Table 1 Oligonucleotide primers used for isolation of *Scleroderma guani* odorant-binding and chemosensory proteins (OBPs and CSPs)

Purpose/Primer Name	Sequence (5′–3′)
cDNA Isolation (RT-PCR)	
Oligo dT-3 site Adaptor Primer	GGCCACGCGTCGACTAGTACTTTTTTTTTTTTTTTTVN
3′ cDNA End Isolation (RACE)	
SguaOBP1-S1 (sense)[a]	CTNTCNGARGCNGAYGT
SguaOBP1-S2 (sense)[a]	CTNAGYGARGCNGAYGT
SguaOBP1-S3 (sense)[a]	TTRTCNGARGCNGAYGT
SguaOBP1-S4 (sense)[a]	TTRAGYGARGCNGAYGT
SguaOBP2-S1 (sense)[b]	GCNGAYAAYGAYGAYCC
SguaCSP1-S1 (sense)[c]	ACNCCNGARTAYTAYAC
Adapter Primer (antisense)	CTGATCTAGAGGTACCGGATCC
5′ cDNA End Isolation (RACE)	
SguaOBP1-AS1 (antisense)[d]	GACACCTTGGTCGTTCATCATAC
SguaOBP2-AS1 (antisense)[d]	TGGCACGGCTCACTGACTGTTA
SguaCSP1-AS1 (antisense)[d]	GAACACTTGGAACATACCGTCTCT
Outer Primer (sense)	GCTGATGGCGATGAATGAACACTG

[a] Corresponds to N-terminal region amino acid sequence: LSEADV.

[b] Corresponds to N-terminal region amino acid sequence: ADNDDP.

[c] Corresponds to N-terminal region amino acid sequence: TPEYYT.

[d] Gene-specific primer

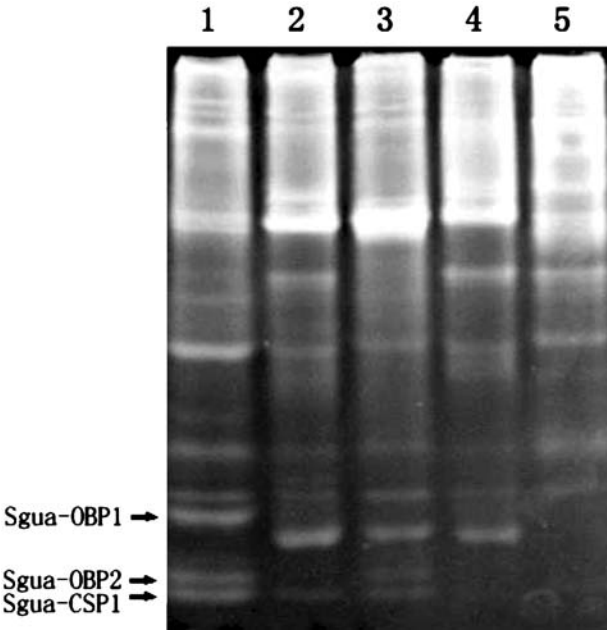

Fig. 1 Electrophoretic analysis under native conditions (15% native PAGE) of soluble antennal proteins from female *Scleroderma guani*. *lane 1*, female antenna; *lane 2*, female legs; *lane 3*, female head; *lane 4*, female thorax; and *lane 5*, female abdomen

its initial discovery. The nematode is likely native to North America (Dwinell 1997), but it has invaded both Asia and Europe (Mota et al. 1999; Kang et al. 2004).

Biological and ecological studies have indicated that the pine sawyer beetle, *Monochamus alternatus* Hope (Coleoptera: Cerambycidae), is the most important insect vector of *B. xylophilus* in China (Ding et al. 2001). Chen et al. (1996) first reported that the release of the parasitoid *Scleroderma guani* Xiao et Wu (Hymenoptera: Bethylidae) to control *M. alternatus* could be a highly effective management tactic for pine wilt disease.

The ant-like bethylid wasp *S. guani* is an ectoparasitoid of many woodboring insects. Since its discovery in Guangdong and Shandong provinces in 1973 and 1975 (Zhang 1980; Qin et al. 1982), respectively, it has been shown to occur in many provinces of China. Its hosts include more than 50 species of insects in 22 families from three orders (Chen and Cheng 2000).

Many studies have shown that *S. guani* could be an ideal candidate for biological control, especially in the suppression of longhorned beetles. Releases of *S. guani* have achieved effective and long-term control for *Anoplophora chinensis* (Chen 1995), *Anoplophora glabripennis* (Shi and Wang 2001), *Aromia bungii* (Jiang et al. 2001), *Mallambyx raddei* (Xie et al. 2000), *M. alternatus* (Xu et al. 2002; Wang et al. 2004), *Phytoecia rufiventris* (Cheng et al. 2003a), *Saperda populnea* (Pi et al. 2001; Feng et al. 2005), *Semanotus bifasciatus* (Li et al. 1993), and *Xylotrechus grayii* (Cheng et al. 2003b).

Odorant-binding proteins (OBPs) and chemosensory proteins (CSPs) are two classes of small, water soluble, extracellular proteins that have been identified from insects in the sensillar lymph of chemosensilla. Their functions may be to solubilize and transport messenger molecules to the olfactory receptors (Kaissling 2001; Pelosi et al. 2005).

The OBPs, subdivided into pheromone binding proteins (PBPs) and general odorant binding proteins (GOBPs), have been identified and/or cloned from various insect orders, such as Lepidoptera (Nagnan-Le Meillour et al. 1996; Picimbon et al. 2001; Zhang et al. 2001; Picimbon and Gadenne 2002), Coleoptera (Peng and Leal 2001; Nagnan-Le Meillour et al. 2004), Dictyoptera (Riviere et al. 2003), Diptera (Koganezawa and Shimada 2002; Vogt et al. 2002), Hymenoptera (Calvello et al. 2003; Krieger and Ross 2005), Isoptera (Ishida et al. 2002a), Orthoptera (Ban et al. 2003a) and Hemiptera (Vogt et al. 1999) since first identified in 1981 (Vogt and Riddiford 1981). The OBPs are presumed to mediate the delivery of odorants to specific receptor proteins embedded in the dendritic membrane (Prestwich 1993). Steinbrecht (1998) proposed that OBPs function to: (1) solubilize and carry olfactory signal molecules; (2) filter signals at the periphery; (3) stimulate the olfactory system; (4) clean the peri-receptor space; and (5) deactivate odorants, but the physiological function of OBPs is still under investigation.

The CSPs (Angeli et al. 1999), variously named as OS-D-like proteins (McKenna et al. 1994), and sensory appendage proteins (Robertson et al. 1999), which have been identified in Phasmatodea (Marchese et al. 2000), Orthoptera (Ban et al. 2002; Ban et al. 2003b), Lepidoptera (Nagnan-Le Meillour et al. 2000; Picimbon et al. 2000), Hymenoptera (Calvello et al. 2003), Diptera (Wanner et al. 2004), Hemiptera (Jacobs et al. 2005), Coleoptera, Dictyoptera, Siphonaptera, and Phthiraptera (unpublished, but was indicated in the Pfam website: http://www.sanger.ac.uk/cgi-bin/Pfam/speciesdist.pl?acc=PF03392&id=OS-D&depth=all), have a wide tissue and anatomical distribution, including the head, antennae, proboscis, thorax, legs, sub-cuticular epithelium, pheromone glands, and ejaculatory duct (Wanner et al. 2004). CSPs share no sequence similarity with OBPs.

Although technology for mass rearing and releasing of *S. guani* has been developed, little is known of the behavioral chemical relationship between *S. guani* and *M. alternatus*.

Fig. 2 Analysis of Sgua-OBP1 protein. (**a**) Nucleotide and deduced amino acid sequences of Sgua-OBP1. The N-terminal sequences are in *bold type*; the putative signal peptide is in *italics*, the start ATG and stop TAA codons are in *bold italics*. The positions of sense (3′RACE) and anti-sense (5′RACE) oligonucleotides used for PCR are indicated. The conserved cysteine residues are *highlighted with gray background*. (**b**) Deduced amino acid sequences of Sgua-OBP1 aligned with seven of its most homologous proteins identified using NCBI BLASTP from other insect species. The conserved cysteine residues are *highlighted with gray background*. (**c**) Neighbor-joining tree (condensed tree, cut-off value is 50%) of sequences similar to Sgua-OBP1. Sequences used in alignment were indicated with species abbreviations followed with taxon identification and accession number. Species abbreviations are: Aaeg: *Aedes aegypti*, Acer: *Apis cerana cerana*, Acup: *Anomala cuprea*, Agam: *Anopheles gambiae*, Amel: *Apis mellifera*, Aoct: *Anomala octiescostata*, Aoct: *Anomala octiescostata*, Aosa: *Anomala osakana*, Aper: *Antheraea pernyi*, Bmor: *Bombyx mori*, Cflo: *Copidosoma floridanum*, Eori: *Exomala orientalis*, Hpic: *Heptophylla picea*, Hvir: *Heliothis virescens*, Llin: *Lygus lineolaris*, Mdom: *Musca domestica*, Msex: *Manduca sexta*, Pdiv: *Phyllopertha diversa*, Pjap: *Popillia japonica*, Pxyl: *Plutella xylostella*, Rpal: *Rhynchophorus palmarum*, Sfru: *Spodoptera frugiperda*, Sgua: *Scleroderma guani*, and Tcas: *Tribolium castaneum*

As a first step toward this understanding, we identified and cloned two odorant-binding proteins (OBPs) and one chemosensory protein (CSP) from female *S. guani*.

Methods and Materials

Insects Scleroderma guani were mass reared in the laboratory by using the yellow mealworm beetle, *Tenebrio molitor* L. (Coleoptera: Tenebrionidae), as a host. The larvae were reared at 28°C and 70% RH; no light was needed. The adults were stored at 10°C after emergence until dissected. Only live insects were dissected.

Sample Preparation and Protein Extraction Live insects were anesthetized on ice. Female antennae and control tissues (head, thorax, abdomen, and legs) were dissected under the microscope by using forceps and immediately transferred into 1.5 ml Eppendorf tubes that were immersed in liquid nitrogen. Tissues were then stored at −70°C until used. For protein extraction, samples were homogenized in an ice-cold glass homogenizer with 20 mM Tris–HCl, pH 7.4, and then centrifuged twice at 12,500×*g* for 10 min at 4°C. The supernatants were evaporated under vacuum (EZ550Q, Ultralow Freezer System, FTS Systems Inc., Stone Ridge, NY, USA). Protein was quantified by the method of Bradford (1976). For each set of experiments, approximately 4,000 antennae, 100 legs, 40 heads, 20 thoraces, and 10 abdomens were analyzed by nondenaturing polyacrylamide gel electrophoresis [15% native-polyacrylamide gel electrophoresis (PAGE)]. The amounts of soluble protein loaded in each lane were approximately 55 μg for antennal extracts and 70 μg each for leg, head, thoracic, and abdominal extracts.

Electrophoresis and Protein Sequencing PAGE was carried out at 100 V (constant voltage) at 4°C. Gels were stained by 0.1% Coomassie brilliant blue R250 in 50% (*v*/*v*) methanol and 10% (*v*/*v*) glacial acetic acid with constant shaking for 2–3 hr and then rinsed with destaining solution (10% methanol, 10% glacial acetic acid). For N-terminal sequencing, proteins were analyzed as above, then electroblotted onto PVDF membranes (0.2 μm, Millipore, Billerica, MA,USA) for 1.5 hr at 40 mA (constant current) and 4°C. Membranes were stained with 0.1% Coomassie brilliant blue R250 in 50% (*v*/*v*) methanol, 7% (*v*/*v*) acetic acid. Bands of interest were carefully excised and processed for sequencing by

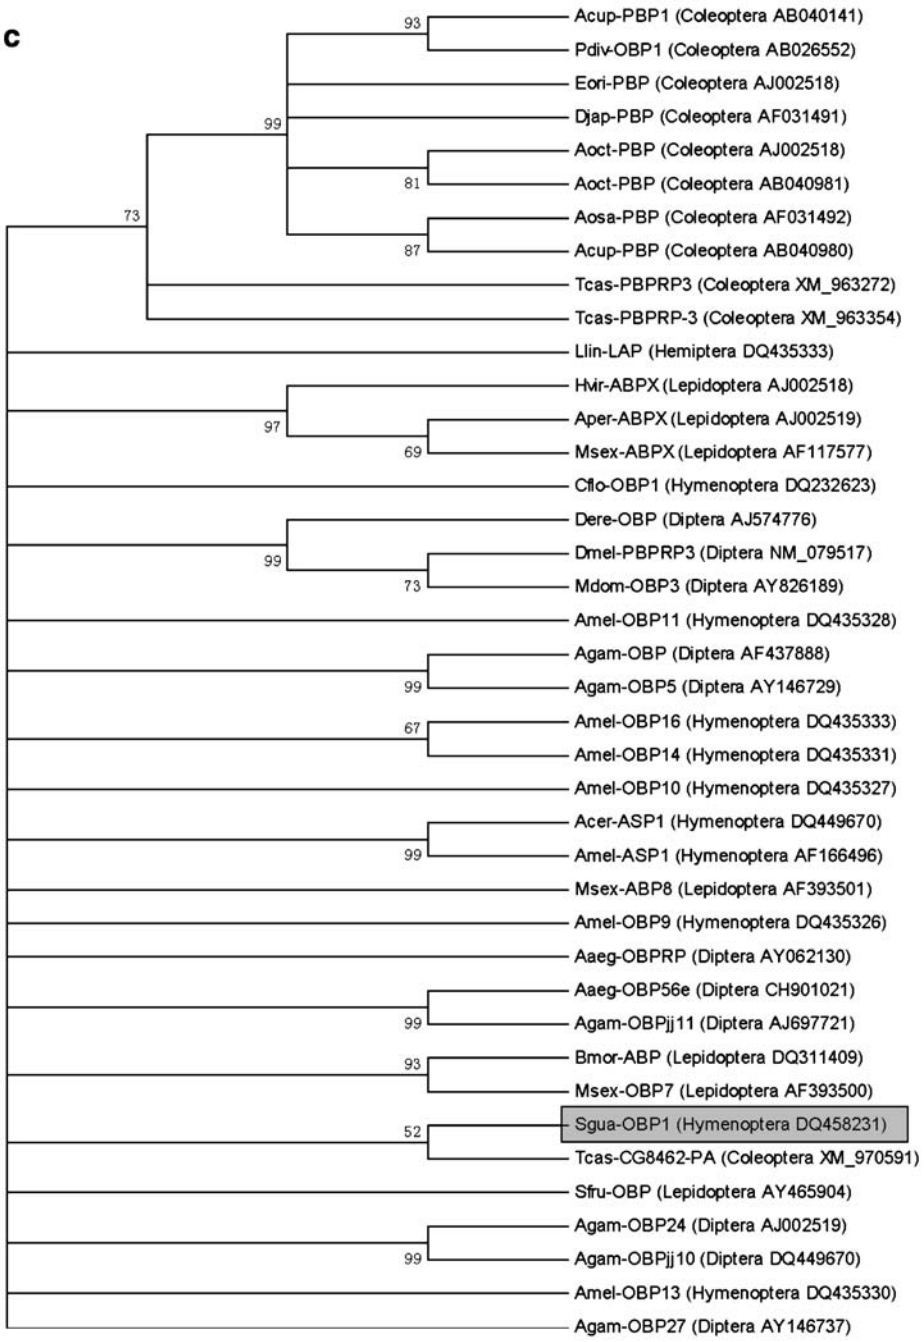

Fig. 2 (continued)

Edman degradation (the Procise® cLC Protein Sequencing System, Applied Biosystems, Shanghai GeneCore BioTechnologies Co., Ltd., Shanghai, China).

RNA Extraction, cDNA Synthesis, and 3′ and 5′ Rapid Amplification of cDNA Ends PCR Total RNA was extracted from 150 female antennae with Tri-Reagent (MRC, Cincinnati, OH, USA) according to the recommended protocol. The first strand cDNA was synthesized by using 3′-full rapid amplification of cDNA ends (RACE) core set (Takara, Dalian, China) according to the manufacturer's protocol. The reaction mixture contained 10 mM $MgCl_2$, deoxyribonucleotide triphosphate (diethylnitrophenyl thiophosphate (dNTP)) mixture (1 mM each), 0.25 U/μl AMV Reverse Transcriptase XL, 1 U/μl RNase inhibitor, 0.125 μM Oligo dT-3 site Adaptor Primer (Takara), template RNA, and sterile water, to a final volume of 20 μl. Polymerase chain reaction (PCR) with the reaction mixture for cDNA synthesis was performed as follows: 30°C (10 min), 50°C (30 min), 95°C (5 min), and 5°C (5 min) (Biometra Tgradient PCR thermocycler, Biometra GmbH i. L., Göttingen, Germany).

3′RACE-PCR Approximately 1 ng of cDNA from female antennae was used for 3′RACE-PCR. Degenerate sense primers were designed on the basis of the protein N-terminal sequences (Table 1) and synthesized by Bio Basic Inc. (Shanghai, China). These primers were used in a pair with an antisense Adapter Primer (Table 1) according to Oligo dT-3 site Adapter Primer in the 3′full RACE core set (Takara). PCR was performed with the following reaction mixture: 1×Ex Taq Buffer (Mg^{2+} free), 2.5 mM $MgCl_2$, 0.2 mM dNTP, 1.5 μM sense primer, 0.2 μM antisense primer, 0.05 U/μl TaKaRa Ex Taq™ Hot Start Version (Takara) in 100 μl reaction volume. Reactions were performed on a Biometra Tgradient PCR thermocycler: 94°C (8 min); 5 cycles of 94°C (30 sec), 37°C (1 min), 2 min ramp, 72°C (1 min); followed by 30 cycles of 94°C (30 sec), 43°C (1 min), 2 min ramp, 72°C (1 min); and, finally, 72°C (10 min). The amplified cDNAs were purified after agarose electrophoresis by using TaKaRa Agarose Gel DNA Purification Kit Ver.2.0 (Takara) and ligated into a pGM-T Vector by using TOP10 Competent Cells (Tiangen Biotech Co., Ltd., Beijing, China). After transformation, positive clones were analyzed by PCR using vector specific primers. Clones of interest were amplified and plasmid DNAs were purified and sequenced in both directions with an ABI 3730 DNA Analyzer (Applied Biosystems, BGI LifeTech Co., Ltd., Beijing, China). Three independent clones for each of the proteins were sequenced to detect possible PCR mutations.

5′RACE-PCR 5′ cDNA sequences were obtained by using FirstChoice® RLM-RACE Kit (Ambion, Foster City, CA, USA) following the recommended protocol. Gene-specific antisense primers were designed from the results of the 3′RACE procedure (Table 1). These primers were used in a pair with a 5′ RACE Outer Primer (FirstChoice® RLM-RACE Kit) as the sense primer (Table 1). Reaction conditions for PCR were: 94°C (4 min); 30 cycles of 94°C (30 sec), 60°C (45 sec), 72°C (45 sec); and finally, 72°C (10 min). The Purified PCR products were ligated into pGM-T and positive clones were sequenced as described above.

Results

Protein Identification and Cloning Crude protein extracts from female antennae were analyzed by native PAGE. To better understand any differences in relative abundances of the target proteins in the various tissues, a greater amount of total protein was loaded for the leg, head, thoracic, and abdominal extracts. Hypothetically, we expected the target proteins

to be more abundant in the antennal extracts, so we hoped to increase the probability of visualizing them in the other tissue extracts if they were present. Coomassie blue staining revealed three bands in female antennal extracts that were tentatively identified as OBPs or CSPs (Fig. 1). These three bands represented highly mobile (i.e., likely small molecular weight proteins). One of them was antennal specific, whereas the other two bands suggested higher abundances in antennal extracts than in those from other tissues. The bands of interest were cut out after electroblotting onto PVDF membranes (0.2 μm, Millipore), and N-terminal sequenced: LSEADVAE (Sgua-OBP1), ADNDDPFESTRFK (Sgua-OBP2), and QESTPEYYTGKWN (Sgua-CSP1).

Full length sequences were obtained from 3′ and 5′ RACE-PCR, and all three were sent to GenBank for BLAST analysis. Two clones coded for members of OBP family; one coded for a member of the CSP family. They were named *Sgua-OBP1*, *Sgua-OBP2*, and *Sgua-CSP1*, respectively, and deposited in GenBank under the accession numbers DQ458231 (Sgua-OBP1 cDNA); DQ458232 (Sgua-OBP2 cDNA), DQ458233 (Sgua-CSP1 cDNA).

Characterization of Sgua-OBP1 The open reading frame (ORF) of Sgua-OBP1 encodes a 133 amino acid protein (Fig. 2a). Application of SignalP 3.0 http://www.cbs.dtu.dk/services/SignalP/) predicted that Sgua-OBP1 has an 18-residue hydrophobic signal peptide and that the mature protein contains 115 amino acid residues. The predicted signal peptide sequence matches the N-terminal amino acid sequence of the isolated protein. The theoretical p*I* (isoelectric point) and Mw (molecular weight) of the mature protein were computed by Compute p*I*/Mw http://www.expasy.org/tools/pi_tool.html). The p*I* is 4.92 and the Mw is 12,606.50. BLAST database analysis on Sgua-OBP1 indicated significant identities with previously described OBPs from other insects. The highest identity was 39% with the protein of Tcas-CG8462-PA (similar to CG8462-PA predicted by automated computational analysis, Coleoptera: *Tribolium castaneum*, Accession number: XM_970591); the next highest identity was 31% with the protein of Amel-OBP13 (Hymenoptera: *Apis mellifera*, Accession number: DQ435330). The alignment of Sgua-OBP1 and its homologs (Fig. 2b) was conducted in ClustalX (Thompson et al. 1997). The neighbor-joining tree for Sgua-OBP1 (Fig. 2c) and for Sgua-OBP2 and Sgua-CSP1 (see below, Figs. 3c and 4c) were constructed using MEGA version 3.1 (Kumar et al. 2004).

Characterization of Sgua-OBP2 The ORF of Sgua-OBP2 encodes a 142-amino acid protein (Fig. 3a). SignalP predicted that Sgua-OBP2 has a 20 residue hydrophobic signal peptide and

Fig. 3 Analysis of Sgua-OBP2 protein. (**a**) Nucleotide and deduced amino acid sequences of Sgua-OBP2. The N-terminal sequences are in *bold type*; the putative signal peptide is in *italics*, the start ATG and stop TGA codons are in *bold italics*. The positions of sense (3′RACE) and anti-sense (5′RACE) oligonucleotides used for PCR are indicated. The conserved cysteine residues are *highlighted with gray background*. (**b**) Deduced amino acid sequences of Sgua-OBP2 aligned with seven of its most homologous proteins identified using NCBI BLASTP from other insect species. The conserved cysteine residues are *highlighted with gray background*. (**c**) Neighbor-joining tree (condensed tree, cut-off value is 50%) of sequences similar to Sgua-OBP2. Sequences used in alignment were indicated with species abbreviations followed with taxon identification and accession number. Species abbreviations are Aaeg: *Aedes aegypti*, Acer: *Apis cerana cerana*, Acup: *Anomala cuprea*, Agam: *Anopheles gambiae*, Amel: *Apis mellifera*, Aoct: *Anomala octiescostata*, Aosa: *Anomala osakana*, Aper: *Antheraea pernyi*, Cqui: *Culex pipiens quinquefasciatus*, Eori: *Exomala orientalis*, Hpic: *Heptophylla picea*, Hvir: *Heliothis virescens*, Msex: *Manduca sexta*, Pdiv: *Phyllopertha diversa*, Pjap: *Popillia japonica*, Rpal: *Rhynchophorus palmarum*, Sexi: *Spodoptera exigua*, Sfru: *Spodoptera frugiperda*, Sgua: *Scleroderma guani*, Slit: *Spodoptera litura*, Snon: *Sesamia nonagrioides*, Tcas: *Tribolium castaneum*, and Znev: *Zootermopsis nevadensis*

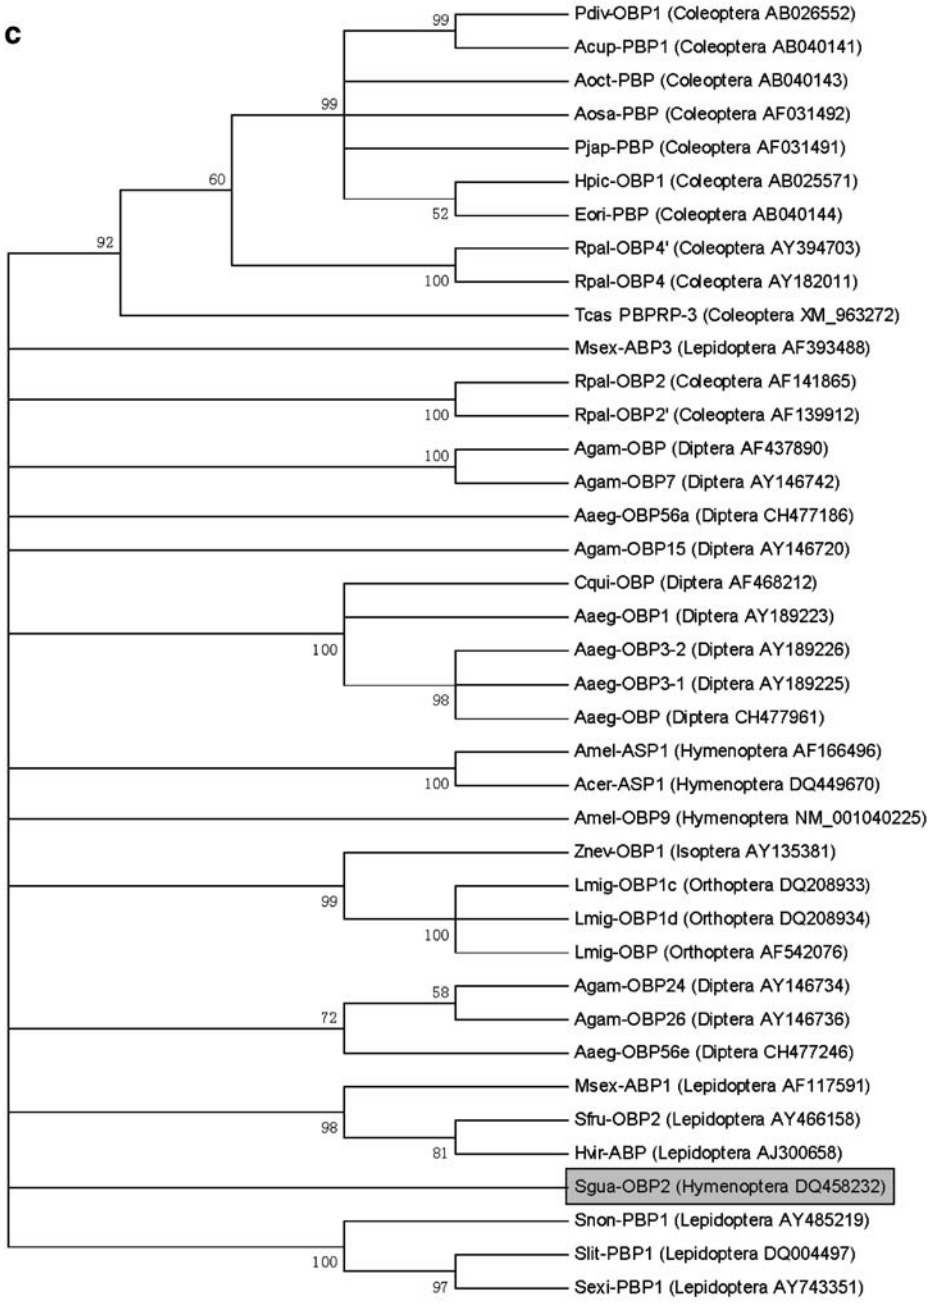

Fig. 3 (continued)

that the mature protein contains 122 amino acid residues. The predicted signal peptide sequence matches the N-terminal amino acid sequence of the isolated protein. The theoretical p*I* (isoelectric point) and Mw (molecular weight) of the mature protein are 4.39 and 14,041.91, respectively. BLASTP analysis also indicated that Sgua-OBP2 is homologous to insect OBPs, but the identities are quite low. The highest identity was less than 30% (Pdiv-OBP1, Coleoptera: *Phyllopertha diversa*; Accession number: AB026552) (Fig. 3b). The alignment between Sgua-OBP1 and Sgua-OBP2 by using matrix of BLOSUM62 (Henikoff and Henikoff 1992) showed no significant similarity (data not shown).

Characterization of Sgua-CSP1 The ORF of Sgua-CSP1 encodes a 129-amino acid protein (Fig. 4a). SignalP predicted a 20-residue hydrophobic signal peptide and that the mature protein contains 109 amino acid residues. The predicted signal peptide sequence matches the N-terminal amino acid sequence of the isolated protein. The theoretical p*I* (isoelectric point) and Mw (molecular weight) of the mature protein are 5.95 and 13,096.95, respectively. BLASTP analysis indicated that Sgua-CSP1 is homologous to other insect CSPs (Fig. 4b). The highest identity with another CSP is 36% (Vcra-CSP, Hymenoptera: *Vespa crabro*, Accession number: AY803290).

Discussion

Generally, OBPs are considered to be antennal-specific, whereas CSPs are widely distributed throughout the body, including the head, antennae, proboscis, thorax, legs, sub-cuticular epithelium, pheromone glands, and ejaculatory duct (Wanner et al. 2004). However, an antennal-specific CSP has been reported in the Argentine ant (Ishida et al. 2002b). Calvello et al. (2003, 2005) also reported an antennal-specific CSP and an OBP expressed in legs and wings in the wasps, *Polistes dominulus* and *Vespa crabro*. In our work, three proteins originally isolated from the female antennae of *S. guani* were expressed differently. The protein Sgua-OBP1 was antennal specific in females; Sgua-OBP2 was present in the antennae and head; and Sgua-CSP1 was distributed broadly throughout the whole insect body. However, native PAGE analysis (Fig. 1) indicated that both Sgua-OBP1 and Sgua-CSP1 were more abundant in antennal extracts than in extracts from any of the other body tissues that we analyzed. In pilot studies (data not shown), extracted protein was loaded for native PAGE by allocating the same quantities (approximately 55 μg) to each lane. The resulting gel showed very weak bands corresponding to Sgua-OBP2 in head and to Sgua-CSP1 in legs, head, thorax and abdomen, respectively. Further research by using immunochemical methods will be necessary to demonstrate more fine structure anatomical expression for these three proteins.

OBPs are usually expressed in sensillar support cells and secreted by these cells into the aqueous sensillar lumen. The proteins have ranged from 120 to 150 amino acids in length and have a mass of approximately 14 kDa. OBPs contain six cysteine residues that form disulfide bonds (a hallmark of OBPs) to stabilize the functionally relevant three-dimensional structure of the protein (Leal et al. 1999; Briand et al. 2001; Horst et al. 2001a, b). CSPs contain 100 to 110 amino acid residues, but have four conserved cysteine residues and six á-helices (Campanacci et al. 2001a, b, 2003). They share no sequence similarity to OBPs. The mature proteins of Sgua-OBP1, Sgua-OBP2, and Sgua-CSP1 are 115, 122, and 109 amino acids in length, and 12, 14, and 13 kDa in mass, respectively. The

Fig. 4 Analysis of Sgua-CSP1 protein. (**a**) Nucleotide and deduced amino acid sequences of Sgua-CSP1. The N-terminal sequences are in *bold type*; the putative signal peptide is in *italics*, the start ATG and stop TAA codons are in *bold italics*. The positions of sense (3′RACE) and anti-sense (5′RACE) oligonucleotides used for PCR are indicated. The conserved cysteine residues are *highlighted with gray background*. (**b**) Deduced amino acid sequences of Sgua-CSP1 aligned with its most homologous protein identified using NCBI BLASTP from other insect species. The conserved cysteine residues are *highlighted with gray background*. (**c**) Neighbor-joining tree (condensed tree, cut-off value is 50%) of sequences similar to Sgua-CSP1 Sequences used in alignment were indicated with species abbreviations followed with taxon identification and accession number. Species abbreviations are Acer: *Apis cerana cerana*, Agam: *Anopheles gambiae*, Amel: *Apis mellifera*, Bmor: *Bombyx mori*, Cfum: *Choristoneura fumiferana*, Cson: *Culicoides sonorensis*, Dmel: *Drosophila melanogaster*, Gori: *Gryllotalpa orientalis*, Hass: *Helicoverpa assulta*, Hvir: *Heliothis virescens*, Hzea: *Helicoverpa zea*, Lmad: *Leucophaea maderae*, Lmig: *Locusta migratoria*, Lobl: *Lonomia oblique*, Mdir: *Metopolophium dirhodum*, Mper: *Myzus persicae*, Msex: *Manduca sexta*, Mvic: *Megoura viciae*, Nrib: *Nasonovia ribis-nigri*, Sgre: *Schistocerca gregaria*, Sgua: *Scleroderma guani*, Slit: *Spodoptera litura*, Tcas: *Tribolium castaneum*, and Vcra: *Vespa crabro*

only point of divergence of our OBPs and CSP from the criteria listed above is that Sgua-CSP1 contains six cysteine residues, instead of the typical four. However, Sgua-CSP1 is not homologous to OBPs from other insects and shares high identity with previously described CSPs, so we have placed it in this group. Further research on the crystal structure and binding properties by NMR will help to clarify the function of this protein.

Database searches suggest that the Sgua-OBP1 and Sgua-OBP2 are homologs of the OBPs from other insects and that Sgua-CSP1 shares more identity with previously described CSPs. However, the identities are all quite low and the neighbor-joining tree analyses of sequences also show very low similarity with other proteins (Figs. 2c, 3c, and 4c). A search of the Protein Family Database http://www.sanger.ac.uk/Software/Pfam/) revealed that approximately 529 OBPs and 183 CSPs have been identified/cloned so far. There are 5 OBPs and 3 CSPs from Dictyoptera; 3 CSPs from Phasmatodea; 3 OBPs and 46 CSPs from Orthoptera; 142 OBPs and 57 CSPs from Lepidoptera; 32 OBPs and 3 CSPs from Coleoptera; 63 OBPs and 12 CSPs from Hymenoptera; 1 CSP from Siphonaptera; 281 OBPs and 31 CSPs from Diptera; 1 CSP from Phthiraptera; and 3 OBPs and 26 CSPs from Hemiptera. Sgua-OBP1, Sgua-OBP2, and Sgua-CSP1 are the first in these groups to be identified from an ectoparasitic wasp, which may explain why these three proteins have quite low identities with other known OBPs and CSPs, which have been isolated and identified primarily from phytophagous insects. Insect predators and parasitoids may locate the adult host by eavesdropping on the sex pheromones emitted by host or may locate the larval host by exploiting the "alarm signals" produced and released by injured plant.

Usually, the sex ratio in *S. guani* is biased in favor of females (17 to 1 female to male). Males only survive several days to copulate (Chen and Cheng 2000). In contrast, female *S. guani* survive much longer to find hosts. We hypothesize that OBPs and CSPs may be differentially expressed in males and females, but it is very difficult to collect males for investigation, so males were not included in the first part of this investigation. In the future, we plan to focus on the identification and cloning of olfactory proteins from male *S. guani*. This will help in determining the specificity of the proteins discussed in this paper and may help to explain their function. Further studies may also include monitoring the expression of the OBPs and CSPs during the life cycle.

Acknowledgments This work was supported by the China National Basic Research Program (973 Program) of Invasion Biology and Control Strategies for Alien Species in Agriculture and Forestry (2002CB111407). We also thank Dr. Patricia Nagnan-Le Meillour (INRA, Versailles, France) for her advice with this work.

these FAAs were not found in ten of the insects studied here, their identification in two additional orders of insects suggests that FAAs are more common than previously reported and may have physiological roles in a wide range of insects besides caterpillars.

Keywords Volicitin · Lepidoptera · *Drosophila* · Teleogryllus · Larvae · Elicitors · LCMS-IT-TOF · Fatty acid amides · Volicitin

Introduction

Volicitin and its related analogs, generically called fatty acid amides (FAAs), were first identified as elicitors that induce plant volatile emission in the context of plant–herbivore interactions (Alborn et al. 1997). The mechanism by which volicitin triggers the systemic release of volatiles by corn plants has been studied in detail (Truitt et al. 2004), but how and why plants have evolved such a complex chemical signaling response to compounds of herbivore origin continues to engage researchers. Equally intriguing from an evolutionary perspective, volicitin and other FAAs exist in the oral secretions of some caterpillar species despite the propensity of some FAAs to elicit volatile emission in plants, thus, ultimately attracting the caterpillar's natural enemies. Lait et al. (2003) reported a key enzyme involved with the biosynthesis of *N*-linolenoyl-L-glutamine, a structural analog of volicitin, in alimentary tissues of *Manduca sexta* larvae. Our recent study of volicitin synthesis by *Spodoptera litura* revealed that glutamine is selectively incorporated into FAAs even though other amino acids are also found in the hemolymph and lumen of the gut (Yoshinaga et al. 2005). This suggests that FAAs could be involved with glutamine metabolism, and we hypothesize that they likely play a fundamental role in the physiology of lepidopteran larvae by virtue of their occurrence in multiple species (Alborn et al. 1997, 2003; Pare et al. 1998; Pohnert et al. 1999; Halitschke et al. 2001; Mori et al. 2001, 2003). Thus far, the search for FAAs has been limited to a small number of caterpillar species. The objective of this study was to search for FAAs in orders of insects other than Lepidoptera. We performed liquid chromatography/mass spectrometry-ion trap-time-of-flight (LCMS-IT-TOF) analysis on extracts from five species of Orthoptera, three species each of Hemiptera and Hymenoptera, and one species each of Coleoptera and Diptera (Table 1).

Methods and Materials

Insect Material and Gut or Larval Extracts Laboratory strains of *Drosophila melanogaster* (Canton S, Oregon R) were reared on artificial diet Formula 4-24 (Carolina Biological Supply Co.) that was supplemented with α-linolenic acid (10 μl/6 g wet diet) to compensate for dietary deficiency. Final instars were removed from the diet, rinsed with distilled water, and blotted dry with a paper towel. Larvae (20 per sample) were boiled in a microcentrifuge tube for 20 min with 10 μl of distilled water to prevent FAA hydrolysis by endogenous enzyme(s). Whole larvae were homogenized in 50 μl of acetonitrile, containing 0.3 μg of *N*-palmitoleoyl-L-glutamine as an internal standard, and then centrifuged for 10 min at 13,000×*g* to obtain a supernatant for LCMS and LCMS-IT-TOF analysis. Adult *Teleogryllus taiwanemma* (laboratory strain) were fed a natural diet of gramineous weeds for 48 hr and then frozen. Other adult specimens of Orthoptera, Hemiptera, Hymenoptera, and Coleoptera were collected from the field and frozen immediately after taxonomic identification. Each of these insects was sliced longitudinally with a razor, and the frozen

midgut contents were transferred, by forceps, to microcentrifuge tubes. Midgut contents (approximately 30 μl) were boiled with 10 μl of distilled water, homogenized with 50 μl of acetonitrile, containing 0.3 μg of *N*-palmitoleoyl-L-glutamine, and centrifuged as described above to obtain a supernatant for LCMS and LCMS-IT-TOF analysis.

LCMS and LCMS-IT-TOF Analyses MS detection focused on ions at *m/z* 421, 422, 423, 424, 405, 406, 407, 408, 277, and 279, by using selected ion monitoring mode. Negative ESI mass spectral measurements were conducted with an LCMS-2010A instrument (Shimadzu, Kyoto) combined with an HPLC system (LC-10ADvp pump, CTO-10ACvp column oven, and SCL-10AVvp system controller; Shimadzu, Kyoto). A reverse-phase column (Mightysil RP-18 GP, 50×2.0 mm i.d.; Kanto Chemical Co., Inc., Tokyo) was eluted (0.25 ml min^{-1}) with a gradient of 20–95% acetonitrile, containing 0.08% acetic acid, in water containing 0.05% acetic acid, over 15 min with column temperature maintained at 40°C. Sample solutions containing FAAs were further analyzed by using a Prominence HPLC system coupled to LCMS-IT-TOF (Shimadzu, Kyoto). A Cosmosil 5C_{18}-AR-II column (50×2.0 mm i.d.; Nakalai Tesque, Kyoto) was eluted (0.2 ml min^{-1}) with a gradient of 20–90% acetonitrile, containing 0.08% acetic acid, in water containing 0.05% acetic acid, over 15 min with column temperature maintained at 40°C. The MS was

operated with probe voltage of 4.50 kV, CDL temperature of 200°C, block heater temperature of 200°C, nebulizer gas flow of 1.5 L min^{-1}, ion accumulation time of 10 msec, MS range of *m/z* 200 to 500, MS^2 range of *m/z* 100 to 500, CID parameters as follows: energy, 80%; collision gas, 100%. The precursor ions of volicitin, *N*-linolenoyl-L-glutamine, *N*-hydroxylinolenoyl-L-glutamic acid, *N*-linolenoyl-L-glutamic acid were *m/z* 421.27 (calculated for $C_{23}H_{37}N_2O_5^-$, 421.2702), 405.27 (calculated for $C_{23}H_{37}N_2O_4^-$, 405.2753), 422.27 (calculated for $C_{23}H_{36}NO_6^-$, 422.2543), 406.27 (calculated for $C_{23}H_{36}NO_5^-$, 406.2593), respectively. MS data were processed with LCMS solution ver. 3.4 software (Shimadzu).

Results and Discussion

From the thirteen non-lepidopteran insect species analyzed by LCMS, we determined that crickets (two species) and the fruit fly possess several kinds of FAAs (Table 1). These compounds were identified by comparison of their retention times and quasi-molecular ions with previously identified FAAs (standards) obtained from regurgitants of larval *S. litura* (Mori et al. 2003) and *M. sexta* (Alborn et al. 2003). *N*-Linolenoyl-L-glutamic acid (compound 7) was the main FAA component in extracts of *T. taiwanemma* (16.6±3.4 μg/insect, *N*=3) and *D. melanogaster* (8.9±1.7 μg/20 larvae, *N*=4). The quantity of *N*-linolenoyl-L-glutamic acid per mass of individual larva from each species was comparable with reported values for *M. sexta* (Alborn et al. 2003) or *N*-linolenoyl-L-glutamine in *S. litura* (unpublished).

For identification of FAAs found in crickets and fruit fly larvae, LCMS-IT-TOF analysis was conducted to obtain additional structural information. The following fragmentation ions were tentatively assigned: Volicitin, obtained from the regurgitant of larval *S. litura*, produces daughter ions at *m/z* 403.26 (dehydrated ion, calculated 403.2597), 385.25 (doubly dehydrated ion, calculated 385.2491), 315.24 (unknown), 231.21 (dehydrated and decarboxylated hydroxylinolenate ion, calculated 231.2113), and 145.06 (glutamine-derived ion, calculated 145.0614). *N*-Linolenoyl-L-glutamine produces daughter ions at *m/z* 387.27 (dehydrated ion, calculated 387.2648), 343.27 (further decarboxylated ion, calculated 343.2749), 233.23 (decarboxylated linolenate ion, calculate 233.2269), and 145.06 (glutamine-derived ion). *N*-Linolenoyl-L-glutamic acid, obtained from *M. sexta* regurgitant, produces daughter ions at *m/z* 388.25 (dehydrated ion, calculated 388.2488), 362.27 (decarboxylated ion, calculated 362.2695), and 277.22 (linolenic acid-derived ion, calculated 277.2168). The fragmentation pattern of FAAs containing glutamine, such as volicitin and *N*-linolenoyl-L-glutamine, typically includes a common glutamine-derived ion. Further MS analysis included manual scanning for daughter ions at *m/z* 277.22, 279.23, and 145.06, corresponding to other linolenoyl-, linoleoyl-, or glutamine conjugates. However, we could not detect any ions suggesting the presence of the related conjugates.

Figure 1 shows MS total ion chromatograms (TICs) with extracted ion chromatograms (XICs) of FAAs obtained from *T. taiwanemma* and *D. melanogaster* and MS^2 mass spectra with corresponding structures of FAAs obtained from *D. melanogaster* larvae. The spectra of *N*-linolenoyl-L-glutamic acid (d) and *N*-linolenoyl-L-glutamine (c) were nearly identical to those of authentic standards. Furthermore, *N*-linoleoyl-L-glutamic acid (e) was identified by its fragmentation pattern, which agreed reasonably with that of *N*-linolenoyl-L-glutamic acid (d). As the volicitin content was too low to yield fragment ions with enough intensity to measure accurately, only the dehydrated ion (*m/z* 403) and glutamine-derived ion (*m/z* 145) were detected along with ions from impurities (a). Spectrum (b) represents an

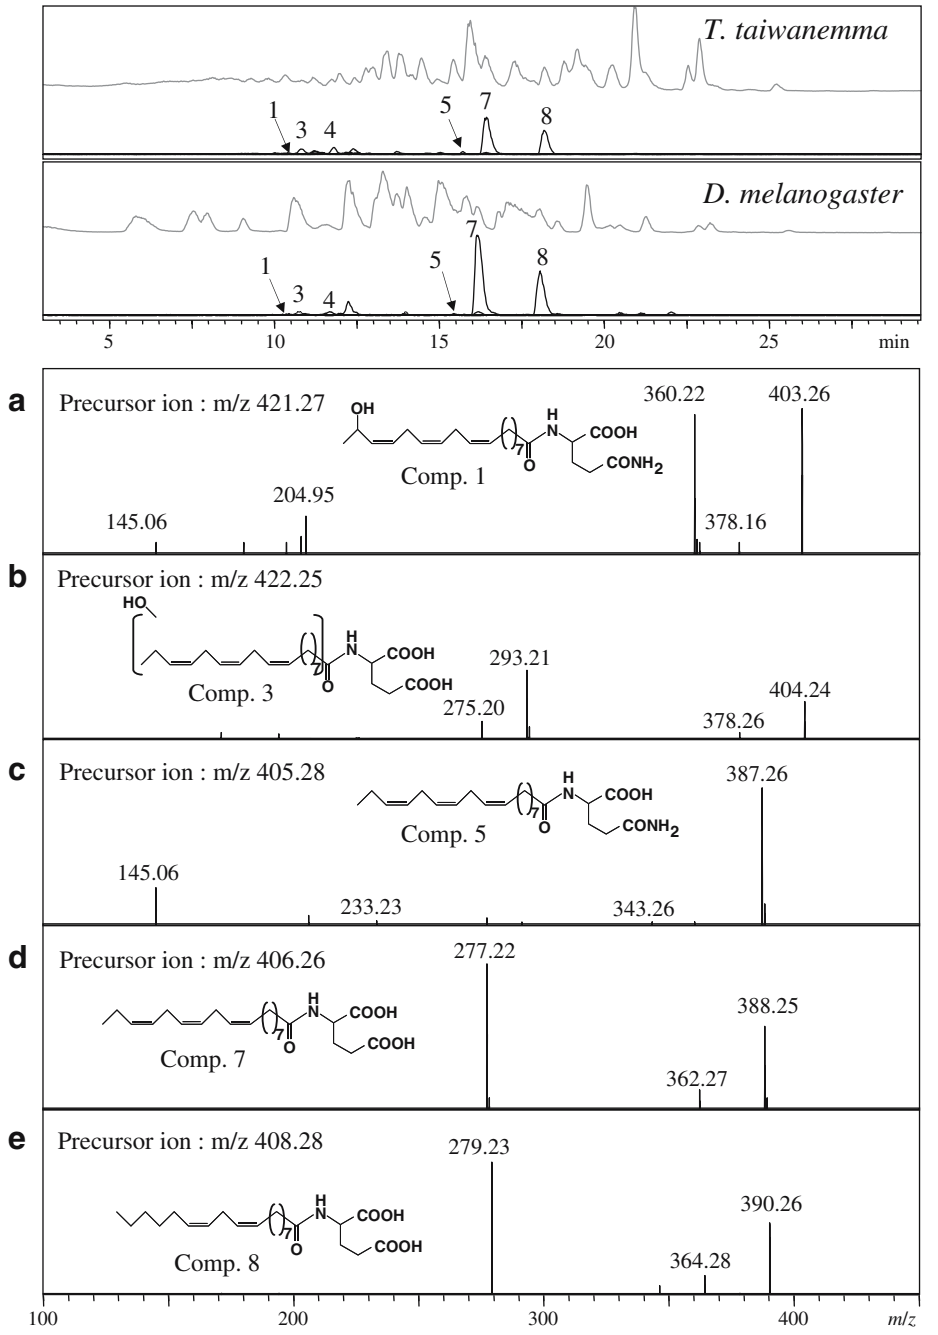

Fig. 1 Mass spectral total ion chromatograms and extracted ion chromatograms of FAAs obtained from *T. taiwanemma* and *D. melanogaster* and MS^2 spectra and structures of **a** volicitin, **b** *N*-hydroxylinolenoyl-L-glutamic acid, **c** *N*-linolenoyl-L-glutamine, **d** *N*-linolenoyl-L-glutamic acid, and **e** *N*-linoleoyl-L-glutamic acid found in the *D. melanogaster* larval extracts (structural analysis incomplete). The compound numbers represent the same compounds as those in Table 1

incompletely characterized FAA, which is thought to be *N*-hydroxylinolenoyl-L-glutamic acid (theoretical *m*/*z* 422.2543), as a presumed quasi-molecular ion appears at *m*/*z* 422.25. The fragmentation pattern agreed with the expected structure; dehydrated ion at *m*/*z* 404.24, doubly dehydrated ion at *m*/*z* 378.26, hydroxylinolenic acid-derived ion at *m*/*z* 293.21, and its dehydrated ion at *m*/*z* 275.20. When *D. melanogaster* larvae were reared on linolenic acid-supplemented artificial diet, peaks corresponding to FAAs containing a linolenic acid moiety had greater intensities and were more easily identified. However, it is not clear whether these FAAs came only from the larval gut. A compound with the same mass fragment patterns (not shown) was also found in the midgut contents of both cricket species. The absolute configuration and position of hydroxylation of the fatty acid moiety in the hydroxylated FAAs have yet to be confirmed. However, these findings are significant, as they indicate that FAAs might have physiological roles in additional orders of insects besides Lepidoptera. Halitschke et al. (2001) postulated that FAAs might simply act as biosurfactants or oil emulsifiers in the caterpillar gut, and indeed, this hypothesis may be applicable to crickets and fruit flies. However, the facts that FAAs identified thus far contain glutamic acid and/or glutamine, but not other amino acids, and hydroxylated FAAs are present in species from at least three different orders, suggest that a specific rather than general function in insect metabolism could also exist. As yet, we have no definitive explanation for their presence.

life for myrmecophiles is also dangerous, as ants are usually highly aggressive toward non-colony members. One way to avoid aggression by ants is to mimic the ants' chemical communication code, i.e., chemical mimicry. According to Vane-Wright (1976) and Dettner and Liepert (1994), chemical mimicry is characterized by an organism (mimic) that simulates volatile or nonvolatile chemical signals of a second living organism (model), which in turn are perceived as signals of interest by a third living organism (operator). In this way the mimic gains fitness because the operator identifies it as an example of the model. In the ant–myrmecophile system, the myrmecophile acts as the mimic, and the ant acts both as model and operator (bipolar system).

The cues generally used in chemical mimicry by myrmecophiles are cuticular hydrocarbons (CHC). In social insects, these substances are generally considered to be the main cues used for nest-mate recognition (Howard and Blomquist 2005). A number of studies indicate that myrmecophilous insects accumulate CHCs on their body surface that qualitatively and quantitatively resemble the CHC pattern of their host ants, thereby manipulating the nest-mate recognition system, and achieving integration into the host colony (e.g., Akino 2002; Elgar and Allan 2004; see reviews by Dettner and Liepert 1994; Howard and Blomquist 2005). Despite the advantages, chemical mimicry of CHCs is also problematic, as it restricts the myrmecophilous insect to just one host nest. Integration into other nests (e.g., to find mates) is risky because adaptation to a new nest-specific CHC pattern takes time, during which the intruder is detectable (Akino et al. 1996).

The imitation of CHCs used in nest-mate recognition might not be the only way for myrmecophilous insects to deceive their hosts. Kistner and Blum (1971) suggested that rove beetles of the genus *Pella* (Staphylinidae: Aleocharinae) produce and release alarm pheromone compounds of their host ants to their own advantage. This hypothesis was based on the observation that crushed individuals of two species of *Pella* and their host ant *Lasius spathebus* gave similar olfactory profiles (Kistner and Blum 1971). Later, this idea was supported by studies that revealed the presence of undecane and 6-methyl-5-hepten-2-one (sulcatone) in the tergal gland secretions of other myrmecophilous *Pella* species (Steidle and Dettner 1993). A tergal gland is present in most myrmecophilous and free-living beetles of the Aleocharinae and is used for defense against ants and other predators (Steidle and Dettner 1993). Undecane and sulcatone occur in two alarm pheromone glands of the beetle's host ant, *Lasius fuliginosus*, the Dufour and the mandibular gland, respectively (Maschwitz 1964; Bernardi et al. 1967). *Pella* beetles, formerly included in the genus *Zyras* (Kistner 1971; Maruyama 2006), live along the foraging trunk routes of *L. fuliginosus* where they prey on living ants or feed on dead ants present in the ants' garbage dumps. When encountering ants, these beetles either show a death-feigning position or, more frequently, present their abdominal tip to the ants. Generally, this behavior prompts the ant to inspect the abdominal tip and allows the beetle to escape. Only in persistent, aggressive inspections does the beetle release its tergal gland secretion, which repels the attacking ant (Hölldobler et al. 1981). This interaction raises the question, how does the beetle gain an advantage from the release of ant alarm pheromone compounds in this situation?

Generally, alarm pheromones in ants serve two different functions (Wilson and Regnier 1971). One of them, the "aggressive alarm", leads to recruitment of more workers and intensified attacks on intruders. The other, the "panic alarm", leads to escape, dispersion, and flight. Whereas the release of aggressive-alarm pheromones seems to be counterproductive for the beetles, the mimicry of panic-alarm pheromones could provide immediate short-term protection in aggressive interactions. This mode of chemical mimicry contrasts with the chemical mimicry of CHCs, which are nonvolatile and provide sustained acceptance in a host colony. This is analogous to volatile "propaganda" pheromones, which are involved in

interspecific interactions of ant species, like slave-making and nest usurpation (Regnier and Wilson 1971; Lenoir et al. 2001).

Experiments by Dumpert (1972) showed that undecane induces aggressive-alarm behavior in *L. fuliginosus.* We hypothesized that sulcatone could mimic a panic-alarm pheromone in *L. fuliginosus* when used by *Pella* beetles to repel their attacking hosts. To examine this hypothesis we: (1) re-analyzed the contents of the tergal gland secretions of two *Pella* beetles, *P. funestus* and *P. humeralis*, and studied the effect of (2) pure undecane and sulcatone, and (3) sulcatone in combination with other compounds of the tergal gland secretions on workers of *L. fuliginosus* in laboratory and field experiments.

Methods and Materials

Insects Beetles were obtained from eight different colonies of *L. fuliginosus* in southwest Germany by collecting substrates around ant nests and sorting out litter on a white underground. The beetles were reared in plastic Petri dishes (diameter 90 mm) at room temperature under daylight (Schminke 1978). Petri dishes were filled with a 5-mm plaster layer, which was moistened daily to maintain humidity. In addition, a small piece of filter paper was provided as shelter. Beetles were fed every second day with dead *L. fuliginosus* workers. *L. fuliginosus* ants were collected in the field at the same sites as the beetles, reared in plastic containers (50.2×35.5×17 cm or 50.2×35.5×25.5 cm), and supplied with aqueous sucrose or honey solution (Maschwitz and Hölldobler 1970). Bhatkar diet was provided every second day to supply the ants with proteins, minerals, and vitamins (Bhatkar and Whitcomb 1970). All insects were identified to species level with the identification keys by Freude et al. (1974) for beetles and Seifert (1996) for ants.

Chemical Analysis of the Tergal Gland Secretions and Ant Alarm Pheromones Volatile tergal gland secretions of the beetles and ant pheromones were collected from the headspace of the organisms by using a solid-phase microextraction (SPME) needle coated with 65 μm Polydimethylsiloxane/Divinylbenzene (Arthur and Pawliszyn 1990). Single beetles were placed in a 60-ml glass flask, and the SPME-fiber was inserted through a rubber plug. To stimulate the release of tergal gland secretion, beetles were stimulated with a magnetic stir bar, which was carefully moved from the outside of the flask toward the beetles with a magnetic stick. After a 10-min adsorption time, the fiber was removed from the flask and placed for 2 min into the heated (250°C) injection port of an Agilent Technologies 6890 gas chromatograph (GC) coupled with a 5973 network mass selective detector. The GC was equipped with a fused-silica-capillary column (HP 5, 30 m×0.2 mm, 0.5 μm film thickness) and programmed as follows: 60°C for 3 min., 60°C to 300°C at 3°C min^{-1}. Helium, at a constant 1.6 ml min^{-1}, was the carrier gas. Chromatographs and mass spectra were analyzed by Enhanced Chemstation software (Agilent technologies) by using Wiley 275 and NIST 2002 databases. For quantitative analyses, calibration curves with synthetic undecane (Aldrich Chemical Co.; purity 99+%), *p*-benzoquinone (Merck & Co;, purity: ≥98%), *p*-toluquinone (Merck & Co., purity: >98%), and 6-methyl-5-hepten-2-one (Aldrich Chemical Co., purity: 99%), from 1 to 30 μg, were generated. The calibration curve of *p*-toluquinone was used to estimate the amount of 2-methoxy-3-methyl-1,4-benzoquinone. Data obtained from these analyses were used to estimate the appropriate concentrations to be used in the bioassays. Six specimens were analyzed for each beetle species. To validate the artificial stimulation, the analysis was repeated with

single beetle specimens together with three workers of *L. fuliginosus*. To study the release of alarm pheromones by the ants, three workers of *L. fuliginosus* were tested under the same conditions.

Role of Sulcatone and Undecane as Alarm Pheromones In a first experiment, we determined whether sulcatone acts as an attractant or repellent on *L. fuliginosus* workers by using feeding tests in the laboratory. Thirty workers of *L. fuliginosus* were placed in a Petri dish without food. After 2 d, an aqueous solution of sucrose (1:1 *w*/*w*) was placed on a feeding platform in the center of the Petri dish next to a piece of filter paper (Whatman Grade I). When at least 10 ants were feeding simultaneously on the sugar water, 10 μl of sulcatone (0.1 μg/μl dissolved in hexane) were applied to the filter paper, and the number of ants at the feeding source counted every 15 sec for 120 sec.

To test the potential alarm pheromone effect of sulcatone and undecane on ant workers in the field, filter paper balls (1 × 1 cm; Whatman Grade I) were treated with 10-μl test solutions and placed on natural foraging trunk routes of *L. fuliginosus*, some 0.5–1.5 m from the nest entrance. Test solutions consisted of undecane (0.42 μg/μl in hexane), sulcatone (0.13 μg/μl in hexane), or hexane (control). The reactions of ants were videotaped for 90 sec, and analyzed later. Behavior was considered aggressive when ants touched the filter paper ball with both antennae and open mandibles or when they were biting into it. Antennation, i.e., touching the filter paper ball with both antennae and closed mandibles, was considered as nonaggressive behavior. The number of ants on the trunk trails varied during the different experimental dates at the different sites. Therefore, the number of passing ants was recorded for 1 min before each test and used to calculate the percentage of reacting ants in relation to the overall number of passing ants.

Effect of Sulcatone Added to Other Compounds Found in the Tergal Gland In the first experiment in the laboratory, 10 ants were placed in a Petri dish with a filter paper ball (see above) in the center. The filter paper ball was treated with one of the following test solutions in hexane: (1) undecane (0.42 μg/μl); (2) *p*-toluquinone (0.39 μg/μl) plus *p*-benzoquinone (0.06 μg/μl); (3) undecane (0.42 μg/μl) and sulcatone (0.13 μg/μl); (4) *p*-toluquinone (0.39 μg/μl), *p*-benzoquinone (0.06 μg/μl), and sulcatone (0.13 μg/μl); (5) hexane (control). A second experiment was performed in the field with filter paper balls placed on foraging trunk routes of *L. fuliginosus* as described above. Two different mixtures (Mix+ and Mix−) of the main tergal gland secretion compounds were applied to the filter paper balls. The concentrations used matched the average composition of the tergal secretion of the two *Pella* species found during beetle–ant interactions in the laboratory. Mix+ consisted of *p*-benzoquinone (0.06 μg/μl), *p*-toluquinone (5.05 μg/μl), undecane (3.09 μg/μl), sulcatone (1.46 μg/μl), and tridecane (0.15 μg/μl). Mix− was similar to Mix+ but without sulcatone. Hexane was used as a control.

Statistics The results of the behavioral assays were analyzed by Mann–Whitney *U* tests followed by sequential Bonferroni correction using the software package STATISTICA 99-Edition. (Stat Soft Inc.)

Results

Chemical Analysis of Tergal Gland Secretions and Ant Alarm Pheromones Twelve different substances were identified in the headspace collections of *Pella* beetles after stimulation with

either a magnetic stir bar or by aggressive ant–beetle interactions. In both *Pella* species, large amounts of sulcatone, *p*-toluquinone, undecane, and 2-methoxy-3-methyl-1,4-benzoquinone were found (Fig. 1, Table 1). Large amounts of undecane and dendrolasin were found in the headspace collections of *L. fuliginosus* workers that had been teased with a magnetic stir bar. Additionally, tridecane, citronellal, neral (*cis*-citral), and geranial (*trans*-citral) were detected, whereas sulcatone was found in low amounts (Fig. 2).

Role of Sulcatone and Undecane as Alarm Pheromones In the feeding experiment, when chemicals were applied to the filter paper, most ants left the platform after application. When

[b] Substances found (+) or not found (−) previously in a study by Steidle and Dettner (1993)

hexane was applied to the filter paper, all the ants returned within 30 sec and resumed feeding for about another 30 sec, after which the number of ants decreased. When sulcatone was applied, only about half the initial number of ants returned to the feeding platform and the number remained low for the duration of the experiment (significantly, $P<0.05$, lower than for the controls for up to 90 sec after the start), suggesting that sulcatone had a repellent effect on workers of *L. fuliginosus* (Fig. 3). In the field experiment, the percentage of ants that antennated paper balls impregnated with sulcatone was significantly lower than the number of ants that antennated filter paper balls with hexane or undecane (Fig. 4A). In addition, undecane stimulated significantly more aggressive behavior than hexane, whereas sulcatone stimulated significantly lower amounts of aggressive behavior than hexane (Fig. 4B). This is consistent with sulcatone having a repellent effect on workers of *L. fuliginosus*, but suggests that undecane stimulates increased aggression.

Effect of Sulcatone Added to Other Compounds Found in the Tergal Gland When quinones or undecane were mixed with sulcatone, the observed aggressive behavior of ants was reduced to a level comparable to that of the control (Fig. 5). In the field experiment, both mixtures (Mix+, Mix−) of the main tergal gland compounds elicited stronger aggressions toward the filter paper balls than the control (Fig. 6). However, less aggressive behavior was observed to the mixture with sulcatone (Mix+) than to the mixture lacking this chemical (Mix−).

Discussion

Twelve compounds, released by *P. funestus* and *P. humeralis* beetles upon being stimulated with a magnetic stir bar or after interactions with worker ants of the species *L. fuliginosus*, were identified. The chemical profiles obtained from beetles stimulated by the stir bar or by interaction with ants were similar, indicating that treatment with the stir bar is an appropriate method to study the tergal gland chemicals released in defensive situations by *Pella* beetles.

There are some discrepancies between the present study and the study of Steidle and Dettner (1993), in which the tergal gland chemistries of 20 species of Aleocharinae, including *P. funestus* and *P. humeralis*, were studied. In contrast to the SPME-headspace method employed in the present study, Steidle and Dettner (1993) placed excised glands in the injection port of the GC. We presume that this methodological difference was responsible for our nondetection of some compounds of low volatility (pentadecane, *n*-heptadecene, 2-methoxy-3-methyl-1.4-hydroquinone) found by Steidle and Dettner (1993). The present study also found several volatile compounds (*n*-decane, undecene, tridecene), not reported by Steidle and Dettner (1993). These substances occur only in smaller amounts, and may have evaporated during the preparation of the tergal glands in the earlier study. Given that, volatile chemicals, rather than compounds of low volatility, probably contribute more to the effect of tergal gland secretions in aggressive interactions, the results from the SPME headspace method are probably more indicative of the defensive chemicals released by the insects than are the data from the excised-gland method.

Regardless of the method used, the main compounds in the defensive secretions of both *Pella* species studied are sulcatone, *p*-toluquinone, undecane, and 2-methoxy-3-methyl-1,4-benzoquinone. Of these, the quinones and undecane can be found in defensive tergal gland secretions of many Aleocharinae (Steidle and Dettner 1993). As demonstrated by topical application experiments with fly larvae, quinones are the main toxins in the secretion, whereas undecane serves as a solvent for the quinones (Steidle and Dettner 1993). Sulcatone has been found only in the myrmecophilous genera *Pella* and *Lomechusa* of the Aleocharinae and not in free-living species to date.

Chemical analyses of the headspace from disturbed workers of *L. fuliginosus* showed the release of undecane, dendrolasin, tridecane, citronellal, neral, geranial, and sulcatone. Undecane has previously been reported as an alarm pheromone in *L. fuliginosus* (Dumpert 1972), and this function was supported by our laboratory and field experiments with *L. fuliginosus* workers. Sulcatone has been previously identified as a component of the mandibular gland secretion (Bernardi et al. 1967), which is considered to contain alarm pheromones (Wilson and Regnier 1971), although no function of sulcatone in *L. fuliginosus* has been reported. Sulcatone has also been described as an alarm pheromone in *Formica* ant species of the same subfamily as *L. fuliginosus* (Duffield et al. 1977) and also in *Iridomyrmex* and *Tapinoma* (Hölldobler and Wilson 1990). In our laboratory feeding experiments, sulcatone repelled a significant number of *L. fuliginosus* workers from an otherwise attractive feeding

source. In the field experiments, it had a general repellent effect. Therefore, we conclude that in *L. fuliginosus*, sulcatone serves as a panic alarm pheromone *sensu* Wilson and Regnier (1971), inducing avoidance and flight and overruling the effect of the aggression-inducing pheromone undecane. It might be released in encounters with superior aggressors or in situations where there are no benefits in fighting, e.g., at remote feeding sites.

Undecane and sulcatone occur in the tergal gland secretions of *P. funestus* and *P. humeralis* and are also released by excited workers of the host ant *L. fuliginosus*. What, then, is the function of sulcatone released by *Pella* rove beetles? Our laboratory and field experiments showed that not only undecane but also a mixture of quinones induce aggression in *L. fuliginosus* workers. However, when sulcatone was added to quinones or undecane in the laboratory and field experiments, there was a reduction in aggression by *L. fuliginosus* workers. Therefore, release of sulcatone blocks the effect of the aggression-inducing chemicals and enables the beetles to use their tergal defensive gland secretion to repel an aggressive ant without inducing more aggression.

In summary, our results support the long-standing hypothesis by Kistner and Blum (1971), formulated for two Japanese *Pella* species, that myrmecophilic insects mimic alarm pheromones of their hosts. Furthermore, the reported case of these *Pella* beetles represents a rare case of chemical mimicry (according to the definition in Dettner and Liepert 1994) in myrmecophilous insects that does not involve cuticular hydrocarbons but other pheromonal cues. It should be noted that chemical mimicry of the alarm pheromone is not the only strategy used by beetles in the genus *Pella* to avoid aggressive interactions with host ants. Other strategies involve behavioral adaptations (e.g., death-feigning), the use of the appeasement gland (Hölldobler et al. 1981), and chemical mimicry of CHC patterns (Akino 2002). From an evolutionary perspective, it is unclear whether the production of sulcatone is a plesiomorphic pre-adaptation enabling the switch to myrmecophily in *Pella*, or whether it has been developed as an apomorphic trait when the beetles were already integrated in ant nests. Interestingly, not all myrmecophilic species of the genus *Pella* produce sulcatone (Stoeffler, unpublished), but it is also found in the highly myrmecophilic species *Lomechusa strumosa*, which belongs to the same tribe Myrmedoniini (Steidle and Dettner 1993). More work including molecular studies to define relationships within the Myrmedoniini is required to determine how myrmecophily and the production of sulcatone evolved in rove beetles of the genus *Pella*.

Acknowledgments We thank Cornelia Gantert for continuous support in the establishment and maintenance of the ant colonies used in this study. Andrea Fuhrmann, Angela Hücklhoven, and Stine Mencl contributed by performing behavioral experiments. The manuscript was improved, thanks to comments of anonymous reviewers and the revision by Dr. Astrid Groot and Simone Kienle.

probable genetic component associated with choice, as insects feeding on corn (*Zea mays* L.) are genetically different from those feeding on mugwort (*Artemisia vulgaris* L.) and hop (*Humulus lupulus* L.; Bethenod et al. 2005; Malausa et al. 2005). Females use plant odors to avoid damaged maize plants (Schurr and Holdaway 1970) or to select some maize hybrids over others (Lupoli et al. 1990), as well as to discriminate among plant species (Udayagiri and Mason 1995). Certain odors are even repellent to them (Binder et al. 1995; Binder and Robbins 1997). Some studies have also documented how contact chemicals, like sugars (Derridj et al. 1986) and surface waxes (Udayagiri and Mason 1997), affect host plant choices and oviposition. These observations suggest that the chemosensory system of ECB females is sensitive to a number of host and nonhost plant chemicals and that despite its large range of hosts, they monitor volatile and contact chemicals that allow them to select the proper plant and avoid "unsuitable" hosts.

In selecting or avoiding a potential host plant, do females use the same stimuli as their larvae? Although some studies have reported that adult females may use stimuli different from larvae to select their host (Roessingh et al. 2000), others suggest that larvae and adults use the same contact stimuli when accepting (Renwick 2002; Miles et al. 2005) or rejecting host plants (Qiu et al. 1998). We have recently shown that larval stages and adult females of the grapevine moth, *Lobesia botrana*, avoid 20-hydroxyecdysone (20E; Calas et al. 2006). 20E, the major molting hormone of insects, is the most common of the PEs, a structurally homogenous class of secondary substances produced by plants (Marion-Poll et al. 2005). PEs are considered to be plant defense compounds (Schmelz et al. 1999, 2000) that mimic the genuine insect hormone. They have been found in the seeds of 5–6% of 5,000 plant species sampled across different plant taxa (Dinan et al. 2001), ranging from primitive ferns, to the more evolved Angiosperms. Therefore, we propose that polyphagous insects like ECB will have been repeatedly exposed to PEs and consequently have evolved strategies to avoid plants using this family of defense compounds.

We have already shown that 20E is deterrent and toxic for ECB larvae (Darazy-Choubaya 2002) and that they have taste receptors that can detect 20E at a threshold of 10^{-6}–10^{-7} M (Marion-Poll and Descoins 2002). Therefore, we tested the hypothesis that ECB adult females would avoid laying eggs on 20E-containing substrates. We first determined if ECB females can detect 20E through neurons in taste sensilla located on the legs or on the ovipositor (Marion-Poll et al. 1992). We also monitored the number of eggs laid on different artificial substrates (filter paper, glass, and nylon) and plants treated with 20E, as well as timing the different sequences of behavior leading to egg laying when females were provided on treated or untreated glass oviposition sites. Our results indicate that ECB adult females detect 20E with their taste receptors and change the duration of certain oviposition behaviors. However, the number of eggs laid only declined when natural rather than artificial substrates were used. Several hypotheses are proposed to explain the differences observed.

Methods and Materials

Chemicals 20E, purified from *Leuzea carthamoides* (Willd.) DC. (Asteraceae; 95% minimum purity with minor ecdysteroids mixtures of polypodine B, ajugasterone C, and inokosterone), was obtained from SciTech (Prague, Czech Republic) and from Lafont (University of Paris VI). It was dissolved in ultrapure water or in ethanol depending on the bioassays. For electrophysiology, 20E was dissolved in 10^{-4} M potassium chloride (KCl, Prolabo) and used at concentrations ranging from 10^{-8} to 10^{-2} M.

Plants Individual maize *Centena* (Pioneer, Toulouse) plants were grown in plastic pots in a greenhouse at INRA Versailles and were used in assays when they had developed eight leaves.

Insects ECB pupae were obtained from INRA Le Magneraud. This strain is reared on an artificial medium and regularly renewed with wild insects. Pupae were maintained in plastic boxes at 25°C under a 16-hr light/8-hr dark photoperiod and 70% relative humidity until adults emerged. We used 24-hr-old virgin females for the electrophysiological studies, to ensure that good recordings were obtained.

Oviposition-choice tests and the observation of oviposition-related behaviors were performed in an environmental chamber (25°C; 70–80% relative humidity) under a 16-hr light/8-hr dark photoperiod. Couples of mature females and males (48 hr old) were placed in cages to mate, and females started to lay eggs at the beginning of the next night. We used this time as a pretest period to check if adults were mated, and the actual behavioral tests were performed at the beginning of the following scotophase.

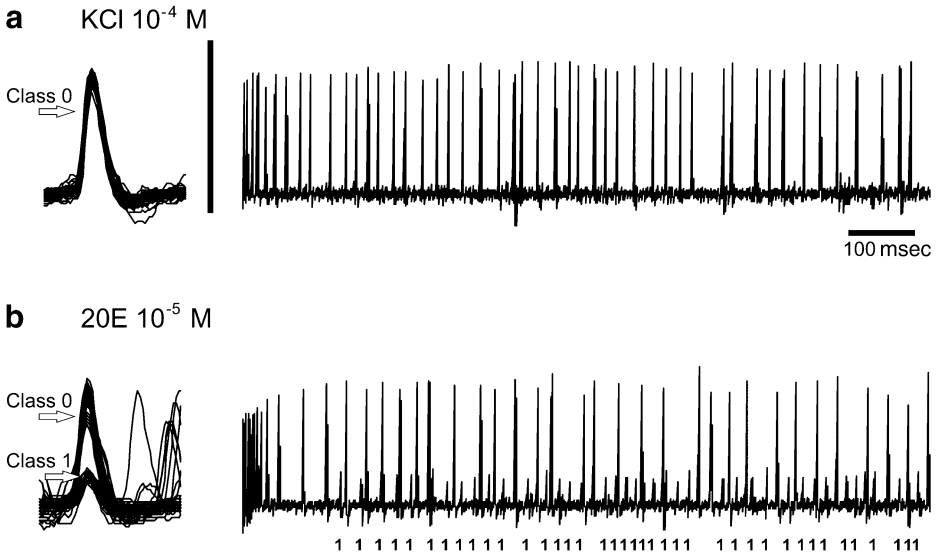
Electrophysiology Before dissection, females were briefly anesthetized with carbon dioxide. For the recording from tarsal sensilla, females were decapitated by using fine scissors and then fixed on a polystyrene block with fine strips of tape. A glass capillary electrode, filled with Ringer solution, was inserted into the abdomen and connected to the ground. One of the prothoracic legs was taped to the support to expose the ventral side of the fifth tarsomere. Two types of taste sensilla were found on the tarsi of ECB adults, CRa and CRb (Marion-Poll et al. 1992), but as CRa sensilla did not respond to 20E (data not shown), measurements were only recorded from the CRb. For the recording from the ovipositor, the distal part of the abdomen was excised with a scalpel and placed on a small silicone dish filled with Ringer solution. Previous observations showed that there are about 12 taste sensilla of type CRa (30–40 μm) on the outer rim of each papilla, within a field of about 200 bristles (80–160 μm; Marion-Poll et al. 1992). These taste sensilla are identifiable under the microscope by their dark, blunt tip. Recordings were made from randomly selected sensilla.

For stimulation, we used glass capillary electrodes (borosilicate glass, outer diameter = 1.0 mm, inner diameter = 0.78 mm) pulled to a 10-μm-diameter tip (Narishige PC-10) filled just before the recording. The electrode was placed on the tip of a sensillum chaeticum by using a Leica MZ12 (×350). The electrical signal was preamplified (TastePROBE DTP-02, Syntech, The Netherlands), amplified (×1,000), and filtered (8-poles Bessel filter: 0.1–30 to 2,800 Hz; CyberAmp, 320, Axon Instruments). The electrical artifact generated at the moment of the contact was detected by the TastePROBE amplifier, which triggered a 2-sec data acquisition. Data were recorded and stored on a computer with a 16-bit A/D conversion card (DT9803 USB A/D; Data Translation, USA) under the control of a custom software, dbWave. Recordings were then analyzed with dbWave, to detect and sort spikes according to their amplitude and shape using interactive procedures.

Responses to the different stimuli were evaluated by counting the total number of spikes of the recording. Series of recordings were done starting with 10^{-4} M KCl (also used as electrolyte of nonconductive solutions) and followed by ascending concentrations of 20E (tarsal sensilla: decadic steps from 10^{-8} to 10^{-2} M; ovipositor: decadic steps from 10^{-6} to 10^{-3} M). Consecutive stimuli on a sensillum were applied at an interval of greater than 2 min to avoid adaptation. Data from the tarsi were collected from 16 insects ($N = 9$–37 recordings × 8 doses) while from ovipositors were collected from ten insects ($N = 12$–26 recordings × 5 doses).

Oviposition Tests on Artificial Substrates The oviposition cages were metal cylinders (height = 20 cm, diameter = 19 cm, 2.5-mm mesh). The top of each cage was closed with a paper, nylon, or glass (19 cm diameter) disk supported by a larger cloth (6-mm mesh). This cloth allowed females to hang on and touch the disk. The two opposing quarters of the disk received 200 μl of a solvent or 10^{-4} to 10^{-2} M of 20E. Ultrapure water was used as the solvent for nylon disks, while ethanol was used for glass and filter paper substrates. After letting the solvent evaporate for 20 min, a disk was placed in a cage containing five females and eight males. We performed ten replicates, each lasting an hour, for each substrate and each concentration.

Oviposition-related Behaviors on Glass Substrates At the beginning of the scotophase, mated females were introduced into small individual nylon cages (height = 12 cm; diameter = 10 cm), topped with a metal cloth (mesh size = 6 mm) and covered by a glass Petri dish (diameter = 11 cm). The surface of the Petri dish facing the inside of the cage was treated with 240 μl of either ethanol or 10^{-4} M 20E in ethanol. We recorded the oviposition behavior from above the cage, under red light, with a digital video camera recorder (Sony DCR-HC20). The behavioral sequences recorded (flying, walking, sweeping, and egg laying) correspond to those previously described for the ECB (Binder and Robbins 1996; Garnier-Geoffroy et al. 1996). Each experimental session lasted 2–3 hr. We monitored the behavior of ten females for each condition (control and 10^{-4} M 20E).



Oviposition Tests on Plants Maize plants were sprayed (Ecospray, VWR, France) with 15 ml of 10^{-4} M 20E or pure water. Half an hour later, when plants were dry, two plants (20E+control or control+control) were placed together in a plastic pot (diameter = 30 cm) filled with vermiculite. The plants were covered with a nylon cage (a conic section: top = 25 cm diameter, bottom = 40 cm diameter, height = 70 cm), and five females were introduced. Experiments were run for 2 hr at the beginning of the scotophase. The number of eggs deposited on each leaf of both plants was noted. The leaves were numbered 1 to 8, from the bottom to the top. We performed ten replicates for choice tests using 20E and five replicates for control tests (control vs. control).

Statistics Statistical tests were done with Minitab 12 software (Minitab, France). Electrophysiological responses were compared with the response to the electrolyte (0.1 mM KCl) using Mann–Whitney (MW)'s *U* test. Oviposition scores were compared by using nonparametric statistics with the Wilcoxon matched-pair signed rank test for choice experiments and the MW test for nonchoice ones.

Results

Taste Sensilla on the Tarsi In CRb sensilla, we found at least two classes of spikes in response to KCl and to 20E, which we called class 0 and class 1. Class 0 is characterized by medium amplitude spikes (1.4–1.8 mV, Fig. 1). Its firing activity was quite high, except at the highest concentration of 20E where it decreased by almost half (average rate: 40 vs. 23 spikes/s; P=0.005; Fig. 2). Although this class of spikes could originate from a "water" cell, its activity did not decrease in the presence of higher concentrations of salt (data not shown).

