=standard errors) followed by *different alphabets* within the same treatment are significantly different at $P=0.05$ (LSD test)

Table 1 Mating success of *B. carambolae* males at 1, 2, and 3 d posttreatment (DPT) of methyl eugenol (ME)

Treatment	Number of Replicates (*N*)*	Mean±SE		*P* Values
		ME-fed	ME-deprived	
1 DPT	12	35.8+2.8	32.5±3.6	0.21
2 DPT	5	26.8±5.0	20.0±8.3	0.09
3 DPT	9	49.9±1.3	29.8±1.9	4.4×10^{-5}

*300 flies (100 each of virgin females, ME-fed and ME-deprived males) in each replicate

male. Anal secretion collected from the ME-fed males contained compound CF in addition to the endogenous pheromonal compounds of a *B. carambolae* male.

Discussion

The pharmacophagy of ME by males of *B. carambolae* has yielded three major findings that have important implications in the chemical ecology of this species: (a) ME was biotransformed (almost immediately) into compound CF, which was temporarily stored in the rectal gland and subsequently released at dusk by the ME-fed males; (b) ME-fed males showed an earlier onset of courtship behavior and were perceived by conspecific females to be more attractive than ME-deprived males, at a time lapse of 3 DPT, as evidenced by the results of the wind tunnel bioassays and field cage trials; and (c) ME-fed males induced an aggregation behavior in conspecifc males during the courtship period, and the aggregated males fed on the anal secretion of the ME-fed males that contained CF together with the male endogenous pheromonal compounds.

B. carambolae, being a dusk-mating species, has its courtship behavior confined to periods between 18:00 to 20:00 hours (photoperiod 12 L:12 D). The fact that males: (a)

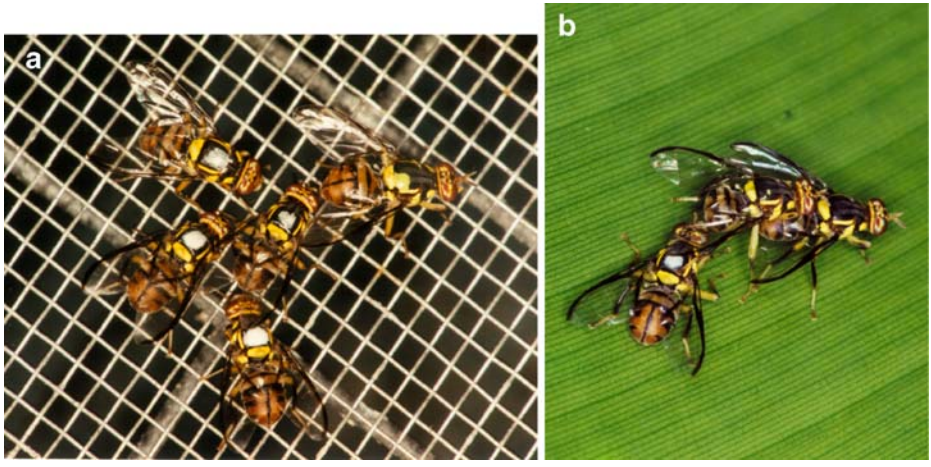

Fig. 4 Methyl eugenol (ME)-deprived *B. carambolae* male(s) (thorax marked with white paint) feeding on the anal secretion of a ME-fed male (**a**) at calling (*top most right side*) and (**b**) at mating in a field cage assay

responded maximally to and fed on ME during the first few hours of photophase (Wee and Tan 2000; Wee et al. 2002); (b) accumulated the biotransformed phenylpropanoid, i.e., CF, within 15 min after ME consumption and stored it in the rectal gland for up to 2 wk (Wee and Tan 2007); and (c) subsequently released CF that is attractive to both conspecific males and females during courtship, supports the hypothesis that ME plays a central and mediating role in the sexual communication of this species. In addition, the detection of ME metabolites in the rectal glands of 83–100% wild males of ME-sensitive *Bactrocera* species indirectly indicates the importance of ME foraging activities and role of ME in the chemical ecology of the ME-sensitive *Bactrocera* species (Tan and Nishida 1998; Wee and Tan 2001).

Interspecific variation is evident in the time lapse between ME feeding and the heightened mating success of *B. carambolae* compared to *B. dorsalis*, a closely related sympatric sibling species of the *dorsalis* complex. ME-fed males have an earlier onset of mating ritual (Hee and Tan 1998) and a higher mating success at just 1 d after feeding on ME (Tan and Nishida 1996, 1998) and continue to enjoy this mating advantage for as long as 3 wk (Shelly and Dewire 1994). Although ME-fed *B. carambolae* males showed a significant sexual attraction at 1 DPT when compared with the ME-deprived males, significant mating success did not occur at 1 or 2 DPT but only at 3 DPT. A similar phenomenon has also been observed for *B. philippinensis*, another *B. dorsalis* sibling species, in which males only had a mating advantage at 3–5 d postfeeding on ME (Shelly et al. 1996). This discrepancy may be explained by a comparison of the quantitative temporal accumulation of ME metabolite (s) in the rectal glands of *B. carambolae* and *B. dorsalis* after consumption of a standard quantity of ME. In both sibling species, ME metabolite(s) increase gradually with time, but with a significant decrease in the accumulation rate (defined as accumulation after partial release of the metabolite(s) during the courtship period) that is only evident at 3 d post-ME feeding for *B. carambolae* compared with 1 d in *B. dorsalis* males (Wee and Tan 2007).

Aggregation behavior or lek formation is commonly observed in the Oriental fruit fly, *B. dorsalis*, and Mediterranean fruit fly, *Ceratitis capitata*. Numerous studies have been attempted to ascertain the role of leks in mating systems of tephritids (Kaspi and Yuval 1999; Shelly and Kaneshiro 1991; Shelly 2000b, 2001b). Generally, it is hypothesized that lekking provides a communal display area where males congregate, thus attracting and courting females and leading to copulation (Emlen and Oring 1977). In *B. carambolae*, the lek behavior was not evidently displayed in the male-to-male attractancy results. However, after feeding on ME, ME-fed males attracted more conspecific males in the wind tunnel, and the attracted males apparently searched for and fed on the anal region of the ME-fed males (as observed in the field cage experiment). CF acts as an aggregation pheromone in male–male communication during the courtship period (evident in the chemical analysis of the anal secretion). The aggregation behavior and anal secretion feeding by ME-deprived males happened just before and during the courtship period. Such behavior may have diverted their attention from mating and contributed partly to the higher mating success in the ME-fed males.

Coniferyl alcohol shows some degree of allomonal activity in deterring vertebrate predators (Nishida and Fukami 1990). However, its role may be limited to intraspecific interaction (pheromonal) in *B. carambolae*. A previous study has shown that with attainment of sexual maturity and the production of endogenous pheromonal compounds, *B. carambolae* males develop an inherent antipredation mechanism against gecko predation. It also shows that having an additional compound, i.e., CF, in the rectal gland of ME-fed *B. carambolae* contributes little/negligible deterrent effect against gecko predation when compared with sexually mature but ME-deprived males (Wee and Tan 2005b).

Methyl eugenol is carcinogenic to vertebrates (Miller et al. 1983; Wee and Tan 2001). ME-attracted tephritids detoxify ME by simple oxidative processes and biotransform it to by-product(s) that are stored in the rectal gland. ME-attracted tephritid male flies usually appear sluggish immediately after ME consumption compared to unfed males (Shelly and Dewire 1994; Wee and Tan 2007). This sluggishness is more obvious in *B. carambolae* than in *B. dorsalis*. It was induced in the former species even after consumption of a minute quantity of ME and eventually caused approximately 10% mortality at 12-d posttreatment (Wee and Tan 2007).

Males of *B. carambolae*: (a) synthesize large amounts of endogenous pheromonal components (the average peak production of the major component, 6-oxo-1-nonanol, was 26.1±12.5 μg/male (Wee and Tan 2005a); (b) produce benzamide that is detected in varying quantities in the aeration products and in the male rectal extracts; and (c) at the same time, engage in ME foraging activity. However, when compared with its sibling species, *B. dorsalis* utilizes an external precursor, i.e., ME, and biotransforms it into chemicals that offer reproductive advantage in mating competition and protection against vertebrate predator (Tan and Nishida 1996, 1998; Hee and Tan 1998; Wee and Tan 2001), whereas *B. carambolae* males spend more metabolic energy. Enzymes are needed to catalyze the various metabolic reactions required to synthesize each of the endogenously synthesized compounds. Resources are used that might otherwise be used for growth or reproduction (Pasteels et al. 1983). From an evolutionary perspective, this suggests that *B. carambolae* is probably less advanced than *B. dorsalis* in species speciation within the *dorsalis* complex.

Acknowledgements This work was funded by Malaysian IRPA grant (NO: 01-02-05-9007) and partly supported by the International Atomic Energy Agency (Contract No. 10570) given to K. H. Tan. We thank Andy R. Gibb (HortResearch, New Zealand) for his comments.

Introduction

Allelopathic compounds can be either actively released by a plant itself (Ridenour and Callaway 2001; Seal et al. 2004) or passively produced during the decomposition process of plant residues (Blum et al. 1999; Tseng et al. 2003; Bonanomi et al. 2006). Downed logs act as nurse or preferred sites for forest seed germination. Although making up only a small percentage of the microsites, they account for a disproportionate percentage of established seedlings. This phenomenon is well documented for a variety of forest types, including temperate forests (Santiago 2000; Takahashi et al. 2000; Brang et al. 2003; Liao et al. 2003; Narukawa et al. 2003) and rain forests (Christy and Mack 1984; Lusk 1995). Different hypotheses for the advantages of downed log seedbeds for establishing tree seedlings have been proposed: high water-holding capacity results in reduced moisture stress (Place 1955; Tubbs 1996), early snow melts on the elevated substratum and can cause a longer growing season (Harmon et al. 1986), infection with pathogenic fungi is reduced (Cheng and Igarashi 1987; O'Hanlon-Manners and Kotanen 2004), impact of competing vegetation is decreased (McKee et al. 1982; Hiura et al. 1996), standing water excludes seedlings from the soil (McKee et al. 1982), phytotoxic compounds released by ground vegetation restrict seedlings to logs (del Moral and Cates 1971). There is no literature describing allelopathy of conifer tree seedlings growing on logs.

The Yuanyang Lake (YYL) Nature Preserve is one of the Long-Term Ecological Research sites in Taiwan. *Chamaecyparis obtusa* var. *formosana* and broadleaf trees coexist in the forest at YYL (Chou et al., 2000). The forest is relatively mature, and *C. obtusa* var. *formosana* is regenerating and sustainable as the dominant species in that area (Chen and Yang 1996; Chou et al. 2000; Liao et al. 2003). *C. obtusa* var. *formosana* is a shade-intolerant species (Chiu et al. 1995; Lo-Cho et al. 1999) and the only species creating both canopy gaps and downed logs in the forest. Those gaps are filled mostly with the seedlings of *C. obtusa* var. *formosana* (Liao et al. 2003). Seedlings establish themselves on downed logs soon after the logs fall. Their survival rate is high on newly downed logs (Chang et al. 2001; Liao et al. 2003). There are more seedlings of *C. obtusa* var. *formosana* than those of broadleaf trees germinating on the newly downed logs (Liao et al. 2003).

Based on a field investigation and previous research, we hypothesized that the bark of newly downed logs possessing allelopathic potential provides a habitat especially suitable for germination and subsequent growth of *C. obtusa* var. *formosana* seedlings. Six kinds of seeds collected from YYL, and along with lettuce and one invasive weed, *Bidens pilosa*, were germinated on the bark of *C. obtusa* var. *formosana*. Their percent germination, survival rates, root length, fresh weight, chlorophyll contents, and soluble protein contents were compared to evaluate the phytotoxic effect of the log bark. Bioassay of a phytotoxic compound isolated from the bark was conducted.

Materials and Methods

Study Site The study site was located in the YYL, on Chi-lan Mountain (24°35′ N, 121°24′ E) in the northeastern part of Taiwan, between 1,650 and 2,432 m altitude. Yanuyang Lake has a maximal depth of 4 m, an area of 3.6 ha. Annual precipitation, mostly contributed by monsoons and typhoons, is between 3,000 and 4,000 mm (Hwang et al. 1996; Wu et al. 2001). Heavy cloud and fog are so frequent that solar radiation is remarkably reduced. Daily solar radiation data at the YYL ranged from 0 to 25 MJ/m^2/day, and the mean air temperatures ranged from 5 to 17.5°C (Hwang et al. 1996). The forest soils are generally

shallow (<60 cm) with granite bedrock underground (Chen and Chiu 2000). The thick organic layer, probably derived from peat, directly covers the primarily weathered bedrock. Poor drainage, originating from the clay or silty clay mineral layer beneath the organic layer, limits the downward movement of minerals, and consequently, retards the development of soil profile (Chiu et al. 1999; Wu et al. 2001). Shallow soil, frequent typhoons, and steep slopes may contribute to the large number of deaths and fallen trees of *C. obtusa* var. *formosana* in the YYL forest community (Lo-Cho et al. 1989; Chang et al. 2001).

The vegetation consists of coniferous forest, hardwood forest, pteridophytes, epiphytes, such as mosses and liverworts, grassland species, and several aquatic plants. Floristic analysis indicated that the forest could be divided into two communities, namely, a coniferous–hardwood community and a swamp or early succession community (Chou et al. 2000). Within the forest, *C. obtusa* var. *formosana* is the dominant species and occupies canopy layer above 20 m height. *Rhododendron formosanum* is predominant among the trees below 10 m height around the lakeside (Chou et al. 2000). According to pollen analysis (Chen and Wu 1999), floristic analysis, and census of seedlings (Chou et al. 2000; Liao et al. 2003), the forest in YYL has existed for at least 4,000 yrs, and it has been speculated that the vegetation, floristic composition, and canopy structure of this forest will not change in the near future.

Seedling Growth Tests Seeds of all species except lettuce and *B. pilosa* were collected in YYL before seed dispersal during the autumn of 2004 and 2005. The seeds of two dominant species (*C. obtusa* var. *formosana* and *R. formosanum*), one grassland species (*Miscanthus transmorrisonensis*), two kinds of broadleaf trees (*Barthea formosana* and *Pieris taiwanensis*), and one conifer tree C. *formosensis* were collected. The bark of new *C. obtusa* var. *formosana*-downed logs was collected for germination tests. After seeds were immersed in water for 3 d, except lettuce, *B. pilosa*, and *M. transmorrisonensis* immersed for 2 hr, all seeds were separately sown on the bark (7×8×0.5 cm) saturated with 50 ml of distilled water or onto one stack of 10 pieces of circle filter paper (90 mm, Advantec Toyo, Japan) saturated with 50 ml of 1.5 mM salicylic acid solution (2-hydroxybenzoic acid; purity ≥99%, Merck) or with distilled water as control. The number of seeds sown on bark or filter paper varied with seed size. Lettuce, *B. pilosa*, *C. obtusa* var. *formosana*, and C. *formosensis* all had 50 seeds/per treatment, whereas *R. formosanum*, *M. transmorrisonensis*, *B. formosana*, and *P. taiwanensis* all had 100 seeds/per treatment for each of 3 reps.

The dose response curve for inhibition of lettuce germination by salicylic acid showed that 1.5 mM was the concentration that completely inhibited lettuce germination similar to that on the bark. Therefore, the concentration of salicylic acid at 1.5 mM was chosen and applied to filter paper. Each treatment was put in one transparent glass container (30π× 3.0 cm) sealed by transparent plastic film (Nan Ya Plastics Industrial Co.) to prevent drying out. All seeds were incubated in a growth chamber with 22±1°C, 16:8 hr day is to night ratio, and illumination of 85 μEm^{-2}. Average percent germination, survival rate, fresh weight, root length, soluble protein content, and chlorophyll content were measured after 7 wk, except those of lettuce and *B. pilosa*, which were measured after 1 wk. Whole seedlings were homogenized in extract medium that contained 50 mM Hepes buffer (pH 7.5), 10 mM 2-mercaptoethanol, 1% polyvinylpyrrolidone (PVP), 2 mM ethylenediaminetetraacetic acid (EDTA)-Na_2, 1 mM $MnCl_2$, 1 mM $MgCl_2$. Extracts were centrifuged at 18,000×*g* for 15 min, and the supernatant was used for determination of protein by Coomassie Blue spectrophotometric assay (Spector 1978) by using dye regent purchased from Bio-Rad, Laboratories, Inc. with bovine serum albumin as the standard. Chlorophyll was determined in 96% ethanol using the absorption coefficients of Wintermans and De Mots (1965). Data were expressed as the ratio of the treatment value

divided by the control in which seeds were germinated in distilled water for making comparisons among various species.

Extraction and Isolation of Phytotoxic Compound Bioassay-guided fractionation and purification based on phytotoxicity against lettuce were conducted. For each separation, the obtained fractions were concentrated and dried under *vacuo* at 40±2°C and then bioassayed against lettuce according to Tseng et al. (2003). The pure or crude compounds were dissolved in spectroscopic grade ethyl acetate to various concentrations and spread onto silica gel thin layer chromatography (TLC) sheets. The ethyl acetate was allowed to evaporate completely in a laminar flow hood. Before bioassay, the TLC sheets were placed into Petri dishes and moistened with distilled water. Test seeds were soaked in distilled water and then placed onto the TLC sheets containing the pure compound or onto control sheets. Petri dishes were sealed with parafilm "M" (American National Can™) and placed in an incubator at 25°C for 48 hr in the dark. Two and a half kilograms of dried chipped bark were extracted with 20 l MeOH at room temperature for 10 d. The extract was evaporated *in vacuo* to yield a residue that was then suspended in H_2O (200 ml) and partitioned with ethyl acetate (500 ml×3). The combined ethyl acetate layer afforded a brown syrup (ca 180 g) that was subsequently chromatographed over silica gel (Merk 70-230, 230-400 mesh, ASTM) by using a hexane/ethyl acetate gradient solvent system. Eventually 22 fractions (F1-F22) were collected. F9–F10 showed the greatest inhibition of lettuce germination. The combination (2.9 g) of F9–F10 was further purified by silica gel column eluted with 0–100% ethyl acetate in dichloromethane, and 13 fractions were collected (F′1–F′13). F′3–F′5 were combined and purified by high-performance liquid chromatography (HPLC) [Merk Lichro CART 250-10 Cat. 1.50179 Lichrosorb Si 60 (7 μm)] and Sephadex LH 20. About 180 mg pure compound with phytotoxicity against lettuce were isolated and identified by spectroscopic identification with an infrared (IR) (Perkin-Elmer 983G Spectrophotometer), proton (^{1}H) and carbon nuclear magnetic resonance (^{13}C NMR) (Varian Unity Plus 400 spectrometer), gas chromatography/mass spectroscopy (GC/MS) (Agilent 6890 N Gas Chromatography /Agilent 5973 N Mass Spectrometer). The GC/MS analyses were carried out by using an Agilent 6890 N GC system coupled to an Agilent 5973 mass selective detector (MSD). The GC column used was an HP-5 MS capillary column (30 m×0.2 mm I.D., 0.33 μm film thickness). The GC was operated in the splitless mode when performing injections with the aid of an Agilent 7683 series autosampler. An injection port temperature at 280°C was used. For the isolated compound and salicylic acid standard analysis, the column temperature was programmed from 80 to 280°C at 15°C/min with a 7-min hold at 240°C and a 4.67-min hold at 280°C. Helium of 99.9% purity was used as the carrier gas at a flow-rate of 1 ml/min. The splitless inlet liner is a deactivated 1/pk single-taper packed with glass wool (Agilent; part number: 5062-3587). Transfer line temperature was 280°C, and a 70-eV electron-impact ionization source was held at 280°C.

Statistics Means were compared by using one-way analysis of variance (ANOVA), Tukey's test and Pearson correlation analysis in SAS statistical software (SAS 2004).

Results

Establishment of Seedlings on Bark of C. obtusa var. formosana All eight seed species were able to germinate on the bark. The germination percentages among five species, lettuce, *M. transmorrisonensis, P. taiwanensis, B. formosana*, and *C. obtusa* var. *formosana* were not significantly different (Fig. 1). *R. formosanum* had the highest germination rate

and *B. pilosa* the lowest. Seedlings of lettuce, *B. pilosa*, and *C. formosensis* were stunted, turned yellow, and died on the bark before harvest. The seedling survival rates of *C. obtusa* var. *formosana* and *R. formosanum* were obviously higher than other species (F=34.08, P<0.001). Differences in seedling survival rate among *M. transmorrisonensis*, *P. taiwanensis*, and *B. formosana* were not significant; however, *M. transmorrisonensis* could barely develop its radicle roots despite normal growth of shoots on the bark (Fig. 2). Fresh weight and root length of *C. obtusa* var. *formosana* and *R. formosanum* were also significantly higher than other species (Fig. 2). In addition, there was a significant positive correlation

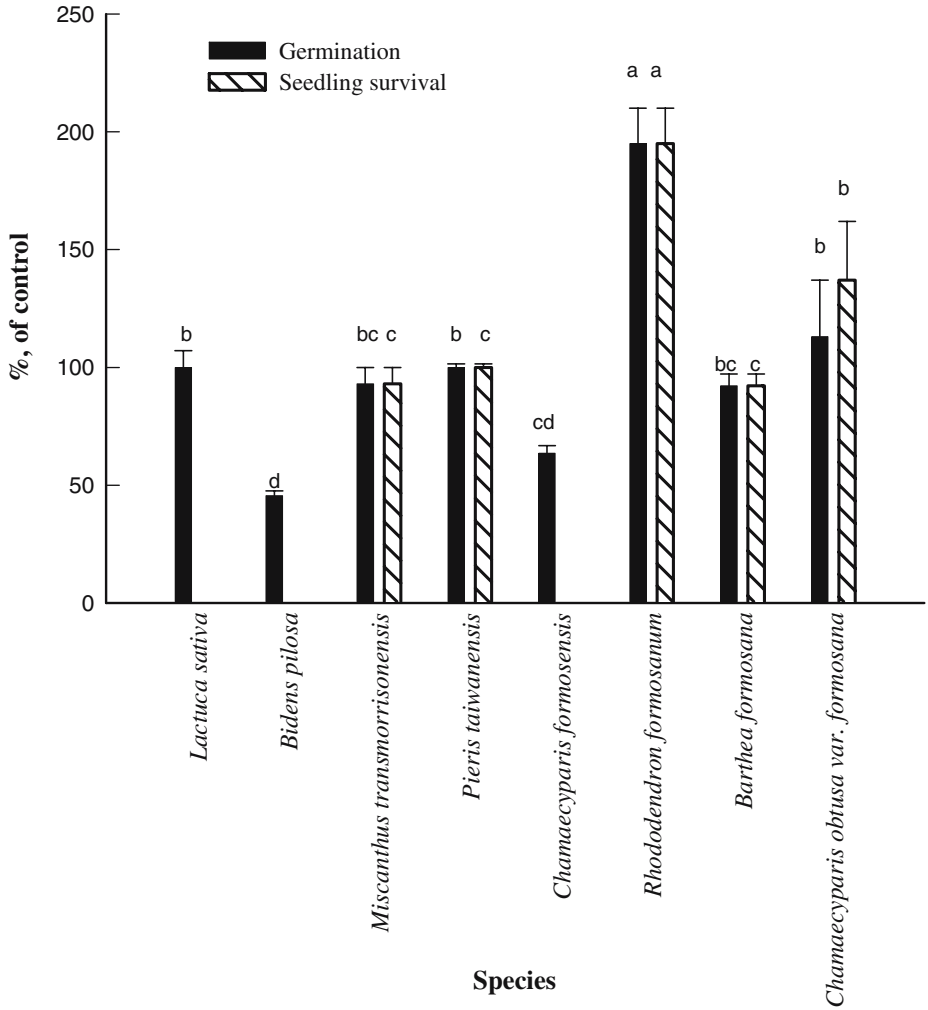

Fig. 1 Germination and seedling survival of different species on bark of *C. obtusa* var. *formosana*. *Different letters above the standard error bars* designate significant differences at the 0.05 level by Tukey's test. The absolute control average values of percent germination are as following: *L. sativa* (86.1%), *B. pilosa* (77.7%), *M. transmorrisonensis* (90.8%), *P. taiwanensis* (91.4%), *C. formosensis* (49.5%), *R. formosanum* (28.0%), *B. formosana* (23.0%), *C. obtusa* var. *formosana* (64.9%). Those survival rates are the same as percent germination for most species except *C. obtusa* var. *formosana*, which was 57.7% because several *C. obtusa* var. *formosana* seedlings were infected by fungi

between fresh weight and root length of *M. transmorrisonensis*, *P. taiwanensis*, *R. formosanum*, *B. formosana*, and *C. obtusa* var. *formosana* (Pearson correlation, r=0.97, P<0.01), indicating that root length of these species was inhibited more than their fresh weight on the bark (Fig. 2).

Soluble Protein and Chlorophyll Contents of Seedlings on Bark Soluble protein contents were not significantly different among those five species established on the bark, *M.*

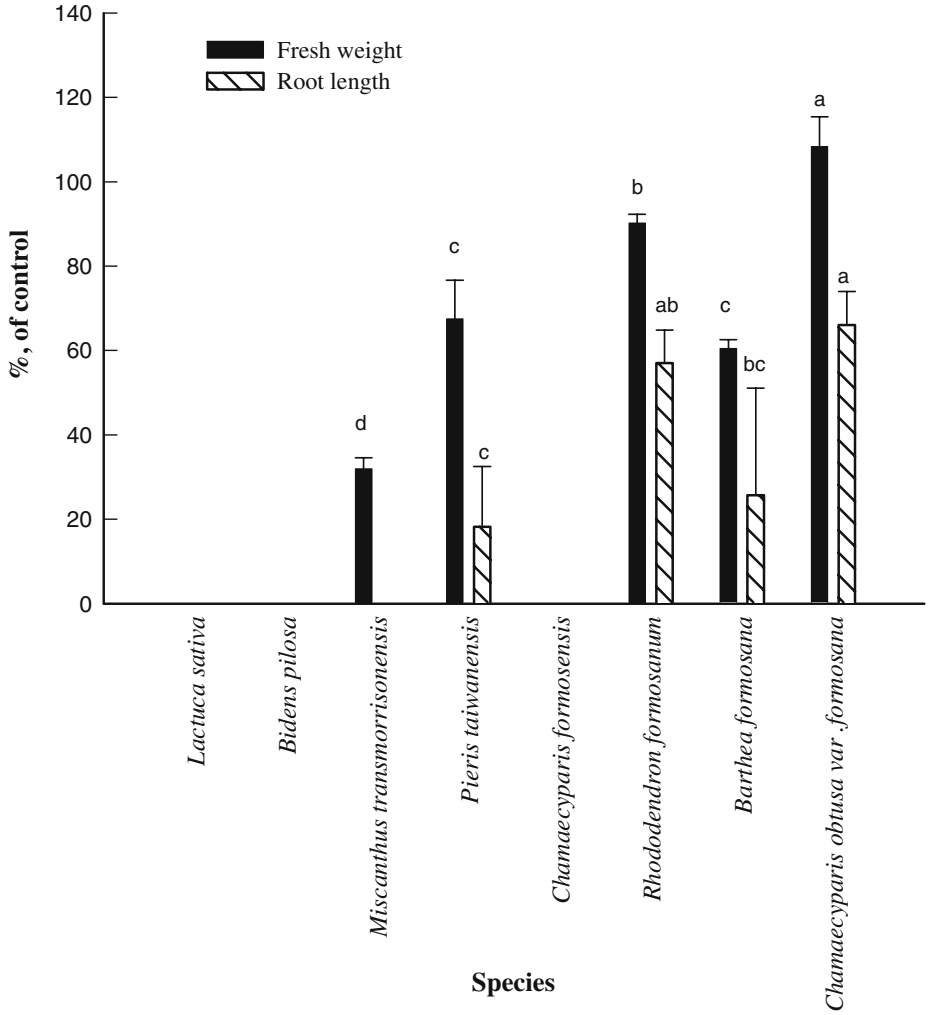

Fig. 2 Fresh weight and root length of different kinds of seedlings grew on bark of *C. obtusa* var. *formosana*. *Different letters above the standard error bars* designate significant differences at the 0.05 level by Tukey's test. The absolute control average values of fresh weight are as following: *L. sativa* (1.08×10^{-2} g), *B. pilosa* (0.84×10^{-2} g), *M. transmorrisonensis* (0.87×10^{-2} g), *P. taiwanensis* (0.34×10^{-2} g), *C. formosensis* (0.69×10^{-2} g), *R. formosanum* (0.25×10^{-2} g), *B. formosana* (0.09×10^{-2} g), *C. obtusa* var. *formosana* (1.41×10^{-2} g). Those of root length are as follows: *L. sativa* (60.7 cm), *B. pilosa* (36.1 cm), *M. transmorrisonensis* (136.0 cm), *P. taiwanensis* (42.6 cm), *C. formosensis* (29.7 cm), *R. formosanum* (20.2 cm), *B. formosana* (6.7 cm), *C. obtusa* var. *formosana* (46.1 cm)

transmorrisonensis, *P. taiwanensis*, *R. formosanum*, *B. formosana*, and *C. obtusa* var. *formosana* (Fig. 3). The chlorophyll contents of *R. formosanum* and *C. obtusa* var. *formosana* were higher than *M. transmorrisonensis*, *P. taiwanensis*, and *B. formosana* (F= 77.4, P<0.001, Fig. 3).

Isolation and Identification of Phytotoxic Compound from Bark About 180 mg pure compound with inhibitory effect on lettuce were isolated from crude methanolic extract of

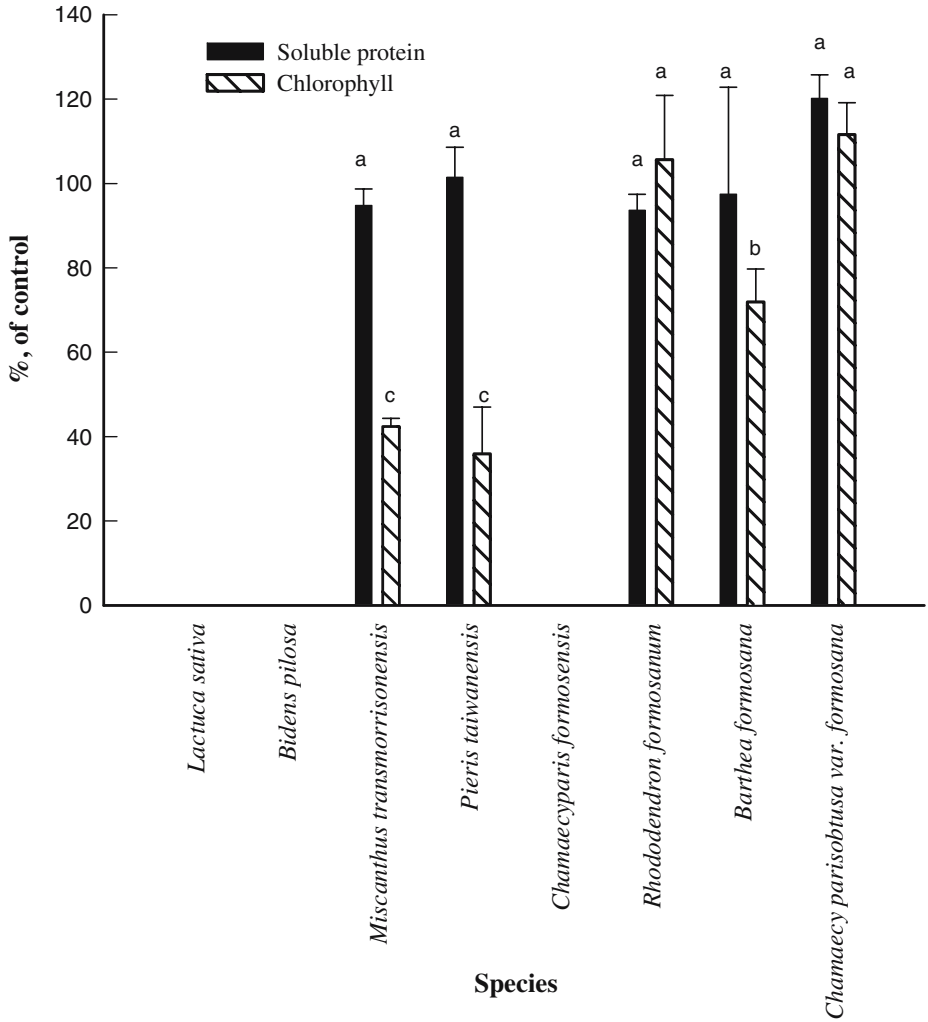

Fig. 3 Soluble protein and chlorophyll contents of seedlings grew on the bark of *C. obtusa* var. *formosana*. *Different letters above the standard error bars* designate significant differences at the 0.05 level by Tukey's test. The absolute control average values of soluble protein are as follows (μg/per one seedling): *L. sativa* (−), *B. pilosa* (106.7), *M. transmorrisonensis* (33.9), *P. taiwanensis* (27.2), *C. formosensis* (50.6), *R. formosanum* (18.8), *B. formosana* (7.4) , *C. obtusa* var. *formosana* (67.0). Those of chlorophyll are as follows (μg/per one seedling): *L. sativa* (−), *B. pilosa* (3.17), *M. transmorrisonensis* (2.05), *P. taiwanensis* (0.42), *C. formosensis* (1.20), *R. formosanum* (0.63), *B. formosana* (0.12), *C. obtusa* var. *formosana* (1.31). Note: "–" indicates that control data were not measured as *L. sativa* could not grow in test treatments

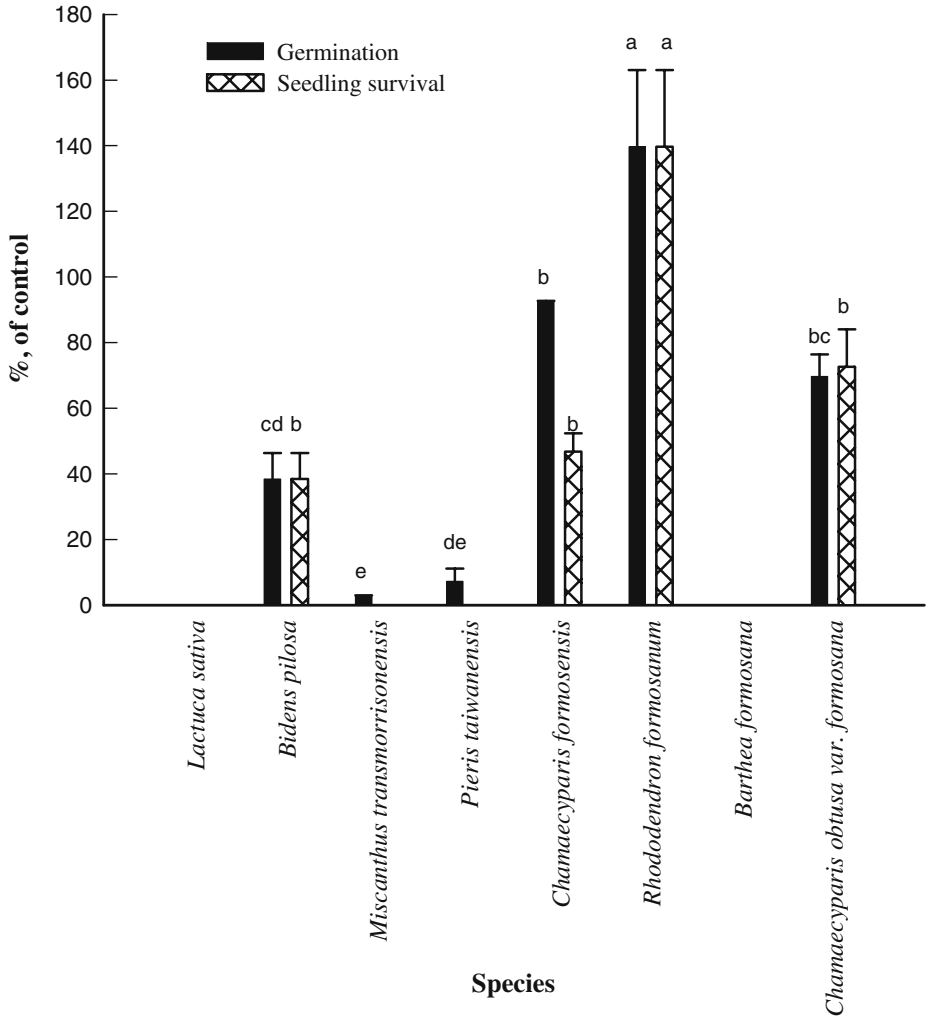

Fig. 4 Effect of salicylic acid on seed germination and seedling survival. *Different letters above the standard error bars* designate significant differences at the 0.05 level by Tukey's test. The absolute control average values were the same as in Fig. 1

the bark (2.5 kg) using bioassay-guided fractionation and purification. The IR spectrum of the isolated compound indicated the presence of a conjugated carboxylic [3,400~2,600 (broad band), 1,667 cm^{-1}], aromatic (1,613, 1,506 cm^{-1}) and hydroxyl (3,232 cm^{-1}) groups. The ^1H NMR showed signals of aromatic protons resonanced at δ_H 7.90 (1 H, dd, J=8.0, 1.6 Hz), 7.50 (1 H, ddd, J=8.4, 7.2, 1.6 Hz), 6.99 (1 H, dd, J=8.4, 1.2 Hz), and 6.91 (1 H, ddd, J=8.0, 7.2, 1.2 Hz), which indicated the *ortho*-substituted aromatic compound. The ^1H NMR data are similar to those of salicylic acid (Lampert et al. 1997; Singh et al. 2004; Emmler et al. 2004). Furthermore, the compound showed an identical retention time and mass spectrum with those of a salicylic acid standard in the GC/MS analysis. Those spectroscopic data were consistent with a structure of salicylic acid. The concentration of salicylic acid in the bark was estimated to be 72.0 μg g^{-1}.

Effect of Salicylic Acid on Seed Germination and Seedling Growth Six of the seeds, *M. transmorrisonensis*, *P. taiwanensis*, *B. pilosa*, *C. formosensis*, *R. formosanum*, and *C. obtusa* var. *formosana*, germinated on the paper with 1.5 mM salicylic acid. Among the six, only those seedlings of *B. pilosa*, *C. formosensis*, *R. formosanum*, and *C. obtusa* var. *formosana* survived on this substrate (Fig. 4). The germination percentages of *M. transmorrisonensis* and *P. taiwanensis* were low, their seedlings did not grow continuously, and they died before harvest. *C. formosensis*, *R. formosanum*, and *C. obtusa* var. *formosana* grew better than the other species, and their fresh weight, root length, and chlorophyll contents were significantly higher than *B. pilosa* (Figs. 5 and 6).

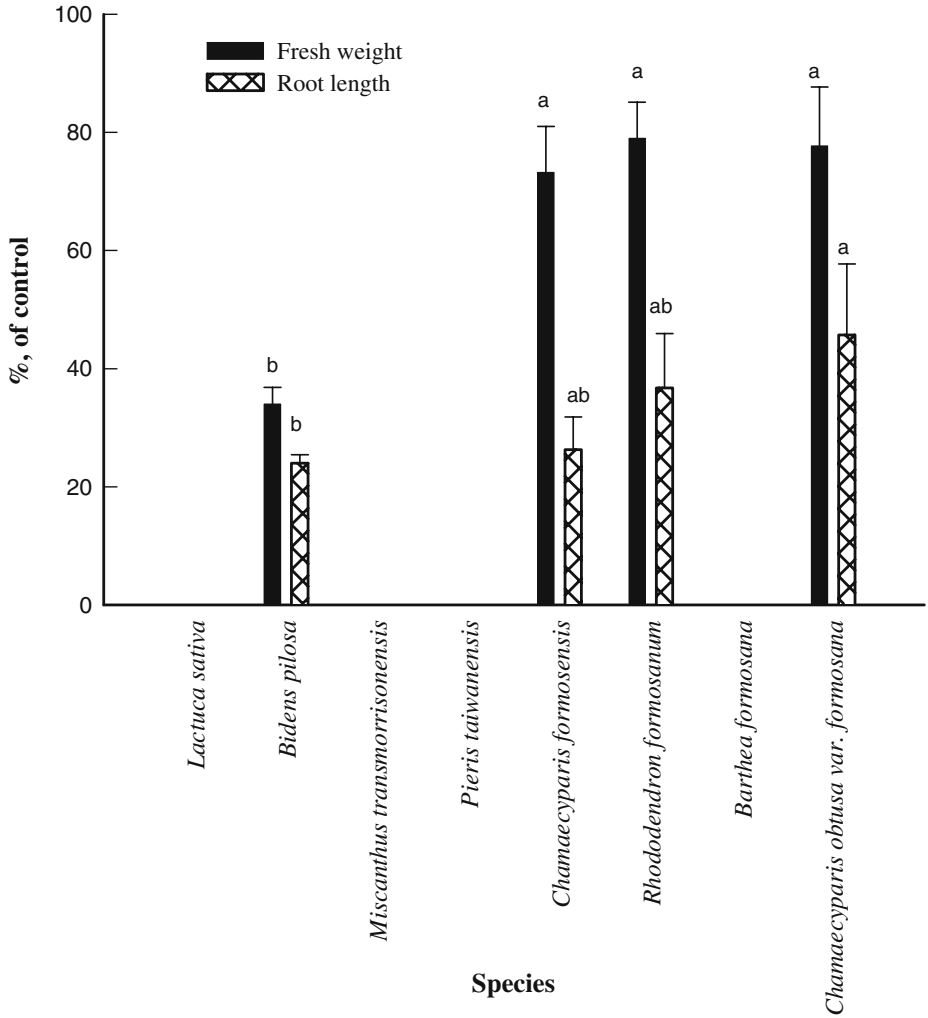

Fig. 5 Effect of salicylic acid on fresh weight and root length of different kinds of seedlings. *Different letters above the standard error bars* designate significant differences at the 0.05 level by Tukey's test. The absolute control average values were the same as in Fig. 2

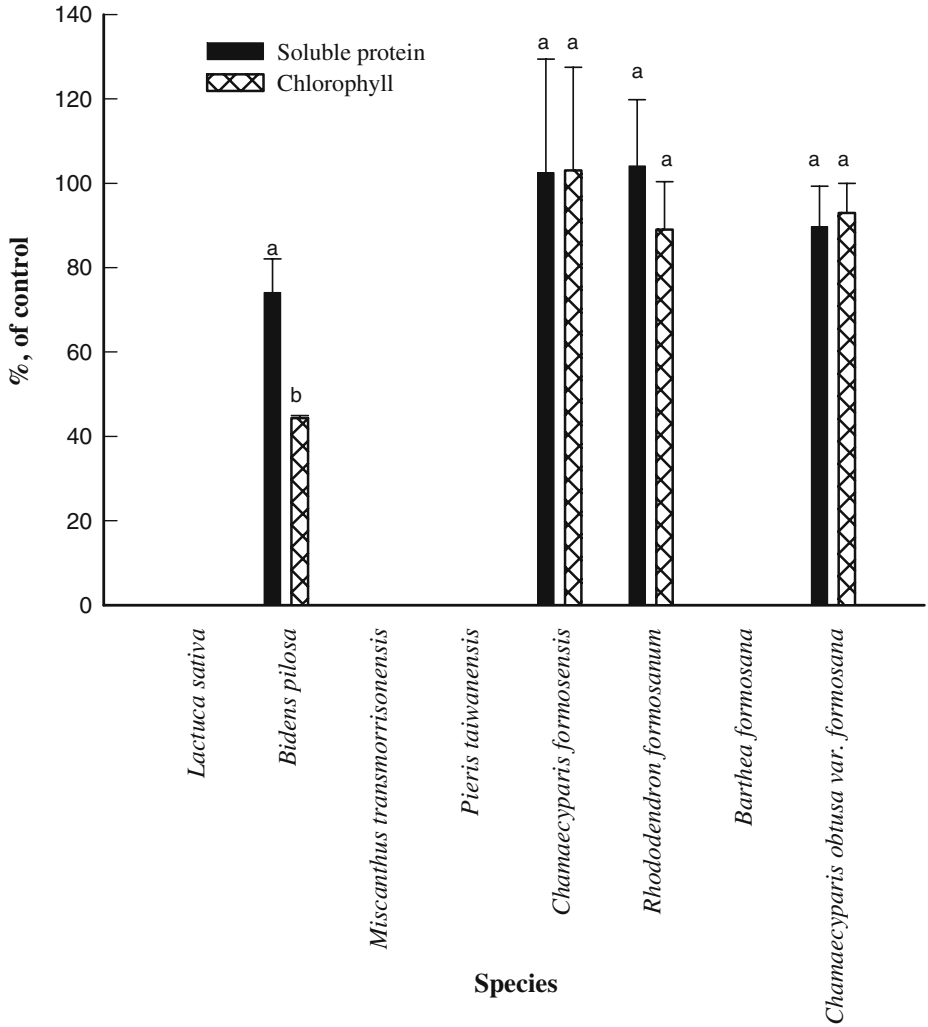

Fig. 6 Effect of salicylic acid on soluble protein and chlorophyll contents of seedlings. *Different letters above the standard error bars* designate significant differences at the 0.05 level by Tukey's test. The absolute control average values were the same as in Fig. 3

Discussion

The most drastic population changes of forest tree species occur during seed and seedling stages (Harper 1977; Harcombe 1987). Downed logs are important seedbeds for *C. obtusa* var. *formosana* due to higher seedling survival rate on them than on rocks and bare soils (Chang et al. 2001). The relative density of *C. obtusa* var. *formosana*, *R. formosanum*, and *B. formosana* measured on the sampled downed logs in YYL forest community were 59.8, 7.46, and 1.5%, respectively (Liao et al. 2003). In particular, nearly five times more *C. obtusa* var. *formosana* seedlings than other broadleaf seedlings were found on the newly downed logs (Liao et al. 2003). The survival rate, fresh weight, root length, and chlorophyll contents of *C. obtusa* var. *formosana* and *R. formosanum* seedlings grown on the bark were

significantly higher than those of *M. transmorrisonensis*, *P. taiwanensis*, and *B. formosana*. Root growth is important for successful establishment of seedlings on logs. Roots can absorb nutrients, penetrate into the clefts of bark, and prevent seedlings from washing away by rain. Bryophytes generally cover downed logs after trees fall. A favorable microhabitat is eventually created for tree seedlings due to the growth of bryophytes, organic matter deposition, bark decay, decayed wood, and humid weather. The layer of organic mater on logs allows root penetration of *C. obstusa* var. *formosana* and other broadleaf species.