Class 1 has smaller amplitude spikes (0.5–0.8 mV) when activated by 20E (Figs. 1 and 2). When near the detection threshold, between 10^{-7} and 10^{-6} M, there was a response delay of 200–300 msec, which decreased at higher concentrations. The activity of this class of spikes

The recordings look very similar at all concentration of 20E. Vertical bar=1 mV

Oviposition Tests on Artificial Substrates Females readily oviposit on all artificial substrates tested. In control vs. control assays, the total number of eggs (mean±s.e.m.) laid during the first hour was similar for glass (207.9±117.5, N=10), paper (201.6±116.4, N=14), and nylon (211.4±112.1, N=10). Similarly, in choice tests, there were no significant differences in the number of eggs laid on the treated and nontreated areas of each disk, for any given concentration and substrate (Fig. 5). We also compared the total number of eggs deposited during the experiment, irrespective of position on the disk. On glass, females laid slightly fewer eggs in the presence of 20E than on control disks (Fig. 5); on paper, there were more eggs on disks treated with high concentrations of 20E (MW: 20E 10^{-2} M/control vs. control/control, P=0.015) than with 10^{-4} M 20E. On nylon, the total number of eggs laid is lower in 20E than the control assays, especially at 10^{-4} M (MW: 20E 10^{-4} M/control vs. control/control: P=0.009). No significant difference in the number of egg masses was noted (data not shown).

Different type of substrates: **a** paper, **b** glass, and **c** nylon. *White bars*: Control (solvent alone); *black bars*: 20E treatment (from 10^{-4} to 10^{-2} M). *Bars* indicate the number of eggs (mean±s.e.m.) laid on treated and nontreated parts. Under each experiment, the total number of eggs laid on the disk (mean±s.e.m.); Mann–Whitney test: control/control vs. 20E/control, *asterisk*, $P<0.05$, *double asterisk*, $P<0.01$. $N=10–14$ (with five females per test). Test duration: 1 hr

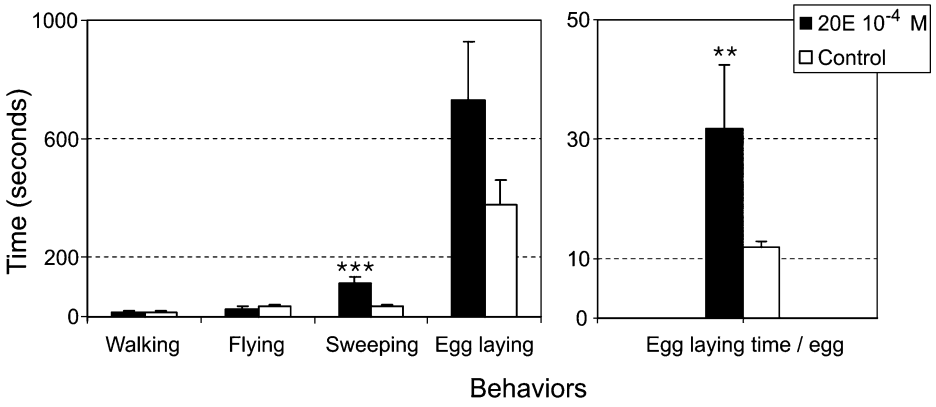

Fig. 6 Oviposition-related behaviors: Female *Ostrinia nubilalis* take longer to lay eggs on glass treated with 20E. *White bars*: Glass Petri dish treated with solvent (control); *black bars*: glass Petri dish treated with 20E 10^{-4} M (diluted in ethanol). *Bars* indicate the time in seconds (mean±s.e.m.) spent by a female for each behavior. N=10 for each treatment. Wilcoxon test: 20E vs. control, *double asterisk*, P<0.01, *triple asterisk*, P<0.001

Oviposition-related Behaviors Most females were initially resting on the side of the cage, before they started to walk or fly. There may be several flights, none exceeding a few seconds because of the size of the cage, before a female landed near the oviposition site. There were no significant difference in walking or flight between the treated and control assays (Fig. 6). Antennal movement occurred just before the flight, as well as during the

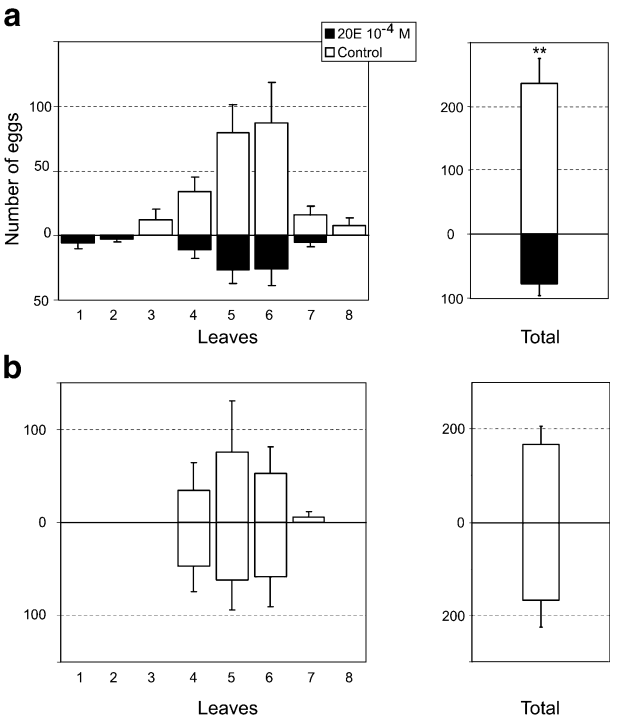

Fig. 7 Oviposition tests on plants: Female *Ostrinia nubilalis* laid significantly fewer eggs on plants treated with 20E. **a** 20E vs. control; **b** control vs. control. *White bars*: Plant treated with ultra pure water; *black bars*: plant treated with 20E 10^{-4} M (diluted in water). *Bars* indicate the number of eggs (mean±s.e.m.) laid on each leaf (1 to 8). Wilcoxon test: control vs. control and 20E vs. control, *double asterisk*, P<0.01. N=10 (20E/control), N=5 (control/control) with five females per test. Test duration: 2 hr

exploration of the substrate, but not during oviposition. The female curved her abdomen and made lateral sweeps of the substrate surface with the expanded lobes of her extruded ovipositor, which lasted significantly longer on treated than control sites (113±22.7 vs. 36.5±3.5 sec; $N=10$; $P<0.001$; Fig. 6). The female immobilized her ovipositor when she started laying eggs, one after another, in consecutive rows. While the total time to lay an egg mass took longer on the 20E substrate than on the control, the difference was not significant, although the time taken to lay each egg was (31.8±10.5 vs. 11.8±1.0 sec; $P<0.01$; Fig. 6).

Oviposition Tests on Plants The total number of eggs deposited in both experiments was comparable (20E vs. control: 315.3±55.8; control vs. control: 333.6±96.0). However, females laid significantly fewer eggs on the treated than on control plants (78.8±17.0 vs. 236.5±38.8; $P<0.01$, $N=10$) and laid more eggs on all nontreated leaves except for positions 1 and 2 (Fig. 7a). For both treatments, females laid more eggs on leaves 5 and 6. For control tests (including two plants sprayed with ultrapure water), females laid similar numbers of eggs on each plant (plant a=167±38.3; plant b=166.6±57.6 eggs), and they only laid eggs on leaves 4 to 7 with a higher number of eggs on leaves 4, 5, and 6 (Fig. 7b). This is in contrast with the distribution in the 20E vs. control, where eggs were laid on leaves 3–8 of the control plant.

Discussion

Females possess taste receptor neurons in CRb sensilla on the ventral part of the distal tarsomere, which respond to 20E, at a threshold similar to that observed in larval receptor neurons (Darazy-Choubaya 2002; Marion-Poll and Descoins 2002). One noticeable difference is that the adult female CRb sensilla have a maximal firing rate at about 50 spikes/s at 10^{-2} M 20E compared with 100–150 spikes/s for the sensilla styloconica of larvae (Marion-Poll and Descoins 2002). Such a difference was already reported between adults and larvae of *L. botrana* (Calas et al. 2006).

We did not detect any sensilla that respond to 20E on the ovipositor, but these findings should be viewed with caution, especially given the increased ovipositor-sweeping times that we observed on 20E-treated glass. We could not sample all sensilla on the ovipositor of the same insect and thus may have missed some sensilla that are responsive to 20E. Furthermore, the spikes obtained from the ovipositor sensilla were too similar in amplitude and shape to sort them accurately.

Females not only have receptors that detect 20E, they also modify their egg laying when the PE is present. However, although ECB females spent more time sweeping and took longer to lay each egg on artificial substrates treated with 20E, the total number of eggs laid on treated and control sites did not differ. In contrast, when the choice assays were carried out by using corn, females clearly avoided ovipositing on treated plants. Furthermore, the actual distribution of eggs on the leaves of treated and untreated plants varied. Preferences for different leaves have been noted in the field, largely related to the available leaf surface area (Spangler and Calvin 2000, 2001). Females laid eggs on leaves 1 and 2 of treated plants, which may be due to difficulties effectively spraying such small leaves. This possibility is supported by the fact that egg masses on treated plants were often at the tips of leaves, which are also difficult to spray. However, the overall results of this study are consistent with our initial hypothesis that ECB females, like larvae, detect and avoid sites with PEs.

It is not clear why ECB females did not avoid ovipositing on artificial substrates treated with 20E. It is possible that the quantities of 20E we used (0.014–14.40 μg/cm^2) were too low to reduce oviposition in the ECB. However, we do not think this is the case. A leaf from a plant like spinach may contain 10–40 μg/cm^2 of 20E (Lafont, personal communication). It is generally believed that much lower concentrations of 20E occur on the surface relative to the total leaf content, given the hydrophobic nature of the cuticle and the absence of an active transport system (Vrieling and Derridj 2003; Müller and Riederer 2005).

Several alternate, not mutually exclusive, explanations exist. The plant cuticle plays a major role in many plant–insect interactions (Espelie et al. 1991; Eigenbrode and Espelie 1995; Eigenbrode 2004; Müller and Riederer 2005), and epicuticular waxes may provide important cues for herbivorous insects, including ECB (Udayagiri and Mason 1997) and other Crambidae (Li and Ishikawa 2006). Some nonvolatile secondary plant compounds such as the cucurbitacins that prevent oviposition by ECB and the beet armyworm, *Spodoptera exigua* (Tallamy et al. 1997), or toosendanin that is avoided by the cabbage looper, *Trichoplusia ni* (Akhtar and Isman 2003) diffuse onto the plant surface and become associated with the waxes (Müller and Riederer 2005). In some cases, synergy of secondary compounds with the epicuticular waxes may occur, and such synergistic interactions enhance the oviposition behavior of the diamond back moth, *Plutella xylostella* (Spencer 1996; Spencer et al. 1999). Therefore, it is possible that plant epicuticular waxes could play a role in the detection of 20E.

Many insects obtain information about plants by probing the leaf surface with their antennae or tarsi before ovipositing (Chapman and Bernays 1989), so a second possibility is that ECB females only integrate information about 20E when it is detected simultaneously with other contact or volatile host plant chemicals (Bruce et al. 2005). For example, *Papilio polyxenes* females laid more eggs on artificial plants treated with a combination of contact stimulants and volatiles than on plants treated only with contact stimulants (Feeny et al. 1989). Similarly, host acceptance in the cabbage root fly, *Delia radicum*, appears to result from a synergistic response to simultaneous olfactory and contact chemo-stimulation (de Jong and Städler 1999). Females might also need to detect primary metabolites, such as soluble sugars or sugar-alcohols on the plant surface, that stimulate oviposition in the ECB and other moths species (Derridj et al. 1986; Lombarkia and Derridj 2002).

Finally, we cannot rule out that the application of 20E affects the physiology of the plant. However, if this were the case, then the effect would have to be rapid because our experiments were completed within 2 hr after treatment. 20E could be taken up and transformed by the plant into a new, more potent molecule. Maize does not produce detectable nonconjugated PEs but is capable of forming polyphosphate ecdysteroids conjugates from precursors like mevalonic acid and cholesterol (Devarenne et al. 1995; Dinan 1998). These conjugates of 20E might be more potent on the sensory system than 20E or could interact with the plant brassinosteroid receptors, which are involved in the physiological reactions of plants to phyto-aggressors or stress (Krishna 2003; Nakashita et al. 2003; Wang and He 2004).

Additional experiments must be carried out to test the hypotheses presented to explain why the presence of 20E on artificial substrates does not deter oviposition by the ECB but does on intact plants. These will include assays that look at oviposition on artificial substrates to which primary metabolites or maize odors have been added. In addition, it will require the analysis of the leaf surface compounds before and after applying 20E, together with an analysis of volatile compounds released to check if the chemicals accessible to female ECB are modified by 20E. It would also be interesting to investigate why 20E on artificial substrates affects oviposition by grape berry moth, *L. botrana*, females (Calas et al.

2006) but not in the case of the ECB. Is this related to the greater variability of cues that a polyphagous species encounters when selecting suitable host plants compared with a monophagous one?

Acknowledgments We thank René Lafont (University Paris VI) for his gift of 20E used in this study and numerous discussions. We thank Alan Cork for reviewing the manuscript as well as two anonymous referees and the editor for their useful suggestions. This work was supported by an INCO-DEV program SUSVEG-ASIA.

Introduction

Insect parasitoids are known to use semiochemicals for location and recognition of hosts (Vinson 1998), and several studies have been published on the use of host-produced kairomones by hymenopteran parasitoids (Vinson 1991, 1998; Godfray 1994; Quicke 1997; Vet 1999). The possibility of using semiochemicals to enhance the efficacy of parasitoids in biological control programs also has been investigated (Lewis and Martin 1990; Vet and Dicke 1992; Powell and Pickett 2003). In the generally accepted paradigm, parasitoids use volatile cues from the host plant complex to locate the habitat of their hosts, and then host-derived stimuli are used for host location, recognition, and acceptance over shorter distances (Vinson 1991, 1998; Vet and Dicke 1992). Host-derived stimuli can be directly emitted by the host stage, or they can be indirectly associated with the attacked host stages (Vinson 1991, 1998; Godfray 1994; Quicke 1997). The switch from cues from the host plant complex to indirect host-derived cues is normally associated with an adjustment of female behavior from a directed movement (e.g., flying from one location to another in the habitat) to a motivated searching response within and around an area contaminated by potential hosts (i.e., reduced linear speed and increase in ortho- and klinokinetic movements; Vinson 1984; 1998).

Indirect host-related cues that elicit arrestment and motivated searching in an area where there is a high probability of finding hosts are often exploited for host location by hymenopteran egg parasitoids in the families Trichogrammatidae and Scelionidae. These egg parasitoids show motivated searching upon contact with indirect host-related cues such as lepidopteran scales (Laing 1937) or pentatomid bug footprints (Colazza et al. 1999b). Motivated searching induced by scales shed by moths has been observed with several *Trichogramma* spp. and with *Telenomus busseolae* Gahan (Laing 1937; Beevers et al. 1981; Lewis et al. 1982; Gardner and van Lenteren 1986; Colazza and Rosi 2001), whereas motivated searching induced by chemical residues left on the substrate by adult pentatomid bugs has been observed with several *Trissolcus* spp. and with *Telenomus podisi* (Ashmed) (Colazza et al. 1999b; Conti et al. 2003, 2004; Borges et al. 2003; Salerno et al. 2006). The motivated searching behavior of egg parasitoids to these types of cues is characterized by an initial prolonged motionless period with the antennae kept in contact with the surface (arrestment response). Then the wasps, while drumming the surface with their antennae, exhibit intense searching behavior of the surrounding area, characterized by variation in orthokinetic and klinotaxic locomotion, and increased turning frequency. In this way, wasps are kept in or around the contaminated area, with the response reinforced by systematic returns to the stimulus after losing contact with it. If no host eggs are found, searching behavior slowly decreases, and the normal walking pattern is gradually resumed (Laing 1937; Gardner and van Lenteren 1986; Colazza et al. 1999b; Conti et al. 2003, 2004; Peri et al. 2006).

Previous papers have demonstrated the importance of chemical residues left by host *Nezara viridula* (L.) (Heteroptera: Pentatomidae) adults in the host location behavior of females of the egg parasitoid *Trissolcus basalis* (Wollaston) (Hymenoptera: Scelionidae). Wasp females were found to have an innate response to host chemical residues, with a strong preference for residues left by *N. viridula* females rather than males (Colazza et al. 1999b; Peri et al. 2006). Furthermore, experience gained during foraging on host chemical

residues can strongly affect a wasp's motivated searching pattern (Peri et al. 2006). The role of host residues in relation to the host specificity of *T. basalis* also has been demonstrated (Salerno et al. 2006).

In this research, the source and the nature of the chemical residues deposited by *N. viridula* adults that induce arrestment responses from *T. basalis* females were investigated. It was found that the hydrocarbons present in the wax layer of *N. viridula* cuticle act as contact kairomones, causing arrestment of female wasps. A homologous series of straight-chain hydrocarbons was identified and quantified in solvent and solid-phase micro-extraction (SPME) extracts of host cuticle. Because the cuticular hydrocarbon profiles of *N. viridula* adults showed qualitative and quantitative sex-specific differences, the roles of specific hydrocarbons in the wasp's arrestment response were examined in behavioral bioassays. A reconstructed blend of straight-chain cuticular hydrocarbons induced arrestment responses by wasp females, and nonadecane (nC_{19}), a male-specific hydrocarbon, was used by *T. basalis* females to discriminate between chemical residues left by host females and host males.

Methods and Materials

Maintenance of Insect Colonies *Nezara viridula* and *T. basalis* colonies were established and reinvigorated regularly with insects collected from fields located around Palermo, Italy. Both colonies were reared in an environmentally controlled room at 25±1°C, 70±10 % R. H., and photoperiod of 16L:8D. The *N. viridula* colony was reared in wooden cages (25× 25×40 cm height) with two 5-cm diam mesh-covered holes for ventilation, and colonies were fed with seasonal fresh vegetables. The colony of *T. basalis* was reared in 16-ml glass tubes and fed with a 10% honey–water solution. Egg masses of *N. viridula* were collected daily and used to maintain both colonies. Single *N. viridula* egg masses were exposed to three–four female wasps and then held in the same environmental conditions until adult emergence. Every 2–3 d, newly emerged *N. viridula* adults were isolated in different rearing cages so that individuals of known age were continuously available for experiments.

Stimulus Preparation Procedure Mated *N. viridula* adults were used in all bioassays. Males were 4- to 8-d-old, whereas females were 2–4 d older to ensure that they were in the pre-ovipositional physiological state; our previous work had shown that *T. basalis* responded strongly to residues associated with mated, gravid host females (Colazza et al. 1999b). Dissected adult body parts, hexane extracts of insect cuticle, and reconstructed blends of synthetic hydrocarbons used for bioassays were prepared as follows:

(1) *Tarsi and Scutella Dissected from Males and Females of N. viridula*. Responses of *T. basalis* females to tarsi and scutella dissected from *N. viridula* adults were tested in arena bioassays. The scutellum was selected as a control body part because it should not be contaminated by compounds from *N. viridula* legs during grooming behaviors. *Nezara viridula* adults were killed by freezing at −18°C for about 1 hr, and dissected under a binocular stereo microscope. Fine scissors were used to clip off the legs at the coxa level, and to cut the scutellum from the pronotum. Dissected legs and scutella were used a few minutes after dissections for bioassays.

(2) *Deproteinized N. viridula Tarsi*. Legs used for the experiment were dissected from adults as described above. The left legs were treated with 1% trypsin-ethylenediaminetetraacetic acid (Trypsin-EDTA) (Sigma, St. Louis, MO, USA) buffered with Hank's

balanced salt solution (HBSS; pH 7.4), whereas the right legs were treated with HBSS only and used as a control. Both sets of legs were incubated at 37°C for 80 min, then rinsed with distilled H_2O, air-dried at room temperature, and used for bioassays.

(3) *Hexane Extracts of N. viridula Cuticular Lipids*. Frozen adults were dissected into legs, wings, pronotum, and scutellum as described above. The inside of the pronotum cuticle was cleaned as thoroughly as possible to remove traces of adhering tissues. The mesonotum, metanotum, and abdomen were not used in experiments because of possible contamination by defensive chemicals from the glandular structures in these body sections, which can induce arrestment of *T. basalis* females (Mattiacci et al. 1993). Dissected body parts from three males and three females were weighed, then placed in 15-ml glass vials and extracted with 10 ml hexane at 30°C for 2 hr. The amount of cuticle obtained (mean±SD) from dissected body parts of three adults was 24±1 mg for males, and 32±3 mg for females. After removal of the body parts, the resulting extracts were evaporated under a gentle nitrogen stream, and redissolved in 1 ml hexane. Extracts were prepared from five groups of three bugs each, and after each extract was checked by GC (see below), the extracts were pooled by gender, and stored at −18°C until assayed.

(4) *Reconstructed Blend of Host Female Straight-Chain Cuticular Hydrocarbons*. A blend of straight-chain alkanes of *N. viridula* females was reconstructed, normalizing the concentrations of the alkanes found in the crude extract (see Table 1) to nonacosane, the most abundant compound. Two stock hydrocarbon blends were prepared as hexane solutions. The first stock solution contained (in mg/l): nC$_{29}$ (1,000), nC$_{26}$ (910), nC$_{27}$ (800), nC$_{31}$ (760), nC$_{28}$ (670), nC$_{25}$ (500), nC$_{24}$ (450), nC$_{30}$ (420), nC$_{23}$ (270), nC$_{32}$ (250), nC$_{33}$ (210), and nC$_{22}$ (190). The second stock solution contained (in mg/l) nC$_{21}$ (700), nC$_{34}$ (500), and nC$_{20}$ (200). The working solution of the total reconstructed blend then was obtained by combining 10 ml of the first stock solution and 1 ml of the second stock solution and diluting it to 100 ml. All hydrocarbons were analytical grade GC standards (Fluka). The reconstructed blends were stored at −18°C until assayed.

(5) *Hexane Extracts of N. viridula Female Blended with Synthetic Nonadecane* (nC$_{19}$). Dissected body parts from 12 *N. viridula* females (155 mg of cuticle) were cut up and divided in four portions, and each portion was extracted in 10 ml of hexane, evaporated under a stream of nitrogen, and redissolved in hexane to a total volume of 1 ml as described above. Then, three of the four extracts were spiked with synthetic nC$_{19}$ in hexane to provide final concentrations of 0.1, 1.0, and 10.0 μg nC$_{19}$ per ml in the spiked extracts. The four extracts were stored at −18°C until assayed.

Open Arena Bioassay Procedure Female *T. basalis* used for bioassays were held with males for 24 hr to ensure that they were mated, then females were individually isolated in small vials with a drop of honey-water and used in bioassays when 2 to 3 d old. Thus, all wasp females were naïve with respect to both oviposition experience and contact with chemical cues produced by their *N. viridula* hosts. Female wasps were allowed to acclimate in the bioassay room for at least 1 hr before bioassays. Bioassays with *T. basalis* females were conducted in open arenas consisting of rectangular filter paper sheets (20×20 cm). In the center of the arena, a 4-cm-diam circle (12.56 cm^2, about 3% of the entire arena), defined by a still image of the arena taken with the video tracking and motion analysis software (see below) so that the arena remained free of any marks, was treated with test

stimuli. The rest of the open arena was left uncontaminated. Each arena was used for testing five wasp females (previous studies had shown that test wasps were unaffected by any residues from previously tested wasps; Colazza et al. 1999b; Peri et al. 2006). For each experiment, the following bioassay procedure was used.

(1) *Tarsi and Scutella Dissected from Males and Females of N. viridula*. Tarsi and scutella, dissected from four males and four females of *N. viridula*, were gently wiped on the test areas of the open arenas with fine forceps. Eighty wasps were tested individually.
(2) *Deproteinized N. viridula Legs.* Legs from six *N. viridula* adults (three males and three females), deproteinized by treatment with trypsin-EDTA or treated with buffer only, were wiped on the treatment areas of the arenas. The experiment was repeated three times for a total of 60 tested wasps.
(3) *Hexane Extracts of N. viridula Cuticular Lipids*. Hexane extracts of male and female *N. viridula* cuticular hydrocarbons were tested at doses of 3×10^{-3}, 1, and 10 dissected adult equivalent (DAE) by pipetting 1, 333, and 3,333 μl of extracts onto the treatment area. Before using the 3×10^{-3} DAE dosage, the aliquot of 1 μl of solution was diluted in 200 μl of hexane to allow even distribution over the entire treated area. The 10 DAE dosage was applied by repetitive pipetting of about 50 μl of solution, allowing the hexane to evaporate between repetitions. For each dosage and for both *N. viridula* genders, 15 *T. basalis* females were tested for a total of 180 wasps.
(4) *Reconstructed Host Female Blend of Straight-chain CHs*. One DAE of the reconstructed hydrocarbon blend was tested by pipetting 40 μl of a hexane solution containing 0.1 mg/ml of the most abundant component (nC$_{29}$) and proportional amounts of the minor components onto the treatment areas. The bioassay was repeated four times with a total of 20 female wasps.
(5) *Hexane Extracts of Female N. viridula, Spiked with Synthetic* nC$_{19}$. Aliquots of extract containing 1 DAE of the crude extract spiked with four different concentrations of nC$_{19}$ were tested by pipetting 333 μl of a solution onto the treatment area of an open arena for each of the different solutions. The experiment was repeated three times for a total of 60 tested wasps.

For experiments 3, 4, and 5, stimuli were applied as drops, and therefore the chemicals on the treated areas were patchily distributed. Wasp females were gently released singly from a small vial (2 ml) onto the center of the treated area. Wasp behavior was scored as "response" when the female, immediately after being released, remained unmoving with the antennae held in contact with the arena surface (arrestment response). Females that did not show the arrestment response after touching the treated area with their antennae were recaptured with the same vial, and retested after ~1 min. Wasps that did not show the arrestment response after three trials were scored as "non-response". After the initial arrestment response, responding females typically started to walk slowly with many turns while drumming the arena surface with their antennae, stopping again each time they came back to the treated area (motivated searching behavior). Wasps' movements were recorded with a video tracking and motion analysis system (see below) until they flew away from or walked off the arena. The time spent on the entire arena was scored as the arena residence time. This value was used, rather than only recording the time spent on the treated area, because we felt that the time spent by wasp females on the entire arena was more representative of the active searching behaviors stimulated by the kairomonal stimuli.

Wasps' walking patterns were recorded with a CCD camera (Sony M370) equipped with a zoom lens and mounted above the center of the arena. The video camera was connected to a video monitor (Sony PVM 2130QM) and a desktop PC equipped with a video frame grabber (Miro PC-TV—Pinnacle Systems, Mountain View, CA, USA). A composite video signal from the camera was fed into custom video tracking and motion analysis software developed for the Linux operating system (Colazza et al. 1999a). A threshold value of 1 mm resolution was used during recordings to minimize creation of artifacts because of noise in the system. Different treatments among different stimuli were tested at the same time, and stimuli were tested on several different days. All experiments were carried out from 1000–1500 hours, in an isolated room at 26±1°C, with the arena illuminated by two 18-cm-long fluorescent lights (full spectrum 5,900 K, 11 W; Lival, Italy).

Analysis of N. viridula Cuticular Hydrocarbons Hexane extracts of *N. viridula* cuticle and body parts were analyzed by gas chromatography (GC) with a Hewlett-Packard 6890 GC (Avondale, PA, USA) with a flame ionization detector (FID), and equipped with an HP5-MS column (30 m×0.2 mm, 0.25-μm film, J&W Scientific, Folsom, CA, USA). A 4-mm ID straight glass injector liner packed with glass wool was used, with the injector temperature at 250°C. Injections (1 μl) were made in splitless mode with helium as carrier gas (1.5 ml/min). The oven temperature program was 150°C for 2 min, then 5°C/min to 280°C, and hold for 20 min. The detector temperature was 300°C. A mixture of *n*-alkanes (nC$_{19}$–nC$_{36}$) (all 99% purity; Fluka) in hexane served as external standards to identify and quantify each compound.

Solid-phase Microextraction of Cuticular Hydrocarbons and Residues Left by N. viridula Adults Direct-contact solid-phase microextraction (DC-SPME) was used to collect *N. viridula* cuticular hydrocarbons and the chemical residues left by *N. viridula* walking on a glass plate (10×10 cm). A 100-μm film thickness polydimethylsiloxane SPME fiber was used (Supelco Inc., Bellefonte, PA, USA), conditioning it before use at 250°C for 30 min in a GC injector port. *Nezara viridula* cuticular hydrocarbons were extracted from freeze-killed adults by gently wiping the SPME fiber over the head, pronotum, and legs for 60 sec. The same fiber was used to sample 10 individuals of the same gender before being desorbed in the GC inlet port. Residues left by *N. viridula* were sampled by wiping the SPME fiber over a glass plate upon which an adult bug had been confined for 1 hr. The same fiber was used to sample the residues left by three adults of the same gender before desorbing the fiber. Samples were analyzed by desorbing the loaded SPME fiber in the GC injector port (270°C) for 2 min, using a 0.75-mm ID glass injector liner in splitless mode, with the same column and temperature program as described above.

Precision and Detection Limits The method linearity of solvent extractions was determined for each identified cuticular *n*-alkane at five concentrations ranging from 1 to 30 ng μl^{-1}, and for each calibration curve the regression coefficient (R^2) was determined. Linearity was considered achieved when R^2 was 0.995. The calibration curves were then used to quantify the amount of each *n*-alkane in the extracts. The limit of quantification (LOQ) was fixed using a solution of hydrocarbon standards at a concentration of 0.5 ng μl^{-1} per compound. The limit of detection (LOD) for each analysis was defined by measuring progressively more dilute concentrations of the identified hydrocarbons until a signal-to-noise ratio of 3:1 was reached. The relative standard deviation (RSD) for each compound was determined.

Statistical Analyses Data sets were first checked for assumptions of normality with a Shapiro-Wilks test at $P=0.05$. The numbers of responding female wasps were analyzed by χ^2 tests for independence in a two-way contingency table. Arena residence times were analyzed by one-way analysis of variance (ANOVA) followed by Tukey's HSD post hoc test for multiple comparisons between means. Contrast analyses between naïve and experienced female wasps from the third experiment were done using *t* tests. All statistical analyses were done using Statistica 6.0 for Windows (StatSoft Inc., Tulsa, OK, USA).

Results

Open Arena Bioassay. Tarsi and Scutellum Dissected from Males and Females of N. viridula Every female *T. basalis* tested (100% of 80 trials) showed arrestment responses when exposed to arenas treated by rubbing with tarsi or scutella dissected from *N. viridula* adults. The wasps' arena residence times were significantly affected by host gender, but not by the two different dissected body parts ($F_{3,\ 76}=8.55$, $P<0.001$, one-way ANOVA) (Fig. 1). Wasps stayed longer on the arenas treated with tarsi and scutella dissected from female hosts than on arenas treated with the analogous dissected body parts from male hosts

Table 1 Straight-chain cuticular hydrocarbons extracted from three female and three male *N. viridula* by hexane extractions of dissected body parts, by DC-SPME of freeze-killed insects, and by DC-SPME of chemical residues left by *N. viridula* adults walking on glass plates

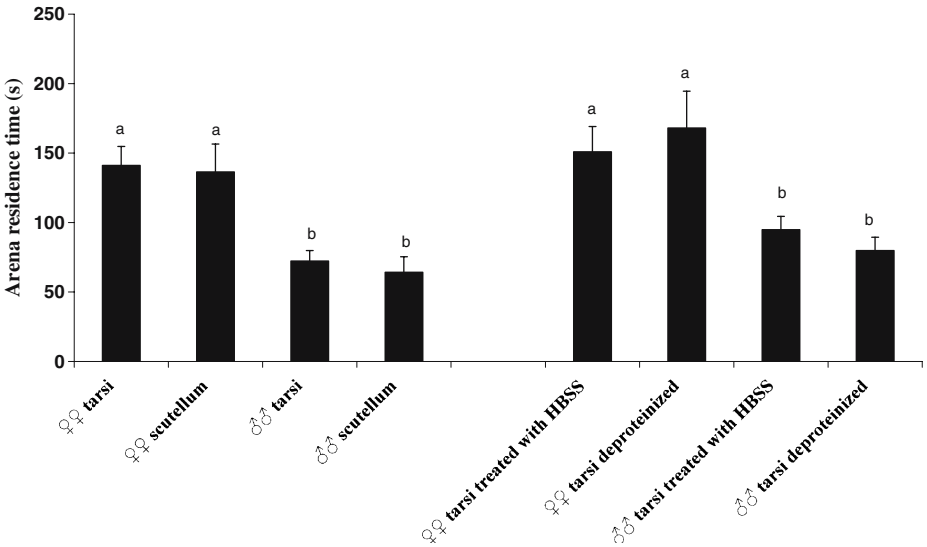

Fig. 1 Arena residence times (sec) of *T. basalis* females tested on arenas on which dissected body parts (tarsi and scutella) from females and males of *N. viridula* had been rubbed. Tarsi and scutella were tested untreated. Tarsi were also tested after they had been deproteinized by treatment with trypsin-EDTA buffered with Hank's balanced salt solution (HBSS), and with controls treated with only HBSS. Bars indicate mean ± SE. Different letters above the bars indicate significantly different means (ANOVA, Tukey HSD)

(Fig. 1). There were no differences in *T. basalis* arena residence times when the arenas were treated with tarsi or scutella dissected from adults of the same gender (Fig. 1).

Deproteinized N. viridula Tarsi Every female wasp (100% of 60 trials) responded to arenas rubbed with host legs deproteinized by treatment with trypsin, or with buffer-treated controls. Consistent with previous results, arena residence times of wasps were influenced by host gender ($F_{3,\ 56}$=5.94, P=0.001, one-way ANOVA; Fig. 1), whereas no differences were observed between the two treatments.

Hexane Extracts of N. viridula Cuticular Lipids Wasps' responses to hexane extracts of *N. viridula* cuticular lipids were significantly affected by dose (expressed as dissected adult equivalent, DAE) applied to test arenas (Fig. 2). Similar percentages of wasps responded to arenas treated with 3×10^{-3} DAE or 1 DAE (χ^2=1.7, P=0.19; χ^2=3.75, P=0.052; for male and female extracts, respectively; Fig. 2). However, fewer wasps responded to arenas treated with 10 DAE compared to arenas treated with 1 DAE (χ^2=10.8, P=0.001; χ^2=5.96, P=0.01; for male and female extracts, respectively; Fig. 2). Wasps that responded to the cuticular extracts showed similar arena residence times ($F_{2,\ 58}$=1.33, P=0.27; ANOVA; $F_{2,\ 65}$=0.4, P=0.70; for male and female extracts, respectively, one-way ANOVA). Similar to previous results, *T. basalis* females spent more time on arenas treated with hexane extracts of females than on arenas treated with extracts of males ($F_{1,\ 127}$=16.32, P<0.001; ANOVA).

Reconstructed Blend of Straight-chain Cuticular Hydrocarbons Most of the wasp females (80% over 20 trials) responded to arenas treated with a reconstructed blend of straight-chain

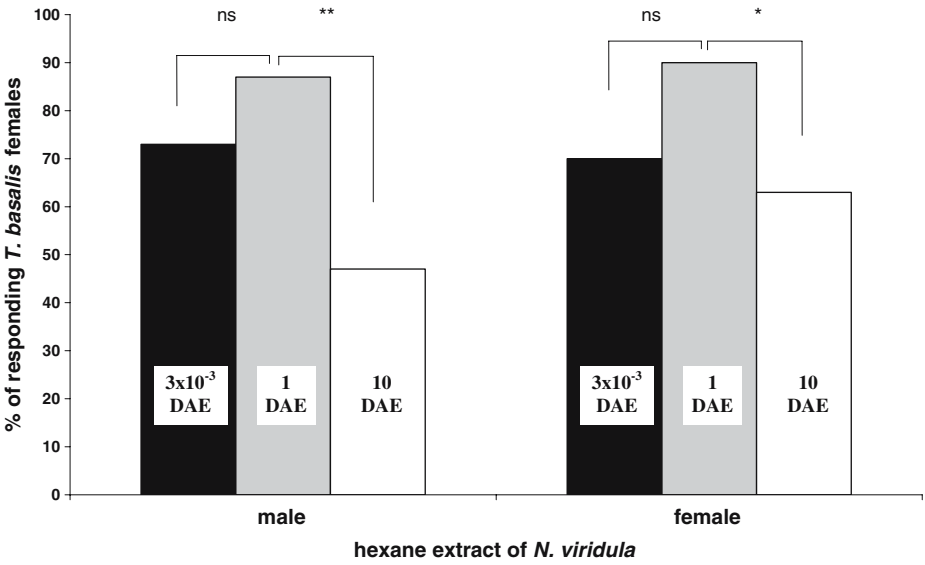

Fig. 2 Percentage of *T. basalis* females that showed arrestment responses to hexane extracts of male and female *N. viridula* applied onto arenas at doses of 3×10^{-3}, 1, and 10 dissected adult equivalents (DAE). Data were compared by χ^2 tests for independence. ns=not significant; *$P\leq0.05$

cuticular hydrocarbons, but females spent less time in these arenas than on arenas treated with crude extracts of *N. viridula* females (209±112 vs. 101±47 sec, for crude extract of *N. viridula* females and reconstructed blend of straight-chain CHs, respectively; $t=3.55$, $df=29$, $P=0.001$, t test).

Hexane Extract of N. viridula Females Spiked with nC$_{19}$ Wasps' arrestment behaviors toward hexane extracts of *N. viridula* females were influenced by the addition of synthetic nC$_{19}$ ($F_{3,\ 54}=4.68$, $P=0.005$, one-way ANOVA; Fig. 3). Every *T. basalis* female (100% of 15 trials) responded to 1 DAE of the crude extract and to 1 DAE of the crude extract spiked with 0.033 and 0.33 μg nC$_{19}$, and their arena residence times were not significantly different (Fig. 3). However, when 1 DAE of the crude extracts was treated with 3.33 μg nC$_{19}$, fewer wasps responded (87% over 15 trials), and they showed reduced arena residence times compared to wasps presented with the unspiked treatment (Fig. 3).

Chemical Analysis of N. viridula CHs Satisfactory validation data for the solvent extraction method in terms of both linearity (R^2 ranged between 0.995 and 0.998) and reproducibility (RSD% better than 20%) were achieved. The LOQs were fixed at 0.5 ng, and the LODs were established at 0.1 ng.

A homologous series of *n*-alkanes with chain lengths from 19 to 36 carbon atoms was identified and quantified in the solvent extracts of *N. viridula* (Table 1). The average amount of all cuticular hydrocarbons extracted from a single *N. viridula* female was about twice that recovered from equivalent weights of male *N. viridula* body parts (3,540±1,138 and 1,818±85 ng mg^{-1} cuticle from females ($N=5$) and males ($N=5$), respectively; $t=-2.61$; $P=0.05$, t test). The hydrocarbon profiles showed consistent sex-specific qualitative and quantitative differences. nC$_{19}$ was detected only in male extracts, where it accounted for

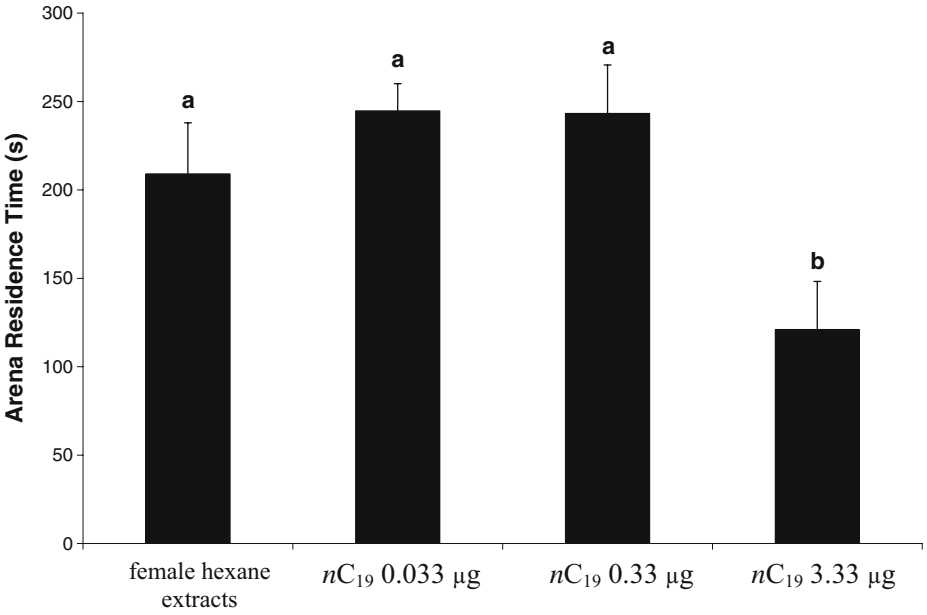

Fig. 3 Arena residence times (sec) of *T. basalis* females tested on arenas treated with aliquots of crude extracts of *N. viridula* females containing increasing concentrations of nC_{19}. For each test, 350 µl of solution was applied. Bars indicate mean±SE. Different letters above the bars indicate significantly different means (ANOVA, Tukey HSD)

3.4±1.1 % of the total hydrocarbons detected (Fig. 4, peak 1). Extracts from females contained significantly more nC_{23}, nC_{24}, and nC_{25} than extracts from males (Fig. 4, peaks 5, 6 and 7; Table 1).

Solid-phase Microextraction of Cuticular Hydrocarbons from Insect Cuticle and from Residues Left by N. viridula Adults Walking on Glass Sampling cuticular hydrocarbons from *N. viridula* adults with DC-SPME did not yield any linear hydrocarbons that were not present in the solvent extracts of *N. viridula* (Table 1). Furthermore, only about half of the total number of compounds identified from solvent extracts were also detected in the DC-SPME extracts (e.g., nC_{19}, nC_{24}, nC_{25}, nC_{26}, nC_{27}, nC_{28}, nC_{29}, nC_{30}, and nC_{31}) (Table 1; Fig. 5). When the chemical residues left by adult female and male *N. viridula* walking on a glass plate were sampled with DC-SPME, straight-chain alkanes from C_{24} to C_{31} were detected in footprints from both sexes, whereas only male footprints contained nC_{19} (Fig. 5, Table 1).

Discussion

Many insects deposit chemical residues on substrates, and these traces can provide intraspecific signals and/or interspecific cues that modify the behaviors of receiving organisms. For example, bumblebees leave residues on flowers that allow conspecifics to avoid recently visited flowers (Eltz 2006). Chemical residues can also serve as kairomones

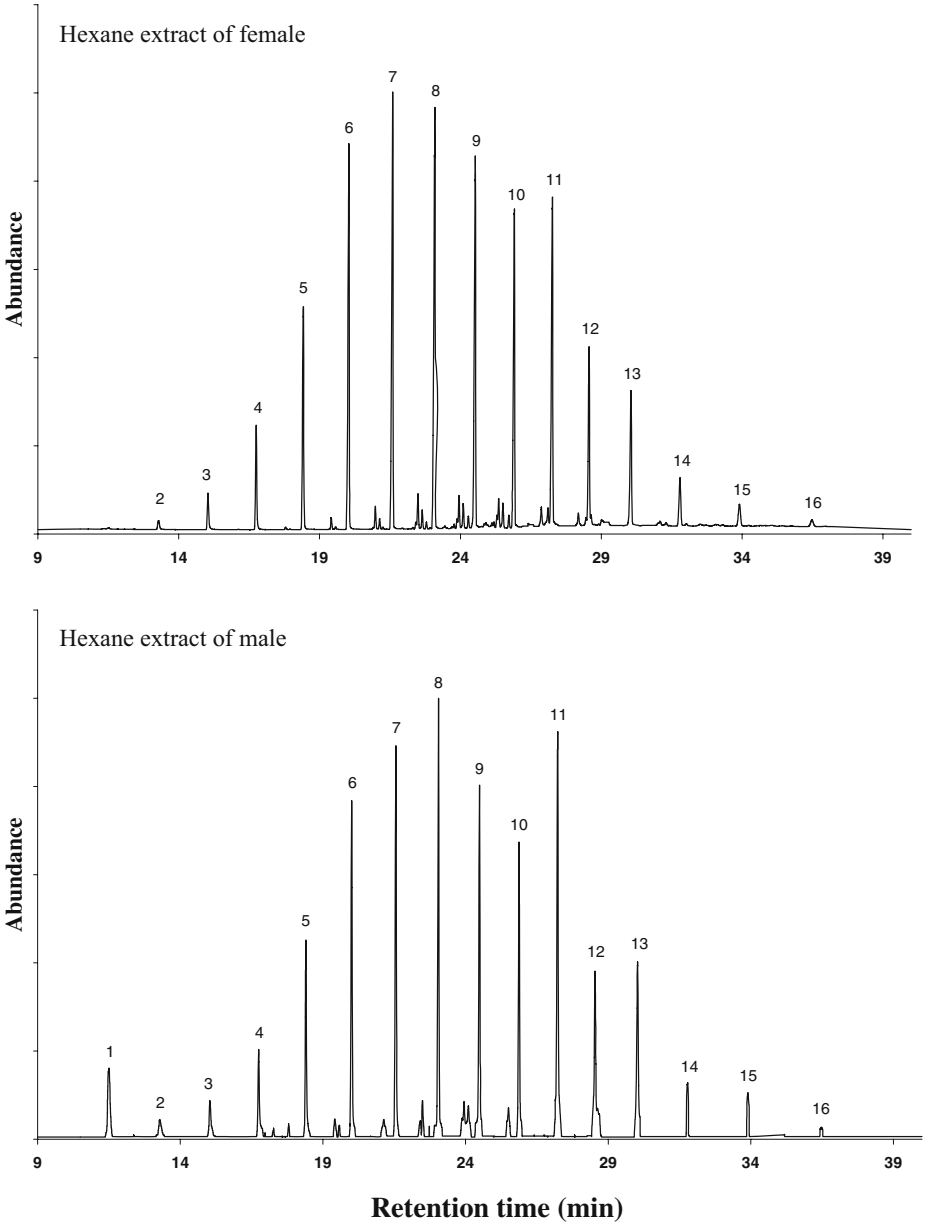

Fig. 4 Representative gas chromatograms of cuticular hydrocarbons extracted from adult female (top) and male (bottom) *N. viridula* with hexane. For peak identities, see Table 1, and "Methods and Materials" for analysis conditions

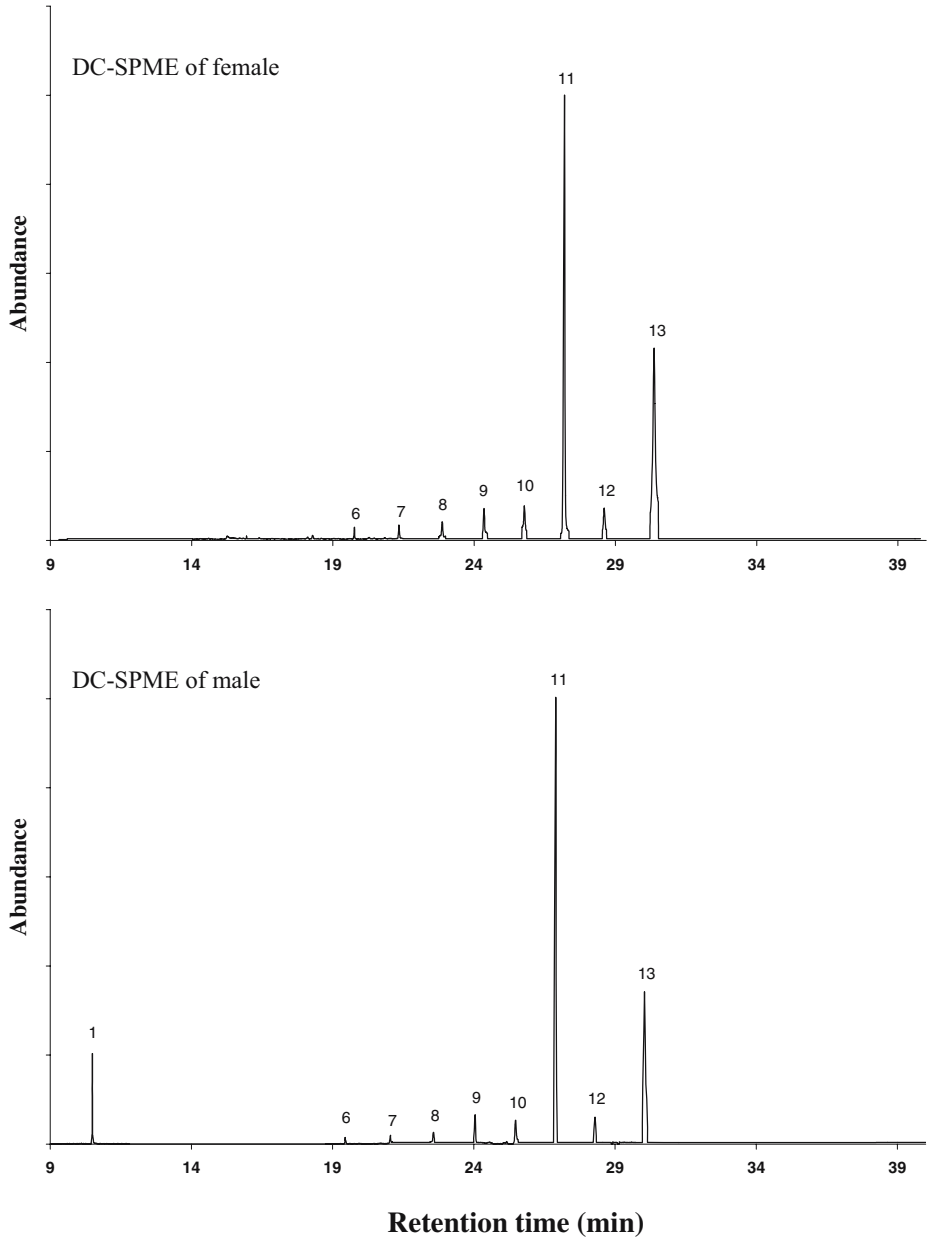

Fig. 5 Representative gas chromatograms of cuticular hydrocarbons extracted from adult female (top) and male (bottom) *N. viridula* with DC-SPME wiping the fiber over the head, pronotum, and legs. For peak identities, see Table 1, and "Methods and Materials" for analysis conditions

for natural enemies, as in the case of trails left by larvae of the pine looper moth, *Bupalus pinarius* L (Lepidoptera: Geometridae), which are exploited as cues by the larval parasitoid *Poecilostictus cothurnatus* (= *Platylabus cothurnatus*) Gravenhorst (Hymenoptera: Ichneumonidae) (Klomp 1981). Chemical residues can also be indirectly associated with the host as is the case with chemical residues left on the substrate by adult pentatomid bugs (Colazza et al. 1999b; Borges et al. 2003; Conti et al. 2003). Various origins for the chemical residues can be considered. For instance, the chemical footprints of lady beetles (Coleoptera: Coccinellidae) are secreted from the tenent hairs on the bottom of the tarsi, and the footprints consist of nonvolatile lipids identical to those in the cuticular waxes (Kosaki and Yamaoka 1996). In nature, lady beetle footprints deter oviposition by conspecifics, and deter foraging by aphid parasitoids (Hemptinne et al. 2001; Nakashima et al. 2004).

Our data showed that chemicals on the tarsi and scutella of *N. viridula* induced motivated searching responses by *T. basalis*. These results suggest that the kairomones mediating these responses are part of the wax layer of *N. viridula*, rather than being secreted by specialized glands such as those on *N. viridula* legs, which are the source of lipid adhesive fluid (Ghazi-Bayat and Hasenfuss 1980), or the tarsal glands situated in the tarsomer (R. Romani and N. Isidoro, personal communication). Whether or not the amounts of secreted cuticular hydrocarbons are more abundant in the tarsi than in the other body parts of *N. viridula* cuticle remains to be determined.

The insect wax layer contains a complex mixture of compounds that include straight-chain saturated and unsaturated hydrocarbons, and methyl-branched hydrocarbons (Gibbs 1998; Howard and Blomquist 2005). Several studies have shown that straight-chain hydrocarbons and related long-chain carboxylic acids that are present in moth scales elicit arrestment responses from foraging *Trichogramma* wasps (Boo and Yang 2000). For example, hexane extracts of adult *Scripophaga incertulas* Walker (Lepidoptera: Pyralidae) elicited searching responses from the egg parasitoid *Trichogramma japonicum* Ashmead (Rani et al. 2007), and straight-chain hydrocarbons from scales of *Plodia interpunctella* (Hübner) (Lepidoptera: Pyralidae) induced searching by *Trichogramma evanescens* Westwood. In the latter species, *n*-tricosane (nC_{23}) was identified as the most active component of the kairomonal blend (Jones et al. 1973).

It had been shown previously that the footprints of pentatomid bugs stimulated motivated searching by scelionid egg parasitoids (Colazza et al. 1999b; Conti et al. 2004), but the chemistry of the footprints had not been investigated. The results of the present study showed that these kairomonal cues are hexane-soluble, suggesting that the cuticular hydrocarbons might be involved. However, a reconstructed blend of straight-chain hydrocarbons extracted from female *N. viridula* induced only weak arrestment responses in *T. basalis* females. Thus, other components of the wax layer of *N. viridula*, such as branched hydrocarbons or more polar components of the wax layer, must be important in the elicitation of the full response. Analyses of *N. viridula* extracts have shown the presence of mono- and dimethyl-branched alkanes, and more polar lipids, and their possible roles in the wasps' responses are under investigation.

A dose-response effect of hexane extracts from the scales of *Choristoneura fumiferana* (Clemens) (Lepidoptera: Tortricidae) has been observed with *T. evanescens* females (Schmidt and Carter 1992). The responses of female *T. basalis* were also clearly influenced by different doses of hexane extracts of adults. *Trissolcus basalis* females responded to approximately 7.3 ng/cm^2 of hydrocarbons, which represents the amount of hydrocarbons (114 ng) applied on the 12.56-cm^2 treated area of the bioassay arenas at the dosage of 3×10^{-3} DAE of *N. viridula* females. It would clearly be an advantage for parasitoid females to perceive low levels of kairomones. Conversely, the adaptive significance of the decreased

responses of *T. basalis* females when presented with the much larger dose of hydrocarbons (e.g., ~30,000 ng/cm^2, applied to the 12.56-cm^2 treatment area, corresponding to the 10-DAE dose), remains unclear.

Indirect host-related cues emitted by both genders of the host can have different spatial-time links with the egg stage. This is particularly important when oviposition occurs far from the adult feeding or mating sites, as is the case with female *N. viridula*, which generally oviposit at sites removed from adult feeding sites (Todd 1989; Colazza et al. 1999b). Under such circumstances, cues associated with host males would be of minimal use to egg parasitoids, because these cues would not help the parasitoids to locate eggs. Instead, egg parasitoid females should optimize their sensitivity to cues produced by host females. The available data support such a scenario, because females of two *Trissolcus* species discriminate between chemical residues left by females or males of their pentatomid hosts (Colazza et al. 1999b; Conti et al. 2004). Similarly, *Telenomus isis* (Polaszek) females are able to discriminate between scales from female or male *Sesamia calamistis* (Hampson) (Lepidoptera: Noctuidae), showing a strong preference for the former (Chabi-Olaye et al. 2001). However, until now, the nature of the semiochemicals that allow egg parasitoids to distinguish between chemical residues left on substrates by male and female hosts had not been elucidated. The chemical and behavioral evidence provided in this paper suggests that *T. basalis* uses *n*-nonadecane, a sex-specific component of the cuticular hydrocarbons of male *N. viridula*, to discriminate between residues left by males or females. Whereas hexane extracts of the cuticular lipids of adult *N. viridula* showed qualitative and quantitative differences in the composition of the straight-chain hydrocarbon fraction, only nC$_{19}$, the male-specific hydrocarbon, was recovered from extracts of males and from DC-SPME of bug footprints. Furthermore, when nC$_{19}$ was added to the crude extracts of *N. viridula* females, *T. basalis* females showed significantly reduced arena residence times, similar to what occurs when female wasps are presented with hexane extracts of host males.

In summary, we report that hydrocarbons from the host cuticle mediate the responses of an egg parasitoid, and we provide the first identification of a kairomone that acts as a host gender recognition cue. Linear alkanes are common in nature, and they are present in the epicuticular waxes of foliage and other plant tissues, where they play an important role in plant physiology, and in the interaction of plants with other organisms (Müller and Riederer 2005). For example, compounds from a phytophagous insect that are adsorbed on the plant surface are used as host-finding kairomones for insect parasitoids (Müller and Riederer 2005), and leaf epicuticular waxes influence the ability of parasitoids to forage, locate, and attack their hosts (McAuslane et al. 2000; Grant and Barbosa 2006). What remains unknown is the mechanism by which an egg parasitoid can distinguish hydrocarbon residues from its host insects amid the waxy background of the plant cuticle. A better understanding of the key compounds involved in the host location process of insect parasitoids could not only provide fundamental ecological knowledge, but also may allow us to improve insect parasitoid efficiency by manipulation of their behavior with reconstructed blends of the relevant kairomones with synthetic compounds.

Introduction

Vogel (1969, 1974) first described floral oils as bee floral rewards. These floral oils are known to have evolved independently in 10 different families of angiosperms: Orchidaceae, Iridaceae, Krameriaceae, Malpighiaceae, Primulaceae, Scrophulariaceae, Solanaceae, Caesalpiniaceae, Gesneriaceae, and Curcubitaceae (Seigler et al. 1978; Steiner 1998).

Particularly interesting are the oil-producing orchids belonging to the subtribe Oncidiinae (Whitten et al. 2000). In the neotropics, many *Oncidium* s.l. (Orchidaceae: Oncidiinae) mimic the flowers of malpighiaceous species. Members of both groups bloom simultaneously and have functionally similar inflorescences, consequently attracting and sharing visitors and pollinators, mainly floral oil-collecting bees (Nierenberg 1972; Williams et al. 2001; Whitten 2006; Silvera 2002). Floral oil-collecting bees, most of which are solitary bees, have evolved independently in five different groups of two bee families: Melittinae (Melittidae), Ctenoplectrini, Centridini, Tapinotaspidini, and Tetrapediini (Apidae) (Steiner 1998; Sigrist and Sazima 2004; Vinson et al. 1997, 2006). These solitary bees presumably apply the oil as it is collected, or with some of their own secretions, to the cell provisions that occupy a portion of the brood cell (Alves dos Santos et al. 2002).

Pollination of many Oncidiinae and malpighiaceous species are mediated by oil-collecting bees. Field observations have revealed pollinaria of an *Oncidium* sp. on the head of *Tetrapedia diversipes* (Alves dos Santos et al. 2002). In addition, *Tetrapedia diversipes* has been observed collecting floral oil from *Oncidium cornigerum* and *O. pubes*, both Oncidiinea species growing at UNICAMP (Singer 2003), and from Malpighiaceae flowers (*Tetrapedia* sp, Neff and Simpson 1981; Sigrist and Sazima 2004).

Previous investigations on the floral oil chemistry of Oncidiinae species revealed that major constituents are asymmetrically substituted diacylglycerols, with a 3, 7- disubstituted fatty acid moiety possessing either acetoxy and/or hydroxyl groups (Reis et al. 2000, 2003, 2006; Reis 2005). However, there is no chemical evidence of *T. diversipes* visiting both Oncidiinae sp and Malpighiacea species and using these oils for survival. Thus, our primary objective was to explore the oil-pollination syndrome by comparing major lipid constituents of a solitary bee nest provision, *T. diversipes* Klug , located close to *Byrsonima intermedia* (Malpighiaceae) and several previously studied Oncidiinae species (*Oncidium pubes*, *Ornithophora radicans*, *Phymatidium delicatulum*, *Phymatidium tillandesioides*, Reis et al. 2000, 2003, 2006).

Methods and Materials

Collection, Extraction, and Purification of *Byrsonima* Floral Oils

Floral oil from *B. intermedia* (Voucher # UEC 95.102) growing at the University of São Paulo (São Paulo, Brazil), December 2003, was collected by washing the flowers with ethyl acetate (10 ml of solvent, 10 flowers, 2 mg of residue after solvent evaporation). Thin layer chromatography revealed one major spot (Rf 0.1, ethyl acetate/hexane 2/8) compatible with the presence of carboxylic acid derivatives. As previously reported for Oncidiinae floral oils (Reis et al. 2000, 2003, 2006; Reis 2005), the unaltered mixture and the mixture methylated with diazomethane were analyzed by ^{1}H NMR. Based on these data, we suggested that the major floral oil constituents were fatty acid derivatives possessing no glycerol moiety.

For a more complete study, fresh flowers (50 g) were dipped into ethyl acetate (40 ml) for 1 min. The ethyl acetate extract (0.68 g) obtained by evaporating the organic solvent was methylated with diazomethane. Purification of the crude extract by silica column chromatography (15 g), eluted with 700 ml of hexane/ethyl acetate (7.5:2.5) furnished a pure methyl ester (35 mg), whose acid moiety is herein named byrsonic acid **1a** (Fig. 3). Colorless oil, $[\alpha]_D^{20} + 4,0(c)0.2$, $CHCl_3$), IR νmax (film) 2923.82, 2852.16, 1740.6, 1458.97, 1430.99, 1241.58, 1022.93 cm-1; HRMS 470.3601 found (calculated 470.3607); 378.343 (16%), 350.313 (36%), 157.078 (100%) , 128.077 (43%). ^{1}H and ^{13}C NMR (Table 1).

Byrsonic Acid Absolute Configuration

Hydrolysis of Byrsonic Acid

Hydrolysis of **1a** (30 mg) in THF/MeOH/H_2O (3:1:1) in the presence of LiOH (Reis et al. 2003) furnished 3,7-dihydroxy-docosanoic acid, which was methylated with diazomethane,

Table 1 1D and 2D NMR [^{1}H (500 MHz, $CDCl_3$) and ^{13}C (125 MHz, $CDCl_3$)] data (HSQC, HMBC) of compound **1a** and 1D NMR ^{1}H (300 MHz, $CDCl_3$) and ^{13}C (75 MHz, $CDCl_3$)] data of **2a** and **3a**

under reduced pressure, to give the *S*-Mosher esters **1e** (0.8 mg, 22% yield). Treatment with *R*-(-)-methoxy-(trifluoromethyl)phenylacetic acid as described above yielded the Mosher ester **1f** (0.8 mg, 22% yield). ^{1}H NMR are in Fig. 2.

Collection, Extraction, and Purification of *Tetrapedia diversipes* Nests

Trap nests were set at the University of São Paulo in São Paulo, Brazil close to Malpighiaceae and Oncidiinae species. Bamboo pieces (15 cm long, 2 cm diam) closed at one end were used for nest construction. The *T. diversipes* nest was collected as soon as the female closed the cell. The bee cell provisions (79 mg) were extracted with methanol for 48 hr. The crude methanol extract (34 mg) was methylated with diazomethane. This was extracted with ethyl acetate (3 mg) and analyzed by gas chromatography-mass spectroscopy (GC-MS) revealing the presence of two major components, **2a** (20%) and **3a** (33%). The methylated crude provision extract (3 mg) was purified by silica gel column chromatography, yielding a mixture of **2a** and **3a** (1 mg), methyl esters derivatives of **2** and **3**. Compound **2a**: (MS, 70 eV): *m/z* 322 (2%), 267 (7%), 157 (100%), 128 (69%), 125 (45%), 103 (26%), and 43 (21%). Compound **3a**: (MS, 70 eV): *m/z* 350 (3%), 295 (7%), 157 (100%), 128 (69%), 125 (20%), 103 (33%), and 43 (24%). ^{1}H and ^{13}C NMR (Table 1).

Instruments

^{1}H NMR spectra were recorded with a Varian INOVA instrument operating at 500 MHz. Tetramethylsilane (TMS; 0.0 ppm) was used as an internal reference. ^{13}C NMR spectra were obtained at 125 MHz in $CDCl_3$, and the reference signal was from the solvent (77.0). GC-MS analyses were carried out by using an Agilent-6890/5973 system equipped with an HP-5 fused silica capillary column (30 m×0.25 mm×0.25 μm). Oven temperature was programmed from 50 to 290°C at 4°C min^{-1}. Injector temperature was 240°C. Helium was used as carrier gas, flow rate 1 ml min^{-1}. Mass spectra were taken at 70 eV with a scanning

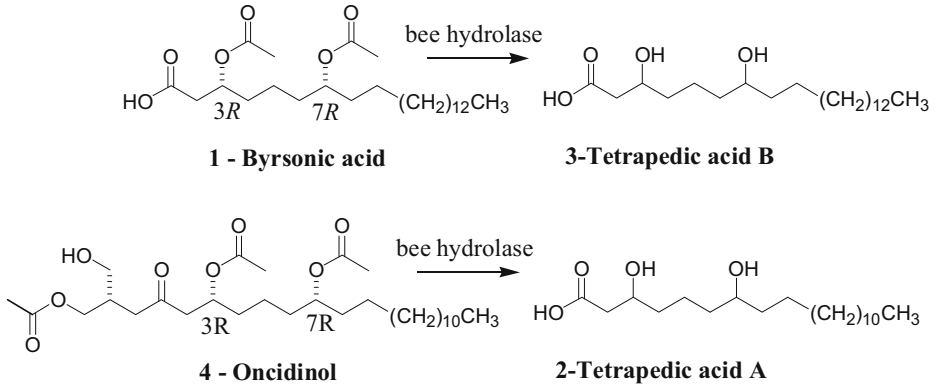

Fig. 3 Byrsonic acid **1** isolated from *Byrsonima intermedia*, Tetrapedic acid A **2** and Tetrapedic acid B **3** isolated from the nest of *Tetrapedia diversipes*, and ondicinol **4** isolated from *Ornithophora radicans* and detected in several other Oncidiinae floral oils (Reis et al. 2003)

speed of 0.84 scans s^{-1} and from *m*/*z* 40 to 700. High-resolution mass spectra at 70 eV were measured on a Micromass VG Autospec mass spectrometer.

Results and Discussion

Byrsonima Intermedia Floral Oil

^{1}H NMR and TLC analyses of *B. intermedia* floral oil revealed that this oil is mainly comprised of free fatty acids. The major fatty acid was isolated by silica gel column chromatography and was named byrsonic acid. Spectral data analysis of byrsonic acid methyl ester **1a** (^{1}H and ^{13}C NMR, 1D and 2D, HSQC, Table 1) revealed two methyl groups belonging to acetoxy groups (d_c 21.20, d_H 2.04; and d_c 21.16, d_H 2.03) and two carbinolic carbons at d_c 70.18 (d_H 5.19, m) and d_c 73.89 (d_H 4.84, m). Analysis of the long-range heteronuclear correlations (H, C HMBC, Table 1) provided evidence that one of the acetoxy groups was located at carbon 3 (d_H 1.61, d_C 38.89). The position of the second acetoxy group was not easily assigned because of a hydrogen signal superposition in the 1D (^{1}H NMR) and 2D NMR (H,H COSY) spectra, mainly between d_H 1.61–1.29. The correlation, J^{1} d_H 1.25 (overlapped) and 1.28, d_c 20.92, in the 2D NMR spectrum (H.C HSQC) indicated the presence of two diastereotopic hydrogens belonging to a methylene carbon (d_c 20.92). The unequivocal proof of this methylene neighborhood was obtained by long-range heteronuclear correlations (H,C HMBC) of hydrogens at d_H 1.38 (weak, ^{3}J, H-5), d_H 1.61 (^{2}J, H-4), d_H 2.53–2.58 (^{2}J, H-2) and carbon at d_c 70.18 (C-3) (Table 1). The weak correlation was assigned to methylene C-5 (d_c 20.92, d_H 1.38 and 1.25). In addition, a ^{2}J coupling between hydrogen at d_H 1.61 (H-4) and carbon at d_c 20.92 (C-5) indicated that this carbon is the C-3–C-5 moiety, and its small chemical shift was assigned to the double shielding *g*-gauche effect of the substituents at C-3 and at C-7 (Duddeck 1986). Unequivocal proof tethering all hydrogens of C-2 to C-7 was achieved by total correlation spectroscopy 1D-TOCSY exciting H-3 (d_H 5.20) by applying shaped pulses and 100 msec of mixing time (optimized value). Therefore, all hydrogen spin systems from C-2 to C-7 were visualized d_H 4.84 (H-7), 2.53 (H-2), 2.58 (H-2), 1.61 (H-4), 1.53 (H-6), 1.38 (H-5), 1.25 (H-5). A second 1D-TOCSY experiment exciting hydrogen-7 (d_H 4.84) and a mixing of 100 msec produced the same ensemble of signals d_H 5.20 (H-3), 2.53 (H-2), 2.58

(H-2), 1.61(H-4), 1.53 (H-6), 1.38 (H-5), 1.25 (H-5, H-8, H-9, H-10). However, the signal amplitude at d_H 1.25 was higher in the second experiment, which is compatible with its neighborhood (aliphatic CH_2 d_H 1.25). Consequently, the suggested structure for byrsonic acid, a novel natural fatty acid, is 3,7-diacetoxy-docosanoic acid **1**.

To determine the absolute configuration of the two asymmetric centers, we applied Mosher's methodology (Dale and Mosher 1973; Sullivan et al. 1973; Ohtani et al. 1991) by strategically modifying one chiral center at a time (Reis et al. 2003) and keeping in mind that the observed Δd^{SR} for certain hydrogens is the sum of the anisotropic effects of all MTPA present, leading to a result that is different from the Δd^{SR} obtained for the polyols with only one MTPA residue. By taking into consideration the above strategy, we first hydrolyzed compound **1a** producing methyl 3,7-dihydroxy-docosanoate **1b**. The selective esterification of hydroxyl-7 of the methyl 3.7-dihydroxy-docosanoate **1b** with (*S*)-MPTA and (*R*)-MPTA produced the derivatives **1c** and **1d**, which were characterized by the H-7 signals at d_H 5.09. The chemical shifts and the difference Δd^{SR} are depicted in Fig. 2. From these results, we suggest a 7-*R* configuration for **1**. To determine the C-3 absolute configuration of **1**, we used the 3,7-di-Mosher ester derivatives **1e** and **1f**. By scrutinizing **1c** and **1d**, we observed that the (*R*)- and (*S*)-MTPA derivatization had little influence on the methoxy group chemical shift of **1c** and **1d**. Therefore, the negative Δd^{SR} values observed in **1e** and **1f** were assigned to the anisotropic influence of the ester group on C-3 (Fig. 2). As a general rule, the effect on C-2 (β-carbonyl) hydrogens of both **1e** and **1f** was 50% larger than in **1c** and **1d**, which allowed a straightforward evaluation of the anisotropic effect arising from the Mosher acid group on C-3. From these observations, we suggest a 3-*R* absolute configuration for compound **1**. Consequently, the novel fatty acid from *B. intermedia*, herein named byrsonic acid, is (3*R*, 7*R*)-3,7-diacetoxy-docosanoic acid **1** (Fig. 3).

Tetrapedia diversipes Nest

Structures **2** and **3** were suggested for the two major components present in the *T. diversipes* nest cell provisions based on spectroscopic characteristics of their methyl ester derivatives **2a** and **3a** (^1H and ^{13}C NMR—Table 1 and MS). The two carbinols at d_c 67.86 (d_H 4.02, m) and d_c 71.81 (d_H 3.59, m) and the methylene carbon (d_c 21.46) were assigned to C-3, C-7, and C-5 of **2a** and **3a**. These spectral features were similar to those displayed by the methylated fatty acid moiety of **1b**. Based on the NMR and MS data, the structures were inferred to be 3,7-dihydroxy-eicosanoic acid (**2**) and 3,7-dihydroxy-docosanoic acid (**3**), two new fatty acids derivatives named tetrapedic acid A and B, respectively.

Byrsonima intermedia (Malpighiaceae), *Ornithophora radicans* (Oncidiinae, Orchidaceae) and *Tetrapedia diversipes* (Tetrapediini, Apidae) Chemical Similarities

Byrsonic acid (**1**) was identified in *B. intermedia* and Oncidinol (**4**) in several Oncidiineae species (*Oncidium hookeri*, *O. longicornu*, *O. varicosum*, *Phymatidium tillandensioides*, and *P. delicatum*) (Reis et al. 2000, 2003, 2006; Reis 2005). These findings are remarkable because both tetrapedic acid A **2**, and tetrapedic acid B **3** can be derived from Oncidiinae and Malpighiaceae species floral oils, which are biotransformed by hydrolases secreted by female mandibules during nest food mass mixing and manipulating (Fig. 3). It has been reported (Alves-Dos-Santos et al. 2002) that females spend a few minutes manipulating and consolidating the collected floral material. Thus, nest building involves not only floral oil harvesting, but also mixing it with secretions that could perform the chemical modifications we have observed (Alves-Dos-Santos et al. 2002). It is not yet clear why plants of unrelated

families such as Orchidaceae and Malpighiaceae produce these rare fatty acids: is it mimicry that lures the bees adapted to Malpighiaceae flowers to visit Orchidaceae?

In summary, this research has revealed that the main constituent of *B. intermedia* floral oil is (3*R*, 7*R*)-3,7-diacetoxy-docosanoic acid (**1**). The similarity of this compound with Oncidinol (**4**), present in the floral oil of Oncidiinae species is intriguing because both possess the same 3,7 substitution pattern and the same 3*R* and 7*R* absolute configurations. The same substitution pattern is present in major fatty acids isolated from *T. diversipes* cell provisions, 3,7-dihydroxy-eicosanoic acid (**2**) and 3,7-dihydroxy-docosanoic acid (**3**), presently named tetrapedic acids A and B, respectively. Both tetrapedic A (C20) and B (C22) may be biotransformation products of Oncidinol and Byrsonic acid by *T. diversipes* hydrolases in the hydropharingeal glands. These are clues to bee visitation and oil collecting from both Oncidiinae and Malpighiacea species, thus indicating that the deceit/pollination syndrome is not true for all Oncidiinae flowers. This is new information on the Apidae/Oncidiinae/Malpighiaceae relationships from a chemical point of view, a subject that has been attracting the attention of biologists since 1969 (Vogel 1974).

Acknowledgements The authors are indebted to FAPESP (Fundação de Amparo a Pesquisa do Estado de São Paulo—grants #01/02794-7, #98/07781-6 and #03/06624-4) and CNPq (Conselho Nacional de Desenvolvimento Científico e Tecnologia) for scholarships and financial support. The authors are also grateful to Vera Lúcia Imperatriz Fonseca and Sandra Regina Capelari Naxara of Universidade de São Paulo-USP for the *Byrsonima intermedia* flowers, and Carol Collins and Volker Bittrich for critical reading and text correction.

monolignol, lignans, phenylethanoids, and secoiridoids. Both qualitative and quantitative differences were observed among the three ash species. Hydroxycoumarins and the phenylethanoids, calceloariosides A and B, were present only in the phloem of Manchurian ash and might represent a mechanism of resistance against EAB.

Introduction

Since its accidental importation from Asia, emerald ash borer (EAB *Agrilus planipennis* Fairmaire (Col: Buprestidae), a phloem-feeding beetle, has infested and killed millions of ash (*Fraxinus* spp.) trees in Indiana, Ohio, Michigan, and Ontario (Herms et al. 2004; Cappaert et al. 2005; Poland and McCullough 2006). As EAB continues to spread, it has the potential to eliminate ash species from natural and urban forests throughout North America. In Ohio alone, there are 3.8 billion white ash trees (Griffith et al. 1991). Unlike congeneric wood-boring beetles endemic to North America, including bronze birch borer (*Agrilus anxius* Gory) and two-lined chestnut borer (*Agrilus bilineatus* Weber) that colonize stressed trees (e.g., Anderson 1944; Dunn et al. 1990), EAB is more aggressive, killing even healthy trees on high quality sites (Haack et al. 2002; Herms et al. 2004; Poland and McCullough 2006).

In a recent common garden study that investigated interspecific variation in ash resistance to EAB, Manchurian ash (*Fraxinus mandshurica* Rupr.) was shown to have low levels of EAB colonization and EAB-induced mortality, while North American ashes experienced high rates of colonization and severe mortality (Rebek et al. 2006). These observations are consistent with the hypothesis that Asian ashes have high resistance to EAB by virtue of their coevolutionary history. Reports indicate that EAB is rare in Asia, where Manchurian ash is a primary host (Haack et al. 2002; Liu et al. 2003; Schaefer 2005), and infestations appear restricted to stressed trees (Gould et al. 2005). This implies that Asian ashes may be generally resistant.

Relatively little research has addressed mechanisms of resistance of angiosperm trees to wood-borers (e.g., Hanks et al. 1999). We propose that in the case of phloem-feeding buprestids, host resistance results from constitutive and induced physical and phytochemical defenses (Dunn et al. 1990). More specifically, defense may have three main components: (1) constitutive, or pre-attack, physical and chemical defenses, such as thick outer bark and preexisting pools of compounds in the phloem that are either toxic and/or serve as deterrents against the insect; (2) immediate, attack-induced *de novo* synthesis and accumulation of specific, low-molecular-weight secondary metabolites, phenolic polymers such as lignin and suberin, and defensive proteins (Kemp and Burden 1986; Bostock and Stermer 1989; Fernandes 1990; Pearce 1996; Kehr 2006), which may slow the growth of the invading organism enough to allow for (3) subsequent formation of wound (necrophylactic) periderms (i.e., callus tissue), which serve to isolate the wound, inhibit the spread of the colonizing organism (e.g., by encapsulation of insect larvae), and reestablish phellogen and cambial integrity (Mullick and Jensen 1973; Mullick 1977; Biggs et al. 1984; Bostock and Stermer 1989; Robinson et al. 2004).

Allelochemicals are represented by a diverse array of plant secondary metabolites, including terpenes and phenolic derivatives such as tannins, flavonoids, and stilbenes. Whether constitutively expressed or induced in response to herbivory, they may serve a wide range of roles. The genus *Fraxinus* belongs to the family Oleaceae, which comprises around 600

species in 25 genera (Wallander and Albert 2000; Perez et al. 2005). The olive (*Olea europaea* L.), cultivated for its fruit and oil, belongs to this family and has been studied extensively with regard to chemical constituents. Compound classes that have been reported to be commonly associated with olives include iridoid glucosides, phenylethanoids, coumarins, and lignan glucosides (Bianco et al. 2001; Jensen et al. 2002; Ryan et al. 2002; Cardoso et al. 2005).

As part of a broader study investigating potential mechanisms of Manchurian ash resistance to EAB, we compared the constitutive composition of secondary metabolites in phloem from the main stem of white (*Fraxinus americana* L.), green (*Fraxinus pennsylvanica* Marsh.), and Manchurian ash. We hypothesized that: (a) Manchurian ash phloem contains concentrations of particular constitutive secondary metabolites different from white and green ash, and (b) that these compounds may be involved in resistance. To date, relatively few studies have investigated the phenolic chemistry of *Fraxinus* spp. phloem (Terazawa and Sasaya 1970; Tsukamoto et al. 1984; 1985; Nykolov et al. 1993; Kostova et al. 1995; Iossifova et al. 1998, 1999) with many focused on manna ash (*Fraxinus ornus* L.) (Steinegger and Brantschen 1959; Kostova 2001). The present paper addresses hypothesis (a), by providing chemical data that will be needed to investigate the role of putative defense compounds in resistance of Manchurian ash to EAB (hypothesis b).

Methods and Materials

Plant Material Eight 4-yr-old saplings each of *F. americana*, *F. mandshurica*, and *F. pennsylvannica* were obtained from Bailey Nursery, Inc., St Paul, MN, USA. The ash saplings had a mean stem height of 181±0.03 (SEM), 216±0.06, and 149±0.03 cm, respectively, and a mean stem diameter of 15.8±0.5, 23.2±0.9, and 12.4±0.3 cm, respectively. The dormant bare-root saplings were stored in the dark at 4°C for 2 wk before sampling.

Chemicals and Reagents Methanol and acetic acid (both HPLC grade) were purchased from Fisher (Pittsburg, PA, USA). Ultrapure water was prepared using a Milli-Q water system (Millipore Ltd, Bedford, MA, USA). Standards of caffeic acid, esculin, and vanillin were purchased from Sigma Aldrich (St. Louis, MO, USA). Chlorogenic acid, fraxin, oleuropein, and verbascoside, were purchased from Extrasynthese (Genay, France). Pinoresinol was purchased from Arbo Nova (Turku, Finland).