Our results are consistent with the census data from the YYL forest (Liao et al. 2003). *C. obtusa* var. *formosana* and *R. formosanum* seedlings established on the downed logs had higher relative densities than did the seedlings of *B. formosana* and *M. transmorrisonensis*, *P. taiwanensis*, and *C. formosensis*, which were either not found on the logs or very few of them were established on the seedbeds. Lettuce and *B. pilosa*, which were not found in the YYL forest, were able to germinate but did not grow on the bark. These results suggest that the bark of *C. obtusa* var. *formosana* with its phytotoxic effect on other species might function as a regeneration niche favoring seedlings of *C. obtusa* var. *formosana* and *R. formosanum*.

To help understand the mechanism of toxicity, a compound was isolated and identified as salicylic acid. Salicylic acid had been reported as an allelopathic chemical and has been isolated during decomposition of plant residues (Chou and Patrick 1976; An et al. 2001; Chung et al. 2001; Park et al. 2006), from root exudates (Pramanik et al. 2000; Seal et al. 2004), leaves (Singh et al. 1989; Chung et al. 2000), and bark of *Populus Canadensis* (Koopmann 2005). Salicylic acid induced several effects depending on the concentration applied. When exceeding a concentration of 0.5 mM, it caused a strong retardation of growth. *Arabidopsis thaliana* appeared bleached, presumably because salicylic acid induced an oxidative stress (Metraux et al. 1990; Rao et al. 1997; Rajjou et al. 2006). Salicylic acid can significantly affect mineral absorption in plants in the field (Harper and Balke 1981), stomatal movements and chlorophyll content (Manthe et al. 1992; Pancheva et al. 1996; Moharekar et al. 2003), and protein content and the rate of photosynthesis were reduced in barley plants by salicylic acid (Pancheva et al. 1996). In the range of 3 to 5 mM, salicylic acid completely inhibited maize embryo germination (Guan and Scandalios 1995). *R. formosanum*, *C. formosensis*, and *C. obtusa* var. *formosana* could grow on filter paper with 1.5 mM salicylic acid, but lettuce, *M. transmorrisonensis*, *P. taiwanensis*, and *B. formosana* did not.

Those species that could not grow or were inhibited on the bark may indeed be affected by salicylic acid. However, it was interesting to find that the two closely related species, namely, *C. formosensis* and *C. obtusa* var. *formosana*, could survive on paper with salicylic acid, but only *C. obtusa* var. *formosana* could grow on bark of *C. obtusa* var. *formosana*. Salicylic acid showed a significant inhibition of *B. pilosa* growth, but the extent of the inhibition was much less than that on the tree bark. Therefore, overall, there is not a very good correlation between effects of salicylic acid and effects of the tree bark when all species are compared. This suggests that salicylic acid may be only part of the story or may be important only for some species. The logs from which we collected bark for this study had fallen down between 0.5 and 2 yrs ago. Although outer layers of the bark from living *C. obstusa* var. *formosana* (ex. 1,000 yrs old) and downed logs are dead tissue and had already been flushed by rain numerous times, salicylic acid was still isolated. How such water-soluble allelochemicals persist in an ecosystem is an interesting question worth further experimentation.

In YYL forest, the canopy gaps created by *C. obtusa* var. *formosana*-downed logs would increase the level of light and provide new seedbeds where seedlings would not be

damaged by flooding from extremely high lake levels during typhoons and monsoons. Because the early growth of naturally regenerated *C. obtusa* var. *formosana* seedlings is slow, they often are suppressed by competing vegetation (Chiu et al. 1993). The bark seedbeds would provide safe sites for emerging seedlings and exclude competition from weeds and shrubs on the forest floor. The allelopathic effect of bark of the newly downed logs might act as a selective pressure that differentially affects various tree species. The two dominant species, *C. obtusa* var. *formosana* and *R. formosanum*, which can grow normally on the bark, could establish themselves on the downed logs and then occupy the gap, which would function as their regeneration niches. Further studies are needed to elucidate the source of the salicylic acid or additional allelochemicals or inhibitors. The interference factors might be due to logs of *C. obtusa* var. *formosana* themselves, or to lichens, fungi, or other microorganisms that distribute on the bark surface.

Acknowledgments The authors express their appreciation to the Forest Conservation and Management Administration, Veterans Affairs Commission, Executive Yuan, Taiwan, for permission to do this study in Yuan-yang Lake Nature Preserve and to Dr. T. H. Wang, Institute of Plant and Microbial Biology, Academia Sinica for laboratory assistance. This study was supported by Grants NSC-92-2313-B133-001 to Y. H. Kuo and M. W. Tseng.

Methods and Materials

Adult EAB were shipped under Animal and Plant Health Inspection Service (APHIS) permit from Brighton, MI, USA, to the Peoria, IL, USA, laboratory within a day of emergence from infested ash logs brought indoors in winter to induce EAB emergence. The beetles were kept segregated by sex at 27°C under a 16:8 (L/D) hour photoperiod and fed foliage of evergreen ash (*Fraxinus uhdei*). Volatiles were collected from both feeding males and females (five per collector) and from foliage alone (135, 119, and 10 total collections, respectively). Apparatus and general procedures were as described by Bartelt et al. (2006) for another beetle species. Volatiles were recovered from filters, foliage was renewed, and any dead beetles were replaced on a daily basis. The methods and equipment of Cossé and Bartelt (2000) were used for gas chromatography–electroantennographic detection (GC-EAD) analysis, except that excised antennae replaced whole-head preparations; 43 beetle-derived samples were analyzed. Equipment for GC-mass spectrometry (GC-MS), GC with flame ionization detector (GC-FID), and nuclear magnetic resonance spectroscopy (NMR) was as described previously (Bartelt et al. 2006). Compound quantitation was by the internal standard method (GC-FID, using heptadecane). Some collections were purified on small open columns of silica gel, eluting with increasing concentrations of diethyl ether in hexane. Purified beetle-derived material (silica gel, 10% ether in hexane) and synthetic lactone were hydrogenated over 10% Pd on carbon and were also derivatized with dimethyl disulfide (DMDS), procedures explained by Attygalle (1998). Chromatographic separations and reactions were monitored by GC-MS. (3*Z*)-dodecen-12-olide was synthesized, and the acquired ^{1}H and ^{13}C NMR spectra matched those reported (Boden et al. 1993).

Results and Discussion

One compound of apparent beetle origin (Fig. 1, arrow) was observed in volatile collections, in addition to plant-related compounds (Fig. 1, a and b). The beetle substance and some from the foliage were antennally active (Fig. 1, c and d). The indicated compound was consistently present in collections from females (129 out of 135, representing eight shipments of beetles), but it was also found in collections from males (52 out of 119) in smaller amounts, near the limit of detection. Mean initial emission rate from females was 10.7 ng/d per beetle (N=22 collections, SD=5.5, age 2–4 d after emergence), whereas the corresponding mean for males was 0.9 ng/d per beetle (N=20 collections, SD=0.6). Emission rates for both females and males decreased over time, being 26 and 19% of the initial values, respectively, for collections 6–7 d after emergence; this drop may simply reflect declining beetle health (typical mortality for shipments was 60% at 7 d after emergence), or it may be a natural pattern. The compound was never detected from foliage. No other antennally active compounds were recognized as likely coming from EAB.

The compound had the polarity of an ester on silica gel, eluting with 5–10% ether in hexane. The mass spectrum (EI, 70 eV) was not in the spectral library: [m/z (%)=196 (M^+, 8), 178 (7), 136 (19), 126 (8), 121 (13), 112 (27), 95 (35), 81 (66), 67 (92), 54 (100), 41 (73)]. Hydrogenation over Pd increased the molecular weight by 2, indicating the compound had one double bond [m/z (%)=198 (M^+, 2), 180 (5), 162 (7), 138 (19), 110 (23), 98 (61), 96 (46), 84 (47), 83 (51), 82 (38), 69 (53), 55 (100), 41 (71)]. This spectrum closely matched12-dodecanolide in the MS library. Therefore, dodecen-12-olides were explored in the literature, and (3*Z*)-dodecen-12-olide had a mass spectrum similar to that observed (Millar et al. 1985; Boden et al. 1993). Interestingly, this lactone is the major component of the male-produced pheromone of the flat grain beetle *Cryptolestes pusillus*

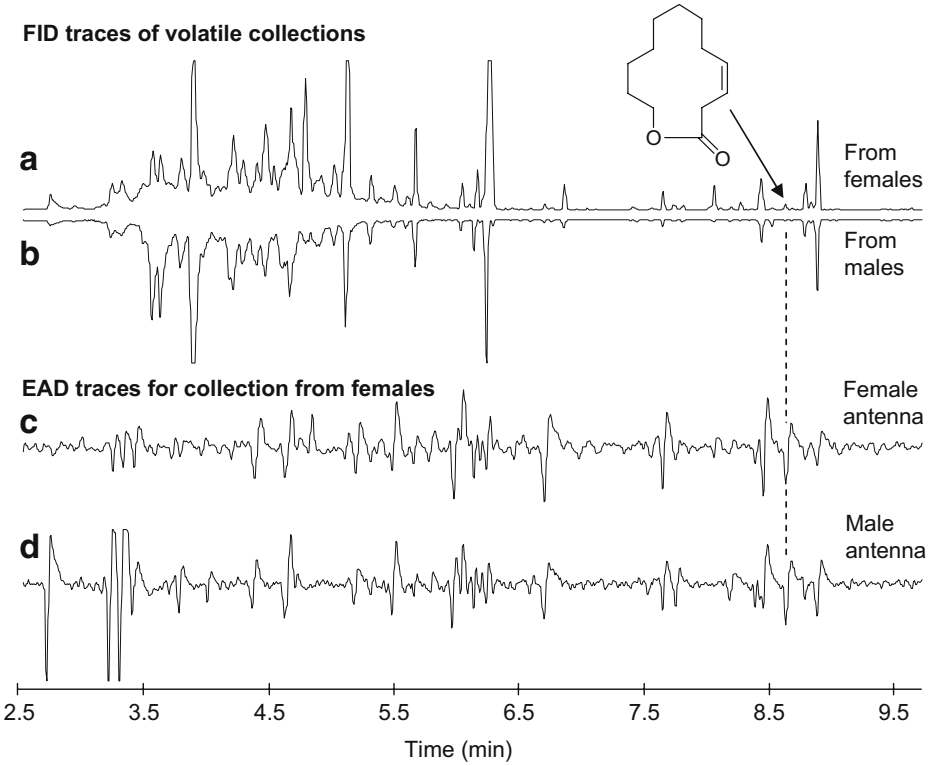

Fig. 1 GC-FID comparison of volatiles collected from female (**a**) and male (**b**) *A. planipennis* feeding on ash foliage and GC-EAD traces of female (**c**) and male (**d**) antennae to a female collection. Structure of (3*Z*)-dodecen-12-olide is shown

(Schönherr) (Coleoptera: Cucujidae) (Millar et al. 1985). It was synthesized as a standard for comparison.

Synthetic (3*Z*)-dodecen-12-olide was identical to the beetle compound by GC retention, mass spectrum, hydrogenation product, and polarity on silica. The trace of *E* isomer in the synthetic lactone (2%) eluted before the beetle compound. The DMDS derivatives of the natural and synthetic lactones gave identical mass spectra [m/z (%)=290 (M^+, 35), 243 (15), 227 (18), 122 (100)]. Mass spectra of lactone DMDS adducts are more complex than open-chain olefins, but direct comparisons would still reveal differences in double-bond position. Together, these data established that the beetle compound was (3*Z*)-dodecen-12-olide (Fig. 1). The synthetic lactone was active by GC-EAD.

Our GC-EAD results were consistent with patterns of field attraction reported for another buprestid, *Agrilus bilineatus* (Weber), in that both males and females responded positively to females (Dunn and Potter 1988); attraction to male *A. bilineatus* was not investigated, and no chemical details were reported. If the lactone has a pheromonal function in EAB, it is likely not a typical sex pheromone because it was detected from both sexes and because the greatest emission (2–4 d after emergence) occurred before the beetles were expected to be sexually mature (e.g., 7 d after emergence, Bauer et al. 2003). An aggregation function is possible, but additional mechanisms such as visual cues are undoubtedly involved in mate finding (Lelito et al., unpublished). Further research is needed to characterize any behavioral activity toward

the EAB lactone, but the urgent need to improve monitoring makes this a high priority. Such studies are planned.

Acknowledgment We thank Karl Vermillion of NCAUR for acquiring the NMR spectra.

Abstract Volatiles from *Ips duplicatus* male hindgut extracts and aeration samples of spruce logs colonized by the virgin males were analyzed by coupled gas chromatography–mass spectrometry (GC-MS), coupled gas chromatography–electroantennographic detection (GC-EAD), and field trapping bioassays in Inner Mongolia, China. GC-MS analyses showed that males from nuptial chambers (for reproduction) produced hindgut volatile profiles similar to those of maturation feeding males from the nonreproductive galleries. The known aggregation pheromone components, ipsdienol (Id) and *E*-myrcenol (EM) are the major constituents of this blend, followed by several minor bark beetle-related compounds: 2-methyl-3-buten-2-ol, ipsenol, *cis*-verbenol, verbenone, 2-phenylethanol, myrtenol, and *trans*-myrtanol. The enantiomeric composition of the Id from the male hindgut extracts was determined to be a racemic mixture (50/50) by enantioselective GC. GC-EAD experiments indicated that *I. duplicatus* antennae from both sexes responded strongly not only to the known aggregation pheromone components, Id and EM, but also to the other minor conspecific-produced compounds. The strongest antennal response was elicited by the major pheromone component, Id, which was ca. 2–3 times higher than that elicited by the second component, EM. Electroantennogram dose-responses indicated that antennal response threshold to Id was

approximately 100 times lower than that of EM. No synergistic effects between these occurred at peripheral level. A strong and repeatable EAD response was found to a trace compound (flame ionization detection undetectable) from both hindgut and aeration samples. The compound was identified as amitinol (At) based on the retention time and a further EAD analysis of a synthetic mixture. In the field trapping experiments, At increased the attraction of *I. duplicatus* to the traps baited with a binary blend of EM/Id (1:1) in a synergistic manner when tested at a low release rate (1:1:0.1) but had no effect on catches at the high release rate (1:1:1). This result suggests that At might be a part of the Chinese *I. duplicatus* aggregation pheromone system. The production ratios of EM/Id from the Inner Mongolian population (EM/Id≈1:2.0–4) were twice as high as those reported from Europe (EM/Id≈1:9), corresponding well with the differences in the optimal response ratios.

Introduction

The double-spined spruce bark engraver, *Ips duplicatus* (Sahlb.), is a spruce (*Picea* spp.) pest insect in Europe and North-East Asia (Lekander et al. 1977; Pfeffer 1995; Zhang et al. 2001). Recent outbreaks in Czech Republic (Knizek and Zahradnik 1996) and continuous outbreaks since the 1950s in Inner Mongolia, China (Zhang et al. 1995; Liu et al. 1998), as well as its status as a vector of phytopathogenic fungi (Krokene and Solheim 1996), pose a serious threat to the spruce forests in these regions.

The aggregation pheromone system of *I. duplicatus* has been intensively studied in Europe, where it consists of two components, racemic ipsdienol (Id) and *E*-myrcenol (EM) (Bakke 1975; Schlyter et al. 1987, 1992; Byers et al. 1990). West palearctic (Norway/Sweden) *I. duplicatus* contain a blend of EM/Id (ca. 1:9), and a synthetic blend of these *de novo* produced components (Ivarsson et al. 1993) is highly competitive to natural pheromone emitted by unpaired males in spruce logs (Schlyter et al. 1992). A recent study comparing the optimal EM/Id proportions for attraction across four populations (Norway, Czech Republic, Great Xingan Mountains, and Inner Mongolia, China) revealed that the Inner Mongolia population has a significantly different optimal response ratio of EM/Id from other populations (Schlyter et al. 2001a). This finding raises questions concerning the production ratio of the two aggregation pheromone components (Id and EM), the enantiomeric composition of Id in the Inner Mongolia population and its potential genetic divergence from the European populations (Lakatos et al., unpublished). Furthermore, a fraction of the *I. duplicatus* population in Inner Mongolia require maturation feeding on wind-thrown or weakened spruce trees in early summer for 1–2 weeks before initiating the normal attacks on standing trees for reproduction (Wang 1992; Zhang et al. 1995). Such a maturation feeding on logs or felled trees demonstrates a strong aggregation pattern, with 20–50 adults (ca. 1:1 of sex ratio) feeding in a single entry "communal" gallery.

In the current study, we tested the following four hypotheses on the Inner Mongolian population of *I. duplicatus*: H_1, "communal maturation feeding" males differ from normal colonizers of fresh host trees in their semiochemical productions; H_2, there is a correspondence between the production and response of the two main pheromone components (and/or their ratios) among the different geographical populations (such as West palearctic and Inner Mongolia); H_3, the enantiomeric composition of the major

pheromone component Id differs between the Chinese and the European populations; and H_4, additional pheromone components may exist that act synergistically with the two main components. These hypotheses were tested by using gas chromatography–mass spectrometry (GC-MS), gas chromatography–electroantennographic detection (GC-EAD), and field trapping bioassays.

Materials and Methods

Field Site

All beetle collections and field trapping experiments were carried out in the National Baiyinaobao Spruce Natural Reserve [*Picea mongolica* (Wu, H.-Q.) Xu, formally *Picea koraiensis* Nakai or *Picea meyeri* or *P. meyeri* var. *mongolica* Wu, as discussed by Xu et al. (1998)] at Keshiketeng Qi (43° 30′–36′ N, 117° 06′–16′ E), Inner Mongolia, China, which is situated in the grassland with a thick layer of sandy soil at the east edge of Hunshandake desert. Since the 1950s, this isolated natural spruce forest has been severely infested by sawflies and *I. duplicatus* (Zhang et al. 1995, 2001; Liu et al. 1998; Schlyter et al. 2001b).

Hindgut Extraction and Headspace Sampling

Field Sampling Ips duplicatus adults were collected at the field site in early June 1994 during natural attacks on *P. mongolica*. Infested spruce trees were cut, and logs exhibiting either beetle maturation feeding in communal chambers or reproduction in nuptial chambers (with the status of one male and 1–2 females per family and no eggs) were transported to the local laboratory. Live beetles caught in pheromone traps were also collected at this time. Hindguts were rapidly dissected from the beetles, extracted in 300 μl of pentane, and pooled separately according to sex and attacking phases (Zhang et al. 2000). The extracts (9–22 guts/sample) were kept at −20°C prior to GC-MS analysis in Sweden.

Laboratory Collection A laboratory culture of live beetles originally collected from the same site as for the field collection/trapping in Inner Mongolia, China, was successfully maintained on Norway spruce (*Picea abies*) logs from 1999 to 2000 at the Swedish University of Agricultural Sciences, Alnarp, in Sweden. Twenty to 30 males, emerged from generation 3 (March 2000), were allowed to colonize 10-cm-diameter spruce bolts with predrilled holes (25°C, 70% RH, 20:4 L/D). After feeding for 24 hr, the bolts with male beetles were placed into polyester bags (Meny Toppits, Terinex, Bedford, England), each equipped with a charcoal filter tube. Headspace volatiles of the male-infested bolts were collected on 30-mg Porapak Q (50–80 mesh, Supelco, Bellefonte, PA, USA) in a 3-mm ID Teflon tube via a portable aeration system as described by Zhang et al. (1999) for 1.5 hr. The Porapak Q collections were each rinsed in 300 μl of diethyl ether. Immediately following headspace collection, the males were excised from the nuptial chambers and hindguts were extracted in 300 μl of hexane. Headspace from an uninfested spruce bolt of similar size taken from the same tree was collected in parallel to serve as a control. Both hindgut extracts and aeration samples were kept at −20°C until GC-EAD and GC-MS analysis. For enantiomeric analysis of Id, a new batch of wild beetles was collected from the same location in Inner Mongolia in October 2006, and beetles were allowed to colonize spruce logs for 24 hr in the laboratory before hindgut extraction with hexane.

GC-MS Analysis

Hindgut extracts from field-collected beetles (in 1994) were analyzed on a combined Hewlett-Packard (HP) 5890 series II gas chromatograph (GC) and an HP 5972 mass selective detector (MSD). Laboratory aeration and hindgut samples (in 2000) were analyzed on a newer model of GC-MSD (HP 6890 GC–HP 5973 MSD). Both GCs were equipped with a 25 m×0.25 mm fused silica column coated with 0.25 μm OV-351 (Ohio Valley Speciality Chemical, Marietta, OH, USA). The GC oven temperature was programmed at 50°C for 2 min, with a rise to 200°C at a rate of 8°C/min, and held at 200°C for 5 min. To clear the column from contaminants, the temperature was then raised at 20°C/min to 250°C and held for 5 min. Injector and transfer line temperatures were maintained at 200 and 225°C, respectively. Helium was used as carrier gas, and the flow was electronically controlled to be a constant 30 cm/sec. Volatiles were identified by comparisons of the retention times and mass spectra with those from the available authentic synthetic compounds, along with those from the computerized data library, NBS75K, and with a custom produced library (KE 1995, Göteborg).

Enantiomeric Composition of Id

A new extract of male hindguts (N=19 in 20 μl of hexane; after 24 hr feeding in spruce log) was made from the freshly collected beetles (2006; see above). The extract (1 μl) was injected splitless into a Varian CP-3800 GC equipped with a fused silica column coated with an optically active stationary phase (Rt-bDEXm™; 30 m×0.25 mm×0.25 μm; Restek, Bellefonte, PA, USA). Helium was used as the carrier gas and the injector/detector temperatures were all 230°C. The column temperature was 80°C for 1 min and rose to 200°C at 2°C/min. To confirm the retention times of enantiomers, a synthetic mixture of ipsenol (Ie), amitinol (At), and Id (100 ng/μl each) was subsequently injected.

GC-EAD and Electroantennogram Responses

Male hindgut extracts or aeration samples (2–3 μl) and synthetic mixture (1–2 μl; consisting of Ie, Id, At, and EM; 30 ng/μl each) were splitlessly injected into an HP-6890 GC equipped with an HP-INNOWAX column (30 m×0.25 mm×0.25 μm). A 1:1 effluent splitter allowed simultaneous flame ionization detection (FID) and EAD of the separated volatile compounds. Hydrogen was used as the carrier gas. The column temperature was 40°C for the first 2 min, rising to 200°C at 10°C/min, and held for 2 min. The outlet for the EAD was inserted into a humidified air-stream (0.5 m/sec) over an *I. duplicatus* antennal preparation. A glass capillary indifferent electrode, filled with Beadle–Ephrussi Ringer solution and grounded via a silver wire, was inserted into the severed beetle's head with the antennae. A similar recording electrode, connected to a high-impedance DC amplifier with automatic baseline drift compensation, was placed in contact with the distal end of the antennal club. The resulting signals were stored on a PC equipped with an intelligent data acquisition controller card and analyzed with the program EAD (version 2.3, Syntech, Hilversum, the Netherlands). For each GC-EAD analysis, *I. duplicatus* antennae from three females and two males were tested.

Electroantennogram (EAG) dose-responses of *I. duplicatus* to synthetic samples of two known pheromone components, Id and EM, were recorded under similar conditions. Stimuli were prepared by applying Id and EM separately and together at a 1:1 ratio (10^{-4} to 10^{1} μg/μl) in 2 μl of hexane on a piece of filter paper (7×15 mm) in a Pasteur pipette. The same total loading amounts on the filter paper were used for the blends as for the individual compound treatments. Compounds were tested at five concentrations from the lowest to the

highest. "Blank control" stimuli (2 μl of hexane solvent per filter paper) were interspersed between different compounds tested. Each stimulus was followed by a period of at least 60 sec of filtered humid air passing over the antenna to ensure recovery of antennal receptors.

Field Trapping

Eight black flight barrier traps (Theyson, Germany) were set up in mid-June, 2001, in a small glade surrounded by a *P. mongolica* stand with dead trees that were killed by *I. duplicatus* the previous year. Traps were arranged in an arc to ensure a similar distance (ca. 20–25 m) from the insect source (the dead trees) for each trap. The distance between traps was ca. 8 m. Two previously known pheromone components, Id and EM (Byers et al. 1990; Schlyter et al. 1992), along with a novel EAD-active compound, At, were tested by using a factorial design, i.e., individually and in all possible combinations. A similar test with a reduced number of treatments was repeated in the same site in early June 2002. Traps together with dispensers were rotated after each replicate (when ≥80–100 beetles were caught in the best trap) in a randomized Latin-square design. All chemicals, source, release devices, and release rates are listed in Table 1.

Statistical Analysis

Trap catch data were transformed by $\log(x+1)$ to fit the assumption of homogeneity of variance for ANOVA. Means were compared by ANOVA followed by the Ryan–Einot–Gabriel–Welsh multiple Q test (SPSS 8.0 for Windows) at $\alpha=0.05$. The sex ratios for the treatments within each experiment were compared with 95% binomial confidence intervals (Newcombe 1998, 2006).

Results

GC-MS Analysis of Hindgut Extracts

Male and female *Ips* beetles are in a nonfeeding phase during dispersal flights. Dispersing beetles of both sexes collected from pheromone traps contained no bark beetle pheromone compounds. Males in the communal maturation feeding chambers produced both Id and EM as major components, with the ratio of EM/Id at ca. 1:4 (Table 2). In addition, several other compounds frequently found in *Ips* beetles, 2-methyl-3-buten-2-ol, Ie, *cis*-verbenol (cV), verbenone (Vn), 2-phenylethanol (PE), myrtenol, and *trans*-myrtanol, were also identified in

[a] Number of hindguts in the extracts

[b] Only the beetle-produced volatiles are considered

the males in trace or minor amounts. No bark beetle-specific compounds were detected from the hindguts of maturation feeding females, except a trace amount of Id. Males from nuptial chambers displayed similar hindgut volatile profiles, both qualitatively and quantitatively, to the maturation feeding males (Table 2). The ratios of EM/Id were estimated as ca. 1:4 to 1:6. Females from the nuptial chambers contained no bark beetle pheromone compounds at detectable level.

Male hindgut and headspace extracts from the laboratory cultures showed a similar GC pattern of male-produced volatiles to the field-collected samples, with both Id and EM as the major components (Table 2; Figs. 1b and 2a). However, the ratio of EM/Id appears to be higher in hindgut extracts (1:2 to 1:2.5) than that in the aeration samples (1:4 to 1:6). In addition to the well-known bark beetle compounds, trace amounts of a green leaf volatile (GLV), 1-hexanol, were also detected from both samples. No Id and EM were identified from the headspace samples of spruce bolts alone, but trace amount of 1-hexanol was detected in addition to large amounts of monoterpenes (Fig. 1a).

Enantiomeric Composition of Id

Enantioselective analysis indicated that males of *I. duplicatus* produced a racemic mixture (50/50) of the major component, Id (Fig. 3a), which was confirmed by the synthetic mixture (Fig. 3b).

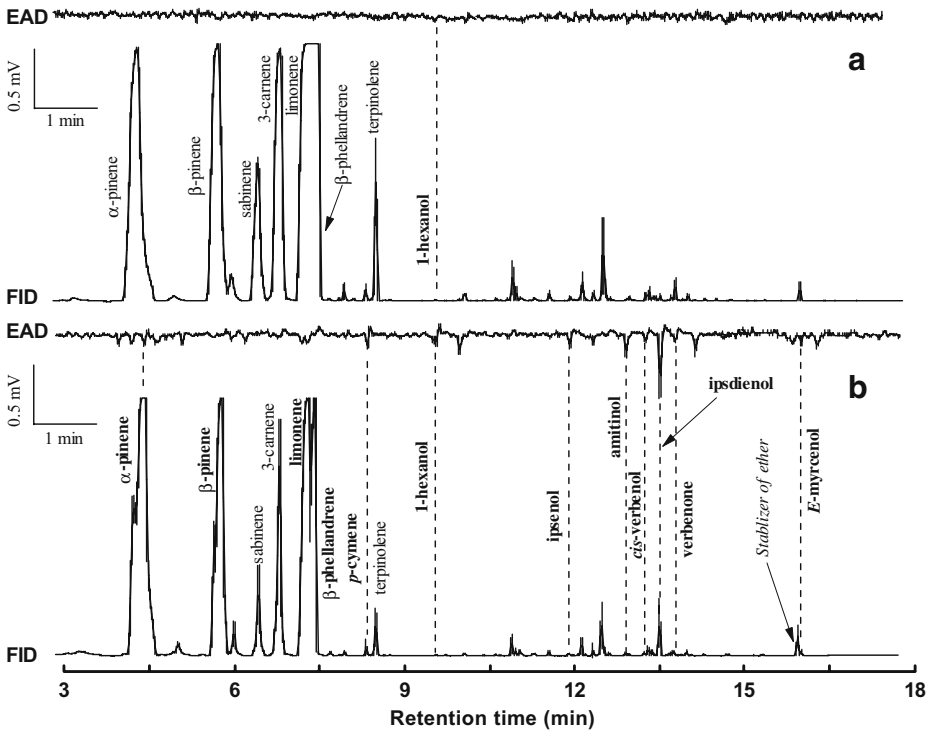

Fig. 1 Simultaneously recorded FID and EAD responses of *I. duplicatus* antennae to aeration samples of **a** a spruce log and **b** a spruce log colonized by 25 males for 24 hr in the lab. EAD-active compounds are labeled in *bold*

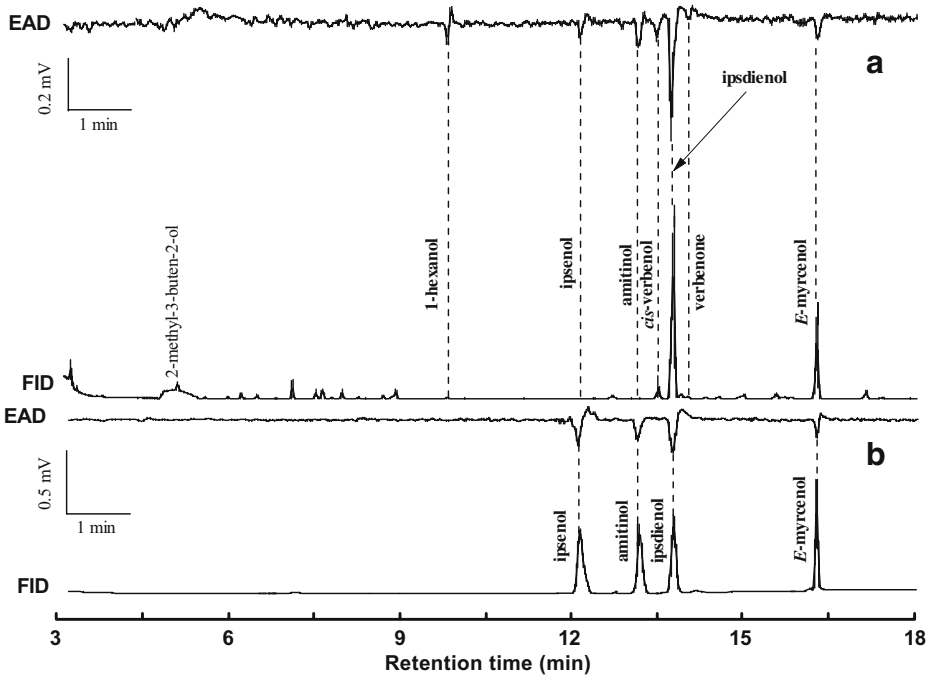

Fig. 2 Simultaneously recorded FID and EAD responses of *I. duplicatus* antennae to hindgut extracts of the males fed in the spruce logs for 24 hr (**a**) and to a synthetic mixture of selected bark beetle pheromone compounds (**b**). EAD-active compounds are labeled in *bold*

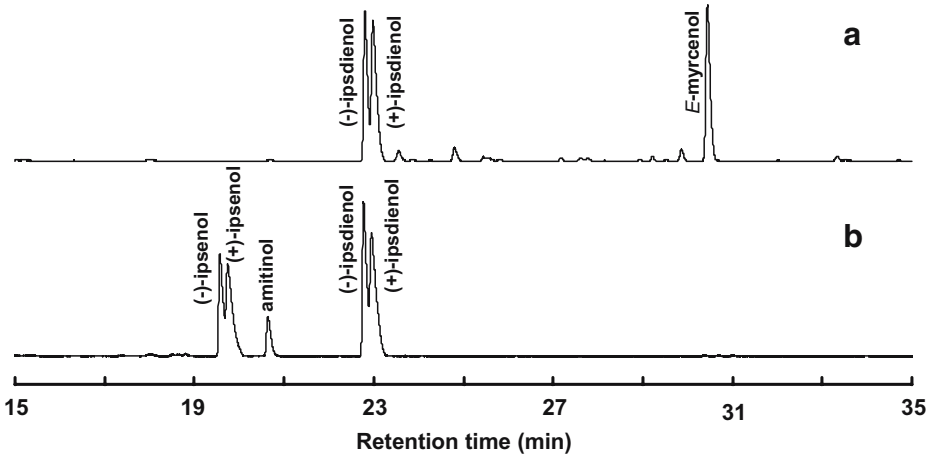

Fig. 3 Enantioselective GC analysis of Id from **a** an *I. duplicatus* hindgut extract of 19 unmated males making nuptial chambers in Norway spruce (*Picea abies*) log for 24 hr and **b** a synthetic mixture of racemic Ie, At, and racemic Id. The elution orders of (+) or (−) enantiomers of Ie and Id were determined according to the results reported in Macias-Samano et al. (1997) and Savoie et al. (1998), of which similar type of column (with the same stationary phase as ours) was used. For Ie and Id, (−)-enantiomers should elute before its corresponding (+)-enantiomers

GC-EAD Recordings and EAG Dose Responses

Coupled GC-EAD analyses on headspace extracts of spruce bolts alone revealed reproducible responses to a trace amount of 1-hexanol and occasionally weak responses to a few monoterpenes such as α-pinene, β-pinene, limonene, β-phellandrene, and *p*-cymene (Fig. 1a). In addition to the weak monoterpene and reproducible 1-hexanol responses, strong EAD responses were found to six additional compounds from both headspace samples of male-infested bolts (Fig. 1b) and male hindgut extracts (Fig. 2a). The strongest EAD responses were recorded to Id, followed by a FID undetected compound, then EM, cV, Ie, and Vn (Fig. 1b, Fig. 2a). Based on the retention time and a further EAD analysis of a synthetic mixture (Fig. 2b), this GC-FID undetectable, antennally active compound was identified as At. No antennal activity to 2-methyl-3-buten-2-ol was found, although the amount produced was comparable to the two major hindgut components, Id and EM (Fig. 2a). No differences in antennal responses between males and females were found.

EAG dose-responses were tested against solvent control to compare the relative sensitivity of *I. duplicatus* antennae to the two major pheromone components, Id and EM, and their potential synergistic effect at a peripheral level. For the three treatments tested, there was a significant effect of dosage on the EAG response (Fig. 4). However, the response threshold to Id (0.1–1 ng/μl) was approximately 100 times lower than that of EM. The dose-response curve for the Id/EM blend was identical to Id alone, which indicated no synergistic effect between these two pheromone components at peripheral level.

Field Trapping

In a field trapping experiment carried out in 2001, a total of 3,848 beetles were caught during 16 replicates. Individual compounds, Id, EM, At, and two binary blends, Id + At and EM + At, caught zero or less than 35 beetles, which were not significantly different from zero. However, the combination of Id and EM was attractive with its total catch of over 1,100 beetles (ca. 35–60 times higher than the individual Id or EM treatments). Addition of At at a high release rate to this mixture (EM/Id/At=1:1:1) did not increase trap catches, whereas a low rate of release of At (EM/Id/At=1:1:0.1) significantly enhanced the numbers of beetles caught by 47% (Fig. 5a). A similar enhancement in trap catches by adding At at a

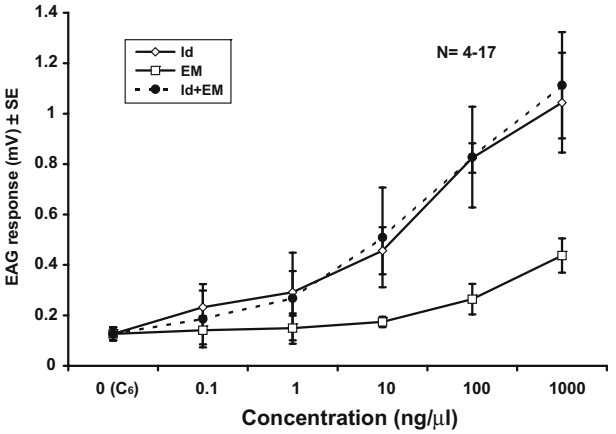

Fig. 4 Responses of *I. duplicatus* antennae (EAG) to various doses of Id, EM, and their combination (Id + EM). Doses are given as nanograms applied to filter paper in the stimulus pipette in hexane solvent

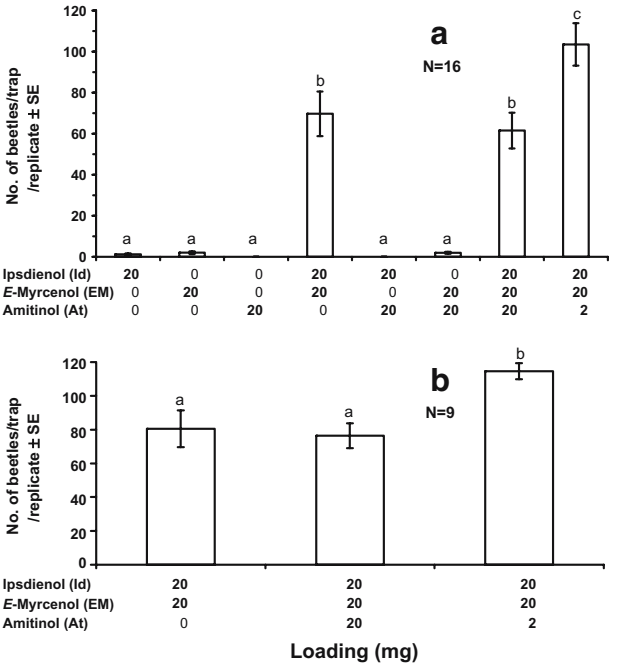

Fig. 5 Captures of *I. duplicatus* in traps baited with **a** the individual pheromone components, Id, EM, and At with all their binary and ternary combinations, June 24–27, 2001, Baiyinaobao, Inner Mongolia, China, and **b** in traps baited with a binary blend (Id/EM) and ternary mixtures with two levels of At release; June 1–3, 2002, Baiyinaobao, Inner Mongolia, China. Bars with the same letter are not significantly different ($P>0.05$) by Ryan–Einot–Gabriel–Welsh multiple Q test after ANOVA on log ($x+1$) transformed data

low rate of release (EM/Id/At=1:1:0.1) was also found in the 2002 field trapping experiment (Fig. 5b). There were no significant differences in sex ratios among different treatments for the two experiments; while the 2002 experiment conducted earlier in the flight period had a much higher "percent males" for comparable baits (Table 3).

Table 3 Proportion of *I. duplicatus* males captured

Test/treatment (mg)	% of Males	95% CI[a]	Total catch
Experiment 1: June 24–27, 2001			
Id (20)	21.1	8.5–43.3	19
EM (20)	25.0	13.3–42.1	32
At (20)	–	–	0
Id + EM (20+20)	11.2	7.3–16.9	1,125[b]
Id + At (20+20)	–	–	0
EM + At (20+20)	25.8	13.7–43.3	31
Id + EM + At (20+20+20)	16.6	11.7–22.9	985[b]
EM + Id + At [20+(20+2)]	10.6	6.9–15.9	1,656[b]
Experiment 2: June 2–4, 2002			
Id + EM (20+20)	27.59	20.27–36.34	724[b]
Id + EM + At (20+20+20)	26.09	18.2–35.89	688[b]
EM + Id + At [20+(20+2)]	29.52	21.65–38.85	1,032[b]

[a] 95% binomial confidence intervals (Newcombe 1998, 2006)

[b] Subsamplings of 100–180 beetles were taken for determination of sex ratios

Discussion

This is the first chemical analysis of the aggregation pheromone system of an Asian population of *I. duplicatus*. Coupled GC-MS results demonstrate that overwintered *I. duplicatus* from Inner Mongolia produce no pheromone components during the early summer prefeeding dispersal flight. Males from the maturation feeding galleries had a hindgut volatile profile similar to the normal reproductive feeding males, with Id and EM as the major pheromone components (Table 2). Other compounds frequently found in *Ips* beetles, such as Ie, cV, PE, myrtenol, and *trans*-myrtanol, were also detected, but mainly in minor or trace amounts. These results reject our first hypothesis concerning the production of different semiochemicals between maturation feeding males and normal reproductive feeding males. The mechanism by which dispersing individuals separate reproductive feeding males from ones under maturation feeding, therefore, remains unknown, because no differences in hindgut volatile profiles were detected. In comparison with European populations, there was no qualitative difference of male hindgut volatiles of normal colonizers; however, the production ratios of EM/Id from the Inner Mongolian population were twice as high as those of the European ones (EM/Id≈1:9) (Schlyter et al. 1992). This corresponds well with the differences in the optimal response ratios from trapping tests (Schlyter et al. 2001a). Thus, this Chinese population not only produces but also prefers a higher proportion of EM in the binary blends than do European populations. Such correspondence supports our second hypothesis on pheromone productions and responses. Enantioselctive GC analysis indicated that males of the Chinese *I. duplicatus* produced their major pheromone component Id in a racemic form, similar to that of the European populations (Schlyter et al. 1992), which leads to the rejection of our third hypothesis on a geographical variation in enantiomeric composition of Id.

Monoterpenes, major components from the headspace samples of the uninfested and the infested spruce logs, elicited weak or no EAD activities at the dosages tested. Interestingly, a trace amount of 1-hexanol was detected from both aeration samples and male hindgut extracts and showed a reproducible EAD-response. 1-Hexanol has been reported previously in the hindguts of *Pityogenes chalcographus* (Francke et al. 1977) and *I. subelongatus* (Zhang et al. 2007) males. This compound is a common GLV and has been considered as one of major EAD-active nonhost volatiles for many conifer-infesting bark beetles, including the *I. duplicatus* (Zhang et al. 1999, 2001). 1-Hexanol alone was inactive as an attraction-inhibitor (at 4 mg/d) but was significantly inhibitory when combined with two other GLV alcohols (Zhang et al. 2001). The function of 1-hexanol (at the low level) from the spruce logs or the hindgut extracts on the host selection behavior of *I. duplicatus* remains unknown.

Our GC-EAD analyses revealed that *I. duplicatus* antennae from both sexes responded strongly, not only to the known aggregation pheromone components, Id and EM, but also to other minor conspecific-produced compounds. EAG dose responses indicated that the antennal response threshold to Id was approximately 100 times lower than that of EM, and no synergistic effects between these two known pheromone components were identified at peripheral level. Strong EAD responses to Ie, cV, Vn, and a FID-undetected compound from both hindgut and aeration samples were also found. Ie, cV, and Vn were also identified from the European populations and were inhibitory to the pheromone attraction (Schlyter et al. 1992). The EAD-active, FID-undetected compound was identified as At and is a pheromone component first reported from *I. aminitus* (Eichhoff) (Francke et al. 1980) and later from *I. tridens* Mannerheim (Poland and Borden 1997). Similarly, At was not detected by GC-FID/MSD from *I. subelongatus* male hindgut extracts, but it was identified

with the aid of GC-EAD technique (Zhang et al. 2007). The present field trapping tests in Inner Mongolia showed that individual Id, EM, and At were inactive, but the binary blend of Id/EM (1:1) was attractive, while addition of a small amount of At to the blend significantly increased the trap catches. Therefore, At might be a component of the aggregation pheromone system of the Chinese *I. duplicatus*, which appears to support our fourth hypothesis that additional pheromone components may act synergistically with the two main components. Surprisingly, the addition of At (<1% of EM and Id) at the high release rate, similar to that of major pheromone components, had little negative effect on trap catches. The EAD detection of At from the hindgut extracts and aeration samples could result from actual production of the compound by the beetles or through acid rearrangement of Id during collection, extraction, storage, or analysis of the samples (Francke et al. 1980). No GC-EAD work has yet been done on the European populations of *I. duplicatus*. Thus, it will be interesting to see if European populations produce and respond in a similar fashion to a trace amount of At. Whether or not At is naturally produced or is a result of rearrangement during the natural production of Id, the synergistic effect (at a low release rate) on attraction to the Id/EM blend may further improve the trap performance for both monitoring and mass-trapping programs against this pest insect (Schlyter et al. 2001b).

It should be noted that our target population in the current study is from an isolated spruce nature reserve in the middle of a desert grass land in the eastern Palearctic (Zhang et al. 2001), which is isolated from other populations of *I. duplicatus* and *Picea*. Therefore, the evolutionary pressure of *I. duplicatus* population in Baiyinaobao, Inner Mongolia, together with its host tree, *P. mongolica*, might have been radically different from populations of the contiguous distribution in the western Palearctic (Europe). A recent study on the genetic structures as assessed by analysis of mitochondrial DNA sequence of *I. duplicatus* populations from Europe and Inner Mongolia, China (the same population as in the current study), revealed a 0.8% sequence divergence between the Asian and the European populations (Lakatos et al., unpublished). This genetic divergence may explain, in part, the differences in pheromone production and behavioral responses between the European populations and the isolated Chinese population.

Acknowledgements We thank Dr. F.-M. Yan, Beijing University, China, for his careful shipment of the live beetles; Dr. S. R. Hill for helpful comments on the manuscript; and Ms. E. Marling for help in the preparation of hindgut extracts for enantioselective analysis. The permission to "thin" a spruce stand at Björnstorp Estate for bark beetle breeding is highly appreciated. This study was supported by grants from SJFR (No. 23.0521/96; No. 24.0293/98) and FORMAS (230-2005-1778) and an EU-INCO project (CT 98-0151).