Extraction One hundred milligrams of stem phloem were ground in liquid nitrogen and extracted twice with 500 μl of 100% methanol over 48 hr in the dark at 4°C. The pooled extract was transferred to a 1.5-ml microcentrifuge tube and centrifuged (12,000×*g* for 5 min) to remove solids. Samples were stored at −20°C and analyzed within 1 wk of extraction.

Analysis of Phenolics with HPLC-UV, HPLC-ESI-MS, and ^{1}H NMR and ^{13}C NMR HPLC with UV detection and HPLC-ESI-MS were used to analyze phenolics. LC-MS analyses were conducted on a Hewlett Packard HPLC system (Palo Alto, CA, USA) model HP 1100 equipped with an HP DAD G1315A detector coupled to a QTof-1 mass spectrometer (Micromass, Manchester, UK). Chromatographic separation was carried out by using a Waters Xterra™ RP18, 5 μm, 4.6×150 mm column and a Waters Xterra ™ RP18, 3.9 μm, 3.0×20 mm guard column. The autosampler and column temperatures were set at 4 and 30°C, respectively.

The binary mobile phase consisted of water/acetic acid (A) (99.9:0.1, *v*/*v*) and methanol/acetic acid (B) (99.9:0.1, *v*/*v*), and the flow rate was set at 1 ml/min. The elution program was as follows (percentages refer to proportion of eluant B): 5–15% (0–15 min); 15–30% (15–35 min); 30–40% (35–40 min); 40–60% (40–50 min); 60–90% (50–55); 100% (55–60 min). The injection volume for all samples was 5 μl. Compound separation was followed by post-column splitting (1:1), passing of the LC effluent through the Photodiode Array (PDA) Detector (scanning range, 200–400 nm) and an electrospray source (source block temperature, 120°C; desolvation temperature, 400°C). The MS detector was optimized to obtain maximum yields of $[M\text{-}H]^-$ ions of epicatechin/flavonoid standards. The optimized parameters in the negative ionization mode were as follows: capillary voltage, 3.2 kV; cone voltage, 32 V. Argon was used as the collision gas at 20 psi and nitrogen as the nebulizing gas at 15 l/hr. For full-scan MS analysis, the spectra were recorded in the range of *m/z* 100–900.

We applied MS detection in survey scan mode to identify the major compounds in the HPLC eluate, and we compared these peaks with the PDA trace. In this MS method, full MS scans (survey) were analyzed on-the-fly by the instrument to identify the most abundant parent ions. The mode temporarily switched to MS/MS mode to perform daughter scans of the presumptive parent ions. Data acquisition and processing were performed by using a MassLynx version 3.5 data system (Micromass).

The identifications of esculin, fraxin, verbascoside, oleuropein, and apigenin were unequivocally confirmed by spiking samples with the respective standards and comparing retention times and ultraviolet (UV) spectra. Additional mass data for syringin was obtained with a LCQ Classic (Finnigan) by using a slightly modified version of the above LC-MS method. Calceolariosides A and B, oleuropein, and pinoresinol glucoside were isolated by semipreparative HPLC and further purified by normal-phase preparative TLC (1,000 μm thickness silica gel plates) with chloroform:methanol:toluene:acetic acid (80:30:8:2). These compounds were analyzed by ^{1}H NMR and ^{13}C NMR. Spectra were obtained in methanol-d_4 by using a Bruker Avance DRX-400 (400 MHz) spectrometer. ^{1}H NMR and ^{13}C NMR spectra were calibrated to the residual solvent peaks at δH 3.31 and δC 49.0, respectively.

Quantification of Selected Phenolics After identification, the compounds (Table 4) were quantified against external standards as mg g^{-1} FW. Lack of suitable external standards made it impossible to quantify all compounds. Contents were expressed as verbascoside equivalents for calceolariosides A and B, fraxin equivalents for fraxetin and mandshurin, esculin equivalents for esculetin and methylesculin, oleuropein equivalents for ligustroside and oleuropein hexoside, pinoresinol equivalents for pinoresinol dihexoside, pinoresinol glucoside, and syringaresinol. Quantitative HPLC analyses were performed on an Alliance 2690 separation module (Waters, Milford, MA, USA) equipped with an autosampler and a 996 Photodiode Array Detector (Waters). The same column and gradient program as described for the LC-MS system were used. The mobile phase consisted of water/acetic acid (A) (98:2, *v*/*v*) and methanol/acetic acid (B) (98:2, *v*/*v*). Monitoring and processing of data were performed at 280 nm.

Statistical Analysis The contents of selected phenolic compounds that were present in two or more ash species were examined by univariate analysis of variance (ANOVA) using SPSS 14.0 for Windows (SPSS Inc., Chicago). Levene's test was used to examine variance equality. Data that did not have equal variances were log-transformed to satisfy this assumption.

Results

Characterization of Phenolic Compounds Among the three ash species, a total of 38 individual compounds were analyzed in detail. The characterization of unknown phenolic compounds was based on comparison of UV, mass spectrometry (MS), MS fragmentation behavior, and published NMR data. Liquid chromatography/tandem mass spectrometry (LC-TMS) with electrospray ionization has proven to be a powerful tool for the characterization of nonvolatile, polar, and thermally labile phenolic compounds obtained from plant extracts (Eyles et al. 2003a, b; Cardoso et al. 2005; March et al. 2006).

Comparison of the ESI-MS/MS data with published data and standards revealed a diverse range of phenolic compounds in the crude phloem extracts including hydroxycoumarins, lignans, phenylethanoids, and secoiridoids. Tables 1, 2, 3 summarize the tentative identification of the chromatographic peaks on the basis of retention times, molecular weights, and the main ions obtained by TMS for compounds in each species. Given that the majority of the compounds detected are known and have been characterized in previous studies (Tables 1, 2 and 3), only brief explanations of the structural analyses of the major compounds are presented (Fig. 1).

Hydroxycoumarins Seven compounds were identified as hydroxycoumarins (**5**, **7**, **8**, **12**, **14**, **15**, and **16**). Most were identified as a glycoside containing one sugar moiety, usually a hexoside as characterized by a neutral loss of 162 Da (Fig. 2). Esculin (**5**) and fraxin (**14**) were identified by comparing with standards. Compound **8** exhibited a $[M\text{-}H]^-$ ion at *m/z* 353 and UV spectrum maxima at 290 and 335 nm. Its MS/MS spectrum included ions at *m/z* 191, which corresponds to a loss of hexose (162 Da) and at *m/z* 176, which corresponds to a loss of a methoxy group (15 Da) from *m/z* 191. These findings are consistent with those reported for methylesculin (Steinegger and Brantschen 1959; Vereecke et al. 1997). Compounds **12** and **15** were tentatively identified as fraxidin hexoside and mandshurin, respectively (Table 2, Fig. 3). Despite both compounds exhibiting the same $[M\text{-}H]^-$ ion at *m/z* 383 and MS/MS spectrum (*m/z* 221, 206), it was possible to identify each compound by comparing their UV spectra to those previously reported (Terazawa and Sasaya 1970; Jensen and Nielsen 1976).

Lignans Compounds **19**, **20**, **26**, and **28** showed maxima of absorption bands at around 281 nm, characteristic of furofuran lignans (Tsukamoto et al. 1984) and similar to the pinoresinol standard. Compounds **19** and **26** were identified as pinoresinol dihexoside and pinoresinol glucoside, respectively. Pinoresinol dihexoside (**19**) displayed a $[M\text{-}H]^-$ ion at *m/z* 681, and its MS/MS spectrum gave ions at *m/z* 519 and 357, originating from successive losses of 162 Da, suggesting the presence of two hexosyl residues. By contrast, pinoresinol glucoside (**26**) yielded only one neutral loss of 162 Da. Furthermore, the ^1H NMR and ^{13}C NMR data of this compound were consistent with the literature values (Bodesheim and Holzl 1997). Compound **22** exhibited a $[M\text{-}H]^-$ ion at *m/z* 523, corresponding to a neutral loss of a hexose moiety (162 Da) and the MS/MS spectrum (*m/z* 329, 359) was consistent with those reported for lariciresinol (Smeds et al. 2006). Thus, this compound was tentatively characterized as lariciresinol hexoside.

Monolignol Compound **10** exhibited an $[M\text{-}H]^-$ ion at *m/z* 371 and its MS/MS gave a $[M\text{-}H\text{-}162]^-$ ion at *m/z* 209, corresponding to the loss of a hexose. Furthermore, the product ion spectrum of *m/z* 371 yielded fragments at *m/z* 194 and 179, indicating the successive losses of 15 Da and the presence of two methoxyl groups (loss of methyl radicals) (Ye et al. 2005).

[a] Tentative identification based on MS data and UV spectrum consistent with literature

[b] Identification confirmed by NMR

[c] Identification based on retention time, mass spectral and UV spectrum consistent with those of standard

Based on these observations and a characteristic UV spectrum with a peak of 265 nm, **10** was tentatively identified as syringin (Wang and Sun 2005).

Secoiridoids Oleuropein (**33**) was identified by comparing with the standard. The ^{1}H NMR and ^{13}C NMR data for this compound were consistent with those found in the literature

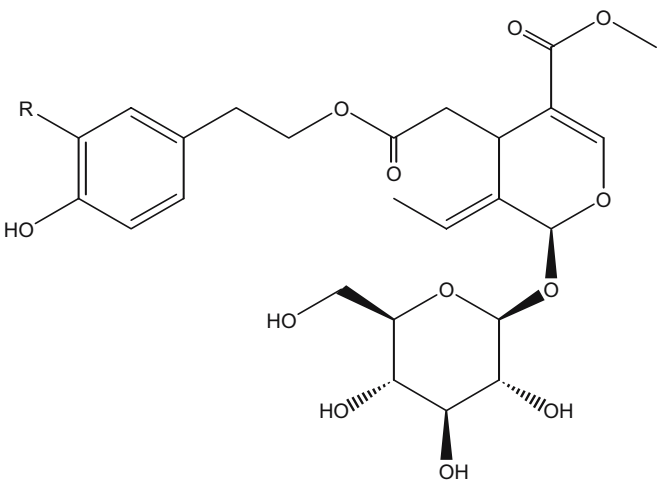
(Tanahashi et al. 1998). Compound **29** exhibited the same characteristic UV spectrum as oleuropein but gave an $[M\text{-}H]^-$ ion at *m/z* 701. Its MS/MS spectrum yielded an intense ion at 539, consistent with a neutral loss of a hexose (162 Da) plus other ions (*m/z* 377, 275, 307) identical to those for oleuropein. Therefore, this compound was tentatively identified as oleuropein hexoside. The MS/MS spectrum of compound **36** yielded ions at *m/z* 291, 361, 223, 179, and 127. These findings are consistent with ligustroside (Ryan et al. 2002). Compound **34** exhibited a similar MS/MS spectrum as ligustroside (*m/z* 361, 291, 259, 159) but with a $[M\text{-}H]^-$ ion at *m/z* 685, which corresponds to an addition of 162 Da. Therefore, it was tentatively identified as a ligustroside derivative.

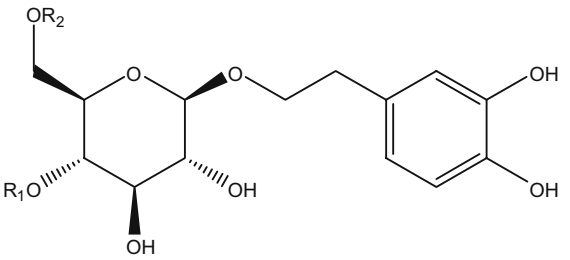


Phenylethanoids Compound **32** was characterized by the $[M\text{-}H]^-$ ion at *m/z* 623 and CID gave two major ions at *m/z* 461 and 161 that are in accordance with the fragmentation of

Monolignol:

Syringin

Secoiridoid glycosides:



Ligustroside: R = H
Oleuropein: R = OH

Fig. 1 (continued)

verbascoside (Cardoso et al. 2005). Compounds **27** and **35** exhibited $[M\text{-}H]^-$ ion at *m/z* 477 with almost identical UV and mass spectra suggesting them to be isomers of the same compound (Fig. 4). In both cases, their MS/MS spectra gave an $[M\text{-}H\text{-}162]^-$ ion at *m/z* 315,

Phenylethanoids:

Calceolarioside A: R_1 = Caffeoyl R_2 = H
Calceolarioside B: R_1 = H R_2 = Caffeoyl

Fig. 1 (continued)

indicating the loss of a caffeic acid moiety. In addition, caffeic acid (*m/z* 179) and its decarboxylated product (*m/z* 135) generated signals of low intensity (Fig. 4). The intense fragment ion at *m/z* 161 is most likely due to the fragmentation of the hexose moiety by the loss of water (Tolonen et al. 2004). Thus, compounds **27** and **35** were assigned as calceolariosides. The ^{1}H NMR and ^{13}C NMR data showed them to be identical with those reported for calceolariosides A (Nicoletti et al. 1986) and B (Ersöz et al. 2002), respectively.

Comparison of the Three Ash Species Both qualitative and quantitative differences were observed among the three species (Fig. 2, Tables 1, 2, 3 and 4). Comparisons of 17 individual phenolic compounds revealed a number of differences in composition as listed in Table 4. In particular, Manchurian ash was distinguished from the North American ash species by the presence of hydroxycoumarins, particularly mandshurin (**15**), fraxin (**14**), and fraxidin hexoside (**12**), in decreasing order of abundance. Other minor hydroxycoumarins that were not detected in either green or white ash included esculin (**5**), esculetin (**7**), methylesculin (**8**), and fraxetin (**16**). The phenylethanoids, calceolariosides A (**27**) and B (**35**), also were only found in Manchurian ash.

The main lignan in green and white ash was syringaresinol (**28**) followed by smaller amounts of pinoresinol glucoside (**26**) and pinoresinol dihexoside (**19**). Manchurian ash contained amounts of pinoresinol dihexoside (**19**) that were 11-fold higher than in green and 10-fold higher than in white ash ($F_{2,23}$=238, P<0.001). Similarly, higher amounts of pinoresinol glucoside (**26**) were found in Manchurian ash than either green (threefold) or white ash (twofold) ($F_{2,23}$=30.3, P<0.001). By contrast, both green and white ash contained over six times more oleuropein hexoside (**29**) than Manchurian ash ($F_{2,23}$=254, P<0.001). No syringaresinol (**28**) was detected in Manchurian ash. White ash had a higher amount of verbascoside (**32**) than either green (twofold) or Manchurian (ninefold) ash ($F_{2,23}$=28.7, P<0.004). From comparison of the chromatographic profiles, both white and

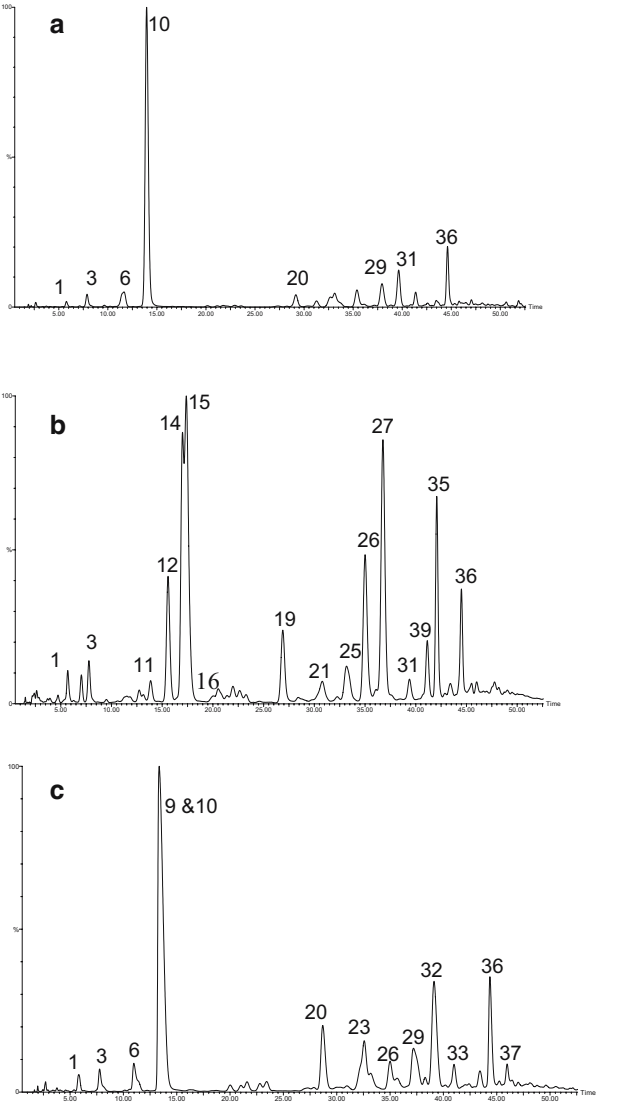


Fig. 2 Comparison of HPLC-UV chromatographic profiles at 280 nm of constitutive phloem extracts (100% methanol) of **a** green ash *Fraxinus pennsylvanica*, **b** Manchurian ash *Fraxinus mandshurica*, and **c** white ash *Fraxinus americana*. For peak assignments of the major peaks, see Tables 1, 2 and 3

green ash appeared to be dominated by the monolignol, syringin (**10**) (Fig. 2). This compound was not present in Manchurian ash.

Discussion

Manchurian ash was distinct from the two Northern American ash species by its unique content of hydroxycoumarins (particularly fraxin, mandshurin, and fraxidin hexoside), calceoloariosides A and B, and significantly higher concentrations of pinoresinol glucoside and pinoresinol dihexoside. The lack of hydroxycoumarins in green and white ash phloem

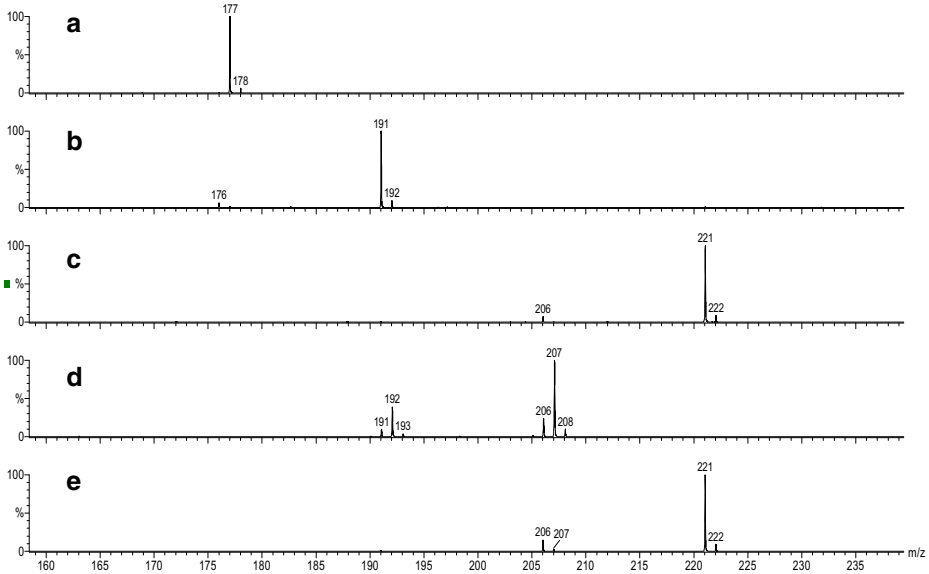

Fig. 3 Negative ion ms^2 spectra of the following hydroxycoumarin hexosides: **a** $[M\text{-}H]^-$ ion at *M/Z* 339 (compound 5), **b** $[M\text{-}H]^-$ ion at *m/z* 353 (compound 8), **c** $[M\text{-}H]^-$ ion at *m/z* 383 (compound 12), **d** $[M\text{-}H]^-$ ion at *m/z* 369 (compound 14), **e** $[M\text{-}H]^-$ ion at *m/z* 383 (compound 15)

was consistent with a previous study that failed to detect esculin, esculetin, chicoriin, or fraxin in the foliage of green or white ash (Santamour 1981). The occurrence of hydroxycoumarins and oleoside-type secoiridoids has been considered a characteristic feature of *Fraxinus* species (Iossifova et al. 1997; Jensen et al. 2002; Perez et al. 2005). In terms of phylogeny, our results suggest that green and white ash are chemotaxonomically distinct from Manchurian ash. This finding is supported by the molecular classifications of Wallander (2001) that placed green and white in the subsection *Melioides* (Endl.) Lingelsh, while Manchurian ash was placed in the subsection *Fraxinus*.

The majority of hydroxycoumarins and lignans we detected in the phloem of Manchurian ash have been previously reported from this species (Terazawa and Sasaya 1970; Tsukamoto et al. 1984, 1985). Compounds that were identified for the first time in this species included calceolariosides A and B, ligustroside, oleuropein hexoside, nuzhenide, tyrosol hexoside, and verbascoside. These compounds have been found in manna ash, which is endemic to the Mediterranean region and south-central Europe (Kostova 2001).

In terms of biological activity, hydroxycoumarins have been correlated with deterrence of insect feeding (Leszczynski et al. 1995). For example, in common annual sunflower (*Helianthus annus* L.), the induced synthesis of two coumarins, ayapin and scopoletin, was identified as one component of a defensive strategy against sunflower beetle (*Zygogramma exclamationis* F.) (Roseland and Grosz 1997). Silva et al. (2006) suggested that many plant β-glucosides, including esculin may impair insect development by inhibiting trehalase, which is a key enzyme controlling glucose availability in insects. We also detected the phenylethanoids, calceloariosides A and B, only in Manchurian ash, but their bioactivity has not been examined. However, another phenylethanoid, verbascoside, had no negative effects on the growth of buckeye butterfly (*Junonia coenia* Hübner) on *Plantago lanceolata* L. (Adler et al. 1995).

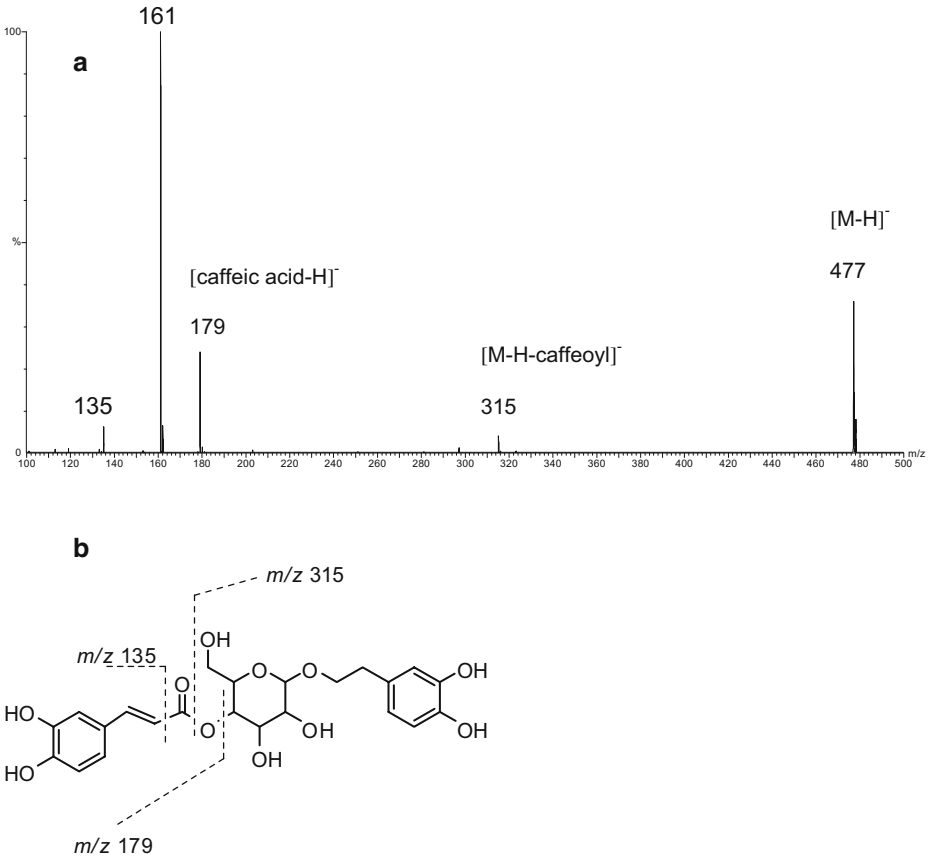

Fig. 4 **a** Negative ion ms^2 spectrum of compound 27; **b** proposed fragmentation pattern for $[M\text{-}H]^-$ ion 477

Secoiridoid glycosides were detected in all three species. As the name implies, the secoiridoids are structurally related to iridoids (cyclopentanoid monoterpenes), an important class of secondary defensive plant compounds, which have been implicated in plant–herbivore interactions (Nieminen et al. 2003; Biere et al. 2004; Harvey et al. 2005; Penuelas et al. 2006). According to Konno et al. (1999, 2001), secoiridoid glycosides such as oleuropein have anti-feedant properties based on their strong protein-complexing activity after hydrolysis by plant β-glucosidases. Biere et al. (2004), however, proposed that for the beet armyworm (*Spodoptera exigua* Hübner), iridoid glycosides may directly act as feeding deterrents rather than post-ingestive inhibitors, due to their extremely bitter taste.

In the present study, pinoresinol glucoside and pinoresinol dihexoside were detected in Manchurian ash in significantly higher amounts than in green or white ash. Structurally, pinoresinol is one of the simplest lignans, being a dimer of two coniferyl alcohol units. Lignans consist of dimers of phenylpropanoid (C6–C3) units enzymatically coupled through linkages between the propane chains (Willfor et al. 2003). A number of lignans have been reported to be insecticidal. For example, pinoresinol has antifeedant activity and inhibits larval growth and molting of the bloodsucking bug (*Rhodnius prolixus* Stal) and the milkweed bug (*Oncopeltus fasciatus* Dallas) (Cabral et al. 1999; Garcia et al. 2000). recently, pinoresinol sequestered from its host plant was found in the defensive secretion produced by glandular hairs of cabbage butterfly caterpillars (*Pieris rapae* L), where it acts as a potent antifeedant to ants (*Formica exsectoides* Forel) (Schroeder et al. (2006).

In summary, we have documented substantial qualitative and quantitative differences between the constitutive phloem chemistry of Manchurian ash, which is resistant to EAB, and North American ash species, which are highly susceptible. Many of the compounds unique to Manchurian ash, or present in higher concentrations, are toxic or deterrent to other herbivores. However, *in vitro* and/or *in vivo* insect bioassays will be required to determine whether any of these actually contribute to EAB resistance of Manchurian ash. While our study focused on constitutive phloem chemistry, induced phytochemical responses to stem invasion are critical components of tree defense to beetles and pathogens (e.g., Bostock and Stermer 1989; Raffa and Klepzig 1992; Franceschi et al. 2005) and may also contribute to resistance of deciduous trees to wood-borers. As such, this study also provides a starting point for investigations of feeding-induced responses of ash to EAB.

Introduction

Goldenseal (*Hydrastis canadensis* L., Ranunculaceae) is an herbaceous perennial that is found in North American under mesic cove forest canopies throughout much of the south and eastern seaboard and north into Canada. The rhizome, rootlets, and root hairs produce medicinally active alkaloids, including the major alkaloids berberine, canadine, and β-hydrastine. Because of the alkaloids, *Hydrastis* is an important dietary supplement, which currently retails at a price of over $160 per pound. Indigenous use of *Hydrastis* by native Americans was widespread for a variety of infectious diseases (Moerman 1986). Today, the rhizome and rootlets are used as an antibacterial treatment, for skin infections, conjunctivitis, otitis media, and urinary tract infections. However, the plant has been aggressively harvested from its native setting (wildcrafted) and is now listed in Appendix II of the Convention on International Trade in Endangered Species (CITES). Because of harvesting pressures and loss of habitat, increasingly more of the raw material for medicinal plant use originates from cultivated sources rather than from wildcrafted plants. Our understanding of reciprocal rhizosphere influence on formation of clinically relevant plant secondary metabolites is woefully inadequate. We have little data on how fungi in the plant root rhizosphere may alter the ratios and makeup of medicinally important plant metabolites or whether those same plant compounds present in root exudates have a selective effect on the composition of the fungal rhizosphere community. Although individual alkaloids, berberine and hydrastine, have been reported to have antifungal activity (Cernakova and Kostalova 2002; Goel et al. 2003), neither *Hydrastis* alkaloids in combination nor the *Hydrastis* whole root extract have been investigated for effect on fungi. This study explores whether the level of association between *Fusarium* and *Hydrastis* can be distinguished by the fungal responses to alkaloid treatments and if the treatment effects are the products of additive or synergistic interactions of two or more *Hydrastis* alkaloids.

Materials and Methods

Fungal Isolation Three media were prepared, Czapeks Dox containing penicillin G (10,000 IU/ml) and streptomycin (10,000 μg/ml), water agar containing the same antibiotics, and carnation leaf agar (Sigma, St. Louis, MO, USA). Wildcrafted and commercial *H. canadensis* seeds (Horizon Herbs, Williams, OR, USA) were sterilized in 10% Clorox and plated on media. After 5 d at room temperature, transfers were made to potato dextrose agar (PDA), and after 7–10 d, the fungi were identified. *Hydrastis canadensis* leaf, stem, rhizome, and rootlet tissue were surface sterilized with 10% Clorox and plated on water agar. Isolates were continuously transferred until pure cultures were growing. *Fusarium* cultures were identified by the *Fusarium* Research Center, Department of Plant Pathology, Pennsylvania State University (PSU). By using a modified staining method (Koske and Gemma 1989), *H. canadensis* root and seed tissue was examined directly for arbuscular mycorrhizae (AM). To detect filamentous, non-AM fungal growth *in situ*, root tissue was dipped in 95% ethanol and flamed briefly. Root tissue was cut into 5-mm sections, and seeds were stripped of their pericarp. Lactophenol blue was added to each tissue, and tissue were examined microscopically (×40). *Hydrastis canadensis* soil samples were collected from soil adhering to the rootlets of *H. canadensis* plants and from a site devoid of *H. canadensis* or any other herbaceous plant. Both soils were screened also for the presence of AM reproductive spores by using screens of increasingly smaller mesh. In addition, soil slurries were prepared and added to the three isolation media. After 3 d, fungi were transferred to PDA

tubes and identified. Corn kernels were added directly to both soil samples to isolate pathogenic fungi. After 14 d, kernels were plated on water agar containing antibiotics. Fungal transfers were made.

Stock Hydrastis Extraction and Standards *Hydrastis canadensis* tissue was air-dried and ground (20 mesh) with a Wiley mill. Root and rhizome samples (100 mg) were defatted with 50 ml *n*-heptane for 2 h on a Labline Orbital Shaker at 100 rpm in dark brown bottles. Samples were filtered (Whatman #1) and then dried for 2 h. Fifty ml 50% methanol: 1% acetic acid were added, and samples were placed on a shaker (100 rpm), 25°C, 24 h. The sample was filtered and re-extracted twice. The three filtrate samples were combined, filter sterilized (Nalgene 0.45 μm), evaporated, and stored in a dark bottle at 5°C. A voucher specimen of *H. canadensis* (#05001ARZ) is stored in the Norton Brown Herbarium, University of Maryland, College Park, MD, USA. Alkaloid standard stock solutions (*w/v*) of 0.12% berberine dihydrochloride (Chromadex, Santa Ana, CA, USA), 0.02% canadine (Chromadex, Santa Ana, CA, USA), 0.08% hydrastinine hydrochloride (Sigma-Aldrich, St. Louis, MO, USA) were prepared and filter sterilized.

Spore Counts Seven treatments were added in 1-ml increments to 125-ml Erlenmeyer flasks wrapped in aluminum foil: three individual alkaloid standards, all three alkaloids combined into a standard mix, a 0.2% (dry *w/v*) *Hydrastis* root extract (05001ARZ), a control of 50% methanol (1% acetic acid), and water. A spore suspension of three *Fusarium* isolates 5001AR (*Fusarium oxysporum*, from *Hydrastis* rootlet tissue), PSU 0-1174 (*Fusarium commune*, from PSU) and 9001ARC (*Fusarium solani*, from *Hydrastis* rhizosphere soil) was prepared. Inoculated carnation leafs were added to distilled water, filtered through sterile cheesecloth, and resuspended in 0.1% Tween 20. One milliliter (10^6 conidia) of each isolate was added to flasks containing treatments and incubated in 25 ml of Czapeks Dox medium for 0,1,2,3, and 4 d. Hyphae were filtered, lyophilized, and dry weight was determined. Filtrate was also collected, lyophilized, and stored at 5°C. Chlamydospore formation and macroconidia germination rates from lyophilized, 4-d-old mycelia were determined with a Bright line hemocytometer and light microscopy (×40).

Mycotoxin Analysis Freeze-dried filtrates were analyzed by using enzyme-linked immunosorbent assay (ELISA; Veratox, Neogen, Lansing, MI) to determine if *Hydrastis* alkaloids altered *Fusarium* mycotoxin production.

Statistical Analysis The data of isoquinoline alkaloid treatment effects on the fungal response, including macroconidial germination and mycotoxin production, were normally distributed; therefore, they were analyzed with a paired *t*-test.

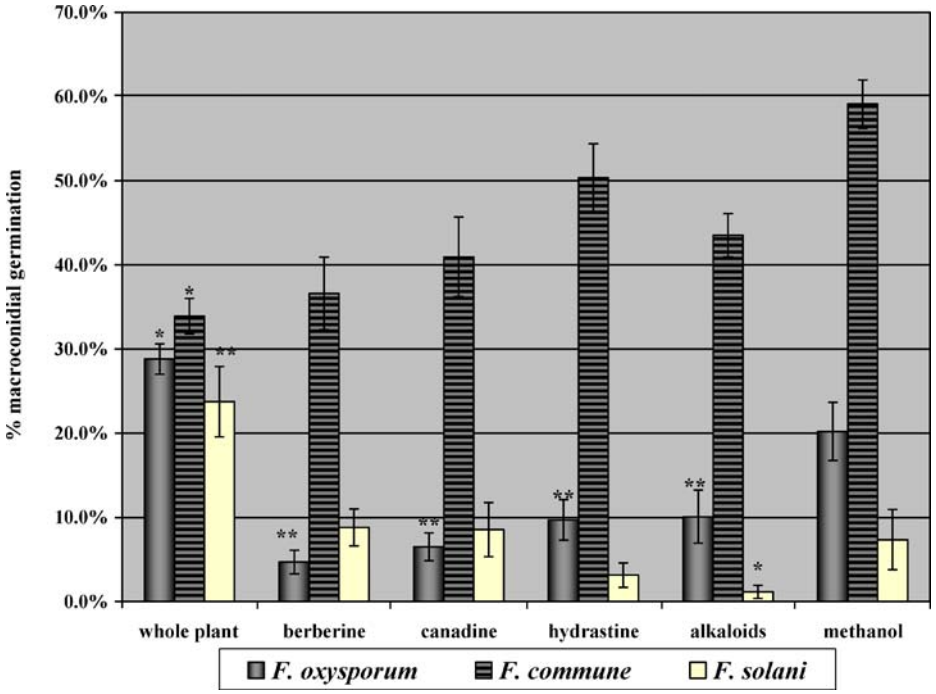
Results and Discussion

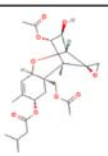
Results from screening *Hydrastis* tissue and surrounding soil provide limited evidence of a selective rhizosphere effect. From native *Hydrastis* plant populations, *F. oxysporum* was isolated from disease-free rootlet and seed tissue, whereas *Pythium* spp. was isolated from seed. The *F. oxysporum* isolate was microscopically detected intracellularly and localized near rootlet tips. In addition, coenocytic hyphae were also detected in the same *Hydrastis* root pericycle tissue from which *F. oxysporum* (05001AR) isolation occurred, although the

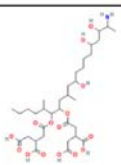
unknown fungus was never isolated in culture. Microscopic examinations of stained *Hydrastis* root tissue provided no evidence for AM fungi, nor were AM chlamydospores found in any of the soil collections. Mesic cove forests where *Hydrastis* was collected are not particularly conducive to high populations of AM fungi. *Fusarium solani* and *Pythium* sp. were present in *Hydrastis* rhizosphere soil. Species isolated from non-rhizosphere soil include *Rhizoctonia solani* and *Gliocladium* spp. Isolates from commercial *Hydrastis* tissue include *F. solani* from rootlet and leaf tissue, and *F. oxysporum* isolated from seed. No fungi were isolated from rhizome or stem tissue of any *Hydrastis* sample. Although the *Hydrastis* rhizosphere soil does not drastically alter the fungal community, the presence of *F. oxysporum* within *Hydrastis* root tissue suggests that elements of *Hydrastis* root exudates may influence the level of association of *Fusarium* species with root tissue.

To model *Hydrastis/Fusarium* interactions at the host plant root interface, an assay was designed based on the assumptions that berberine, canadine, and hydrastine are present in *Hydrastis* root exudates, as evidenced by plant cell culture experiments (Maddox et al. 1999). The whole root extract was chosen to model the complex of compounds present in *Hydrastis* root exudates. Analysis with liquid chromatography-mass spectroscopy (data not shown) indicated that the whole root extract contained berberine, canadine, and hydrastine. Based on previous *Hydrastis* extraction studies (Galeffi et al. 1997; Gentry et al. 1998; McNamara et al. 2004), minor alkaloids and non-alkaloid components should also be present. Three *Fusarium* species exhibiting different levels of association with *Hydrastis* root tissue and rhizosphere were identified. Treatment effects on *Fusarium* growth and spore formation were not significant for the three species (data not reported). However, macroconidia germination rates represented a significant response factor, as summarized in Fig. 1. All individual alkaloid treatments significantly inhibited *F. oxysporum* macroconidia germination (75–100%), whereas the whole root extract treatment stimulated germination (25%). *Fusarium solani* germination was significantly stimulated by the whole root extract (200%), whereas only the alkaloid standard treatment inhibited spore germination (75%). In contrast, the germination rate of the non-*Hydrastis* isolate, *F. commune*, was inhibited by all treatments; especially by the whole root extract treatments (40%). The components responsible for the inhibition of macroconidia germination of the *Hydrastis* isolates appear to be berberine and canadine. None of the major alkaloid compound(s) found in the whole root extract stimulated any isolate, whereas only the *Hydrastis* isolates were stimulated by the whole root extract. The results suggest that non-alkaloid components and/or minor alkaloids were stimulatory singly or synergistically, although additional experiments are required to be certain of the active component. Because disease symptoms were absent in the *Hydrastis* root tissue from which the *F. oxysporum* was isolated, this suggests that the isolate is nonpathogenic and may be endophytic. Gunawardena et al. (2005) noted that *Pisum sativa* (pea) root exudates stimulated macroconidia germination in *F. solani* species complex (*Nectria haematococca*) in a host-specific pattern and influenced the establishment of the endophytic relationship. Although the *F. commune* isolate exhibited the highest macroconidia germination rates, only the *Hydrastis* isolates responded positively to the whole root extract treatment by increasing germination rates. Growth within *Hydrastis* root tissue occurred only with the *F. oxysporum* isolate, suggesting that signal compounds present in the extract may be influencing the endophytic status.

Changes to the cultural media pH can influence fungal response. Both *F. commune* and *F. solani* exhibited a similar pattern of pH change with treatments, except that the changes in the pH values for *F. commune* whole root extract and methanol treatments lagged slightly (data not shown). The change in pH values for *F. oxysporum* whole root extract and methanol treatments were similar to the *F. commune* isolate. However, the initial pH values







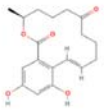


Fig. 1 Isoquinoline alkaloid effect on germination of macroconidia by three *Fusarium* spp. grown in Czapeks Dox liquid media. Treatments—berberine 0.12 mg ml−1, canadine 0.02 mg ml−1, hydrastine 0.08 mg ml−1, and whole root extract 2.00 mg ml−1—were dissolved in 1 ml of 50% methanol/1% acetic acid solvent and added to 25 ml of culture medium containing 1.0 ml fungal inoculum (approx. 106 conidia ml−1). Samples (N=12) expressed per mg of dry weight mycelia on d 4 of the assay (*error bars* the standard deviation of the error, *P<0.05, **P<0.01, paired t-test)

of individual alkaloid treatments were higher than the other isolates (pH 6.5 vs. pH 4.75), and remained fairly constant during the study. It is unclear which element was buffering the media—the basicity of alkaloid treatments or the response of the endophytic isolate. In either case, treatment replicates were randomized with respect to both fungus and treatment, which suggests that the pH pattern exhibited is unique to the endophytic isolate and is not because of differences in pH between alkaloid medium and the control.

Production and excretion of mycotoxins might also play a role during interactions at the rhizoplane. All *Fusarium* isolates were screened for mycotoxins at the end of the growth phase on d 4 (Table 1). Ueno et al. (1977) reported that the *F. commune* isolate was capable of producing the mycotoxin zearalenone (ZON) in culture. The results indicate that the mycotoxin was present in the water treatment during our assay. All other treatments, particularly berberine, canadine, and whole root extract, inhibited the production of ZON in the *F. commune* isolate, which did not produce any other mycotoxin. The *F. solani* isolate did not produce detectable mycotoxin levels in any treatment. All alkaloid treatments were inhibitory to fumonisin production, especially berberine. Canadine significantly stimulated T-2 mycotoxin production by the *F. oxysporum* endophyte, whereas hydrastine had less of a stimulatory effect. The alkaloid standard treatment significantly stimulated production of ZON by *F. oxysporum*. The whole root extract, canadine, and methanol treatments had no effect, whereas berberine and hydrastine treatments had an inhibitory effect on ZON production. Because the ratios of major alkaloids were approximately equal between the

The data for this graph was collected from the same experiment as Fig. 1. Sample measurements ($N=3$) were taken of mycelia filtered from culture on d 4 using Neogen ELISA fluorescence plate reader. Results expressed as ng metabolite/mg dry weight mycelia.

*$P<0.05$, paired *t*-test

whole root extract and alkaloid standard treatments, the results suggest a synergistic effect among the three alkaloids that was able to overcome the inhibitory effects of berberine and hydrastine in the alkaloid standard treatment but not in the whole root extract treatment. It is possible that minor alkaloids or non-alkaloid components of the whole root extract prevented the synergistic interaction. Overall, mycotoxin mass values were near the limits of detection for the Neogen ELISA kit used in this study. However, preliminary screening indicated that the *F. oxysporum* endophyte is metabolically more active in producing mycotoxins and, thus, may be more competitive with other rhizosphere fungi at the *Hydrastis* rhizoplane.

As cultivated *Hydrastis* roots are used more frequently for the manufacture of commercial herbal medicine rather than wildcrafted sources, future work is required to understand if the endophytic status of *F. oxysporum* alters the alkaloid content and ratios of *Hydrastis* root tissue. This study provides the first evidence that medicinally active *Hydrastis* alkaloids influence *Fusarium* isolates in the rhizosphere.

Acknowledgements I acknowledge Paul Strauss, for permission to wildcraft goldenseal on United Plant Savers land and Alex Johnson for contributions to the ELISA detection. This study is part of the Ph.D. dissertation research undertaken by Michael C. Tims.

For a fast and reliable bioassay, the test plant species must germinate uniformly and grow relatively quickly (Dayan et al. 2000). Increasingly, plant biologists have been turning to *Arabidopsis*, the favored system for the study of plant molecular genetics and development (Mitchell-Olds 2001; Shimizu and Purugganan 2005). Specifically, *Arabidopsis thaliana* (L.) Heynh. is a useful test species because it shows uniform germination and rapid growth, and thus represents an excellent model for the study of plant responses to allelochemicals and other environmental toxins (Baerson et al. 2005).

In this study, we selected two response parameters, seed germination and root radicle elongation, to obtain preliminary assessments of the activity of 21 plant secondary metabolites commonly considered as natural phytotoxins (Reigosa et al. 1999). *Arabidopsis thaliana* was used as plant model. Dose–response curves were obtained for each test compound, allowing the determination of several key parameters including the inhibition threshold (lowest concentration required to initiate inhibition), the IC_{50} (concentration required to obtain 50% inhibition), and the lowest complete inhibition concentration (LCIC) for each effect. These parameters are important because they establish a frame of reference to which subsequent tests can be compared (Dayan et al. 2000).

Methods and Materials

Three experiments were performed. The first evaluated the effects of the different compounds on germination. The other two evaluated effects on root elongation in the presence and absence of nutrient solutions.

Chemicals

Twenty-one molecules were tested, all obtained from Sigma-Aldrich (St. Louis, MO, USA), with the exception of protocatechualdehyde (Merck, Germany). Stock solutions of test compounds were made in different solvents based on the compound's solubility: 1 M ethanol for eucalyptol, quercetin, vanillin, sinapinic acid, syringic acid, syringaldehyde, vanillic acid, ferulic acid, *p*-coumaric acid, chlorogenic acid, and rutin; 1 M dimethyl sulfoxide for gallic acid, gentisic acid, *p*-hydroxybenzoic acid, protocatechuic acid, *trans*-cinnamic acid, 2-benzoxazolinone (BOA), protocachualdehyde, and tyrosol; and 2×10^{-3} M distilled water for the less soluble juglone and L-mimosine (see Fig. 1 for all structures).

From these stocks, various aqueous solutions were made up and adjusted to pH 6 with NaOH (Jose and Gillespie 1998; Martin et al. 2002): 10, 50, 100, 500, 750, and 1,000 μM for the germination test and root elongation without nutrients test, and 125, 250, 500, and 1,000 μM for the root elongation with nutrients test. In all experiments, a control with distilled water and another control with the solvent were prepared.

Seeds

Seeds of *A. thaliana* L. (Heynh.), ecotype Columbia, obtained from Herbiseed, were surface-sterilized as described in Baerson et al. (2005).

Bioassays

For germination tests and root elongation tests without nutrients, seeds were placed in 24-well plates with 1.25-cm-diam Whatman no.1 paper disks (Maidstone, England), and

watered with 200 μl of the test solution or control. All control and test treatments were replicated three times for germination tests, and eight times with 8 pregerminated seeds, for root elongation tests without nutrients. For root elongation with nutrients supplied, 25 seeds were placed in square petri plates with a semisolid media containing 0.5× Murashige and Skoog salts, 1× Gamborg's B5 vitamins, 1% sucrose (w/v), and 2% Gelrite® (w/v) adjusted to pH 6. All treatments and controls were replicated four times.

Plates were placed in a cold chamber for 3 d at 4°C to synchronize germination. Plates with cold stratified seeds were then transferred to a growth chamber with day/night temperatures of 22 and 20°C, respectively. Average light intensity was maintained at ~80 μmol m^{-2} sec^{-1} during a 16-hr light cycle.

Germination was assessed at 0, 12, 24, 36, and 48 hr with a magnifying glass. The data were used to calculate the germination index G_T, and all alternative indices (*S*, speed of germination; AS, speed of accumulated germination; CRG, coefficient of rate of germination; and MGT, mean total germination) as described in Chiapusio et al. (1997).

Before measurement of roots, plates were frozen at −18°C. Radicle length was measured 6 d after the beginning of the experiment in the test without nutrients, and 14 d after in the test with nutrients.

Statistical Analysis

Mean germination and mean germination indices were compared to their respective controls by using the Mann–Whitney *U* test ($P<0.05$). All dose–response curves were modeled by regression analysis with SPSS® models (linear, logarithmic, inverse, quadratic, cubic, potential, growth, and exponential), and tested by using the Mann–Whitney *U* test ($P<0.05$) selected on the basis of the determination coefficient.

Results and Discussion

Germination Tests

The organic solvents used for dissolving the compounds had no significant effects, either in the germination or root elongation tests.

Total germination, G_T, is an overall assessment of the effect on germination (inhibition, stimulation, or no action) (Chiapusio et al. 1997). G_T was affected by more than half the molecules tested (*trans*-cinnamic, ferulic, *p*-hydroxybenzoic, sinapinic, *p*-coumaric, gentisic, and gallic acids, and protocatechualdehyde, vanillin, L-mimosine, and juglone).

trans-Cinnamic and ferulic acids inhibited *A. thaliana* total germination above 500 and 750 μM, respectively (Fig. 2). This inhibition is stronger than that reported by Li et al. (1993) for *Lactuca sativa* L., in which an inhibitory effect required a concentration greater than 10^{-3} M. Reigosa et al. (1999) found that these compounds have a stimulatory effect or no action on various weeds. In the present study, *p*-hydroxybenzoic acid was also inhibitory at 750 and 1,000 μM (Fig. 2). No actions of *p*-hydroxybenzoic and ferulic acids on *Poa annua* L. germination were reported by Wu et al. (1998). Gentisic acid and protocatechualdehyde had inhibitory effects on total germination only at 1,000 μM (Fig. 2). In contrast, Chiapusio et al. (1997) found no action of gentisic acid on *L. sativa* germination. The two molecules with the strongest inhibitory effects were L-mimosine and juglone; juglone totally inhibited germination at concentrations above 100 μM (Fig. 2). This compound, which has been previously reported as a potent allelochemical (Szabo 2000), also had effects on the other four germination indices (Table 1).

Four compounds—vanillic acid, L-mimosine, juglone, and *trans*-cinnamic acid—delayed *A. thaliana* germination at the highest concentration tested (Table 1). Juglone was the only compound for which the three dose–response curve parameters could be calculated. By using

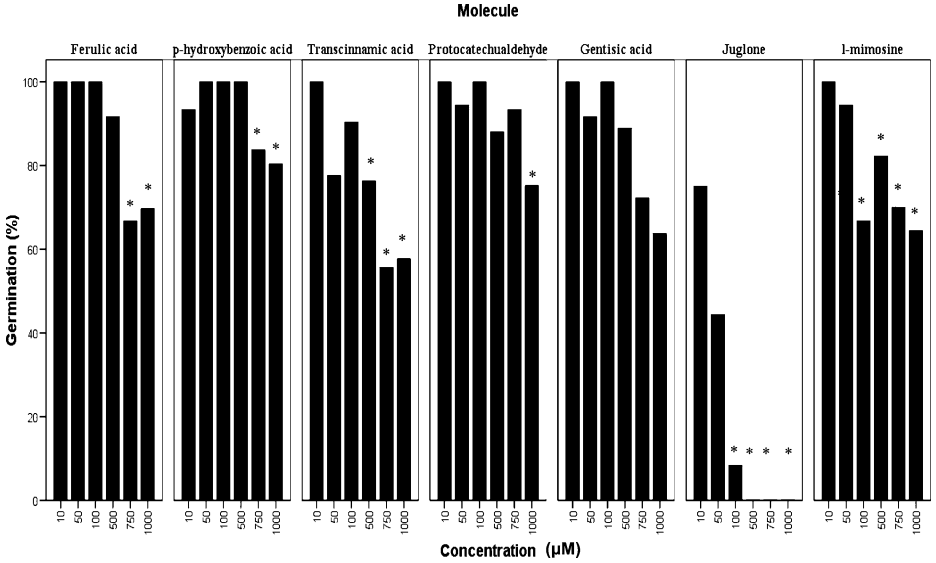

Fig. 2 Inhibitory effects of different concentrations (WM) of seven of the molecules assayed on total germination (%) of *A. thaliana*. *Indicates significant differences at the 0.05 level compared with control by Mann–Whitney *U* tests

a logarithmic adjustment: the inhibition threshold was ~20 μM, the IC_{50} ~40 μM, and LCIC ~100 μM. For the other compounds the highest concentration assayed was near the inhibition threshold.

Tyrosol, quercetin, BOA, rutin, eucalyptol, syringaldehyde, and syringic, and vanillic, protocatechuic, and chlorogenic acids had no significant effects on *A. thaliana* total germination (data not shown). Likewise Angelini et al. (2003) found that eucalyptol had no effect on the germination of three weed species.

Root Elongation Tests

Radicle length was inhibited by the most of the compounds tested both without nutrients (L-mimosine, juglone, syringaldehyde, protocatechualdehyde, vanillin, BOA, and *trans*-cinnamic, gentisic, gallic, syringic, vanillic, sinapinic, chlorogenic, ferulic, *p*-coumaric, protocatechuic, and *p*-hydroxybenzoic acids), and with nutrients (L-mimosine, juglone, syringaldehyde, protocatechualdehyde, vanillin, BOA, and *trans*-cinnamic, gallic, syringic, vanillic, sinapinic, chlorogenic, ferulic, *p*-coumaric, protocatechuic, and *p*-hydroxybenzoic acids).

Table 2 summarizes the inhibitory effects of the tested compounds on root growth of *A. thaliana* in the absence of nutrients, using the best-fit equation based on the coefficient of determination (r^2), and estimated values of IC_{50} and IC_{80}, for the 21 compounds assayed in the root elongation test without nutrient supply. Table 3 summarizes the inhibitory effects of the tested compounds on root growth in the presence of nutrients.

L-Mimosine and juglone had the strongest inhibitory effects on root growth of *A. thaliana* seedlings in the absence of nutrient solution (Table 2). Jose and Gillespie (1998) reported similar inhibition of root growth by these compounds in a study of corn and soybean.

Ferulic and *p*-coumaric acids likewise strongly inhibited root length in the absence of nutrients (Table 2). In contrast, Reddy and Rao (1999) found that ferulic acid improved tobacco growth whereas *p*-coumaric acid was inhibitory. This is line with the view that different plant species can vary enormously in their response to potentially allelopathic substances (Baleroni et al. 2000).

Table 1 Effects of various concentrations of juglone, L-mimosine, *trans*-cinnamic, and vanillic acids on germination indices (S, AS, CRG, and MGT)

Concentration (μM)	Molecule								
	Juglone				L-Mimosine		*trans*-Cinnamic Acid		Vanillic Acid
	S	AS	CRG	MGT	S	AS	S	AS	S
Control	55.6	123.7	3.3	111.8	55.6	132.7	55.6	132.7	155.6
10	42.6	106.8	3.3	113.3	57.6	135.7	61.1	145.0	51.9
50	40.4	97.1	3.1	95.6	47.2	113.8	49.5	122.9	51.8
100	5.6	9.9	0*	47.3*	46.6	118.9	55.8	135.0	69.1
500	0*	0*	0*	0 b	45.2	111.3	42.3	107.5	47.6
750	2.2*	2.2*	0*	16.0	4.8	108.2	35.9*	84.8*	45.5

Ferulic acid	$y = 77.11e^{-0.0036x}$	0.911	120.3	374.9
p-Coumaric acid	$y = 79.06e^{-0.0035x}$	0.939	143.2	392.7
Syringaldehyde	$y = 73.45e^{-0.0023x}$	0.884	167.2	565.5
Vanillin	$y = -19.34\ \ln(x) + 144.82$	0.880	172.6	622.4
Protocatechuic acid	$y = 89.77e^{-0.0032x}$	0.858	182.9	469.2
p-Hydroxybenzoic acid	$y = 97.97e^{-0.0035x}$	0.908	192.2	453.9
BOA	$y = 98.80e^{-0.0011x}$	0.689	619.1	1,452.1
Protocatechualdehyde	$y = -0.0574\ x + 91.39$	0.527	721.1	1,243.7
Eucalyptol	$y = 0.034\ x + 66.38$	0.488	N.I.	N.I.
Rutin	$y = 8 \cdot 10^{-8}x^3 + 10^{-4}x^2 - 0.05x + 69$	0.189	N.I.	N.I.
Tyrosol	$y = -2 \cdot 10^{-7}x^3 + 4 \cdot 10^{-4}x^2 - 0.3x + 118$	0.367	N.I.	N.I.
Quercetin	$y = 3 \cdot 10^{-8}x^3 + 10^{-5}x^2 - 0.03x + 80$	0.093	N.I.	N.I.

r^2 = Determination coefficient, IC50 = concentration required to obtain 50% root growth inhibition, IC80 = concentration required to obtain 80% root growth inhibition, N.I. = not inhibitory

Vanillic, *p*-coumaric, ferulic, and *p*-hydroxybenzoic acids inhibited radicle elongation in the test without nutrients (Table 2 and Fig. 3). Janovicek et al. (1997) reported similar findings with wheat seedlings, especially above 10^{-4} M.

In the test with nutrient solution, the order of phytotoxic effects of the different compounds changed (Table 3). The most active compound was protocatechualdehyde, whereas L-mimosine and juglone had less marked effects.

Nutrient limitation had a synergic effect with phytotoxicity. In the presence of nutrients, a higher concentration was necessary to obtain a reduction of 50% in root growth than without nutrients. This observation is in agreement with the results of Belz and Hurle (2004), who found that nutrient reduction increased the inhibitory effects of BOA. Availability of macronutrients like nitrogen is, along with light, the most important parameter in seedling growth and development. Martin et al. (2002) demonstrated that *A. thaliana* is phenotypically, physiologically, and metabolically affected by nitrogen deficit. Filleur et al. (2005) showed that *A. thaliana* has a box gene related to the modulation of root growth in response to the external supply of nitrogen. Even limitations in phosphate reduce root growth (Chevalier et al. 2003; López-Bucio et al. 2002). Thus, the observed effects in the experiment without nutrient solution could be explained by the lack of nitrogen and phosphate.

Four compounds—eucalyptol, rutin, tyrosol, and quercetin—did not show any appreciable effect on root growth (data not shown). Fig. 3 shows dose–response relationships for 6 of the remaining 17 tested compounds (juglone, protocatechualdehyde, and syringic, gallic, ferulic, and *p*-coumaric acids). A comparison of the structures and inhibitory effects of these six

Gentisic acid	$y = 172.61\ x - 0.1122$	0.676	N.I.	N.I.
Quercetin	$y = -8 \cdot 10^{-5}x^2 - 0.08\ x + 96$	0.695	N.I.	N.I.

r^2 = Determination coefficient, IC50 = concentration required to obtain 50% root growth inhibition, IC80 = concentration required to obtain 80% root growth inhibition,. N.I. = not inhibitory.

compounds (Fig. 3) indicates that the most strongly inhibitory was the naphthoquinone juglone, followed by the hydroxybenzoic acids, gallic and syringic acids (Fig. 3 and Table 2), in which two phenolic hydroxy or methoxy groups (respectively) are substituted at ortho-positions to a phenolic hydroxyl group (Fig. 1). The hydroxycinnamic acids ferulic and *p*-coumaric acids, with only one hydroxy group, showed only weak inhibitory activity (Fig. 1). Of these six compounds, that showing the lowest inhibitory activity was the benzaldehyde protocatechualdehyde (Fig. 3).

In the absence of nutrients (Table 2 and Fig. 3), phenols that are structurally similar (Fig. 1) presented a range of phytotoxic effects. The strongest effect was produced by the molecules with acid radical (hydroxybenzoic acids), followed by the molecules with propenoic radical (hydroxycinnamic acids), and finally the molecules with aldehyde radical (benzaldehydes). In the presence of nutrients (Table 3 and Fig. 4), the molecules with aldehyde radical induced greater inhibition than the molecules with acid and propenoic radicals, in this order. Moreover, both in the presence and absence of nutrients the hydroxy radical had a greater effect than the methoxy radical.

In the present study, the hydroxybenzoic acids had a stronger effect than the hydroxycinnamic acids, which is in line with the results of Nakai et al. (2001). A possible explanation for this is that oxidative damage is greater in plants treated with hydroxybenzoic acids because they have less antioxidative effect. Another explanation could be that these compounds have more efficient interactions with cellular enzymes, but if so, the actual mechanism remains to be determined (Campos et al. 2003).

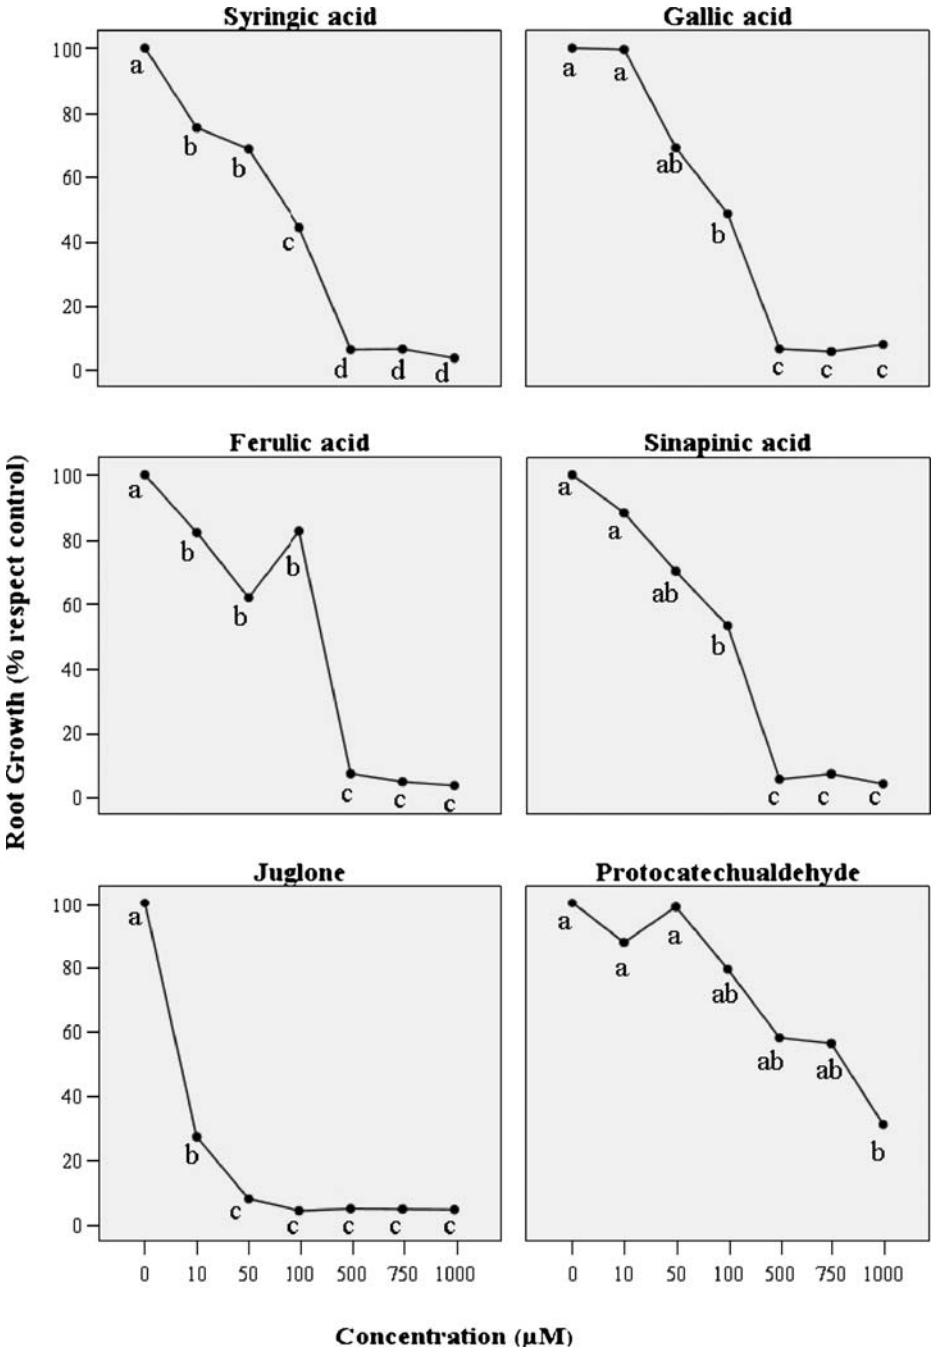

Fig. 3 Dose–response curves for root length growth (percentage with respect to control) in *A. thaliana* treated with six potential allelopathic compounds, at concentrations from 0 to 1,000 µM, without nutrients. Means with a different letter are significantly different ($P<0.05$, Mann–Whitney *U* test)

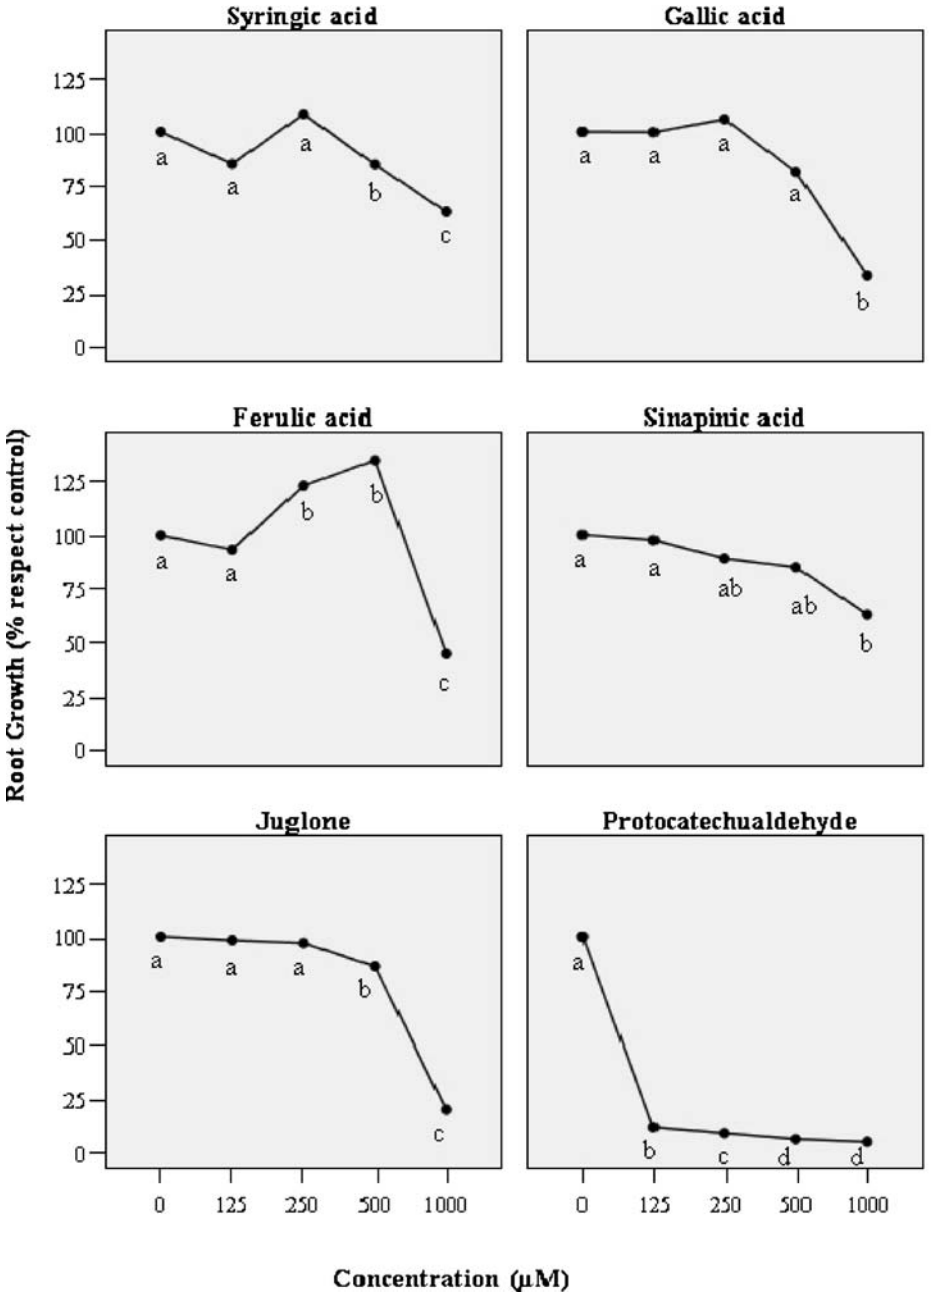

Fig. 4 Dose–response curves for root length growth (percentage with respect to control) in *A. thaliana* treated with six potential allelopathic compounds, at concentrations from 0 to 1,000 µM, with added nutrients. Means with a different letter are significantly different ($P<0.05$, Mann–Whitney U tests)

In summary, target species vary in their responses to phenolic compounds (Jose and Gillespie 1998; Dayan et al. 2000). In general, phenolic acids affect seedling growth more than germination (Reigosa et al. 1999). Hydroxybenzoic acids seem to be more toxic than the structurally similar hydroxycinnamic acids.

Introduction

Ozone (O_3) is recognized as the most widespread and phytotoxic air pollutant in the northeastern part of North America (Skelly et al. 1997). Ozone is a strong oxidant, injuring plant tissues and disturbing the anatomical, biochemical, and physiological function of plants (Skäby et al. 1998; Kley et al. 1999). Also, it is known to affect carbon allocation and cause disturbance in carbon transport within and between plant organs (Laurence et al. 1994).

Plant secondary compounds in needles often deter herbivores and interfere with infections by fungi (Beckman 2000). Thus, changes in secondary metabolism as a result of gaseous air pollution are potentially important for the health of forests. Conifers produce oleoresin, a complex mixture of terpenoids, mainly composed of diterpene resin acids with minor amounts of monoterpenes and sesquiterpenes (Phillips and Croteau 1999). Oleoresin compounds act as feeding deterrents or stimulants to a wide variety of herbivores (Manninen 1999). Earlier studies have indicated slight O_3 effects on the concentrations of monoterpene (Kainulainen et al. 1998) and resin acids (Kainulainen et al. 1995, 2000) in conifers, whereas O_3 increased the concentration of total phenolic compounds (Rosemann et al. 1991; Booker at al. 1996). Another study, which examined pine (*Pinus* spp.) and spruce (*Picea* spp.) exposed to ozone and different nitrogen availability, concluded that elevated levels of O_3 do not affect the concentration of terpenoids from conifer stemwood (Manninen et al. 2002).

Lignin and other phenolic compounds in the foliage of plants may also be affected by O_3. Molecular and biochemical studies suggest that O_3 induces the synthesis of cinnamic acid derivatives via the shikimic and phenylpropanoid pathways (Rosemann et al. 1991; Eckey-Kalthenbach et al. 1994). Phenylpropanoid derivatives that are reported to accumulate in conifer needles in response to O_3 include hydroxycinnamic acids (Kicinski et al. 1988), flavonoids (Langebartels et al. 1990), and proanthocyanidins (Jordan et al. 1991). Lignin content in needles was not significantly affected by O_3 exposure although catechin (precursor to tannins) concentration increased with increased levels (Booker et al. 1996). One study examined the concentration of simple phenols in pine (*Pinus halepensis* Mill.) needles as bioindicators of NO, NO_2, and O_3 air pollution. Of the phenols studied, only vanillin decreased in concentration with measured increases in O_3.

The purpose of this study was to determine whether 2-yr-old white pine (*Pinus strobus* L.) foliage exposed to O_3 under field conditions affected the phenolic and resin acid concentrations in their needles. Comparatively little work has been done on this subject with *P. strobus*, a commercially important species in the Maritime provinces of Canada. Pine forest productivity is predicted to be reduced by current levels of ambient O_3 in the region (Charland et al. 1994).

Phenolic and resin acids were measured in the needles of clones originating from populations growing in two different regions with different air pollution levels. Profiling of the phenolic and acidic compounds was done directly on needles by using a relatively new and rapid method of analysis, i.e., thermally assisted hydrolysis and methylation gas chromatography/mass spectrometry (THM-GC/MS) with trimethylsulfonium hydroxide (TMSH) as the methylating reagent. The THM-GC/MS technique has been used to measure resin acid components (Simon et al. 2001; Watts and de la Rie 2002; Scalarone et al. 2003) phenolic acids (Zhang 1993; Zapf and Stan 1999; Yokoi et al. 2003) and lignins (Vane 2003; Klingberg et al. 2005) in complex biomaterials.

Materials and Methods

Plant Material and O_3 Treatment Needles used in this investigation were from treated branches of grafted clones of two genotypes used in a clonal orchard experiment described by Charland et al. (1994). The experiment involved ozone fumigation of 2-yr-old branches of 6-yr-old grafted white pine saplings (ramets) originating from Sudbury, Ontario (ozone-tolerant clone) and the Acadia Forest Experimental Station, New Brunswick (ozone-sensitive clone). Each ramet carried one replicate of all the branch treatments and received carbon-filtered air (10–15 ppb), 80 ppb, or 200 ppb ozone through separate branch chambers on randomly selected 2-yr-old branches. For this investigation, branches were fumigated daily for 40 d with O_3 [treatment profiles mimicking naturally occurring event shape maximizing at 10–15 (filtered air), 80 or 200 ppb] using a branch chamber fumigation system as outlined in Charland et al. 1995.

Experimental Design The experiment consisted of randomly distributed clonal plots of white pine within a uniform old nursery. Each plot contained at least six evenly spaced ramets. Three randomly chosen ramets (replicates) were shaded (57% shade) with shade cloth enclosures, whereas the other three were left in the open. Two-year-old branches on each ramet were randomly selected for treatment fumigations with the use of the Canadian Forest Service In-canopy branch chambers fumigation system. The system is further described in Charland et al. (1994, 1995).

Needle Samples Needles (40 from each plant) were removed from branches of each ozone treatment. Sampling was done at the same time of day to avoid diurnal fluctuations. Needles were dried at 60°C overnight, then ground to a fine powder before being stored in an airtight vial at −20°C.

Thermally-Assisted Hydrolysis Methylation Analysis THM-GC/MS analyses were carried out with TMSH as the preferred methylating reagent for resin acids as suggested in previous studies (Pastorova et al. 1997; Madonna et al. 2001). A small amount of ground needles (~250 μg) was placed into a pyrolysis sample cup, and 5 μl of TMSH (25% in methanol, Sigma-Aldrich) was added. The methanol was evaporated under a stream of N_2 before the sample cup was placed in standby position of the furnace pyrolyzer. The sample/TMSH mixture was then subjected to thermochemolysis by dropping the pyrolysis cup into the 400°C pyrolysis zone. Identification of the methylated phenolic and resin acid constituents of pine needles was based on retention times and mass spectral data of standard methylated phenolic standards and from compiled mass spectra of methylated diterpenoid resin acids (Zinkel and Magee 1987). Relative concentrations of phenolic and resin acids are reported as TIC (total ion chromatogram) peak area of individual compounds per μg of sample analyzed. THM-GC/MS was carried out by using a vertical microfurnace pyrolyzer (Py; Frontier Lab) interfaced to an HP5890 GC equipped with an HP 5971A MS as described in a previous paper (Estevez and Helleur 2005). A Frontier Lab UA-5 capillary column (25 m×0.25 mm i.d.; 0.25 μm thickness) was used. The instrumental settings were as follows: Py furnace, 400°C; Py interface and GC injector, 280°C; column pressure, 10 psi He; split flow, 20 ml/min; GC oven program, 100 to 230°C at 20°C/min, to 240°C at 1.5°C/min, to 300°C at 20°C/min; MS interface temperature 280°C, 70 eV, full mass scan mode from 40–550 amu.

Statistical Analysis Mean and standard error of the methylated phenolic acid compounds 1 and 3 were calculated from resulting chromatographic mean peak area per μg of sample. Statistical analysis of mean peak areas of these compounds found in needles exposed to ozone treatment, and shade/sun treatment for each clone-type were conducted by using the ANOVA statistical software PROC GLM in SAS (v.8.02).

Results

Metabolites Identified by THM- GC/MS The resulting total ion chromatograms of the TMSH thermochemolysis products of fumigated needles of ozone-tolerant and ozone-sensitive white pine are shown in Fig. 1. Five common phenolic and four distinctive diterpenoid resin acids were identified as their permethylated derivatives (Table 1). The original structures of these phenolic and resin acids are shown in Fig. 2. Although the original purpose of this study was to examine concentration changes in phenolic acids caused by O_3 fumigation, chromatographic profile differences of the resin acids between ozone-tolerant and ozone-sensitive clones were also observed (Fig. 1) showing a phenotypic variation within the two white pine clones. This distinctive resin acid profile may become useful in distinguishing tree populations that can be differentially adapted to air pollutants.

All major resin acids identified are labdane-type resin acids common in pine needles (Fig. 2). Anticopalic acid has been reported to be the principal resin acid in *P. strobus* needles (Zinkel and Spalding 1972) and was the most abundant resin acid in both pine clones. Three other resin acids, 3-oxoanticopalic, 3β-hydroxyanticopalic, and 3,4-cyclo-anticopalic acids, were identified as the other major resin acids in needles of the ozone-

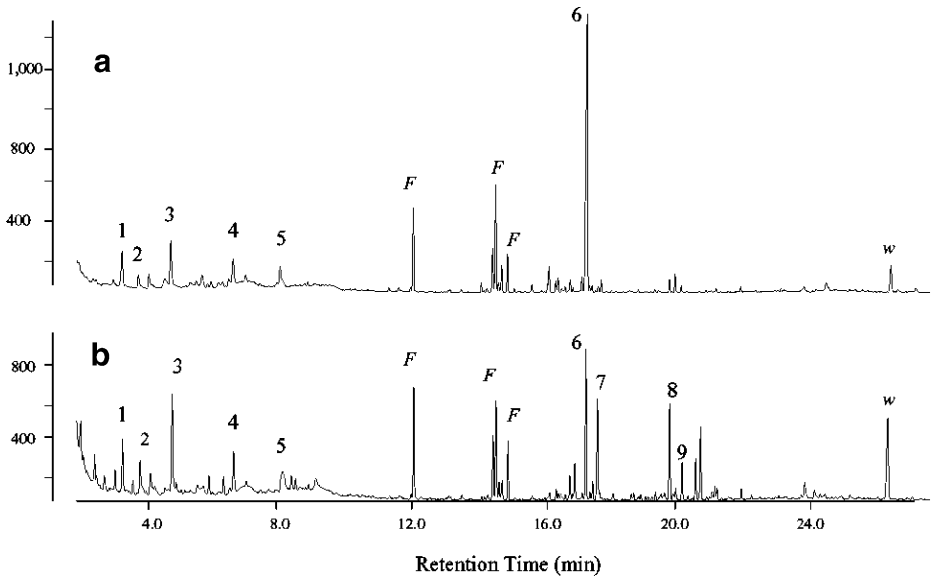

Fig. 1 Total ion chromatogram of the thermally assisted methylation products of **a** needles of ozone-tolerant *P. strobus* (200 ppb O_3 treatment.) and **b** needles of ozone-sensitive *P. strobus* (200 ppb O_3 treatment); the identity of the numbered peaks are listed in Table 1 and their nonmethylated structures shown in Fig. 2; *F*, fatty acid methyl esters, *w*, 10-nonacosanol

Table 1 List of permethylated phenolic and resin acids identified in *P. strobus* needles using thermally assisted methylation GC/MS

Peak[a]	RT (min)	Identity	Molecular Weight
1	3.45	3-Methoxybenzoic acid, methyl ester	166
2	3.82	4-Methoxybenzoic acid, methyl ester	166
3	4.58	3,4-Dimethoxybenzoic acid, methyl ester	196
4	8.74	2-Propenoic acid, 3-(4-methoxyphenyl) methyl ester	192
5	8.32	2-Propenoic acid, 3-(3,4-dimethoxyphenyl) methyl ester	222
6	17.51	Anticopalic acid, methyl ester	318
7	17.86	Cycloanticopalic acid, methyl ester	316
8	19.52	3-Oxoanticopalic acid, methyl ester	332
9	20.14	3β- Hydroxylanticopalic acid, methyl ester	334

[a] Peak numbers are those labeled in Fig. 1

sensitive pine. Conifer needles are also rich in epicuticular waxes. The major wax component of *P. strobus* as identified in Fig. 1 is the long chain alcohol, 10-nonacosanol.

Phenolic Acid Levels among Different Treatments and White Pine Populations Only 1-yr-old needles showed statistically meaningful variation in phenolic composition. 3-Hydroxybenzoic and 3,4-dihydroxybenzoic acids showed significant effects ($P<0.05$) with ozone exposure (Table 2). The combined results for both clones are graphically shown in Fig. 3. The sun/shade experiment had no statistically significant differences. These ozone-responsive phenolic compounds decrease in concentration with increased ozone dosage, by as much as 75% of the control level in the case of 200 ppb ozone (Fig. 3). At the 80 ppb ozone treatment, the ozone-tolerant pine (Sudbury clone) showed a more noticeable decrease in both phenolics, whereas both clones showed a substantial decrease at high exposure (200 ppb), as illustrated in Fig. 4.

Resin Acids and Ozone Treatment There was no noticeable change in resin acid concentrations in the needles of either the ozone-tolerant or ozone-sensitive white pines with O_3 fumigation. A new but unidentifiable chromatographic peak (RT=20.83 min, Fig. 1) was observed in needles of ozone-sensitive white pine fumigated at high (200 ppb) ozone levels. Its mass spectrum resembled a diterpene resin acid with a molecular weight of 332 amu. It is possible that this compound is an oxidized form of anticopalic acid formed as the result of high levels of oxidant. Further experimentation and mass spectral characterization is required to identify this product.