Introduction

The Yunnan pine caterpillar moth *Dendrolimus houi* Lajonquière (Lepidoptera: Lasiocampidae) is an economically important defoliator of coniferous forests in southwestern China, especially in Yunnan Province. The moth's preferred host is *Pinus yunnanensis* Franch., but it also feeds on other *Pinus* species, such as *P. langhianensis* Chev., *P. armandii* Franch., *P. massoniana* Lamb, and *P. densata* Mast., as well as *Platycladus orientalis* (L.) Franco, *Cupressus funebris* Endl., *Keteleeria fortunei* (Murr.) Carr., and *Cryptomeria fortunei* Hooibrenk ex Otto et Dietr. (Hou 1987; Chen 1990; Yin et al. 2002; Guo et al. 2003). In most counties of Simao prefecture, *D. houi* has two generations and overwinters as larvae. Adult flights usually occur in June/July and October/November. Most damage is caused by 4th–7th instars in March–April and in August. During outbreak years, *D. houi* can kill thousands to millions of hectares of forests (Chai et al. 2002). Outbreaks of this herbivore across southwestern China have stimulated extensive application of synthetic pyrethroids or naturally derived insecticidal compounds, which has resulted in severe negative effects on biodiversity and natural enemies of herbivores in the ecosystem. To control *D. houi* effectively, monitoring of its population outbreaks has been initiated (Chai et al. 2002; Zhao et al. 2003; Guo et al. 2003). Identification of the sex pheromone of *D. houi* was undertaken in the hope that the synthetic pheromone would be of value for population monitoring and for control by mating disruption (Kong et al. 2004).

There are five species in the genus *Dendrolimus* for which sex pheromones or attractants have been identified (Chen et al. 1980; Ando et al. 1982; Meng and Wang 1983; Priesner et al. 1984; Kovalev et al. 1993; Zhao et al. 1993; Klun et al. 2000; Kong et al. 2001, 2003, 2005; Khrimian et al. 2002; Zhao et al. 2004). The sex pheromones share a common chemical theme of being C_{12} (*Z*,*E*)-5,7-dienes with alcohol, acetate, propionate, or aldehyde functional groups.

The sex pheromone communication system of *D. houi* has received considerable attention because of its economic importance. However, until now its sex pheromone had not been elucidated. Recently, preliminary analyses of extracts of the sex pheromone glands of *D. houi* indicated the presence of (5*E*,7*Z*)-5,7-dodecadien-1-ol (*E*5,*Z*7-12:OH) and its corresponding acetate and aldehyde, and the conjugated double-bond position was fixed at the 5,7 position (Kong et al. 2004). In this paper, we report further details of the sex pheromone components of *D. houi*, and the results of laboratory and field tests of the pheromone.

Methods and Materials

Insects A laboratory colony of *D. houi* was started from cocoons collected in the field in Simao Prefecture, Yunnan Province. Pupae were sexed and allowed to emerge in a controlled environment room at 23±1°C, 60–80% hazard ratio (R.H.), and L16:D8 photoperiod. Female moths were used for pheromone extractions 1 or 2 d after emergence, and male moths were used for coupled gas chromatography–electroantennographic detection (GC–EAD) analyses.

Female Calling and Pheromone Collection The diel rhythm of calling behavior was observed for 1- to 4-d-old virgin females (N=126) in a controlled environment room. Observations were made under red light (3 l×) at 1-hr intervals during the scotophase.

Abdominal tips of virgin females including the pheromone gland were removed from 1- to 2-d-old calling females, 2–3 hr into the scotophase. The excised glands were extracted in 20 μl hexane for 20 min at room temperature, and then the extracts were transferred to a clean glass tube. Extracts from 6 or 15 abdominal tips were combined and concentrated to 2–3 μl by using a slow stream of N_2 before GC–EAD or GC–mass spectrometry (MS) analysis. If not used immediately, tubes were sealed and stored at −20°C.

Collections of airborne female sex pheromones were carried out by solid phase microextraction (SPME) with a polydimethylsiloxane fiber (100 μm coating; Supelco, Inc., Bellefonte, PA, USA). The fiber was conditioned in the GC injector (230°C) for 10 min before sampling. Single 1-d-old virgin females were transferred to a glass jar (250 ml) sealed with Parafilm, which was kept for 30 min in the controlled environment room mentioned above. Then the fiber was introduced into the headspace. After a 24-hr exposure, the fiber was retracted and the chemicals absorbed by the fiber were analyzed by GC as described below.

Chemicals Authentic standards were purchased from Chemtech B. V. (Amsterdam, the Netherlands) and purified in our laboratory by packed column GC (2 m×3.2 mm glass column, 8% PEG 20M on 80–100 mesh Chromosorb G-HP) described previously (Kong et al. 2001) to 99% purity for GC–EAD analysis, and > 95% for field tests. A standard solution containing the four stereoisomers of 5,7-dodecadien-1-ol (5,7-12:OH) and its corresponding acetates and aldehydes was prepared. A hydrocarbon standard solution (500 μg/ml in chloroform) was purchased from AccuStandard (New Haven, CT, USA).

Gas Chromatography–Electroantennographic Detection Gland extracts (15 female equivalents) were analyzed by GC–EAD with a Hewlett-Packard (HP) 5890 Series II GC equipped with a splitless injection system and a BP-20 column (25 m×0.25 mm i.d.× 0.25 μm film, SGE Pty. Ltd., Melbourne, Australia) programmed at 80°C for 1 min, then to 200°C at 10°C/min and held at 200°C for 30 min. The column effluent was split equally by an outlet splitter (SGE Co., part # OSS-2) between a flame ionization detector (FID) and an EAD male moth antennal preparation with 10 ml/min N_2 supplied as make-up gas. The EAD effluent was directed through a transfer line (250°C) to an L-shaped glass tube (7 mm i.d.), where it was mixed with purified humidified air (~ 500 ml/min), and then directed over the antennal preparation. The moth antenna was suspended between glass capillary electrodes filled with insect physiological saline (7.5 g NaCl, 0.21 g $CaCl_2$, 0.35 g KCl, 0.20 g $NaHCO_3$ per liter distilled water). The EAD responses were amplified tenfold with a probe amplifier, and data acquisition and analysis were performed with GC–EAD software (Syntech, Hilversum, the Netherlands).

Gas Chromatography and GC–Mass Spectrometry Analyses Pheromone gland extracts were analyzed by GC (Hewlett-Packard 6890 with flame ionization detector) and GC–MS (Finnigan Trace DSQ GC–MS, EI mode, 70 eV) with identification based on comparison of retention times and mass spectra with those of synthetic standards.

GC analyses were carried out on polar (DB-WAX, 30 m×0.25 mm i.d.×0.25 μm film; J&W Scientific, Folsom, CA, USA) and nonpolar (DB-5, 30 m×0.25 mm i.d.×0.25 μm film; J&W Scientific) columns with the injector at 200°C and oven temperature programmed from 80°C (1 min hold) to 220°C at 8°C/min, then held 10 min, using N_2 carrier gas. Introduction of chemicals from the SPME fiber onto the GC was by thermal desorption for 3 min in the injector at 200°C, then the analysis was performed under the same conditions as above. The DB-WAX column resolved the geometric isomers of

5,7-dodecadienal (5,7-12:Ald), 5,7-dodecadien-1-yl acetate (5,7-12:OAc), and 5,7-12:OH. The elution order of the isomers from the DB-WAX column was *ZE*, *EZ*, *ZZ*, and *EE*. For pheromone titer determination, individual pheromone gland extracts were prepared (N=21) and 4 ng (*Z*)-12-tetradecen-1-yl acetate (*Z*12-14:OAc) were added as internal standard (2 ng/μl). Absolute concentrations were calculated from the integrated peak area of each component relative to that of the internal standard.

GC–MS analyses were carried out on the DB-WAX column (as mentioned above), in which the full scan (41–460 amu) and selected ion monitoring (SIM) were recorded simultaneously. We scanned several intense and characteristic masses to ensure high sensitivity and selectivity. We selected *m/z* 224 (M^+), 164 (M^+-CH_3COOH), and 136 $\left(C_{10}H_{16}^+\right)$ to characterize the acetates of dodecadienols, *m/z* 182 (M^+) and 164 (M^+-H_2O) for dodecadienols, 180 (M^+) and 136 (M^+-CH_3CHO) for dodecadienals, 164 (M^+-H_2O) and 138 (M^+-C_2H_4O) for dodecenals, 166 (M^+-CH_3COOH) for dodecenyl acetates, 166 (M^+-H_2O) and 138 (M^+- C_2H_5OH) for dodecenols, and 238 (M^+) and 164 (M^+- CH_3CH_2COOH) for propionates of dodecadienols. The choice of these ions was based on mass spectra of the standards. The carrier gas was helium with a constant flow of 1.0 ml/min. Injector temperature was 220°C, and the split valve was off for 1 min. The temperature program was 60°C for 1 min, 6°C/min to 220°C, and hold for 10 min at 220°C. The GC-MS ion source and transfer line temperatures were 250°C and 220°C, respectively. After injection of six female-equivalent extracts, a reference sample was analyzed containing 5,7-diunsaturated C_{12} alcohols, aldehydes, acetates, (5*Z*,7*E*)-5,7-dodecadien-1-yl propionate (*Z*5,*E*7-12:OPr), and the monounsaturated compounds (*Z*)-5-dodecen-1-ol (*Z*5-12:OH), (*Z*)-5-dodecenal (*Z*5-12:Ald), and (*Z*)-5-dodecenyl acetate (*Z*5-12:OAc).

Field Tests Gray rubber septa (The West Company, Phoenixville, PA, USA), precleaned with ethanol, were treated with appropriate amounts of chemicals in hexane and then stabilized by adding butylated hydroxytoluene (BHT, 20 μg/μl) as antioxidant dissolved in dichloromethane (200 μg/septum). Controls were treated with 100 μl hexane and 200 μg BHT. Traps were placed in the field in three replications in 2004 (October 16 to November 17) and four replications each in 2005 (September 29 to November 8) and 2006 (June 19 to July 4) in the same pine forest near Simao city, Yunnan Province where cocoons had been obtained. Lures were left unchanged for the entire flight period. Sticky wing traps constructed from two pieces of cardboard (42×28 cm) were used in all field experiments. The septum was suspended on a wire at the center of the traps, 1–2 cm above the sticky trap bottoms. Virgin *D. houi* females in small mesh cages suspended in traps (N=4) were used as positive controls. Female moths were renewed every 4 d. Traps were deployed in a complete randomized block design. Traps were hung from branches of pine trees, about 1.5 m above the ground, at 15-m intervals. The numbers of moths in traps were checked and recorded at 1- to 2-d intervals, depending on weather conditions.

Data Analysis The data from field tests were analyzed by analysis of variance (ANOVA) after $\log(x+1)$ transformation. If significant effects were detected ($P<0.05$), LSD post hoc tests was used to separate differences between treatments. Kováts retention indices of each compound on each column were calculated from the formula for programmed temperature runs,

$$\mathrm{KI} = 100n + 100(N-n) \times \frac{\mathrm{Rt(unknown)} - \mathrm{Rt}(n)}{\mathrm{Rt}(N) - \mathrm{Rt}(n)},$$

where n and N are the carbon numbers of the *n*-alkane standards on either side of a given compound, Rt(unknown) is the retention time of the unknown, and Rt(n) and Rt(N) are the

retention times of the hydrocarbon standards (Marques et al. 2000). The KI data were calculated according to the retention times of GC–MS analyses, and the programmed temperature runs were performed under the same conditions as described above.

Results

GC–EAD and GC Analyses of the Gland Extracts of Females Three components in the crude gland extracts of *D. houi* elicited EAD responses, with component c (Rt: 14.08 min) giving the largest response (mean mV $\pm$ SD, $0.87 \pm 0.22, N = 6$) in all cases. Component b (Rt: 13.07 min) gave smaller but consistent responses (mean mV $\pm$ SD, 0.54 ± 0.12, $N = 6$), whereas component a (Rt: 11.15 min) gave small and less consistent responses (mean mV $\pm$ SD, $0.21 \pm 0.04, N = 4$) (Fig. 1). By comparing the GC–EAD retention times with those of synthetic standards, male moth antennae responded to *E*5,*Z*7-12:OH, *E*5,*Z*7-12:OAc, and *E*5,*Z*7-12:Ald components, c, b, and a, respectively. The three components in the pheromone gland extracts that elicited EAD responses were further identified by comparison of retention times with those of reference compounds on both polar (DB-WAX) and nonpolar (DB-5) GC columns. On average, 14.7±12.9 ng (± SD) of *E*5,*Z*7-12:OH, 5.8±5.4 ng of *E*5,*Z*7-12:OAc, and 0.8±1.4 ng of *E*5,*Z*7-12:Ald were found in extracts, corresponding to a ratio of 100:39.7:5.6. The proportions of other isomers of the alcohol, acetate, and aldehyde in the sex pheromone gland extracts of *D. houi* were below the GC detection threshold, but were determined by SIM–GC–MS.

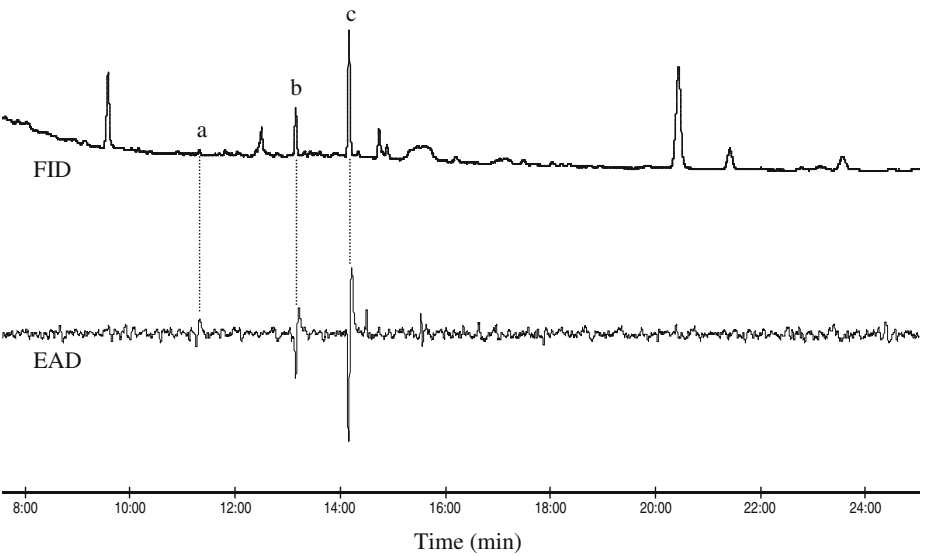

Fig. 1 Gas chromatography–electroantennographic detection (GC–EAD) traces from analysis of hexane extracts of the sex pheromone glands of *D. houi* virgin females (15 female equivalent; FID: flame ionization detector; EAD: male *D. houi* antenna). a, b, and c: FID peaks corresponding to electroantennography (EAG) responses. BP-20 column (see Methods and Materials)

Stereochemistry of the EAD-Active Components The retention indices of the three EAD-active components in solvent extracts (five female equivalents) from female pheromone glands on polar (DB-WAX) and nonpolar (DB-5) GC column were identical to those of synthetic *E*5,*Z*7-12:OH, *E*5,*Z*7-12:OAc, and *E*5,*Z*7-12:Ald, and markedly different from the retention indices of the other isomers (Table 1). In SPME collections of pheromone components from live females, three major peaks were seen, two of which had retention times on DB-WAX coinciding with those of synthetic *E*5,*Z*7-12:OH (20.22 min) and *E*5, *Z*7-12:OAc (18.87 min). There was also a very small peak at the retention time of *E*5,*Z*7-12:Ald (16.51 min) (Fig. 2), and, the identity of this peak was verified from its mass spectrum. Complete resolution of the stereoisomers of all three EAD-active components substantiated the stereochemistry of the insect-produced compounds. The 5,7 position of the conjugated diene had been determined previously (Kong et al. 2004).

GC–MS Analyses of Gland Extracts of Females The presence of *E*5,*Z*7-12:Ald and its corresponding acetate and alcohol in extracts of female moths was confirmed with GC–MS analyses (Fig. 3). The identity of *E*5,*Z*7-12:OH as the major component of the pheromone of *D. houi* was indicated by the appearance of ions of *m*/*z* 182 (M^+, $C_{12}H_{22}O^+$, 7%) and 164 $\left(C_{12}H_{20}^+, 36\%\right)$ with a retention time of 22.87 min agreeing with that for the same ions and retention time of a synthetic sample of *E*5,*Z*7-12:OH. The spectra had other similarities including fragment ions at *m*/*z* 135 (M^+-C_2H_7O, 11%), 121 (M^+-C_3H_9O, 23%), and 79 $\left(C_6H_7^+, 81\%\right)$. The presence of *E*5,*Z*7-12:OAc in pheromone gland extracts was indicated by ions with *m*/*z* 224 (M^+, 18%), 164 (M^+-CH_3COOH, 49%), and 136 $\left(C_{10}H_{16}^+, 27\%\right)$ with a retention time coinciding with that for synthetic *E*5,*Z*7-12:OAc (21.39 min). Finally, the appearance of ions with *m*/*z* 180 (M^+, 13%) and 136 (M^+-CH_3CHO, 27%) at 18.47 min confirmed the presence of the *E*5,*Z*7-12:Ald. The retention behavior of authentic *E*5,*Z*7-12:Ald corresponded exactly with that of synthetic *E*5,*Z*7-12:Ald (18.47 min). In addition, other diagnostic fragment ions at *m*/*z* 162 (M^+-H_2O, 4%), 151 (M^+-CHO, 8%), and 79 $\left(C_6H_7^+, 100\%\right)$ were also observed within the mass spectra of the synthetic and insect-

produced (Fig. 3). Thus, the GC-MS information suggested that the pine moth sex pheromone gland extracts contained *E*5,*Z*7-12:OH, *E*5,*Z*7-12:OAc, and *E*5,*Z*7-12:Ald.

To examine whether other pheromone-like compounds were present in the gland extracts, we monitored some characteristic ions, but did not detect *m*/*z* 164 (M^+-H_2O) and 138 (M^+-C_2H_4O) for dodecenals or 166 (M^+-CH_3COOH) for dodecenyl acetates at retention times corresponding to those of synthetic samples of *Z*5-12:Ald (15.73 min) and *Z*5-12:OAc (18.88 min). The same procedure excluded the presence of any dodecadienyl propionates as components of the gland extracts. However, the appearance in the mass spectrum of ions with *m*/*z* 166 (M^+-18, 6%) and 138 (M^+-46, 6%) (20.46 min) suggested the presence of a trace amount of *Z*5-12:OH (0.1% compared to that of *E*5,*Z*7-12:OH). In addition, according to diagnostic ions and retention time matches, we found possible trace amounts of (5*Z*,7*E*)-5, 7-dodecadien-1-ol (*Z*5,*E*7-12:OH, 0.7% compared to that of *E*5,*Z*7-12:OH) and (5*E*,7*E*)-5, 7-dodecadien-1-ol (*E*5,*E*7-12:OH, 0.7% to *E*5,*Z*7-isomer) by further examination of the reconstructed ion chromatogram of the female extracts. There were also possible trace amounts of *Z*5,*E*7-12:OAc (0.8% compared to *E*5,*Z*7-12:OAc), *Z*5,*Z*7-12:OAc (0.2% to *E*5,

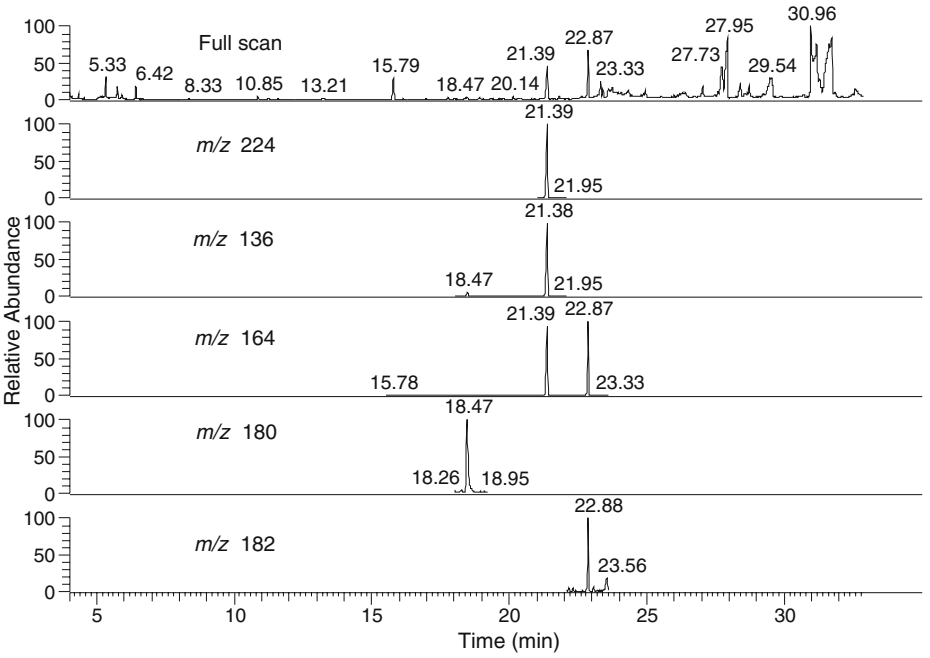

Fig. 3 Representative total ion and selected ion monitoring chromatograms of hexane extracts of calling female *D. houi* (6 FE). Analysis conditions are described in Methods and Materials

*Z*7-12:OAc), and *E*5,*E*7-12:OAc (0.8% to *E*5,*Z*7-12:OAc). No other isomers of *E*5,*Z*7-12:Ald were observed by GC–MS.

Field Tests In the first field test in 2004, the three components that elicited EAD response were not attractive to male *D. houi* moths as single components at doses of 1,000 μg, whereas lures with all binary combinations of *E*5,*Z*7-12:OH, *E*5,*Z*7-12:OAc, and *E*5,*Z*7-12:Ald in the ratios found in analyses of pheromone gland extracts only resulted in a few captures over the second flight period. Traps baited with a 23:9.3:1 blend of alcohol/acetate/aldehyde were significantly more attractive than other treatments, suggesting that all three components were necessary for attraction (Table 2).