Discussion

This study involved the chemical profiling of phenolic and diterpene resin acids in needles of two (ozone-tolerant and ozone-sensitive) white pine clones fumigated with different ozone levels [12–15 (control), 80 and 200 ppb] for 40 d under field conditions. The metabolites of needles were successfully measured by using a relatively new approach to "whole sample" chemical profiling, that being TMSH-GC/MS. Short-term O_3 fumigation affects the levels of two phenolic acids, i.e., 3-hydroxybenzoic and 3,4-dihydroxybenzoic acids, in that both showed a substantial decrease in concentration with increased ozone exposure; as much as a 75% decrease in relative concentration (Figs. 3 and 4).

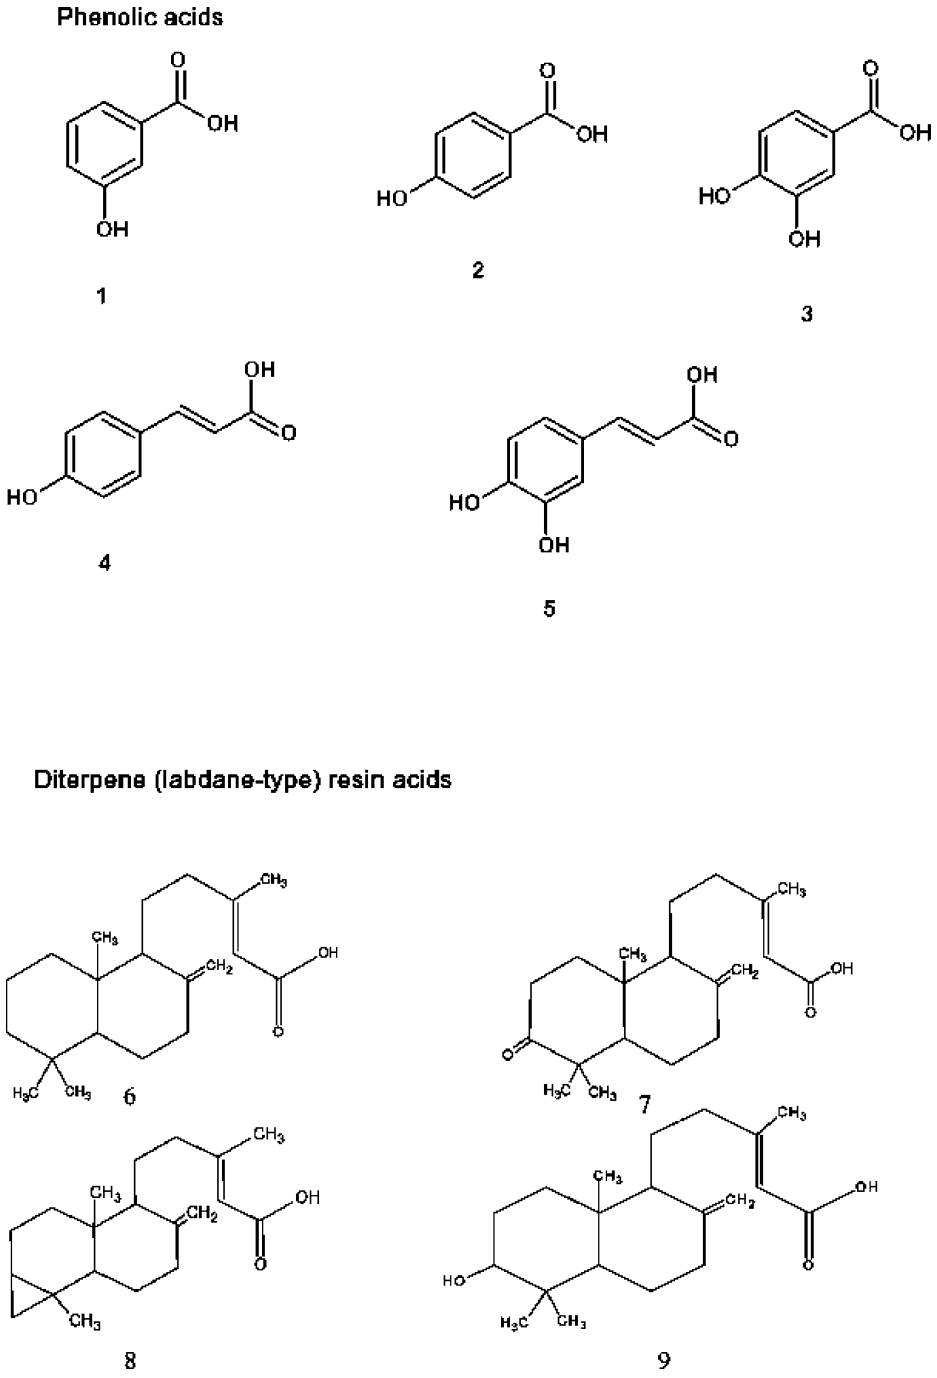

Fig. 2 Structures of phenolic acids and diterpene resin acids identified by THM-GC/MS in white pine needles. Compound *1* (3-hydroxybenzoic acid) and *3* (3,4-dihydroxybenzoic acid) were used as phenolic indicators of ozone exposure. The diterpene resin acids are anticopalic (*6*), 3-oxoanticopalic (*7*), 3,4-cycloanticopalic (*8*), and 3β-hydroxyanticopalic acids (*9*)

These two phenolic acid-THM products likely originate from the photosynthetic shikimate pathway that produces significant amounts of aromatic-containing secondary metabolites (i.e., flavonoids, tannins, and lignin). It is believed that ozone either inhibits the shikimate synthetic pathway, thus decreasing the amounts of 3-hydroxybenzoic acid and 3,4-hydroxybenzoic acid intermediates, or alters the pathway in preference of the synthesis of other secondary metabolite intermediates (Zhang 1993). A previous study (Katoh et al. 1989) determined that the shikimate pathway was affected in cedar needles by exposure of the plant to air pollution, including the oxidant SO_2.

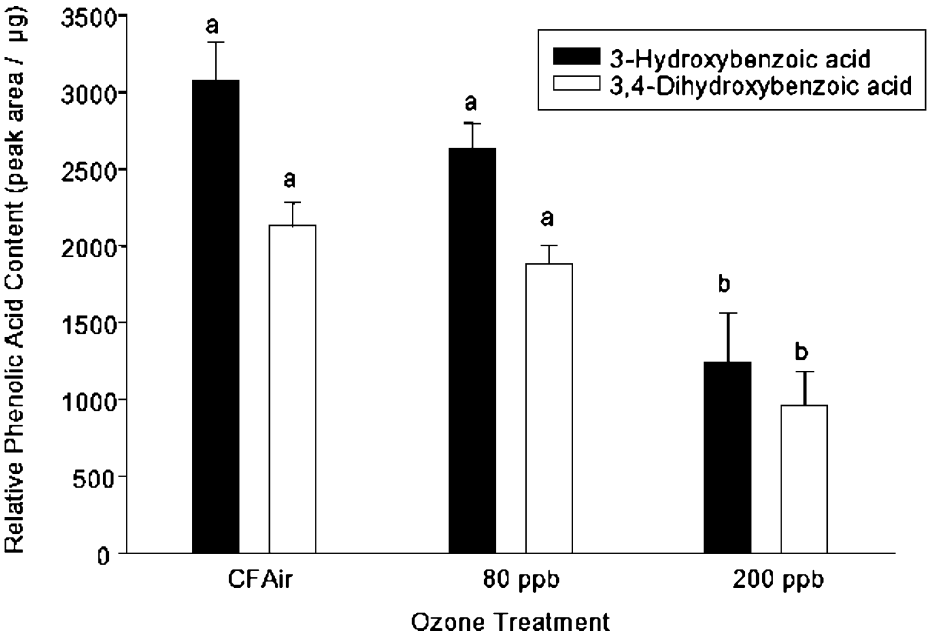

Fig. 3 Effect of ozone treatment on levels of phenolic acid compounds, 3-hydroxybenzoic acid and 3,4-dihydroxybenzoic acid of all clone samples. Data values used for each sample were mean of triplicate chemical analyses. Mean values shown are from three replicate exposures ±1 SE. *CFAir*, carbon-filtered air. *Letters* indicate Duncan's separation of means of compound ($P<0.001$)

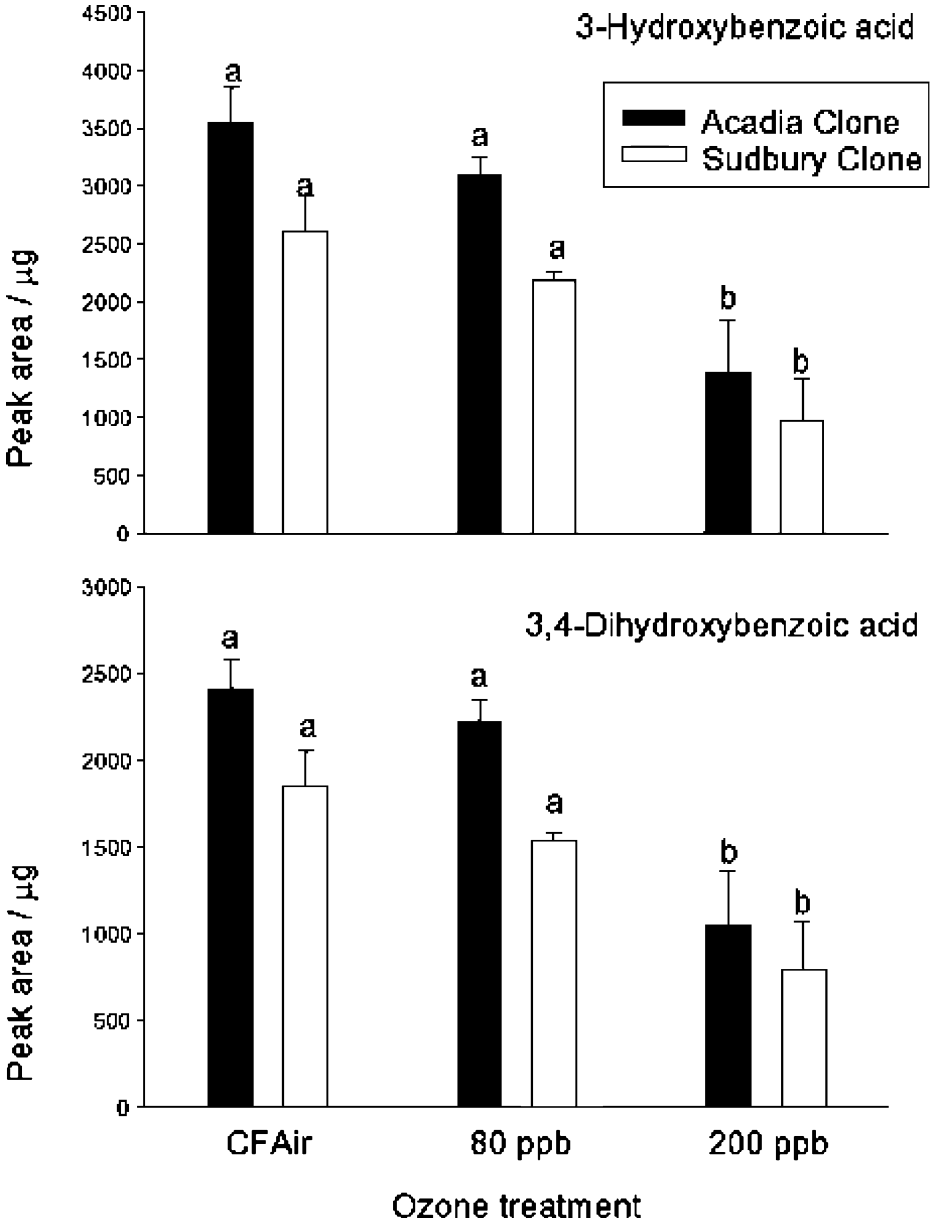

Fig. 4 Variation in relative content of 3-hydroxylbenzoic acid and 3,4-dihydroxybenzoic acid in needles of ozone-sensitive (Acadia clone) and ozone-tolerant (Sudbury clone) *P. strobus* fumigated with ozone. Data values used for each sample were the mean of triplicate chemical analyses. Mean values shown are from three replicate exposures ±1 SE. *CFAir*, carbon-filtered air. *Letters* indicate Duncan's separation of means by clone ($P<0.001$)

Our study has shown the presence of two ozone-sensitive chemical markers. Monitoring of these two phenolics may play a future role in biomonitoring of ozone levels and its impact on forest productivity. Our experimental approach of using rapid THM-GC/MS analysis is compatible with rapid chemical profiling of biomaterials as it involves little

sample preparation, uses no extraction solvents, and has the advantage of utilizing the whole sample, which allows for other biomarkers to be profiled simultaneously (i.e., fatty acids, terpenes, waxes, phenols, etc.).

Compositional differences in the major diterpene resin acids were observed between the needles of ozone-tolerant and ozone-sensitive pine populations. The four major resin acids, anticopalic, 3-oxoanticopalic, 3β-hydroxyanticopalic, and 3,4-cycloanticopalic acids, were present in the ozone-sensitive pine, whereas only anticopalic acid was present in the ozone-tolerant pine (Fig. 1). This phenotypic variation in resin acids within these white pines may be useful in distinguishing populations that may be differentially adapted to air pollutants.

THM-GC/MS data from the white pine needles fumigated at high ozone exposure (200 ppb) indicate the presence of an oxidized diterpene resin acid product. Future research will be undertaken to identify this and possibly other O_3 oxidation products as additional chemical markers in ozone-exposed trees.

Acknowledgment The authors thank Frontier Laboratories (Japan) for allowing the use of the vertical microfurnace pyrolyzer. Funding from NSERC and Memorial University is acknowledged.

Introduction

The minute pirate bugs, family Anthocoridae (Hemiptera: Heteroptera), includes about 500 species worldwide, many of which are important predators in agroecosystems (Lattin 1999). As their name implies, minute pirate bugs are small (1.5–4.5 mm), and most are general predators of small soft-bodied insects and mites (Henry 1988). At least in North America, anthocorids in the genus *Orius* are significant predators across the widest range of crops of all the predacious heteropterans (Yeargan 1998), particularly in crops where they are able to supplement their carnivorous diet with pollen (Coll and Ridgway 1995; Coll and Guershon 2002). Some *Orius* spp. are also commercially available for augmentative biocontrol in greenhouse horticulture (Glenister 1998).

Minute pirate bugs often exploit cues associated with prey to direct their foraging (Lattin 1999). The most clear-cut and extreme example of this phenomenon is for *Elatophilus* spp., which use the sex pheromones of their prey, *Matsucoccus* spp. (Homoptera: Margarodidae), as kairomones to find these prey (Mendel et al. 2004). Similarly, Teerling et al. (1993) demonstrated that *O. tristicolor* (White) intensified searching in the presence of the alarm pheromone (decyl and dodecyl acetates) of one of its preferred prey, the western flower thrips *Frankliniella occidentalis* (Pergande) (Thysanoptera: Thripidae). For the insidious flower bug, *O. insidiosus* (Say), Beekman et al. (1991) found that successful biological control of thrips was host-plant-dependent. Volatiles emanating from plants being fed upon by potential prey are exploited by *Anthocoris* and *Orius* spp. as prey-finding kairomones (Dwumfour 1992; Drukker and Scutareanu 1993; Drukker et al. 1995; Venzon et al. 1999; VanLaerhoven et al. 2000). *Anthocoris nemoralis* (F.) has learned to associate the presence of the herbivore-induced plant volatile, methyl salicylate, with prey (Drukker et al. 2000). Subsequently, methyl salicylate and certain other herbivore-induced plant volatiles have been shown to attract a variety of beneficial insects in the field, including *O. tristicolor* (James 2003, 2005; James and Price 2004). In corn, *O. insidiosus* is attracted to chemicals emanating from corn silks, thereby steering them toward likely spots to find eggs of the corn earworm (silks) and the European corn borer (leaves near the corn ear; Reid and Lampman 1989; Reid 1991). Perhaps, the most unusual semiochemical relationship noted for anthocorids is attraction to and feeding on humans (Aldrich, personal observation; Henry 1988). This behavior is reminiscent of their close relatives, the bed bugs (Cimicidae; Schuh and Slater 1995), but *Orius* bites are intensely painful, whereas those of bed bugs are painless. Feeding on mammalian blood by *Orius* may be more prevalent than now appreciated (Krinsky et al. 1980), but the distance from which the bugs are attracted to mammalian body odors and the identity of the responsible chemicals are unknown.

Detailed investigations of an Oriental minute pirate bug, *Orius sauteri* (Poppius), have revealed another intraspecific level of chemical communication that modulates foraging (Nakashima et al. 2002) and mate-finding (Nakashima and Hirose 1999). Female *O. sauteri* avoided areas where the female itself had searched previously, but did not avoid areas searched by conspecific females (Nakashima et al. 2002). There was no evidence males used such a patch-marking system. However, *O. sauteri* males offered a choice between leaflets on which virgin or mated females had walked vs. leaflets not exposed to conspecific females spent significantly longer on female-treated leaflets (Nakashima and Hirose 1999). The patch-marking signal must be relatively volatile, as this mark faded after only an hour, whereas the female-produced trail sex pheromone is much more persistent and evidently does not attract males even from short distances.

Notwithstanding the discovery that *O. sauteri* males ultimately orient to the trail sex pheromone to find a mate (Nakashima and Hirose 1999), the possibility remains that *Orius* and

other anthocorids also produce pheromones attractive to conspecifics over distances beyond the confines of a single leaf or plant. Indeed, for some time, we have known that *O. insidiosus* exhibits a pronounced sexual dimorphism of the metathoracic scent gland secretion (Aldrich and Puapoomchareon 1996). Therefore, the research presented herein was conducted with *O. insidiosus* to: (1) determine if the female-specific volatiles are part of a long-range attractant pheromone; (2) test the attractiveness of certain herbivore- and pathogen-induced volatiles (Li et al. 2002); and (3) examine the importance of contact chemoreception in mate-finding.

Methods and Materials

Insects *O. insidiosus* used for natural product identifications and for olfactometer attraction bioassays were purchased from Bunting Biological Control (Colchester, UK), and Koppert Biological Systems (Romulus, MI, USA). Young virgin *O. insidiosus* adults were separated by sex under a dissecting microscope and maintained separately in clear 500-ml plastic containers with fine-mesh nylon screen lids in a growth chamber at 27±1°C, a 16:8-hr (L/D) photoperiod, and 60–65% relative humidity. Rearing containers were provisioned with Angoumois grain moth eggs [*Sitotroga cerealella* (Olivier); BioFac, Mathis, TX, USA] sprinkled onto the sticky side of 2×6.5 cm Post-it® notepad paper, distilled water in two cotton-plugged shell vials (1.4×6 cm), and green beans, *Phaseolus vulgaris* L., washed in a 5.25% sodium hypochlorite solution then rinsed with tap water. Egg sheets and fresh green beans were replaced four times per week.

O. insidiosus adults for arrestant bioassays originated from the Novartis I 500 Ori-line® strain (Oxnard, CA, USA). The colony was maintained as described above, except that prey consisted of eggs of the Mediterranean flour moth, *Ephestia kuehniella* Zeller (Beneficial Insectary, Oak Run, CA, USA), and sterile wide-mouth quart mason jars covered with organdy cloth lids were used as rearing containers. Fresh beans and moth eggs were added three times a week. The used beans were removed and placed on elevated metal screens in mason jars lying on their side. Fresh beans and *Ephestia* eggs were added to these jars three times a week until the *O. insidiosus* eggs hatched, nymphs molted, and virgin adults of known age were segregated by sex by examination of the genitalia under a dissecting microscope.

Sample Collection Virgin 3- to 8-d-old male and female *O. insidiosus* adults were used for extractions. Whole-body extracts were prepared by immersing adults in CH_2Cl_2 (50 adults/150–200 µl CH_2Cl_2/sample) for 5 min, drying with anhydrous Na_2SO_4, and transferring the solvent extract to a clean cone-bottom vial with a syringe. Airborne extracts were prepared from batches of ca 250 males or females transferred to 15×1.5 cm i.d. glass columns with an aspirator after chilling in a refrigerator. Columns were provisioned with *Sitotroga* eggs on paper as above, and air was drawn over the bugs by house vacuum at 100 ml/min through a humidifier and an activated charcoal prefilter (30/40 mesh; Aldrich Chemical, Milwaukee, WI, USA) for 3 hr without the downstream sampling filter to eliminate possible contaminating volatiles. Then, a precision filter containing 2 mg of activated charcoal (Brechbühler AG, Switzerland) was connected downstream from the bugs and sampled continuously for periods up to 3 d in a room ~25°C with fluorescent lights on a 16:8 hr L/D cycle. Trapped volatiles were subsequently extracted from the filter with ~70 µl of CH_2Cl_2 and stored in a freezer until analysis. Metathoracic scent gland (MTG) extracts were prepared by dissecting the glands from CO_2-anesthetized insects under tap water (4 MTGs /25 µl CH_2Cl_2/sample), drying with anhydrous Na_2SO_4, and storing in a freezer until analysis. Tap water was used for dissections because the use of distilled water results in rapid swelling of tissue as a result of osmosis.

Chemical Analysis Samples were analyzed by gas chromatography (GC) on a DB-1 column (0.25-μm film; 30 m×0.25 mm i.d.; J&W Scientific, Folsom, CA, USA) or an SPB-1 fused silica capillary column (0.25-μm film; 20 m×0.25 mm i.d.; Supelco, Bellefonte, PA, USA) in a Varian 3500 GC with helium as a carrier gas (50 cm/sec), a temperature program from 50°C for 2 min to 235°C at 15°C/min hold 2 min, in the splitless mode with a flame ionization detector.

Electron impact mass spectral (EI-MS) data were obtained using a Hewlett Packard 5971 GC-MS instrument at 70 ev, with an HP-5 column (0.11-μm film; 25 m×0.2 mm i.d.), programmed as above. Some EI-MS data were obtained with a Finnigan 4500 GC-MS at 70 ev and a DB-1 column (0.25-μm film; 30 m×0.25 mm i.d.) with helium as the carrier gas (linear flow=40 cm/sec) programmed from 50°C for 2 min to 180°C at 5°C/min, then at 10°C/min to 260°C. Chemical ionization mass spectrometry (CI-MS), with CH_4 and NH_3 as the reagent gases, was performed with a Hitachi M-80B mass spectrometer at 70 ev, with an SPB-1 column (60 m×0.25 mm i.d.) programmed from 60 to 220°C at 3°C/min.

GC-FT-IR spectra for female whole-body extracts were obtained using a GC/IRD/MSD system (HP 5890/HP 5965B/HP 5970B) at IRD transfer lines of 250°C, flow cell 250°C, resolution 8 cm, with a TC-WAX column (60 m×0.32 mm i.d.; GL Sciences, Tokyo, Japan), programmed from 70 to 220°C at 3°C/min, with helium as the carrier gas (linear flow=40 cm/sec).

Chemical Standards The following were purchased commercially (chiral compounds were racemic): (*E*)-2,7-octadienol (98%; TCI America, Portland, OR, USA); (*E*)-2-octenal (97%), (*E*)-2-decenal (96%), (*E*)-2-hexenal (98%), (*Z*)-3-hexenal (92.5%), (*Z*)-3-hexenyl acetate (98%), (*E*)-β-farnesene (90%), and ethyl (*E*,*Z*)-2,4-decadienoate (95%; Bedoukian Research, Danbury, CT, USA); (*Z*)-3-hexen-1-ol (98%), indole (98%), (*E*)-nerolidol (90%), methyl jasmonate (95%), (*E*)-2-octenoic acid (85%), (*E*,*E*)-2,4-decadienal (85%), dodecane (99%), and tridecane (99%; Aldrich Chemical); linalool (95%; SCM Glidco Organics, Jacksonville, FL, USA); methyl salicylate (95%) (Fisher Scientific, Fair Lawn, NJ, USA).

(*E*,*Z*)-2,4-Decadienal was prepared by reduction of ethyl (*E*,*Z*)-2,4-decadienoate (10 g, 94.8%, Bedoukian) with diisobutylaluminium hydride (DIBAH) followed by Swern oxidation of the corresponding alcohol to the aldehyde as follows. A solution of DIBAH (50 ml, 1.0 M in hexane) was added dropwise for 40 min to a cool solution of ethyl (2*E*,4*Z*)-decadienoate at −70°C (acetone-dry ice bath) under nitrogen. After 2 hr, under the same conditions as above, an additional 50 ml of DIBAH (1.0 M in hexane) was added dropwise to the reaction mixture to react completely with the remaining ester. Then, the mixture was gradually warmed to room temperature, poured into an ice-cold aqueous solution of NH_4Cl, and extracted with ether. The ether layer was successively washed with saturated $NaHCO_3$ (aq), brine, dried with $MgSO_4$, and concentrated. The crude product was filtered through silica gel (15 g) and eluted with 350 ml of hexane/EtOAc (85:15). The filtrate was concentrated to give a quantitative yield of (*E*,*Z*)-2,4-decadienol with 89.8% geometrical purity as checked by GC. This alcohol was subjected to Swern oxidation without further purification. Dry dimethyl sulfoxide (8.6 ml) was added dropwise to an acetone-dry ice cooled solution of oxalyl chloride (ClCOCOCl, 5 ml) in dry CH_2Cl_2 (100 ml) under nitrogen. After stirring for 5 min, a solution of (*E*,*Z*)-2,4-decadienol (7.7 g) in dry CH_2Cl_2 (10 ml) was added dropwise to the Swern reagent. The reaction mixture was stirred at −50–60°C for 20 min, then cooled to −70°C, and dry triethyl amine (35 ml) was gradually added to the reaction mixture. After stirring for 15 min, the reaction mixture was allowed to stand overnight in a refrigerator, poured into iced water, and extracted with pentane. The organic layer was successively washed with cool 1 N HCl (aq), water, saturated $NaHCO_3$, brine, dried with $MgSO_4$, and concentrated. The crude product was filtered through silica gel (10 g) and eluted with 200 ml of pentane. The filtrate was concentrated to give 6.9 g

(90.8%) of (*E*,*Z*)-2,4-decadienal. This was further purified by flash silica gel column chromatography (silica gel 250 g, eluted with hexane/EtOAc; 50:1) and distillation to give (*E*,*Z*)-2,4-decadienal (b.p. 73°C, 0.9 mmHg) with 83.9% geometrical purity.

(*E*)-2,7-Octadienal was prepared by conventional oxidation of (*E*)-2,7-octadienol with manganese dioxide (MnO_2). MnO_2 (13.9 g, Aldrich Chemical) was gradually added in one portion to a vigorously stirred solution of (*E*)-2,7-octadienol (5 g, 98% purity, TCI America) at room temperature. After 24 hr, the GC analysis showed 50% of starting material. Therefore, three additional amounts of 13.9 g of MnO_2 were added to the reaction mixture after 24, 45, and 66 hr to complete the reaction. Then, the reaction mixture was filtered through silica gel and eluted with CH_2Cl_2. The filtrate was concentrated and further purified by distillation (b.p. 82–84°C, 18 mmHg).

(*E*)-2,9-Decadienal and (3*E*)-4,8-dimethyl-1,3,7-nonatriene were synthesized by previously described methods (Pattenden and Weedon 1968; Bestmann et al. 1989). (*E*)-2,7-Octadienoic acid was prepared by oxidation of the corresponding aldehyde. (*E*)-4-Oxo-2-octenal and (*E*)-4-oxo-2-decenal were obtained from a CH_2Cl_2 extract of first instar southern green stink bugs, *Nezara viridula* (L.) (Borges and Aldrich 1992).

Compounds were identified by comparison of their mass spectra to published mass spectra and/or the mass spectra of the authentic standards. Subsequently, all of the compounds tentatively identified by mass spectral data were cross-checked by comparison of the GC retention of the natural product to that of an authentic standard using the GC conditions described above and coinjection.

Y-tube Olfactometer Bioassay The responses of individual *O. insidiosus* adults to conspecific adults and extracts of adults were tested in a Y-tube olfactometer. The Y-tube was made from 8.0 mm i.d. Pyrex® glass with a base length of 6.75 cm and arms 6.5 cm in length at an angle of 45° to each other. Air to the olfactometer was supplied by a compressed air cylinder, regulated to 60 psi head pressure, passed through a charcoal filter (10 cm; 30/40 mesh) and water bubbler, then split into two streams, each of which entered a flow meter adjusted to provide 370 ml/min of air per arm. Silicone rubber tubing (Masterflex®, Cole-Parmer Instrument, Vernon Hills, IL, USA) was used to connect the humidifier and flow meters in line and to fasten glass tubes (3.7×0.6 cm o.d.) to each olfactometer arm. When live insects were used as a treatment, fine-mesh nylon screen was secured at both ends of the upstream glass tube to contain the insect; a maximum of five tests were performed with the same live insect in the source chamber. Drummond Microcaps® (5 μl; Thomas Scientific, Swedesboro, NJ, USA) filled with extracts or solvent and placed in the holding tubes served as dispensers for chemical treatments. Smoke was used initially to visualize the flow, verifying that there was no backflow from one arm into the other arm. Tests were conducted in a room (25±2°C) with fluorescent overhead lighting, with the Y-tube laid horizontally on a light table covered with white paper to provide diffuse bottom lighting.

Only virgin adults were used as source insects and test subjects. Single source insects were introduced into the upstream holding tube by placing the open end of the tube over a bug and allowing the insect to walk into the tube, then securing the screen on the other end and fastening the tube onto one arm of the olfactometer; the control holding tube on the other arm was empty. Test insects were introduced into the base of the Y-tube as described above, which seemed to minimize disorientation of the bugs. The test started once the Y-tube was laid down horizontally. Test insects were given 10 min to respond. A positive response was scored when an individual entered an arm of the olfactometer and remained for at least 30 sec, at which point, the test was stopped. Insects that failed to choose either arm of the Y-tube were excluded from analyses. Each age class (3- to 4-, 5- to 6-, and 7- to 8-d-old insects) was

tested about 20 times for a given treatment, and treatments were interchanged between arms after ten trials. Test insects were used for only one test. After each series of tests, the Y-tube and holding chambers were washed in hot detergent, rinsed with acetone, and dried in an oven for 30 min.

Preparation of Lures Lures for field tests were prepared by applying CH_2Cl_2 solutions of the various treatments to gray rubber septa (9 mm, Soxhlet extracted overnight with CH_2Cl_2; West Pharmaceutical Services, Kearney, NE, USA) and allowing the solvent to evaporate in a fume hood. Treatments tested in the field are listed in Table 1. Treatment A was a solvent only control; treatment B consisted of the major female-specific compound alone, (*E*)-2,7-octadienal; treatment C contained (*E*)-2,7-octadienal plus the major alkenal common to both sexes, (*E*)-2-octenal; treatment D added (*E*)-2,9-decadienal and (*E*)-2-decenal to components in blend C; treatment E consisted of compounds reportedly induced by caterpillar feeding on corn seedlings (Turlings et al. 1991), a favorite host of *O. insidiosus* (Yeargan 1998); and treatment F contained methyl salicylate and methyl jasmonate, herbivore- and pathogen-induced plant volatiles (Li et al. 2002) previously found to be attractive to various beneficial insects (James 2005). For treatments B–D, the most abundant compound in each blend was arbitrarily assigned a concentration of 0.5 mg active ingredient per 100 μl of CH_2Cl_2, and concentrations of the other compounds in these blends were determined based on the ratio of their chromatogram area counts to that of the most abundant compound in the blend. Components in blend E were combined according to their percentages as found by Turlings et al. (1991). Methyl salicylate and methyl jasmonate in treatment F were tested at a 10 mg each/100 μl CH_2Cl_2.

Field Trapping Tests of potential attractants were conducted during the 1999 growing season at the University of Maryland Agricultural Research Farm and the US Department

[a] Means are the weekly number of males caught per trap per treatment. Means followed by a different letter are significantly different ($P<0.05$).

of Agriculture (USDA) Agricultural Research Center, Beltsville, MD, USA. Traps were deployed in plantings of *Bacillus thuringiensis* (*Bt*)-based transgenic sweet corn (Attribute GH0937- Rogers Brand, Novartis Seeds, Boise, ID, USA) in five plots ≥1 km apart as follows. Each plot had four plantings (April 27, May 10, June 1, and June 15) consisting of eight 30-m rows (~9,000 plants/ha; spacing ≈77 cm), with drip irrigation, and standard fertilizer and herbicide applications. Six delta sticky traps (Agrisense, Fresno, CA, USA) randomly baited with a lure for one of the treatments hung inside the trap were placed 9 m apart on stakes in each planting from 1 June–15 September. Traps were elevated each week to a height equal to the top of the corn plants in that particular planting until they were 1 m off the ground, at which height, they remained for the rest of the experiment. Traps were rebaited, and the sticky trap liners (Trécé, Salinas, CA, USA) were replaced weekly. Used trap liners were brought to the laboratory and examined under a microscope to count the number of *O. insidiosus* male and female adults captured.

Arrestant Bioassays Individual fifth-instar nymphs were placed in Petri dishes (5.7-cm diameter) with a small piece of chlorinated-rinsed green bean and a 1 × 1 cm piece of sticky notepad paper with *Ephestia* eggs. Newly eclosed male and female adults were maintained in separate mason jars with food, and mated individuals used for experiments were allowed to mate in rearing jars for 24 hr before use. Adults of the desired age and mating status were transferred individually to 28-ml plastic cups (Jet Plastica, Hatfield, PA, USA) covered with a cardboard lid and a 4.25-cm filter paper in the bottom and held in a growth chamber under conditions described above. After 24 hr, the exposed filter paper was removed and immediately placed 2 cm apart from an untreated control filter paper in a covered 10-cm glass Petri dish on a countertop in a room approximately 25°C with fluorescent lights. Test insects (i.e., responders, the same age as the treatment insect) were placed in the middle of the Petri dish using an aspirator and were observed for 10 min. The time spent by the responder on the filter papers (treatment vs. control) and elapsed time spent on each filter paper per visit were recorded. Bioassays were conducted between 10:00 A.M. and 3:00 P.M.

The first experiment tested the response of virgin *Orius* males to filter paper exposed to conspecific virgin females ranging in age from 1–6 d old. In each of these choice tests, the male was the same age as the female used in the treatment. Tests were conducted using 1-, 2-, 4-, and 6-d-old females, and each test was repeated 12 times with different filter papers and male adults.

The second experiment tested the response of virgin *Orius* females to filter paper exposed to conspecific virgin females or males ranging in age from 1–4 d old. In each of these choice tests, the female was the same age as the *Orius* adults used in the treatment, and each test was repeated six times on two different days with different filter paper treatments and *Orius* test females.

A third set of experiments was conducted in a similar manner as the first two experiments except that 2- to 4-d-old virgin male *Orius* responders were also tested against a treatment prepared by exposure of filter paper to 2- to 4-d-old mated *Orius* females. Paired choice tests were repeated 12 times over three different days using 2- to 4-d-old *Orius* test males as responders to filter papers exposed to 2- to 4-d-old conspecific virgin or mated females, 2- to 4-d-old virgin females vs. untreated filter paper, 2- to 4-d-old mated females vs. control paper, and 2- to 4-d-old virgin males vs. the control.

Statistical Analyses Y-tube olfactometer bioassay data were analyzed using the Wilcoxon signed-ranks test (Gravetter and Wallnau 1992). Field trapping data and the responses of *O. insidiosus* males to the arrestant produced by female *O. insidiosus* at various ages, were analyzed using analysis of variance PROC MIXED (SAS Institute 1996). If these field or

arrestant data did not meet the underlying assumption of homogeneity of variances, subsets of data with common variances were partitioned before analysis. When F values were significant ($P<0.05$), treatment means were compared using the least significant difference ($P<0.05$) procedure. The experiments comparing male and female responses to filter paper exposed to various *O. insidiosus* sources were analyzed separately using PROC TTEST (SAS Institute 1996). Tests for equal variance were conducted on the data set for each test day, and the appropriate test for either equal or unequal variances was used. Mean comparisons with $P<0.05$ were significantly different.

Results

Identification of Volatile Chemicals Chemicals identified from extracts of *O. insidiosus* males and females are listed (Fig. 1). Extracts of both male and female *O. insidiosus* adults have sex-specific compounds, as well as compounds occurring in both sexes (Figs. 2, 3 and 4). *(E)*-2-Octenal (**3**) was the most prominent component produced by both males and females;

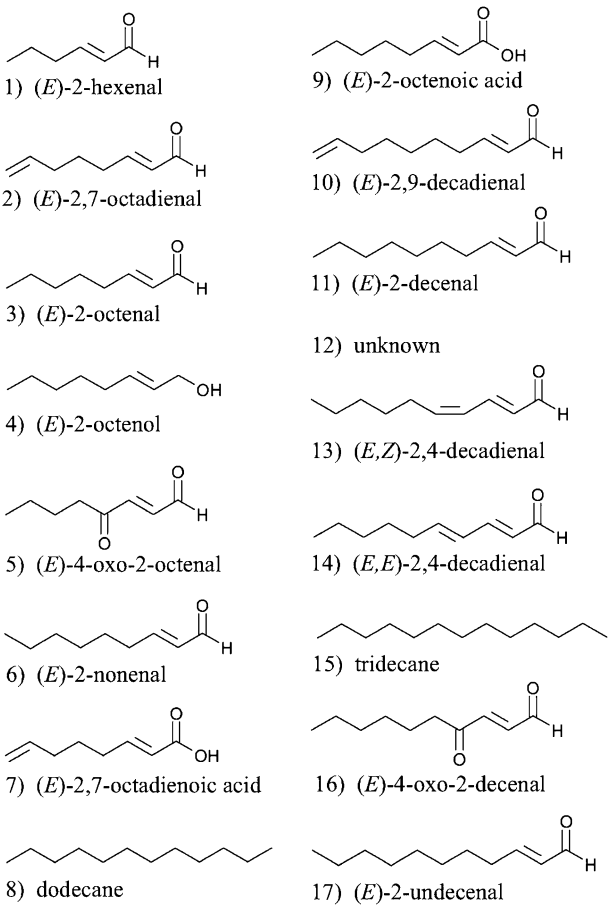

Fig. 1 Chemicals identified from extracts of *Orius insidiosus* adults

this compound was detected in whole-body extracts (Fig. 2), extracts of the metathoracic scent gland (Fig. 3), and aeration extracts (Fig. 4). Compound **2** eluted 0.11–0.15 min before (*E*)-2-octenal under the GC conditions employed and was observed only from females (all types of extracts; Figs. 2, 3 and 4). CI-MS indicated a molecular weight (MW) of 124, suggesting an octadienal structure, and FT-IR data exhibited an absorption peak at 3,085 cm^{-1}, characteristic of a terminal double bond (Leal et al. 1992). Compound **2** from natural extracts co-eluted with synthetic (*E*)-2,7-octadienal, thus, confirming the identity of this, the major female-specific volatile. Other female-specific compounds that were detected in whole-body and/or metathoracic gland extracts are compounds **7**, **10**, and **11** (Figs. 2 and 3), identified as (*E*)-2,7-octadienoic acid, (*E*)-2,9-decadienal and (*E*)-2-decenal, respectively. Compound **15**, identified as *n*-tridecane, was the major male-specific compound in all three types of extracts (Figs. 2, 3 and 4). The various other compounds not mentioned above and listed in Fig. 1 occurred at relatively low levels in either whole-body and/or metathoracic scent gland extracts (Figs. 2 and 3). Compound **a** observed in aeration extracts from both males and females (Fig. 4) has a MW of 126 based on CI-MS data, and may be the *(Z)*-isomer of octenal; compound **b** (MW 154) is an unidentified solvent impurity.

Y-tube Olfactometer Bioassay Live 3- to 4- and 5- to 6-d-old virgin *O. insidiosus* females were significantly attractive ($P<0.01$) to conspecific males of the same age, and whole-body extracts of 5- to 6- and 7- to 8-d-old virgin females significantly ($P<0.01$) attracted males (Fig. 5). On the contrary, virgin *O. insidiosus* males and extracts thereof were unattractive to conspecific females or, in the case of 5- to 6-d-old live males, were significantly ($P<0.01$) repellent to females (Fig. 6).

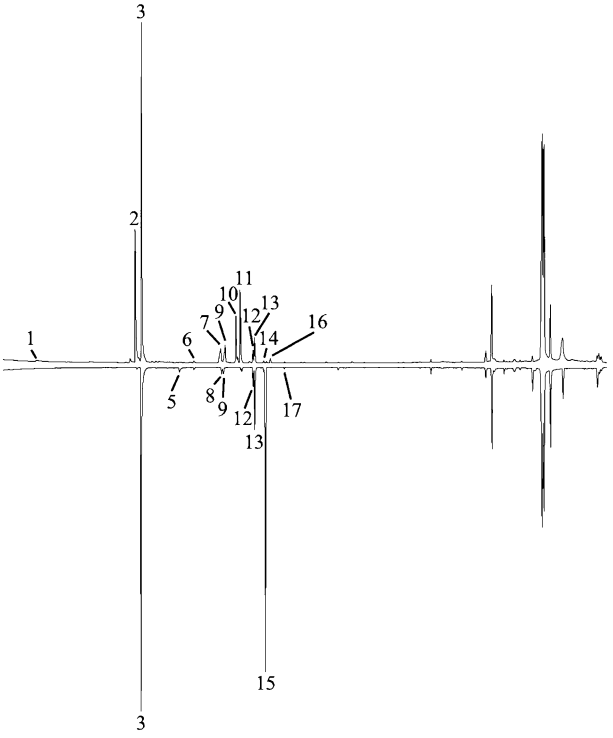

Fig. 2 Gas chromatograms and compounds identified from whole-body extracts of adult *Orius insidiosus* females (*top*) and males (*bottom*). Numbers correspond to structures in Fig. 1

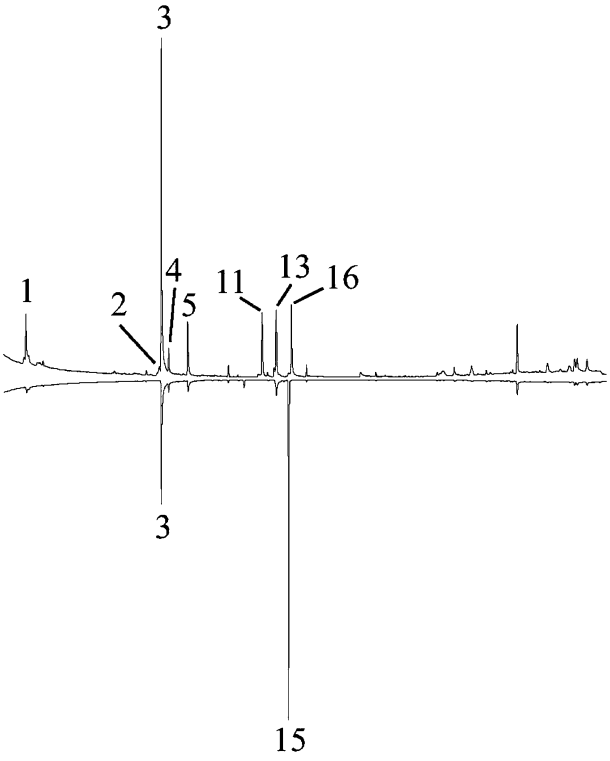

Fig. 3 Gas chromatograms and compounds identified from metathoracic scent gland extracts of adult *Orius insidiosus* females (*top*) and males (*bottom*). Numbers correspond to structures in Fig. 1

Field Trapping Significantly more males were caught in traps baited with (*E*)-2,7-octadienal and (*E*)-2-octenal than all other treatments (Table 1, C). The addition of other female-specific compounds (Table 1, D) resulted in a significant decrease in male attraction equivalent to that for (*E*)-2,7-octadienal alone (Table 1, B). Treatments E and F, designed to mimic volatiles induced by plant injury, attracted significantly fewer males than did the CH_2Cl_2-baited control traps.

Arrestant Bioassays The total time spent by virgin *O. insidiosus* males on filter paper exposed to virgin conspecific females was significantly greater than the time spent on untreated filter paper for all age classes tested (Table 2). The time spent per visit by males on filter paper exposed to females indicated that the arrestant effect was strongest when 1- or 2-d-old females were used to treat filter paper ($P<0.001$ in both cases) than when older females were used ($P<0.05$ for 4-d-old females and not significant for 6-d-old-females; Table 2).

The total time spent by virgin *O. insidiosus* females on filter paper exposed to virgin conspecific females was also significantly greater ($P<0.05$) than the time spent on untreated filter paper (Table 3). Conversely, females showed no preference for filter paper exposed to males vs. control filter paper, and in one data subset (test day 2; total time) avoided male-treated paper (Table 3).

Comparisons of the arrestant affect of virgin vs. mated *O. insidiosus* females toward conspecific males indicated that the mating status of females did not significantly alter the

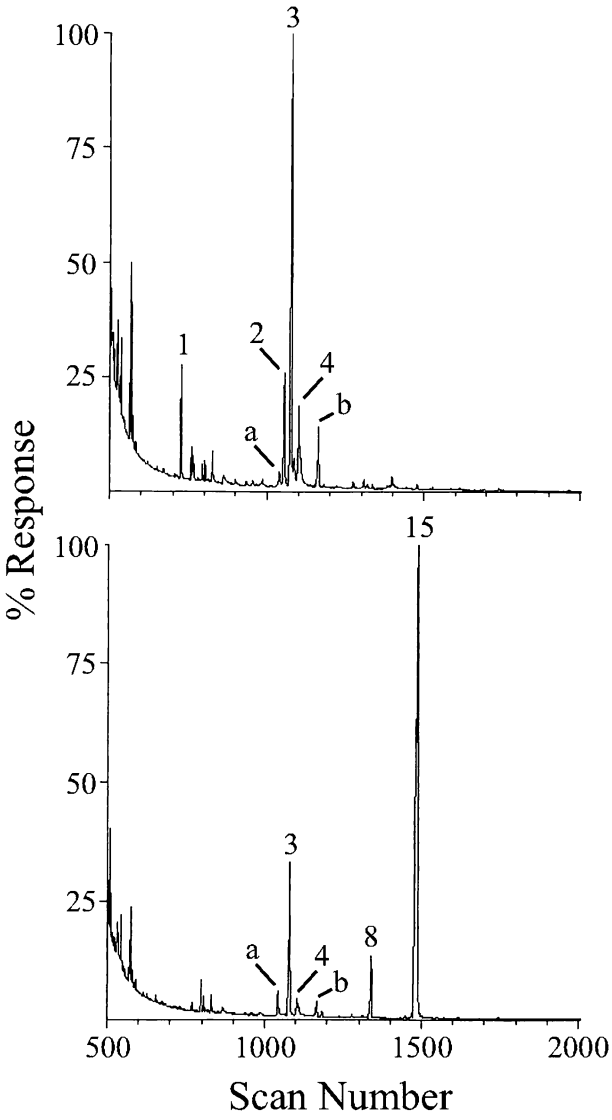

Fig. 4 Gas chromatograms and compounds identified from aeration extracts of adult *Orius insidiosus* females (*top*) and male (*bottom*) (*a* and *b* are an unidentified 126 molecular weight compound and a solvent impurity, respectively). Numbers correspond to structures in Fig. 1

positive response of males (Fig. 7). On two out of three test days, males were significantly arrested by filter paper exposed to virgin or mated females vs. untreated control filter paper (Fig. 7), an effect substantiated by data (not shown) recorded for time spent per visit by males responding to treated filter paper.

In general, before coming into contact with female-exposed filter paper, both males and females walked around the Petri dish with infrequent turns. Once they came in contact with the female-exposed filter paper, however, they usually stopped and briefly examined the paper, then appeared to walk faster and turn more frequently. If they walked off the filter paper, they usually returned quickly. Once an individual encountered the female-treated paper, it behaved in this manner for the remainder of the 10-min test.

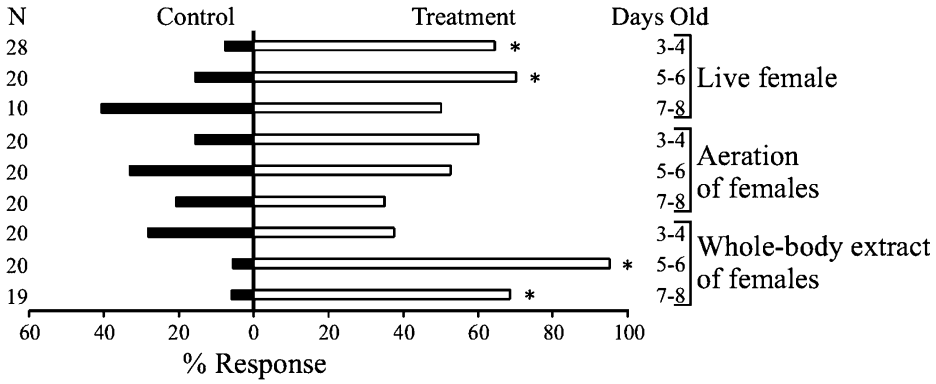

Fig. 5 Y-tube olfactometer bioassay results of virgin *Orius insidiosus* males of varying ages to conspecific females, aeration extracts of females, and whole-body extracts of females (*asterisk* denotes statistical significance at the 0.01 confidence level). Controls consisted of clean filter paper

Discussion

Orius insidiosus females produce a sex pheromone consisting of the female-specific compound, (*E*)-2,7-octadienal, and a compound emitted by both sexes, (*E*)-2-octenal. The *raison d'être* for the C_{10} female-specific compounds, (*E*)-2-decenal and (*E*)-2,9-decadienal, is unclear, as addition of these compounds to the octadienal/octenal blend actually reduced attraction of *O. insidiosus* males in the field. In any case, this system is another example of a heteropteran whose attractant pheromone consists of a sex-specific compound with a non-sex-specific compound, a situation encountered for various female plant bugs (Miridae) (Millar et al. 1997; Millar and Rice 1998; Zhang and Aldrich 2003) and male milkweed bugs (Lygaeidae: Lygaeinae) (Aldrich et al. 1997, 1999). Curiously, although the Anthocoridae and Lygaeidae are rather distantly related within the order (Schuh and Slater 1995) and opposite sexes produce the pheromones, the key pheromone component for milkweed bugs is also a terminally unsaturated octadienyl compound: (*E*)-2,7-octadienyl acetate (male-specific).

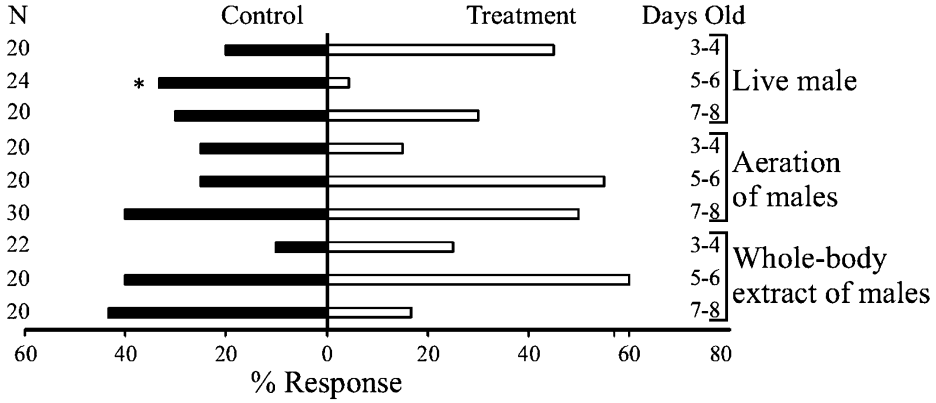

Fig. 6 Y-tube olfactometer bioassay results of virgin *Orius insidiosus* females of varying ages to conspecific males, aeration extracts of males, and whole-body extracts of males (*asterisk* denotes statistical significance at the 0.01 confidence level). Controls consisted of clean filter paper

6	12	106±27	30±11.0	<0.05	21±4.8	15.0±4.8	NS

[a] Test males were the same age as the treatment female.

Clearly, the *Orius* pheromone components come from the metathoracic scent gland, as do those of mirids and lygaeines, so this is yet another case of a heteropteran insect producing its sex pheromone in the gland whose primary, probably ancestral, function is defensive (Aldrich 1988).

Our tests of synthetic lures that mimic induced corn volatiles and herbivore- or pathogen-induced plant volatiles (treatments E and F, respectively; Table 1) did not result in any demonstrable attraction of *O. insidiosus* adults. On the contrary, significantly fewer *Orius* adults were caught in traps baited with these lures than in control traps. In particular, we expected to observe a positive effect for the methyl salicylate/methyl jasmonate lure because the western Nearctic pirate bug species, *O. tristicolor*, was attracted to methyl salicylate in the field (James and Price 2004). Possibly, this discrepancy is caused by differential responsiveness between *O. tristicolor* and *O. insidiosus*. A more likely reason may be dose-related: James and Price (2004) used sachets that continuously released up to 60 mg of methyl salicylate per day, whereas our traps were baited weekly with lures containing a total of 10 mg of methyl salicylate.

Research on the trail (Nakashima and Hirose 1999) and patch-marking (Nakashima et al. 2002) pheromones of *O. sauteri* support the contention that female dispersion is primarily influenced by food resources, whereas male dispersion is guided more by the need to find mates (Nakashima and Hirose 2003). As *Orius* spp. search for prey by walking on plants, it is not surprising that females finally advertise their presence to males via non-volatile chemicals deposited on the substrate (Nakashima and Hirose 1999). For *O. insidiosus*, we

Table 3 Total time spent and time spent per visit by virgin *Orius insidiosus* adult females[a] on filter paper exposed to conspecific virgin females or males for 24 hr vs. clean filter paper

Total Time (sec; X±SE)					Time/Visit (sec; X±SE)

[a] Test females were the same age as the treatment insect.

[b] Due to heterogeneity of variances, these data were analyzed as subsets performed on two different days.

[c] Test insects were virgin 1- to 4-d-old adults.

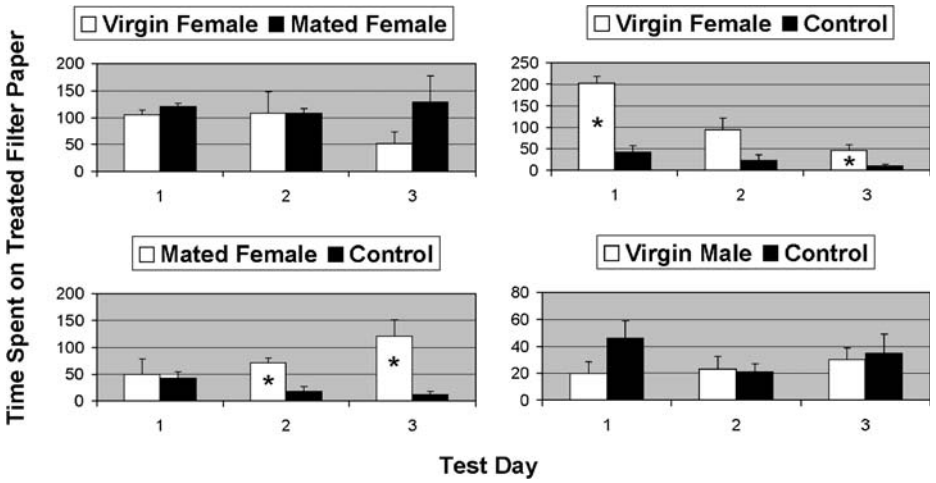

Fig. 7 Arrestment of virgin *Orius insidiosus* males given a choice of filter papers exposed to conspecific virgin females, mated females, virgin males, or untreated controls (*asterisk* denotes statistical significance at the 0.05 confidence level)

have likewise found that virgin males are strongly arrested and stimulated to search in areas previously exposed to conspecific virgin or mated females. Additionally, we showed that virgin *O. insidiosus* females were retained and stimulated to search the area of filter paper exposed to conspecific females. The behavior triggered in *O. insidiosus* males by substrate-borne chemicals from conspecific females is obviously adaptive for a male seeking a mate; however, it seems unlikely that a female orients to chemicals from a conspecific female to improve her chances of mating. In fact, the response of *O. insidiosus* females to chemicals from conspecific females is contrary to the bulk of evidence on marking pheromones in phytophagous and parasitic insects where females avoid resources marked by conspecific, congeneric, or even cross-ordinal females (Doumbia et al. 1998; Hemptinne et al. 2001; Nufio and Papaj 2001; Ruzicka 2001a, b; Laubertie et al. 2006). Perhaps prey or pollen sought by foraging *Orius* females are not so limiting as to result in competition requiring avoidance of conspecific foragers. On the contrary, the prior presence of conspecific females may be a cue (sensu Nufio and Papaj 2001) that potential prey are in the vicinity.

The semiochemical milieu of minute pirate bugs, particularly *Orius* spp., provides a glimpse of the reliance that these tiny insects have on chemical communication. Foraging is chemically influenced by plant synomones (Reid and Lampman 1989; Beekman et al. 1991; Reid 1991), perhaps even pollen odors (Dobson and Bergstrom 2000; yet to be investigated for *Orius* spp.), host allomones (e.g., Teerling et al. 1993), and incidental cues (kairomones) from potential prey (Nakashima and Hirose 2003). Evidence presented herein suggests that a foraging female is able to sense chemically the past presence of conspecific females, information that she may factor into her ongoing foraging strategy (Nakashima et al. 2002). *Orius* females can even privately communicate to themselves that they have recently explored a certain territory (Nakashima et al. 2002). Besides prey-related semiochemicals, there are mate-seeking signals such as trail or arrestant pheromones (data presented herein and Nakashima and Hirose 1999) and longer range volatile sex pheromones, as we have shown for *O. insidiosus*. Our discovery of a sex pheromone for *O. insidiosus* is tempered by the reality that trap catches per week were very low (approximately four males). This reality may be indicative that the volatile sex pheromone is a weak signal among those employed for

mate-finding or that there remain technical deficiencies in the research such as improper dosages/release rates of the pheromone or missing active components.

The complexity of semiochemical relationships in the Anthocoridae tends to reinforce emerging information on the semiochemical relationships of other Heteroptera. For example, among the phytophagous terrestrial bugs whose members undoubtedly produce long-range attractant pheromones (McBrien and Millar 1999), there is convincing evidence that egg parasitoids detect female-specific host cues by intercepting both volatile pheromonal cues (Leal et al. 1995) and non-volatile cues (Colazza et al. 1999; Borges et al. 2003). In the case of chemical footprints exploited by stink bug egg parasitoids (Colazza et al. 1999; Borges et al. 2003), it is certain that the female stink bugs are not leaving these chemical traces to help parasitoids find their eggs. Pentatomid adults are evidently tuned into each other through non-volatile chemical signals in ways that at present can only be surmised. Similarly, tachinid fly parasitoids exploit the volatile pheromones to find potential heteropteran hosts (Aldrich 1995b; Aldrich et al. 2006), but the bugs are not totally helpless in this regard because coevolution has endowed at least some species with non-volatile cuticular compounds that blunt their recognition by tachinid parasitoids (Aldrich 1995a). Concurrent with the chemical channels of communication, many land bugs communicate via substrate vibrations at close range (e.g., Çokl et al. 2001). In fact, male bugs may modulate pheromone emission in response to vibratory signals from conspecifics (Miklas et al. 2003). Finally, some heteropterans apparently utilize the pheromones of competitors as kairomones to find suitable host plants (Endo et al. 2006). This type of interspecific cross-attraction may be more common in the Heteroptera than currently appreciated (Slaymaker and Tugwell 1984; Tada et al. 2001; Aldrich et al. 2007).

From a practical standpoint, the fact that only *O. insidiosus* males are attracted to the octadienal/octenal pheromone blend limits the utility of this pheromone for enhancing biological control. A more fruitful target for a useful artificial semiochemical with which to enhance the biocontrol potential of the insidious flower bug and other *Orius* spp. may be the non-volatile female-specific compounds shown here to arrest females as well as males.

Acknowledgments We thank Sarah Ferguson and Tev Barros, CAIBL, for technical assistance and Dawn Harrison, BARC Diet and Human Performance Laboratory for assistance in obtaining mass spectral data.

Introduction

Broad-spectrum and persistent insecticides have measurable ecotoxic impacts on the environment, as well as leaving undesirable residues in the human food chain. Alternative control tactics are urgently needed, and odorant-based tactics have already been demonstrated to offer valuable solutions for a range of pest species (El-Sayed 2007). Insects are highly responsive to natural and synthetic odorants used for mate and host location, and these innate responses have provided many opportunities for intervention and control with strategies based on volatile semiochemicals. Early use of odorants involved systems for monitoring, but in recent decades, they have increasingly been developed into direct control tactics (e.g., Minks and Cardé 1997; Suckling and Karg 2000).

In this paper, we propose a new multiple species interference system ("Ménage-à-Trois for Insects") in which we consider a system to control one or two species by disrupting mating (Fig. 1). We suggest that the placement of a sufficiently powerful odorant onto one species ("Species A") would act as a lure for individuals of a second species ("Species B") and interfere with mating of one or both species. Attractants could interfere with mating success of recipient first species by deliberately causing the second one to chase it, thereby interfering with its ability to find a mate (Ménage 1). We also hypothesized that the second species could fail to mate at the normal rate if individuals expended most of their effort in pursuing the lure instead of a conspecific mate (Ménage 2). To our knowledge, this concept has never been tested. This approach could lead to a new range of tactics for a wide range of target pests, including cross-order systems (e.g., Diptera-Lepidoptera) and could lead to a new sustainable pest management tactic with reduced insecticide use.

A number of criteria must be met for this novel concept to succeed with sympatric species: there must be a suitable way of loading the odorant onto the "lure" species; the odorant must not increase mortality or decrease fitness of treated individuals; the odorant must persist for long enough to attract the second species; the second species must be sufficiently attracted to actually reduce the level of mating.

Fruit flies (Diptera: Tephritidae) are significant economic pests of horticultural crops in many countries, and many different control tactics have been developed. These include male annihilation (mass-trapping of males), bait sprays, sanitation (removal of infested fruit from the field), biological control, and the sterile insect technique (Cunningham 1989). Semiochemical attractants have been used as part of fruit fly detection, eradication, or long-term pest management programs for decades (Beroza et al. 1961). These insects, therefore, offer a good system to test the concept, especially as they can be easily reared in large quantities.

We, therefore, selected oriental fruit fly *Bactrocera dorsalis* (Hendel) and melon fly *B. cucurbitae* (Coquillett) as in both of these species females are attracted to males for mating at dusk. The male attractants available in this system are methyl eugenol and cuelure, which are highly attractive to oriental fruit flies (Cunningham 1989) and melon flies (Keiser et al. 1973), respectively.

We focused on four main questions: (1) would the application of a semiochemical attractant for an individual cause increased mortality?; (2) could we apply sufficient attractant to one species that would induce significant attraction of the second species?; (3) would there be behavioral effects of this cross-species attractant application on the baited and the attracted flies?; and (4) what would be the effects of the application of the attractant on mating of the attracted species (Ménage 1 in Fig. 1) and on the baited one (Ménage 2)? These questions were addressed through a series of laboratory and field cage experiments to provide "proof of concept" for this new cross-species disruption concept.

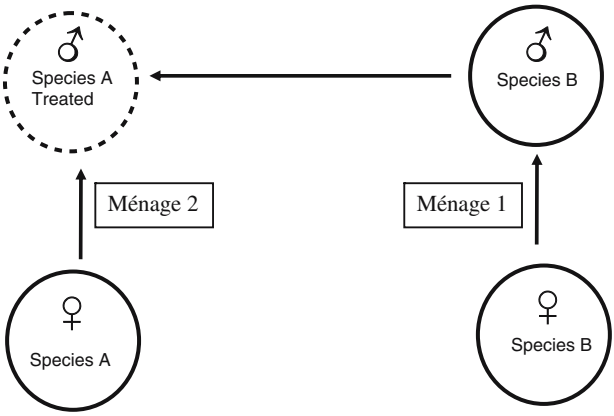

Fig. 1 Overview of components of the proposed "Ménage-à-Trois for Insects" system, where males of *Species A* are treated with an attractant for *Species B*, and the conspecific mating of each species is evaluated as an outcome

Materials and Methods

Insects Sterile laboratory-reared melon and oriental fruit fly pupae were obtained from the USDA-ARS Pacific Basin Agricultural Research Center's rearing facility in Honolulu, Hawaii. Pupae, shipped by air from Honolulu to Hilo, were subsequently held under natural photoperiod in 30×30×30-cm cubical screened cages at 26–28°C and 60–75% RH. Flies were immobilized after emergence, separated by sex in a cold room (4°C), placed in 11.5× 7.5-cm plastic containers (55 individuals/cage) with nylon mesh covers, and provided with water, sugar, and hydrolyzed protein. Laboratory colonies of oriental fruit fly with a sex-linked marker for white pupal color in females (McInnis et al. 2004) were used, where indicated, to reduce cost of sorting by sex. Virgin flies were typically 8–10 days old, unless otherwise indicated.

Toxicology The proof of concept for this approach requires that the odorants do not cause mortality to the treated insects (A). A dose response for methyl eugenol (4-allyl-1,2-dimethoxybenzene; 99.52%, Farmatech Int. North Bend, WA, USA) was obtained for topical application of 1 μl of acetone containing 0, 0.001, 0.003, 0.01, 0.03, 0.10, and 0.30 μl of methyl eugenol per fly onto the thorax of chilled (−10°C for <5 min) melon flies held on crushed ice for 2–3 min with a topical applicator (Hamilton PB600-1 Repeating Dispenser, Hamilton Company Reno, NV, USA). Fifteen mated flies of each sex (age) were treated per replicate (three replicates per dose, total of 45 flies of each sex per dose), which were then placed in cages containing water and protein at 22°C. Mortality was recorded at 1, 2, 3, 4, 7, 10, and 14 days after treatment. The identical procedure was used to determine the effect of cuelure [4-(4-acetoxyphenyl)-2-butanone; >96%, Interchem Technologies, Tijuana, Mexico] on oriental fruit flies.

Wind Tunnel Choice Tests Melon fly Treated with Methyl Eugenol. Virgin male melon flies (11–12 days old) were chilled (as above) and topically dosed with 1 μl of 10% methyl eugenol in acetone (100 ng) on the thorax and allowed to recover for several minutes. Treated and untreated (control) males were then rechilled and tethered by the thorax with cotton thread attached by cyanoacrylate superglue (Instabond Super Glue, Accrabond, Olive Branch, MS, USA). The other end of the tether (c. 5 cm length) was tied to the top of a 2.5-cm entomology pin, which was then stuck through the center of a 15-cm-diameter filter paper (no. 2, Whatman UK, Maidstone, UK) into a rubber bung (2.5 cm high). This

enabled the tethered flies to move freely around the flat circular arena above a clean paper background platform (15×21 cm) at 30 cm elevation above the ground. Quality assurance tests of treated and tethered flies showed the capacity for sustained flight in the laboratory. The two arenas (treated and control flies) were placed at the upwind end and in the middle of a flight tunnel (1×1×2 m length, Jang and Light 1991) operated at 0.1 m/s wind speed, 275 lux. The left and right placement of the treatment and control pair was alternated between replicates. There was a distance of 5 cm between the lower paper platforms and the same distance between the edges of the circular arenas.

Each replicate used newly treated tethered flies and circular arenas, as well as 25 virgin flies (10–14 days old) released simultaneously 1.3 m downwind from the lure flies. There were a total of 16 replicates performed, each one lasting 15 min. The occurrence of the following behaviors were recorded for Species B (oriental fruit flies): landing (present on the upper surface of the filter paper), approach (<1 cm) to the tethered Species A, physical contact (bumping or licking Species A), substrate feeding (i.e., on regurgitate), and the total number of flies involved in arena behaviors during the assay. For species A (melon flies), avoidance (walking) or escape (tethered flight or jumping) behaviors were recorded.

Oriental Fruit Flies Treated with Cuelure. This wind tunnel choice experiment was repeated but using 100 ng of cuelure applied to oriental fruit flies (Species A) in the presence of 25 melon flies (Species B) (16 replicates).

Field Cage Olfactometer The attractiveness of treated Species A to a known population size of Species B was assessed. Jackson traps (Epsky et al. 1996) for oriental fruit flies were baited with either a single treated melon fly or filter paper (100 or 300 ng of methyl eugenol) on a rotating olfactometer in a screened 3×3×2.5-m field cage (Jang et al. 1997). One hundred virgin male oriental fruit flies were then introduced, and traps were checked after 24 h. The same protocol was used, releasing 100 virgin melon flies into the cage when traps were baited with either single treated oriental fruit flies or filter paper (100 or 300 ng of cuelure). There were five replicates of each treatment for each compound.

Field Trapping with Treated Flies Jackson traps were used to determine the potential for field attraction of individual flies of the two species at a papaya orchard (Kapoho, HI; Latitude 19.51 N, Longitude 154.85 W). Virgin male melon flies were topically treated with 100 or 300 ng of methyl eugenol, and single flies were placed onto the sticky base. Filter papers (4.25 cm, Schleicher & Schuell Inc., Keene, NH, USA) treated with the same loadings and folded into a raised triangle were used as a positive control. Fifteen replicates

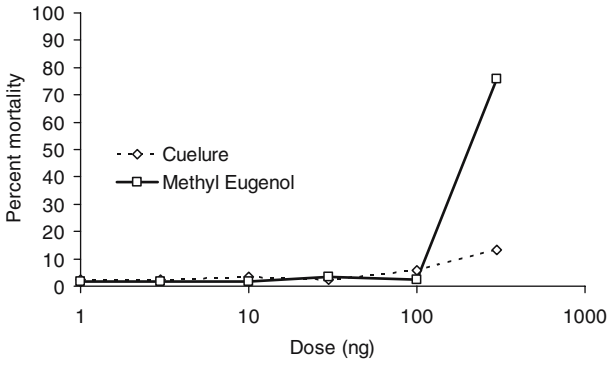

Fig. 2 Dose responses of oriental fruit flies and melon flies to topically applied cuelure and methyl eugenol 1 week after treatment

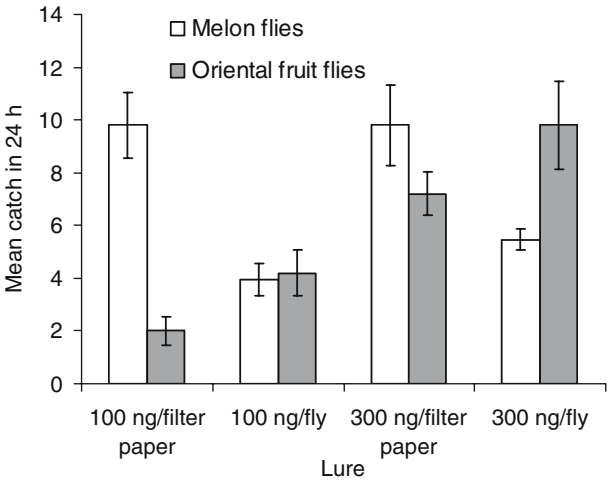

Fig. 3 The number of wild oriental fruit fly and melon fly males attracted to heterospecific males or filter papers treated with 100 ng of methyl eugenol or cuelure, respectively, in Jackson traps over 24 h at a papaya orchard in Hawaii

of each treatment were prepared and checked for catch after 24 h. Again, the same protocol was used with male oriental fruit flies treated with 100 or 300 ng of cuelure along with filter paper controls with these loadings. Catch per trap (15 replicates) was also recorded after 24 h.

Trapping in Large Field Cage The longevity of the attractive effect of 100 ng of methyl eugenol on living melon flies to oriental fruit flies was determined by simultaneously testing individuals treated 6, 3, 2, 1, and 0 days before the experiment. Two replicates of fly-baited Jackson traps (along with a blank control) were hung on plants in a large screen cage (4.2×10.6×1.7 m, of C32A mesh, Synthetic Industries, Gainesville, GA, USA). Traps were hung in blocked lines with trap positions randomly assigned within each replicate (line). Approximately 1,000 sterile virgin male melon flies were then released into the cage. Traps were checked after 24 h. This test was repeated on three occasions, providing six replicates in total.

Mating Incidence in Small Cages The mating success of sexually mature virgin flies of both Species A and B (Ménage 1 and Ménage 2 in Fig. 1) was assessed in six treatments for each lure. For Species A, the impact on fitness was determined by comparing mating of treated males and untreated females with or without the presence of a male of Species B, with control pairs, to determine the effect of treatment on Species A mating. For Species B,

Table 1 The means (+SEM) of attraction- and rejection-related behaviors in a 15-min wind tunnel choice test when oriental fruit flies (Species B) were exposed to melon flies treated with methyl eugenol or untreated controls (Species A)

Species – Parameter	Treatment (+SEM)		Control (+SEM)		*P*
B – landing	19.33	(3.79)	0.47	(0.33)	0.001
B – approach (<1 cm)	13.67	(1.93)	0.07	(0.06)	0.001
B – contact	139.47	(31.71)	0.00	(0.00)	0.001
B – substrate feeding	2.07	(0.86)	0.00	(0.00)	0.005
B – no. of flies participating	3.36	(0.50)	0.07	(0.07)	0.001
A – avoidance (walking)	6.13	(1.05)	0.00	(0.00)	0.001
A – escape (flight)	4.00	(0.99)	0.00	(0.00)	0.002

the effect of male displacement through chasing treated males of Species A on mating incidence of Species B was similarly assessed.

For methyl eugenol, the ménage treatments (1 and 2) were: (a) a methyl eugenol-treated melon fly male with one male and female oriental fruit fly; (b) a control melon fly male with one male and one female oriental fruit fly; (c) just one male and one female oriental fruit fly; (d) one methyl eugenol-treated male and one female melon fly with one male oriental fruit fly; (e) a control male and one female melon fly with one male oriental fruit fly; and (f) a control male and a female melon fly. The first three treatments tested the potential of Ménage 2, whereas the second three treatments tested Ménage 1.

Melon fly males were treated topically with 0.1 μl of methyl eugenol in 1 μl of acetone (100 ng) or 1 μl acetone alone (controls). Forty pairs of each of the six combinations were caged in aluminum mesh cylinders (15 cm diameter, 15 cm tall) covered with plastic wrap over each end held with rubber bands and placed into a covered outdoor field cage under natural light 4 h before visual assessment of mating incidence (i.e., pairs in copula) at 8:00 P.M., 1 h after the start of scotophase (7:00 P.M). Forty pairs of each of the six combinations were caged in aluminum mesh cylinders and placed into a covered outdoor screen field cage for 24 h before visual assessment of mating.

The equivalent protocol of six treatments was used for cuelure applied to oriental fruit fly males, again with 40 replicates.

Mating Incidence in Field Cages Eighty to one hundred virgin male oriental fruit flies were treated with 100 ng cuelure or acetone alone (control) and released together in the afternoon with the same number of virgin females, 80–100 pairs of virgin melon flies into a screen

Table 2 The means (+SEM) of attraction- and rejection-related behaviors in a 15-min wind tunnel choice test when melon flies (Species B) were exposed to oriental fruit flies treated with cuelure or untreated controls (Species A)

Species – Parameter	Treatment (+SEM)		Control (+SEM)		*P*

Table 3 Mating incidence of virgin oriental fruit flies and melon flies in small cages with and without treatment of melon fly males with methyl eugenol

Ménage-à-Trois Treatment 1			Total Pairs of Oriental Fruit Flies	Percent of Oriental Fruit Flies Mating
Methyl eugenol-treated melon fly male	Male Oriental fruit fly	Female Oriental fruit fly	40	82.5
Control melon fly male	Male Oriental fruit fly	Female Oriental fruit fly	40	90.0
–	Male Oriental fruit fly	Female Oriental fruit fly	40	72.5
Ménage-à-Trois Treatment 2			Total pairs of Melon flies	Percent of Melon fly mating
Methyl eugenol-treated melon fly male	Female melon fly	Male Oriental fruit fly	36	11.1
Control melon fly male	Female melon fly	Male Oriental fruit fly	40	95.0
Methyl eugenol-treated melon fly male	Female melon fly	–	38	23.7

cage (3×3×2.5 m), and mating pairs in copula collected 1 h after the onset of scotophase and assessed the next day. This experiment was replicated ×3. The experiment was also repeated with topical dosing of melon flies with 100 ng of methyl eugenol or acetone alone, and assessment of mating incidence was done in the same way.

Statistical Analyses Analysis of variance was performed on log-transformed trap counts to stabilize the variance (Zar 1984). Values were backtransformed by antilog for presentation in the original units. Chi-squared tests were used to analyze mating incidence and effect of odor toxicity by sex (Zar 1984). Paired *t*-tests were used to compare the incidence of

Cuelure-treated Oriental fruit fly male	Female Oriental fruit fly	–	40	82.5

Table 5 Mating incidence of oriental fruit flies and melon flies in outdoor field cages after treatment of oriental fruit flies with 100 ng of cuelure or melon flies with 100 ng of methyl eugenol compared to controls

Treatment	Total Pairs Oriental Fruit Fly	Percent of Oriental Fruit Flies Mating	Total Pairs Melon Fly	Percent of Melon Flies Mating
Cuelure-treated Oriental fruit fly male	293	32.1	377	65.5
Control Oriental fruit fly male	300	56.3	282	66.0
Methyl eugenol-treated melon fly male	202	58.9	187	1.6
Control melon fly male	185	67.0	350	81.7

attraction- and rejection-related behaviors between treatment and controls in wind tunnel choice tests after log-transformation to stabilize the variance (Zar 1984).

Results

Toxicology There was no difference between sexes for either odorant at the highest dose (methyl eugenol χ^2=0.0, *df*=1, *P*=1.0; cuelure χ^2=3.086, *df*=1, *P*=0.079), and the data were, therefore, pooled for sex. The toxicity of methyl eugenol to melon flies was <5% at concentrations up to and including 100 ng per fly but dramatically increased in the 300 ng treatment (Fig. 2). The majority of the mortality occurred within 24 h (data not shown). A similar pattern was observed when oriental fruit flies were treated with cuelure (Fig. 2), although toxicity at 300 ng per fly was lower. Control mortality after a week was <2% for both species.

Field Cage Olfactometer Male oriental fruit flies dosed with 100 and 300 ng of cuelure were as attractive to male melon flies as filter papers loaded in the same way. There was no significant difference in catch between the four treatments ($F_{3,16}$=0.15, *P*=0.93; filter papers or flies at 100 and 300 ng loadings) with a backtransformed mean (+SEM) catch per trap per 24 h of melon flies to cuelure of 8.5+1.1 flies. Similar results were seen in the number of oriental fruit flies attracted to methyl eugenol at 100 and 300 ng loadings on filter papers or melon flies ($F_{3,16}$=0.49, *P*=0.7) with a backtransformed mean catch per trap per 24 h of 11.8+1.1.

Field Trapping Jackson traps baited with methyl eugenol-treated flies or filter paper caught wild oriental fruit flies. Similarly, traps baited with flies or filter paper loaded with cuelure attracted melon flies (Fig. 3). Significant differences were evident for both attractants between substrate and loading: oriental fruit fly to methyl eugenol ($F_{3,56}$=13.70, *P*<0.001); melon fly to cuelure ($F_{3,56}$=15.10, *P*<0.001). Filter papers were more attractive than flies loaded with cuelure, whereas higher catches were obtained with the higher loading (300 ng) of methyl eugenol.

Trapping in a Large Field Cage Recapture of oriental fruit flies was highly significantly for time since treatment (analysis of variance on angular transformed data; $F_{5,30}$=24.99, *P*< 0.001), and insects treated with methyl eugenol on the day of release yielded 70% of the total recaptures (Fig. 4), amounting to 15.1+2.3% of flies released. Catches in the blank controls were 1% (+0.5) of the total.

Wind Tunnel Choice Tests Male oriental fruit flies were attracted to methyl eugenol-treated male melon flies (Table 1), and in separate experiments, the male melon flies were attracted to cuelure-treated oriental fruit flies (Table 2, Supplementary Material). In both cases, the various parameters were different between treatment and control. Species B flies closely approached and interacted with treated males of the other species, which in turn showed avoidance behaviors. Aggressive chasing of treated flies by the other species appeared like conspecific aggressive behavior with a quick hit or head butt and jump backward.

Mating Incidence In small cages, there was no difference in mating incidence of oriental fruit flies (72.5–90%; Table 3) with or without methyl eugenol-treated melon flies present (χ^2=4.119, *df*=2, *P*=0.128). However, the mating of male melon flies was reduced by their treatment with methyl eugenol (Table 3). There was no effect of cuelure-treated oriental fruit fly males on melon fly mating nor did the treatment with cuelure affect their own mating (Table 4; χ^2=2.018, *df*=1, *P*=0.155).

However, in the larger outdoor field cages, there was a reduction in the mating incidence of oriental fruit flies treated with cuelure (Species A) compared to the untreated controls (Table 5; χ^2= 33.315, *df*=1, *P*<0.001). However, mating of melon flies (Species B) was unaffected by cuelure-treated oriental fruit flies (Table 5; ÷^{2}=2.519, *df*=1, *P*=0.112). Methyl eugenol treatment of melon fly males reduced their mating success compared to controls (χ^2=314.7, *df*=1, *P*<0.001; Species A), but there was no effect on the oriental fruit flies (Species B; χ^2=2.7, *df*=1, *P*=0.10).

Discussion

These experiments have demonstrated that 100 ng amounts of two types of attractants applied topically to laboratory-reared fruit flies were not toxic over the period of 1 week, thus meeting the first requirement of lack of toxicity for the model system. There was evidence that a topical dose of methyl eugenol of 300 ng was toxic to melon flies, and this higher dose was not examined further in behavioral and mating experiments, although it was included in trapping experiments for comparison with cuelure, which was not toxic at this dose.

The 100-ng dose of each lure attracted multiple individuals of the target species in an outdoor field cage and in the field. Results in the rotating olfactometer in a field cage with laboratory-reared flies were more consistent than results with wild flies, presumably because of the more controlled conditions. However, both types of experiments demonstrated potentially useful levels of attraction with living fruit fly lures loaded with 100 ng of attractants. The large field cage experiment indicated that male melon flies treated with 100 ng of methyl eugenol were effectively capable of attracting oriental fruit flies for 1 day. A greater longevity of effect would presumably be an advantage for such a system.

The 100-ng doses also induced an interesting range of close range behaviors that involved physical contact with the loaded flies both in the wind tunnel and in cages. In the most intense situation, where escape was partially prevented by tethering, physical contact between the chasing male occurred an average of about 10 times a minute for prolonged periods.

In one of the two attractant-fly systems examined, it is possible that a significant problem would arise whereby the treatment could increase mating incidence. For example, methyl eugenol is also a phago-stimulant capable of increasing the competitive mating fitness of males that have fed upon it (Shelly and Dewire 1994; Shelly et al. 2005). A similar, although short-lived effect, has been reported for cuelure (Shelly and Villalobos 1995); however, here, no significant difference in the mating incidence of melon flies was evident in the presence of cuelure-treated oriental fruit flies.

The final test of mating incidence in an outdoor field cage with cuelure applied to oriental fruit flies did show an impact on their overnight mating frequency. Methyl eugenol treatment reduced mating of melon flies even more dramatically. The fact that the cuelure or methyl eugenol treatments to Species A had no effect on mating of Species B flies in both cases appeared to be due to a behavioral switch from attraction to the para-pheromone lure earlier in the day to mating behavior over the crepuscular period. The incidence of lek formation in male flies on the ceiling of the field cage appeared to increase toward dusk, although it was not specifically recorded. In the field cage experiments with odorant-treated males, lower mating incidence at dusk was recorded, but accurate recording of male chasing of treated males was not practical, so such a behavioral explanation for the failure of this ménage-à-trois model would require further examination. A possibly analogous switch in behavior between mated and unmated flies to either male pheromone or host odor for oviposition has been reported by Jang (1995) for females of another tephritid, *Ceratitis capitata* (medfly). This behavioral limitation would appear to be a significant problem for these fruit fly models but would not necessarily apply in other cases. It is also possible that the topical treatment created repellency from treated males, effectively rendering them unattractive to females at close range. Alternatively, a sublethal impact with reduced male proclivity for mating may be responsible. Further experiments to examine this effect could be valuable, as this could eventually lead to a new tactic based on loading of wild male melon flies with methyl eugenol to reduce mating incidence.

A better system for the ménage-à-trois concept might offer a greater degree of behavioral synchrony between the elements of attraction and mating, which were separated by time in the two models tested here. For example, it might be more successful to interrupt mating in medfly (which mates in the morning) with the presentation of an attractant (such as cuelure or methyl eugenol) to other species. The potential impact of treatment of males of two species with reciprocal lures was not examined. It is possible that this would have a greater success rate against fruit flies than the single components alone.

Whereas it might be of interest to investigate the response of males of one species to male lures placed onto females of another species, this variation was also not examined here. This was in part because of the present lack of female lures for wild flies and the unlikelihood of a scenario of releasing laboratory-reared female flies, as they can damage fruit. However, the potential of this approach could be of interest to investigate in the future as it might facilitate the development of a tactic that uses hybrid sterility (a form of the sterile insect technique) in fruit flies (McInnis et al. 1999). Odorants attractive to males of another species that were placed on females of a closely related species could serve the function of bringing the pair into close proximity before the mating period. The potential for combination of the Sterile Insect Technique with the current approach is significant, given fruit flies as potential targets. However, if Species A were treated and innundatively released as part of a sterile insect program, impact on mating of the treated males (as seen here) could be detrimental to the control of Species A by SIT, which would require evaluation of the trade-off. Use of mass-reared medflies and other insects as a potential source of point source distribution of pheromone for mating disruption is under investigation.

Several of the main issues considerations for the proof of concept of this novel approach have been addressed here, although the impact on mating was limited or absent with these models. Another limitation to the approach is the requirement for both species in the system to be present at the same location. Although there are many locations where both of the fruit fly species examined here are present together, this requirement would limit the potential utility, unless the second species is released proactively, for example, as sterile

insects. Systems of large-scale odorant delivery would also need to be developed, and there are other practical issues that would need to be addressed. It may be possible to get this concept to work more effectively in a completely different model system. A much greater understanding of conditions under which the ménage-à-trois concept will or will not work is needed before practical application will be possible. This work offers novelty in presenting attractants on a moving target, in this case, another insect. Other applications for this concept remain to be developed.

Acknowledgments D. M. Suckling undertook this project with a Fellowship under the Organization for Economic Cooperation and Development Cooperative Research Programme: Biological Resource Management for Sustainable Agricultural Systems. Other support was provided by the US Department of Agriculture, Agriculture Research Service, HortResearch, and the New Zealand Foundation for Research Science and Technology (CO6X0301). Don McInnis provided invaluable insights into mating assessment in fruit flies and comments on the manuscript. Kellie Nagai helped with preparation of material for experiments.

Introduction

Erannis (recently renamed to *Agriopis*) *bajaria* Denis et Schiffermüller (Lepidoptera: Geometridae: Ennominae) is a south and central European winter-flying geometrid moth that is adapted to low temperatures. Females are wingless and climb up plant stems where they emit a pheromone blend to attract males in a similar way as described for *E. aurantiaria* and *E. defoliaria* (Tvermyr 1969). Known geometrid moth pheromones are usually long-chain polyunsaturated hydrocarbons and their oxygenated derivatives (Millar 2000). The pheromone blend of *E. bajaria* was reported to consist of (3*Z*,6*Z*,9*Z*)-3,6,9-octadecatriene (3*Z*,6*Z*,9*Z*-18:H) and (3*Z*,6*Z*,9*Z*)-3,6,9-nonadecatriene (3*Z*,6*Z*,9*Z*-19:H) (Szöcs et al. 1996). Although 3*Z*,6*Z*,9*Z*-18:H attracts conspecific males as a single component, the addition of 3*Z*,6*Z*,9*Z*-19:H is strongly synergistic, and a 1:1 mixture of both compounds proved to be the optimal attractant for males in field bioassays (Szöcs et al., unpublished).

Polyene hydrocarbon pheromones are biosynthetically derived from linoleic acid or α-linolenic acid and usually contain an odd number of carbons in the chain with (6*Z*,9*Z*) or (3*Z*,6*Z*,9*Z*) arrangement of the double bonds. The precursor acids are chain elongated by two-carbon acetate units via malonate, when necessary, and the terminal carboxyl group is reductively removed by decarboxylation or decarbonylation (Jurenka 2004). This process produces pheromones with an odd number of carbon atoms, as shown in detail by applying labeled precursors to *Estigmene acrea* (Rule and Roelofs 1989). Less information is available about the biosynthesis of such pheromones with an even numbered chain, which occasionally occur as components of some pheromones, e.g., in *E. bajaria*. Direct reduction of the polar carboxyl moiety of polyunsaturated even numbered fatty acids, perhaps with corresponding aldehydes and alcohols as intermediates, was proposed by Millar (2000) and was recently described to be working in a bacterium (Park 2005). In contrast, we postulated that chain shortening might take place in two consecutive steps, removing one carbon in each step, producing hydrocarbons with one or two carbons less than the parent fatty acids. Therefore, experiments with labeled precursors were performed with *E. bajaria* to elucidate the pathway furnishing 3*Z*,6*Z*,9*Z*-18:H and 3*Z*,6*Z*,9*Z*-19:H.

Methods and Material

Preparation of Deuterium-Labeled Compounds Heating methyl linolenate (9*Z*,12*Z*,15*Z*-18:COOMe) with freshly prepared sodium methoxide in CH_3OD under reflux for 8 hr yielded the corresponding deuterated methyl ester [2,2-$^2H_2$]-9*Z*,12*Z*,15*Z*-18:COOMe in 95% yield. The deuterated methyl ester was reduced with lithium aluminum deuteride in refluxing diethyl ether to furnish pure [1,1,2,2-$^2H_4$]-9*Z*,12*Z*,15*Z*-18:OH in 89% yield. This alcohol was transformed to the corresponding iodide [1,1,2,2-$^2H_4$]-9*Z*,12*Z*,15*Z*-18:I under Mitsunobu conditions in 69% yield. Subsequently, the carbon chain was elongated by nucleophilic substitution with tetraethylammonium cyanide in 89% yield, followed by reduction of the cyanide with diisobutylaluminum hydride to form [2,2,3,3-$^2H_4$]-10*Z*,13*Z*,16*Z*-19:Al. This aldehyde was reduced to the corresponding alcohol which then was oxidized with pyridinium dichromate in dimethylformamide to furnish [2,2,3,3-$^2H_4$]-

10*Z*,13*Z*,16*Z*-19:COOH in 30% yield over two steps. Direct oxidation of the [$^2H_4$]-aldehyde resulted in a lower yield and an impure product that was difficult to isolate. [3,3,4,4-$^2H_4$]-11*Z*,14*Z*,17*Z*-20:COOH was obtained by similar transformations after converting [1,1,2,2-$^2H_4$]-9*Z*,12*Z*,15*Z*-18:I into [3,3,4,4-$^2H_4$]-(11*Z*,14*Z*,17*Z*-)-11,14,17-icosatrienenitrile by C_2-elongation with acetonitrile, followed by saponification of the nitrile in 61% overall yield (Taber and Kong 1997).

Insects Adults were collected at Nadap, Hungary and were kept under outdoor conditions at PPI HAS (Budapest) in 4-l glass jars equipped with sheets of filter paper as oviposition substrates. The following spring, eggs were placed on buds of blackthorn (*Prunus spinosa* L.) enclosed in sleeve cages. Before pupation, larvae were transferred to cages containing sterilized soil for pupation. Pupae were sexed, and emerging adults were collected daily.

Experiments with Labeled Precursors The deuterium-labeled compounds [1,1,2,2-$^2H_4$]-9*Z*,12*Z*,15*Z*-18:OH, [2,2,3,3-$^2H_4$]-10*Z*,13*Z*,16*Z*-19:COOH, and [3,3,4,4-$^2H_4$]-11*Z*,14*Z*,17*Z*-20:COOH were topically applied in DMSO solution (20 μg/μl; total amount applied, 1 to 2 μl/female) on the ovipositor tip. This procedure was performed 2 hr before the normal diel calling period. During the calling period, ovipositor tips (containing the pheromone gland) were dissected and extracted in hexane for 5 min. Extracts were stored at −65°C until analysis by gas chromatography–mass spectrometry (GC-MS). About 15 female equivalents were combined for one analysis.

Gas Chromatography–Mass Spectrometry GC/MS analyses were carried out on an HP 6890 Series GC connected to an HP 5973 mass selective detector (Hewlett-Packard) fitted with a BPX5 column (25 m, 0.22 mm i.d., 0.25-μm film, SGE). Mass spectra (70 eV) were recorded in both scan and multiple ion monitoring mode (MIM). The GC was programmed as follows: 2 min at 50°C, then to 320°C at 5°C/min, operating in splitless mode (60 sec valve time).

Results and Discussion

Several deuterium-labeled precursors were synthesized and topically applied to the pheromone glands of females of *E. bajaria*. Subsequently, extracts of the pheromone glands were analyzed by GC/MS. Because of the low pheromone titer, samples of about 15 female equivalents were pooled for analyses. After topical application of [2,2,3,3-$^2H_4$]-10*Z*,13*Z*,16*Z*-19:COOH, 17,17,18,18-$^2H_4$-3*Z*,6*Z*,9*Z*-18:H was detected in the extracts along with the unlabeled compound. Application of [3,3,4,4-$^2H_4$]-11*Z*,14*Z*,17*Z*-20:COOH also yielded the labeled triene, but in lesser amounts. In the latter case, all four ^2H atoms of the labeled acid were incorporated into 3*Z*,6*Z*,9*Z*-18:H. Incorporation of the deuterium label into the polyenes was checked by GC/MS in MIM scan mode. Mass spectra of 3,6,9-alkatrienes usually exhibit a molecular ion and a signal generated by loss of a 56-amu fragment that includes carbons 1 to 4 (Becker et al. 1983). In the case of [17,17,18,18-$^2H_4$]-3*Z*,6*Z*,9*Z*-18:H, the molecular ion (M^+) of the unlabeled compound (*m*/*z* 248) and its diagnostic fragment M^+-56 (*m*/*z* 192) should be shifted by 4 amu to *m*/*z* 252 and *m*/*z* 196, respectively. Table 1 shows the results obtained when MIM was performed using the ions *m*/*z* 192, *m*/*z* 196, *m*/*z* 248, and *m*/*z* 252. Mean incorporation rates of 5.7% in the case of [2,2,3,3-$^2H_4$]-10*Z*,13*Z*,16*Z*-19:COOH and 1.9% in the case of [3,3,4,4-$^2H_4$]-11*Z*,14*Z*,17*Z*-20:COOH were calculated from the ion intensities $I_{196}/(I_{192}+I_{196})$ and $I_{252}/(I_{252}+I_{248})$.

Table 1 Relative intensities of ions found in GC/MS multiple ion monitoring analysis at the retention time of 3*Z*,6*Z*,9*Z*-18:H[a]

	$I_{192}+I_{196}$	I_{196}	$I_{196}/(I_{192}+I_{196})$	$I_{248}+I_{252}$	I_{252}	$I_{252}/(I_{248}+I_{252})$
[D4]-10*Z*,13*Z*,16*Z*-19:COOH	106.5	6.5	0.061	105.6	5.6	0.053
[D4]-11*Z*,14*Z*,17*Z*-20:COOH	101.1	1.1	0.011	102.7	2.7	0.026
[D4]-9*Z*,12*Z*,15*Z*-18:OH	100.0	0	0	100.0	0	0

[a] The earlier elution of the deuterated isotopomer is accounted for by summing the intensities of the ions from the start until the end of both peaks. I_y Relative intensity of the ion of *m*/*z* y (%)

The analytical results proved that both 10*Z*,13*Z*,16*Z*-19:COOH and 11*Z*,14*Z*,17*Z*-20:COOH are biosynthetic precursors of 3*Z*,6*Z*,9*Z*-18:H. Furthermore, when topically applied to the gland, the alcohol [1,1,2,2-$^2H_4$]-9*Z*,12*Z*,15*Z*-18:OH did not provide labeled 3*Z*,6*Z*,9*Z*-18:H, which excludes the possibility that linolenic acid is directly reduced via the alcohol to 3*Z*,6*Z*,9*Z*-18:H, as proposed by Millar (2000). A biosynthetic pathway taking into account the results of our labeling experiments is summarized in Fig. 1. Linolenic acid, taken up from the diet and most likely conjugated to CoA, is chain-elongated in the conventional sequence with malonate to yield 11*Z*,14*Z*,17*Z*-20:CoA. α-Oxidation then results in loss of one carbon to give 10*Z*,13*Z*,16*Z*-19:CoA. This precursor is then converted into 3*Z*,6*Z*,9*Z*-18:H, probably via 10*Z*,13*Z*,16*Z*-19:Al (Reed et al. 1995; Jurenka 2004). In contrast, removal of C-1 of 11*Z*,14*Z*,17*Z*-20:CoA after the conventional process (Rule and Roelofs 1989) furnishes 3*Z*,6*Z*,9*Z*-19:H.

To the best of our knowledge, α-oxidation of unbranched fatty acids in animals has not been reported before, although α-oxidation of linolenic acid has been shown to occur in humans (Matsunaga et al. 1997). This mechanism must now be considered to be involved in pheromone biosynthesis in other species as well.

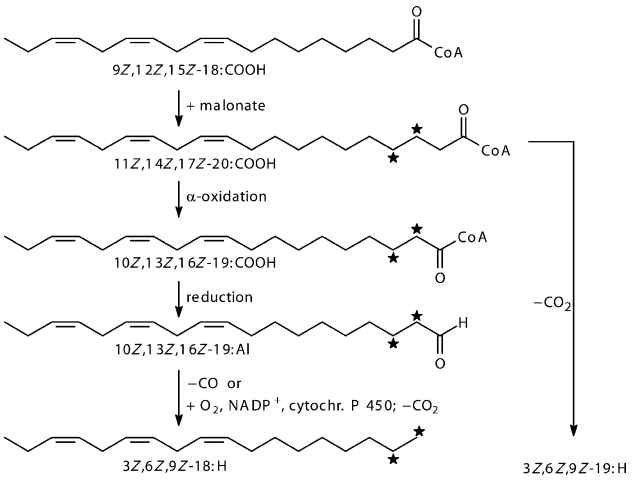

Fig. 1 Proposed biosynthetic pathway for the formation of 3*Z*,6*Z*,9*Z*-18:H based on the results of treatment of female moths with [2,2,3,3-$^2H_4$]-10*Z*,13*Z*,16*Z*-19:COOH and [3,3,4,4-$^2H_4$]-11*Z*,14*Z*,17*Z*-20:COOH. *Stars* indicate the positions of the deuterium labels

the pheromone models of other bark beetles could benefit from systematic reexamination using newer technologies. Additionally, baits fortified with (+)-*endo*-brevicomin may enhance pest management strategies that exploit attractants for *D. frontalis*.

Introduction

The pheromone system of the southern pine beetle, *Dendroctonus frontalis*, Zimmermann (Coleoptera: Curculionidae: Scolytinae), an aggressive tree-killer of *Pinus* spp. in southern North America and Central America, has been studied since the mid-1960s (reviewed in Smith et al. 1993). According to the model proposed by Renwick and Vité (1969) and subsequently refined (Vité and Francke 1976; Payne 1980; Smith et al. 1993), female beetles (the "pioneer" sex) initiate colonization of new host trees by boring into the bark while releasing the aggregation pheromone components frontalin and *trans*-verbenol. Frontalin is considered the major component of the aggregation pheromone, based both upon its ability to attract conspecifics in the absence of other compounds and the failure of any compound or combination to attract *D. frontalis* in its absence (Smith et al. 1993; Skillen et al. 1997). A blend of frontalin, *trans*-verbenol, and *alpha*-pinene (released by the host) attracts both sexes: males that pair with established females and females that initiate their own entrances in the bark. Attraction of sufficient numbers of conspecifics results in a lethal "mass attack" in which the host's constitutive resin defenses become so compromised that beetles can feed and reproduce unimpeded in the phloem. Arriving males produce verbenone and *endo*-brevicomin, compounds thought to interrupt attraction to the aggregation pheromone once the host is fully colonized and cause termination of mass attack.

Evidence that male-produced *endo*-brevicomin and verbenone function as antiaggregation pheromones includes: (1) production solely or predominantly by the second-arriving sex (Pitman et al. 1969; Hughes 1973), (2) the ability to inhibit attraction of *D. frontalis* to traps baited with frontalin plus *trans*-verbenol and/or host-compounds (Renwick and Vité 1970; Vité and Renwick 1971; Payne et al. 1978; Salom et al. 1992), and (3) the ability of devices releasing these compounds to reduce the numbers of beetles landing on hosts (Payne et al. 1977; Payne and Richerson 1979) or stop the expansion of individual *D. frontalis* infestations (Payne et al. 1992). However, Billings (1985) reported that low release rates of *endo*-brevicomin and verbenone enhanced attraction of flying *D. frontalis*. Subsequently, Vité et al. (1985) demonstrated that pure (+)-*endo*-brevicomin increased catches of *D. frontalis* in traps baited with frontalin and turpentine, whereas the (−)-enantiomer had an antagonistic effect.

The true function of *endo*-brevicomin in the biology of *D. frontalis* has remained unclear for at least two reasons. First, conflicting evidence exists regarding the enantiomeric composition of *endo*-brevicomin (Redlich et al. 1987; Grosman et al. 1997), hence the relative amounts of the apparently repellant (−) and the attractive (+)-enantiomers produced by *D. frontalis* is uncertain. Second, addition of male *D. frontalis* to female-infested pine bolts failed to alter responses of conspecifics (Coster et al. 1977; Svihra 1982), suggesting that male-produced semiochemicals neither inhibit nor enhance aggregation during host colonization.

In this paper, we reexamine the role of male beetles in semiochemical-mediated host colonization by *D. frontalis*. We assayed whether male beetles could alter attraction of conspecifics to female attacks when living pines were used as the host substrate rather than

pine bolts as in earlier studies. We then performed electroantennogram studies with volatiles derived from both newly emerged and mining *D. frontalis* to identify potential male-produced aggregation pheromone components, and we compared olfactory sensitivity for (+)-*endo*-brevicomin, a candidate male-produced aggregation pheromone component, against its antipode and the enantiomers of frontalin. We examined the influence of both feeding and pairing on the quantity and enantiomeric composition of *endo*-brevicomin produced by male *D. frontalis* and performed field trapping bioassays to determine the behavioral activity of (+)-*endo*-brevicomin and elucidate its likely function in host colonization.

Materials and Methods

Experimental Insects Adult *D. frontalis* were collected in a rearing box fitted with a refrigerated insect trap (Browne 1972) as they emerged from bark or bolts taken from naturally infested trees cut in the National Forests of Mississippi and Alabama in 2002–2006. Beetles were held for up to 1 week at 4°C in plastic Petri plates lined with pieces of moistened Kimwipe® (Kimberly-Clark, Roswell, GA, USA). Beetles were sexed by the mycangial bulge on the female pronotum and the deep median groove on the male frons (Wood 1982). Only undamaged beetles were used in experiments.

Attraction of D. frontalis to Artificially Infested Trees Within a mixed pine/hardwood stand that had a suboutbreak population of *D. frontalis* (Homochitto National Forest, Mississippi, 31.5° N, 91.2° W), we selected pairs of adjacent, apparently healthy loblolly pines, *Pinus taeda* L. Trees in each pair were 15–40 cm DBH (diameter breast height), located >100 m from any other pair, and >100 m from the nearest *D. frontalis*-infested tree. A saran screen cage (32 mesh, 1.0 m tall) was wrapped around the trunk of each tree at a height of 1–1.5 m. Access to the cage interior was through a Velcro® closure that ran the length of the cage; the top and bottom of the cage were sealed tightly to the bark with a 10-cm-wide strip of duct tape. To preclude beetle entry or escape through bark fissures, the outer bark was smoothed with a draw-knife where the top and bottom of the cage were taped to the tree. To prevent attacks by wild beetles, all noncaged portions from the soil to base of the crown were wrapped with clear polyethylene sheeting (6-ml thickness) secured with duct tape. Pines closer than 10 m to the caged trees were either removed or had their boles wrapped in sheeting to prevent "spillover" attacks. To promote successful attack of the trees by caged beetles, the primary resin defenses of each tree were challenged by stripping a 10-cm-wide girdle of bark immediately below the cages during the day before and again on the day of introduction of female beetles to the cages.

On one tree of each pair, 100 *D. frontalis* females were sealed into the cage, and then, three nonbaited, 12-unit multiple funnel traps (Chemtica International, San Jose, Costa Rica) were suspended against the outside of the cage equidistant around the tree circumference. On the following day, trap catch was collected, and then, either 100 males or no further beetles were added to the cage, as determined by a coin toss. Beetles were collected again 2 and 4 days later. Peak attraction to naturally infested trees and artificially infested logs occurs 2–3 days after initiation of attacks (Coster and Vité 1965; Coster et al. 1977). After the final trap collection, infested trees were immediately felled, and the caged portions were removed for dissection in the laboratory. Approximately 1 week after felling of the first tree of each pair, the entire procedure was repeated on the second tree except that it received the opposite treatment with regard to the introduction of males. In total, eight

pairs of trees were assayed between 20 June and 1 August 2006. We used paired *t* tests to identify treatment effects on trap catch and numbers of attacks on trees. The proportions of males trapped per tree were normalized with $arcsin\sqrt{x}$, and treatments were compared with Student's *t* test. Bonferroni's adjustment (α=0.017) was applied to comparisons of catch within the three trapping intervals.

Electrophysiological Analyses We examined relative olfactory sensitivities of *D. frontalis* to volatile compounds isolated from males. We quantitatively analyzed coupled gas chromatography-electroantennographic detection (GC-EAD) responses of beetles to 11 male-produced compounds that were shown in a previous, qualitative study to have olfactory activity (Sullivan 2005). In that study, single antennae from male and female *D. frontalis* were exposed to 0.1 beetle equivalents of the mid/hindgut extract of 100 newly emerged male *D. frontalis.* We also performed new GC-EAD analyses on the antennae of ten male and ten female *D. frontalis* exposed to volatiles from male beetles that had been paired with a female in a pine bolt <1 day (extraction treatment 3, below). The pooled pentane extract from 15 males was concentrated until approximately 1 μl equaled 0.2 beetle equivalents, and this quantity was injected into the GC, thus delivering 0.1 beetle equivalents to the antennal preparation (the effluent was split 1:1 between the GC's flame ionization detector [FID] and the antennal preparation). Otherwise, the GC-EAD apparatus and procedures were identical to those published by Sullivan (2005). For both GC-EAD data sets, raw response voltages for all compounds that produced an EAD deflection with at least four antennae were log transformed and then analyzed by repeated-measures analysis of variance (ANOVA) and Tukey's pairwise tests (α=0.05; SPSS 1997).

Because *endo*-brevicomin consistently produced greater antennogram responses than any other male-derived volatile, we generated dose–response curves to compare the relative olfactory sensitivity of *D. frontalis* to the separated enantiomers of both *endo*-brevicomin and the female-produced aggregation pheromone component frontalin. Antennae were exposed to mixtures containing tenfold dilutions of frontalin and *endo*-brevicomin (approximately 1000, 100, 10, 1, 0.1, 0.01, and 0.001 ng/μl of each enantiomer delivered to the antennae) as well as the EAD-active internal standard (−)-verbenone at a fixed concentration (100 ng). Each experimental replicate consisted of a single GC-EAD run with a fresh antennal preparation and one of the dilutions assayed in random order. Enantiomers were separated on a GammaDex-225 column (30 m×0.25 mm×0.25 μm film; Supelco, Bellefonte, PA, USA) by using the temperature program 5°/min from 60 to 117°, then 45°/min to 225° held 5 min. This program produced a 0.18- to 0.28-min separation between the GC peaks of both the frontalin and *endo*-brevicomin enantiomers and a >3.0-min separation between peaks of the three compounds (Fig. 1). We were unable to identify a chiral column phase that reversed the elution order of the enantiomers of frontalin and *endo*-brevicomin, hence all GC-EAD runs were performed with (+)-frontalin and (−)-*endo*-brevicomin eluting ahead of their respective antipodes. To ensure that recent exposure to the antipode was not reducing antennal responses to the second-eluting enantiomer, GC-EAD runs were performed both with synthetically purified, single enantiomers (Phero Tech Inc., Delta, BC, Canada; 94–97% enantiomeric purity; two to four replicates per dilution) as well as racemic mixtures (four replicates per dilution) of frontalin and *endo*-brevicomin. Mean response voltages did not differ significantly between these data sets at any concentration (nonparametric *t* test, α=0.05, Microsoft® EXCEL 2002); therefore, the data were pooled. To minimize variation as a result of inconsistent quality of the antennal preparations, response voltages to frontalin and *endo*-brevicomin enantiomers were computed relative to response voltage to the internal standard, (−)-verbenone. The threshold of detection for each

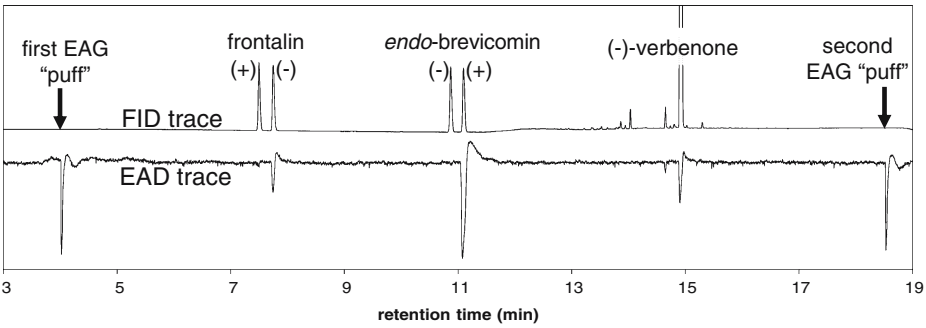

Fig. 1 GC-EAD trace from a male *D. frontalis* antenna exposed to one of the doses (10 ng) used to calculate dose–response curves for *D. frontalis* sensitivity to the enantiomers of frontalin and *endo*-brevicomin. The *upper* trace is from the GC's flame ionization detector (*FID*), while the *lower* trace is from the electroantennographic detector (*EAD*). Enantiomers were separated on a *gamma*-cyclodextrin-phase capillary GC column. Verbenone was included in each injected dilution as an electrophysiologically active internal standard, and an electroantennogram (*EAG*) stimulus (consisting of a blend of *D. frontalis* semiochemicals in a pasteur pipette) was "puffed" over the antenna at the beginning and at the end of each GC-EAD run to estimate decline in overall responsiveness of the antennal preparation during this interval

enantiomer was calculated as the lowest concentration for which the EAD deflection voltage exceeded the 90th percentile of the height of background noise on at least three out of eight runs ($P<0.038$, table of cumulative binomial probabilities; Bhattacharyya and Johnson 1977). Mean and standard error of responses to enantiomers were calculated for concentrations that exceeded the threshold of detection. To calculate the actual concentration of each enantiomer exposed to the antenna, the integration area of each FID peak during 0.2 s at maximum peak height was divided by the total integration area, multiplied by the known total quantity of enantiomer eluting, and then divided by the volume of air transferring the effluent to the antenna every 0.2 s (i.e., 1.33 ml).

For all GC-EAD data sets, the heights of signal voltage deflections in each GC-EAD run were corrected for the inevitable loss of responsiveness in the antennae that occurred over the duration of the run. This correction was accomplished by measuring the decline in electroantennogram (EAG) response to a uniform stimulus (a mixture of *D. frontalis* semiochemicals delivered from a Pasteur pipette) "puffed" over the antenna at the beginning and end of each GC-EAD run (Fig. 1). The percent reduction in height of the response to the second EAG stimulus relative to the first was assumed to be a linear function of time and to affect all stimulants equally.

Pheromone Isolation and Analysis We used procedures described by Sullivan (2005) and determined the influence of feeding and pairing on the quantities of *endo*-brevicomin, frontalin, verbenone, and myrtenol produced by one or both sexes of *D. frontalis*. We sampled volatiles from individual beetles that either (1) were newly emerged (i.e., had appeared in the rearing box during the previous 3 days), (2) had been mining singly in a freshly cut loblolly pine bolt for <1 day, or (3) had been mining in a bolt with a mate for <1 day (females had initiated galleries 1 day before the introduction of males). To obtain attacks on bolts, we confined beetles within gelatin capsule halves secured over 1-mm-diameter holes drilled into the bark. Beetles that produced frass in treatments 2 and 3 were carefully dissected from the bark and kept up to 4 h at 0–4°C before headspace sampling. To collect volatiles from beetles, they were held singly for 16–20 h at room temperature in static headspace sampling enclosures (Sullivan 2005) containing ~3 mg of Super Q

adsorbent (Alltech, Deerfield, IL, USA). Afterward, the Super Q and the excised mid/hindgut of each beetle were extracted together in a total of 100 μl pentane spiked with 180 ng of the internal standard heptyl acetate. In one experiment, 31–34 individuals per treatment per sex were sampled from a single pool of beetles derived from infestations in the Chickasawhay National Forest of southeastern Mississippi (31.5° N, 89.0° W). In addition, we checked for possible regional variation in the enantiomeric ratios of *endo*-brevicomin by sampling additional males in treatment 3 above from both the Homochitto National Forest in western Mississippi (31.4° N, 91.1° W; N=4) and the Talladega National Forest of Alabama (32.9° N, 87.1° W, N=11).

The samples were analyzed on a Hewlett-Packard 6890-5973 coupled GC/mass spectral detector (GC-MSD) with helium as the carrier gas. Two microliters of sample were injected in splitless mode and analyzed with both nonchiral phase (INNOWax; 60 m×0.25 mm×0.25 μm film; Agilent Technologies, Wilmington, DE, USA) and chiral phase (Gamma-Dex-225; 30 m×0.25 mm×0.25 μm film; Supelco) capillary GC columns. For nonchiral GC-MS runs, the oven program was 40°C for 1 min, 16°C/min to 80°C, then 7°C/min to 230°C; for chiral runs, it was 40°C for 1 min, 5°C/min to 70°C, 2°C/min to 155°C, then 25°C/min to 220°C, or alternatively, 40°C for 1 min, then 5°C/min to 220°C. Analytes were quantified in the nonchiral runs by using response curves calculated from analyses of a dilution sequence of known quantities of compounds. Quantitative differences among treatment groups within sex were analyzed with a Kruskal–Wallis ANOVA followed by Dunn's test for pairwise comparisons (α=0.05; SPSS 1997).

Enantiomers of frontalin and *endo*-brevicomin in the samples were identified by retention time matches on the chiral column with synthetic standards of these enantiomers supplied by Phero Tech. We confirmed the optical rotation of the chiral *endo*-brevicomin standards by polarimetry. Enantiomeric ratios of frontalin and *endo*-brevicomin were calculated by examining single ion chromatograms of diagnostic ions for each compound (100 and 114 amu, respectively) and then computing the ratio of the integration areas of peaks at the confirmed retention times of the (+)- and (−)-enantiomers. Response of the MSD had been found to be essentially linear through the range of enantiomer concentrations examined.

Attraction of D. frontalis to Synthetic Baits We evaluated the behavioral responses of *D. frontalis* to synthetic (+)-*endo*-brevicomin baits by using 12-unit multiple funnel traps erected within the same stand used for the artificially infested tree experiment during a period when it was experiencing a declining outbreak of *D. frontalis*. Traps were located >100 m apart, >10 m from the nearest susceptible pine, and >1 km from the nearest known multiple-tree *D. frontalis* infestation. They were suspended from metal poles with the bottom funnel ~1 m above the ground. Bait bioassay 1 (12 replicates; 18 September–17 October 2005) compared four bait treatments: pine turpentine; turpentine and (+)-*endo*-brevicomin; turpentine and racemic frontalin; (+)-*endo*-brevicomin, racemic frontalin, and turpentine. Bait bioassay 2 (nine replicates; 17 January–1 March 2006) compared five bait treatments: unbaited trap; racemic frontalin; (+)-*endo*-brevicomin; racemic frontalin and (+)-*endo*-brevicomin; (+)-*endo*-brevicomin, racemic frontalin, and turpentine.

The frontalin bait consisted of two, 400-μl-capacity LDPE microcentrifuge tubes containing racemic frontalin (>95% purity, Chemtica International). Turpentine (steam distilled from loblolly pine; Hercules Inc., Brunswick, GA, USA) was released from a 250-ml-capacity brown glass bottle with a piece of 1 cm diameter cotton dental wick immersed in the turpentine and protruding 2.5 cm through the cap. The (+)-*endo*-brevicomin was synthesized by the combination of procedures reported by Mori and Seu (1985) and Mori

and Kiyota (1992) that employs lipase-catalyzed desymmetrization of a diol and Wacker oxidation of an olefin and was >99% enantiomerically and >95% chemically pure. It was released from a 1.17-mm i.d. glass capillary sealed at one end and suspended open-end up inside an inverted 2-ml glass vial. The frontalin and *endo*-brevicomin baits were suspended at the fourth funnel from the bottom of the trap, whereas the turpentine bottle was placed within the funnel immediately below the trap top (to protect the exposed wick from rain). Release rates were measured for all baits within a fume hood at 23±2°C, either gravimetrically (turpentine, 7 g/day; frontalin, 5 mg/day) or by loss of volume in the capillary (*endo*-brevicomin, 0.2 μl/day=0.2 mg/day). Trap cups were filled with a few centimeters of propylene glycol and water, and catch was collected every 1–2 weeks. Traps were arranged into three lines with one trap per treatment and 150±50 m between traps. Treatments were assigned at random within lines and rerandomized without replacement to any previous position each time catch was collected. Each rerandomization/collection per trap line was one complete statistical block (=replicate). Raw catches of male and female *D. frontalis* were transformed with $log(X+0.5)$ and analyzed for significant differences among treatment means by using a two-way ANOVA (factors were treatment and block) and Tukey's pairwise comparisons ($\alpha=0.05$; SPSS 1997). For bait treatments that trapped more than one insect, the proportion of males trapped per replicate was transformed ($arcsin\sqrt{x}$), and treatments were compared with Student's *t* test.

Results

Attraction of D. frontalis to Artificially Infested Trees In the first 2 days after introduction of males, trees caged with both sexes of *D. frontalis* attracted significantly greater numbers of conspecifics than trees caged with females alone (Fig. 2). This difference disappeared during the next 2 days. Beetle catch summed for all 4 days after introduction of males was likewise significantly higher for trees infested with both sexes (paired *t* test; $P<0.001$). For this same period, sex ratio (M/F) of beetles trapped at trees with both sexes (1.2:1), and females only (1.6:1) did not differ significantly (*t* test; $P=0.82$). Dissections of the caged portions of trees revealed that both treatments had similar numbers of attacks initiated into the phloem (female only, 56.0±2.4; both sexes, 59.6±4.5; paired *t* test, $P=0.37$) and

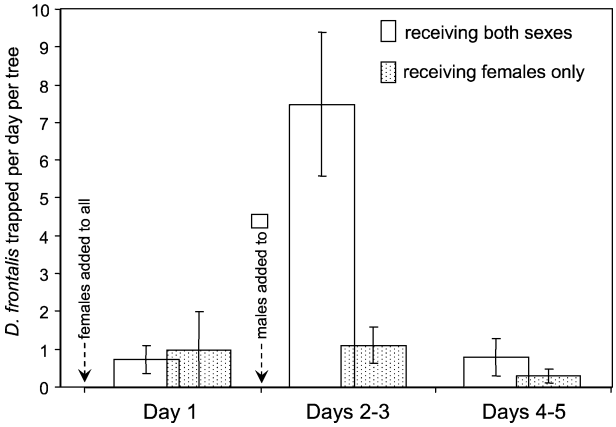

Fig. 2 Mean catches (±SE) of *D. frontalis* in traps affixed to live pines artificially infested either with conspecific females or with both sexes. Catch was significantly different between treatments on days 2–3 but not day 1 or days 4–5 (Paired *t* test, $P<0.017$)

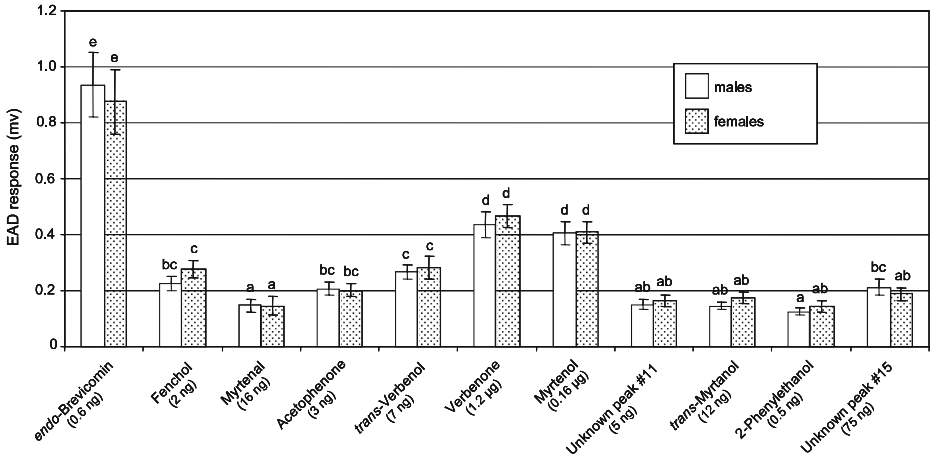

Fig. 3 Mean (±SE) EAD response by antennae of *D. frontalis* exposed to 0.1 insect equivalents of pooled gut extract of 100 newly emerged male *D. frontalis* (Sullivan 2005). Within sex, means associated with the same *letter* were not significantly different (α=0.05, Tukey test). The approximate quantity of each compound exposed to the antenna is given in *parentheses*

confirmed that, in trees that had received both sexes, a substantial number of males had successfully paired with females in galleries (30.6±4.6). Greater numbers of galleries with live, solitary females were found in female-only trees (18.4±2.6) compared to trees receiving both sexes (5.3±1.5; paired *t* test P=0.005). Live, solitary females had mined in the phloem an average of 3.73±0.16 cm, whereas live pairs had mined 7.81±0.22 cm (nonparametric *t* test, P<0.001).

Electrophysiological Analyses In GC-EAD analyses of 0.1 insect equivalents of extract from newly emerged *D. frontalis* males, antennae of both sexes responded with

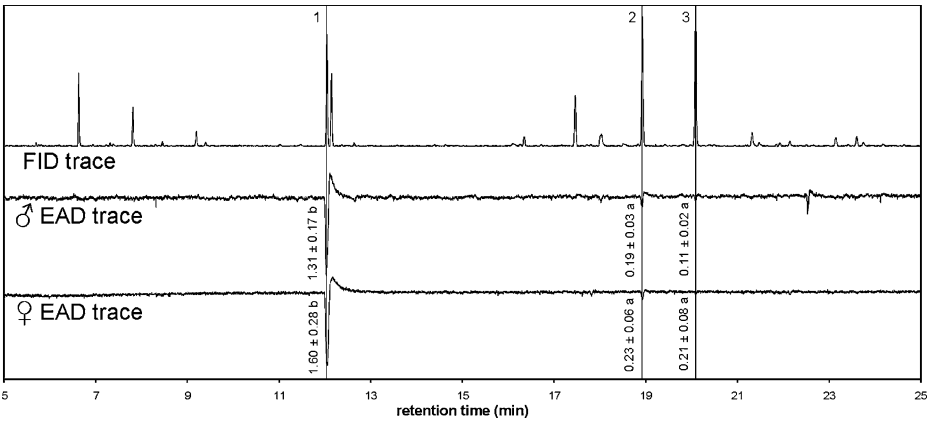

Fig. 4 GC-EAD traces of individual *D. frontalis* exposed to 0.1 insect equivalents of the pooled aerations/extracts of 15 male *D. frontalis* that had been paired in a pine bolt with a female beetle for approximately 1 day. *Peaks* detected by the flame ionization detector (*FID*) that consistently coincided with an EAD deflection from either sex are numbered: *endo*-brevicomin, *1*; verbenone, *2*; myrtenol, *3*. Values adjacent to each EAD peak represent the mean (±SE mv) response of ten sampled antennae. Within sex, means associated with the same *letter* were not significantly different (Tukey test; α=0.05)

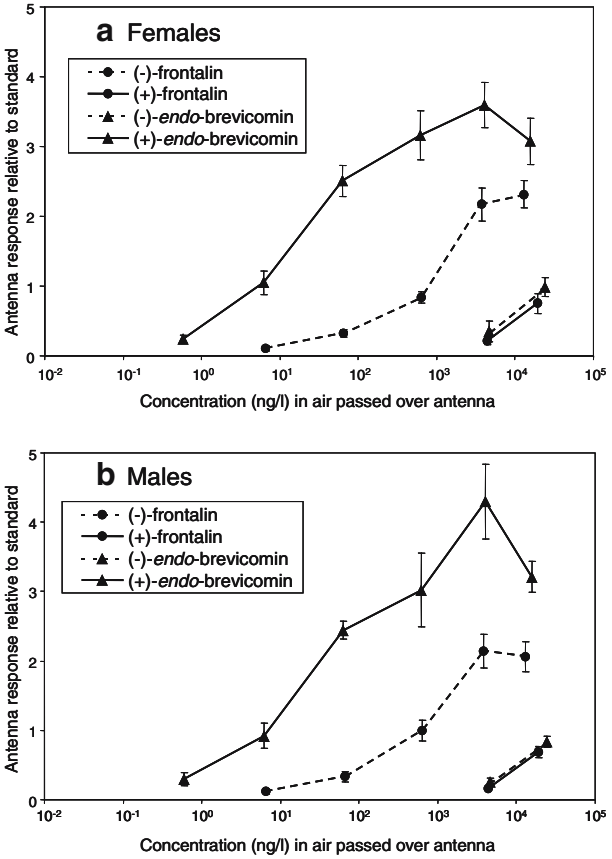

Fig. 5 Dose–response curves of EAD responses of female (**a**) and male (**b**) *D. frontalis* to the enantiomers of frontalin and *endo*-brevicomin resolved on a *gamma*-cyclodextrin-phase capillary column. *Data points* (mean response±SE) are shown only for concentrations for which the antennae registered a response that was significantly above the level of background noise (see text); hence, the furthest *leftward* point of each plot represents the response threshold for the enantiomer. The lowest concentration tested was 0.06 ng/l

significantly higher voltages to *endo*-brevicomin than any other olfactory stimulant (Fig. 3). We found no olfactory stimulants in volatiles sampled from feeding, paired males that were not also produced by newly emerged individuals. When 0.1 insect equivalents of pooled volatiles from paired, mining males were analyzed by GC-EAD, only three compounds produced consistent responses from the antennae: *endo*-brevicomin, verbenone, and myrtenol (Fig. 4). *endo*-Brevicomin elicited significantly greater voltages from the antennae than either of the other two olfactory stimulants from paired males.

Exposure of *D. frontalis* antennae by chiral GC-EAD to a logarithmic progression of doses of the enantiomers of frontalin and *endo*-brevicomin revealed that, for both sexes, the threshold of detection for (+)-*endo*-brevicomin was four orders of magnitude lower than for either (−)-*endo*-brevicomin or (+)-frontalin and one order of magnitude lower than for (−)-frontalin (Fig. 5). The threshold of detection for (−)-frontalin was three orders of magnitude lower than for its antipode. Through the entire range of concentrations tested, the mean response voltage elicited in the antennae was apparently higher for (+)-*endo*-brevicomin than for either enantiomer of frontalin or for (−)-*endo*-brevicomin.

Pheromone Isolation and Analysis Significant quantities of frontalin were detected from females and *endo*-brevicomin from males, whether newly emerged, mining singly, or mining in pairs (Fig. 6a). With a threshold of detection of approximately 1 ng per beetle, frontalin was detected in only six of 110 male beetles sampled. These six came from all

three treatment categories, and with one exception (9.5 ng from a male mining singly), the quantity detected was <3 ng. Similarly, traces of *endo*-brevicomin (1–3 ng) were detected in only seven of 96 females sampled. In contrast, *endo*-brevicomin was detected in 90% of emergent males, 81% of solitary mining males, and 100% of paired males; frontalin was detected in 100% of sampled females.

The quantity of frontalin detected from females excised while mining in a pine bolt was significantly (ninefold) higher than from newly emerged females (Fig. 6a). Less frontalin was detected from paired, mining females than females mining singly; however, these paired females had been in the bolt 1 day longer than the solitary ones, hence the relative effects of pairing vs time spent mining could not be distinguished. Males that had paired with a female in a gallery produced higher quantities of *endo*-brevicomin than males that were either newly emerged (15-fold) or mining singly (fivefold), whereas males mining singly did not differ significantly from newly emerged beetles (Fig. 6a). Peak recorded production of frontalin by females (i.e., females mining solitary, 547±63 ng per beetle) was nearly twice the peak production of *endo*-brevicomin by males (i.e., males mining paired, 291±55 ng per beetle). In contrast to *endo*-brevicomin, production of both verbenone and myrtenol were higher in newly emerged males than in those that were mining in a bolt either alone or paired, and the presence of a female did not significantly alter the production of these monoterpenes by mining males (Fig. 6b).

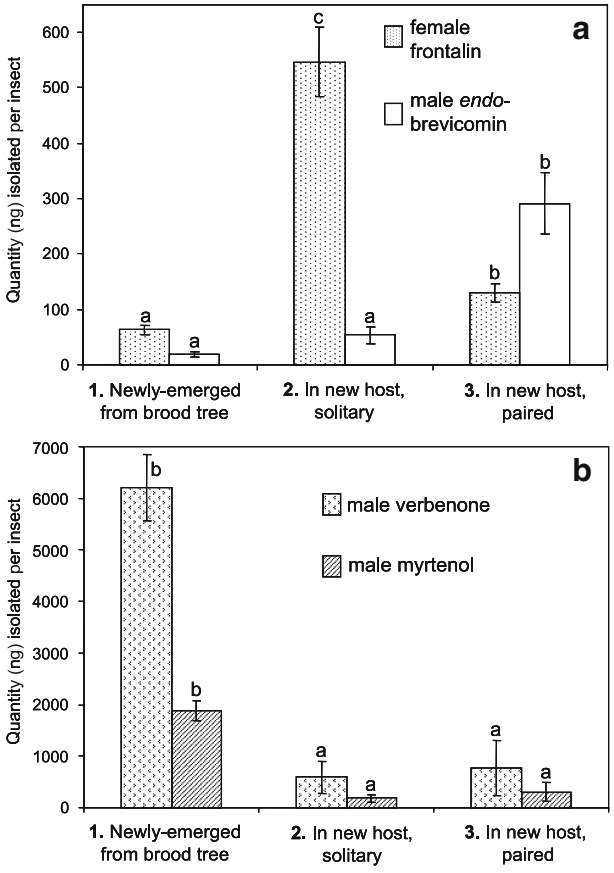

Fig. 6 Mean quantities (±SE) of volatiles isolated from individual *D. frontalis*: the bicyclic ketals frontalin and *endo*-brevicomin from females and males, respectively (**a**) and the monoterpenes verbenone and myrtenol from males (**b**). Beetles (N=31–34) either (*1*) had emerged within the previous 24 h from portions of a naturally infested pine, (*2*) had been infested onto a fresh pine bolt 1 day earlier, or (*3*) had been paired with a mate in a pine bolt for 1 day. In treatment 3, females had been allowed to initiate a nuptial chamber for 1 day before introduction of male beetles and thus had been in the bolt 2 days when sampled. Within sex/compound, *bars* associated with the same *letter* were not significantly different (Dunn's test, α=0.05)

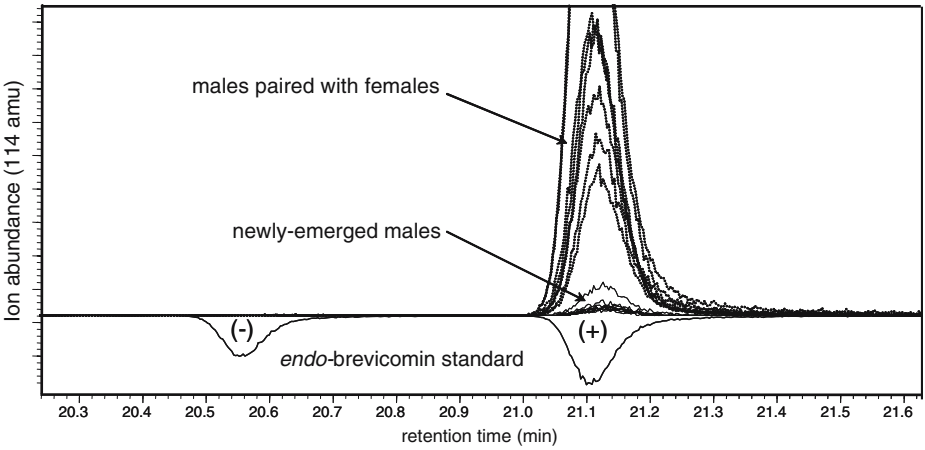

Fig. 7 Superimposed GC-MS single-ion chromatograms of volatiles from male *D. frontalis* resolved on an enantioselective GC column. Shown are eight traces each of aerations/extracts of either newly emerged males (positive traces, *solid lines*) or males paired with a female in a pine bolt <1 day (*dotted lines*), as well as a retention time standard containing a 1:2 ratio of (−):(+) *endo*-brevicomin (*inverted trace*)

Only the (+)-enantiomer of *endo*-brevicomin was isolated from male beetles, irrespective of beetle treatment category or source population (Fig. 7). Because the amount of (−)-*endo*-brevicomin never exceeded the MSD's threshold of detection in any sample, the mean enantiomeric ratio was not less than 86.5% (+):13.5% (−)±2.2% [i.e., the mean ratio of the quantity of (+)-*endo*-brevicomin to the threshold of detection observed in newly emerged males] for any treatment group or sampled population (Table 1). This lower limit of confidence is probably conservative given the fact that the ratio of (+)-*endo*-brevicomin to the threshold of detection exceeded 99:1 [i.e., >99% (+)-*endo*-brevicomin] in 18 samples. For female samples where both enantiomers of frontalin exceeded the threshold of detection (88 of 96), the mean enantiomeric ratio was 95.4% (−): 4.6% (+)±0.7% SD. Feeding and/or pairing had no significant effect on the enantiomeric ratio of female frontalin (Kruskal–Wallis ANOVA, H=0.4843, df=2, P=0.79).

Attraction of D. frontalis to Synthetic Baits In bait bioassay 1 (Fig. 8), traps baited with turpentine, (+)-*endo*-brevicomin, and frontalin caught significantly more *D. frontalis* of either sex than turpentine either alone or paired with either frontalin or *endo*-brevicomin. Neither turpentine alone nor the combination of turpentine and (+)-*endo*-brevicomin attracted any *D. frontalis*, whereas turpentine combined with frontalin attracted greater numbers of males (and total beetles; P=0.014) than these treatments. Addition of (+)-*endo*-brevicomin to frontalin/turpentine-baited traps resulted in a drop in the sex ratio of the responding beetles (M/F) from 3.4:1 to 1.3:1 (P=0.032). In bait bioassay 2 (Fig. 9), traps baited with the combination of turpentine, (+)-*endo*-brevicomin, and frontalin caught significantly more *D. frontalis* of either sex than traps either lacking baits or baited with frontalin and/or (+)-*endo*-brevicomin in the absence of turpentine. Traps baited with (+)-*endo*-brevicomin alone failed to attract more beetles than nonbaited traps, whereas traps baited with frontalin alone attracted more females (and total beetles; P=0.024) than nonbaited traps. Traps baited with frontalin and (+)-*endo*-brevicomin did not differ significantly in catches from either nonbaited traps or traps baited with frontalin alone. The sex ratios (M/F) trapped by frontalin alone (1.6:1), frontalin/(+)-*endo*-brevicomin (1.1:1),

Table 1 Enantiomeric ratio of *endo*-brevicomin in volatiles collected from male *D. frontalis* as the minimum possible percentage of the (+)−enantiomer

Beetle Origin	Beetle Condition		
	Newly Emerged	Mining Singly	Mining Paired
31.5° N, 89.0° W	>86.5[a]±2.2%[b] (27)[c]	>92.3±1.9% (22)	>98.6±0.4% (31)
32.9° N, 87.1° W	n/a	n/a	>98.7±0.2% (11)
31.4° N, 91.1° W	n/a	n/a	>98.6±0.2% (4)

[a] Mean ratio (as a percentage) of the abundance of the (+)-enantiomer to the threshold of detection of the MSD. Since (−)-*endo*-brevicomin was not detected, its greatest possible quantity in any sample was less than the threshold of detection.

[b] Standard error of the mean

[c] Sample size (*N*)

and frontalin/(+)-*endo*-brevicomin/turpentine (1.8:1) did not significantly differ ($P>0.18$); however, low numbers trapped by the turpentine-lacking treatments gave insufficient power to these comparisons.

Discussion

Our data provide the first direct evidence that *D. frontalis* males can enhance the aggregation of conspecifics to pines undergoing colonization (Fig. 2), implying that mass attack is mediated by pheromone components from both sexes. Thus *D. frontalis* resembles congeners *D. adjunctus* Blandford (Hughes et al. 1976), *D. brevicomis* LeConte (Wood and Bedard 1977), and *D. ponderosae* Hopkins (Borden et al. 1987) that have been shown to aggregate on pines in response to pheromone components from both sexes. However, two previous studies showed that pine bolts artificially infested with *D. frontalis* pairs were no more attractive to conspecifics than those infested solely with females (Coster et al. 1977; Svihra 1982). Whereas our girdling of experimental trees likely improved the chances of successful beetle attack and establishment (Tisdale et al. 2003), the defensive responses of these trees remained strong, as evidenced by pitch tubes at most beetle entrance holes and

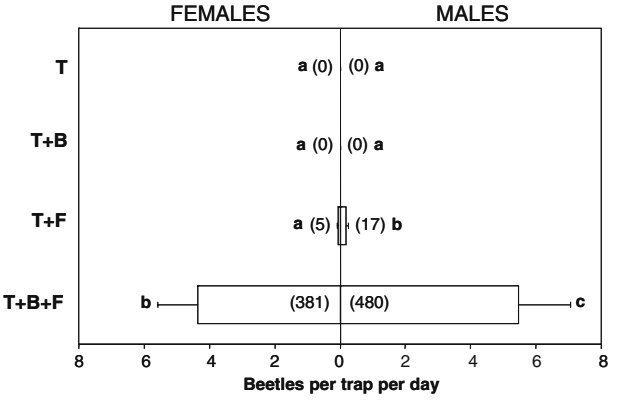

Fig. 8 Bait bioassay 1: Mean (+SE) catch of *D. frontalis* in multiple-funnel traps baited with loblolly pine turpentine (*T*), (+)-*endo*-brevicomin (*B*), and/or racemic frontalin (*F*). Within sex, *bars* associated with the same *letter* were not significantly different (Tukey test, $\alpha=0.05$). Total catch for each treatment/sex is given in *parentheses*

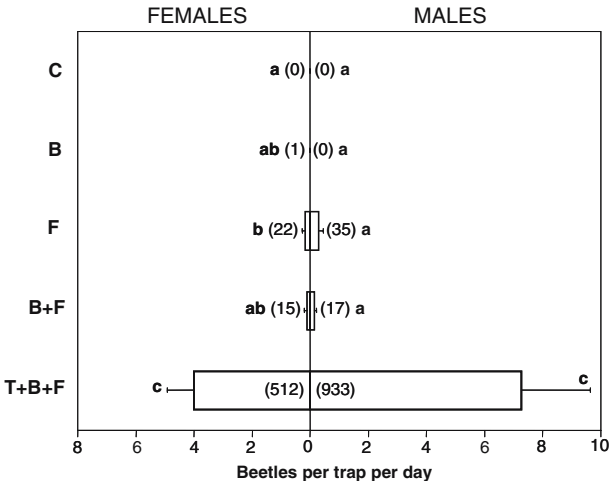

Fig. 9 Bait bioassay 2: Mean (+SE) catch of *D. frontalis* in multiple-funnel traps baited with loblolly pine turpentine (*T*), (+)-*endo*-brevicomin (*B*), and/or racemic frontalin (*F*) or nothing (*C*). Within sex, *bars* associated with the same *letter* were not significantly different (Tukey test, α=0.05). Total catch for each treatment/sex is given in *parentheses*

numerous beetles found "pitched" into their galleries. In contrast, pitch tubes rarely occur at entrances when beetles attack pine bolts (personal observation). Bolts cut from trees recently infested with *D. frontalis* rapidly lose attractiveness to conspecifics, and high host moisture content and resin exudation have been associated with enhanced aggregation by *D. frontalis* and other *Dendroctonus* spp. (Vité and Renwick 1968; Vité and Pitman, 1968). High resin production may delay beetle pairs from extending their galleries into the phloem and thus prolong pheromone release near the entrances. *D. frontalis* will sometimes attack and reproduce in dead or dying hosts, such as felled trees, that are presumably similar in quality to bolts (Moser et al. 1987); however, during outbreaks, they predominantly attack healthy trees. Hence, our infested-tree study may provide a more accurate picture of pheromone dynamics for outbreak-phase *D. frontalis*.

Bark beetles typically possess disproportionate olfactory sensitivity to components of their aggregation pheromones, which function over large distances and at low concentrations (Dickens 1979; Whitehead 1986; Smith et al. 1988). The exceptionally strong electrophysiological responses that (+)-*endo*-brevicomin elicited in the antennae of both sexes of *D. frontalis* singled-out this compound as a likely aggregation pheromone component (Figs. 3, 4, and 5). This result was also consistent with evidence that only the (+)-enantiomer of *endo*-brevicomin is attractive to *D. frontalis* (Vité et al. 1985). Dickens and Payne (1977) reported that among seven known semiochemicals for *D. frontalis*, *endo*-brevicomin ranked second only to frontalin in the percentage of olfactory acceptor sites occupied during odorant saturation.

Vité and Renwick (1971) reported that *endo*-brevicomin was produced merely in "subnanogram quantities by certain males" and therefore questioned whether this compound was a true pheromone for *D. frontalis*. Grosman et al. (1997) isolated an average of 17 ng *endo*-brevicomin per male beetle from three geographically isolated *D. frontalis* populations. These earlier studies examined only newly emerged beetles (Pitman et al. 1969; Grosman et al. 1997), which according to our data, produce relatively small amounts of *endo*-brevicomin (Fig. 6a). In contrast, we isolated nearly 300 ng *endo*-brevicomin on average from paired males, an amount roughly comparable to the frontalin isolated from mining females.

Production of frontalin in females was stimulated by mining in the host, whereas *endo*-brevicomin production in males was stimulated by pairing (Fig. 6a). In contrast, other male-produced compounds such as verbenone and myrtenol declined in concentration once males

entered the bark (Fig. 6b; Sullivan 2005). The majority of such compounds (including verbenone, myrtenol, fenchol, myrtenal, acetophenone, *trans*-myrtanol, and 2-phenylethanol) are attractant antagonists (Payne et al. 1978; Sullivan 2005; Sullivan et al. 2007), and the separation in the timing of their production relative to *endo*-brevicomin is consistent with differing behavioral functions. This finding also suggests that synthesis and/or accumulation of *endo*-brevicomin is regulated by physiological mechanisms different from other male-produced compounds. In support of this inference, treatment of 5-day-old, callow adult male *D. frontalis* with either juvenile hormone II or the juvenile hormone analog methoprene stimulated an increase in hindgut concentrations of *endo*-brevicomin but not verbenone or myrtenol (Bridges 1982). Independent regulation of *endo*-brevicomin is also implied by evidence that bark beetle-produced bicyclic ketals like brevicomin and frontalin are synthesized de novo, whereas oxygenated monoterpenes such as verbenone and myrtenol may be derived from ingested or inhaled host monoterpenes (Hughes 1973; Seybold and Tittiger 2003).

Vité et al. (1985) first hypothesized that the complete aggregation pheromone of *D. frontalis* included male-produced (+)-*endo*-brevicomin, which they found to cause a fivefold increase in attraction to female-produced frontalin and host terpenes. Our data confirm their results (Fig. 8) while documenting a remarkable 40-fold enhancement effect from the addition of (+)-*endo*-brevicomin to a frontalin/host terpene bait. However, Vité et al. (1985) also showed that (−)-*endo*-brevicomin is an attractant antagonist, and there are conflicting data on the enantiomeric ratios of *endo*-brevicomin produced by *D. frontalis* males. Redlich et al. (1987) found approximately 97% of the (+)-enantiomer when they used enantioselective capillary GC-MS to analyze aerations and hindgut extracts of emergent male *D. frontalis*. Grosman et al. (1997) used enantioselective GC-FID to analyze gut extracts from emergent males from three different populations and reported a range of 9–21% (+) with no significant variation among regions. In contrast, our examination of aerations/extracts of male *D. frontalis* using enantioselective GC-MS failed to detect even trace quantities of (−)-*endo*-brevicomin, despite detecting the (+)-enantiomer at hundreds of times the detection threshold of the MSD (Fig. 7).

The disparity among these three data sets was most likely caused by differences in the reliability of the analytical techniques, because no significant geographic variation in the enantiomeric ratio of *endo*-brevicomin was identified in our data or those of Grosman et al. (1997). Our findings and those of Redlich et al. (1987) both indicated that the (+)-enantiomer was predominant, and both studies were performed by using MSD chromatograms of single, diagnostic ions for *endo*-brevicomin. This procedure would have largely ensured that only the target molecule was quantified and would have prevented overestimation of the abundance of (−)-*endo*-brevicomin because of coelution of compounds indistinguishable by FID alone, as could have occurred in the study of Grosman et al. (1997). Additionally, our study provided a more meaningful picture of *endo*-brevicomin chirality than previous ones, because it examined paired males, apparently the only life stage that produces this compound in large quantities. The greater olfactory sensitivity of both sexes for (+)-*endo*-brevicomin and (−)-frontalin than for the respective antipodes (Fig. 5; Payne et al. 1982) mirrors the greater production of these enantiomers by the insects. Thus, the totality of evidence indicates that *D. frontalis* is utilizing only (+)-*endo*-brevicomin, the attractive enantiomer as shown by Vité et al. (1985).

Among *Dendroctonus* spp., a pheromone component produced predominantly by one sex typically elicits the strongest attractive response from the opposite sex (Vité and Pitman 1969; Hughes et al. 1976; Borden et al. 1987; Payne et al. 1987). In concurrence, Vité et al.

(1985) observed that addition of male-produced (+)-*endo*-brevicomin to attractant-baited traps shifted the sex ratio (M/F) from 4.6:1 to 2.0:1. In our study, both the introduction of males to female-infested trees and the addition of (+)-*endo*-brevicomin to traps baited with frontalin either alone or with turpentine caused the male-biased sex ratio of attracted beetles to shift closer to a balance between the sexes. However, these sex ratio differences were statistically significant only in bait bioassay 1, possibly because of the low catch of beetles by at least one of the treatments in these various pairwise comparisons. Our GC-EAD studies showed that the sexes differed little in their olfactory sensitivity for (+)-*endo*-brevicomin (Fig. 5), indicating that any sexually dimorphic behavioral responses to (+)-*endo*-brevicomin are not reflected in sex-specific abundance of olfactory receptors.

The dramatic increase in beetle attraction observed when (+)-*endo*-brevicomin was added to frontalin/turpentine suggests that this compound is an important component of the *D. frontalis* aggregation pheromone and that it is critical in mediating successful mass attacks on host trees. However, in contrast to frontalin, (+)-*endo*-brevicomin appeared to be entirely unattractive to *D. frontalis* in the absence of other compounds (Fig. 9) and showed no ability to act synergistically with turpentine (Fig. 8; Billings 1985). Hence, the male and female aggregation pheromone components do not play equivalent or reciprocal roles. Curiously, (+)-*endo*-brevicomin exhibited no synergistic activity with frontalin alone (Fig. 9), but the low catch by these treatments gave inadequate statistical power to their comparison. *Dendroctonus* males are not known to initiate attacks; hence, the failure of *D. frontalis* to respond to male pheromone components alone or with host odors seems consistent with females' exclusive role as pioneers. Nonetheless, attraction to male-produced compounds in the absence of those from females has been documented in *D. adjunctus* (Hughes et al. 1976) and *D. terebrans* (Olivier; Payne et al. 1987; Phillips et al. 1990), and the male-produced compound frontalin can induce *D. ponderosae* to colonize baited pines (Borden et al. 1990).

Several earlier studies showed that (±)-*endo*-brevicomin can inhibit *D. frontalis* from responding to attractant-baited traps or landing on host trees (Vité and Renwick 1971; Payne et al. 1978; Richerson and Payne 1979; Salom et al. 1992). These findings prompted the conclusion that *endo*-brevicomin functioned as an antiaggregation pheromone for this species (Payne 1980; Skillen et al. 1997). However, after their discovery of the opposing activities of the enantiomers of *endo*-brevicomin, Vité et al. (1985) theorized that the inhibitory activity of the racemate was because of the antagonistic activity of the (−)-enantiomer overriding the attractive activity of the (+)-enantiomer.

We propose that male *D. frontalis* accelerate the aggregation of conspecifics to trees undergoing attack by releasing (+)-*endo*-brevicomin that acts synergistically with frontalin from females and host resin terpenes. The potential fitness benefits to pheromone-producing males are enhanced survival for both themselves and their offspring, as attracting greater numbers of attacking conspecifics should help assure rapid and complete disruption of host defenses. Alternately, males and females responding to hosts releasing (+)-*endo*-brevicomin, frontalin, and host terpenes (hosts infested with at least some beetle pairs) may avoid the high risks of mortality encountered by pioneer beetles that are first to initiate attacks on a particular tree (Pureswaran et al. 2006). Our data also indicate that the attractant currently used for monitoring populations of *D. frontalis* with traps (frontalin and turpentine; Skillen et al. 1997) is incomplete and that the addition of (+)-*endo*-brevicomin may enhance detection of low-density beetle populations. Additionally, this novel, enhanced-potency bait may prove efficacious in trap-out and other attractant-based management strategies for *D. frontalis.*

Acknowledgments We thank Brad Hoosier, Erich Vallery, Tessa Bauman, Chris Young, Jolie Mahfouz, James McDonald, and Alicia Niño for technical assistance; Drs. K. Fuhshuku and Y. Masuda of RIKEN, Japan, for help with the synthesis of (+)-*endo*-brevicomin; Mark Dalusky for providing us with *D. frontalis* from Alabama; Lee Dunnam, Homochitto National Forest, Mississippi, for assistance and cooperation in field studies; Larry Roton for useful insights that greatly influenced our thinking on this topic; Rhonda Tam and Jessica Norris for administrative assistance; Steve Clarke, Jim Meeker, and John Reeve for critical readings of earlier versions of this manuscript; and John Borden for extensive editing of the final text.

behavior associated with feeding by larvae, much less is known about the mechanisms and ecological significance of experience-induced changes in host selection and oviposition behavior in adults (Papaj and Prokopy 1989; Schoonhoven et al. 2005). For example, oviposition on nonhost plants by various insects has been reported in both laboratory (Firempong and Zalucki 1990; Nylin et al. 2000; Solarz and Newman 2001) and field trials (Ampong-Nyarko et al. 1994; Prokopy et al. 1996), but little is known about the proximate mechanisms of this phenomenon and, consequently, sensory confusion or oviposition "mistakes" are often assumed (Larsson and Ekbom 1995). More recently, prior experience of nonhost plants by females has been found to induce oviposition on nonhost plants (Zhang and Liu 2006).

Olfactory cues are known to be central to host selection behavior in phytophagous insects (De Moreas et al. 2001; Schoonhoven et al. 2005). Here, we use laboratory experiments to examine whether early adult experience with nonhost plant odors can alter host selection behavior of the diamondback moth, *Plutella xylostella*, a specialist herbivore of cruciferous plants, so as to accept a nonhost plant for oviposition. In previous experiments with this insect, we moved mature larvae from host plants to pupate and emerge on nonhost plants. Thus, females with experience on nonhost plants were unavoidably associated with partial food restriction at the mature larval stage (Zhang and Liu 2006). Such food restriction may occur in nature when mature larvae facing food shortage are driven to move around and pupate on nonhost plants. Therefore, we examined the effect of larval food restriction on adult olfactory responses and oviposition preference. Our study demonstrates, for the first time, that olfactory experience during early adulthood alone plays a major role in the experience-induced changes of oviposition responses to nonhost plants. Insects that had experienced volatiles of a nonhost plant were attracted by its volatiles and were more likely to accept it for oviposition. Also, we show for the first time that larval starvation does not affect oviposition preference toward host and nonhost plants.

Methods and Materials

Insects and Plants *P. xylostella* was originally collected from a cabbage farm in a suburb of Hangzhou, China in October 2004 and maintained on common cabbage, *Brassica oleracea* L. var. *capitata*, cultivar Jing-feng No. 1, in a temperature-controlled room at 26±1°C, 60–70% RH with a 14L:10D photoperiod. The culture was replenished once a year with field-collected material and maintained for 10–15 generations when used in the experiments. The host plant Chinese cabbage, *Brassica campestris* L. ssp. *pekinensis*, cultivar Zao-shu No. 5, and a nonhost plant pea, *Pisum sativum* L. var. *arvense*, cultivar Zhongwan No. 2, were used in the olfactory and oviposition tests. All experiments utilized potted Chinese cabbage at the 5–6 fully expanded true leaf stage and potted pea with 20–25 fully expanded leaves grown in greenhouses under ambient temperature, humidity, and natural lighting. In olfactometer and oviposition choice tests, care was taken to use host plants and nonhost plants that had similar leaf areas.

Performance on Chinese Cabbage and Pea Plants: Survival, Development, and Body Size Four hundred *P. xylostella* eggs, deposited on plastic sheets, were taken from the *P. xylostella* culture. The eggs were randomly divided into two cohorts of 100 and 300, and the two cohorts of eggs were placed onto 10 plants of Chinese cabbage and 30 plants of pea (10 eggs on each plant), respectively. The two cohorts were reared at 26±1°C, 60–70% RH, and a 14L:10D photoperiod. Daily observations were made on survival, development, and

feeding until pupation. Pupae were collected within 24 hr of pupation and weighed individually to the nearest 0.1 mg (with a Mettler-Toledo AE200 electronic balance) as an index of body size. Pupae were placed individually in 2×8-cm glass tubes covered with a cotton plug until adult emergence. We recorded the following variables: (1) survival of eggs, larvae, and pupae, (2) development duration from egg to pupation, and (3) pupal weight.

Fecundity and Longevity Fecundity and longevity were observed by using detached leaves of Chinese cabbage as an oviposition substrate in a small rearing cage. The cage consisted of a clear, cylindrical, and ventilated plastic container (14.5-cm high, with a 9-cm-diameter top and 13-cm-diameter base). A cabbage leaf was fixed in the cage by inserting its petiole through a hole in the center of the base. The cage was placed onto a 500-ml glass bottle containing tap water, and the petiole of the cabbage leaf was inserted in the water to maintain freshness.

Twenty replicates were conducted for the cohort reared on Chinese cabbage. For the cohort reared on pea, no observation could be made on fecundity as only two male adults emerged. For each replicate, one female and one male (<24 hr postemergence) were placed into a rearing cage for mating and oviposition (15% honey–water solution provided as food). Eggs deposited on the leaf and cage walls were counted each morning, and adults were transferred to a new leaf in a clean cage until death. We assessed two variables: (1) total number of eggs laid and (2) longevity of adults.

Experience Treatments and Olfactory/Oviposition Preference: Experience Treatments To investigate the effects of early adult experience with pea volatiles or larval food restriction, or both, on the olfactory/oviposition preference of *P. xylostella* females, we used the following four treatments for the test insects.

(1) No experience and no food restriction. A batch of ~600 *P. xylostella* eggs were reared on four large plants of common cabbages at the precupping stage in a temperature-controlled room at 26±1°C, 60–70% RH, and a 14L:10D photoperiod. Each plant had 16–20 full-grown leaves, and the four plants provided more than enough food for development of the cohort from hatching to pupation. On the 13th day, approximately 500 pupae were obtained from the cohort. In an attempt to remove all external chemical cues from the larval environment, the pupae were taken out of their cocoons and thoroughly washed in demineralized water using the procedure described by Liu and Liu (2006b). After washing, pupae were placed into a sterilized cage (50×50×50 cm in size) for adults to emerge. Until used in olfactory/oviposition preference tests at 2–3 d postemergence, adults were not exposed to any plant odors.
(2) Larval food restriction. Insects were reared the same way as in (1), except that mature fourth instars were moved manually onto plastic sheets for them to pupate. Pupae were washed using the same procedure as above. After washing, pupae were placed into a sterilized cage (50×50×50 cm in size) for adults to emerge. Adults were deprived of any plant odors as in (1) before being used in olfactory/oviposition preference tests at 2–3 d postemergence.
(3) Pea odor experience. Insects were reared, and pupae were washed the same way as in (1). After washing, pupae were placed into a sterilized cage (40×40×40 cm in size) for adults to emerge.

A wind tunnel (Fig. 1) was set up in a separate temperature-controlled room at 25±2°C. Five potted pea plants were placed into the chamber in front of the fan, and the *P. xylostella* pupae, from which adults were to emerge in a day, were placed into the next chamber

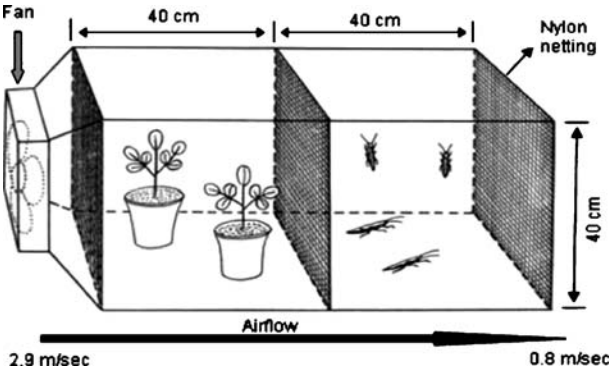

Fig. 1 Diagram showing how moths were exposed to odors of nonhost pea plants in a wind tunnel

(Fig. 1). The wind speed at the inlet of the tunnel was approximately 2.9 m/sec and 0.8 m/sec at the outlet. Consistent airflow was maintained after the placement of pupae into the tunnel. Adults were exposed to the pea volatiles during emergence and for 2–3 d after emergence, before they were used in olfactory/oviposition preference tests.

(4) Pea plant experience. Insects were reared on common cabbage from egg to late fourth instar as in (1) above, and then the mature larvae were moved manually onto pea plants to force them to pupate on the nonhost. Insects were left to emerge naturally on the pea plants. Adults were enclosed with the pea plants in a cage until used in olfactory/oviposition preference tests at 2–3 d postemergence.

Thirty pupae were randomly taken from each of four treatments and weighed individually as an index of body size. Adults were always provided with 15% honey–water as food upon emergence.

Olfactory Responses The responses of *P. xylostella* females to volatiles of Chinese cabbage and/or pea plants were assessed with a Y-tube olfactometer. The transparent glass Y-tube olfactometer had a 20-cm stem and two 20-cm arms at a 75° angle, and its internal diameter measured 4 cm (Fig. 2). At the middle of each arm, there was a glass funnel (diameter of port = 8 mm) pasted on the inner wall. Just after this port, there was a 25-mm vertical male ground-glass connector for a 100-ml "moth-trapping" bulb. A stainless steel mesh screen was placed just after the connector and served to block the passage of the moths and force them to move upward into the moth-trapping bulb (Fig. 2). Each arm ended with a 25-mm female ground-glass connector, and was then connected to separate glass containers holding the odor sources. Air was filtered through activated charcoal, humidified, and split into two air streams that fed through the glass containers to the olfactometer at a rate of 200 ml/min in each arm. All bioassays were conducted in a temperature-controlled room at 25°C, illuminated only by a 15 W red light, between 19:00–23:00 h when the moths were expected to be most active.