Optimization tests of the ratios of *E*5,*Z*7-alcohol, acetate, and aldehyde were conducted in 2005. In each of the three tests, the dose of *E*5,*Z*7-12:OH was held constant (5,000 μg/septum). In the first test (Table 3, experiment 1), lures loaded with a fixed ratio (5:1) of *E*5, *Z*7-12:OAc spiked with various amounts of *E*5,*Z*7-12:Ald all attracted similar numbers of moths. Increasing the amount of *E*5,*Z*7-12:Ald from 0.2% to 25% with respect to the major component, *E*5, *Z*7-12:OH, when *E*5, *Z*7-12:OAc was held constant at 2,000 μg/septum also had no effect on male moth catches (Table 3, experiment 2). However, increasing the amount of *E*5, *Z*7-12:OAc from 1.25% to 80% with respect to the major component, *E*5, *Z*7-12:OH, when *E*5, *Z*7-12:Ald was held constant at 250 μg/septum, showed a maximum catch at 5%, whereas other ratios were not different from each other (Table 3, experiment 3). These tests suggested that the ratio of *E*5, *Z*7-12:OAc to *E*5, *Z*7-12:Ald might be more important than the ratio of either component to *E*5, *Z*7-12:OH. Further field tests in 2006 were conducted to discriminate the effects of component ratios. In the first test, *E*5, *Z*7-12:OAc and *E*5, *Z*7-12:Ald were each held constant at 250 μg/septum, whereas the dose of *E*5,

[a] Experiments were conducted in Simao City, Yunnan Province (three replicates, October 16–November 17, 2004). For ANOVA, data were transformed to log (x+1). Means followed by the same letter are not significantly different at the 5% confidence level by LSD test ($F_{(4,\ 10)}$=7.69, P<0.004).

*Z*7-12:OH was varied. All blends tested were equally attractive (Table 4, Experiment 1), suggesting that the ratio of *E*5,*Z*7-12:OH to the acetate and aldehyde was not as important as that of acetate to aldehyde. A second test was conducted in which *E*5,*Z*7-12:OH was held constant (5,000 μg/septum) and the amount of acetate and aldehyde (1:1) was varied. Increasing the amounts of the acetate and aldehyde relative to *E*5,*Z*7-12:OH had no effect on male moth captures (Table 4, Experiment 2). A final trial compared a synthetic pheromone blend (20:1:1) to virgin females (Table 4, Experiment 3). This three-component

blend was comparable to the attractiveness of virgin female *D. houi* moths (Table 4, Experiment 3).

Discussion

In view of the prevalence of *Z*5,*E*7-12:X as known sex pheromone components of the genus *Dendrolimus*, we tried the *Z*5,*E*7-aldehyde, alcohol, acetate, and propionate in preliminary field tests in 2001 and 2002, but none of these compounds in different combinations was attractive. In this paper, we presented evidence of the presence of three components, *E*5,*Z*7-12:OH, *E*5,*Z*7-12:OAc, and *E*5,*Z*7-12:Ald in volatiles emitted by calling females and in hexane extracts of female sex pheromone glands of *D. houi*. When tested separately or in binary mixtures, *E*5,*Z*7-12:OH, *E*5,*Z*7-12:OAc, and *E*5,*Z*7-12:Ald attracted a few *D. houi* males, but none of the binary blends was as attractive as the three component blend, indicating that all three components were necessary for optimal attraction. Further field tests confirmed the attractiveness of a blend similar to that found in pheromone gland extracts. However, further attempts to optimize the three-component blend were not straightforward. Further optimization may be warranted to find an effective blend while simultaneously minimizing the total dose of pheromone.

This is the first time that *E*5,*Z*7-isomers of alcohol, acetate, and aldehyde have been identified as sex pheromone components in *Dendrolimus* species. *ZE*- and *EZ*-isomers of 5,7-12:Ald, 5,7-12:OH, and 5,7-12:OAc may be involved as sex pheromone components in *Dendrolimus*, just as in *Malacosoma*, a related genus in which many species use *Z*5,*E*7- and *E*5,*Z*7-isomers in their sex pheromones. For example, *M. disstria* Hübner produced *Z*5,*E*7-12:Ald as a principal pheromone component and *Z*5,*E*7-12:OH as a minor component

(Chisholm et al. 1980). *E*5,*Z*7-12:Ald and *E*5,*Z*7-12:OH have been reported as sex pheromone components of *M. californicum* (Packard) (Underhill et al. 1980), *M. americanum* (F.) (Kochansky et al. 1996), and *M. neustrium* L. (Rotundo et al. 2004). However, *E*5,*Z*7-12:OH, *E*5,*Z*7-12:OAc, and *E*5,*Z*7-12:Ald have not been identified previously from any species in the genus *Dendrolimus*.

Dendrolimus houi and *D. kikuchii* are two closely related pine caterpillar species that cause major damage in pine forests in Yunnan province. Because *D. kikuchii* uses the *Z*5, *E*7-isomers of the acetate and alcohol components as its sex pheromone (Kong et al. 2001, 2005), differing pheromone chemistry provides a mechanism for reproductive isolation in these two sympatric *Dendrolimus* species. However, interspecific cross-attraction to synthetic pheromones of the two species was observed in field studies. Furthermore, the ratios and release rates of respective components also may be important for the two sympatric species to achieve separate communication channels. Other possible mechanisms may contribute to reproductive isolation between *D. houi* and *D. kikuchii*. For example, our laboratory investigations (unpublished) of the calling behaviors have shown that calling by *D. houi* peaks early into scotophase (~ 2 hr after dark) with a different periodicity than the other *Dendrolimus* spp. that we have investigated. In contrast, the peak of calling activity for *D. kikuchii* occurred 7–8 hr after the onset of scotophase. Thus, the different diurnal activity patterns suggest little overlap of female calling periods, which may assist in maintaining reproductive isolation of *D. houi* and *D. kikuchii*.

Structural similarities of pheromone components of *Dendrolimus* spp. may parallel phylogenetic relationships between species. The characteristics of the sex pheromones and sex attractants identified in *Dendrolimus*, together with genetic evidence, show that two groups of *Dendrolimus* species can be distinguished. The first group includes *D. pini* and *D. superans*, in which *Z*5,*E*7-12:Ald alone or in blends with the corresponding alcohol are attractive to males, whereas *Z*5,*E*7-12:OAc acts as an antagonist (Priesner et al. 1984; Kovalev et al. 1993; Kong et al. 2001). The second group includes *D. spectabilis*, *D. punctatus*, *D. tabulaeformis*, and *D. kikuchii*, in which the males are attracted by *Z*5,*E*7-12:OAc and its corresponding alcohol and/or propionate but inhibited by *Z*5,*E*7-12:Ald (Chen et al. 1980; Ando et al. 1982; Meng and Wang 1983; Kong et al. 2001, 2003). According to the sex pheromone blend identified in this paper, *D. houi* may represent the first of yet another group in *Dendrolimus*, which would provide an additional character for more precise grouping of the species within the genus. The differentiation of sex pheromones among closely related species may have been involved in the speciation process (Löfstedt 1993; Byers 2005, 2006). Further studies of the sex pheromones of other members of the genus and of pheromone-binding proteins in the antennae of male *D. houi* and *D. kikuchii* are in progress.

Acknowledgments The authors thank Lou Yong-gen for his critical review of the manuscript. We are also grateful to John A. Byers and Blanka Kalinová for their constructive comments and revision of the manuscript. Thanks are also due to Jocelyn G. Millar for technical assistance and advice. We are indebted to Liu Hong-ping, Tong Qing, and Mao Jia-ying and their staffs for assistance with field experiments. Fig. 1 Structures of the copulation release pheromone of *Callosobruchus chinensis*L. and *C. maculatus* and derivatization reaction

available. In an attempt to determine the absolute configuration of the natural product, both enantiomers of (**1**) were synthesized and assayed on male weevils (Mori et al. 1983). However, both enantiomers were active, and thus, the absolute configuration of the natural product was difficult to infer. Although several racemic (Tanaka et al. 1982; Kang and Lee 1987; Fontana et al. 1993; Wenkert and Khatuya 1999) and enantioselective (Gramatica et al. 1985; Giersch and Schulte-Elte 1990; Abo and Mori 1993; Yu et al. 2002; Nanda and Scott 2004) syntheses of (**1**) have been reported, the absolute configuration of the natural product has thus far remained obscure.

Recently, we reported the synthesis (Nakai et al. 2005) and determination of the stereoisomeric composition (Yajima et al. 2006) of the copulation release pheromone of the cowpea weevil, *C. maculatus*, [2,6-dimethyloctane-1,8-dioic acid (**2**)] (Nojima et al. 2007) using the Ohrui–Akasaka method (Akasaka et al. 1997, 1998; Akasaka and Ohrui 1999, 2004; Imaizumi et al. 2003). In this methodology, the crude natural product was derivatized directly to the corresponding Ohrui-Akasaka ester [(*bis*-2-(2,3-anthracenedicarboximido)-1-cyclohexyl (2ACyclo-O) ester (**5**) or *bis*-2-(2,3-anthracenedicarboximido)-1-propyl (2A1P-O) ester (**6**)] and analyzed by 2D-high-performance liquid chromatography (HPLC) without extensive purification. We found that the natural product is stereochemically impure, and the stereoisomeric composition of natural (**2**) was determined to be (2*R*,6*S*):(2*S*,6*R*):(2*S*,6*S*):(2*R*,6*R*)=43:38:18:trace (Yajima et al. 2006). This result indicated that it should be possible to establish the absolute configuration or stereoisomeric composition of natural (**1**) using the same method. As the Ohrui–Akasaka method employs a fluorescence detector instead of a UV detector for the HPLC analysis, femtomolar amounts of the material are sufficient for analysis. The absolute configurations of the biologically active natural products have been determined by using the Ohrui–Akasaka method (Akasaka et al. 2000, 2002; Morohashi

et al. 2000; Matsuhashi and Shimada 2002; Tashiro et al. 2002; Ohshiro et al. 2006). This technique has potential as a useful methodology for insect pheromone chemistry.

Methods and Materials

Azuki Bean Weevils, Callosobruchus chinensis L.

The weevils were maintained on azuki bean, *Vigna angularis* Dainagon, at 27°C and 60% relative humidity.

Collection and Fractionation of Copulation Release Pheromone, Callosobruchusic Acid

Collection was carried out according to Tanaka et al. (1981). A laboratory-maintained colony of *C. chinensis* L. was reared on azuki bean (*V. angularis*, Dainagon) at 27°C and 60% relative humidity in darkness. Newly emerged adults were sexed, and a group of several hundred virgin females was kept in a Petri dish (90 mm i.d.×60 mm height) with a pile of filter papers (40×20 cm) corrugated in 1-cm sections as shelters. After 20–27 d under these same conditions, the filter papers were Soxhlet-extracted with ether for 1 d. Extracts were combined, and the solvent was evaporated in vacuo. Extracts were dissolved in ether, and the solution was fractionated into neutral, acidic, and basic fractions with 5% NaOH aq and 5% HCl aq. The resulting acidic compounds were filtered through a short silica gel (1 g) column with hexane-ethyl acetate (30:1 to 0:100) as eluting solvent to remove highly polar compounds such as proteins or carbohydrates to give 7.0 mg of crude material.

Preparation of the Authentic Sample of (*R*)-(-)-Callosobruchusic Acid

Optically active (*R*)-(-)-callosobruchusic acid (**1**) was synthesized by using the method described by Mori et al. (1983). Based on ^{1}H NMR analysis of the synthetic intermediate, the enantiomeric purity of the synthetic **1** was estimated to be ca. 80% e.e. ^{1}H NMR spectra were recorded on a JNM-A400 spectrometer (Jeol Ltd., Tokyo, Japan). The spectral data of all the synthetic intermediates were in good accord with the reported data (Mori et al. 1983).

Preparation of Authentic *bis*-2-(2,3-Anthracenedicarboximido)-1-cyclohexyl (2ACyclo-O) Ester Derivative of the Synthetic **1** [(1*S*,2*S*)-R-**4** and (1*R*,2*R*)-R-**4**]

To a portion of synthetic (*R*)-**1** (ca. 1 mg, 5 mmol) in MeCN/toluene (1:1), (1*R*,2*R*)- or (1*S*,2*S*)- *bis*-2-(2,3-anthracenedicarboximido)-1-cyclohexanol [2ACyclo-OH (**3**), excess amount], 4-*N*,*N*-dimethylaminopyridine (DMAP, excess amount) and 2-(3-dimethylamino-propyl)-1-ethylcarbodiimide hydrochloride (EDC, excess amount) were successively added, and the mixture was stirred at 40°C for 24 hr. An aliquot was then loaded onto a silica gel TLC plate (10 cm length, Silica gel 60 F_{254}, Art-5744, Merck, Lindenplatz, Haar, Germany) and developed with hexane/EtOAc (4:1, *v*/*v*). The target spot, detected by fluorescence, was collected, packed in a Pasteur pipette and eluted with EtOAc/MeOH (5:1, *v*/*v*). After evaporation of the solvent with N_2 gas stream, the residue was purified by HPLC to give (1*R*,2*R*)-*R*-**4** or (1*S*,2*S*)-*R*-**4**. The HPLC conditions were as follows. Column: Develosil C30-UG-3 (4.6 mm i.d.×150 mm, Nomura Chemical Co., Aichi, Japan), mobile phase: MeCN/THF=9:1, temp: 20°C, flow rate: 1.0 ml/min. The structures of the synthetic samples were confirmed based on MS spectra recorded on a JMS-700 spectrometer (Jeol,

Ltd., Tokyo, Japan). The observed MS data were as follows: MS (FAB, positive): *m/z* 877 (8, M+Na), 832 (5), 803 (5), 441 (43), 413 (100), 391 (100), 328 (71), 279 (87), 225 (100), 223 (37); HRMS (FAB, positive): $[M+Na]^+$ 877.37 ($C_{54}H_{50}N_2O_8Na$; calc. 877.35).

Preparation of 2ACyclo-O Ester Derivative of the Natural Product

To a portion of the crude extract (ca. 1 mg, ca. 50 nmol) in MeCN/toluene (1:1), excess amounts of (1*R*,2*R*)- or (1*S*,2*S*)- 2ACyclo-OH (**3**), DMAP, and EDC were added successively, and the mixture was stirred at 40°C for 24 hr. An aliquot was then loaded onto a silica gel TLC plate (10 cm length, Silica gel 60 F_{254}, Art -5744, Merck) and developed with hexane/EtOAc (4:1, *v/v*). The target spot, detected by fluorescence, was collected, packed in a Pasteur pipette and eluted with EtOAc/MeOH (5:1, *v/v*). Partial evaporation of the solvent with N_2 gas stream gave (1*R*,2*R*)-*nat*-**4** or (1*S*,2*S*)-*nat*-**4**. The resulting sample was used directly for 2D-HPLC analysis.

2D-HPLC Analysis of 2ACyclo-O Ester Derivative [(1*S*,2*S*)-nat-**4** and (1*R*,2*R*)-nat-**4**]

To achieve complete separation of the target compounds from any impurities, we examined a two-dimensional HPLC (2D-HPLC) analysis method. 2D-HPLC in which two columns with different properties are used often results in improved separation (Erni and Frei 1978). The prepared (1*S*,2*S*)-*nat*-**4** or (1*R*,2*R*)-*nat*-**4** was injected using a Rheodyn 7125 loop injector (20 μl) and separated on two reverse-phase columns (first column: Develosil ODS-A-3, 4.6 mm i.d.×150 mm, second column: Develosil C30-UG-3, 4.6 mm i.d.×150 mm, Nomura Chemical Co., Aichi, Japan). Separation was performed by using two different solvent systems: first column, MeOH/H_2O=9:1 at a flow rate 0.6 ml/min (pump: CCPM, Tosoh Co., Tokyo, Japan) at 20°C (water bath); second column, MeCN/THF=76:24 (*v/v*) at a flow rate 0.6 ml/min (pump: PU-920, Jasco Co.) at 0°C (ice-water bath). The target fraction from the first column was injected into the second column using a six-way bulb system (PT-8000, Tosoh Co.). Detection was carried out by monitoring fluorescence intensity at 462 nm (excitation at 298 nm) using a FP-920 fluorescence detector (Jasco Co., Tokyo, Japan).

Results

Preparation of Authentic 2ACyclo-O Ester Derivatives [(1*S*,2*S*)-*R*-**4** and (1*R*,2*R*)-*R*-**4**]

As the (*S*)-isomer of synthetic **1** was not available, (1*S*,2*S*)- and (1*R*,2*R*)-2ACyclo-O derivatives of (*R*)-**1** [(1*S*,2*S*)-*R*-**4** and (1*R*,2*R*)-*R*-**4**] were prepared and subjected to analysis. In the preliminary experiment, both isomers were easily separated by using a single column (Fig. 2a) [Develosil ODS-A-3, MeCN/H_2O=9:1 (0.6 ml/min)] at 20°C (water bath). Retention times of the two isomers were 38.8 min [peak 1: (1*S*,2*S*)-*R*-**4**] and 52.8 min [peak 2: (1*R*,2*R*)-*R*-**4**], respectively. The separation factor α is estimated to be 1.39 (retention factors k': 13.9 and 19.3) for this separation of the enantiomers. As synthetic **1** was not enantiomerically pure, additional peaks were also observed on the chromatograms. Based on HPLC analysis, the enantiomeric excess of synthetic **1** was estimated to be 78.6–80.7% e.e. This result was in good accord with the ^1H NMR analysis of the synthetic intermediate. The major components were separated by HPLC to give pure samples of (1*S*,2*S*)-*R*-**4** and (1*R*,2*R*)-*R*-**4**.

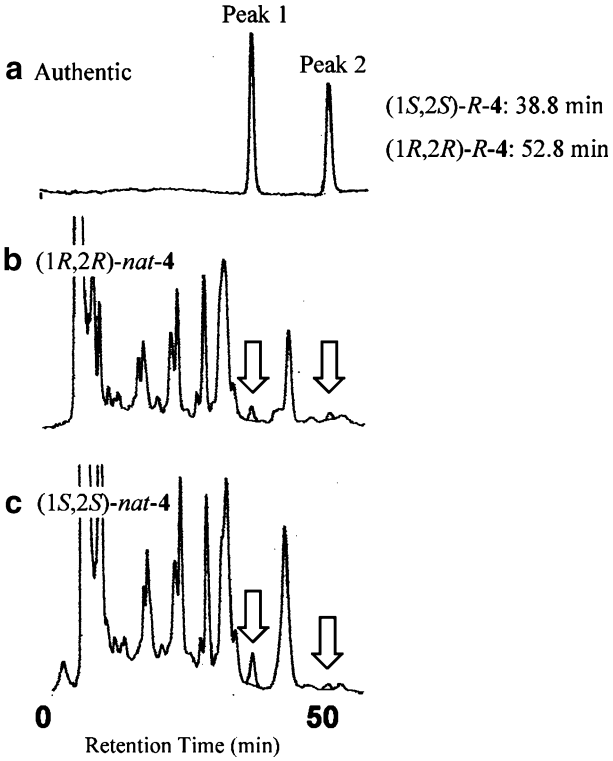

Fig. 2 HPLC chromatograms of 2ACyclo-O derivatives of synthetic callosobruchusic acid (a), (1*R*,2*R*)-*nat*-**4** (b), and (1*S*,2*S*)-*nat*-**4** (c). Peak 1: (1*S*,2*S*)-*R*-**4**; peak 2: (1*R*,2*R*)-*R*-**4**

Preliminary Analysis of 2ACyclo-O Ester Derivatives of the Natural Product [(1*S*,2*S*)-nat-**4** and (1*R*,2*R*)-nat-**4**]

In the same manner as for synthetic **1**, two portions (ca. 1 mg) of the crude extract were treated with (1*S*,2*S*)- and (1*R*,2*R*)-2ACyclo-OH to give the two isomers (1*S*,2*S*)-*nat*-**4** and (1*R*,2*R*)-*nat*-**4**, and these samples were subjected to HPLC analysis (Fig. 2b, c). The resulting chromatograms showed many peaks, but the target peaks 1 and 2, corresponding to those of (1*S*,2*S*)- and (1*R*,2*R*)-*R*-**4**, were observed. The peak area ratios of peaks 1 and 2 were 2.99:1 (panel B) and 6.31:1 (panel C). As the stereochemistry of the 2ACyclo-OH in the two samples were inverted with respect to each other, the peak area ratios should also have been inverted. This result indicated that the peaks did not consist of a single component, and therefore, some unidentified impurity was present.

2D-HPLC Analyses of 2ACyclo-O Derivatives

The Develosil C30-UG-3 column contains triacontyl alkyl chains and is doubly endcapped with trimethylsilyl groups, but the packing in the ODS-A-3 column does not share these properties. Because of their differing properties, the two columns were suitable for use in 2D-HPLC analysis. To avoid re-incorporation with impurities in the second column, only the target fraction, with a retention time of 36.6–39.9 or 50.7–54.6 min, was directly injected into the second column. To achieve this, a six-way bulb system (PT-8000, Tosoh Co.) was employed, and individual analysis of each target fraction was carried out. The chromatograms of the 2D-HPLC analyses of 2ACyclo-O derivatives are shown in Fig 3.

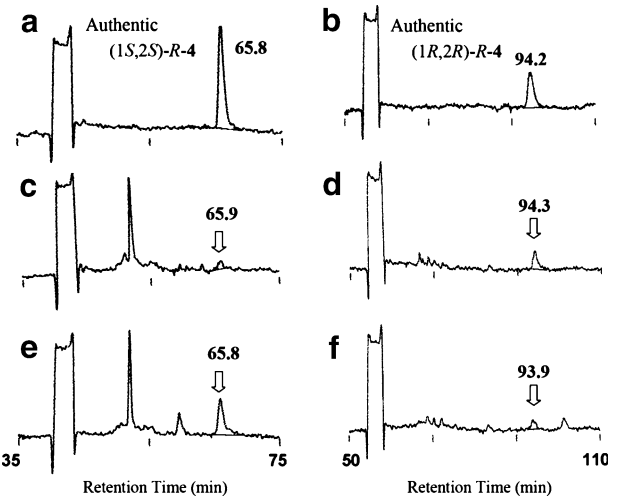

Fig. 3 Chromatograms of the 36.6- to 39.9-min fraction (a, c, and e) and the 50.7- to 54.6-min fraction (b, d, and f) obtained by 2D-HPLC analysis. (1*R*,2*R*)-*nat*-**4** (c and d); (1*S*,2*S*)-*nat*-**4** (e and f)

The overall retention times (over both columns) of the standard samples [(1*S*,2*S*)-*R*-**4** and (1*R*,2*R*)-*R*-**4**] were 65.8 min (peak 3, Fig. 3a) and 94.2 min (peak 4, Fig. 3b). Both isomers of **4** were observed in the chromatograms of the natural product derivatives (Fig. 3c, d, e, f). This result indicates that the natural callosobruchusic acid (**1**) is enantiomerically impure. The observed peak areas, which correspond to the stereoisomeric composition of the enantiomers of **1**, are listed in Table 1. Peak area ratios were in good accord with each other: peak 3/peak 4=1:3.38 (c and d) and 3.31:1 (e and f). As two enantiomers of 2ACyclo-OH were used for derivatization, the retention times of the two isomers of **4** were inverted with respect to each other. This accordance cannot be considered a coincidence. Based on the fact that the absolute configuration of the synthetic sample was *R*, the stereochemical composition of the natural callosobruchusic acid (**1**) was concluded to be *R*/*S*=3.3–3.4:1.

Discussion

As the identification of callosobruchusic acid (**1**) by Tanaka et al. (1981), several synthetic and biological studies of this pheromone component have been conducted. However, the absolute configuration of the natural product has heretofore remained obscure because of the scarcity and difficulty in purification of the natural product. The usual analytical method for chiral insect pheromones is GC analysis with a chiral stationary phase (Mori 1998). In the case of callosobruchusic acid (**1**), chiral GC analysis could not be carried out because

Table 1 Peak areas of 2ACyclo-O derivatives of the natural product in 2D-HPLC

Panel Fig. 3	2ACyclo-OH	Area		Absolute configuration (**1**)
		Peak 3	Peak 4	
B	1*R*,2*R*	1.39×10^5		*S*
C	1*R*,2*R*		4.70×10^5	*R*
D	1*S*,2*S*		7.67×10^5	*R*
E	1*S*,2*S*	2.32×10^5		*S*

the compound is not volatile enough to inject into a chiral column without decomposition. To overcome this problem, we used the Ohrui–Akasaka method. The natural pheromone was collected from 2,862 virgin female azuki bean weevils, and analysis was performed by using the unpurified crude sample. Although many peaks were observed on the resulting chromatograms, separation of the derivatives of the natural product was achieved using a 2D-HPLC technique. The natural pheromone was shown to be enantiomerically impure. As callosobruchusic acid (**1**) contains a carbonyl group next to a chiral center, accidental enolization of the carbonyl group can lead to racemization at C-2. However, by using a synthetic sample of **1**, it was shown that no racemization occurred during isolation, purification, or derivatization under the conditions used in this experiment. Thus, the ratio of enantiomers in the natural product was determined to be *R*/*S*=3.3–3.4:1. In studies of the relationship between stereochemistry and biological activity of **1**, Mori et al. (1983) found that (*R*)-**1** is just more than half as active as (*S*)-**1** [the dose necessary for 50% copulation release (ED_{50} value) for (*S*)-**1** was 6.5 ng, whereas that of (*R*)-**1** was 11.4 ng]. This means that female *C. chinensis* L. produce more of the less active enantiomer than the more active one. The reason for the lower level of production of the pheromone is unknown. The stereoisomeric composition of the copulation release pheromone of *C. maculatus* (**2**) was 2*R*,6*S*/2*S*,6*R*/2*S*,6*S*/2*R*,6*R*=43:38:18:trace, and there was a tendency for the more abundant isomer in the natural product to be more active (Yajima et al. 2006). We conclude that the biosynthesis and recognition of pheromones in weevils may not be strictly controlled.

Acknowledgments We wish to acknowledge the technical help provided by Professor K. Ohsawa, Professor S. Yajima, and Mr. K. Shimomura (Tokyo University of Agriculture) in the isolation of the pheromone.

females, indicating that female moths continuously produce pheromone. A pheromone biosynthesis activating neuropeptide (PBAN)-like neuropeptide did not affect sex pheromone production as indicated by injection of synthetic PBAN and decapitation of *U. ornatrix* female adults. When the labeled precursor, D_4-9,12,15-18:acid, was injected into the early pupal stage, the most abundantly labeled hydrocarbons were 3,6,9-21:Hy and 1,3,6,9-21:Hy in the female adults. This result indicated that 3,6,9-21:Hy could be biosynthesized from linolenic acid through chain elongation and decarboxylation. To determine how 1,3,6,9-21:Hy is produced, D_4-3,6,9-21:Hy was injected into pupae and monitored for incorporation of label. No label was incorporated into 1,3,6,9-21:Hy, although a large amount of triene, 3,6,9-21:Hy, was recovered in the pheromone gland. This indicates that *U. ornatrix* females do not use 3,6,9-21:Hy to produce 1,3,6,9-21:Hy, and the terminal double bond is introduced earlier in the biosynthetic pathway.

Keywords Pheromone · Hydrocarbon · Biosynthesis · PBAN · Arctiidae · Lepidoptera

Introduction

One major group (type I) of moth sex pheromones is composed of linear fatty acid-derived compounds, 12–18 carbons in chain length, with an oxygenated functional group and one to three double bonds. A second major class (type 2) of sex pheromones is based on hydrocarbons with a polyene and/or epoxide functional group. This class of pheromones is typically found in four large moth families, the Geometridae, Noctuidae, Arctiidae, and Lymantridae (Byer 2006; Witzgall et al. 2004). The polyene type is biosynthesized from diet-derived linoleic or linolenic acids and characterized by 17–23 carbon chains with 1–4 double bonds, and 0–2 epoxides (Millar 2000).

Typically, type I sex pheromones are biosynthesized by specific enzymes in the pheromone gland and released by calling females (Jurenka 2003). In contrast, biosynthesis of type 2 occurs in specialized cells, oenocytes, that are associated with epidermal cells (Diehl 1975). The hydrocarbon pheromone of the arctiid moth, *Holomelina aurantiaca*, is biosynthesized in oenocytes and transported through the hemolymph to the pheromone gland for storage and release (Schal et al. 1998). In the lymantriid moth, *Lymantria dispar*, biosynthesis of the alkene precursor of the epoxide sex pheromone, occurs in oenocyte cells by chain elongation, desaturation, and decarboxylation. The alkene is transported to the pheromone gland and converted to (+)-disparlure by epoxidation (Jurenka et al. 2003). Polyene hydrocarbon precursors are present in the hemolymph of geometrid and arctiid moths, with the pheromone epoxide made in the pheromone gland (Wei et al. 2003, 2004).

Utetheisa ornatrix is broadly distributed over North America east of the Rockies and extends into South America, including Brazil, Argentina, and Chile (Pease 1968). Like many arctiid moths, *U. ornatrix* females produce a hydrocarbon pheromone and release it during the scotophase (Conner et al. 1980). The major sex pheromone component of *U. ornatrix* was identified as (*Z*,*Z*,*Z*)-3,6,9-heneicosatriene (3,6,9-21:Hy). This component attracted male moths in the field (Conner et al. 1980). Subsequently, however, a different composition of sex attractant was found in this species, varying geographically within populations, and from year to year. This blend consisted of 3,6,9-21:Hy along with (*Z*,*Z*,*Z*)-1,3,6,9-heneicosatetraene (1,3,6,9-21:Hy) as a minor component (Huang et al. 1983; Jain et al. 1983). Recently, (*Z*,*Z*,*Z*)-3,6,9-eicosatriene 3,6,9-20:Hy has also been identified as a minor component produced by females of this species (Lim et al. 2007).

The male sex pheromone and related mating behavior of *U. ornatrix* has been studied comprehensively. After being attracted to the female, through the long distance sex

pheromone, the male courts the female by releasing hydroxydanaidal, derived from host plant pyrrolizidine alkaloids, obtained during larval feeding on seeds of *Crotalaria* spp. (Eisner and Meinwald 1995). The alkaloids are toxic, and female *U. ornatrix* may derive protection from predators by receiving these additional alkaloids during mating (Conner and Weller 2004). Because a female transfers some proportion of these alkaloids to her eggs, her offspring may also benefit (Iyengar and Eisner 1999; del Campo et al. 2005). Recent observations indicate that females appear to signal more vigorously in the presence of signaling neighbors, and they time their signaling in relation to their neighbors' signaling activity. This phenomenon has been described as "female pheromonal chorusing" (Lim and Greenfield 2007). This behavior indicates that females detect female-produced pheromone, as previously demonstrated by gas chromatography-electroantennographic detection (GC-EAD) studies (Grant and O'Connell 2000; Lim et al. 2007).

In the present study, by using gas chromatography-mass spectrometry (GC-MS) and GC-EAD analyses, we determined that 1,3,6,9-21:Hy is the major pheromone component in most females of a *U. ornatrix* colony originally collected from a population in Florida. However, about 10% of females in our colony produced large amounts of 3,6,9-21:Hy and no C-21 tetraene. By using deuterium-labeled fatty acid and hydrocarbon precursors, we determined that biosynthesis of 1,3,6,9-21:Hy occurred by chain elongation of linolenic acid. We further determined that a brain factor, such as the pheromone biosynthesis activating neuropeptide (PBAN), is not directly involved in regulating pheromone production.

Methods and Materials

Insects Colonies of *U. ornatrix* (Lepidoptera, Artiidae) were collected at the Archbold Biological Station (Highlands County, Florida, US). Larvae were reared on a pinto-bean diet mixed with seeds of the host plant, *Crotalaria mucronata* (Leguminoseae), as described (Dussourd et al. 1991) in an environmental chamber under a L:D14:10 at 26°C at the University of Kansas. Pupae were shipped to Iowa State University, where they were sexed and allowed to emerge separately. A sucrose solution (10%) was provided to adults. Virgin female adults or pupae were used throughout this study.

Chemicals (6,6,7,7-D_4)-9,12,15-octadecatrienoic (linolenic) acid (D_4-9,12,15-18:acid) was synthesized as described (Rakoff 1988). (12,12,13,13-D_4)-(*Z*,*Z*,*Z*)-3,6,9-heneicosatriene (D_4-3,6,9-21:Hy) was synthesized from D_4-9,12,15-18:acid, following procedures reported in Dogra et al. (1989). ^{1}H-NMR: δ 0.88 (3H, *t*, *J*=6.8 Hz, CH_3, C_{21}), 0.98 (3 H, *t*, *J*= 7.4 Hz, CH_3, C_1), 1.26–1.36 (18 H, *m*, CH_2, $C_{12–20}$), 2.04 (2 H, *d*, *J*=6.8 Hz, CH_2–C=, C_{11}), 2.08 (2 H, *m*, CH_2–C=, C_2), 2.80 (4 H, *t*, *J*=6.0 Hz, =C–CH_2–C=, $C_{5,8}$), 5.33–5.41 (6 H, *m*, CH=). ^{13}C-NMR: δ 14.11, 14.26, 20.54, 22.69, 25.52, 25.60, 27.00, 29.30, 29.35, 29.60, 29.64, 29.65, 29.66, 29.68, 31.93, 127.12, 127.56, 128.23, 128.30, 130.42, 131.94. EI-MS *m*/*z* (%): 294 $[M]^+$ (4), 265 (1), 238 (22), 184 (2), 170 (2), 149 (4), 135 (10), 121 (10), 108 (95), 95 (48), 93 (48), 79 (100), 67 (52), 55 (32). Synthetic *Helicoverpa zea* PBAN (Peninsula Laboratories, Belmont, CA, USA) was dissolved in an insect saline (21 mM KCl, 12 mM NaCl, 3 mM $CaCl_2$, 18 mM $MgCl_2$, 170 mM glucose, and 5 mM pipes buffer at pH 6.6 using KOH) before injection.

Incorporation and Hydrogenation Procedures The putative pheromone precursors, D_4-9,12,15-18:acid and D_4-3,6,9-21:Hy, were used to determine the biosynthetic pathway by injection directly into the hemocoel of pupae. Deuterium-labeled compounds were dissolved in vegetable oil and injected into 1- to 2-d-old female pupae. To investigate the

effect of PBAN, a saline solution with or without PBAN (10–50 pmol) was injected through abdominal intersegmental membranes into the hemocoel of 1- to 4-d-old decapitated females. Insects were incubated for 1 hr at room temperature, before the pheromone glands were removed, extracted, and analyzed for pheromones as described previously (Choi et al. 2002).

Hydrogenation of the unsaturated hydrocarbon pheromone, extracted from female pheromone glands, was conducted as follows. Hydrocarbon pheromone was purified by silica gel column chromatography. The purified hydrocarbon was dissolved in 100 μl of hexane in a glass bottle containing 10 mg palladium (5% wt on activated carbon; Sigma Chemical Co., St Louis, MO, USA). A hydrogen gas balloon covered the bottle for 2 hrs at room temperature before the hydrocarbon was extracted with hexane (100–200 μl), purified by silica gel column chromatography, and analyzed by gas chromatography (GC) and mass spectrometry (MS) as described below.

GC-EAD Analyses For GC-EAD analysis, a Hewlett-Packard 5890 Series II GC, equipped with a DB-5 column (30 m×0.25 mm ID, J & W Scientific, CA, USA) and a 50:50 effluent split, allowed simultaneous flame ionization detection (FID) and EAD of the gland extracts. The oven temperature program used was, 60°C for 1 min and increased to 250°C at 10°C min^{-1}. Helium was the carrier gas. Gland extracts were concentrated to 10–20 μl, under a gentle stream of nitrogen, and 1 μl was injected into the GC column in splitless mode. The outlet for the EAD was supplied with purified, humidified air flowing over the antennal preparation at 600 ml min^{-1}.

Whole-body preparations were used for EAD experiments. A virgin male or female moth was immobilized on a plasticine block with small U-shaped copper wires, and its antennae were restrained with thin copper wires. A glass microelectrode (tip diameter ≈ 1 mm, 0.86 mm I.D., A-M Systems Inc., WA, USA), filled with 0.1 M KCl, was introduced

Fig. 4 Representative partial mass chromatograms obtained from GC-MS analysis of hexane extracts of pheromone glands of *U. ornatrix* after injection of 0.5 μl vegetable oil or 0.5 μl vegetable oil containing 50 μg D_4-9,12,15-18:acid into female pupae. The *top two chromatograms* were from females producing 3,6,9-21:Hy, and the *bottom two chromatograms* were from females producing predominantly 1,3,6,9-21:Hy. The GC-MS was set in the selective ion mode to detect *m/z* 288, 290, 292, and 294. Ions 292 and 294 are shown in *bold* and represent the label incorporation from the deuterium-labeled substrates

through the cuticle of the distal part of the antenna and served as a recording electrode; another glass microelectrode penetrated the moth's compound eye to serve as a reference electrode. Silver–silver chloride junctions were used to maintain electrical contact between the electrodes and amplifier. The electroantennogram signal was first amplified with a high-input impedance (>10 Ω) headstage preamplifier (Syntech®, Hilversum, The Netherlands), and further processed with a PC-based signal processing system (Syntech®).

Analyses by GC and GC-MS Glands were extracted with hexane (100 μl), containing 100 ng octadecane (18:Hy) as internal standard, for 10 min. Extracts were analyzed by GC or selected ion monitoring GC-MS. Incorporation of the labeled precursors into pheromones was determined by GC-MS with a Hewlett-Packard 5890 II mass selective detector coupled with a Hewlett-Packard 5890 GC equipped with a 30-m capillary column, DB-5 (30 m×0.25 mm; J&W Scientific, CA, USA). The oven was programmed from 50°C for 1 min, to 300°C at 10°C min^{-1}. The mass selective detector was used in the selected ion monitoring mode to detect the following characteristic *m/z*: 254 for octadecane (18:Hy), 276 for 3,6,9-20:Hy, 296 for heneicosane (21:Hy), 292 for 6,9-heneicoadiene, 290 for 3,6,9,-21:Hy, and 288 for 1,3,6,9-21:Hy. Labeled compounds were detected by using the characteristic ion +4. Adult females were extracted for pheromone and analyzed by GC-MS as described above.

Results and Discussion

Both 1,3,6,9-21:Hy and 3,6,9-21:Hy were detected in pheromone gland extracts of adults of all ages. The amounts of the two components showed a similar pattern with age between scotophase and photophase. Low amounts of both compounds were found in females during the late pupal stage (Fig. 1). The amount of 1,3,6,9-21:Hy varied greatly among individuals. The mean amount found in adult females was similar at all ages measured. However, the amount in 1-d-old females was greater than that in late pupae (Fig. 1B). The amount of 3,6,9-21:Hy (Fig. 1A) was similar for females of different age (including pupae), and roughly 1/30 that of 1,3,6,9-21:Hy (Fig. 1). These results indicate that sex pheromone biosynthesis starts in the late pupal stage, has increased by eclosion, and is maintained over at least 7 days. Thus, female adults are able to start calling and mate soon after emergence. This finding is consistent with previous work demonstrating that female adults are most active with respect to calling and mating at age 1- to 2-day-old (Conner et al. 1980; Itagaki and Conner 1987; Lim and Greenfield 2007).

GC analysis of pheromone gland extracts showed several peaks, including a very broad peak (Fig. 2B). Analysis indicated that all of these peaks, including the broad part of the chromatogram, had similar mass spectra, with the ion 288 prominent. The first peak was identified as 1,3,6,9-21:Hy based on comparison with published GC-MS data (Jain et al. 1983). This 21-carbon tetraene is unstable and the broad peak and peaks with longer retention times may result from thermolysis of this compound with rearrangement of double bonds into

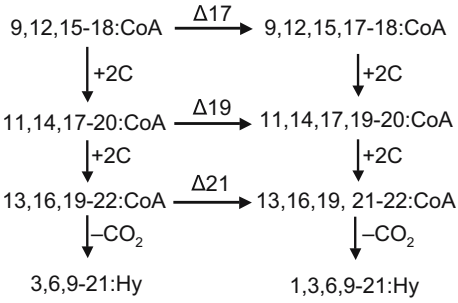

Fig. 5 Proposed biosynthetic pathways for production of the hydrocarbon sex pheromone components in *U. ornatrix*

conjugated configurations, such as 2,3,6,9-21:Hy. Hydrogenation of the extract resulted in the detection of only saturated 21:Hy. The areas of the peaks with longer retention times were also reduced if the GC temperatures for the injector and oven were decreased (unpublished data), supporting their formation from thermolysis of 1,3,6,9-21:Hy.

3,6,9-21:Hy, was initially identified as the major pheromone component of *U. ornatrix* females (Conner et al. 1980). In the present study, however, most females (~90%) produced about 1/30 the amount of this compound compared to 1,3,6,9-21:Hy. About 10% of female moths analyzed (several hundred) in our colony produced only a large amount (1,500–2,000 ng) of 3,6,9-21:Hy, without any tetraene (Fig. 2A). This result indicates that our colony may consist of two distinct pheromone types and that there may be two distinct populations present in the collection area in Florida. It has been noted previously that different geographical populations of *U. ornatrix* have different major and minor sex pheromone components (Conner et al. 1980; Huang et al. 1983; Jain et al. 1983). In their natural habitat, *U. ornatrix* host plants grow in highly populated patches. Presumably because of specificity to their hosts, *U. ornatrix* populations also show a clumped distribution. Such patchy distributions may allow for the formation of two pheromone types within a broader habitat. Further work is needed to determine the distributions of these two pheromonal types in populations in North and South America (Pease 1968).

Decapitated female moths appeared to accumulate 3,6,9-21:Hy and 1,3,6,9-21:Hy compared to same age normal females. Females, decapitated at 1-d-old, had roughly 3,300 ng of 1,3,6,9-21:Hy when 4-d old (Fig. 3), whereas 4-d-old intact females had roughly 1,000 ng of 1,3,6,9-21:Hy (Fig. 1). This result suggests that decapitated female moths continued to produce pheromone from oenocyte cells for transport to the pheromone gland, but probably did not release pheromone, as did intact females, due to the disconnect of the abdominal ganglia from the brain. The pheromone gland of female *U. ornatrix* consists of a long pair of slender tubes that extend forward to the sixth abdominal segment (Conner et al. 1980). Control of *U. ornatrix* rhythmic pheromone gland exposure by the terminal abdominal ganglion has previously been demonstrated (Itagaki and Conner 1987).

Although female *U. ornatrix* produce relatively large amounts of 1,3,6,9-21:Hy, only trace amounts were detected in the hemolymph during scotophase and photophase (unpublished data). This could be explained in several ways. First, transport of the hydrocarbon from the oenocytes to the pheromone gland may occur at a different time from when the hemolymph was collected. Second, the oenocyte cells are closely associated with the pheromone gland, and thus, transport through the hemolymph may not occur. Third, it is also possible that the pheromone gland directly produces the hydrocarbon pheromones. Further research will deduce which is the case.

A PBAN-like neuropeptide does not appear to influence hydrocarbon sex pheromone production in *U. ornatrix*, as indicated by similar amounts of pheromone being found in

decapitated females injected with either synthetic PBAN or saline (Fig. 3) and the increase in hydrocarbon quantities after decapitation discussed previously. PBAN is also not involved in hydrocarbon pheromone production in the noctuid moth, *Anticarsia gemmatalis*, (Jeong 2003). In other species of moths producing type 2 pheromones, PBAN regulates epoxidation after the uptake of hydrocarbons in the pheromone gland (Ando et al. 1997; Jurenka et al. 2003). Recently, it was shown that PBAN could regulate the uptake of hydrocarbon into pheromone glands of geometrid moths (Wei et al. 2004).

Fig. 4 shows results obtained from GC-MS analysis of pheromone gland extracts in which females were injected with labeled precursors. When D_4-9,12,15-18:acid was injected into the early pupal stage, the most abundantly labeled hydrocarbons in *U. ornatrix* adults were 3,6,9-21:Hy and 1,3,6,9-21:Hy. This indicates that 3,6,9-21:Hy could be biosynthesized by chain elongation and decarboxylation of linolenic acid. Typically, hydrocarbon pheromone biosynthesis occurs through modification of fatty acid metabolic pathways (Jurenka 2003). Labeling of the major pheromone component, 1,3,6,9-21:Hy, is of greater interest because it could be produced through two possible pathways based on when the terminal desaturation occurs (Fig. 5). To determine which pathway occurs, D_4-3,6,9-21:Hy was injected into pupae. No label was incorporated in 1,3,6,9-21:Hy, although a large amount of labeled triene, 3,6,9-21:Hy, was recovered. This suggests that *U. ornatrix* females do not use 3,6,9-21:Hy to produce 1,3,6,9-21:Hy. To determine when the terminal desaturation occurs in the biosynthetic pathway, additional studies will require the synthesis and injection of various chain-length precursors.

WITZGALL, P., LINDBLOM, T. BENGTSSON, M., and TOTH, M. 2004. The Pherolist. (http://www-pherolist.slu.se/pherolist.php).

We used isopentyl acetate (IPA), the principal component of the sting alarm pheromone in the honey bee, *Apis mellifera*, which elicits a response similar to that of the whole pheromone blend (Boch et al. 1962). Alarm pheromone provokes rapid defensive behavior, although longer-term effects are suggested by the observation that colonies that have been disturbed apparently remain aroused over a longer period (Winston 1987). Colony defense in honey bees typically begins with the release of alarm pheromone by "guard bees" at the hive entrance, which then provokes other bees to move to the entrance to face the intruder(s).

We first tested the effect of alarm pheromone exposure on longer latency behavior by repeatedly exposing bees to IPA in the field or laboratory. We then measured the effect of IPA exposure on the expression of the immediate early gene (IEG) and transcription factor, *c-Jun*, in the antennal lobes (ALs), the primary olfactory centers in the insect brain. Immediate early genes are involved in synaptic plasticity and are known to link experience

Fig. 1 Effect of exposure to alarm pheromone, or other odors, on honey bee behavior and *c-Jun* brain expression. **a** Repeated exposure to IPA caused a significant increase in colony arousal under natural conditions (two-way repeated measures ANOVA, colony: $F_{6,17}=81.92$, $P<0.001$, time exposure: $F_{4,68}=6.87$, $P<0.001$, interaction colony × time exposure: $F_{24,68}=0.88$, $P=0.621$). *Different letters* indicate significant differences in colony responsiveness over time (Tukey *post hoc* test, 1 vs. 3: $P<0.001$, 2 vs. 3: $P<0.01$, 1 vs. 4 and 5: $P<0.05$). Similar results were obtained for analyses based on number of bees responding relative to the first response (colony: $F_{6,17}=1.18$, $P=0.363$, time exposure: $F_{4,68}=3.09$, $P<0.001$, interaction colony × time exposure: $F_{24,68}=1.24$, $P=0.239$). The number of bees at the nest entrance ranged from 6 to 58 bees, and the mean lowest and highest responses were 30.7±13.5 and 65.4±23 bees, respectively. **b** Repeated exposure to IPA caused a significant decrease in responsiveness in the laboratory (rearing condition: $F_{1,18}=512.03$, $P<0.001$; time exposure: $F_{4,72}=94.31$, $P<0.001$; rearing condition × time exposure: $F_{4,72}=26.15$, $P<0.001$). Assays performed on caged bees reared either in typical colonies in the field or in laboratory cages (both $N=10$ cages). Isopentyl acetate-induced increase in *c-Jun* expression in the ALs of bees in typical colonies in the field (**c**) and laboratory cages (**d**). **e** Effect of exposure to known plant odors (limonene or hexanal) on *c-Jun* expression. Tests were performed as for IPA in the laboratory; colony-reared bees were exposed for 60 sec to 5 μl of neat odorant. We performed two trials, each with one control cage (filter paper alone) and two treatment cages, for each odor ($N=7$–8 individuals analyzed/cage). *Triple asterisks* represent $P<0.001$, Mann–Whitney rank sum test. Data show mean±SD. *Numbers in bars* show numbers of individual brains assayed

to changes in gene expression (Clayton 2000). The IEG *c-Jun* is expressed in neural circuits involved in olfaction in mammals (Baba et al. 1997).