For each replicate, a group of four female moths were released at the down-wind end of the Y-tube stem and left in the olfactometer to respond for 15 min. When a moth walked up to the upwind end of an olfactometer arm, either within 4 cm of the blocking screen or into the corresponding moth-trapping bulb at the end of 15 min, it was recorded as making a choice for the odor of that arm. When a moth did not reach the end of either arm within 15 min, it was recorded as "no response". Each moth was used only once. After testing five groups of moths, the connections of the odor sources to the olfactometer arms were

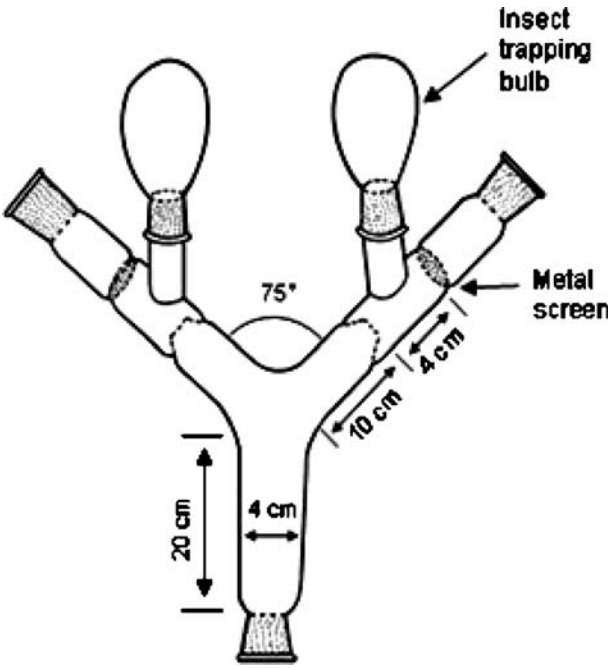

Fig. 2 An overview of the Y-tube olfactometer used in choice tests. The insect-trapping bulb enabled moths making a choice to be more easily identified when testing more than 1 moth in the olfactometer

exchanged to remove any asymmetrical bias in the set-up and the test plants were replaced by new ones of the corresponding categories. The olfactometer tube and glass container were thoroughly washed with alcohol at the end of the observations for a given treatment, and dried overnight in an oven at 200°C.

We first tested the responses of control moths from the culture to the apparatus with just clean air flowing down each arm. Mated females at 2–3 d postemergence were used, and 64 moths were tested to observe the background rate of "no response" as well as any potential bias in arms.

The responses of moths in the "no experience" and "pea plant experience" treatments were tested to odors of each of the following three choices: Chinese cabbage vs. air, pea vs. air, and Chinese cabbage vs. pea. Moths in both "larval food restriction" and "pea odor experience" treatments were tested only to odors of the dual-choice of Chinese cabbage vs. pea. Twenty groups of four female moths each (i.e., 80 moths in total) were assessed for each combination of experience treatment and volatile choice.

Oviposition Preference Oviposition by *P. xylostella* females from each of the four experience treatments was tested in two no-choice tests and/or one choice test:

(a) No-choice test with host plant. One Chinese cabbage plant was placed into the center of a ventilated cage constructed with a wire metal frame covered on all sides with black plastic sheets. The cage had an internal volume of 40×40×40 cm with two 15×15 cm screened windows on the front and backsides for ventilation. At 19:00, four females were released into each cage (no food was provided). After 12 hr in darkness at 26°C, moths were removed, and all eggs deposited on each plant, pot, and the inner surface of the cage, were counted.

(b) No-choice test with nonhost plant. The same procedure as in (a) was used, except that pea was used as the test plant.
(c) Choice test with host and nonhost plants. One Chinese cabbage and one pea were placed in diagonally opposite corners of the same cage, so that the foliage of the two plants was approximately 20 cm apart at the closest point. At 19:00, four females were released into the center of each cage. After 12 hr in darkness at 26°C, the moths were removed and the eggs deposited on each of the two plants, the pots, and inner surface of the cage, were counted.

Ten replicates (four moths per replicate) were conducted for each experience treatment.

Statistical Analysis All proportional data were transformed by arcsine square root for analysis and were backtransformed to percentages for presentation. For comparing performance of *P. xylostella* on cabbage and pea, percentages or mean values between the two plants were analyzed with Student *t* test. For the olfactometer bioassays, a replicated *G* test of goodness-of-fit was used to analyze the frequency distributions of the choices made by females in each treatment, with the null hypothesis of no preference, and a test of independence in two-way tables was used to compare frequency distributions between different treatments (Sokal and Rohlf 1995). The mean numbers of eggs laid by females among the eight plants × experience treatments were analyzed by one-way ANOVA, and means were compared pairwise by using the LSD procedure. The mean proportions of eggs deposited on cabbage or pea plants in the no-choice tests between females from "no experience" and "pea plant experience" treatments were analyzed with Student *t* test. The mean proportions of eggs deposited on pea plants in the dual-choice tests among females from the four experience treatments were analyzed with one-way ANOVA, and means were compared pairwise by using the LSD procedure. The statistical software, BIOMstat (version 3.30 q, Applied Biostatistics, Inc., NY, USA) was used for the statistical analysis.

Results

Performance on Chinese Cabbage and Pea Plants The two cohorts of eggs for tests on Chinese cabbage and pea had similar and high percentages of hatching (Table 1). Little feeding by larvae occurred on pea compared to that on Chinese cabbage. By the 12th day after hatching, most larvae on Chinese cabbage developed normally to pupation, whereas 266 of the 280 larvae on pea died in the first or second instar, and the remaining 14 were still small. Successful survival from hatching to pupation was low on pea compared to that on Chinese cabbage (Table 1). The development time from egg hatch to pupation on pea was twice as long as that on Chinese cabbage, whereas the weight of pupae from pea was only half of that from Chinese cabbage (Table 1). Females reared from Chinese cabbage laid on average 345 eggs, whereas no females were obtained from pea. For this reason, fecundity could not be assessed on this plant (Table 1).

Olfactory and Oviposition Preference The average weights of pupae differed among the four experience treatments ($F=12.96$, $df=3$, $P<0.001$). Compared to the pupal weight in the "no experience" treatment (6.8 mg), the pupal weights in both "larval food restriction" (5.4 mg) and "pea plant experience" (5.7 mg) treatments were significantly lower (larval food restriction: $P<0.001$; pea plant experience: $P<0.001$), but that in the "pea odor experience" treatment (6.4 mg) was not ($P=0.09$).

Table 1 Performance of *Plutella xylostella* reared on Chinese cabbage and pea plants

Parameters	Plants	
	Chinese Cabbage	Pea
Total number of eggs at start of test	100	300
% Survival of eggs	95.0 a	93.3 a[a]
% Survival from hatching to pupation	81.0 a	1.1 b
Development time (days) from hatching to pupation	10.2±0.1 b	21.0±0.1 a
Pupal weight (mg)	5.9±0.1 a	2.8±0.1 b
% survival of pupae	97.4 a	66.7 b
Number of eggs laid per female	345.3±13.3	–[b]
Adult longevity (days)	9.7±0.3 a	7.3±0.5 b

[a] Percentages or means ± SE on the same row followed by the same letter do not differ significantly ($P<0.05$).

[b] As only two male adults emerged on pea, no observation on fecundity could be conducted.

Olfactory Responses In the tests with 64 control moths, 21 (32.8%) exhibited "no response," while 24 (37.5%) and 19 (29.7%) responded to the two arms, respectively. The results indicated no bias between the arms ($G=0.576$, $df=1$, $P=0.45$).

A higher proportion (70%) of moths in the "no experience" treatment made their choice toward Chinese cabbage, when provided with a choice between volatiles emanating from Chinese cabbage and air. In contrast, the proportion of moths in the "pea plant experience" treatment that chose Chinese cabbage decreased to 45%, resulting in similar responses to Chinese cabbage and air. The relative proportions of moths making their choice between Chinese cabbage and air differed significantly between the two treatments (Fig. 3a).

A lower proportion (31%) of moths in the "no experience" treatment made their choice toward pea rather than air, when provided with a choice between volatiles emanating from pea and air. Remarkably, the proportion of moths choosing pea increased to 62% in the "pea plant experience" treatment, resulting in a significant preference for pea. The relative proportions of moths making their choice between pea and air differed significantly between the two treatments (Fig. 3b).

When provided with a choice between volatiles of Chinese cabbage and those of pea, a higher proportion (64%) of moths made their choice toward Chinese cabbage in the "no experience" treatment. The proportion of moths choosing Chinese cabbage decreased to 55% in the "larval food restriction" treatment, but the relative proportions of moths making their choice toward the two plants did not differ between the two treatments (Fig. 3c). In contrast, the proportion of moths choosing Chinese cabbage decreased to 32 and 40% in the "pea odor experience" and "pea plant experience" treatments, whereas the proportion of moths choosing pea correspondingly increased in the two treatments (Fig. 3c). The relative proportions of moths making their choice toward the two plants did not differ between the "pea odor experience" and "pea plant experience" treatments, but the relative proportions of these two treatments differed from that of the "no experience" treatment (Fig. 3c).

Number of Eggs Laid The number of eggs laid on Chinese cabbage by females in "no experience" treatment can be regarded as the normal level of oviposition by the test insects. When provided with Chinese cabbage, the females in the "pea plant experience" treatment laid significantly fewer eggs compared to the normal level. When provided with pea, females in the "no experience" treatment laid only one third of the eggs of the normal level,

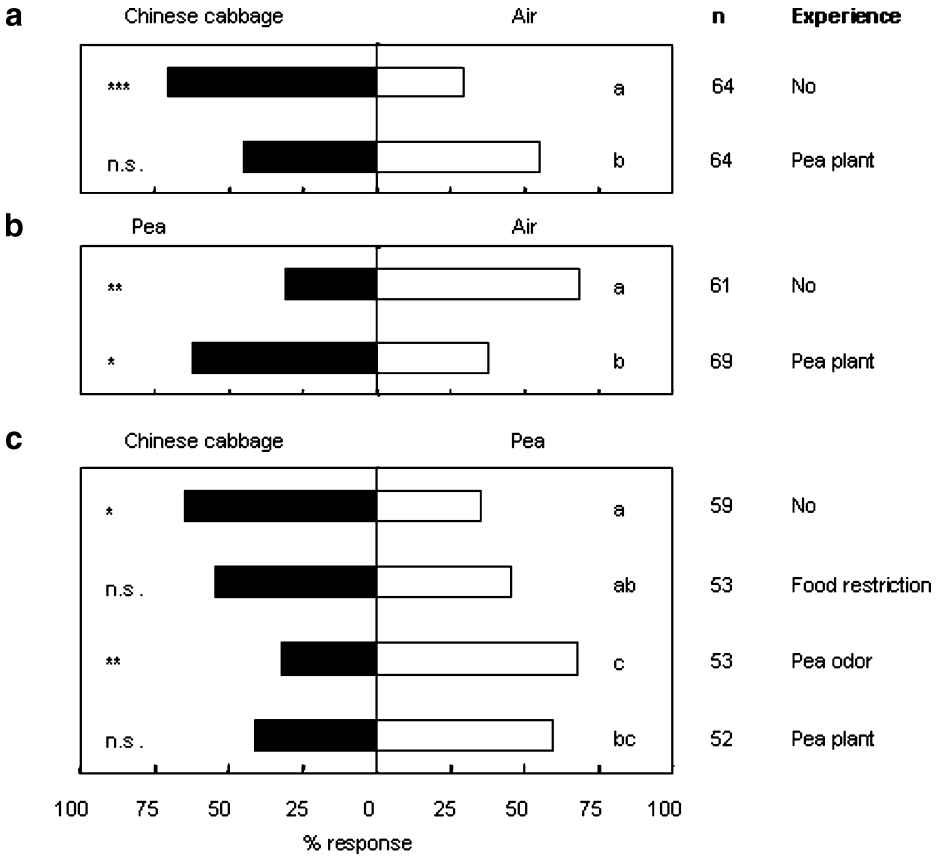

Fig. 3 Effect of early adult experience of pea in the form of odor or whole plant as well as effect of larval food restriction on responses of *Plutella xylostella* females to volatiles of "Chinese cabbage vs. air" (**a**), "pea vs. air" (**b**), and "Chinese cabbage vs. pea" (**c**) in a Y-tube olfactometer. The number of females (*N*) that made a choice in a treatment is given on the right side of the bars; asterisks on the left indicate significant differences within a choice test (**P*<0.05, ***P*<0.01, ****P*<0.001, n.s. = not significant). Within figures **a**, **b**, or **c**, the bars of different experience treatments followed by the same letter on the right indicate no significant difference (*P*<0.05) between them

and those in the "pea plant experience" treatment also laid fewer eggs than the normal level (Table 2). When provided with Chinese cabbage and pea, females in the "no experience" and "pea odor experience" treatments laid similar numbers of eggs compared to the normal level; females in the "larval food restriction" and the "pea plant experience" treatment appeared to lay fewer eggs than the normal level. However, the difference between either of the two treatments and the normal level was not significant due to the large variation among replicates (Table 2).

Oviposition Preference In no-choice tests that used Chinese cabbage, females of the "no experience" and "pea plant experience" treatments laid on average 96 and 99% of their eggs on the host plants, with the remainder on pots and cage surface. The proportions of eggs laid on cabbage did not differ between the two treatments (Table 3).

In no-choice tests with pea, the proportion of eggs laid on pea by females of the "pea plant experience" treatment was significantly higher than that of the "no experience"

Table 2 Mean number of eggs laid on Chinese cabbage and/or pea by *Plutella xylostella* females that experienced larval food restriction, pea odor, or pea plants

Plant	Experience Treatments			
	No Experience	Larval Food Restriction	Pea Odor	Pea Plant
Cabbage only	102.4±14.4 ab[a]	–	–	67.3±6.0 cd
Pea only	28.3±4.2 e	–	–	53.7±4.6 d
Cabbage and pea	98.8±13.0 ab	86.0±11.0 abc	111.4±14.0 a	78.2±10.3 bcd

[a] Ten replicates were conducted for each of the eight plant×experience treatments, means ± SE in the table followed by the same letter do not differ significantly ($P<0.05$).

treatment, although females in both treatments laid the majority of their eggs on pots and cage surface (Table 3).

In choice tests with Chinese cabbage and pea, females in each of the four treatments laid >90% of their eggs on the two plants, with the remainder on pots and cage surface (not considered in the data analysis). Although females in each of the four experience treatments laid nearly all, or the majority, of their eggs on Chinese cabbage, the proportions of eggs laid on pea differed among the four treatments ($F=15.7$, $df=3$, $P<0.001$). Compared to the proportion of eggs laid on pea by females of the "no experience" treatment, the proportion was higher in the "pea odor experience" ($P<0.001$) and "pea plant experience" treatment ($P<0.001$), but that of the "larval food restriction" treatment was not (Fig. 4). Moreover, the proportions in the "pea odor experience" and "pea plant experience" treatments were similar ($P=0.88$; Fig. 4).

Discussion

Survival of *P. xylostella* from egg to adult on the pea cultivar tested was <1%, and the few resulting adults were much smaller, as indicated by their reduced pupal weight, than those that fed on Chinese cabbage (Table 1). Our cohort on pea only produced two adult males, so it is not clear if *P. xylostella* developing on this pea cultivar are capable of producing eggs, a requirement for a plant to be considered a host (Ward 1988). In view of the very low survival of the test cohort on pea and the lack of records of *P. xylostella* larval populations on any pea plants in the field from China, we regard the pea cultivar used in this study as a nonhost plant of the local *P. xylostella* population.

Naïve *P. xylostella* females showed an aversion to volatiles emanating from pea (Fig. 3b), and rarely accepted pea for oviposition (Table 3 and Fig. 4). However, when newly emerged females were given prior experience with pea plants, they showed a

Table 3 Percentages of eggs laid on chinese cabbage or pea plants in no-choice tests by *Plutella xylostella* females with or without prior experience of pea plants

Experience Treatment	Plants in No-Choice Tests[a]	
	Cabbage	Pea
No experience	96.2±1.3 a	3.3 ± 1.5 a
Pea plant experience	98.9±0.6 a	20.3 ± 8.3 b

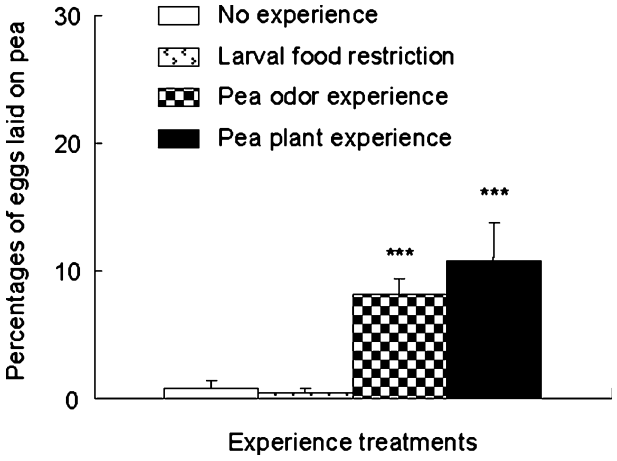

Fig. 4 Percentages of eggs laid on pea plants by *Plutella xylostella* females with various prior experiences in dual-choice tests with Chinese cabbage and pea. Ten replicates were conducted for each of the four experience treatments. Error bars indicate standard error of means, and an asterisk above a column indicates significant difference between that treatment and the "no experience" treatment (***$P<0.001$)

preference for volatiles of pea (Fig. 3b), and increased their acceptance of pea for oviposition in both no-choice and choice conditions (Table 3 and Fig. 4). More remarkably, females that were given an experience of pea volatiles alone, without physical contact of the plants, similarly increased their preference for volatiles of pea and their acceptance of pea plants for oviposition (Figs. 3c and 4). Females in the "larval food restriction" treatment experienced a level of food shortage during the mature larval stage similar to that of the females in the "pea plant experience" treatment, and their olfactory responses and oviposition preference were unaffected (Figs. 3c and 4). Thus, it seems likely that the oviposition behavior of females in the "pea plant experience" treatment was little affected by larval food restriction, and their altered oviposition preference (Fig. 4) was due mainly to olfactory experience. Previous studies have shown that experience of nonhost plants (Zhang and Liu 2006) or nonhost plant chemicals (Liu et al. 2005; Liu and Liu 2006a) by *P. xylostella* can change subsequent oviposition behavior, but these studies could not distinguish between contact experience of nonhost semiochemicals and olfactory experience of volatiles.

In our experiments, females in the "no experience" and "larval food restriction" treatments exhibited similar olfactory responses and nearly identical oviposition preference toward Chinese cabbage and pea plants (Figs. 3c and 4), although the females from "larval food restriction" had a lower pupal weight as well as a lower number of eggs laid on the first day when plants were offered (Table 2). Thus, partial food restriction at the mature larval stage reduced fitness, but did not alter oviposition behavior of the ensuing females. The unchanged oviposition behavior suggests that partial food restriction did not affect oviposition motivation of the ensuing adults, or that the treatment affected oviposition motivation, but oviposition motivation did not alter oviposition preference (Monks and Kelly 2003). To our knowledge, the effect of larval food restriction on oviposition preference among plants has not been examined for any other insects, although many studies have been conducted to investigate the effect of larval environment on oviposition behavior through retention of learning. These studies generally demonstrate that preimaginal conditioning does not affect oviposition preference in holemetabolous insects (Papaj and Prokopy 1989; Rojas and Wyatt 1999; Liu and Liu 2006b).

The modification of host selection behavior by experience is a widespread phenomenon in phytophagous insects (Papaj and Prokopy 1989; Schoonhoven et al. 2005). Although empirical evidence for such learning-associated behavior has been collected mostly from

larvae (Jermy 1987; Schoonhoven et al. 2005), documented cases for adults have been increasing (Cunningham et al. 1998a, b; Rojas and Wyatt 1999; Held et al. 2001; Cunningham et al. 2004; Liu et al. 2005). These case studies of changes in behavior due to olfactory experience, especially changes in oviposition preference, indicate that oviposition on nonhost plants due to olfactory learning, as exhibited by *P. xylostella*, may occur in many phytophagous insects, especially for night-flying insects that use mainly plant volatiles to locate host plants for oviposition, with visual cues playing a minor or negligible role in host plant finding (Schoonhoven et al. 2005; Couty et al. 2006).

Females in the "pea odor experience" and "pea plant experience" treatments were more attracted by pea volatiles than by volatiles of Chinese cabbage (Fig. 3c), yet they deposited only about 10% of their eggs on pea plants in the dual-choice oviposition preference tests with these two plants (Fig. 4). The contrary responses between olfaction and oviposition seemed to indicate that physical features and/or contact chemicals of pea deterred acceptance and oviposition by *P. xylostella*.

In nature, *P. xylostella* usually pupate on host plants, and females experience first the semiochemicals of the host plants on which they emerge. Females have a strong innate preference for volatiles of cruciferous plants (Fig. 3, Liu et al. 2005; Couty et al. 2006), and olfactory learning further increases their preference for the volatiles they first experience (Liu and Liu 2006a, b). Consequently, newly emerged females usually land and accept cruciferous host plants for oviposition, and the insect species runs little risk of laying eggs on nonhost plants.

A small proportion of naïve females oriented to pea odors (Fig. 3b), although this proportion could not be distinguished from females that may simply have been responding to air movement. Gupta and Thorsteinson (1960) found that a population of *P. xylostella* from Canada showed some olfactory response to pea plants. It is possible that there is a degree of preadaptation to this nonhost through shared common host signals, and that experience increases moth responsiveness to the nonhost plant, similar to the findings of Bengtsson et al. (2006). In our study, *P. xylostella* achieved very low survival on cultivar Zhongwan No. 2 of *Pisum sativum* L. var. *arvense*, and the same experimental population of this insect achieved virtually no survival on cultivar Qiwanyiji of the same variety of pea in a previous study (Zhang and Liu 2006). However, in a separate experiment, we found that this population of *P. xylostella* achieved 6% survival to adulthood on cultivar Zhongwan No. 5 of *Pisum sativum* L. var. *arvense*, and the ensuing females laid on average 107 eggs on Chinese cabbage (unpublished data). Gupta and Thorsteinson (1960) also demonstrated low levels of survival on pea for *P. xylostella*. It appears that different varieties and cultivars of pea vary in suitability to performance of *P. xylostella*, and it is possible that geographic populations of *P. xylostella* vary in their physiological adaptation to utilize pea plants. Larval performance on novel host plants may show a higher variability than on normal host plants, and the heritability for growth performance may also be higher on novel host plants (Ueno et al. 2001). Thus, if the behavioral barrier for adults is overcome and a large number of eggs are laid on novel plants, survival of the immature stages may be selected for (Löhr and Gathu 2002). Subsequently, if some offspring show an increased acceptance of novel host plants, as a result of either a conditioned or inherited behavior (Hora et al. 2005; Zhang and Liu 2006), further oviposition on novel plants could act to initiate a host range expansion.

Such experience induced oviposition activities on novel plants by phytophagous insects may be more likely to happen in crop ecosystems. For example, in many crop systems novel crop species are cultivated as monocultures over large areas, and, consequently, the ovipositing females repeatedly encounter the novel plants in host foraging. In more

diversified crop systems, plots of host crops are surrounded by plots of nonhost crops, and when host crops are suddenly harvested, individuals of the pest insects, including mature larvae and adults, left without food are forced to move onto the nearby nonhost crops. In Kenya, a field *P. xylostella* population on pea crops was first found when the population density on the usual host plants in the area was very high (Löhr and Gathu 2002).

Insect–plant associations show a general pattern of predominance of specialists over generalists and a strong taxonomic conservation in host plant use (Lopez-Vaamonde et al. 2003; Schoonhoven et al. 2005). However, recent studies on the directionality of host range evolution in phytophagous insects suggest that host range evolution is a highly dynamic process and seems characterized by repeated phases of contraction and expansion (Janz et al. 2001; Termonia et al. 2001; Nosil 2002; Lopez-Vaamonde et al. 2003; Janz et al. 2006). Many phytophagous insects are capable of including new plant species within their diets. Cases of host range expansion by phytophagous insects have been observed to include novel plant species from the same genus or family (Feder et al. 1990; Berenbaum and Zangerl 1991; Carroll and Boyd 1992; Fox et al. 1997; Louda et al. 1997; Solarz and Newman 2001) or from different families (Bowers et al. 1992; Singer et al. 1993; Camara 1997). For phytophagous insects with relatively immobile larvae, such as many Lepidoptera, colonization of a potential host plant may be precluded by the failure of females to recognize the potential host as a suitable oviposition site. Larvae can often feed and survive on plants that are not usually accepted as oviposition substrates by adult females (Thomas et al., 1987; Ueno et al. 2001; Schoonhoven et al. 2005). Thus, behavioral adaptations, such as changes of host selection behavior induced by olfactory experience, may be the primary mechanism driving novel host associations, with physiological adaptations a secondary result of behavioral changes (Wcislo 1989; Gassmann et al. 2006).

In many cases of host range expansion, native insects have incorporated exotic plants into their diet (Thomas et al. 1987; Feder et al. 1990; Carroll and Boyd 1992; Fox et al. 1997; Solarz and Newman 2001; Carroll et al. 2005), or exotic insects have incorporated native plants into their diet (Berenbaum and Zangerl 1991; Bowers et al. 1992; Louda et al. 1997). In fact, the majority of phytophagous insects accumulated by introduced plants, such as cacao and sugarcane, are recruited from the native, local faunas in the regions of introduction (Strong 1979). As biological invasions are occurring at a higher rate with each passing year, chances for new associations between insects and plants are increasing. New introductions of exotic insects, as well as the environmental changes of decreasing availability of ancestral hosts and increasing availability of exotic hosts, will present more opportunities for host range expansion to occur (Bowers et al. 1992; Singer et al. 1993). Consequently, exotic insects may feed on novel, native plants and so speed up the success of invasion, whereas native insects may feed on novel, exotic plants and thus contribute to the resistance of community to biological invasion.

Introduction

Although plants accumulate hundreds of different defensive compounds that prevent herbivore consumption, herbivores themselves have devised enzymatic means that detoxify plant defensive metabolites. Recently, two reports have demonstrated the detoxification of glucosinolates by insects (Ratzka et al. 2002; Wittstock et al. 2004). Glucosinolates are a group of *S*-β-glucosides found in members of the plant order Capparales (Halkier and Gershenzon 2006) that are present in crop plants such as broccoli, cabbage, and rocket salad, as well as in wild crucifers such as desert cabbage (*Schouwia purpurea*) and stinkweed (*Thlaspi arvense*). They are stored in the vacuole of the plant cell and are hydrolyzed by the enzyme myrosinase upon disruption of the cell by insect feeding or mechanical disturbance. Myrosinase, a thioglucosidase, cleaves glucose from the core glucosinolate structure, yielding an unstable amino acid-derived aglucone that rapidly rearranges to form a variety of products including isothiocyanates, thiocyanates, epithionitriles, and nitriles. This so-called "mustard oil bomb" (Matile 1980) releases volatile products of glucosinolate hydrolysis that are often toxic to insects (Wittstock et al. 2003). Some insects, however, have overcome the toxicity of glucosinolates and incorporate glucosinolate-containing plants into their diets. Specialist herbivores, such as larvae of the diamondback moth (*Plutella xylostella*), larvae of the cabbage white butterfly (*Pieris rapae*), the cabbage stem flea beetle (*Psylliodes chrysocephala*), the cabbage aphid (*Brevicoryne brassicae*), and the crucifer flea beetle (*Phyllotreta cruciferae*), feed exclusively on glucosinolate-containing plants, whereas generalist herbivores including slugs and snails, the aphid *Myzus persicae*, and the desert locust *Schistocerca gregaria* feed on a larger variety of plants, only some of which contain glucosinolates.

Two different enzymatic mechanisms have been described for the detoxification of glucosinolates by specialist herbivores. Diamondback moth larvae possess an enzyme, glucosinolate sulfatase (GSS), which cleaves the sulfate group yielding desulfoglucosinolates (Ratzka et al. 2002). Because the plant enzyme myrosinase catalyzes glucose hydrolysis only from intact glucosinolates and not from desulfoglucosinolates, no toxic glucosinolate hydrolysis products are formed in the presence of GSS. In larvae of *Pieris rapae*, however, a different method is employed by the insect for circumventing the toxic effects of glucosinolates in its diet (Wittstock et al. 2004). *P. rapae* larvae possess a "nitrile-specifying protein" (NSP) in their gut. NSP prevents the formation of isothiocyanates during glucosinolate hydrolysis, instead directing the aglucone of the glucosinolate to form a nitrile. Nitriles are less toxic than isothiocyanates, and the presence of this enzyme allows *P. rapae* larvae to feed extensively on plants containing glucosinolates.

Generalist herbivores that occasionally feed on glucosinolate-containing plants must also be able to avoid the toxic effects of these plant compounds, but little is known about the mechanisms involved. The desert locust, *Schistocerca gregaria*, is a generalist feeder that includes the annual crucifer *Schouwia purpurea* in its diet (Ghaout et al. 1991; Culmsee 2002). Although *S. purpurea* has a glucosinolate content tenfold higher than most cruciferous crop plants (Ghaout et al. 1991; Fahey et al. 2001), the desert locust is reported to eat the plant without any detrimental effects (El Sayed et al. 1996; Mainguet et al. 2000). Thus, this insect must be adept at circumventing glucosinolate toxicity. In this report, we show that desert locusts possess glucosinolate sulfatase activity in their gut, which alters the core structure of glucosinolates, preventing the release of toxic hydrolysis products by myrosinase. The enzyme is induced to higher levels when locusts feed on glucosinolate-containing plants. The ability of a generalist herbivore to modulate the level of detoxification machinery in response to the presence and absence of a toxin may reduce the physiological costs of detoxification.

Materials and Methods

Plants, Insects and Other Materials Seeds of *S. purpurea*, collected from wild plants in Mauritania, were a gift of Mohamed Lemine, FAO Locust Center, Nouakchott, Mauritania. Plants were germinated and grown in ordinary potting soil (Klasmann–Deilmann Tonsubstrat, Geeste–Gross Hesepe, Germany) in a greenhouse under a diurnal cycle of 14:10 h L:D at 22–26°C. Desert locusts (adult females unless otherwise indicated) were provided from a culture reared at Martin Luther University, Halle, Germany as described (Seidelmann et al. 2005) and were maintained in a growth chamber at 35°C during the day and 25°C during the night, 30% relative humidity, and a 12:12 h L:D cycle. In culture, before experimental feeding of *S. purpurea*, locusts were fed primarily with wheat grass and dry oatmeal with occasional supplements of Chinese cabbage and savoy cabbage. Most of the glucosinolate substrates used (indol-3-ylmethyl-, (*S*)-2-hydroxy-3-butenyl-, and 3-butenyl-glucosinolate) were isolated in the laboratory. However, sinigrin and all other chemicals were purchased from Sigma.

Glucosinolate and Glucosinolate Product Analysis Glucosinolates were extracted from *S. purpurea* leaves, stems, and flowers by using a modification of the method described in Brown et al. (2003). Fresh tissue (100–300 mg) was homogenized by a Polytron in 4 ml of 80% (aqueous) methanol containing 0.05–0.1 μmol *p*-hydroxybenzyl glucosinolate as an internal standard and 30 μmol $Pb(OAc)_2$ and 30 μmol $Ba(OAc)_2$ to precipitate protein and free sulfate ions. Samples were centrifuged at 4,000×*g* for 10 min, and the resulting supernatant was loaded onto an anion-exchange column (DEAE-Sephadex A-25) to bind intact glucosinolates. The column was washed sequentially with 67% (aqueous) methanol and 0.02 M Mes, pH 5.2, before being capped overnight with 50 μl of a *Helix pomatia* sulfatase solution. The resulting desulfated glucosinolates were eluted from the column with 60% (aqueous) methanol, and the eluent was evaporated to dryness under nitrogen at 50°C before being resuspended in water. To analyze both desulfoglucosinolates and intact glucosinolates from desert locust feces, the eluent obtained during sample loading on the anion exchange column and washing of the column was retained. This fraction, which would be expected to contain any desulfoglucosinolates present, was evaporated to dryness as described above and resuspended in water for high performance liquid chromatography (HPLC) analysis. The intact glucosinolates from feces that bound to the anion-exchange column were desulfated as already described.

Samples were separated by HPLC (Agilent HP1100 Series) fitted with a C-18 reversed-phase column (Supelcosil RP-18, 250×4.6 mm i.d., 5-μm particle size, Supelco, Sigma–Aldrich Chemie GmbH, Taufkirchen, Germany) using a water (Solvent A)-acetonitrile (Solvent B) gradient at a flow rate of 1 ml min^{-1} at ambient temperature. The 38-min run consisted of 1.5% B (1 min), 1.5–5.0% B (5 min), 5.0–7.0% B (2 min), 7.0–21.0% B (10 min), 21.0–29.0% B (5 min), 29.0–43.0% B (7 min), 43.0–100.0% B (0.5 min), a 2.5-min hold at 100.0% B, 100.0–1.5% B (0.1 min), and a 4.9-min hold at 1.5% B. Eluent was monitored at 229 nm. Desulfated glucosinolates were identified by comparison of their retention times and UV spectra to those of purified standards previously extracted in our laboratory (Reichelt et al. 2002; Brown et al. 2003). Compounds were quantified by A_{229nm} relative to the internal standard with response factors reported in the literature (Brown et al. 2003). To confirm the presence of desulfoglucosinolates in feces, extracts were incubated with *Caldocellum saccharolyticum* β-*O*-glucosidase, an enzyme shown to hydrolyze only desulfoglucosinolates and not intact glucosinolates (Wathelet et al. 2001).

Analysis of glucosinolate hydrolysis products originating from *S. purpurea* leaves, flowers, and stems,and in desert locust feces was performed as described in Lambrix et al. (2001).

Enzyme Extraction, Assay, and Characterization Insects were chilled at −20°C for 20 min before dissection. The entire gut was removed from the thorax and abdomen, rinsed in 20 mM Mops, pH 6.9, and homogenized via Polytron in 5 ml of the same buffer. The homogenate was centrifuged for 20 min at 48,000×*g*, and the supernatant was reserved for assay. The standard assay consisted of 10 mM of glucosinolate and 1–5 μg total protein in 100 μl of 20 mM Mops, pH 6.9, and was conducted at 25°C. The reaction was initiated by addition of the substrate glucosinolate and was stopped by the addition of 500 μl of methanol after 4 min. To separate intact glucosinolates from desulfoglucosinolates, 200 μl of a 10% (w/v) aqueous suspension of DEAE-Sephadex were added to the assay. DEAE-bound intact glucosinolates were removed from the suspension by filtration over glass wool. The eluate containing desulfoglucosinolates was prepared for HPLC as described above for glucosinolate extraction from plant tissues, except that samples were dissolved in 20 mM Mops, pH 6.9 containing 250 μg ml^{-1} myrosinase to hydrolyze any residual intact glucosinolates that did not bind to the DEAE.

The cell-free gut extract was assayed for arylsulfatase activity by combining 20 μg of total protein and 5 mM 4-nitrocatechol sulfate with 10 mM Tris-HCl, 100 mM KCl, and 5 mM ethylenediamine tetraacetic acid (EDTA), pH 6.3, in a total volume of 0.5 ml. After 60 min incubation at 25°C, the reaction was stopped by the addition of 0.5 ml of 5 N NaOH, and the absorbance of the resulting 4-nitrocatechol was measured at an absorbance of 515 nm. For inhibitor experiments, EDTA was omitted from the assay buffer. Protein levels were determined by using the Bio-Rad reagent with BSA as the standard.

Statistical Analysis Statistical analysis of intact glucosinolate and glucosinolate hydrolysis product variation among plant organs, as well as variation in glucosinolate sulfatase activity during locust development and under different feeding protocols, was accomplished either by one-way analysis of variance (ANOVA) followed by the Student–Newman–Keuls test or by Kruskal–Wallis one-way ANOVA followed by Dunn's test as indicated in the figure legends. The software used was SigmaStat 3.5, and significant differences were determined at $P<0.05$.

Results

Glucosinolate Composition of S. purpurea To determine the glucosinolate composition that desert locusts are exposed to when feeding on *S. purpurea*, a typical component of its diet, tissues of this species were extracted, and the isolated glucosinolates were analyzed by HPLC. The glucosinolate profiles of leaves, flowers, and stems (Fig. 1) are similar, dominated by 3-butenyl glucosinolate (64–92% of total glucosinolates), with significant amounts of (*S*)-2-hydroxy-3-butenyl glucosinolate (5–22%) and indol-3-ylmethyl glucosinolate (2–19%). In all tissues besides the young leaf, trace amounts (up to 0.4%) of (*R*)-2-hydroxy-3-butenyl glucosinolate were detected, whereas 4-hydroxyindol-3-ylmethyl glucosinolate was detected at trace levels in the flower and in the younger leaves. There was no indication of significant compositional differences among the plants used in this study.

The total amount of glucosinolates in different organs varies enormously (Fig. 2), being highest in the buds and young, expanding leaves (>150 μmol g dry $weight^{-1}$), at intermediate levels (100–150 μmol g dry $weight^{-1}$) in flowers, the upper stems, and middle leaves, and lowest (10–50 μmol g dry $weight^{-1}$) in the cotyledons, first true leaves, and lowest part of the stem. All of these tissues, including stems, flowers, and leaves of all ages

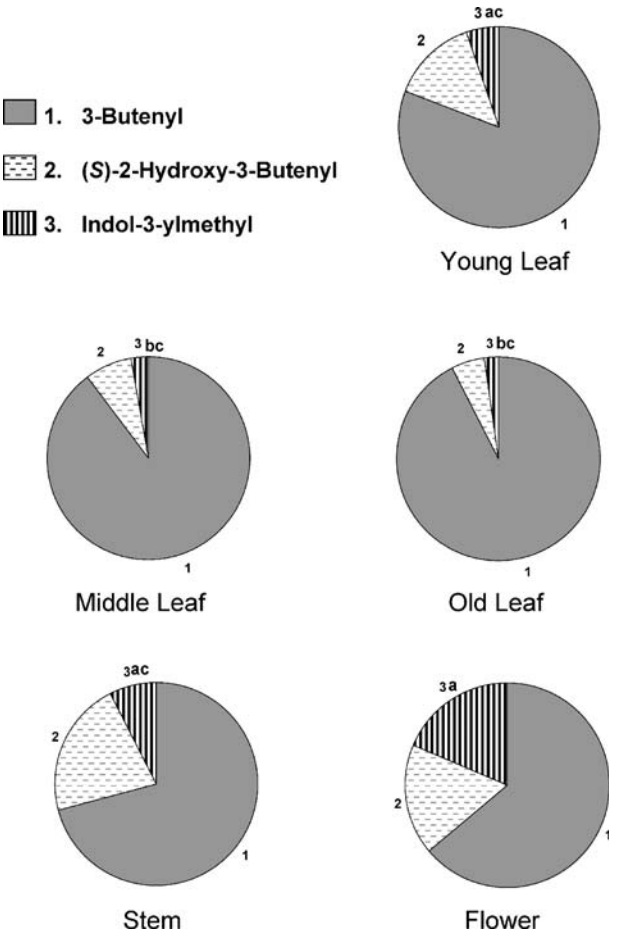

Fig. 1 Glucosinolate composition of above-ground organs of *S. purpurea*, all of which are eaten by the desert locust. Values represent the means of nine samples; for each organ type, three samples were harvested from each of three different plants. Indol-3-ylmethyl glucosinolate varied significantly ($P<0.05$) among organs with differences indicated by *letters* in the figure as determined by ANOVA followed by a Student–Newman–Keuls test on the means of the raw data before conversion to percentages for the pie chart. There were no significant differences in the means of 3-butenyl glucosinolate or (*S*)-2-hydroxy-3-butenyl glucosinolate among the organs analyzed

were eaten by the desert locust under the conditions of our experiments. Insects that had no previous experience with *S. purpurea* were observed to first eat older leaves then proceed to younger leaves when the older leaves were consumed.

Glucosinolate Hydrolysis Products of S. purpurea The biological activity of glucosinolates depends on their myrosinase-catalyzed degradation to various products. To analyze what desert locusts might naturally encounter during feeding on *S. purpurea*, leaves were mechanically macerated and allowed to autolyze in water for 5 min so that the endogenous glucosinolate pool was exposed to the native myrosinase as well as any other glucosinolate-modifying enzymes present in the plant. The main hydrolysis product in all plants analyzed (≥56%) was the epithionitrile, 3-epithiobutyl cyanide [3-(thiirane-2-yl)propane nitrile] (Fig. 3) demonstrating that *S. purpurea* possesses an epithiospecifier protein (Lambrix et al. 2001; Burow et al. 2006). The amount of 3-epithiobutyl cyanide was higher in the young leaf as compared to the old leaf, flowers, and stems ($P<0.05$ by one-way ANOVA followed by Student–Newman–Keuls test). 3-Butenyl isothiocyanate, considered more toxic than the corresponding nitrile and epithionitriles, was also formed, but this comprised less than 7% of the total glucosinolate hydrolysis products under all conditions. Low amounts of

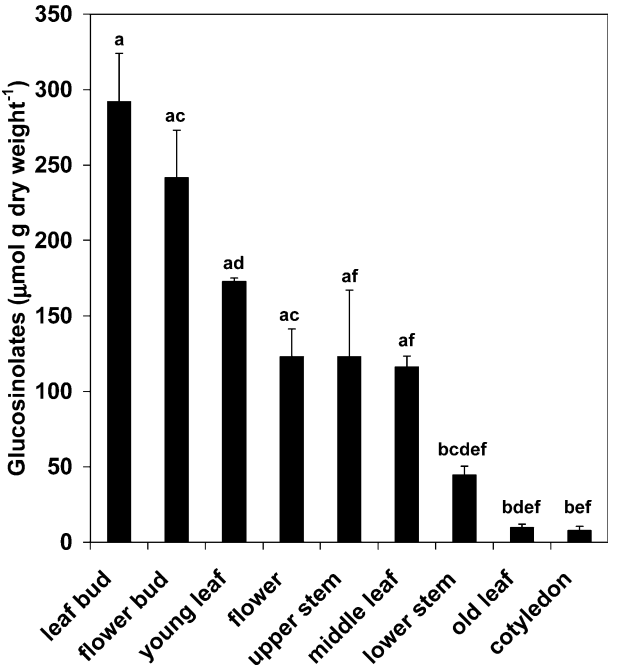

Fig. 2 Total glucosinolate content of *S. purpurea* above-ground tissues of a 5-week-old flowering plant. Values are the means±SE for three samples per tissue. Significant differences ($P<0.05$) among organs are indicated by different *letters above bars* and were determined by Kruskal–Wallis one-way ANOVA on ranks followed by Dunn's test

indoleacetonitrile (1.6–4.2%), (*S*)-2-hydroxy-3-epithiobutyl cyanide (0.4–7.1%), and 3-butenyl cyanide (1.2–1.6%) were also produced by the plant.

Glucosinolate Metabolites Found in the Desert Locust To get an overview of the glucosinolate metabolism of the desert locust, insects were allowed to feed on *S. purpurea*, and the guts and feces were analyzed for the presence of possible glucosinolate metabolites, including glucosinolates with modified side chains, desulfoglucosinolates, and the various hydrolysis products found in the plant. The main metabolites observed (99% of total in both the gut and feces) were desulfoglucosinolates. The remaining metabolites were hydrolysis products, primarily 3-epithiobutyl cyanide. These data suggested that desert locusts possess a glucosinolate sulfatase activity in the gut similar to that demonstrated in *Plutella xylostella* (Ratzka et al. 2002).

Demonstration and Characterization of GSS in Desert Locust Guts Cell-free extracts of the alimentary canal of locusts fed with *S. purpurea* were able to convert intact glucosinolates into desulfoglucosinolates. Activity was linear for 5 min incubation time at a concentration of 0.5–20 µg protein ml^{-1}. The assay was primarily studied with allyl glucosinolate (sinigrin) as substrate, but the enzyme was also shown to be active to a varying degree with all of the glucosinolates found in *S. purpurea*: 3-butenyl-, (*S*)-2-hydroxy-3-butenyl-, and indol-3-ylmethyl-glucosinolate, as well as benzyl- and *p*-hydroxybenzyl glucosinolate (Table 1). The preparation yielded a K_m for sinigrin of 11 mM and a V_{max} of 109 µmol min^{-1} mg $protein^{-1}$, and a K_m for (*S*)-2-hydroxy-3-butenyl glucosinolate of 113 mM, and a V_{max} of 764 µmol min^{-1} mg $protein^{-1}$. The enzyme displayed a sharp pH optimum at 6.5 (range tested: 2.5–11; half-maxima: 5.8 and 7.7), which corresponds closely to the pH of the gut (6.2 in locusts fed solely *S. purpurea*). It was inhibited strongly by Na_2SO_3 and slightly by Na_2HPO_4 and NaF (Fig. 7). GSS activity was detected in the head, foregut,

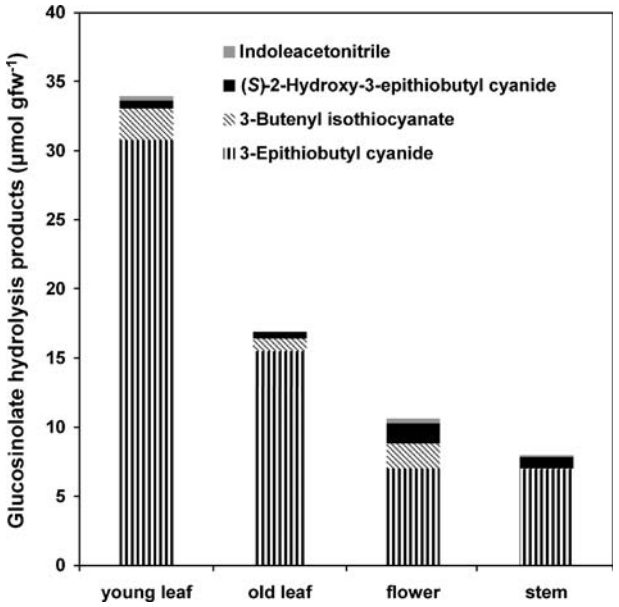

Fig. 3 Glucosinolate hydrolysis products of *S. purpurea*. Values represent the means of three samples each from three different plants. Hydrolysis of 3-butenyl glucosinolate results in the formation of two stereoisomers of 3-epithiobutyl cyanide and hydrolysis of (*S*)-2-hydroxy-3-butenyl glucosinolate results in the formation of two stereoisomers of (*S*)-2-hydroxy-3-epithiobutyl cyanide. Our chromatographic analysis did not differentiate between these stereoisomers. 3-Butenyl cyanide was detected at trace levels in this experiment but is not depicted in this figure because of its much lower level relative to 3-butenyl isothiocyanate. One-way ANOVA with a post hoc Student–Newman–Keuls test indicated a significant difference ($P<0.05$) between the amount of the major product 3-epithiobutyl cyanide in the young leaf as compared to the other organs examined

gastric caecae, midgut, and hindgut of all desert locusts at similar levels (data not shown). It was also present in all larval stages when fed with *S. purpurea* as well as in both male and female adults (Fig. 4). The enzyme was extremely stable, retaining 75% of its activity after 3 months of storage at room temperature as compared to boiled controls and losing no activity after 3 months of storage at 4 or −20°C. The extract could be heated to 70°C for 10 min with no loss of activity. The stability of this enzyme may be due its location in the highly proteolytic environment of the insect gut.

Table 1 Glucosinolate sulfatase activity in extracts of desert locust guts with various glucosinolate substrates

Glucosinolate	GSS Activity (µmol min^{-1} mg $protein^{-1}$)
Allyl	9.92±1.1
3-Butenyl	8.52±0.9
Indol-3-ylmethyl	7.92±0.9
p-Hydroxybenzyl	7.59±0.5
(*S*)-2-Hydroxy-3-butenyl	6.04±0.9
Benzyl	3.8±0.2

Each value is the mean of at least three replicate assays. All assays were performed with 1 mM of respective glucosinolate substrate.

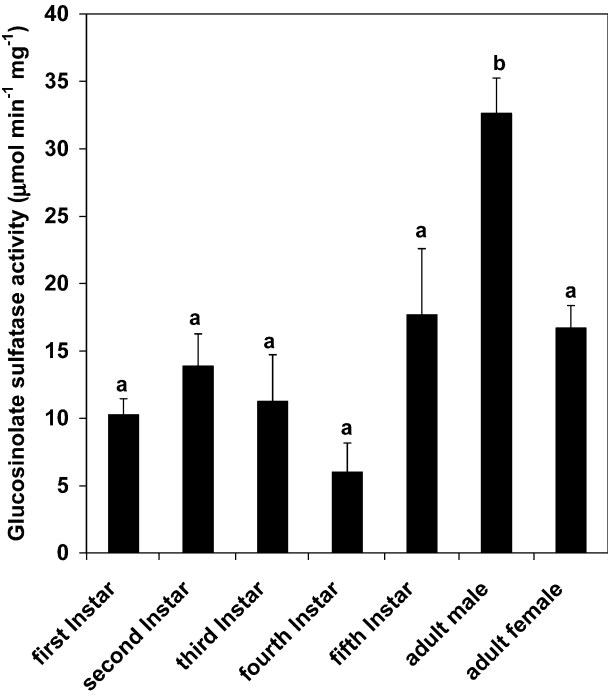

Fig. 4 Glucosinolate sulfatase activity during larval development of desert locust. Values represent the mean±SE for three assays each comprising a whole body extract of three locusts for the first through fifth instars and a gut extract of three locusts for the adult male and female. Significant differences ($P<0.05$) between developmental stages are indicated by different *letters above bars* and were determined by one-way ANOVA followed by a Student–Newman–Keuls test

Induction of GSS in Gut Upon Introduction of Glucosinolates to a Nonglucosinolate Containing Diet The desert locust is a generalist feeder that feeds on *S. purpurea* when this plant is abundant in its local environment but feeds on other nonglucosinolate-containing plants as well (Ghaout et al. 1991; Culmsee 2002). To determine whether its glucosinolate sulfatase activity was constitutive or induced upon ingestion of glucosinolates, adult females were fed on a diet of wheat for 3 days before being switched to *S. purpurea* for 9 days. After 9 days, the insects were returned to a wheat diet. Insects were sampled periodically and assayed for gut GSS activity, feces desulfoglucosinolates, and feces glucosinolate hydrolysis products. The data are shown in Fig. 5. At the beginning of the experiment, when insects were fed only wheat, GSS activity was low but measurable at 2 µmol min^{-1} mg $protein^{-1}$. Upon *S. purpurea* feeding, this activity increased tenfold to 20 µmol min^{-1} mg total $protein^{-1}$ after 9 days (the difference in GSS activity in locusts feeding on wheat vs feeding on *S. purpurea* was significant at $P<0.05$). A fourfold increase was already evident after 3 days of *S. purpurea* feeding. When insects were taken off the *S. purpurea* diet and returned to wheat, the GSS activity showed a declining trend to approximately 10 µmol min^{-1} mg total $protein^{-1}$ (not statistically significant) and remained at that level for 6 days. Coincident with the rise in GSS activity during feeding on *S. purpurea*, desulfoglucosinolates were detected at high levels in the feces of locusts. Only trace levels of desulfoglucosinolates were observed in the feces of insects before *S. purpurea* feeding. These were probably carried over from feeding on Chinese cabbage (*Brassica pekinensis*) before the start of the experiment. Similarly, when the insects were switched from *S. purpurea* to wheat, desulfoglucosinolates continued to appear in the feces after the removal of glucosinolates from the diet.

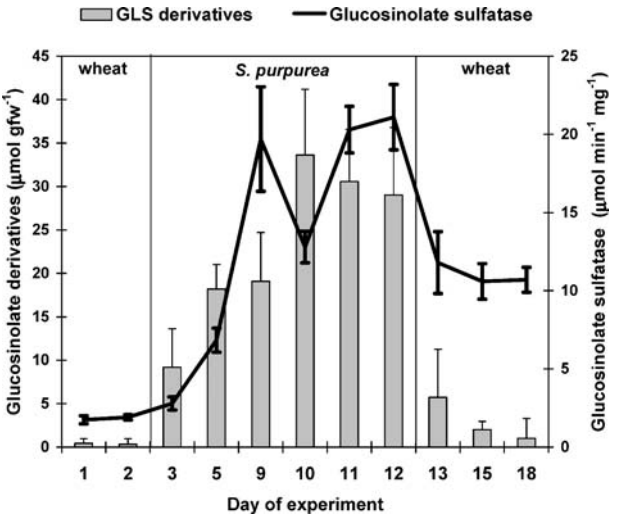

Fig. 5 Induction of GSS activity in desert locust gut and appearance of glucosinolate derivatives in feces during feeding on different diets. Values represent three measurements for each timepoint, and the experiment was repeated three times with similar results. Data for one experiment are shown. Glucosinolate derivatives consist primarily of desulfoglucosinolates, with trace amounts of 3-epithiobutyl cyanide, (*S*)-2-hydroxy-3-epithiobutyl cyanide, 3-butenyl isothiocyanate, and indoleacetonitrile. Kruskal–Wallis one-way ANOVA on Ranks followed by the Dunn's test ($P<0.05$) showed that (1) GSS activity was significantly higher in locusts fed with *S. purpurea* and locusts fed with wheat after exposure to *S. purpurea* than in insects with no prior exposure to *S. purpurea* and (2) that glucosinolate derivatives were significantly higher in feces of locusts fed with *S. purpurea* vs wheat

Relationship of GSS to Arylsulfatase Because an arylsulfatase activity has been described in the crop liquor of the desert locust (Robinson et al. 1953), it was of interest to determine its relationship to GSS. Arylsulfatases catalyze desulfonation of sulfate esters and sulfamates and have been isolated from many prokaryotes and eukaryotes including insects (Hanson et al. 2004). By using 4-nitrocatechol as a substrate, we measured a K_m in desert locust gut extracts of 1.8 mM, significantly lower than that observed for sinigrin (11 mM) or (*S*)-2-hydroxy-3-butenyl glucosinolate (113 mM). However, the V_{max} of 4-nitrocatechol is relatively low at 0.03 µmol min^{-1} mg^{-1}. When the catalytic efficiencies (V_{max}/K_m) of these activities are calculated, the GSS activity is much more efficient (19.6 for sinigrin and 6.8 for (*S*)-2-hydroxy-3-butenyl glucosinolate) than the arylsulfatase activity (V_{max}/K_m= 0.017). Furthermore, when arylsulfatase activity was assayed from insects switched from wheat to *S. purpurea*, and back to wheat again, it was observed that this activity was induced concomitantly with GSS (Fig. 6). Arylsulfatase activity showed a similar response as GSS to most of the tested inhibitors with the exception of Na_2HPO_4 (Fig. 7).

Discussion

The desert locust, *S. gregaria*, is a generalist that occasionally feeds on *S. purpurea*, a plant containing high levels of glucosinolates. As glucosinolates are deterrent and toxic to many insects (Halkier and Gershenzon 2006), it was of interest to learn how desert locusts are

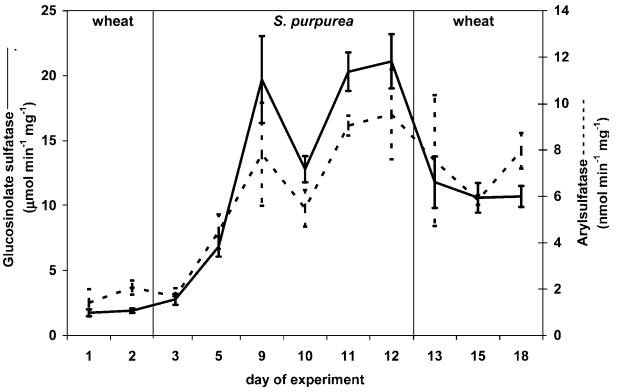

Fig. 6 Comparison of glucosinolate sulfatase and arylsulfatase activities during desert locust feeding on *S. purpurea* and wheat. Values represent mean±SE for three replicates of each assay per timepoint. Assays for each activity were optimized separately to insure linearity over the range of incubation times and protein concentrations employed

able to tolerate the presence of glucosinolates in their diet. We showed that desert locusts possess a glucosinolate sulfatase in their alimentary canal, which cleaves the sulfate group efficiently from all glucosinolates tested, rendering them inert to myrosinase activity. The resulting desulfoglucosinolates are excreted in high quantities in the feces. Glucosinolate sulfatase was first described for larvae of the diamondback moth (*Plutella xylostella*; Ratzka et al. 2002). Both the *P. xylostella* enzyme and the desert locust enzyme have broad specificity for aliphatic, indolic, and aromatic glucosinolates. The snail *Helix pomatia*, a generalist herbivore, also possesses a glucosinolate sulfatase in its gut, but it is unclear whether this enzyme is able to detoxify glucosinolates when the animal feeds on cruciferous plants (Ratzka et al. 2002).

Feeding on glucosinolate-containing tissue causes other biochemical changes in the locust gut including suppression of β-glucosidases and induction of a myrosinase activity, possibly of insect origin (Mainguet et al. 2000). However, the broad substrate specificity of the glucosinolate sulfatase, its high activity in vitro and its inducibility upon switching to a glucosinolate-containing diet accompanied by the mass appearance of desulfoglucosinolates in the feces, suggests that desulfation of glucosinolates is the major route of glucosinolate detoxification in locusts.

Although *S. purpurea* contains nearly ten times the level of glucosinolates of other crucifers, such as *Arabidopsis thaliana*, this potential toxicity is tempered by the fact that the plant generates primarily nitriles rather than isothiocyanates when tissue is macerated.

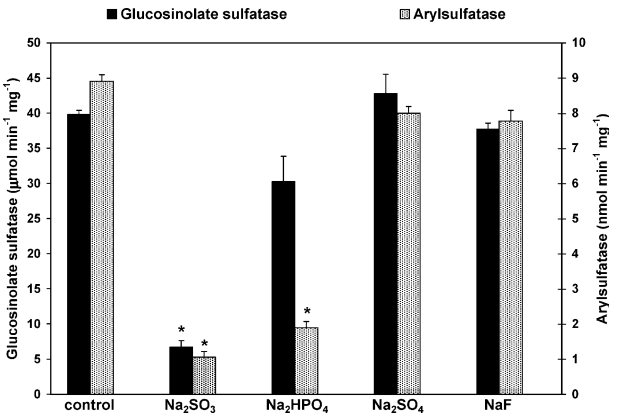

Fig. 7 Inhibitors of glucosinolate sulfatase and arylsulfatase activities in desert locust gut. Values represent the mean±SE for three replicates. Treatments significantly different ($P<0.05$) from their respective controls as determined by one-way ANOVA with a post hoc Student–Newman–Keuls test are indicated with an *asterisk*

Isothiocyanates are thought to be generally more toxic to insects than nitriles (Wittstock et al. 2003) and have been shown to be deterrent to locust feeding (El Sayed et al. 1996). However, our experiments showed that desert locusts do not encounter isothiocyanates in significant levels when feeding on *S. purpurea*.

The locust gut extract catalyzed the desulfation of 4-nitrocatechol, indicative of arylsulfatase activity, as well as the desulfation of glucosinolates. Although GSS was not purified to homogeneity in this study, the fact that the arylsulfatase activity was induced along with GSS during feeding on *S. purpurea* and that they had similar inhibitor profiles suggests strongly that the activities are catalyzed by the same protein. Arylsulfatases were first isolated based on their ability to catalyze the desulfation of model compounds and were later found to desulfate biologically more relevant molecules (Hanson et al. 2004). Arylsulfatase has been implicated in the molting of southern armyworm larvae, but its function and biological substrates in insects are not well understood (Yang et al. 1973; Pellicia et al. 1987). It is known that insects possess sulfated ecdysone conjugates (Koolman 1973) proposed to be inactive storage forms of ecdysone, and it is conceivable that arylsulfatases are involved in their metabolism. However, ecdysteroid localization is limited to the ovaries, hemolymph, and eggs, rather than the gut, and thus, it is unlikely that GSS is involved in ecdysteroid turnover. Furthermore, the induction of GSS activity by dietary factors seems to preclude its involvement in molting, as molting is a tightly regulated process, and *S. purpurea* feeding did not disrupt larval development (data not shown).

Other enzymes have been implicated in glucosinolate detoxification in insects in addition to glucosinolate sulfatase and the NSP from *P. rapae* that diverts glucosinolate hydrolysis from isothiocyanates to nitriles (Wittstock et al. 2004). Francis et al. (2005) reported that glutathione transferase activity is higher in the aphid *Myzus persicae* when it feeds on the glucosinolate-containing plants *Brassica napus* and *Sinapis alba* as compared to when it feeds on beans. Unfortunately, this study does not provide direct chemical evidence of glucosinolate detoxification because the enzymes were assayed with artificial substrates, such as 1-chloro-2,4-dinitrobenzene, rather than with glucosinolates or their products (Francis et al. 2005). Wadleigh and Yu (1988) have provided in vitro evidence for a glutathione transferase that conjugates isothiocyanates with glutathione in midgut extracts of the larvae of the cabbage looper (*Trichoplusia ni*) and the fall armyworm (*Spodoptera frugida*) but did not demonstrate the presence of these conjugates in larval feces. In animals, it is known that isothiocyanates are conjugated to glutathione (Zhang et al. 1995) before excretion as a mercapturic acid conjugate. The presence of an insect myrosinase has been reported in the cabbage aphid *Brevicoryne brassicae* (Francis et al. 2002; Husebye et al. 2005); however, as yet, no evidence has been presented that this myrosinase participates in glucosinolate detoxification in vivo. It seems rather to function in the insect's own defense against predators. On the contrary, our work and the study of Ratzka et al. (2002) on *Plutella xylostella* glucosinolate sulfatases, as well as the results of Wittstock et al. (2004) on NSP, provide strong evidence for direct glucosinolate detoxification by insects.

When first offered *S. purpurea*, desert locusts were observed to regulate their glucosinolate exposure by feeding preferentially on older tissues with lower levels of glucosinolates. This behavior may be necessary to prevent toxicity until glucosinolate sulfatase activity is sufficiently induced. A tenfold induction in GSS was observed after switching from wheat to *S. purpurea* in this study. Induction of detoxification enzymes in the insect gut is a common response to the presence of toxic plant secondary metabolites in the diet. For example, the bruchid *Callosobruchus maculatus* tolerates toxic thiosulfinates and disulfides produced by leek (*Allium porrum*) by inducing the activity of a glutathione-

S-transferase implicated in detoxification of these defensive sulfur compounds (Dugravot et al. 2004). Specific cytochrome P450s are induced in the midgut of tobacco hornworm larvae (*Manduca sexta*) that detoxify nicotine and aldrin (Snyder and Glendinning 1996) and in parsnip webworm (*Depressaria pastinacella*) and swallowtail caterpillars (*Papilio* spp.) that detoxify furanocoumarins (Li et al. 2004b; McDonnell et al. 2004). Transcription of members of the furanocoumarin-metabolizing cytochrome P450 *CYP6B* family is induced in all species of *Papilio* examined to date during feeding on furanocoumarin-containing plants, and the magnitude of the induction correlates positively with the amount of furanocoumarins ingested, which varies depending on the feeding preferences of individual species (Cohen et al. 1992; Li et al. 2001). The induction of a detoxification enzyme when the insect feeds on a plant containing its substrate, rather than its continuous presence in the gut, may function to minimize the metabolic costs of processing food (Schoonhoven et al. 2005). Thus, it is not surprising that the glucosinolate detoxifying enzyme of the desert locust, glucosinolate sulfatase, is seen only in substantial amounts after initial feeding on glucosinolate-containing plants.

The inducibility of detoxification enzymes may be a common trait in generalist feeders, like the desert locust. In comparing generalist and specialist feeding herbivores, generalists are expected to encounter a larger variety of plant defense metabolites and thus may have evolved a broader detoxification capacity. However, this does not preclude generalists and specialists from employing similar mechanisms of detoxification. Indeed, furanocoumarins are detoxified by the same subfamily of cytochrome P450s (*CYP6B*) in both generalist and specialist lepidopteran species (Li et al. 2007). Generalist lepidopterans appear to possess a greater variety of cytochrome P450s with broader substrate specificity and a greater degree of inducibility (Li et al. 2004a, 2007). Nevertheless, the basic mode of detoxification is similar. This is also true for glucosinolates where both the specialist diamondback moth (Ratzka et al. 2002) and the generalist desert locust metabolize glucosinolates via desulfation.

Acknowledgments We thank Karsten Seidelmann and Sigi Hertel for providing us with *S. gregaria*, Mohamed Lemine for the gift of *S. purpurea* seeds, Tamara Krügel and Andreas Weber for growing the plants, and Michael Reichelt for substrate preparation and maintenance of the HPLCs and GCs, as well as for helpful discussions. The Max Planck Society provided financial support.

Introduction

Plants have evolved defenses against herbivores that use a wide array of direct mechanisms (Karban and Baldwin 1997). Direct defense mechanisms include morphological adaptations that impede herbivore colonization and movement on the plant, such as hairs, waxy leaf surfaces, or sticky secretions (van Dam and Hare 1998; Muller and Riederer 2005). Most plants also produce secondary metabolites that affect herbivore behavior and development. Allelochemicals may function as feeding deterrents for generalist herbivores (Akhtar and Isman 2004) or exhibit toxic effects on the development and physiology of herbivores by reducing their rates of growth and increasing mortality (Giamoustaris and Mithen 1995; Wold and Marquis 1997; van Dam et al. 2000). On the other hand, many herbivores have evolved specific metabolic adaptations that enable them to detoxify or excrete allelochemicals and their breakdown products (Ratzka et al. 2002; Wittstock et al. 2004). Still other species utilize plant allelochemicals as feeding and/or oviposition stimulants (Carter and Feeny 1999; Renwick and Lopez 1999) or sequester them as a putative defense against predators and parasitoids (Hunter 2000; Muller et al. 2001).

Several studies have found that there is considerable genetic variation in the expression of secondary plant metabolites, even in populations that are located in close proximity to each other (Fox 1981; Moyes et al. 2000; Agrawal 2005). This variation is thought to represent an adaptive response to a suite of selection pressures that may vary even over limited spatial and/or temporal gradients (Moyes et al. 2000). Biotic selection pressures, such as attack from herbivores and pathogens, and abiotic selection pressures, such as exposure to wind or access to water and nutrients, may play an important role in shaping the evolution of direct defenses in plants (Agrawal 2005). Competition with other plants may also be an important factor resulting in a trade-off between growth and defense (van Dam et al. 2000).

Most researchers now agree that natural enemies of arthropod herbivores, such as parasitoids and predators, must also be considered in models examining the evolution of direct defense strategies in plants (Price et al. 1980). This approach has generally argued that natural enemies, by regulating herbivore populations, can act as important selective agents by reducing the need for plants to invest in chemical defenses when these are costly to maintain (van Dam et al. 2000; Ode et al. 2004). However, one of the major problems with this argument is that it assumes that the development of natural enemies is independent of plant quality, thus ignoring that natural enemies obtain their nutrition indirectly from the plant through the herbivore. A number of studies have reported that allelochemicals in the diet of hosts or prey negatively affect the development of their parasitoids and predators (Barbosa et al. 1986, Duffey et al. 1986; Gunasena et al. 1990; Traugott and Stamp 1996; Havill and Raffa 2000; reviewed by Harvey 2005 and Ode 2006). Further, the effects of allelochemicals may even be manifested in the fourth trophic level (Orr and Boethel 1986; Harvey et al. 2003; Soler et al. 2005), showing that they can work their way up through the food chain.

In this study, we compared the development of the small cabbage white butterfly, *Pieris rapae* L. (Lepidoptera: Pieridae), and its gregarious ectoparasitoid, *Pteromalus puparum* L. (Hymenoptera: Pteromalidae) when the herbivore was reared on three wild populations and one cultivar of cabbage, *Brassica oleracea* L. (Capparales: Brassicaceae). Previous work found that there were significant differences in the expression of glucosinolates in wild

cabbage plants among the different Dorset populations (Mithen et al. 1995; Moyes et al. 2000). Domestication in *B. oleracea* has also resulted in a significant reduction of foliar levels of glucosinolates (Benrey et al. 1998). We included a cabbage cultivar with low levels of glucosinolates compared to the wild Dorset populations. *Pieris rapae* is a specialist herbivore that feeds exclusively on plants producing glucosinolates (Mithen et al. 1995; Renwick and Lopez 1999). Glucosinolates and their breakdown products act as feeding deterrents or exhibit detrimental effects on the growth and development of herbivores, pathogens, and nematodes (Potter et al. 1999; Li et al. 2000; Buskov et al. 2002). On the other hand, they are also known to act as oviposition and feeding stimulants for specialist herbivores such as *Pieris rapae* (van Loon and Schoonhoven 1999; Renwick and Lopez 1999).

We compared pupal weight of *Pieris rapae* caterpillars that were reared in the laboratory on the three wild strains and cultivar of *B. oleracea*. We then examined adult wasp body mass and development time in *Pteromalus puparum* when reared from pupae of *Pieris rapae*. Finally, we measured levels of glucosinolates in foliage of *B. oleracea*. The main aim of the experiment was to determine if there are differences in plant quality among the different strains of *B. oleracea*, based on foliar levels of glucosinolates, and if these are reflected in patterns of herbivore and parasitoid development.

Methods and Materials

Plants Seeds of *B. oleracea* were collected from three populations growing on or close to chalk cliffs along the south coast of Great Britain, near Swanage, Dorset. Two of the populations (Winspit, Kimmeridge) are located less than 5 km from each another; the third (Old Harry) occurs approximately 10 km east of the Winspit population. The coordinates for each of the populations are: Old Harry (50°38′N, 1°55′E), Kimmeridge (50°35′N, 2°03′E), and Winspit (50°34′N, 2°02′E). In addition, a cultivated strain of *B. oleracea* (Brussels sprout) cv. Cyrus was included.

Seeds from the different strains were germinated in the first week of October, 2005. Seedlings were transferred to 2.1-l pots filled with potting soil consisting of approximately 30% sand, 5% clay, and 65% peat. Plants were grown at The Netherlands Institute of Ecology, Heteren, in a greenhouse at 22±2°C, 40–80% RH, with a photoperiod of at least 16 hr. If the light dropped below 500 μmol photons m^{-2} sec^{-1} during the 16 hr photoperiod, supplementary illumination was supplied by high-pressure mercury lamps. Plants were watered daily. Starting when 4-wk old, the plants were fertilized once a week with 0.5 regular Hoagland solution, which was applied to the soil. All *B. oleracea* plants were 7-wk old when they were used in experiments.

Insects Pieris rapae feeds exclusively on plants in the Order Capparales that produce glucosinolates, and especially on species of the Brassicaceae, and is considered to be a major pest in cabbage crops in many parts of the world. During its development, *Pieris rapae* passes through five instars before pupating on leaves or stems of the plant. *Pteromalus puparum* is known to attack pupae in several families of butterflies, including species of the Nympahlidae and Pieridae (Lei et al. 1997; Barron et al. 2004; Wold-Burkness et al. 2005). It is considered to be an important biological control agent of *Pieris rapae* (Lee and Heimpel 2005). The parasitoid must first host-feed before initiating oogenesis. Host feeding occurs when the female parasitoid creates a wound in the host cuticle by repeatedly inserting and removing her ovipositor over the course of several minutes. After this time, haemolymph begins oozing

through the wound and is consumed by the parasitoid. Eggs usually are produced within 48 hr of a host-feeding bout.

All insects used in the experiments originated from cabbage fields in the vicinity of Wageningen. Cultures of all herbivores were maintained in the laboratory on Brussels sprouts cv. Cyrus for many years and reared in climate rooms at 22±2°C, 40–80% r.h, and a light regime of L16:D8. *Pteromalus puparum* were obtained from pupae of *Pieris rapae* and the closely related large cabbage white butterfly *P. brassicae* in June, 2005 and were thereafter reared on pupae of *P. brassicae*. Parasitized butterfly pupae were maintained in large Petri dishes (20-cm diameter) and were monitored until adult parasitoid emergence. Emerged adult wasps were then placed in separate Petri dishes and were provided with water and honey *ad libitum*. For parasitism, we used females that were 5- to 10-d old after adult emergence.

Development of Pieris rapae and Pteromalus puparum on B. oleracea To compare the effects of plant quality on herbivore and parasitoid development, *Pieris rapae* and *Pteromalus puparum* were reared on three wild strains and one cultivar of *B. oleracea*. To obtain eggs of *Pieris rapae*, one plant from each strain was placed in an insect-rearing cage containing at least 50 adult butterflies for 4 hr. After this period, plants were removed from the cages and placed in a rearing room until the eggs hatched. When the larvae reached the second instar (=L2), they were transferred to new plants with a distribution of nine larvae per plant. A total of six plants were used to rear 54 *Pieris rapae* per strain. During their development, caterpillars were allowed to develop and move around freely on the plants until they reached the final instar. When larvae had developed into late fifth instar, they were transferred to plastic containers (15×10×10 cm) with some leaf material from the plants they were previously feeding on. After pupation, the pupae were carefully collected and weighed on a Cahn C-29 microbalance (Cahn Instruments, Cerritos, CA, USA; accuracy, ±1 μg). A subset of these weighed pupae was used for parasitism by the parasitoid, *Pteromalus puparum* (see below). In addition to pupal mass, egg-to-pupa development time and survival (egg-to-pupa) were recorded when reared on the different plant strains. Plants with insects were maintained in a greenhouse compartment under the same conditions as described in "Plant" section.

A subset of 15 pupae reared from each strain of *B. oleracea* was selected to be parasitized by *Pteromalus puparum*, ensuring that there were no significant differences in mean pupal fresh mass (Table 2). This avoided the potential problem of disentangling the effects of pupal mass and plant strain on parasitoid development. Individual, mated parasitoid females that had previously been host-fed were provided with single pupae of *Pieris rapae* originating from one of the four *B. oleracea* strains in large Petri dishes for 24 hr (thus, the number of female parasitoids used was the same as for the number of pupae in Table 2). After this time, the female wasps were removed, and the parasitized butterfly pupae were monitored several times daily until adult parasitoid emergence. Newly emerged wasps were sexed, killed by freezing, and then placed in a preheated oven at 70°C for 3 d to obtain dry-mass data. All wasps within broods were then weighed on the Cahn balance. Development times were recorded as the number of days between the termination of the initial 24-hr parasitism period and adult eclosion. Unfortunately, some parasitoids failed to parasitize *Pieris rapae* pupae (i.e., adult butterflies enclosed), and these were eliminated from analyses. The sample size (hosts parasitized) was therefore: Cyrus=12, Kimmeridge=7, Old Harry=14, and Winspit=7.

Glucosinolate Analyses As an indicator of direct plant defense, we measured glucosinolate concentrations in leaf tissues of *B. oleracea* from the different strains. All plants that were used for insect development, six plants per plant strain, were also sampled for glucosinolate analysis. When leaf samples were taken, the damaged plant groups had been exposed to

Pieris rapae feeding for 7 d. Two discs, 7-mm diameter, were punched per leaf, one from each central part of a leaf half, and six fully unfolded leaves were sampled per plant. Leaf discs were pooled per plant in 2-ml Eppendorf vials and frozen in liquid nitrogen immediately after sampling and stored at −80°C. Samples were later freeze-dried and pulverized. Fifty-milligram aliquots of freeze-dried material were weighed in 2-ml centrifuge tubes. Glucosinolates were extracted and purified as described by van Dam et al. (2004). Glucosinolates were separated on a reverse phase C-18 column (Alltima C-18, 3 μm, 150×4.6 mm, Alltech,Deerfield, IL, USA) on high performance liquid chromatography (HPLC; Dionex, Sunnyvale, CA, USA) with an acetonitrile-water-gradient. Detection was performed with a Dionex PDA-100 photodiode array detector set to scan from 200 to 350 nm. For quantification, sinigrin (Sigma, St. Louis, MO, USA) was used as an external standard. Peaks were integrated at 229 nm for which standard response factors have been defined. Leaf tissues of *B. oleracea* contain aliphatic and indole glucosinolates. The aliphatic glucosinolates have a side chain length derived from a propyl (C3) or butyl (C4) group. These different glucosinolates (indoles, C3, C4) were identified based on their retention times and UV spectra compared to those of pure compounds (sinigrin, Sigma, St, Louis, MO., USA), glucotropaeolin, glucobrassicin (kindly provided by M. Reichelt, MPI for Chemical Ecology, Jena, Germany), or compared to a certified oil seed reference (EC Community Bureau of Reference BCR-367R, Fluka, Buchs, Switzerland). For a more detailed description of the method, see van Dam et al. (2004).

Statistical Analyses Survival of *Pieris rapae* was analyzed by using a chi-square test. Data on development time and pupal mass of *Pieris rapae*, brood size of *Pteromalus puparum*, and glucosinolate content in the different *B. oleracea* strains were analyzed by analysis of variance (ANOVA) with plant strain as factor. Normality and homogeneity of variance were checked by inspection of the residuals after model fitting and transformed if necessary. Brood size was square-root transformed; glucosinolate contents were log-transformed. The Tukey–Kramer method was used for multiple comparisons of means. For *Pteromalus puparum* development time and adult weight, multiple datapoints were associated to each host pupa. Therefore, these data were analyzed with a mixed model (REML) in Genstat 7. The analysis calculates Wald-type *F*-statistics and can process different sources of variation, enabling the use of all individuals rather than using averages per host (Piepho et al. 2003). Data were analyzed with strain, sex (male or female), and the interaction as fixed factors and host pupa as random factor. Predicted means and standard errors and individual comparisons estimated after model fitting were used for presentation of the results.

Results

Glucosinolate Profiles Total glucosinolate levels were higher in the wild populations than in the cultivar (Fig. 1). The rank order of total glucosinolates levels in the different populations is: Cultivar < Kimmeridge < Old Harry < Winspit. Glucosinolate concentrations of individual compounds differed significantly among the populations, except for glucoraphanin, progoitrin, and 4-hydroxy glucobrassicin (Table 1). In Winspit and Old Harry plants, the aliphatic glucosinolate with the highest concentration was gluconapin, although levels of gluconapin were significantly higher in Winspit than in Old Harry plants. In the cultivar, glucoiberin dominated the aliphatic glucosinolate profile. In contrast, Kimmeridge plants contained low levels of aliphatic glucosinolates (<2 μg/g DW all aliphatic glucosinolates combined). The wild populations contained significantly higher levels of the indole

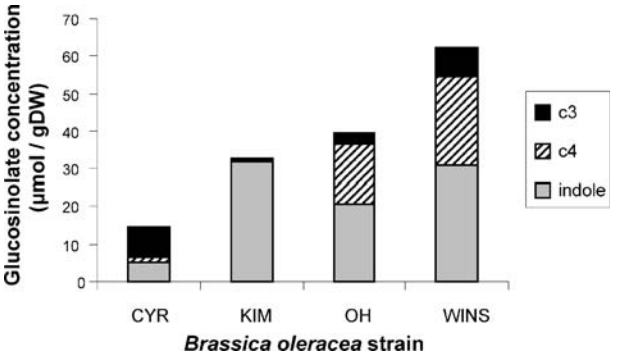

Fig. 1 Mean total glucosinolate concentrations (N=6) in foliage of one cultivar (*CYR*) and three wild populations of *B. oleracea* (*KIM*, *OH* and *WINS*) after 7 d of feeding by *Pieris rapae*. Total glucosinolates are divided into propyl (*C3*) derived aliphatic, butyl (*C4*) derived aliphatic, and indole glucosinolates

glucosinolate glucobrassicin than the cultivar. Furthermore, the Kimmeridge and Winspit plants contained higher amounts of neoglucobrassicin than the other two populations.

Development of Unparasitized Pieris rapae on Different Strains of Brassica oleracea Survival of *Pieris rapae* varied with plant strain in *B. oleracea* ($\chi^2_3 = 9.69$, P=0.021). Herbivore survival to pupation was almost 90% or higher in all strains with the exception of Kimmeridge plants, where only 76% of caterpillars successfully pupated (Fig. 2a).

Pupal mass varied with plant strain in *B. oleracea* plants ($F_{3,186}$=44.58, P<0.001; Fig. 2b). Pupae were largest when larvae of *Pieris rapae* were reared on the cultivar (Cyrus) and Old Harry plants and smallest when reared on Kimmeridge plants (Fig. 1). Plants from the Winspit population were of intermediate quality. Larval development time in *Pieris rapae* also varied with plant strain ($F_{3,186}$=4.99, P=0.002). *Pieris rapae* larvae took much longer to reach pupation on Kimmeridge plants than on Cyrus or Old Harry plants (Fig. 2c). Development time was also slightly prolonged on Winspit plants.

Table 1 Glucosinolate concentrations (mean±SE µmol/g DW) in foliage of four different populations of *Brassica oleracea* damaged by *Pieris rapae* for 7 d

Populations	Kimmeridge (N=6)	Old Harry (N=6)	Winspit (N=6)	Cultivar (N=6)	ANOVA $F_{3,24}$	P Value

Cyrus	12	165.97±3.13 a
Kimmeridge	7	161.67±8.00 a
Old Harry	14	162.83±4.65 a
Winspit	7	162.99±7.52 a

Wet weights with the same letter are not significantly different ($P>0.05$).