Methods and Materials

Effect of Alarm Pheromone on Behavior Bees were exposed to a 60-sec presentation of 2.5 μl IPA, diluted in mineral oil (1/10) (Sigma-Aldrich, St Louis, MO, USA) (Collins and Rothenbuhler 1978), every 30 min ($N=5$ successive exposures). Mineral oil alone did not elicit a response (data not shown).

In the field assay, the pheromone solution was applied on a filter paper presented at the hive entrance ($N=7$ colonies, 2–4 replicates/colony, 24 replicates total). To measure colony arousal, the number of responding bees was determined from photographic snapshots of the hive entrance 0, 15, 30, 60, and 120 sec before and 15, 30, 60, and 120 sec after IPA exposure. Colony arousal was measured as the difference between the mean number of bees at the hive entrance before and after IPA exposure. The intensity of colony response at each exposure was ranked from lowest (rank 1) to highest (rank 5).

The laboratory assay was performed with cages of 25 8-d-old bees reared either in a typical colony in the field or in cages in the laboratory. Cage-reared bees were removed from their hive prior to eclosion by transferring honeycomb frames containing pupae to an incubator (33°C). They were then placed in cages upon eclosion and supplied with honey, pollen, and water. The cages were kept under a cardboard box (with holes on each side) at 32±2°C, 70–90% relative humidity (RH), and 12:12-hr light/dark photoperiod. Both colony- and cage-reared bees were transferred to test cages 4 hr prior to testing. This was done to minimize the effects of any exposure to alarm pheromone that might have occurred during transfer (IEG expression returns to basal levels 4 hr after stimulation; Clayton 2000). The IPA-treated filter paper was inserted under the wire floor of a Plexiglas cage (10×10×7 cm), and the wing fanning response was quantified. This assay has been shown to give responses that correlate with field behavior (Collins and Rothenbuhler 1978). Tests were conducted in a light room at 28±2°C and 30–40% RH.

Effect of Alarm Pheromone on IEG Expression *c-Jun* expression was analyzed 30 min after one exposure to IPA, a timescale appropriate for detecting an increase in IEG mRNA

(Clayton 2000). In the field experiment, bees standing at the hive entrance were randomly collected before IPA exposure (control); then, the colony was exposed to IPA for 60 sec, and the bees that rapidly approached the filter paper and behaved aggressively toward other bees were collected and placed in a Plexiglas cage for 30 min. In the laboratory experiment, bees exposed to either mineral oil (control) or IPA were frozen in liquid nitrogen 30 min after exposure. We performed three trials of the field assay, three trials of the laboratory assay with colony-reared bees (each one with one control cage and two treatment cages, N=5–12 individuals analyzed/cage), and two trials of the laboratory assay with cage-reared bees (each one with one control cage and two treatment cages, N=7–8 individuals analyzed/cage). Bees were held at −80°C until AL dissection and mRNA quantification by real-time quantitative reverse-transcriptase PCR (Grozinger et al. 2003). *c-Jun* mRNA levels were normalized to an mRNA loading control "housekeeping" gene (*rp49*). Primer sequences (5′ to 3′) were *c-Jun*, forward: CGTGGCGGCATCCAAA; *c-Jun*, reverse: CCCTTCAGCAATTTAACCTTATCTTC; (control gene) *rp49*, forward: GGAACT GGAAGTTTTAATGATGCA; and *rp49*, reverse: CAACAATGGATTTACGTTTT TTACTG. *c-Jun* expression was also determined following exposure to the known plant odorants, limonene and hexanal (Sigma-Aldrich).

Results and Discussion

Isopentyl acetate exposure affected subsequent behavioral responses of bees to alarm pheromone. There was a significant increase in the number of bees at the hive entrance over the first 1.5 hr before the response leveled off (Fig. 1a). Isopentyl acetate exposure also affected behavior in the laboratory but opposite to the field experiment; both colony- and cage-reared bees showed a significant decrease in responsiveness for at least 2.5 hr in response to IPA (Fig. 1b). The laboratory response of cage-reared bees was greatly attenuated relative to colony-reared bees (Fig. 1b). This is consistent with previous findings on the effects of queenlessness and social isolation on brain development (Gascuel and Masson 1987; Morgan et al. 1998).

The exposure of typical honey bee colonies in the field to IPA caused a significant increase in *c-Jun* expression (Fig. 1c). An equivalent *c-Jun* induction was also seen in response to IPA exposure in the laboratory, despite the opposite behavioral responses observed in the field and laboratory (Fig. 1a, b). The *c-Jun* response occurred equivalently in both colony- and cage-reared bees (Fig. 1d), although the behavioral response was stronger in colony-reared bees.

We tested the selectivity of this IEG response by exposing bees in cages to two other biologically relevant volatile odors: hexanal, a ubiquitous component of green leaf volatiles, and limonene, a floral odor. Hexanal induced *c-Jun*, but limonene did not (Fig. 1e). Speculation on the reasons for these contrasting results is beyond the scope of the present study; nevertheless, our results indicate that this particular IEG response in bees is not specific to alarm pheromone but is selective.

This is the first demonstration that a releaser pheromone can affect longer-latency behavioral response probabilities and cause changes in brain gene expression. These results demonstrate a genomic response to a releaser pheromone that is behaviorally related, although the genomic response appears to be less sensitive to behavioral context than does the behavior itself. *c-Jun* induction may initiate the response to alarm pheromone in ALs,

but integration with other mechanosensory and visual stimuli relevant to colony defense, present in the field but absent in the lab environment, apparently occurs at higher levels of the brain to shape the behavioral response (Li and Strausfeld 1999). Our findings blur the long-standing distinction between primer and releaser pheromones and highlight the pervasiveness of social regulation of brain gene expression (Robinson et al. 2005).

thysanurans (Trembay and Gries 2003). Most of these insects inhabit enclosed microhabitats with little air movement, potentially rendering volatile pheromones less effective than contact pheromones. Moreover, many species that deploy contact pheromones for communication belong to primitive taxonomic insect orders (Grimaldi and Engel 2005). Identification of these chemicals will contribute to our understanding of pheromone evolution (Roelofs et al. 2002; Wertheim et al. 2005).

Here, we studied pheromonal communication in three primitive, synanthropic thysanurans, the common silverfish, *Lepisma saccharina* L., giant silverfish, *Ctenolepisma longicaudata* Escherich, and the firebrat, *Thermobia domestica* (Packard). Male, female, and nymph *T. domestica* produce, and respond to an aggregation pheromone (Trembay and Gries 2003) but require physical contact to perceive it. A similar communication system may exist in *L. saccharina* and *C. longicaudata*, as they also aggregate within human dwellings. Aggregating thysanurans maintain contact via antennae and caudal appendages (Tremblay 2002; NW, personal observation), suggesting that the pheromone may be associated with these or other body parts, although one cannot discount salivary secretions as yet another potential source. All three species can be found in the same shelter (NW, personal observation), and thus may be able to recognize con- and heterospecific pheromones.

Our objectives were to test the following hypotheses: 1) male, female, and nymph *L. saccharina* and *C. longicaudata* produce and respond to aggregation pheromone; 2) pheromone perception requires physical contact; 3) frass, scales, antennae, caudal filaments, or salivary secretions constitute the source of the *L. saccharina* pheromone; and 4) pheromones of *L. saccharina*, *C. longicaudata*, and *T. domestica* elicit a behavioral response by closely related heterospecifics.

Methods and Materials

Collection and Rearing of Experimental Insects

Thermobia domestica, *C. longicaudata*, and *L. saccharina* were collected by placing Petri dish (14×8 cm) traps baited with Quaker® oats on or around autoclaves and boilers at Simon Fraser University. Approximately 1,000 *L. saccharina* were also obtained from a laboratory colony at the University of Sussex. Insects were maintained in glass rearing jars (10×12 cm) provisioned with a moist cotton wick, a Petri dish (3×1 cm) containing Quaker® oats, and a corrugated cone of filter paper (CCOFP; Whatman® No. 1, 125-mm diam) as a shelter. Each jar housed either 100 males, females or juveniles, or a mixed group (100 insects total) of all stages. Jars were kept in a Plexiglas® container (30×22×22 cm) in contact with a heating rock (Zoo Med Labs, Inc., San Luis Obispo, CA, USA) so that the within-jar temperature ranged between 24° and 38°C depending on the proximity to the heat source. A within-jar relative humidity of 70–85% was maintained by leaving an open jar of water in contact with the heating rock. This range of humidity and temperature ensured optimal abiotic conditions for each of these species (Sweetman 1938, 1939; Spencer 1959). Insects were reared and tested under an 8L:16D photoperiod (Sweetman 1938, 1939).

General Bioassay Procedures

Lepisma saccharina, *T. domestica*, and *C. longicaudata* naturally reside within confined spaces with little or no air movement (Spencer 1930; Sweetman 1938). Thus, still-air "olfactometers" were used for all experiments. They consisted of a central Pyrex® glass

Petri dish connected to two lateral Petri dishes (each dish 9×3 cm) via tubing (2×2.5 cm) (Trembay and Gries 2003). Olfactometers were housed within opaque plastic bins (35×31×11 cm) (Columbia Plastics Ltd. ®, Vancouver, BC, CA), allowing diffuse but not directional light to enter. Each lateral chamber of an olfactometer received a filter paper (Whatman® No. 1, 125-mm diam) that was folded twice and formed into a cone, with the tip facing the central chamber. Cones served as shelters, resulting in few nonresponding individuals during bioassays (NW, personal observation). For each replicate, an insect (previously isolated for 16 hr) was released into the central chamber 6 hr after the onset of scotophase, and its position was recorded 16 hr later (2 hr before the start of scotophase). Each replicate was run at 24±2°C and 70–85% relative humidity (RH). Olfactometers were washed with hot water and Sparklene™ detergent, and were oven-dried at 125°C for 3 hr between each assay.

Specific Experiments

In experiments 1–9 and 10–18, we tested the hypothesis that male, female, and nymph *L. saccharina* and *C. longicaudata* produce and respond to species-specific pheromone. The CCOFP (see above) was removed from rearing jars after 3 d of exposure to 100 insects, brushed off to remove insect-derived frass and scales, and then cut into eight equal pieces. A single piece was then inserted into the paper cone located within the treatment chamber of each olfactometer. The paper cone in the corresponding control chamber received a piece of CCOFP that had been removed from rearing jars containing oats and a moist wick, but no insects.

In experiments 19–20 and 21–22, we tested the hypothesis that female *L. saccharina* (experiments 19–20) and *C. longicaudata* (experiments 21–22) require physical contact to perceive and respond to their aggregation pheromone. Considering that pheromone production and perception was neither gender- nor adult-specific in preceding experiments, this hypothesis was tested only with females. A CCOFP exposed for 3 d to a mixed group of male, female, and nymph conspecifics (100 insects total) was placed so as to be accessible (see above) or inaccessible in the treatment chamber of an olfactometer. Inaccessible stimuli were suspended above a nylon mesh, stretched over the rim of the chamber and thus out of reach for test insects. Control stimuli from rearing jars containing only oats and a moist wick were tested in a similar manner. One female *L. saccharina* or *C. longicaudata* was bioassayed in each replicate.

In experiments 23–26, we tested the hypothesis that *L. saccharina*-derived frass (experiment 23), body scales (experiment 24), antennae or caudal filaments (experiment 25), or salivary gland secretions (experiment 26) constitute the source of the aggregation pheromone. The test stimuli were prepared from: (1) dry fecal pellets (0.5 mg) recovered from female rearing jars after 3 d; (2) scales (0.5 mg) brushed off dorsal and ventral surfaces of 10 cold-anaesthetized females; (3) four antennae and six caudal filaments removed from four cold-anaesthetized females, or (4) macerated salivary glands excised from three cold-anaesthetized females. Each stimulus was spread within the paper cone shelter of a randomly assigned treatment chamber of an olfactometer. Paper cone shelters within the control chamber received no test stimulus. One female *L. saccharina* was bioassayed in each replicate.

In experiments 27–35, we tested the hypothesis that *L. saccharina*, *C. longicaudata*, and *T. domestica* respond to pheromones from con- and heterospecifics. Test stimuli consisted of a piece of CCOFP (see experiments 1–18) previously exposed to a mixed group of male, female, and juvenile insects. This was inserted into paper cones within the treatment

chamber of each olfactometer. Control chambers contained a piece of CCOFP from rearing jars containing only oats and a moist wick. One female *L. saccharina*, *C. longicaudata*, or *T. domestica* was bioassayed in each replicate.

Numbers of insects responding to test stimuli in each experiment were analyzed by χ^2 test, with JMP™ software (SAS®, Cary NC, USA). The significance level was set at $P \leq 0.05$. Insects found within the central chamber or connecting tunnels of olfactometers at termination of experiments were considered nonresponders and were not included in statistical analyses.

Results and Discussion

Male, female, and juvenile *L. saccharina* all exhibited significant arrestment responses to a piece of CCOFP previously exposed to either male, female, or juvenile conspecifics (Fig. 1). Similar results were obtained with *C. longicaudata* (Fig. 2). Female *L. saccharina* and *C. longicaudata* required physical contact with the pheromone to respond to it (Fig. 3). Neither dried insect-derived frass, body scales, antennae, caudal filaments, nor macerated salivary glands removed from females elicited significant arrestment responses by female *L. saccharina* (Fig. 4). Females of all species responded to conspecific pheromones, but varied in their response to those of heterospecifics. Female *C. longicaudata* were arrested by both heterospecific pheromones, female *L. saccharina* by neither, and female *T. domestica* responded only to that from *C. longicaudata* (Fig. 5).

The arrestant type pheromone of *T. domestica* (Trembay and Gries 2003), *L. saccharina* and *C. longicaudata* (this study) may be particularly suitable for marking potential shelters that provide appropriate microclimatic conditions (temperature, humidity), protection from predators, as well as access to food, water, and potential mates. We argue that increases in population density and consequently pheromone deposition may facilitate detection of suitable shelters, and may thus be correlated with the fitness of individual thysanurans. This correlation, an Allee effect (Stephens et al. 1999), is believed to be the driving force behind the evolution of aggregation pheromones (Wertheim et al. 2005) and may also help explain the increased survival of *T. domestica* nymphs when they were reared in groups rather than in isolation (Sweetman 1938).

Nonvolatile insect pheromones identified thus far are discrete or complexed fatty acids (Naumann et al. 1991; Finidori-Logli et al. 1996; Kugimiya et al. 2002), saccharides

An asterisk (*) indicates a significant preference for a particular test stimulus (χ^2 test; $^*P<0.05$, $^{**}P<0.01$). Numbers in brackets indicate numbers of nonresponding insects

(Nojima et al. 1999, 2002), or steroids (Sakuma and Fukami 1993; Kugimiya et al. 2003). All of these pheromones are easily extracted with solvents of polarity similar to that of the pheromones themselves. Our preliminary attempts to extract thysanuran pheromones with diverse polar and nonpolar solvents failed, suggesting that thysanuran pheromones may possess both polar and nonpolar segments. Such amphipathicity would allow micellar formation or polymerization, and adherence of the pheromone to solid substrates. Two amphipathic steroidal glucoside pheromones (Blattellastanoside-A and Blattellastanoside-B) have been isolated from the German cockroach, *Blattella germanica* (Sakuma and Fukami 1993). Similar to thysanuran pheromones, they are produced by males, females, and nymphs, are perceived upon contact, and elicit arrestment (Ishii and Kuwahara 1967, 1968).

The nonvolatile and nonlabile nature of thysanuran pheromones make them suitable as aggregation and shelter markers. Such pheromones resist evaporation even at temperatures of 27–38°C, the range required by *C. longicaudata* and *T. domestica* (Adams 1959; Spencer 1959). Thus, the pheromone would not saturate the confined space typically inhabited by thysanurans, nor cause adaptation and habituation of their olfactory system. Moreover, a nonpolar or amphipathic pheromone does not readily dissolve in the humid microclimate (55–97% RH) that thysanurans require to prevent desiccation (Sweetman 1938, 1939; Adams 1959).

An asterisk (*) indicates a significant preference for a particular test stimulus (χ^2 test; $^*P<0.05$, $^{**}P<0.01$). Numbers in brackets indicate numbers of nonresponding insects

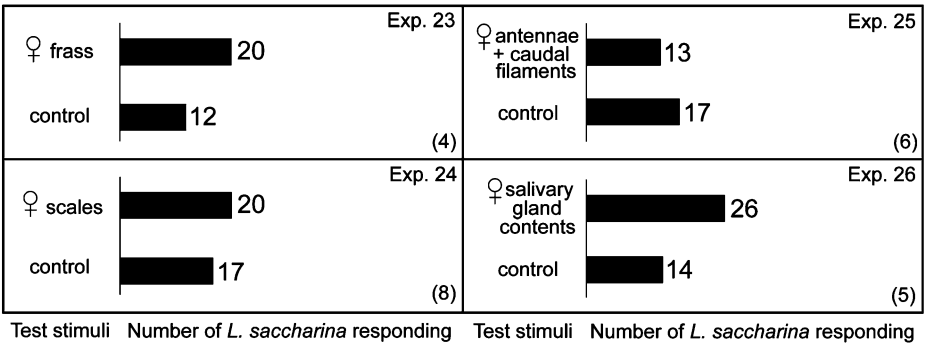

Fig. 4 Number of female *L. saccharina* responding to conspecific frass, scales, antennae and caudal filaments, or salivary gland contents. Numbers near bars indicate the number of insects responding to the test stimulus. In each experiment, there was no significant preference for a test stimulus (χ^2 test; $P<0.05$, $^{**}P<0.01$). Numbers in brackets indicate numbers of nonresponding insects

The aggregation pheromones of *L. saccharina*, *C. longicaudata* (Figs. 1 and 2), and *T. domestica* (Trembay and Gries 2003) are produced by females, males, and nymphs, suggesting they are derived from a source common to nymphs and adults. However, none of the potential pheromone sources tested previously (Trembay and Gries 2003) or in this study (Fig. 4) elicited significant arrestment in any of these species. Frass and macerated salivary glands appear to have caused some arrestment responses (Fig. 5) and ought to be investigated further, particularly in light of reports that the aggregation pheromone of European earwigs, *Forficula auricularia*, is present in frass and shed cuticle (Walker et al. 1993) or tibial glands (Sauphanor 1992). We also investigated the possibility that the arrestment behavior was caused merely by insect-induced physical and chemical changes of the shelter, or food sources therein. However, we dismissed this possibility, as glass surfaces exposed to insects for several days in the absence of food elicited strong arrestment by conspecifics (data not shown), clearly indicating that the insects deposit signals.

Relatedness between *C. longicaudata*, *T. domestica*, and *L. saccharina* can be investigated based on diverse criteria. Morphologically, *C. longicaudata* and *T. domestica* are more similar to each other than they are to *L. saccharina*. Arrestment response by *C. longicaudata*, but not *L. saccharina*, to the *T. domestica* pheromone (Trembay and Gries 2003), and lack of arrestment response to heterospecific pheromone between *T. domestica*

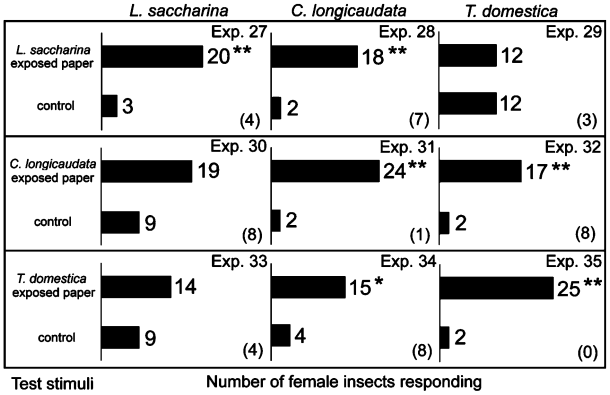

Fig. 5 Number of female *L. saccharina*, *C. longicaudata*, or *T. domestica* responding to a piece of filter paper previously exposed to conspecific or heterospecific male, female, and juveniles. Numbers near bars indicate the number of insects responding to the test stimulus. An asterisk (*) indicates a significant preference for a particular test stimulus (χ^2 test; $^{*}P<0.05$, $^{**}P<0.01$). Numbers in brackets indicate numbers of nonresponding insects

and *L. saccharina* (Fig. 5), all support the idea that *C. longicaudata* and *T. domestica* are more closely related to each other than they are to *L. saccharina* (Mendes 1991). A definitive conclusion, however, must await analyses of all three species by molecular genetics. The fact that *C. longicaudata* females respond to both *L. saccharina* and *T. domestica* pheromone (Fig. 5) is somewhat surprising, but may be explained by the probability of co-inhabiting a shelter with one of these heterospecifics. *Lepisma saccharina* and *T. domestica* prefer shelter temperatures between 21–27°C and 27–43°C, respectively (Spencer 1930, 1959; Sweetman 1938, 1939), and by selecting such discrete temperature regimes they are effectively isolated. In contrast, *C. longicaudata* is readily found in shelters at temperatures between 17°C and 30°C (Lindsay 1940), overlapping those of both *L. saccharina* and *T. domestica*. Thus, *C. longicaudata* may frequently encounter suitable shelters of either *L. saccharina* or *T. domestica* and may have evolved the ability to recognize their respective pheromones.

Acknowledgments We thank Dave Booth for supplying *Lepisma saccharina*, Michelle Tremblay for advice on the capture and rearing of all thysanuran species, Robert Britton, Andrew Lewis, Allen Haddrell, Regine Gries, Grigori Khaskin, and Aleksander Miroshnychenko for help and advice regarding preliminary chemical analyses, Kate Mclellan, and all laboratory colleagues for their advice throughout this project, as well as Jeremy McNeil and two anonymous reviewers for constructive comments. The research was supported by a Natural Sciences and Engineering Research Council of Canada (NSERC)-Industrial Research Chair to G.G. with SC Johnson Canada, Pherotech International Inc. and Global Forest Science (GF-18-2007-226 and GF-18-2007-227) as the industrial sponsors.