Pupal Mass of Pieris rapae Parasitized by Pteromlaus puparum Pupal mass of *Pieris rapae* selected for parasitism by *Pteromalus puparum* did not vary significantly across the different *B. oleracea* strains ($F_{3,36}=0.12$, $P=0.95$; Table 2). Irrespective of plant strain, the mean pupal mass of *Pieris rapae* that produced parasitoids was consistently between 160 and 165 mg (Table 1).

Primary Brood Size and Development of Pteromalus puparum on Pieris rapae pupae A total of 904 parasitoids emerged from 40 host pupae that had been reared on the four populations of *B. oleracea*. Brood size in *Pteromalus puparum* did not vary significantly when emerging from *Pieris rapae* pupae reared in the different strains of *B. oleracea* ($F_{1,36}=0.56$, $P=0.64$; Fig. 3). Typical brood sizes were in the range of 20–26 wasps per host pupa (Fig. 3).

Body mass in *Pteromalus puparum* varied among strains of *B. oleracea* (Wald=11.48, $P=0.009$), but the interaction between strain and sex was also highly significant (Wald=26.09, $P<0.001$). Overall, female wasps were larger than male wasps resulting in a significant difference between offspring sex (Wald=289.24, $P<0.001$). Parasitoid body mass varied among strains in male wasps (Wald=14.02, $P=0.003$; Fig. 4a) but not in female wasps (Wald=4.76, $P=0.19$; Fig. 4b). In male parasitoids, the largest wasps developed in Cyrus and Old Harry plants, whereas the smallest developed in plants from the Kimmeridge population. Winspit plants were of intermediate quality in this respect. Although there was no effect of plant strain in female wasps, the trend was similar to that observed in male wasps (Fig. 4a,b).

Egg-to-adult development time in *Pteromalus puparum* did not vary significantly among the different strains of *B. oleracea* (strain, Wald=2.89, $P=0.41$; strain × sex, Wald=0.58; $P=0.90$; Fig. 4c,d) but did vary with offspring sex (Wald=14.89, $P<0.001$). *Pteromalus puparum* is protandrous, with female wasps taking longer to complete their development than male wasps. Development in *Pteromalus puparum* takes about 3 wk to be completed.

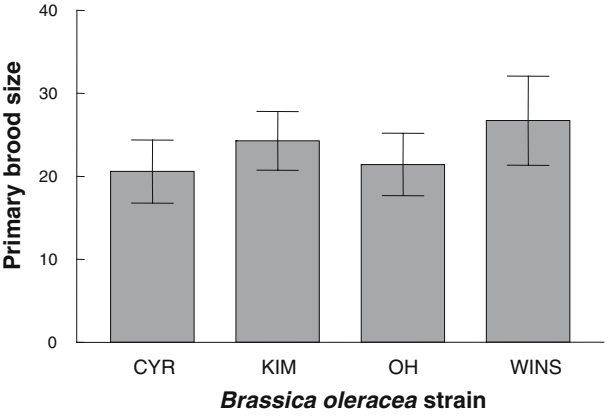

Fig. 3 Mean (±SE) brood size of *Pteromlaus puparum* emerging from pupae of *Pieris rapae* that were in turn reared on three wild populations and a cultivar of *Brassica oleracea*. Sample sizes (number of *Pieris rapae* pupae producing adult *Pteromlaus puparum* wasps from each plant population): Cyrus $N=12$, Kimmeridge $N=7$, Old Harry $N=14$, Winspit $N=7$

Mean (±SE) adult mass (mg), of **a** males wasps and **b** female wasps; mean (±SE) development time from oviposition until pupation (d) of **c** male wasps, and **d** female wasps. Means and standard errors are estimated after model fitting. *Bars with the same letters* are not significantly different (Tukey's tests, $P>0.05$). Sample size as in Fig. 2

Discussion

We found that pupal mass of *Pieris rapae* and adult body mass of *Pteromalus puparum* varied nonlinearly with total glucosinolate levels in the four strains of *B. oleracea*. However, both the herbivore and its parasitoid appeared to be similarly affected by differences in plant quality. In both species, the largest individuals developed on the cultivar and Old Harry plants, whereas body mass was greatly reduced when developing on plants from the Kimmeridge population. Winspit plants were of intermediate quality. In *Pieris rapae* (but not *Pteromalus puparum*), development time also was extended for larvae reared on Kimmeridge plants. The similarity in the effect of plant strain on the body mass of *Pieris rapae* and *Pteromalus puparum* reveals that qualitative constraints on the herbivore were passed from the second to the third trophic level. Several other studies have reported variable effects of plant quality, probably mediated by allelochemicals, on the performance of insect parasitoids and predators (Campbell and Duffey 1979; Barbosa et al. 1986, Gunasena et al. 1990; Havill and Raffa 2000; Harvey et al. 2003, 2005, 2007).

If herbivore and parasitoid performance were positively correlated with total glucosinolate levels, we would have predicted that the rank order of plant quality would be cultivar > Kimmeridge > Old Harry > Winspit. However, this was not the case, suggesting that total glucosinolate content does not determine plant quality for *Pieris rapae*. Glucosinolates and especially their hydrolysis products, (iso)thiocyanates, are known to be active against insect herbivory (Li et al. 2000; Wittstock et al. 2004). However, *Pieris rapae* has developed an effective detoxification mechanism, which redirects the hydrolysis of glucosinolates into less toxic nitriles through the activity of a nitrile specifier protein (Wittstock et al. 2004). This glucosinolate detoxification system may render *Pieris rapae* relatively insensitive to high levels of glucosinolates.

The only glucosinolate compound that affected the performance of *Pieris rapae* was the indole glucosinolate, neoglucobrassicin. High concentrations of neoglucobrassicin in plants from the Kimmeridge and Winspit populations corresponded to reduced biomass and prolonged development of the herbivore when reared on these two populations. Indole glucosinolates are known to be induced by herbivory and fungal infection and to affect the growth and development of insect herbivores deleteriously (Rostás et al. 2002; Irwin et al. 2003). Levels of primary metabolites, such as nitrogen and amino acids, were not measured in this study. Although levels of these are unlikely to be limiting in cruciferous plants for herbivores (Soler et al. 2005), significantly different levels of nitrogen have been recorded in wild and cultivated species of crucifers (Slansky and Feeny 1977). In addition, levels of the enzyme myrosinase, which catalyzes the hydrolysis of glucosinolates, may also have varied in the different populations (Mithen 2001; Fahey et al. 2002).

In wild populations of *B. oleracea* growing along the south coast of England, previous work in the field also found that there was considerable variation in the expression of glucosinolates (Mithen et al. 1995; Moyes et al. 2000). However, although glucosinolates measured in plants from the same populations as those used in this study exhibited similar differences among populations (e.g., with Winspit plants containing the highest and Kimmeridge plants the lowest concentrations), overall total levels of glucosinolates in all three were higher than recorded here (Moyes et al. 2000).

The effect of plant quality on parasitoid size in *Pteromalus puparum* was more pronounced in male than in female wasps. For instance, adult male wasps emerging from *Pieris rapae* that had fed on Kimmeridge plants were almost 50% smaller, in terms of dry mass, than conspecifics emerging from hosts that had fed on the cultivar or Old Harry plants. By contrast, this difference in females, which was not significant statistically, was

less than 25%. This variation may be attributable to differing levels of selection in male and female wasps to achieve optimal body size. Although large size presumably benefits both sexes, large females are assumed to gain more in terms of fitness than males because egg production is more constrained in small females than sperm production is in small males (Charnov 1982).

As mentioned earlier, Wittstock et al. (2004) reported that *Pieris rapae* larvae do not sequester glucosinolates during feeding, but instead utilize a nitrile specifier protein in the gut to break them down into more harmless nitriles that are excreted with the feces. This suggests that internal host fluids and tissues should be less toxic for natural enemies that attack insects such as *Pieris rapae* than is the case with hosts or prey that actively sequester plant toxins into their own body tissues (Hunter 2000). However, other studies with herbivores that detoxify or excrete harmful plant allelochemicals have shown that the development of parasitoids may still be correlated negatively with levels of allelochemicals in host diet (Campbell and Duffey 1979; Barbosa et al. 1986, Harvey et al. 2007). In some parasitoids, trace amounts of secondary plant metabolites have also been found in their by-products, including cocoon silk and/or the meconium (Barbosa et al. 1986; Bowers 2003).

In addition to the wild *B. oleracea* populations, genetic variation in the expression of allelochemicals has been studied extensively in only a few species of wild plants, including both forbs and trees (Fritz et al. 2003; Lawrence et al. 2003; Ode et al. 2004; Zangerl and Berenbaum 2005; Loney et al. 2006). Interpopulation differences in the expression of allelochemicals may be driven by the intensity of selection from herbivores, particularly if natural enemies are scarce or absent (Ode et al. 2004; Zangerl and Berenbaum 2005). Reciprocally, this can have profound effects on plant selection and performance in generalist herbivores, although studies have focused mainly on mammals, such as brush-possums in Australia (O'Reilly-Wapstra et al. 2005; Loney et al. 2006). However, population-related differences in secondary plant chemistry have also been shown to affect the performance of arthropod natural enemies such as parasitoids and predators (Harvey et al. 2005; this study). One of the major shortcomings of existing studies is that detailed information is lacking on the possible factors underlying variation in phenotypic traits such as defense in plants. This should be the focus of future research.

A recent study by Gols et al. (2007) revealed that even under controlled conditions, levels of glucosinolates in shoots of two species of cultivated crucifers changed dramatically over the course of a single growing season. As a result, the development of two insect herbivores and their parasitoids also differed in each of three replicates that were performed (Gols et al. 2007). This suggests that, had further replicates been performed, the effects described here may also have varied temporally in line with changes in plant quality. Nonetheless, under a given set of conditions, we have shown that population-related differences in plant quality can have significant and uniform effects on the development of a herbivore and its parasitoid. Further studies are being planned in which spatial and temporal aspects of interactions involving natural and manipulated populations of *B. oleracea* and its lepidopteran herbivore–parasitoid complexes are investigated. These studies will help to explain factors accounting for the dramatic differences in secondary chemistry among populations of wild cabbage along the south England coast and will shed further light on the relative importance of biotic and abiotic processes shaping direct defense plant strategies in plants.

Acknowledgments The authors thank Leo Koopman and Andre Gidding at Wageningen University, NL, for supplying larvae of *Pieris rapae*, James Bullock of the Centre for Ecology and Hydrology in Dorset, England, for supplying seeds from wild cabbage populations, Nicole van Dam for interpreting glucosinolate profiles and Wim van der Putten and Roxina Soler for their constructive comments on an earlier version of the manuscript.

protecting against future infection by pathogens (Friedrich et al. 1996). The plant elicitor benzo-(1,2,3)-thiadiazole-7-carbothioic acid *S*-methyl ester (BTH), also known as acibenzolar-*S*-methyl and Actigard®, is a functional analog of salicylic acid that activates SAR in both monocots and dicots (Gorlach et al. 1996; Lawton et al. 1996). Foliar application of BTH induces pathogen response genes typically associated with SAR and provides protection against an array of bacterial, fungal, and viral plant pathogens in cotton and other plants (Friedrich et al. 1996; Gorlach et al. 1996; Inbar et al. 1998; Colson-Hanks et al. 2000; Maxson-Stein et al. 2002; Bokshi et al. 2003; Zhu et al. 2003; Baysal et al. 2005). Further, foliar application of BTH to tomato foliage was shown to decrease leafminer and whitefly densities (Inbar et al. 1998; Nombela et al. 2005) and aphid population growth (Boughton et al. 2006). Because of the efficacy of BTH in protecting against phytopathogens and some types of insects in several cropping systems, this elicitor, along with other SAR activators, may be used with increasing frequency in integrated pest management (IPM) systems (reviewed in the study of Vallad and Goodman 2004).

While SAR-activated plants may be protected from phytopathogens, they may also be more vulnerable to chewing herbivores. Lepidopteran larvae feeding on naïve plants induce a variety of directly toxic and/or antinutritive compounds through the jasmonate-dependent wound response pathway (reviewed in the work of Duffey and Stout 1996; Bi et al. 1997a; Chen et al. 2005; reviewed in the paper of Felton 2005). The compounds induced in response to herbivore feeding reduce lepidopteran growth and can alter lepidopteran susceptibility to insect pathogens, depending on the system (Ali et al. 1998; Hoover et al. 1998b). SAR induction can inhibit this jasmonate-dependent response pathway (reviewed in the study of Felton and Korth 2000; Thaler et al. 2002; Cipollini et al. 2004) and may make plants previously challenged by phytopathogens more suitable hosts for lepidopteran larvae than naïve plants or plants previously damaged by chewing herbivores (Stout et al. 1999; Inbar et al. 2001; reviewed in Rostas et al. 2003). Although the apparent potential for SAR induction to influence lepidopteran susceptibility to insect pathogens and other natural enemies is great, the extent to which there is compatibility of SAR with natural enemies of lepidopterans has not been fully explored (but see the work of Rostas and Hilker 2003 for a review).

One class of insect natural enemies are the baculoviruses, a group of orally infectious, dsDNA viruses of arthropods that commonly infect lepidopteran larvae (reviewed in the paper of Bonning 2005). The family Baculoviridae is divided into the genera Granulovirus and Nucleopolyhedrovirus (NPV) (Theilmann et al. 2005). NPVs are found in nature as environmentally resistant proteinaceous occlusion bodies (OB) on host plant foliage, and susceptible larvae become infected when they consume at least one OB (reviewed in the study of Bonning 2005). Upon ingestion, the OB is degraded in the alkaline midgut of the host (Pritchett et al. 1982), releasing occlusion-derived virions, which pass through the peritrophic matrix and infect midgut epithelial cells (Granados and Lawler 1981). NPVs replicate in the nucleus of infected cells; progeny virions bud from infected midgut cells and enter associated tracheolar cells and hemocytes, spreading the infection to other tissues, eventually killing the host.

Most baculoviruses are highly host specific, infecting, at the extremes, from 1 to 40 lepidopteran species (reviewed in the paper of Cory and Myers 2003). Because of their high degree of host specificity, baculoviruses have been considered candidate pest control agents (reviewed in the work of Szewczyk et al. 2006). The potential of baculoviruses as bioinsecticides has not been fully realized due in part to the high cost of production, inactivation by ultraviolet light, and a slow speed of kill. As these issues are addressed, baculoviruses could be implemented more frequently as a part of IPM strategies. Thus, it is important to assess how baculoviral efficacy is influenced by other components of IPM. In

this study, we analyzed whether cotton foliar peroxidase activity and quantities of phenolic compounds change after SAR induction by BTH. Furthermore, we evaluated the influence of SAR induction on pathogenicity of the baculovirus *Autographa californica* multiple nucleopolyhedrovirus (AcMNPV) to *Heliothis virescens* larvae.

Methods and Materials

Insect Rearing Heliothis virescens eggs were acquired from the North Carolina State University Insectary, from a colony that started in 1997 (Raleigh, NC, USA). Larvae were grown in groups through the third stadium on semisynthetic diet (Southland Products, Lake Village, AR, USA) in wax-lined paper cups (Xpedx, Harrisburg, PA, USA) at 25°C and a 16L:8D photoperiod.

Plant Growing Conditions Cotton, *Gossypium hirsutum* cv. Maxxa, seeds were donated by the California Planting Cotton Seed Distributors (Bakersfield, CA, USA). Seeds were sown individually in sterile soil in plastic pots, fertilized at planting with slow-release 14–14–14 fertilizer, and grown in an Conviron® environmental chamber under a day:night temperature regime of 29:24°C and a 16L:8D photoperiod.

Plant Treatments BTH (Actigard®) was provided by Syngenta/Novartis (Greensboro, NC, USA). A 0.056-g/l solution of BTH (Actigard® 50WG) in ultrapure water was sprayed to run off on upper leaf surfaces of six-node cotton plants. Control plants were left untreated or sprayed with ultrapure water. Plants to be treated were removed from the chamber for application of solutions to prevent drift to control plants. The concentration of 0.056 g/l used is similar to concentrations of 0.035 g/l (Colson-Hanks and Deverall 2000) and 0.05 g/l (Jabaji-Hare and Neate 2005) applied to cotton foliage in previous studies, yet is much lower than the 0.8 g/l applied by Inbar et al. (2001). We found higher concentrations than those used here phytotoxic to this cultivar of cotton.

Four days after treatment, the top two fully expanded leaves of all control and BTH-treated plants were removed. Foliage removed for use included leaves 5 and 6 (the cotyledons were not counted) from eight-node plants. A subsample of intact leaves from the water and BTH treatment groups was frozen in liquid nitrogen and stored at −80°C for phytochemical assays. Foliage from untreated and BTH-treated plants was fed to larvae to determine the influence of SAR activation on pupal weight and viral mortality.

Foliar Assays Peroxidase activity was measured in untreated and BTH-treated cotton foliage using a guaiacol/hydrogen peroxide substrate by measuring the change in absorbance at OD_{470}, as described previously (Bi et al. 1997a), except that the assay was modified for use with a microplate reader. Peroxidase activity is reported as change in absorbance, with one unit of activity=0.001 ΔOD_{470} per milligram of foliage per minute. Three untreated and three BTH-treated plants were used for the peroxidase assay, with three measurements conducted per plant. Leaves from positions 5 and 6 were combined and used from each plant.

Phenolic compounds were extracted from water-treated and BTH-treated cotton foliage in 50:50 acetone to water at 60°C for 20–24 hr. This extract was used for the following assays. Total phenolics were measured with the Folin-Ciocalteau reagent with caffeic acid as the standard at OD_{720} (Singleton and Rossi 1965). Dihydroxyphenolics were measured by using the 0.5% diphenylborinic acid–ethanolamine complex with chlorogenic acid as the

standard at OD_{365} (Broadway et al. 1986). Condensed tannins were measured with the vanillin–HCl assay with catechin as the standard at OD_{500} (Price et al. 1978; Bi et al. 1997a). A SpectraMax 190 (Molecular Devices, Sunnyvale, CA, USA) was used for all of the above spectrophotometric measurements. For the dihydroxy- and total phenolic assays, five water-treated and three BTH-treated plants were used, with three measurements made per plant. For the condensed tannin assay, three water-treated and two BTH-treated plants were used, with three measurements made per plant. Leaves from positions 5 and 6 were combined and used from each plant. The same foliar samples were used for all of the above phenolic assays.

Influence of SAR Induction on Time to Pupation and Pupal Weight Newly molted second instars of *H. virescens* were transferred individually to 30 ml plastic cups containing artificial diet or foliage from BTH-treated or untreated cotton plants and were allowed to feed *ad libitum*. Larvae were maintained at 28°C until pupation, and fresh foliage was provided as needed. Weight was recorded at pupation, with 31–38 pupae weighed per treatment group. Foliage was taken from 50 BTH-treated and 50 control plants to feed larvae; within each treatment group, foliage was randomly distributed among larvae. Foliage was harvested from treated plants 4–7 d after BTH application from nonsquaring plants. We have found that foliar peroxidase activity remains significantly elevated in BTH-treated plants relative to controls for at least 7 d after treatment. Foliage was concurrently harvested from control plants.

Virus Preparation AcMNPV-hsp70/*lacZ*, provided by Suzanne Thiem (Michigan State University, East Lansing, MI, USA), was amplified in *H. virescens* larvae. Occlusion bodies (OB) were harvested from virus-killed cadavers and partially purified by using ultrapure water as described previously (Hoover et al. 1995), quantified with a hemacytometer, and stored at 4°C in neutrally buoyant 60% glycerol with 0.002% sodium azide (Engelhard et al. 1994). We used a genetically modified construct of AcMNPV because, although this experiment did not require lacZ expression, concurrent experiments did, and this gene does not affect viral performance.

Influence of SAR Induction on Viral Mortality of H. virescens Newly molted fourth instars of *H. virescens* were transferred individually to a 30-ml plastic cup containing artificial diet or foliage from BTH-treated or untreated cotton plants and were allowed to feed for 8 hr. Eight hours postmolt was used because it was the earliest time point at which the midgut was full of plant material or artificial diet for all larvae based on the time at which frass was first produced. The susceptibility of *H. virescens* larvae to fatal viral infection decreases as larvae age within an instar, so controlling for age postmolt is essential (Washburn et al. 1995). Foliage was taken from 35 BTH-treated and 35 control plants to feed larvae. Within each treatment group, harvested foliage was randomly distributed among larvae.

After feeding for 8 hr, larvae were microinoculated *per os* with 95 OBs of AcMNPV-hsp70/*lacZ* in a 1-ml aliquot by using a PAX 100 microapplicator (Burkard Scientific, Middlesex, UK) holding a 1-ml tuberculin syringe with 32-gauge blunt needle (Popper Precision Instruments, Lincoln, RI, USA). After inoculation, the larvae were returned to their respective preinoculation food of artificial diet or foliage from BTH-treated or untreated cotton plants. Insects were maintained at 28°C and were checked daily for mortality or pupation. All cotton-fed larvae were transferred to artificial diet after molting to the fifth instar for ease of handling. This transfer does not influence mortality since larvae clear midgut infections during the first molt after viral challenge (Washburn et al. 1995). Two trials were performed with larvae fed with BTH-treated and untreated cotton foliage,

and three trials were performed with larvae fed with artificial diet. The first trial included all three treatment groups; subsequent trials included artificial diet and either BTH-treated or untreated cotton foliage. Some 25 to 30 artificial diet-fed larvae and 40–50 cotton-fed larvae were inoculated for each trial.

Data Analysis Data were analyzed with SAS (SAS Institute 2003). Measurements of foliar peroxidase activity and quantities of phenolic compounds were compared between control and BTH-treated plants using the general linear model with Tukey post hoc analysis (proc GLM). The effects of food and BTH treatment on *H. virescens* time to pupation and pupal weights were also determined using the general linear model with Tukey post hoc analysis (proc GLM). The influence of food, BTH application, and their interaction on the proportion of *H. virescens* larvae killed by virus was assessed using the analysis of variance for categorical data (proc CATMOD) (Zar 1999).

Results

Foliar BTH treatment increased cotton peroxidase activity 2.5-fold over that observed in untreated plants (F=6.49, df=1, P=0.029; Fig. 1), indicative of induction of systemic acquired resistance (SAR) (Inbar et al. 2001). Benzo-(1,2,3)-thiadiazole-7-carbothioic acid *S*-methyl ester application also resulted in large increases in certain phenolic classes. For instance, we observed a nearly twofold increase in total phenolics (F=31.62, df=1, P=0.011; Fig. 2) and a 2.4-fold increase in condensed tannins in foliage of BTH-treated plants (F=12.58, df=1, P=0.038; Fig. 3) compared with water-treated controls. However, application of BTH did not significantly affect the foliar concentration of dihydroxyphenolics (F=1.31, df=1, P=0.335; Fig. 3).

Consumption of control foliage by *H. virescens* larvae increased time to pupation, relative to artificial diet and BTH-treated foliage (F=24.82, df=2, P<0.001) (Fig. 4). Interestingly, the developmental rate of larvae fed with artificial diet and those fed with BTH-treated foliage was similar (Fig. 4). In contrast, consumption of induced foliage did not impact pupal weight (Fig. 5) nor did we observe a marked increased in consumption of BTH-treated cotton foliage relative to untreated foliage (data not shown). The pupal weights of larvae fed with untreated or induced foliage were similar (F=0.66, df=1, P=0.421).

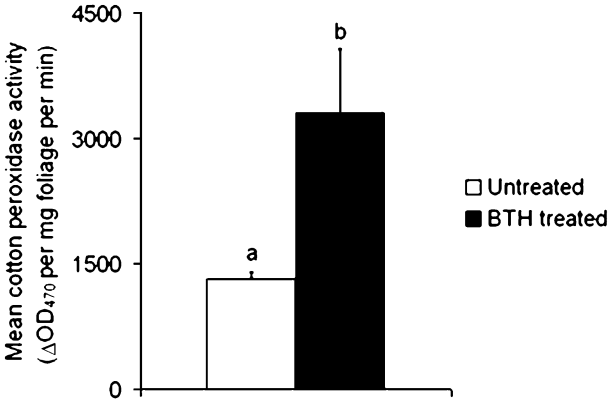

Fig. 1 Mean peroxidase activity measured at 96 hr post-spray, shown as change in activity per milligram of cotton foliage per minute. *Error bars* represent one standard error of the mean; N=3 plants per treatment. The general linear model with Tukey post hoc analysis was used to compare peroxidase activities; *small letters* indicate significant differences between treatments (F=6.49, df=1, P=0.029)

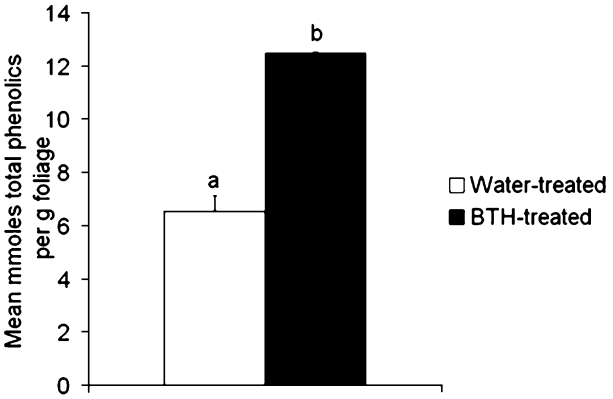

Fig. 2 Mean concentrations of total phenolics measured at 90 and 96 hr post-spray with water or BTH. *Error bars* represent one standard error of the mean. N=5 plants for water treatment and 3 for BTH treatment. The general linear model with Tukey post hoc analysis was used to compare levels of phenolics; *small letters* indicate significant differences between treatments (F=31.62, df=1, P=0.011)

Further, larvae fed with artificial diet displayed dramatically higher pupal weights than larvae fed with either treated or untreated cotton foliage (F=95.24, df=2, P<0.001; Fig. 5).

Although some classes of phenolics and peroxidase activities were induced by BTH treatment, consumption of induced foliage did not significantly influence *H. virescens* larval susceptibility to a well-known natural enemy of this host, the baculovirus AcMNPV (Fig. 6). Larvae fed with BTH-treated cotton foliage experienced a similar level of viral mortality as larvae fed with untreated foliage (χ^2=1.11, df=1, P=0.292). However, when larvae consumed induced or uninduced foliage, they were 1.3-fold more resistant to mortal infection than larvae fed with artificial diet (χ^2=21.64, df=1, P<0.001; Fig. 6).

Discussion

Application of BTH to foliage of a number of plant species is known to induce SAR, conferring resistance to phytopathogens (Friedrich et al. 1996; Inbar et al. 1998; Maxson-

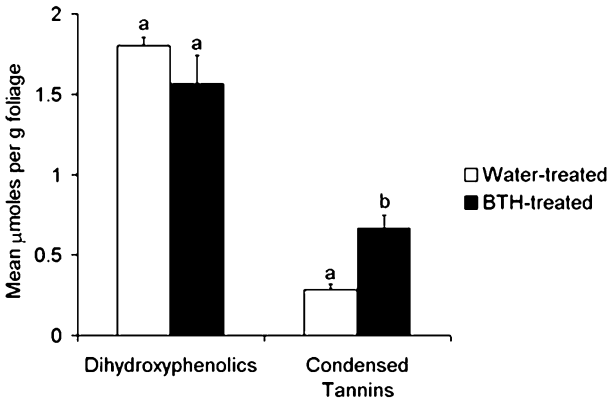

Fig. 3 Mean concentrations of dihydroxyphenolics and condensed tannins measured at 90 and 96 hr post-spray with water or BTH. *Error bars* represent one standard error of the mean. For the dihydroxyphenolics assay, N=5 plants for water treatment and 3 for BTH treatment. For the condensed tannin assay, N=3 plants for water treatment and 2 for BTH treatment. The general linear model with Tukey post hoc analysis was used to compare levels of phenolics; *small letters* indicate significant differences between treatments (dihydroxyphenolics: F=1.31, df=1, P=0.335; condensed tannins: F=12.58, df=1, P=0.038)

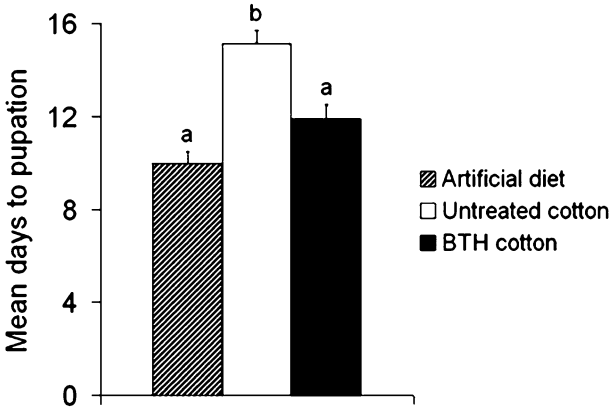

Fig. 4 Mean time to pupation of *H. virescens* fed with artificial diet or foliage from untreated or BTH-treated cotton plants from second instar to pupation. *Error bars* represent one standard error of the mean; N=35 larvae fed with artificial diet, 37 fed with untreated foliage, and 22 fed with BTH-treated foliage. The general linear model with Tukey post hoc analysis was used to compare times to pupation; *small letters* indicate significant differences between treatments (F=24.82, df=2, P<0.001)

Stein et al. 2002; Bokshi et al. 2003; Baysal et al. 2005) and, in some cases, to phloem-feeding insects such as aphids and whiteflies (Nombela et al. 2005; Boughton et al. 2006). However, SAR activation by BTH or salicylic acid in tomato or cotton foliage did not influence growth rate or survival of larval *Helicoverpa zea* (Bi et al. 1997b; Stout et al. 1999; Inbar et al. 2001). We found that although SAR activation by application of BTH to cotton plants increased foliar peroxidase activity, condensed tannins, and total phenolics, consumption of induced foliage did not affect *H. virescens* pupal weight compared with water-treated or untreated foliage. Likewise, Inbar et al. (2001) reported that while BTH applied to cotton foliage activated SAR—as evidenced by increased foliar peroxidase, chitinase, and β-1,3-glucanase—consumption of foliage from BTH-treated plants did not alter growth or survival of larval *Helicoverpa armigera*. Similarly, *H. zea* larvae fed with foliage from cotton plants treated with either salicylic acid or methyl salicylate grew as well as those that fed on untreated foliage (Bi et al. 1997b).

Increases in foliar phenolic levels after activation of the SAR pathway by BTH have been recently reported in strawberries (Hukkanen et al. 2007). Here, we found a similar

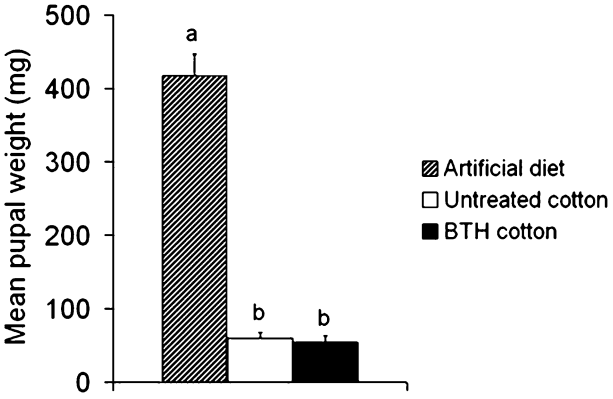

Fig. 5 Mean pupal weight of *H. virescens* fed with artificial diet or foliage from untreated or BTH-treated cotton plants from second instar to pupation. *Error bars* represent one standard error of the mean; N=35 larvae fed with artificial diet, 37 fed with untreated foliage, and 22 fed with BTH-treated foliage. The general linear model with Tukey post hoc analysis was used to compare pupal weights; *small letters* indicate significant differences between treatments (artificial diet versus cotton foliage: F=95.24, df=2, P<0.001; untreated versus BTH-treated cotton: F=0.66, df=1, P=0.421)

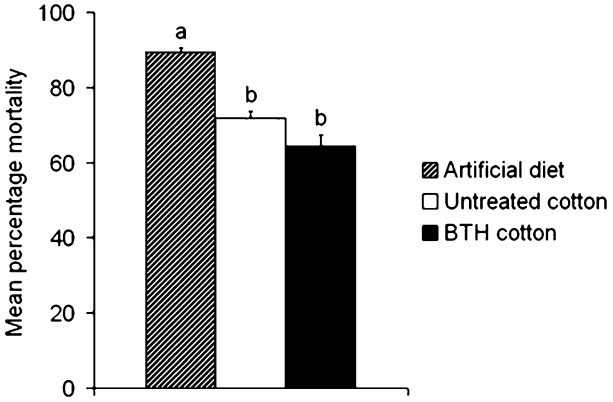

Fig. 6 Mean percentage mortality of *H. virescens* larvae fed with artificial diet or foliage from untreated or BTH-treated cotton plants before AcMNPV inoculation. The influence of food and BTH treatment on larval mortality was determined using the analysis of variance for categorical data (artificial diet versus cotton foliage: χ^2=21.64, *df*=1, *P*<0.001; untreated versus BTH-treated cotton: χ^2=1.11, *df*=1, *P*=0.292). *Error bars* represent one standard error of the mean; *N*=23–33 larvae fed with artificial diet, 38–53 larvae fed with untreated foliage, and 45–49 larvae fed with BTH-treated foliage. Two trials were performed with larvae fed with BTH-treated and untreated cotton foliage, and three trials were performed with larvae fed with artificial diet

result in BTH-treated cotton foliage. However, despite the induction of condensed tannins in treated foliage, we did not observe any influence of BTH treatment on *H. virescens* pupal weight. There is a large body of literature on cotton and other plants, suggesting that condensed tannins reduce growth in lepidopteran larvae (Feeny 1968; Chan et al. 1978; Kopper et al. 2002; Nomura and Itioka 2002; but see the study of Ayers et al. 1997 for a review). Also, while consumption of condensed tannins extracted from cotton has been shown to reduce larval mass in artificial diet experiments (Chan et al. 1978; Klocke and Chan 1982; Reese et al. 1982; Navon et al. 1983), the opposite is true *in planta*, where greater levels of foliar condensed tannins have either been positively correlated with or shown not to influence larval weight (Hanny 1980; Hedin et al. 1983; Mulrooney et al. 1985; McColl and Noble 1992; Smith et al. 1992). Although our results agree with previous experiments that used plant foliage, the tannin levels observed in the plants used in our experiments were fairly low, possibly resulting from suboptimal lighting (Dudt and Shure 1994). Thus, we cannot rule out the possibility that tannin levels in our plants were simply too low to have an effect on *H. virescens* pupal weight. At the same time, inconsistencies in experimental outcomes between artificial diet and *in planta* are common and likely reflect the numerous differences in chemical composition between artificial diet and plant foliage. The activity of specific phenolic compounds is known to depend in large part on chemical mixture and the environment in which reactions occur (Bernays et al. 1989; Appel 1993; Duffey and Stout 1996; Hoover et al. 1998b, c).

Just as we did not observe an influence of SAR activation on growth of *H. virescens* larvae, we also saw no influence of induced foliage on *H. virescens* larval susceptibility to baculoviral infection despite significant increases in peroxidase activity and condensed tannins. Peroxidase, condensed tannins, and dihydroxyphenolics have been implicated in altering baculoviral pathogenicity to lepidopteran larvae (Felton et al. 1987; Keating et al. 1988; Felton and Duffey 1990; Young et al. 1995; Hoover et al. 1998a, b; Ali et al. 1999). In particular, dihydroxyphenolics and tannins decrease mortal baculovirus infection in artificial diet experiments (Keating et al. 1989; Felton and Duffey 1990; Young et al. 1995).

While these compounds were demonstrated to influence baculoviral efficacy individually, they may act differently in mixture. Hoover et al. (1998b) found that, when considered individually, both peroxidase and condensed tannins reduced mortality of *H. virescens* larvae fed with cotton foliage. However, when considered in a mixed model, peroxidase reduced larval mortality, whereas condensed tannins increased mortality (Hoover et al. 1998c). Because we measured increased levels of both of these phytochemicals in induced foliage, it is possible that the failure of induced plants to affect *H. virescens* larval mortality may be explained by offsetting influences of peroxidase and condensed tannins, as suggested by the model of Hoover et al. (1998b).

The effect of SAR may have been different if the larvae had been fed through their entire life cycle on foliage. The underlying impetus for our experimental design was to specifically address a hypothesis suggested by Hoover et al. (1998c) that states that foliar peroxidase is negatively related to larval mortality by virus during the process of initial infection. Exposure to induced foliage during the instar in which viral challenge occurs was sufficient to test the proposed hypothesis but may not reflect what would happen in the field with long-term exposure, particularly given that feeding on plants throughout an insect's life cycle can have profound effects on insect–pathogen interactions (see review by Cory and Hoover 2006).

In summary, despite significant changes in several phytochemical components in BTH-treated plants, activators of SAR are likely to be compatible with microbial control agents such as baculoviruses in an IPM system.

Acknowledgments We thank Tony Pomicter and Mike Grove for their assistance with experiments and phenolic assays and Diana Cox-Foster, Kelly Johnson, and A. Daniel Jones for their valuable discussions. We thank Syngenta for supplying the BTH. This work was a part of the dissertation of R.P. and was funded by the National Science Foundation Integrated Organismal Biology Program, Grant No. IBN-0077710.

Introduction

Plants defend themselves against herbivorous insects with a plethora of mechanical and chemical devices. Next to constitutive defense, plants can also respond to herbivore attack with increased metabolite production and enzyme activities (Dicke and Hilker 2003). These induced defenses are thought to have evolved as a cost-saving strategy for plants growing under nutrient limited conditions (Zangerl 2003). Specialist herbivores can show various countermeasures as adaptations to the specific constitutive metabolites of their host plants (Hartmann and Ober 2000; Agerbirk et al. 2006), and some might also be able to cope with induced defenses. However, their performance and behavior may be impacted (Agrawal and Kurashige 2003). In contrast, generalists invest in more common detoxification strategies (Wadleigh and Yu 1988; Schoonhoven et al. 1998) but lack specific adaptations. Thus, from the plants perspective, there exists a dilemma: While they defend themselves chemically against a variety of generalists, nondeterred specialists can use these metabolites as host finding and oviposition cues. Furthermore, highly adapted specialists use plant toxins for their own protection against members of the third trophic level by sequestration ("lethal plant defense paradox", Fordyce 2001). For the plant, it might be adaptive to respond differently to attack depending on the inducing organism, e.g., with regard to the degree of specialization of the feeding insect (Baldwin and Preston 1999; Schwachtje et al. 2006).

In Brassicaceae, glucosinolates and their hydrolyzing enzymes, the myrosinases, form a constitutive defense system against herbivores and microorganisms (Halkier and Gershenzon 2006). Glucosinolates consist of a thioglucoside moiety linked to a variety of amino-acid-derived side chains (Bones and Rossiter 2006). Myrosinases (thioglucoside glucohydrolases, EC 3.2.1.147) occur in various isoforms that are either soluble under nondenaturing conditions or insoluble because of complex formation with myrosinase-binding proteins (MBP; Rask et al. 2000; Eriksson et al. 2002). The myrosinase subunits of the insoluble complexes are active, and a strongly modified protocol for the quantification of insoluble as well as soluble fractions of myrosinase has been proposed (Müller and Martens 2005; Martin and Müller 2007). A variety of specialist insects developed means of circumvention and detoxification of the glucosinolate–myrosinase system (Bones and Rossiter 2006, and references therein). Larvae of the turnip sawfly *Athalia rosae* L. (Hymenoptera: Tenthredinidae), which feed on different species of Brassicaceae, sequester certain glucosinolates of their host plants within their hemolymph (Müller et al. 2001; Müller and Wittstock 2005) and can use these for their own defense (Müller et al. 2002; Müller and Brakefield 2003).

Glucosinolates and myrosinases have also been shown to be inducible in many ways (e.g., Rostás et al. 2002; Pontoppidan et al. 2005; see also references in Martin and Müller 2007). Feeding by *A. rosae* larvae induced short-term increases in levels of glucosinolates and myrosinase activities in damaged leaves of *Sinapis alba* L. cv. Salvo (Martin and Müller 2007). However, the specificity of this effect with regard to the inducing agent and its

ecological relevance for the glucosinolate-sequestering herbivore remained unclear. In general, the specificity of a plant's induction response is dependent upon the inducing agent and the feeding mode of the herbivore (Walling 2000; Dicke and Hilker 2003). Furthermore, the vascular architecture can constrain induction patterns within a plant (Orians 2005). In Brassicaceae, studies comparing induction responses to three agents, mechanical damage, specialist, and generalist feeding, have to date focused only on gene expression (Reymond et al. 2004). In pairwise comparisons, changes in gene expression and in chemical and mechanical defenses have been found (Agrawal 2000; Reymond et al. 2004; de Vos et al. 2006; Widarto et al. 2006). However, effects on myrosinases have been studied mainly in isolation from glucosinolates (but see Siemens and Mitchell-Olds 1998; Andréasson et al. 2001). Specialist behavior and performance is affected to different degrees by induced responses of plants (Agrawal 2000; de Vos et al. 2006). None of the insects investigated with regard to behavior uses plant defenses for its own protection.

The aims of this study were to investigate the specificity of induction responses of *S. alba* that we described recently (Martin and Müller 2007) and to characterize its ecological relevance for larvae and for adult females of the glucosinolate-sequestering specialist *A. rosae*. Specificity of response was investigated at different levels. At the level of induction mode, plants were treated in three different ways with either mechanical wounding, feeding by generalist caterpillars, or by the specialist larvae of *A. rosae*. At the plant level, we used a different cultivar of *S. alba* than in a previous study. We determined glucosinolate concentrations and myrosinase activities (soluble and insoluble fractions) in local as well as adjacent older and younger leaf tissues after 24 hr of induction on *S. alba* cv. Silenda plants. To investigate potential directions for signal transport, connectivity of phloem bundles between these tissues was followed with a dye. Subsequent behavioral studies with larvae and with adult females of *A. rosae* were performed to evaluate the consequences of specific induction responses of the plant on the specialist. In this way, a triple comparison of induction effects of a generalist, a specialist, and wounding was investigated with respect to both induced plant response and induced resistance against a specialist herbivore.

Methods and Materials

Planting and Induction Experiment Seeds of *S. alba* L. cv. Silenda (Kiepenkerl, Norken, Germany) were sown in mid-January 2005 and kept in a climate chamber at 25°C, 16:8 hr L/D cycle, and 70% relative humidity (light source: Osram L 58 W/25 Universal White, 4150 lumens, Osram, Munich, Germany). After 7 d, seedlings were transferred to individual pots (9 cm diameter; 7 cm height) containing unfertilized soil (peat, pH 6). After 21 d, when five to six true leaves had developed, plants received one of the following five treatments on the second youngest leaf to investigate the specificity of the plant's response: (a) one male larva of the specialist *A. rosae* (6 d after egg hatch, third instar; larval weight 32.7±1.6 mg, mean± SE, N=8) enclosed with the leaf in a muslin bag (8×10 cm, 1 mm mesh width); (b) one caterpillar of the generalist *Spodoptera frugiperda* J. E. Smith (Lepidoptera: Noctuidae; 7 d after egg hatch, third instar; caterpillar weight 21.7±1.5 mg, mean±SE, N=8) in a bag; (c) mechanical damage made by three holes (one in the morning at 10 A.M., one in the afternoon at 4 P.M., and one the next morning at 8 A.M.) punched with a cork borer (1.5 cm diameter) and the leaf enclosed in a bag; (d) a bag only; and (e) no treatment. Effects of herbivore damage on myrosinase gene expression had been shown to be more resembled by cutting with scissors than by crushing with forceps (Pontoppidan et al. 2005). Therefore, we used a cork borer as a cutting tool to remove equivalent amounts of leaf tissue. Seven to eight replicates

per treatment were prepared. Plants of all treatments were placed in random order in the climate chamber. Sawfly larvae were taken from a laboratory culture established from a field collection in Germany the previous autumn and kept on *S. alba*. Caterpillars of *S. frugiperda* were obtained from Bayer CropScience AG (Monheim, Germany) as eggs and were reared on an artificial diet based on kidney beans (modified from King and Leppla 1984).

Insects and muslin bags were removed after 24 hr, and photos were taken of treated leaves to determine the pattern and degree of damage. Samples for chemical analyses were taken from damaged leaves as well as from the flanking upper and lower leaves. Leaves were cut longitudinally, weighed, frozen in liquid nitrogen, and stored at −80°C for later analysis. This allowed us to analyze both glucosinolate and myrosinase levels from the same leaves.

Analysis of Glucosinolates Frozen samples were freeze-dried, weighed, and pulverized in a mill (Retsch, MM301, Haan, Germany). Glucosinolates were extracted in 80% methanol after addition of 20 µl of a 5 mM solution of 2-propenylglucosinolate (Merck, Darmstadt, Germany) as internal standard. Glucosinolate analysis was performed by conversion to desulfoglucosinolates as described elsewhere (Agerbirk et al. 2001). For analysis of desulfoglucosinolates, samples were subjected to HPLC analysis on a 1100 Series chromatograph (Hewlett-Packard, Waldbronn, Germany) with a quaternary pump and a 1,040 M diode array detector. Elution was accomplished on a Supelco C-18 column (Supelcosil LC-18, 250×4.6 mm, 5 µm, Supelco, Bellefonte, PA, USA) with a gradient (solvent A, water; solvent B, methanol) of 0–5% B (10 min), 5–38% B (24 min), followed by a cleaning cycle. Desulfoglucosinolates were identified by comparison of retention times and UV spectra to those of purified standards and identities that had been further confirmed by liquid chromatography/mass spectrometry (Müller et al. 2001; Müller and Martens 2005). Peaks were quantified by peak area at 229 nm (4 nm bandwidth) relative to the area of the internal standard peak, by applying the response factors as used by Brown et al. (2003) and Martin and Müller (2007).

Analysis of Myrosinase Activity Myrosinase activity was determined by photometric quantification of released glucose from the externally added substrate *p*-OH-benzylglucosinolate (obtained from glucosinolates.com, Denmark), which is the dominant glucosinolate in *S. alba*. The myrosinase extraction protocol followed Müller and Martens (2005) and Martin and Müller (2007). Frozen leaf material was pulverized in a mill, extracted in buffer (200 mM Tris, 10 mM EDTA, pH 5.5) on ice, centrifuged, and supernatants were purified via ion-exchange columns (DEAE Sephadex A-25 welled in acetic acid buffer; Sigma-Aldrich, St. Louis, MO, USA) to eliminate internal glucosinolates. Purified extracts served as source to determine soluble myrosinase activities. The remaining pellets were suspended in buffer, and two further tests were performed. Half of each pellet suspension was diluted with buffer to determine the activity of insoluble myrosinases. The other half was centrifuged, and supernatants were discarded. The resulting pellets were suspended in half of the corresponding purified extract. Thereby, a suspension was obtained with a reconstituted ratio of soluble and insoluble myrosinases similar to the crude, unpurified extract but without interfering internal glucosinolates. Soluble protein concentrations of purified extracts were determined according to Bradford (1976) and were adjusted to protein concentrations of 200 µg ml^{-1}. Both suspensions were diluted the same way as the purified extracts.

Activities of soluble and insoluble fractions of myrosinases were determined individually and together for each leaf sample on 96-well microplates. The three enzyme preparations were each added to four wells. Two wells served as test wells into which 2 mM *p*-OH-benzylglucosinolate-phosphate buffer was added as substrate to measure kinetics of glucose

release. Two additional wells served as respective background controls that received only phosphate buffer to measure levels of internal glucose and light scattering. Glucose was detected by addition of 50 µl freshly mixed color reagent, including glucose oxidase, peroxidase, 4-aminoantipyrine, and phenol (Kunst et al. 1984; Siemens and Mitchell-Olds 1998) and quantified by reading the absorbance at 492 nm on a Multiskan EX (Thermo Labsystems, Vantaa, Finland) for 45 min at room temperature (22 to 24°C). Means of the two replicate measurements were calculated after subtraction of the means of the two background controls. A glucose dilution series was included in each assay. The rates of coloration that can be impacted by ascorbic acid (Kleinwächter and Selmar 2004) were not affected by ascorbate under our assay conditions (Travers-Martin et al. unpublished data). The resulting enzyme kinetics were analyzed for a linear range of myrosinase activity. Whereas the specific activity (Units mg^{-1} protein) is used to characterize an enzyme's activation status (Moss 1984; Stranger and Mitchell-Olds 2005), the concentration of myrosinase activity in relation to tissue fresh weight is a measure of the plant tissue's capacity to produce harmful hydrolysis products. Myrosinase activity concentrations are given in nanomoles of glucose released per minute and per milligram fresh weight of sample (fw) in this study, as we focused on the ecological effects.

Analysis of Soluble Protein and Water Contents Protein concentrations were obtained from purified extracts of the myrosinase assay. Soluble protein concentration was measured in duplicate of two dilutions according to Bradford (1976). Water contents of tissues were determined after freeze-drying of samples used for glucosinolate analysis.

Behavioral Experiments with Athalia rosae To investigate the behavioral response of specialist *A. rosae* larvae to metabolite changes in plant tissues evoked by different induction modes, *S. alba* plants were induced as described above with treatments a, b, c, and d. Twenty replicates were prepared per treatment. After 24 hr of induction, bags and insects were removed, and each plant received one male *A. rosae* larva (4 d after egg hatch, third instar; larval weight 16.3±1.3 mg, mean±SE, N=80). Larvae were placed onto the soil of the pot near the base of the plant and were allowed to move freely to and on the plants. Time until first feeding and feeding sites at the first and nine subsequent time points (90, 215, 285, 350, 405, 635 min after start of the test on the same day and 1,265, 1,340, 1,430 min after start of the test on the next day) were recorded within 24 hr. To determine oviposition behavior of *A. rosae* on differently treated *S. alba*, plants were induced as described above with 14 replicates per treatment. After 24 hr of induction and after the removal of bags and insects, plants were placed into large muslin bags (20×60×10 cm, mesh width 1 mm), and each received one naive (without oviposition experience), unmated female *A. rosae* (4 d after hatching from pupae, female weight 23.1±0.4 mg, mean±SE, N=52) for 24 hr. Numbers of eggs were counted for each leaf separately. Locations of larval feeding and egg deposition within 24 hr on differently induced plants were grouped into two categories in behavioral tests. Category I included the treated leaf and all younger ones in the upper plant region because induction effects were strongest in these tissues. Category II included all older leaves below the treated leaf, where induction effects were less pronounced. A preference index of categories (PI_c) was calculated per female as [(number of eggs on category I)−(number of eggs on category II)]/total number of eggs. The extreme values of 1 and −1 represent preferences for categories I and II, respectively.

Plant Vascular Connectivity For the determination of the vascular connections of the second youngest leaf of *S. alba*, nine plants were subjected to phloem staining with

rhodamin B modified from Orians et al. (2000). Plants were wounded on the second youngest leaf with a cork borer (three holes, no time delay, 5 mm diameter). A droplet of 25 μl of a 0.25% solution of rhodamin B in nanopure water was applied to each of the wounded areas and sealed with parafilm and silicone grease (Wacker, Munich, Germany) to minimize evaporation. After 24 hr of stain relocation in the phloem, treated leaves as well as the adjacent upper and lower leaves and stem parts were harvested. Samples were freeze-dried and pulverized in a mill. Rhodamin B was removed by three subsequent extractions with 400 μl of nanopure water for leaves and 200 μl for stems. Supernatants were separated from pellets by centrifugation twice at room temperature for 10 min at 16,060×*g*. Supernatants were analyzed for rhodamin B content by reading the absorbance at 570 nm on a Multiplate EX photometer. A standard dilution series of rhodamin B was included on each microplate.

Statistical Analyses Differences in damage patterns and in induction patterns of water contents, soluble protein, glucosinolate, and myrosinase activity concentrations between treatments in organs of identical age were analyzed by one-way analysis of variance (ANOVA) followed by HSD tests for imbalanced number of subsets. Variance homogeneity was examined by Levené tests, and data were log- or squareroot-transformed where needed. Control groups without and with bag treatment were analyzed for effects of the muslin bag on induction responses by *t*-tests. Treatment effects on the number of damage sites were analyzed by Mann–Whitney *U* tests that were tied and Bonferroni corrected.

In behavioral assays, the distribution of feeding sites of *A. rosae* larvae was grouped into two categories (see above), and homogeneity of subsets between the four plant treatments was analyzed by χ^2-tests (4×2). Plant treatment effects on time until first feeding of larvae, on egg deposition sites (PI_c), and on numbers of eggs laid by adults were analyzed by one-way ANOVA followed by honestly significant difference (HSD) tests for imbalanced number of subsets. Numbers of eggs within one treatment were examined for differences between both categories by Wilcoxon tests for matched pairs.

Differences of percentages in rhodamin B dye distribution were analyzed by using Wilcoxon tests for matched pairs. To analyze whether weight and dye content of a particular organ were correlated, Pearson–Product moment correlations were executed over all tissues, over only leaves, or only stems.

Results

Induction patterns of plants treated with muslin bags only and nontreated plants only differed in protein concentration and the three myrosinase activity concentrations (soluble, insoluble, and combination of both) in local leaf tissue, which were reduced up to 20% as a result of bag treatment. All other traits in local tissue and each trait measured in systemic tissues were not significantly different between these plant treatments. Bag treatment was the more relevant control compared to damage treatments.

Damage Patterns Within 24 hr, caterpillars of the generalist *S. frugiperda* consumed almost the same amount of leaf tissue as the specialist *A. rosae* larvae but produced a 1.7-fold higher number of damage sites (generalist, 10.5±1.1; specialist, 6.1±0.6; mean±SE, N=8; Mann–Whitney *U* test, Z=−2.6, P=0.020; Fig. 1). Thereby, the total wound length caused by the generalist was nearly twice as long as that caused by the specialist (total wound

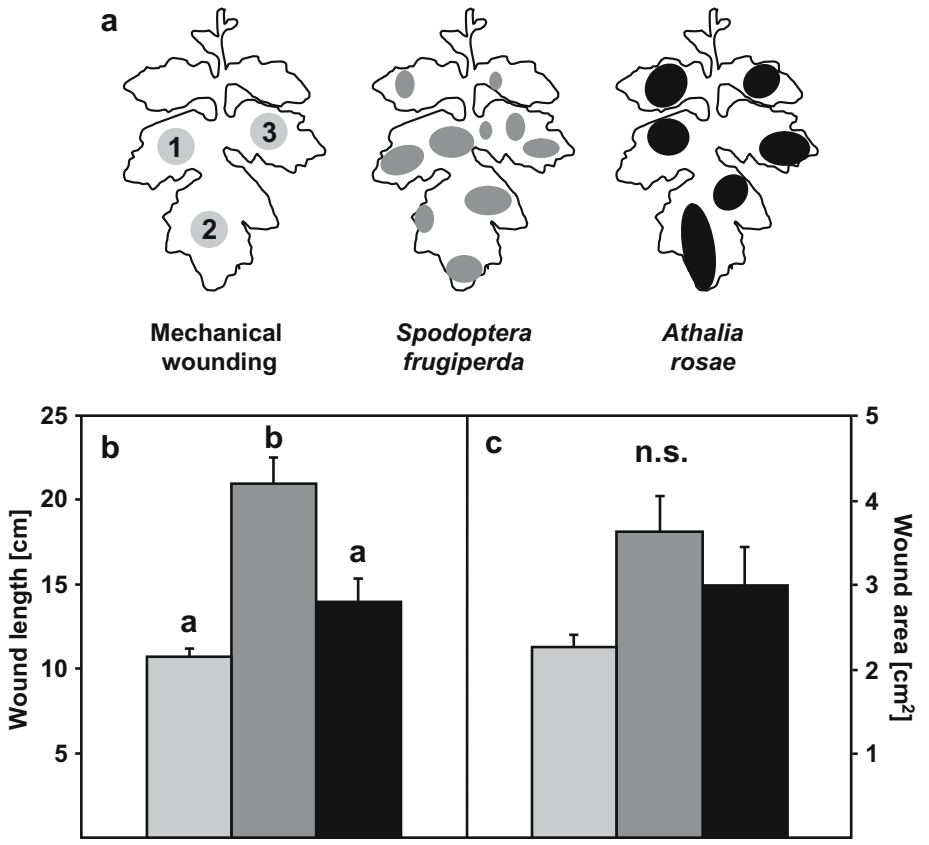

Fig. 1 Damage treatments of *Sinapis alba* leaves: **a** damage patterns after mechanical wounding (three holes at different time points: 10 A.M.; 4 P.M.; 8 A.M., 3 hr before harvest), feeding by *Spodoptera frugiperda* or *Athalia rosae* including mean number of damage sites; wound length (**b**) and removed tissue area (**c**) were determined by photo analysis compared to standards, *letters above bars* indicate significant differences (ANOVA, HSD tests: $P<0.01$, *n.s.* not significant), mean+SE, $N=6–8$

length was calculated as the sum of the perimeters of all damage sites) (ANOVA, $F=16.47$, $df=2$, $P<0.001$; HSD for imbalanced number of subsets $P=0.002$; Fig. 1). Damage by mechanical wounding was similar to feeding by *A. rosae* with respect to wound length and area but not to the number of damage sites that were different (Mann–Whitney *U* test, $Z=-3.1$, $P=0.004$; Fig. 1).

Glucosinolate Concentrations and Myrosinase Activities Eight glucosinolates were detected according to their retention times and UV-spectra in *S. alba* cv. Silenda leaves in decreasing relative amounts: *p*-OH-benzylglucosinolate (85–95%), benzylglucosinolate (5–14%), 4-methoxy-indol-3-ylmethylglucosinolate, indol-3-ylmethylglucosinolate, phenylethylglucosinolate, and three minor putative aromatic glucosinolates not identified. The sum of all six minor compounds represents only about 1% of the sum of all glucosinolates (=total glucosinolates). Capacities of the leaf tissues to hydrolyze glucosinolates were tested as myrosinase activity concentrations against the main glucosinolate *p*-OH-benzylglucosinolate. Total myrosinase activity of a tissue consists of soluble and insoluble fractions that were tested together. Constitutive concentrations of total glucosinolates and total myrosinase

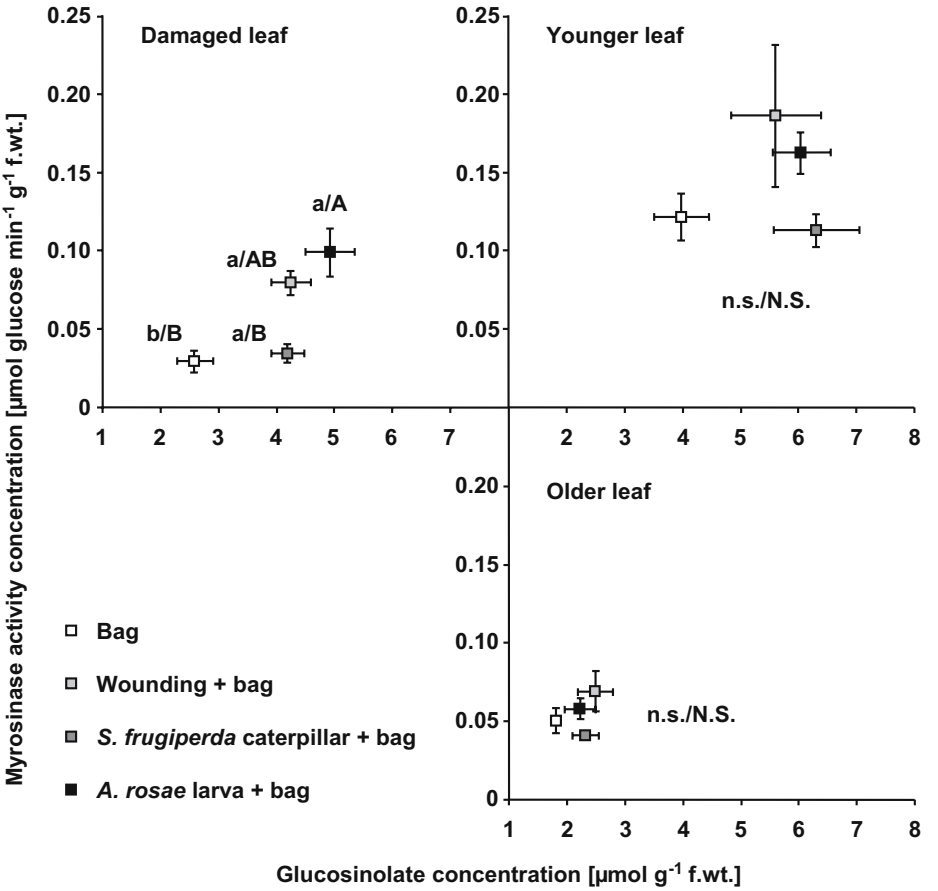

Fig. 2 Correlations of total glucosinolate concentration (sum of eight individual compounds, µmol g^{-1} fw, mean±SE) and total myrosinase activity concentration (µmol glucose min^{-1} g^{-1} fw, mean±SE) in leaves of *Sinapis alba*. The second youngest leaf was treated with mechanical wounding (cork borer), one medium-sized *Spodoptera frugiperda* caterpillar, or one large larva of *Athalia rosae* enclosed in a muslin bag for 24 hr. Bagged leaves without any further treatment served as controls (N=6–8 per treatment). *Letters above bars* indicate significant differences (ANOVA, HSD tests: $P<0.05$, *n.s.* not significant). *Lower case letters* refer to glucosinolate concentrations, *upper case letters* to myrosinase activity concentrations

activity were highest in tissues of younger leaves and decreased more than twofold with leaf age. Upon damage treatment, concentrations of glucosinolates in locally induced leaves increased about 80%, irrespective of inducing agent (Fig. 2). In contrast, significant increases by threefold in concentrations of total myrosinase activity were found in damaged leaves treated with mechanical wounding or specialist feeding only but not in leaves treated with generalist caterpillars. In systemic tissues, increases seemed to be more pronounced in younger than in older leaves, revealing the same patterns as in damaged leaves, but these differences were not significant because of high variation of individual values compared to differences in damaged tissue.

Individual glucosinolates showed different responses (Table 1). Whereas the absolute increase in concentration was highest for the main glucosinolate compound *p*-OH-benzylglucosinolate, indol-3-ylmethylglucosinolate concentrations were increased with the highest relative factor compared to bag-treated controls. In damaged leaves, *p*-OH-

**Differences from control in HSD test: $P<0.001$

benzylglucosinolate concentrations increased by a factor of 1.4, 1.6, or 1.9 because of mechanical, generalist, or specialist damage, respectively, compared to the bag control, whereas the corresponding factors for indol-3-ylmethylglucosinolate were 2.4, 3.8, and 3.7. Significant differences of individual glucosinolates compared to control were found only for insect treatments but not for mechanical wounding in damaged leaves. The pattern of benzylglucosinolate induction appeared to be different from the others: In damaged leaves, wounding resulted in the highest increase (13.2±4.6% of total glucosinolates, mean±SE, N=7) although not significant, *S. frugiperda* feeding in intermediate increases (11.3±2.4%), and *A. rosae* feeding had almost no effect (6.0±1.7%) compared to bag treatment (7.4±1.9%).

Overall, increases of soluble myrosinase activity concentrations were low (Fig. 3). In contrast, concentrations of insoluble myrosinase activities increased significantly in damaged leaves compared to controls by a factor of 3.3 or 4.4 as a result of mechanical wounding or specialist feeding, respectively. Generalist feeding had no effect on either soluble or insoluble myrosinase activity concentration in any of the leaves tested.

Soluble Protein and Water Content Protein concentrations were strongly influenced by treatment in damaged leaves (ANOVA, F=4.16, df=3, P=0.016, data were square-root

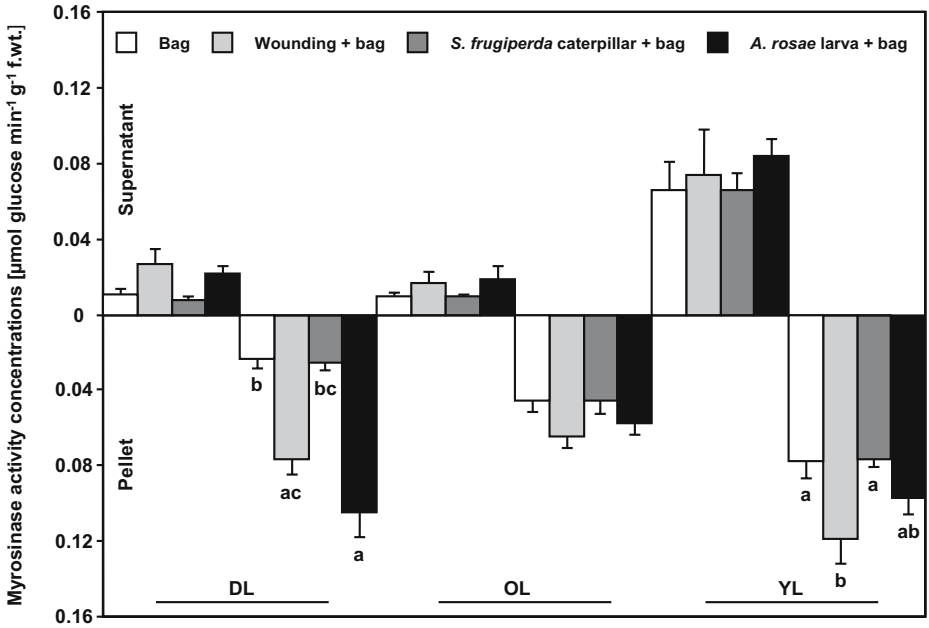

Fig. 3 Levels of myrosinase activity concentrations (µmol glucose min^{-1} g^{-1} fw, mean+SE) of soluble (supernatant, *upper panel*) and insoluble (pellet, *lower panel*) fractions in leaves of *Sinapis alba*. The second youngest leaf was treated with mechanical wounding (cork borer), one medium-sized *Spodoptera frugiperda* caterpillar, or one large larva of *Athalia rosae* enclosed in a muslin bag for 24 hr. Bagged leaves without any further treatment served as controls (N=6–8 per treatment). *Letters above bars* indicate significant differences (ANOVA, HSD tests: P<0.05). *DL* Damaged leaf; *OL* older leaf; *YL* younger leaf

transformed to ensure variance homogeneity). Both mechanical wounding (4.9±0.3 mg g^{-1} fresh weight, mean±SE) and feeding by *A. rosae* larvae (4.7±0.9 mg g^{-1} f.wt.) induced soluble protein concentrations by a factor of 1.7 compared to bag treated leaves (2.9± 0.4 mg g^{-1} f.wt.), but *S. frugiperda* caterpillar feeding had no effect (3.3±0.4 mg g^{-1} f.wt.). Differences to controls were significant only for mechanical wounding with P=0.030 (HSD tests). In systemic leaves, *A. rosae* feeding seemed to have stronger effects than the other two damage treatments compared to bag-treated controls, but none of the differences was significant (ANOVA, F=2.38, df=3, P=0.092). Apparent decreases in water content (range, 88.1 to 90.7%) were found only with mechanical wounding, but differences were small and not significant for any organ compared to bag-treated controls.

Behavioral Experiments with Athalia rosae The proportion of larvae feeding on younger tissues in the upper plant region was low in the beginning and increased during the 24-hr test from about 25 to 50% of the larvae feeding in category I. There were no significant differences in attack pattern on differently treated plants at any of the time points tested (χ^2-tests). Time to first feeding as a measure of whole plant acceptance was not significantly affected by plant treatment (ANOVA, F=0.51, df=3, P=0.674).

In the 24-hr test period, each female laid on average 39.2±1.7 eggs (mean±SE, N=52), with no significant differences between plant treatments (ANOVA, F=1.01, df=3, P= 0.397). The mean distribution of eggs laid in categories I and II were similar for all treatments except for mechanical wounding where overall significantly more eggs were laid on older than on younger leaves (Fig. 4). Females did not show any preference for any of

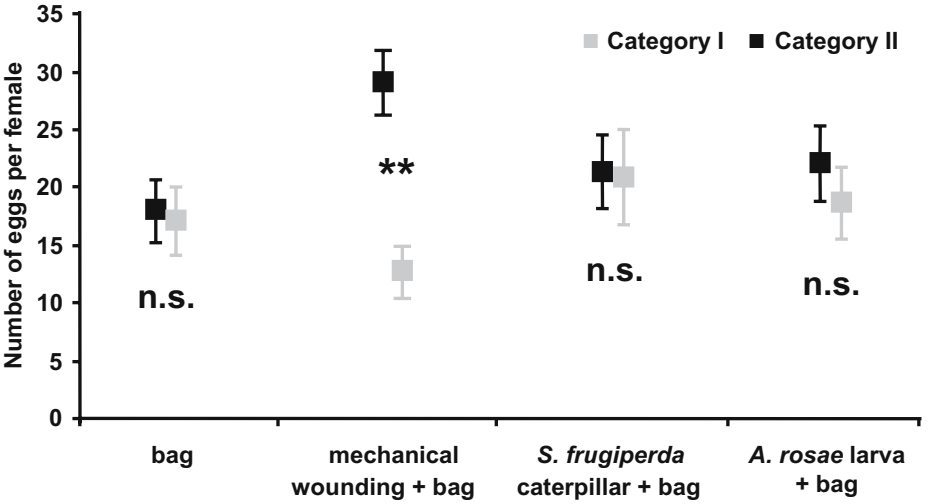

Fig. 4 Number of eggs per female (mean±SE) on category I (induced and younger) and II (all older) leaves of *Sinapis alba* in a 24 hr test. The second youngest leaf was pretreated with mechanical wounding (cork borer), one medium-sized *Spodoptera frugiperda* caterpillar, or one large larva of *Athalia rosae* enclosed in a muslin bag for 24 hr. Bagged leaves without any further treatment served as controls (N=14 per treatment). One female *A. rosae* was enclosed in large muslin bags with one plant for 24 hr. Differences in mean number of eggs per category were tested by Wilcoxon tests for matched pairs (**P<0.01, *n.s.* not significant)

these categories within plants treated with bags only (PI_c=−0.05±0.14, mean±SE, N=14; Wilcoxon test, Z=0.38, P=0.706), with *S. frugiperda* caterpillars (PI_c=−0.07±0.12, N=14; Wilcoxon test, Z=0.06, P=0.950), or *A. rosae* larvae (PI_c=−0.08±0.12, N=10; Wilcoxon test, Z=0.30, P=0.767). However, a clear preference for category II leaves was found in plants treated with mechanical wounding (PI_c=−0.39±0.16, N=14; Wilcoxon test, Z=2.76, P=0.006). No significant effects because of treatment of plants were found for PI_c of individual females (ANOVA, F=1.87, df=3, P=0.147).

Plant Vascular Connectivity Rhodamin B content was higher in leaves than in stems. Signals of stem tissue samples were below the detection limit in many cases. The recovery rate of applied dye was 81±6% (mean±SE, N=9). Some of the dye was incorporated into the hydrophobic sealing grease and could not be solubilized by nanopure water. The distribution of dye among the five organs was 35.1±2.7% (mean±SE, N=9) in treated leaves, 40.7±1.8% in younger leaves, 19.4±2.8% in older leaves, 4.5±0.6% in younger stems, and in older stems 7.5±1.3% of the recovered amount of rhodamin B per plant. The dye accumulated in treated and younger leaves, with significant differences between older leaves and treated leaves (Wilcoxon test, Z=2.07, P=0.038) and between older and younger leaves (Wilcoxon test, Z=2.54, P=0.011). We found an overall correlation between organ fresh weight and accumulated dye per organ within all tissues (Pearson's correlation coefficient, R^2=0.29, $F_{1,32}$=13.6, P<0.001), but not within leaves or stems only.

Discussion

Specificity According to Mode of Induction Plants of *S. alba* cv. Silenda treated with mechanical wounding, generalist, or specialist feeding induced total glucosinolate

concentrations to a similar extent, yet their composition varied. Mechanical wounding and feeding by *A. rosae* larvae on *S. alba* leaves induced increases in protein and myrosinase activity concentrations mostly to the same extent, but no significant increase in those parameters could be found in leaves damaged by *S. frugiperda* (Fig. 2). Plant responses to different inducing agents roughly reflect the differences in wounding patterns. Damage patterns (Fig. 1) after mechanical wounding and specialist *A. rosae* feeding were similar, but damage inflicted by generalist caterpillars of *S. frugiperda* resulted in about twice longer wound perimeters, a measure for dose of damage.

A dose-dependency of damage was shown previously for the induction of indolic and aliphatic glucosinolates upon mechanical wounding (Koritsas et al. 1991; Bodnaryk 1992) and upon application of the wound-induced plant hormone jasmonic acid (Bodnaryk 1992; Doughty et al. 1995). Probably, dose-dependent influences also exist for induction of aromatic glucosinolate concentrations or myrosinase activities in *S. alba*. Many plant responses, however, are dependent on the concentration, place, and mode of action of elicitors present in saliva or oviposition secretion of a given herbivore (Felton and Eichenseer 1999; Hilker and Meiners 2006 and references therein). Salivary compounds do not always elicit an increase of metabolites. Glucose oxidase or pH-effects that influence methanol release were shown to inhibit plant responses that otherwise occur upon mechanical wounding (Musser et al. 2005; Bede et al. 2006; von Dahl et al. 2006). We did not detect glucose oxidase activity in head or body extracts of *S. frugiperda* nor in extracts of *A. rosae* by using the method described by Eichenseer et al. (1999) (data not shown). Other elicitors, i.e., fatty acid-amides, have also been reported for caterpillars of *S. frugiperda* (Spiteller and Boland 2003). Additionally, the temporal pattern of wounding can be important for induction, as has been shown for the release of volatiles in lima beans as result of feeding by *Spodoptera littoralis* (Boisd.) (Mithöfer et al. 2005). We applied mechanical damage three times, interspaced as to mimic not only spatial but also broad-scale temporal pattern of herbivore feeding. Nevertheless, we are aware that herbivore feeding differed from our mechanical treatment because plant tissue was removed in small bits by the herbivores but in larger bulks by cork borer wounding.

Within an individual plant, the stronger response to damage in treated and younger systemic tissue compared to older systemic tissue in *S. alba* cv. Silenda can be explained by the tissue connectivity that was visualized by the transport of the dye rhodamin B. The amount of dye recovered after 24 hr was about twice higher in treated and younger than in older leaves. The relocation of dye among leaves was not correlated to organ biomass and is thought to be a result of source–sink relationships modulating bulk phloem flows (Orians 2005). Similar relationships of induction responses among differently aged leaves have also been found in other systems (Orians et al. 2000; Viswanathan and Thaler 2004). The differences in strength of response between local and systemic younger leaf tissues might be based on a "signal" delay in systemic tissue because of transportation processes.

Specificity According to Plant Cultivar Variation in quantity and quality of plant defenses is known to occur among species, individual plants, and different organs (Brown et al. 2003; Charron et al. 2005). Crop production, for which a diversity of cultivars have been bred, adds another level of specificity (for *S. alba* see: Hopkins et al. 1998a, b; Schuster-Gajzágó et al. 2006). However, few studies have compared these cultivars with respect to induction properties of glucosinolates and even fewer to those of myrosinase activity (Ludwig-Müller et al. 1997; Hopkins et al. 1998a, b; Andréasson et al. 2001). The *S. alba* cultivar Silenda used in this study and the *S. alba* cultivar Salvo previously investigated (Martin and Müller 2007) differed not only with respect to constitutive glucosinolate and myrosinase activity

concentrations but also with respect to induction responses to feeding by larvae of *A. rosae*. Upon induction with 6-d-old larvae, local responses in damaged leaves were stronger in the cultivar Silenda than in Salvo for total glucosinolate concentrations as well as for all three myrosinase activity concentrations (soluble, insoluble, and combination of both). The systemic response of glucosinolate concentrations was stronger in the cultivar Silenda, but changes of myrosinase activity concentrations were stronger in leaves of the cultivar Salvo. Thus, we showed that specificity of short-term induction response upon feeding by a glucosinolate-sequestering specialist herbivore varies strongly with respect to cultivar, as has also been shown for studies of long-term induction effects of the nonsequestering specialist *Delia floralis* (Fall.) (Hopkins et al. 1998a, b) and of pathogens (Ludwig-Müller et al. 1997; Andréasson et al. 2001) in other Brassicaceae.

Consequences for Interaction The defensive properties of differentially induced plants and their acceptability were tested against subsequent attacks of *A. rosae* larvae and egg-laying females. Larvae usually prefer to move to the upper plant parts (personal observation). When placed at the bottom of a plant pot, movement of larval feeding pattern was comparable on all differently pretreated plants. Thus, larvae seem to be unaffected by different plant induction states, specifically in the upper plant region where changes are more pronounced. Females distributed their eggs similarly on young and old plant parts in most plant treatments (Fig. 4). However, marginal behavioral modifications were observed in response to mechanically wounded plants, where females laid fewer eggs on damaged and younger systemic than on older leaves. These plants showed differences in glucosinolate profiles, especially in benzylglucosinolate concentrations, compared to the other treatments. Females of *A. rosae* responded differently to isothiocyanates, the hydrolysis products of glucosinolates, with varying side-chains (Barker et al. 2006), but it is not clear whether altered glucosinolate profiles in *S. alba* might have influenced choices for egg deposition sites in our bioassays. In other systems, side chain modifications of glucosinolates led to modulations in disease resistance (Brader et al. 2006) and in specialist feeding damage (Giamoustaris and Mithen 1995) but not in generalist feeding and performance (Giamoustaris and Mithen 1995; Burow et al. 2006). Overall, the observed induction responses in *S. alba* did not serve as rapid plant protection against *A. rosae* larvae or egg-laying females, regardless of the inducing agent. However, long-term induction responses were not investigated in this study, and such studies might reveal different aspects of resistance against a sequestering herbivore in the field. In a former study, almost no differences were found in the long-term development of larvae and adults of *A. rosae* raised on *Brassica juncea* lines with differing glucosinolate and myrosinase contents (Müller and Sieling 2006). In contrast, other nonsequestering specialists have been found to have a reduced performance in long-term (Agrawal 2000) and short-term trials (de Vos et al. 2006) on induced plants. The glucosinolate-sequestering herbivore *A. rosae* thus seems highly tolerant to variation in the glucosinolate–myrosinase system evoked either by rapid induction changes or by permanent modifications in different inbred lines.

Induction responses in *S. alba* do not seem to benefit the plant, but rather its opponents: The sequestering specialist might profit from increased glucosinolate levels and thus increased protection because of sequestration. The generalist herbivore suppresses induction responses of hydrolyzing enzymes and might obtain less toxic food this way. Therefore, in *S. alba*, the lethal plant defense paradox (Fordyce 2001) is present for the cultivar Silenda, as increased glucosinolates means benefits for the sequestering herbivore (Müller et al. 2002). The selective increase, as a result of *A. rosae* feeding, of myrosinase activity concentrations only in systemic leaves of the cultivar Salvo (Martin and Müller 2007) might have a

protective function for the plant. In *B. juncea*, *A. rosae* larval feeding reduced glucosinolate and myrosinase activity levels within 24 hr (Müller and Sieling 2006). This suggests that not only has the lethal plant defense paradox been solved to different extents in plants but also that there is no universal short-term response of plants to one herbivore.

The induction responses found for the glucosinolate–myrosinase system in *S. alba* showed some specificity because of the inducing agent. Glucosinolates and myrosinases revealed different induction patterns pointing at separate regulation mechanisms. Insect-derived elicitors and the redistribution of a potential signal via the phloem seem likely to be involved in this specificity. Nevertheless, these plant differences were not mirrored in behavioral responses of larvae or adult females of *A. rosae*.

Acknowledgments The authors thank M. Riederer for making lab space and HPLC equipment available, D. Imes and D. Paltian for help with numerous extractions and the Bayer AG for *Spodoptera frugiperda* eggs. triterpenoid saponins. Some authors also distinguish a third group, the so-called steroidal amines that can be classified as steroidal alkaloids (Bruneton 1995). Steroidal saponins consist of a steroidal aglycone, a C_{27} spirostane, generally composed of a six-ring structure (Fig. 1a). Within fresh plant tissues, the hydroxyl group in the 26-position participates in a glycosidic linkage, and the aglycone structure remains as pentacyclic furostane (Fig. 1b). Triterpenoid saponins consist of a triterpenoid aglycone composed of a C_{30} pentacyclic structure (Fig. 1c; Sparg et al. 2004).

Saponin concentrations in different alfalfa varieties have been reported and range from 0.8–2% (Pedersen and Wang 1971; Majak et al. 1980). Pecetti et al. (2006) also showed saponin differences among alfalfa cultivars with compounds such as medicagenic acid and zanhic acid.

Saponins are toxic to herbivorous insects (Ishaaya et al. 1969; Shany et al. 1970; Oleszek et al. 1992), are reported to be important resistance factors to the pea aphid, and have been suggested a potentially useful for alfalfa resistance breeding programs (Horber et al. 1974). High saponin content in some alfalfa cultivars is related to resistance against the pea aphid, *Acyrthosiphon pisum* (Pedersen et al. 1976). Saponins have also been shown to interfere with aphid feeding behavior (Golawska et al. 2006).

In this paper, the effects of isolated alfalfa saponins on pea aphid feeding behavior are examined in detail. Three major alfalfa saponins—(**1**) 3GlcA, 28AraRhaXyl medicagenic acid glycoside, (**2**) 3GlcA, 28AraRha medicagenic acid glycoside, and (**3**) zanhic acid tridesmoside—were used in *in vitro* experiments. Saponin effects on aphid probing of the plant peripheral tissues and phloem phase were studied.

Methods and Materials

Aphid Culture The pea aphid, *A. pisum* Harris, wingless females were used in all feeding behavior experiments and came from a stock culture kept at the University of Podlasie, Siedlce, Poland. Aphids were collected from a laboratory culture reared on broad been (*Vicia faba* L. var. Start) and maintained in an environmental chamber at about 21°C, L16:D8 photoperiod, and 70% RH.

Chemicals Individual saponins were obtained from the Institute of Soil Science and Plant Cultivation, Pulawy, Poland. Compounds **1**, **2** and **3** (Fig. 2) were isolated from alfalfa as described by Oleszek et al. (1990).

Application of Tested Compounds The effect of saponins on pea aphid feeding behavior was investigated *in vitro*, using sucrose–agarose gels. Control gels (without saponins) were prepared by incorporating 1.25% agarose (Sigma A-0169) into 30% sucrose solution. Experimental gels (containing saponins) were prepared by incorporating individual saponins at concentrations of 50 or 100 ppm. After stirring, the mixtures were heated in

Compound	Aglycon	R	R_1	R_2
1	I	GlcA	H	-Ara-Rha-Xyl
2	II	GlcA	H	-Ara-Rha
3	III	-Glc-Glc-Glc-	-Ara-	-Ara-Rha-Xyl-Api

Fig. 2 Structures of compounds 1–3

a water bath (75°C for 30 min) and then poured into plastic rings covered by a stretched Parafilm M® membrane. Transparent gels formed after 1–2 min and offered to aphids for probing.

Electrical Penetration Graph Recordings The probing behavior of adult apterous aphids was recorded using a DC electrical penetration graph (EPG) amplifier (type Giga-4). Aphids were connected to the EPG system by a 2-cm gold wire (20 μm in diameter) and attached with conductive silver point (Demetron, L2027, Darmstadt, Germany). A second electrode was introduced into the gel. EPG recordings were performed inside a Faraday cage under laboratory conditions (ca 24°C for 4 hr). Collected insects were starved for 2 hr and then placed onto gels. Pea aphid probing behavior was recorded as follows: One adult apterous aphid was placed onto each gel and EPG recordings were made for 10 aphids on 10 different gels without saponins (control) and 10 gels for each concentration of the tested compounds. Aphid feeding behavior was monitored for 4 hr.

EPG Analysis Acquisition and analysis of EPG signals were done with STYLET 2.2 software (ref). Waveform patterns were identified according to Tjallingii (1990). Insect feeding behavior was based on aphid activities and noted as follows: non-probing (np pattern, aphids cannot start probing), path (C pattern—pathway; penetration of peripheral tissues—epidermis and mesophyll), salivation into sieve elements (E1 pattern), ingestion of phloem sap (E2 pattern—aphid feeding), and ingestion of xylem sap (G pattern). EPG parameters were measured in each group and recalculated per one insect. Data obtained with experimental and control insects were subjected to one-way analysis of variance followed by Duncan's test.

Results

Saponins clearly affect feeding behavior of *A. pisum*. EPG recordings indicated that the pea aphid behaved in a variable manner while probing artificial diets containing test compounds. On each occasion, aphid-probing activity was composed of major EPG patterns: pathways (C), sieve element salivation (E1), phloem sap ingestion (E2), and xylem sap ingestion (G) (Table 1). Among the saponins studied, **2** and **3** were more

effective modulators of probing behavior than **1**. The total number of gel penetrations by the pea aphids and duration of the pathways were reduced by higher concentrations of compounds (Table 2). Compounds **1** (at 100 ppm), **2** (at both 50 and 100 ppm), and **3** (at 50 ppm) reduced the number of gel penetrations by approximately half. At 100 ppm, compound **3** decreased the number of penetrations by four times (Table 2). Saponins also prolonged the first probe by experimental aphids compared to controls—about twice the duration for saponins **1** and **2** at concentrations of 50 and 100 ppm, and over seven times in the case of saponin **3** at 100 ppm (Table 2). For all tested saponins, reduction in average duration of probing activity in relation to control gels was observed (Table 2).

A similar tendency was found for aphid salivation into sieve elements and phloem sap ingestion (Table 3). At a concentration of 50 ppm, all saponins reduced duration until the first E1 pattern and for 3GlcA, 28AraRhaXyl medicagenic acid up to seven times. Prolongation of such aphid activity was observed for **1** and **2** at a concentration of 100 ppm and **3** at 50 ppm. Generally, the tested concentrations of **2** and **3** reduced total time of pea aphid salivation into the gels (Table 3). Saponins also modified the duration of the first

phloem sap ingestion (Table 3). In addition, the total time of this aphid activity was prolonged in the presence of all 3 saponins at 50 ppm. Higher concentrations (100 ppm) reduced the duration of phloem sap ingestion except for **1** (Table 3).

Compound **1** did not affect xylem sap ingestion at the tested concentrations (Table 4). When **2** was added to gels, pea aphid activity corresponding to xylem sap ingestion did not occur (Table 4). At the lower concentration, compound **3** reduced this phase of aphid feeding behavior and at the higher concentration completely stopped this activity.

Discussion

The EPG recordings of pea aphid probing of sucrose–agarose gels containing different concentrations of saponins showed clear differences in feeding behavior. Generally, higher concentrations caused reduction of aphid activities that corresponded to ingestion of phloem and xylem sap. Similar findings have been reported previously for saponins isolated from seeds of *Barringtonia asiatica* in relation to *Epilachna* sp. larvae (Herlt et al. 2002). EPG results indicated moreover that the pea aphid avoided ingesting saponins. The concentrations of saponins used in this study corresponded to levels within a low-saponin line of alfalfa and were lower than those found in high-saponin lines of the Radius cultivar (Staszewski et al. 1994). Thus, the antibiotic effect of alfalfa saponins on pea aphid might be even stronger in a high-saponin line.

Synergism among the tested saponins was not studied in these experiments; however, synergistic interactions among saponins may occur within alfalfa tissues. Horber et al. (1974) and Adel et al. (2000) reported that saponins may act synergistically. Moreover, they may also act synergistically with other groups of alfalfa allelochemicals as reported for other plants and insects (Sutherland et al. 1982; Berenbaum 1985).

The results here obtained did not confirm earlier reports by Oleszek et al. (1992). The tested compounds may be antifeedant compounds for pea aphid—Fabaceae relationships. Szynkarczyk et al. (2000) showed that *A. pisum* fed on high-saponin alfalfa lines reduced pea aphid performance and phloem sap ingestion. Golawska et al. (2006) further showed differences in pea aphid feeding behavior on alfalfa with low and high saponin content. Aphids fed on high-saponin lines had prolonged penetration of the epidermis and mesophyll (pattern C) and showed a significant reduction in phloem sap ingestion. On

the other hand, negative effects of saponins on herbivore performance, e.g., reduction of growth and pupal mass, could be a consequence of shortening or suppressing the feeding process. Thus, the results presented here confirm that alfalfa saponins are natural feeding barriers for phytophagous insects (Sutherland et al. 1982; Meisner and Mitchell 1983; Potter and Kimmerer 1989; Jain and Tripathi 1991; Nozzolillo et al. 1997). Agrell et al. (2003) demonstrated that alfalfa showed an herbivore-induced resistance based on saponins and that such induction affected feeding behavior and exerted negative effects on herbivore physiology. We documented that saponin *3* is important in chemical interactions between host-plants and herbivores. Moreover, a similar reduction in insect food consumption by saponins has been reported by Adel et al. (2000). They were the major cause of diminished body growth and possibly extension of the feeding period. Alfalfa saponins administered to larval *Spodoptera littoralis* through diet caused prolongation of both larval and pupal stages, retarded growth, increased mortality, and reduced fecundity and fertility. There are data also that indicate that saponins slow the passage of food through the gut, perhaps by reducing digestibility, and may secondarily influence food uptake. Inhibition of digestive enzymes (Ishaaya and Birk 1965) and interference with sterol metabolism (Ishaaya et al. 1969; Shany et al. 1970) also may be involved with the effects of alfalfa saponins on food processing in *S. littoralis.* In addition, extension of pupal instars and reduction of adult fertility have been reported by Hubrecht et al. (1989). Szynkarczyk et al. (2001) and Golawska et al. (2005) found a negative relationship between saponin concentration and development of pea aphids on alfalfa lines. Horber (1972) used commercial saponins isolated from alfalfa and found that even low concentrations may exert an adverse effect on the pea aphid. Finally, there are reports of the high toxicity of saponins to other insects (Bondi and Birk 1968; Applebaum et al. 1969; Thorp and Briggs 1972; Sutherland et al. 1975a, b).

The current studies suggest that saponins *1*, *2*, and *3* are toxic toward the pea aphid and may have potential as alfalfa resistance factors toward the pea aphid. Thus, it might be worthwhile to modify saponin levels in the breeding of modern alfalfa lines with biotechnologically introduced genes that regulate saponin concentration and composition.

Acknowledgments I thank Prof. W. Oleszek (Institute of Soil Science and Plant Cultivation, Pulawy, Poland) for providing samples of individual saponins.

photobiont. The fungal partner often produces so-called lichen substances, i.e., secondary acetone-extractable metabolites (Huneck and Yoshimura 1996). These are chemically diverse compounds, generally biosynthesized through the acetate–mevalonate pathway, but some through the shikimic acid pathway (pulvinic acid derivatives). Brown melanic compounds are complex and poorly known polymers of phenolic compounds (recently reviewed for microorganisms including fungi by Plonka and Grabacka 2006). They cannot be extracted, but they can be quantified by spectral reflectance measurements.

Most lichen substances, including melanic compounds, strongly absorb UV-B radiation, and colored compounds additionally absorb some visible radiation. Some compounds are located in the upper cortex of the lichen thallus (e.g., usnic acid, parietin, and melanic compounds), and may screen the underlying algal cells from excess UV-B and/or visible radiation (Ertl 1951; Büdel and Lange 1994; Dietz et al. 2000; Gauslaa and Solhaug 2001; Solhaug et al. 2003; Nybakken et al. 2004). Variations in thallus color and contents of cortical substances between sun and shade forms of some lichen species were acknowledged early and interpreted as acclimation to different light regimes (Richardson 1967; Rundel 1969). Many medullary substances, often located within the photobiont level, are assumed to screen excess solar radiation because of their strong UV-B absorbance. In addition, both medullary and cortical lichen substances function as herbivore defense (Slansky 1979; Lawrey 1983; Gauslaa 2005; Nimis and Skert 2006), allelopathics (Pyatt 1967; Brown and Mikola 1974; Fisher 1979), and/or antibiotics (Gudjónsdóttir and Ingólfsdóttir 1997; Cocchietto et al. 2002). Such functional roles imply that a species' success, in some ways, depends on the concentration and composition of lichen substances.

In a previous study, we assessed growth in three epiphytic old forest lichens (the green-algal *Usnea longissima*, the cyanobacterial *Pseudocyphellaria crocata*, and the tripartite *Lobaria pulmonaria*) transplanted into three successional stands in boreal spruce forests (dense young forests, open old forests, and clear-cuts) at three locations along a rainfall gradient (Atlantic, suboceanic, and continental climatic zones) (Gauslaa et al. in press). The low light in the young forests severely restricted growth of all three species, and for the alectorioid *U. longissima*, low light limited growth even in the open old forests. The two foliose species grew best in old forests, and showed some damage in terms of chlorophyll degradation because of excess light in the sun-exposed clear-cuts. For all species, growth was substantially higher in the Atlantic rainforest compared with the drier suboceanic and continental locations.

As part of a search for mechanisms behind the reported variation in acclimation traits for the three studied lichens (Gauslaa et al. in press), an objective was to assess possible successional stand-specific differences in secondary chemistry. Lichen substances with functional roles in sun protection are expected to increase along the light gradient. Both *L. pulmonaria* (Gauslaa and Solhaug 2001) and *P. crocata* can produce cortical melanic, nonextractable pigments, which may absorb substantial quantities of visible light in addition to UV-B (Nybakken et al. 2004). The two melanic species showed signs of damage in the exposed clear-cuts during the transplantation (Gauslaa et al. in press), presumably because of excess temperatures (Thus, according to the results of Gauslaa et al., we expected the most successful cortical screen to be found in the third species, *U. longissima*, which showed no signs of photodamage and even had the highest growth on the clear-cuts.).

Methods and Materials

Lichen Material All lichens were collected in boreal *Picea abies*-dominated forests. *Lobaria pulmonaria* (L.) Hoffm. was collected in rainforests in Overhalla (64°27′N 11°53′E,

15 m asl) and Namsos (64°25′N 11°25′E, 20 m asl) in Nord-Trøndelag, Norway from twigs of *P. abies* and scattered stems of *Salix caprea*. *Usnea longissima* Ach. was collected from lower branches of spruce trees in steep, NE-facing open and old forests in Toten (60° 35′N, 11° 02′E, 600–700 m asl), Oppland, E Norway. *Pseudocyphellaria crocata* (L.) Vain. was collected in two locations in Namsos (64°25′N 11°25′E, 20 m asl and 64°25′N 11°25′E, 40 m asl) and one in Namdalseid (64°20′N 11°17′E, 40 m asl). All thalli were air-dried in the lab at the collection day. During the approximately 1-mo period between collection and transplantation, thalli were stored air-dry in a fridge. Further details are given in Gauslaa et al. (in press).

Study Sites Three *P. abies*-dominated transplantation locations were chosen: an Atlantic location with coastal rainforest in Namsos, Nord-Trøndelag, W Norway (64°25′N 11°27′E, 30 m asl); a suboceanic location in Siljan, Telemark, SE Norway (59°22′N 9°45′E, 500 m asl); and a continental location in Kullbäcksliden, near Umeå, Västerbotten, N Sweden (64° 10′N 19°40′E, 250 m asl). Total mean daily temperatures were 12–13°C in all three areas during the transplantation period. The rainfall during the transplantation period varied between 440 mm (81 rainy days) in the Atlantic location and 276 mm (54 rainy days) in the continental location, with the suboceanic location (309 mm; 43 rainy days) in between. *Lobaria pulmonaria* and *U. longissima* were transplanted to all three sites because they are native to all three respective climatic zones. The rainforest lichen *P. crocata* was only transplanted to the Atlantic zone to which it is restricted. In the present study, the two foliose lichens *P. crocata* and *L. pulmonaria* were measured from the Atlantic site only, whereas the most responsive species in terms of growth (Gauslaa et al. in press), *U. longissima*, was measured from all three climatic zones.

Transplantation Experiment Before and after the transplantation period, the hydrated thallus area was measured with a leaf area meter (LI3100 Li-Cor, Lincoln, NE, USA). Thereafter, lichens were desiccated 48 hr at 20°C before recording the dry weight. Four randomly chosen thalli of *L. pulmonaria* were fastened with a thin thread onto nylon net on each of 45 square frames (15.9×15.9 cm). Because of limited material of *P. crocata*, only two to three thalli were fastened in the same way on each of 45 new frames. Lobes of these two foliose lichens were positioned horizontally. The position simulates the typical orientation of the lichens on *P. abies* where they are restricted to branches and thin twigs. Each of the pendulous *U. longissima* thalli was fastened with a thin thread through small holes to one of four vertical sticks on frames similar to those used for the foliose lichens. The sticks allowed a vertical hanging position of pendulous thalli. The lower lichen parts were hanging freely above the horizontally located frames. Frames with *U. longissima* were placed in all three sites, 45 frames on each, on a horizontal frame holder on a stick 1 m above the ground. Fifteen frames with each lichen species were randomly placed in each of three successional stands at each transplantation location: (1) even-aged young and closed canopy stand, mean indirect site factor (ISF) according to Anderson (1964): 0.141–0.224; (2) old forest with gaps, ISF: 0.229–0.278; and (3) open clear-cut areas ISF: 0.647–0.840. The ISF is the proportion of diffuse solar radiation reaching a given location, relative to that in a location with no sky obstructions (see Gauslaa et al. in press for description of measurements of ISF). Transplants were kept in the field from June 11 to September 30 (the Atlantic site; 110 d, 81 rainy days with 440 mm rainfall), June 13 to October 1 (the suboceanic site; 111 d, 43 rainy days with 309 mm), and June 18 to October 4 (continental site; 111 d, 54 rainy days with 276 mm), all in year 2005. After harvest, the transplants were transported to the lab the same day and left to dry at room temperature.

Extraction of Lichen Compounds Preliminary experiments showed that the secondary compounds were extracted completely from the thin alectorioid *U. longissima* by rinsing intact air-dry thalli in pure acetone. Two thalli from each frame (30 thalli per successional stage at each site) were put into 10-ml glass tubes and 5–7 ml of acetone was added. After 20 min of extraction, the acetone was poured into 30-ml glass tubes, and new acetone was added to the thalli. The extraction was repeated three times, the four supernatants combined, and the acetone was left to evaporate from the glass tubes in a 50°C water bath in a fume cap. Dried extracts were stored dark and dry for a maximum of 24 hr before they were dissolved in 10 ml of acetone and run on high-performance liquid chromatography (HPLC).

Preliminary tests for the thick foliose *L. pulmonaria* and *P. crocata* showed that the secondary compounds were extracted most efficiently from hydrated thalli immersed in *N*, *N*-dimethylformamide (DMF). Two thalli from each frame (30 thalli per successional stage) were cut into two equal parts, one was randomly selected, and weight and area were measured. The selected part was then put in 10 (*L. pulmonaria*) or 5 (*P. crocata*) ml of DMF and left for 5 d in a dark fridge before the DMF extract was run on HPLC.

HPLC Analysis Lichen extracts were analyzed on a 1100 Series HPLC (Agilent Technologies, Waldbronn, Germany) including a 1,040-M diodearraydetector. Separation was achieved on an ODS Hypersil 60×4.6 mm column. Oven and injector temperatures were 25 and 22°C, respectively. The injection volume was 20 μl for DMF extracts and 10 μl for acetone extracts, and the flow rate was 2 ml min^{-1}. Solvent A consisted of 0.25% orthophosphoric acid and 1.5% tetrahydrofuran in Millipore water, whereas solvent B was 100% methanol. The run started with 30% B. Within 15 min, solvent B was increased to 70% and further to 100% the next 15 min, and then isocratically in 100% B for a further 5 min. At the end of the run, solvent B was reduced to 30% within 1 min, and the column flushed with 30% B for 5 min before the next run started.

The detection wavelength was 245 nm, and the identification of compounds was based on retention times, online UV spectra, cochromatography of commercial standards (diffractaic acid and norstictic acid [Gaia Chemicals, Gaylordsville, USA]; usnic acid [Sigma, St. Louis, USA]; tenuiorin and stictic acid standards provided by Prof. Harrie Sipman [Botanical Museum, Berlin]; and peristictic, methyl norstictic, and constictic acids by Prof. John Elix [National University of Australia, Canberra]), and HPLC-MS (Agilent Technologies) (see Table 1 for HPLC-MS data). Conditions for HPLC/API-ES (positive ions) were as follows: a Hypersil RP C18 column with ID of 2 mm and 10 cm length, ES fragmentor voltage of 80, flow rate of 0.4 ml min^{-1}, and injected volume of 5 μl. The fragments of the lichen compounds produced by HPLC/API-ES are displayed in Table 1. The compounds were quantified against response curves of the above-mentioned standards. The constictic, peristictic, cryptostictic, and methyl norstictic acids were quantified by using the response curve of norstictic acid, whereas for tenuiorin derivatives, the tenuiorin standard curve was used.

Reflectance Measurements Melanic pigmentation can be quantified by measuring the reflectance (400–1,000 nm) from the lichen surface (Solhaug et al. 2003). Reflectance spectra were recorded by holding dry or wet lichen thalli against an integrating sphere (model ISP-50-REFL Ocean Optics, NL-6961 LL Eerbeek, The Netherlands) illuminated by a halogen lamp (model DH2000, OceanOptics) through a 600-μm-thick optical fiber connected to the input port of the integrating sphere. Reflectance was detected by a spectrometer (model SD2000, Ocean Optics) connected to the output port of the sphere

Table 1 HPLC-detected compounds with available HPLC-MS data for the three lichen species

Lichen Species	HPLC-MS Data
Lobaria pulmonaria

with a 400-μm-thick fiber. Percent reflectance was calculated on the basis of a dark spectrum and a reference spectrum from a white reference tile (WS-2, OceanOptics).

Statistical Analyses The data for *L. pulmonaria* and *P. crocata*, assessed from one location only, were analyzed in a one-way ANOVA with forest type as factor and concentration of lichen compounds as effect. *Usnea longissima* was analyzed in a two-way ANOVA with site and successional stand as factors and concentration of lichen compounds as effects (SigmaStat for Windows). The reflectance data were analyzed with the nonparametric Kruskal–Wallis test (Systat).

Results

The three studied species differed substantially in their total concentration of extractable secondary compounds (Fig. 1). *Lobaria pulmonaria* had the lowest concentration with a mean value of 3.1%, *P. crocata* the highest (7.1% of dry weight). *Usnea longissima* showed an intermediate level (5.0%), but at the same time displayed the widest total range (1–11% of dry weight; Fig. 1). When recorded on area basis, however, *U. longissima*, had the highest content of secondary compounds (7.0–9.5 g m^2; Table 2), nearly three times higher than in *L. pulmonaria* with *P. crocata* in between.

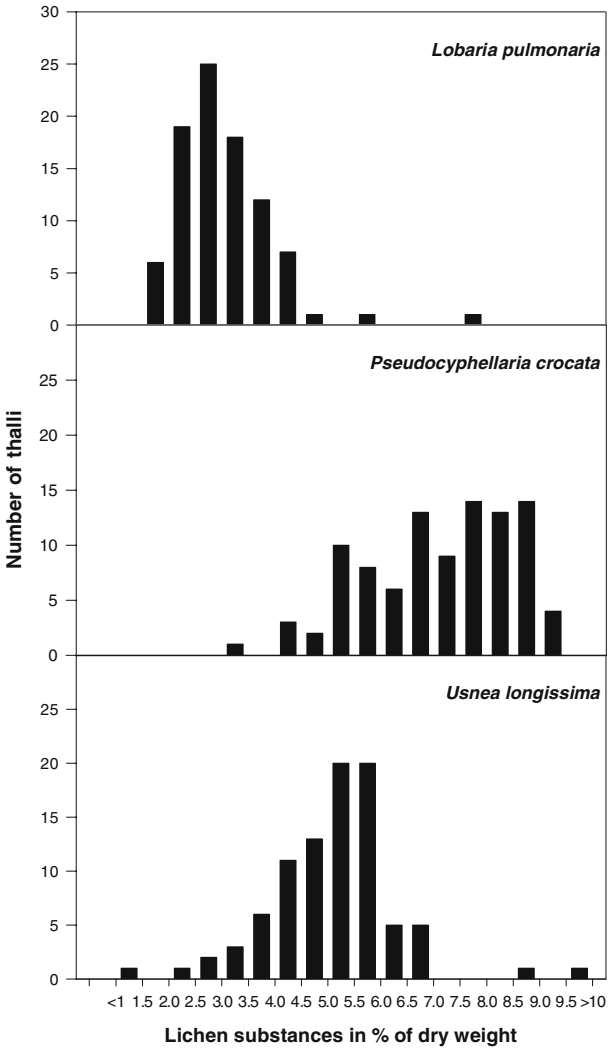

Fig. 1 Number of thalli of *L. pulmonaria*, *P. crocata*, and *U. longissima* in different concentration classes (% of DW) with respect to extractable secondary compounds

All extractable secondary compounds in *L. pulmonaria* were depsidones (Table 2). Stictic acid was the major compound, constituting 62% of the total amount of extractable secondary compounds on a dry weight basis. Constictic and peristictic acid represented together 32%, meaning that cryptostictic, norstictic, and methyl norstictic acid were minor compounds with a combined contribution of only 6% of the total secondary pool (Table 2). Only one minor compound, methyl norstictic acid, varied significantly between the successional stages, showing higher concentrations per dry weight and contents per thallus area in the clear-cuts than in forested stands.

Pseudocyphellaria crocata had a large pool of many extractable secondary compounds (Table 2). Like *L. pulmonaria*, it contained the depsidones stictic and constictic acid, but in consistently lower concentrations (7–9% of total extractable pool; Table 2). Tenuiorin, the major depside, accounted for as much as 50% of the total amount of lichen compounds in *P. crocata*. An additional eight unidentified compounds with UV and MS spectra resembling

those of tenuiorin were found, representing more than 40% of the total pool. These are referred to as tenuiorin derivatives 1 to 8. The yellow pulvinic acid derivate calycin, present only in cortex-deficient soredia and small pseudocyphellae (unpublished data), was not detectable in extracts of whole thalli. As many as 8 out of the 11 compounds in *P. crocata* differed significantly between forest stands (Table 2) when calculated on a dry weight basis, whereas 6 compounds were affected on area basis. The trend, however, varied among the compounds. The content of constictic acid, stictic acid, tenuiorin derivatives 5 and 8, and tenuiorin (the three latter only per dry weight) was highest in the clear-cut transplants, whereas tenuiorin derivatives 1, 3 (only per area), 4, and 6 were lowest on the clear-cuts (Table 2).

The melanic pigmentation in the upper cortex of both *L. pulmonaria* and *P. crocata* was consistently darker, evidenced as lower reflectance, in clear-cut transplants than in those from the old and the young forest (Fig. 2). This was the case for both visible and far-red wavelength ranges ($P<0.001$, ANOVA; data not shown), and for both air-dry and hydrated thalli ($P<0.001$, ANOVA; data not shown).

Usnea longissima contained two detectable secondary lichen compounds, the medullary depside diffractaic acid and the cortical dibenzofuran derivative usnic acid (Table 2). Usnic

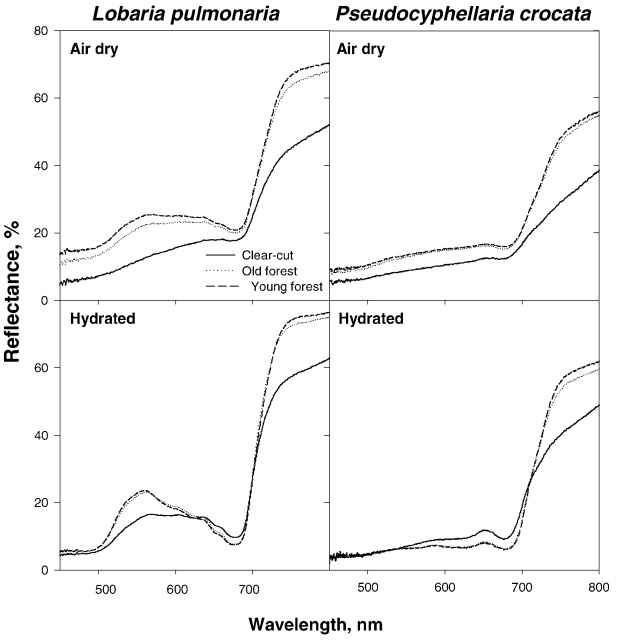

Fig. 2 Reflectance (%) from the upper surface of air dry and hydrated *L. pulmonaria* and *P. crocata* thalli transplanted to clear-cuts, old forests, and young forests in an Atlantic rainforest environment in W Norway

acid was the major compound, constituting more than 90% of the total amount of secondary substances. Because the transplantation of *U. longissima* was repeated at three locations along a regional climatic gradient from rain forests to drier continental forests, a two-way ANOVA that also included the rainfall gradient was run. The successional stage had a strong influence on the secondary chemistry, as the concentration of usnic acid was highest in thalli from the clear-cuts compared with both old and young forests and the concentration of diffractaic acid was slightly lower in clear-cut transplants (Fig. 3). The steep rainfall gradient (locality) did not give any significant contribution alone (Fig. 3). However, there was a significant interaction effect because the old forest transplants in the Atlantic location had elevated content of usnic acid per thallus area compared to the clear-cut as well as young forest transplants. No such interactions were seen for the diffractaic acid (Fig. 3).

There was no significant correlation between the concentration of extractable lichen substances and the dry weight gain of lichen thalli for any of the investigated species (data not shown).

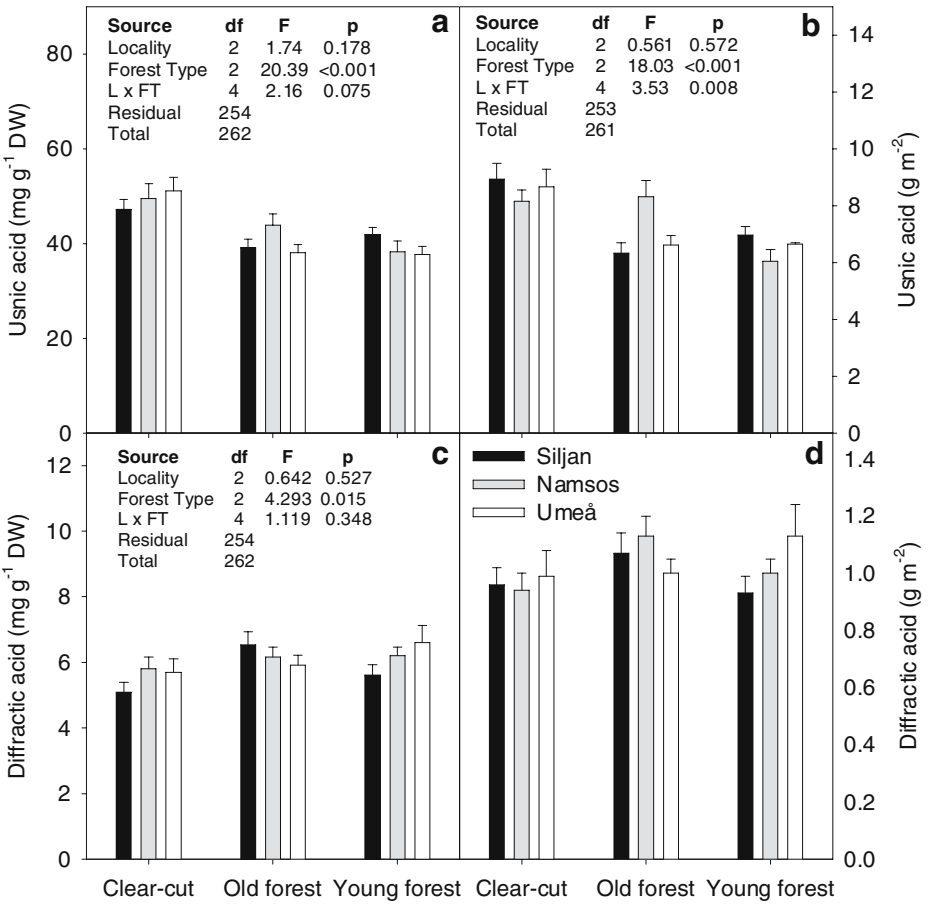

Fig. 3 Secondary compounds in *U. longissima* transplants from three successional stands (clear-cut, old, and young forest) and three climatic zones [Suboceanic (Siljan), Atlantic (Namsos), and Continental (Umeå) zones]. Means±SE are given as concentrations (**a**, **c**) and content per area (**b**, **d**). **a**, **b** Usnic acid. **c**, **d** Diffractaic acid. A two-way ANOVA table is given when at least one factor gives a significant effect

Discussion

The cortical lichen substances, usnic acid in *U. longissima*, and the melanic pigmentation in *L. pulmonaria* and *P. crocata* increased with increasing canopy openness, which suggests common functional roles of the dibenzofurane derivative and melanin as light protection. Browning of light-exposed upper cortices is a well-known phenomenon for some tripartite (*L. pulmonaria*; Solhaug et al. 2003) and green-algal lichens (Nybakken et al. 2000; Nybakken and Julkunen-Tiitto 2006), but has not previously been quantified for purely cyanobacterial lichens like *P. crocata*. Melanins are located in an intact, upper cortex screen that underlies photobionts, thus potentially protecting against UV as well as visible radiation (Gauslaa and Solhaug 2001). Usnic acid in solution strongly absorbs UV-B, some UV-A, and small amounts of blue light (McEvoy et al. 2006). However, extractable cortical compounds like usnic acid are located as numerous tiny crystals outside fungal hyphae. Such external crystals cause extensive scattering of light, meaning that crystals of usnic acid probably screen a wider range of visible light than recorded when they are dissolved. Measurements of the transmittance in a thin crust of usnic acid crystals, spread out on a UV-transmitting Plexiglas, show that the crystals significantly screen visible wavelength ranges at wavelengths where no absorption occurs in solution (K.A. Solhaug, unpublished data). *Usnea* species are too finely constructed to allow preparation of cortex fragments for measuring transmittance, but measurements of transmittance through upper cortices of the usnic acid containing *Nephroma arcticum* (Maria McEvoy, unpublished data) showed up to 50% screening in the visible range. *Usnea longissima* did not experience any photoinhibitory damage during the transplantation on exposed clear-cuts (Gauslaa et al. in press), despite the fact that *Usnea* species are inhabited by trebouxioid photobionts, which are considered to be highly susceptible to high light (Ahmadjian 1959). The *U. longissima* transplants had the highest growth rates in clear-cuts (dry weight gain: 13, 26, and 38% in young forest, old forest, and clear cut, respectively; Gauslaa et al. in press), where the content of usnic acid is highest (Table 2). By contrast, the two foliose species grew best in the old forest (dry weight gain: *L. pulmonaria* 29, 35, and 26%; *P. crocata* 32, 36, and 23% in young forest, old forest, and clear cut, respectively) and showed strong chlorophyll degradation in the clear-cuts (Gauslaa et al. in press), despite the rapid and strong formation of cortical melanins in the thalli. These contrasting responses suggest that a solar screen formed by tiny bright and reflecting crystals of usnic acid is a safer solar radiation screen compared with a melanic screen, likely because dark melanic pigments may jeopardize photochemical processes with excess heat because of their high absorbance of solar radiation (Gauslaa and Solhaug 1999, 2001).

Many medullary compounds are located mainly in the photobiont layer. Their position has been claimed to be consistent with screening of solar radiation (Fahselt and Alstrup 1997). Our overall negative results (Table 2) provide evidence against a general light-protecting function for these UV-B-absorbing medullary compounds. However, many individual medullary compounds did show stand-specific responses, particularly in *P. crocata*, although these trends were generally weak or with contrasting directions (Table 2). This might result from changed priorities in metabolism because of different environmental conditions experienced by lichens in the studied forest successional stages. Stictic acid has a growth-retarding effect on larvae of the polyphagous insect herbivore *Spodoptera littoralis* (Emmerich et al. 1993; Giez et al. 1994). Other than this, there is little knowledge of any functional role of the individual compounds found in *L. pulmonaria* and *P. crocata*. Because many compounds are unidentified, and synthetic pathways are not clear, we refrain from postulating about these responses in further detail.

In *U. longissima*, the medullary depside diffractaic acid responded in an inverse pattern to the cortical dibenzofuran derivative usnic acid (Fig. 3). In clear-cuts, where much carbon is spent for new growth as well as for synthesis of usnic acid, the production of diffractaic acid probably has a lower priority. However, various depsides have been shown to have toxic or deterrent effects on herbivores (Rundel 1978; Giez et al. 1994). Increased concentration of diffractaic acid in the shade could be a response to increased pressure from lichen-feeding invertebrates and decomposing microorganisms under shading canopies. The opposite trends, thus, suggest different roles for cortical and medullary substances in *U. longissima*.

There was no difference in concentration of lichen substances in *U. longissima* along the rainfall gradient (Atlantic–suboceanic–continental locations). Quantification of canopy cover based on hemispherical digital photos (Gauslaa et al. in press) showed that differences among the localities in indirect solar radiation were much lower than the differences among successional stages. This suggests that the concentration of secondary compounds in *U. longissima* is more dependent on canopy openness than rainfall. We would expect humidity (time in the wet and active state; Palmqvist 2000) and amount of sunlight to be important for the build up of carbon available for production and time for synthesis of the secondary compounds. However, we have no data on the actual amount of solar irradiation for the wet, physiologically active periods of the thalli. Open sites, relative to forested stands, are likely to experience frequent cooling below the dew point during nights, meaning that light availability and humidity may be confounding factors.

In summary, the synthesis of the UV-B absorbing cortical compounds usnic acid and melanins seems to be part of an acclimation to increased light exposure. However, usnic acid seems to be a more flexible screen than the brown melanins because it allows maximal thallus growth in fully exposed sites. The medullary compounds in the studied species seem hardly to function as solar screens despite their strong absorbance in the UV-B range.

Acknowledgements We thank Kristin Palmqvist, Håkon Holien, Lise Cats Myhre, Olga Hilmo, Mikael Ohlson, and Camilla Iversen for help with collection of lichen samples, set-up and/or maintenance of the experiments. We are also indebted to Professor Harrie Sipman at the Botanical Museum in Berlin, Germany, for giving us standards of the lichen compounds tenuiorin and stictic acid; and to Professor John Elix, University of Canberra, Australia and Professor Riitta Julkunen-Tiitto, University of Joensuu, Finland for help with identification of lichen substances. This study was supported by the Norwegian Research Council (project number 15778/V40).

of CA and AT may be due to the reactive hydroxyl groups at positions 2 and 4 of ring A, instead of the less reactive methoxyl at the same positions in both BO and MA. In the field comparisons, total quantified phenolics were significantly higher near Mexico City for both lichens, except for the tolerant *R. asahinae* at one site. Nevertheless, only the latter species had significantly increased PAC values at all sites near the city. This result is explained by species-dependent changes in individual phenolics. At the polluted sites, *R. asahinae* had consistently higher contents of its most reactive phenolic, US, with values approximately twice that of the control site. In contrast, *P. stuppeum* only increased its less reactive SA (26–35%), but this was counteracted by CA and, to a lesser extent, AT degradation. Thus, the substantial increase in US at the polluted sites appears to be associated with the current ecological success of *R. asahinae* near the city. On the other hand, the inability of *P. stuppeum* to overcome degradation of its most reactive phenolic (CA) at the same sites seems to partially explain the declining status of this lichen. These results provide evidence for a protective mechanism in lichens against air pollution based on secondary metabolites, which may eventually determine which species survive in forests stressed by oxidative air pollution.

Keywords Lichen secondary metabolites · Ozone reactivity · Antioxidant activity · Free radical scavenging activity against DPPH$^{\bullet}$

Introduction

Lichens are an ancient, large, and ubiquitous group of symbiotic fungi that obtain carbon from specific photosynthetic partners, which are either green algae or cyanobacteria, or both in some cases (Nash III 1996). Part of that carbon is used to synthesize a variety of secondary metabolites, also known as lichen substances. There are about 850 identified lichen secondary metabolites, many of which are phenolics deposited as crystals on the fungal cell walls (Huneck and Yoshimura 1996). Depending upon the species, secondary metabolites constitute 0.1–25% of the lichen thallus on a dry weight basis, but values of 5–10% are more frequent (Dayan and Romagni 2001). Each lichen species has a defined set of secondary metabolites, which can vary quantitatively and qualitatively as influenced by environmental factors such as light intensity and moisture and by intrinsic factors such as genetics, age, and vitality (BeGora and Fashelt 2000). The variability of secondary metabolites induced by the environment demonstrates the importance of these substances for the ecological adaptiveness of lichens.

Some evidence for the biological activity of the lichen substances derives from studies looking for natural compounds with antibiotic, antitumoral, or antioxidant activity for pharmaceutical and food uses (e.g., Hidalgo et al. 1994; Lauterwein et al. 1995; Ingólfsdóttir et al. 1998; Müller 2001; Gülçin et al. 2002; Toledo et al. 2003). Lichen compounds are also being tested as alternative, environmentally friendly, pesticides for agriculture (Dayan and Romagni 2001). Most functions attributed to these metabolites are protective, including filtration of harmful ultraviolet (UV) radiation, deterrence of herbivores, defense against microorganisms, and as allelopathic compounds (e.g., Clark et al. 1999; BeGora and Fashelt 2000; Toledo et al. 2003).

It has been suggested that lichen secondary metabolites may respond to environmental pollution (e.g., Silberstein et al. 1996; Caviglia et al. 2001; MacGillivray and Helleur 2001;

Cabral 2002). In the case of air pollution, lichens are used frequently as biomonitors or bioindicators but their phenolics are rarely measured as response variables. The potential of phenolics for studying lichen responses to air pollution can be inferred from their antioxidant properties and their ability to form insoluble complexes with some metals (Silberstein et al. 1996; Takani et al. 2002). The protective role of phenolics against reactive oxygen species (ROS), including O_3, is well documented for vascular plants (Ranieri et al. 1996). It is, however, questioned whether lichen phenolics play a similar role basically because of their extracellular location (e.g., Kranner et al. 2005). Nevertheless, because of this location, we hypothesized that lichen phenolics may provide some degree of protection to vital lichen cell compartments by reducing the amount of environmental oxidants at the cell wall surface. A possible mechanism for that to occur could be provided by surface gas–solid oxidation reactions. These reactions are rather common to both inert and biological surfaces, especially when organic compounds containing such reactive groups as double-bonds, aromatic hydroxyls, halogens, or carbonyls are present. An example of such surface reactions is the ozonolysis of polyaromatic hydrocarbons on aerosol particles (Pöschl et al. 2001; Hearns and Smith 2004).

Although deleterious effects of O_3 on vascular plants are well-documented (e.g., Krupa et al. 2001), in the case of lichens, such evidence is scarce and contradictory (e.g., Nash III and Sigal 1979; Ross and Nash III 1983; McCune 1988; Scheidegger and Schroeter 1995; Tarhanen et al. 1997). There are pollution-sensitive and pollution-tolerant lichen species (Silberstein et al. 1996), but insufficient consideration has so far been given to the mechanisms that protect resistant lichens from the effect of toxic exposure. A field study conducted in Canada by MacGillivray and Helleur (2001) looked for correlations between lichen phenolic contents and ground-level concentrations of O_3 (17–31 ppb). They found that phenolic contents tended to decrease with O_3 concentration, except for salazinic acid (SA), which increased slightly in *Usnea dasypoga*. This latter increase was interpreted by the authors as a protective biochemical response, and they proposed that SA could be a potential biomarker for O_3 pollution. Such an interpretation is a complex hypothesis requiring more field and laboratory evidence. If it were statistically accepted and extended to other phenolics, it could eventually be possible to take advantage of the great diversity of lichen secondary metabolites to identify responses toward specific air pollutants, an unsolved problem in most lichen field studies.

We report here experimental and observational results from a study that addressed two basic questions related to that hypothesis: (a) Do lichen phenolics react with O_3 and exhibit free radical scavenging properties? and (b) Do lichen populations chronically exposed to heavy oxidative air pollution differ significantly in phenolic profiles from unexposed populations? The first question was answered by kinetic experiments to determine the reactivity between six different lichen phenolics and ozone and their free radical scavenging power. Three major phenolics of two epiphytic lichen species with contrasting tolerance to heavy oxidative air pollution from Mexico City were studied. For this purpose, solutions of pure isolates of these compounds were exposed in vitro to O_3 and diphenyl picryl hidrazyl ($DPPH^{\bullet}$). This latter compound is commonly used to assess the free radical scavenging capacity of whole plant or lichen extracts, as well as specific plant phenolics (e.g., Brand-Williams et al. 1995; Arlorio et al. 2005; Behera et al. 2005). The second question was addressed by comparing the field contents of the same phenolics in samples of the same lichen species between fir forests chronically exposed to urban emissions from Mexico City and a relatively unpolluted and well-conserved fir forest. One more site comparison was based on the potential antioxidative capacity (PAC) provided to the lichens by the measured phenolics.

Methods and Materials

Study Area and Lichen Material The Mexico City Metropolitan Area (MCMA) is the largest, most populated (ca. 20 million people) and most air-polluted urban area in Mexico. During the last 15 years of systematic air monitoring, O_3 has been the most critical pollutant in this area, and this situation was probably similar in previous years. That is attributed to elevated local emissions of O_3 precursors (e.g., VOCs and NO_x) by over 3.5 million vehicles and a variety of industrial and domestic emission sources powered by fossil fuels. Ozone photochemical formation is enhanced by the high solar irradiation received at this high-elevation tropical city and topographical and meteorological conditions that restrict natural ventilation (Blake and Rowland 1995; Bravo and Torres 2002; GDF 2002). The MCMA (2,240 m above sea level) is located at the SW corner of the Mexico Basin, which is surrounded almost entirely by forested, high-elevation mountains (2,000 m above the urban floor, Fig. 1). This region provides a good opportunity to study effects from urban emissions on the natural vegetation. The oak and conifer forests located to the S–SW of the MCMA are the most affected by air pollution because they are closer to the urban area and lie predominantly downwind of it. The current knowledge on this topic was recently compiled by Fenn et al. (2002). Ozone monitoring and studies on oxidative injury to sacred fir (*Abies religiosa*) at Desierto de los Leones, where 100 ppb O_3 maximum hourly concentrations occur throughout most of the year along with 200–300 ppb monthly peaks (Alvarado-Rosales and Hernández-Tejeda 2002), indicate that oxidant air pollution is a major local forest disturbance factor.

The lichens *Ramalina asahinae* and *Parmotrema stuppeum* (Fig. 2) were chosen because they represent, according to data of Zambrano and Nash III (2000), two contrasting cases of

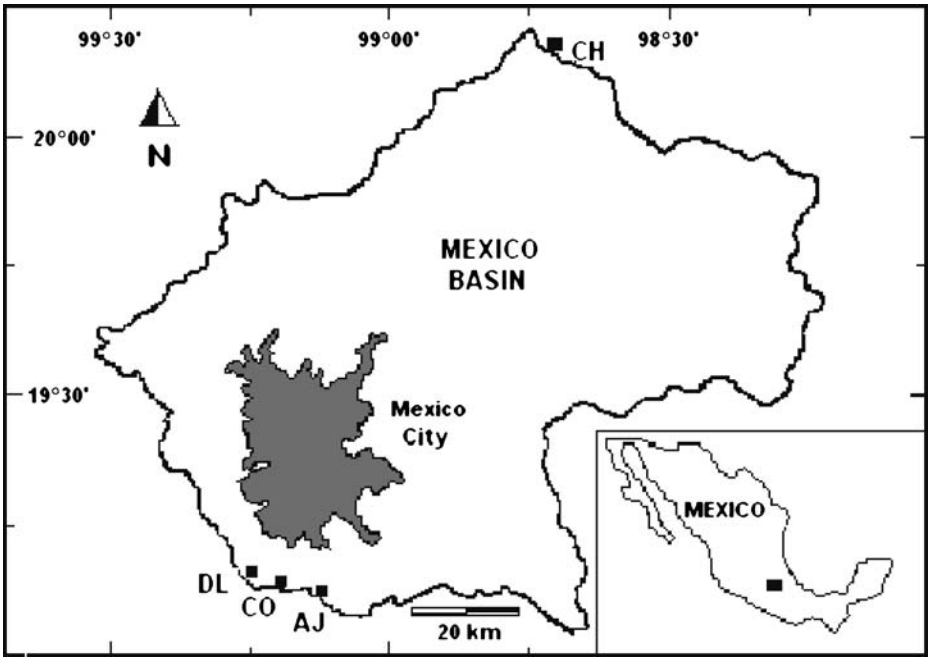

Fig. 1 Study sites. Ajusco Volcano, *AJ*; Dinamos de Contreras, *CO*; El Chico National Park, *CH* (control site); Desierto de los Leones, *DL*

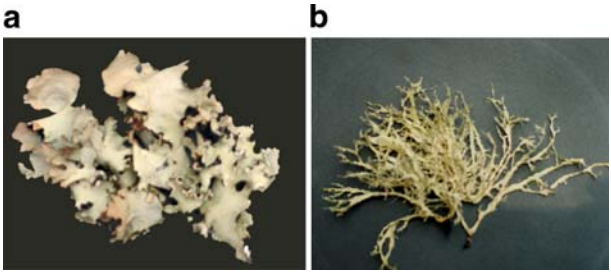

Fig. 2 Photos of lichens **a** *Parmotrema stuppeum* and **b** *Ramalina asahinae*

species tolerance toward chronic exposition to high levels of air pollution in forests near Mexico City. *Ramalina asahinae*, cited as *R*. cf. *farinacea* by Zambrano and Nash III (2000), is the dominant and thus tolerant, epiphytic lichen of sacred fir. In contrast, and compared to similar sites less exposed to the urban emissions, *P. stuppeum* is severely depleted in abundance. However, this species is abundant in fir forests far from the reach of urban emissions. For example, at El Chico National Park (CH, Fig. 1), where the sacred fir forests still sustain healthy epiphytic lichen communities, *P. stuppeum* is the dominant species; whereas, *R. asahinae* ranks fourth in abundance (Zambrano and Nash III 2000).

All lichen samples for field comparisons of phenolic contents were collected between mid-January and mid-February, 2004. After a nested experimental design, three fir forests located 8–12 km to the S–SW of Mexico City were compared to a control site ca. 100 km N of the city (Fig. 1, Table 1). Lichens were sampled only from the trunks of sacred firs to minimize variability because of substrate differences. Within-site variation was assessed by sampling three forest stands per site. Stands were separated by at least 150 m. A lichen sample was defined as the material of each species (about 200 mg air-dry weight) obtained from one tree. Nine samples per stand were obtained; i.e., 27 samples per site. *P. stuppeum* was not sampled at one site near Mexico City (Ajusco Volcano), where this species is almost extinct. Air-dried lichen samples were carried to the laboratory in paper bags. Taxonomical identification was done by conventional lichenological techniques.

Preparation of Lichen Extracts for Field Comparisons Samples (ca. 30 mg) from the newest, marginal thalli portions were desiccated on drierite for 48 h. Dry, mortar-ground samples (20 mg) were extracted for 1 h with 5 ml of 1:1 acetone and methanol (Burdick & Jackson) and spiked with benzophenone (BZ; 0.25 mg ml^{-1}, Sigma Aldrich) as internal standard. Extracts were filtered through a millipore™ membrane filter (0.45 μm), and the filtrates were submitted to high-performance liquid chromatography (HPLC). A chromatogram of a *P. stuppeum* extract is shown in Fig. 3.

Isolation and Characterization of Lichen Phenolics Six lichen phenolics (LP) were tested for antioxidant capacity. All were isolated by conventional chromatographic techniques (Ramaut et al. 1978; Jayaprakasha et al. 1998) from materials collected at the control site. SA, atranorin (AT), and chloroatranorin (CA) were isolated from *P. stuppeum*; boninic acid (BO), 2-*O*-methylsekikaic acid (MA), and usnic acid (US) were obtained from *R. asahinae* (Fig. 4). The purity of isolates was confirmed by HPLC, and their identity was determined

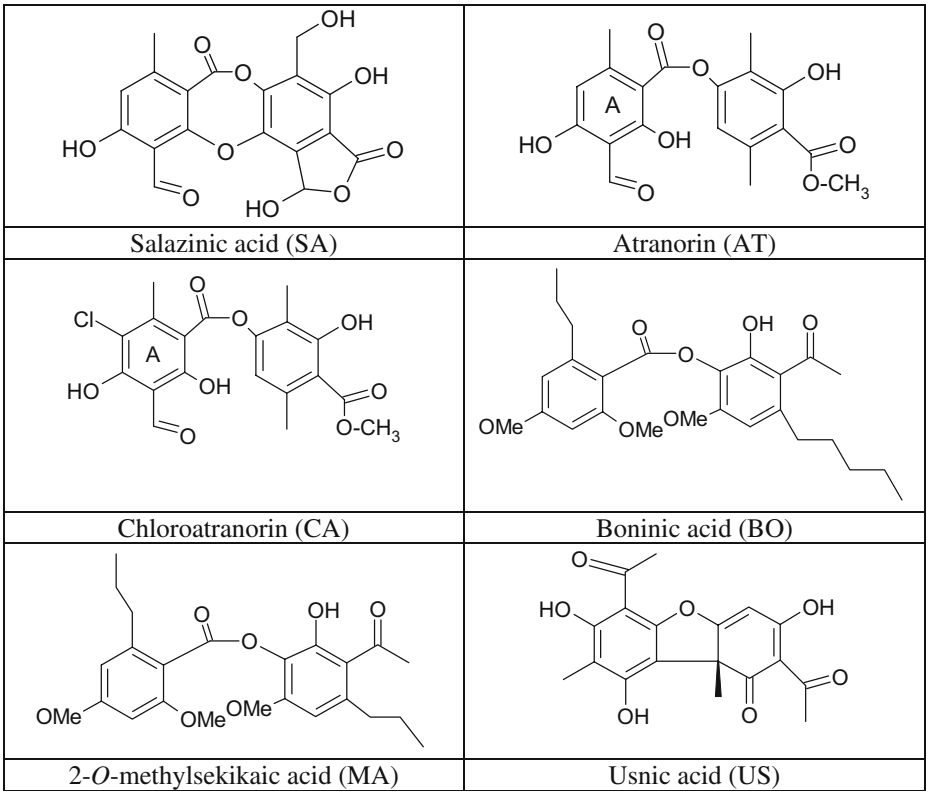

Fig. 4 Lichen phenolics included in this study

by comparing measured UV, infrared, nuclear magnetic resonance, and mass spectrometry values with those reported by Eifler-Lima et al. (2000) and Huneck and Yoshimura (1996).

HPLC Analysis of LP Quantification of LP for field comparisons and ozonation experiments was conducted with a liquid chromatograph (Agilent HP, 1100 series) equipped with diode-array detector and Nucleosil 100-5 C18 column (Agilent, 250×4.0 mm, 5 μm particle, 100 Å pore). Runs started with 50% methanol (Burdick & Jackson) and 50% water (Fermont) added with 1% orthophosphoric acid (Baker). The flow rate was 0.7 ml min^{-1}. Methanol was increased to 70% within 7 min and to 100% during the after 13 min. Runs continued isocratically for six additional minutes. Finally, methanol was brought to 50% within 1 min and the column flushed for 5 min. Injections were administered in 20 μl volumes, and the detector wavelength was set at 254 nm. An internal standard, benzophenone, was included in each sample.

Kinetic Studies of LP with Ozone Reaction rates of lichen phenolics with O_3 were empirically determined by aqueous ozonation at 20°C, under conditions where the initial concentration of lichen phenolic was low compared to the initial ozone concentration: $[LP]_0 << [O_3]_0$. Molar aqueous solutions of each LP (SA, 503.1×10^{-6}; AT, 105.5×10^{-6}; CA, $1{,}128\times10^{-6}$; BO, $1{,}305.0\times10^{-6}$; MA, 364.0×10^{-6}, and US, $1{,}074.0\times10^{-6}$) added with benzophenone as internal standard were mixed with ozonated water in glass reaction vessels (350 ml). Stock ozonated water solutions were prepared by bubbling water with O_3 from a Polyozone generator (Polimetrics, Inc. Model T-816, 330 series) fed with pure commercial oxygen. The initial concentration of O_3 in water was determined by the iodine method (Skoog and West 1990). Because $[O_3]$ decreased by less than 5% during experiments, as determined by final measurements, it can be assumed that $[O_3]$ was constant during the experiments.

After mixing solutions, a subsample was drawn at different times to quantify the remaining [LP]. To minimize further ozonolysis of LP before the HPLC measurements, the residual O_3 was eliminated by bubbling the sample with pure oxygen. All experiments included procedural blank and unozonated sample solutions.

Under the used reaction conditions (i.e., $[O_3]$ in large excess compared to [LP]), the less concentrated reactant decays exponentially, and thus a pseudo-first-order kinetics can be assumed. This is a common assumption in ozonation studies (e.g., McDowell et al. 2005). According to Eq. 1

$$[\mathrm{LP}] = [\mathrm{LP}]_0 e^{-k_{\mathrm{obs}}t} \tag{1}$$

where [LP] is the lichen phenolic concentration at any time (t), as quantified by HPLC, $[LP]_0$ is the lichen phenolic concentration at time zero, and k_{obs} is the pseudo-first-order rate constant.

The pseudo-first-order rate constant was calculated from Eq 2, where ln[LP] is linearly dependent on time in all cases and from the slope of this plot.

$$\ln[\mathrm{LP}] = \ln[\mathrm{LP}]_0 - k_{\mathrm{obs}}\, t \tag{2}$$

The second-order-rate constant (k_2) was calculated for each LP from Eq. 3

$$-\mathrm{d}[\mathrm{LP}]/\mathrm{d}t = k_{\mathrm{obs}}[\mathrm{LP}] = k_2[\mathrm{O_3}][\mathrm{LP}] \tag{3}$$

Free Radical Scavenging Activity of LP by the DPPH• Method The free radical scavenging activity of lichen phenolics was determined by reaction with the DPPH• free radical at

20°C, according to Brand-Williams et al. (1995). Briefly, fresh DPPH$^{\bullet}$ methanol solutions were mixed with fresh methanol solutions of each LP. The amount of reacted DPPH$^{\bullet}$ was calculated from the decrease in absorbance at 515 nm as measured with an UV-visible spectrophotometer (Perkin Elmer, Lambda 25) and using a previously determined calibration curve. Absorbance was recorded at 0.1 min after mixing the reactants. Afterwards, it was recorded every 15 min until reaching the reaction plateau. Each LP required a different concentration interval to estimate its reaction rate. These intervals were determined by preliminary experiments (in moles of LP/mole DPPH$^{\bullet}$): SA, 5.0–180.0; AT, 0.25–80.0; BO, 5.0–180.0; MA, 1.0–80.0; and US, 0.25–80.0. Ascorbic acid (AA) was used as positive control at a concentration range of 0.069–0.509. The antiradical power (ARP) of each LP was calculated following Brand-Williams et al. (1995).

Kinetic Studies of LP with DPPH$^{\bullet}$ Plots and fittings of experimental data were done with the Table Curve 2D v5.01 program following Suja et al. (2004). Experiments were conducted at 20.0°C. The second-order rate constants were calculated for each compound as a measure of radical scavenging capacity. To determine constants, each phenolic required a different concentration interval with respect to DPPH$^{\bullet}$ (number of moles of LP/mole DPPH$^{\bullet}$): 19.1–94.2 for SA; 19.7–82.7 for AT; 22.1–33.1 for CA; 42.64–97.53 for BO; 21.4–87.7 for MA; and 20.2–51.0 for US. The decay of [DPPH$^{\bullet}$] was assumed to follow a pseudo-first-order kinetics under the condition that $[DPPH^{\bullet}]_0 \ll [LP]_0$. According to Eq. 4

$$[DPPH^{\bullet}] = [DPPH^{\bullet}]_0 e^{-K_{obs}t} \quad (4)$$

k_{obs} and second-order rate constants (k_2) were calculated as for the ozonolysis of lichen phenolics.

Results and Discussion

The epiphytic lichens *R. asahinae* and *P. stuppeum* were studied to explore whether their major secondary metabolites are involved in the tolerance of the first species and the sensitivity of the second species to chronic habitat exposure to high levels of oxidative air pollution from Mexico City.

Antioxidant and Free Radical Scavenging Activity of LP The six tested phenolics had some degree of in vitro antioxidant activity and free-radical scavenging capacity. Table 2 shows the experimental second order reaction rate constants (k_2-O_3 and k_2-$_{DPPH^{\bullet}}$) and the ARP of these lichen compounds. ARP was expressed as $1/EC_{50}$ (Brand-Williams et al. 1995), where EC_{50} is the phenolic concentration that decreases the DPPH$^{\bullet}$ concentration by 50% as illustrated in Fig. 5. According to the kinetic constants (Table 2), the following decreasing reactivity trends were determined for the studied phenolics: CA>>AT>US>SA≥BO≥MA for O_3 and CA> AT>US>MA>SA=BO both for the DPPH$^{\bullet}$ and the ARP criteria. The reactivity ranking for the three most reactive compounds was thus concordant between k_2-$_{O3}$ and k_2-$_{DPPH^{\bullet}}$, but minor ordering discrepancies occurred for the less reactive ones, which was probably because of reaction details that merit further analysis. The most reactive secondary metabolite of *P. stuppeum*, CA, disappeared so rapidly upon contact with O_3 that k_2-O_3 could not be determined under our experimental conditions. However, the DPPH$^{\bullet}$ experimental model showed that CA scavenged this free radical at rates 150 and 733% higher than AT and SA, respectively. Atranorin reacted with O_3 and DPPH$^{\bullet}$ at about twice the rate that SA reacted

with the same stressors. In the case of *R. asahinae*, the most reactive compound was US. It reacted with O_3 at rates 58 and 72% higher than BO and MA, respectively, and it reacted with DPPH$^{\bullet}$ at rates 192 and 40% higher than BO and MA.

It is not yet possible to compare directly these reactivity rates with results from other lichen phenolic studies because of different experimental models among them (e.g., Hidalgo et al. 1994; Jayaprakasha and Rao 2000; Toledo et al. 2003). Some authors tested whole lichen extracts with DPPH$^{\bullet}$ (e.g., Gülçin et al. 2002; Odabasoglu et al. 2004), in which case, the antioxidant capacity of individual phenolics was not determined. With whole lichen extracts, the antioxidant capacity of phenolics is confounded with that from other cell compounds in the mixtures. Lichen depsidones have been reported as more efficient antioxidants (Hidalgo et al. 1994) and also as more cytotoxic (Correche et al. 2004) than depsides. Our results show that depsides (AT and CA) had higher antioxidant capacity than SA (a depsidone) and the meta-depsides BO and MA. In view of the limited experimental and

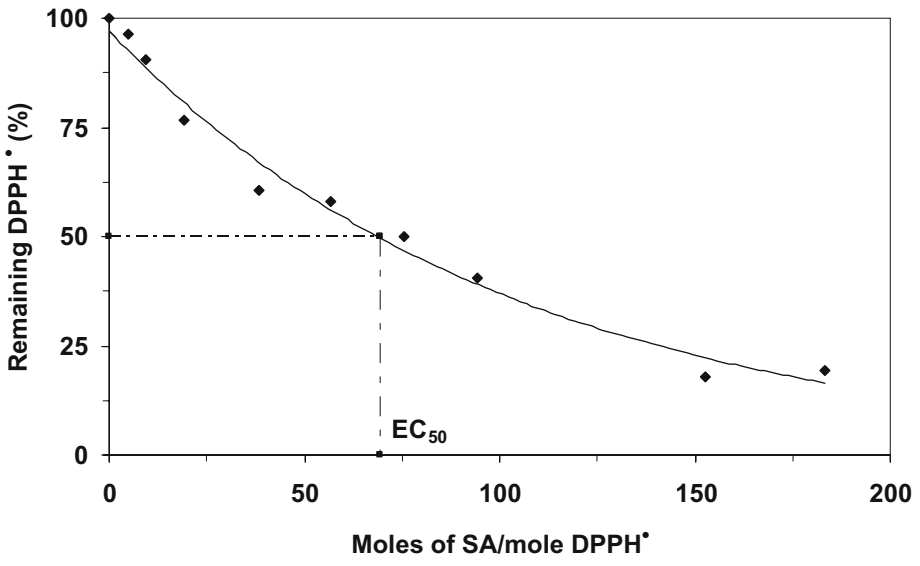

Fig. 5 Disappearance of DPPH$^{\bullet}$ as a function of salazinic acid (*SA*) concentration. EC_{50} was the SA concentration causing a 50% decrease in DPPH$^{\bullet}$ absorbance

theoretical data available on the antioxidative properties of lichen phenolics, it is still not possible to generalize at the chemical group level. However, it can be hypothesized that AT and CA were more effective antioxidants than BO and MA because they contain hydroxyl groups at positions 2 and 4 of ring A instead of the methoxyl group that both BO and MA have at the same ring positions. Such a hypothesis is consistent with reported positive correlations between the number of hydroxyl groups in the aromatic rings of phenolic acids and the antioxidative and antiradical activity of these compounds (Sroka and Cisowski 2003). The lower reactivity of AT compared to its homologue CA, which has chlorine at position 5, may be due to inductive electron withdrawal of this atom over the *o*- and *p*-phenolic groups of ring A, which may propitiate a higher hydrogen-donating ability of the OH group in the *p*-position of the CA molecule (Burton et al. 1985).

Compared to the common cellularly soluble antioxidant AA, which we used as positive control in the $DPPH^{\bullet}$ experiments, all of the tested phenolics had a rather slow antiradical activity. The reaction between $DPPH^{\bullet}$ and AA reached its plateau within a few minutes compared to over 6 h for all the phenolics (data not shown). Consequently, even the most reactive of the tested phenolics (ARP: 0.11–0.59, Table 2) had a much lower antiradical power than AA (ARP=3.70). According to Brand-Williams et al. (1995), other vascular plant phenolics showed even higher ARP values; e.g., caffeic (11.0) and gallic acids (12.5). However, some plant phenolics reported by the same authors had similar or lower ARP values than the lichen phenolics tested herein; e.g., coumarin, vanillin, and vanillic acid (0.02, 0.05, and 0.17, respectively).

The location of phenolics in the lichen body is a constant feature used by lichenologists as a taxonomical character. Its biological importance was observed in the context of protection from harmful light irradiation (Fahselt 1994). Interestingly, the most reactive phenolics of *P. stuppeum* (CA and AT) and *R. asahinae* (US) are located at the thallus cortex (Culberson and Culberson 1976; Nash III and Elix 2001), which is the thallus region in contact with the surrounding air, whereas the less reactive SA, BO, and MA are medullary and thus less directly exposed. Such reactivity distribution suggests that lichen phenolics, at least those most reactive and cortical, provide some degree of protection against environmental oxidants by limiting their entrance into more internal tissues and the vital cell interior. Reactions between secondary metabolites and O_3 at the lichen surface are likely to occur, but this needs experimental demonstration. Some authors suggest that reactions between trace atmospheric gases and organic compounds on solid or liquid surfaces could be biologically important because they are faster than previously thought (e.g., Donaldson et al. 2005). For instance, ozonolysis of complex organic compounds such as polyaromatic hydrocarbons is documented to occur at the surface of atmospheric aerosol particles and known to be enhanced by low air humidity (Pöschl et al. 2001). Thus, in contrast with pollutants requiring the presence of water or metabolically active cells or tissues to cause injury, O_3 can be expected to degrade biological compounds on dry surfaces. That could be of great importance for organisms growing under O_3 stress, as this pollutant reaches its maximum ambient air concentration at the driest hours of the day. It could be hypothesized that the most reactive cortical phenolics of lichens degrade the most during the midday-early afternoon hours, when the air is driest and these organisms less metabolically active.

Cocchietto et al. (2002) stated that the biological role of lichen substances is strictly species-specific. Our results confirm this view. For instance, by simply summing up the reactivity constants or ARP values in Table 2, the air-pollution sensitive *P. stuppeum* would have a higher potential antioxidant capacity because of phenolics than the resistant *R. asahinae*, which would be a paradox. Such an apparently contradictory result is explained

in the following section once the reactivity rates are combined with the field contents of phenolics in those lichens.

Phenolic Contents in Field Samples Table 3 compares field contents of individual and total quantified phenolics (TQP) in the studied lichens. For *R. asahinae*, TQP was on average 9.2% of the lichen dry weight at the control site, increasing near Mexico City to 9.7, 10.5, and 13.5% at Desierto de los Leones, Ajusco Volcano, and Contreras, respectively. For *P. stuppeum*, TQP represented 7.6% of the lichen dry weight at the control site and increased near the city to 9.1 and 9.8% at Desierto de los Leones and Contreras, respectively. Except for the tolerant *R. asahinae* at Desierto de los Leones, where it had similar TQP values to the control site, the increases near the city were highly significant ($P<0.001$, Table 3), and they can be interpreted as a generalized lichen response to the polluted conditions. However, this still does not explain yet why at the polluted sites *R. asahinae* is dominant, and *P. stuppeum* is severely reduced.

On an individual compound basis, the less reactive and medullary compounds of each species (BO and SA) were more abundant by an order of magnitude than the most reactive, cortical ones (AT, CA, and US, Table 3). This negative correlation between compound abundance and reactivity was nonlinear (Fig. 6). Accordingly, for the studied lichens, it can be established that under natural conditions phenolic degradation increased with reactivity. The site comparisons of individual phenolics had more complex patterns, but they allow one to identify which compounds were responsible for the TQP increases near Mexico City (Table 3). Only BO and US (*R. asahinae*) and SA (*P. stuppeum*) increased consistently near the city; AT and CA (*P. stuppeum*) decreased. MA (*R. asahinae*) had similar levels to the control site (except at Contreras where it increased). The highest and most consistent proportional increase was for US, the most reactive phenolic of *R. asahinae*, which doubled its concentrations near the city. The less reactive and largest contributor to TQP for *R. asahinae*, BO, increased at Ajusco (11%) and Contreras (43%) but not at Desierto de los Leones, which explains why this species did not differ there from the control site in TQP levels. For *P. stuppeum*, only SA increased significantly at Desierto de los Leones (26%) and Contreras (35%); whereas CA, the most reactive phenolic, decreased, respectively, by

This plot included all six phenolics evaluated in this study. *Lines* fitted as power functions. R^2 values: El Chico (control site), 0.82; Desierto de los Leones, 0.90; Contreras, 0.92

13 and 31% at the same sites. Finally, AT, the second most reactive phenolic of *P. stuppeum*, also decreased (35%) at Desierto de Los Leones, but it did not differ from control values at Contreras. Thus, the TQP increase for this latter species at the polluted sites is attributable to extra production of SA, its less reactive medullary compound.

The potential meaning of the differences in phenolic contents for the tolerance of local lichens toward chronic oxidative air pollution was approximated by weighting the amount of each compound with its anti-free radical capacity: $k_{2\text{-DPPH}}{}^{\bullet}$ [LP]. This product represents a measure of the partial contribution of each phenolic to the total PAC provided by the lichen substances. The $k_{2\text{-DPPH}}{}^{\bullet}$ was used as weighting factor instead of $k_{2\text{-O3}}$ because this latter constant could not be determined for CA (Table 2). Nevertheless, because both constants lead to the same reactivity ranking for the most reactive phenolics and because weighting contents by another constant would not introduce extra variability into the data matrix, similar results could be expected from using either constant. Table 4 shows the site comparisons by lichen PAC values. The tolerant *R. asahinae* increased significantly its total antioxidative capacity ($P<0.001$) at all sites near the city: 13% at Desierto de los Leones, 20% at Ajusco, and 52% at Contreras. The significant PAC increase for this tolerant species at Desierto de los Leones should be emphasized because its TQP did not differ from control values (Table 3). In contrast, the significant increase in TQP for the sensitive *P. stuppeum* at this site did not suffice to elevate its PAC, which was due to degradation of CA and AT. Thus, the potential antioxidative capacity of *P. stuppeum* at Desierto de los Leones depended on its less reactive SA. At Contreras, this species had a PAC greater than at the control site, which was also due to increased concentrations of SA.

Fig. 7 summarizes how these two lichen species respond to the Mexico City environs by changing their phenolic profiles in a sharply different manner. This figure plots the ratios

between concentrations in lichen tissue of the more reactive (cortical) and the less reactive (medullary) phenolics (MRP/LRP). The control site ratios can be interpreted as an average cortex-to-medulla phenolic reactivity balance when the lichens grow under low oxidative stress. At the polluted forests, this ratio increased by 45–96% in tolerant *R. asahinae* and decreased by 35–38% for the sensitive *P. stuppeum*. It could be hypothesized that these ratios reflect the degree of oxidative air pollution stress at a given site. If this is correct,

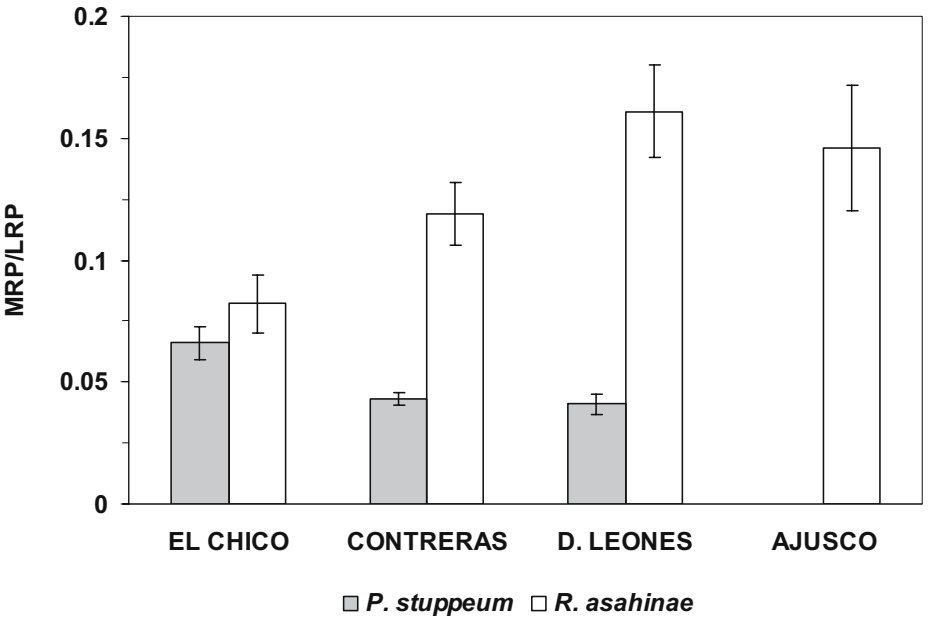

Fig. 7 Mean concentration ratio of the most reactive cortical phenolic (*MRP*) to the less reactive medullary phenolic (*LRP*) for field samples of *P. stuppeum* (CA/SA) and *R. asahinae* (US/BO) growing in fir forests near Mexico City. *Error bars* represent the 95% confidence intervals, $N=27$

Contreras would be the least stressed of the studied sites near the city. Both lichens had their highest absolute increases in phenolic contents at this site, which is probably an exacerbated response from still healthy samples. Levels of AT (*P. stuppeum*) at Contreras were similar to the control site, indicating still balanced biosynthesis and degradation rates for this compound. This hypothesis needs testing by further studies relating site oxidant air pollution levels with lichen phenolic profiles. It should be considered that the antioxidant protection of lichens provided by phenolics is only partial because they also contain other important apoplastic and symplastic antioxidative protection systems (Silberstein et al. 1996; Kranner et al. 2005).

These results showed that lichen secondary metabolites reflect the long-term exposure to oxidant air pollution near Mexico City. They seem to explain partially why *R. asahinae* currently dominates the severely simplified epiphytic lichen communities of the fir forests near Mexico City (Zambrano and Nash III 2000). They also add support for a lichen air-pollution protective mechanism based on secondary metabolites. Such a mechanism may not be universal to lichens as it depends on species specific strategies to modify the balance between phenolic degradation and biosynthesis, as reflected by their ratio between highly reactive and less reactive compounds. The ability of each species to modify these ratios may ultimately prove to be critical for lichen survival in forests severely affected by oxidative air pollution.

In summary, we can state that the six lichen secondary metabolites evaluated in this study showed differential antioxidant and free antiradical activity when mixed, respectively, with O_3 or $DPPH^{\bullet}$ solutions. Although this does not show unequivocally that lichen substances respond under natural conditions to O_3, the comparison of major phenolics between these two species with contrasting tolerance to air pollution from Mexico City does provide support for such a possibility. First, the phenolics with the greatest antioxidant activity, US from *R. asahinae* and CA and AT from *P. stuppeum*, were those deposited on the cortical hyphae, which are the lichen cells most exposed to the atmosphere. This finding, together with the available evidence on surface ozonolysis of complex organic compounds from other experimental systems, suggests that these phenolics likely react with O_3 and thus provide some degree of antioxidative protection under field conditions. Second, the phenolic profiles of the air-pollution tolerant *R. asahinae* and the sensitive *P. stuppeum* differed quantitatively between the chronically polluted and unpolluted forests around Mexico City. Both species had higher TQP near the city, but only *R. asahinae* had higher PAC values in the near-urban sites. The high PAC values in *R. asahinae* were traced to substantial increases in US, the most reactive phenolic of this species. In contrast, the air pollution-sensitive *P. stuppeum* showed significant degradation of CA, its most protective phenolic at the same sites. Together, these results support the hypothesis that lichen phenolics contribute to the antioxidant defenses of these organisms in places affected by chronic oxidative air pollution. The research approach of combining lichen phenolic contents with antioxidative measurements revealed aspects of the differential importance of these compounds, which otherwise may have not been captured. Because lichens are also protected by other apoplastic and symplastic antioxidative systems, to fully assess the use of lichen phenolics as biomarkers for oxidative air pollution, other experiments are needed, such as controlled fumigations with O_3 and observational studies correlating field phenolic contents with air pollution levels.

Acknowledgments This study was supported by the IMP Security and Environmental Research Program. We thank Dr. Luis Zamudio, Corrosion Laboratory, IMP, for doing the NMR analyses of the lichen phenolic isolates, and Dr. Mark Fenn, with the Pacific Southwest Research Station (USDA Forest Service), for improving the English.

found in all orders of demosponges (McClintock and Baker 2001), a large number of which have potential for development into bioproducts (Sipkema et al. 2005; Paul et al. 2006). The temperate marine sponge *Haliclona* sp. (Demospongiae; Haplosclerida; Chalinidae) has attracted considerable attention because of its production of the potent cytotoxic natural product salicylihalamide A (Fig. 1). Salicylihalamide A represents a class of compounds that has a unique chemical scaffold different from that of known antitumor compounds (Erickson et al. 1997). Its mode of action is via the inhibition of mammalian vacuole ATPase activity, which is implicated in pathological processes such as osteoporosis, renal disease, HIV infection, and tumor metastasis (Boyd et al. 2001). Salicylihalamide A is currently undergoing preclinical trials; however, its success as a drug is hindered by lack of a reliable supply (Newman and Cragg 2004). Whereas salicylihalamide A has been synthesized (Wu et al. 2000), this is currently not an economically viable option for supply. The greatest potential for securing commercial quantities of salicylihalamide A is through harvesting either wild or cultured biomass (Munro et al. 1999), highlighting the importance of developing an understanding of the natural concentrations of the compound (Munro et al. 1999).

New populations of *Haliclona* sp. have been discovered since the sponge was initially collected in 1989 at Rottnest Island (Erickson et al. 1997). Closer inspection of these new populations has resulted in the identification of two morphologies that have similar spicule and skeletal characteristics (unpublished data). The first morphology (green *Haliclona*) has a deep green coloration, an amorphous shape, and varying numbers of oscules. The oscules are chimney-like in shape and extend outwards at least 20 mm from the main sponge. The sponge mesohyl is open with large internal canals present. The second morphology (brown *Haliclona*) has a brown coloration, a mound shaped body, and small, slightly raised oscules that extend less than 5 mm above the surface. The oscules are numerous, and the sponge has a compact mesohyl with few internal canals. Closer inspection of the original voucher sample showed that salicylihalamide A was isolated from the green morphology. The brown morphology has not yet been examined. Understanding the natural concentrations of secondary metabolites provides information on both the biology and ecology of the source organism, such as the relationships between populations and individuals (Turon et al. 1996; Lopez-Legentil et al. 2005), the physiology of the source organism (Turon et al. 1996; Duckworth and Battershill 2001), and environmental influences (Thompson et al. 1987; Maida et al. 1993; Page et al. 2005). Limited ecological information exists for both morphologies of *Haliclona* sp., with most literature restricted to the chemistry of the green *Haliclona*.

Spatial variation in concentrations of secondary metabolites has been documented in several cnidarians (Harvell et al. 1993; Maida et al. 1993; Kelman et al. 2000; Marti et al. 2005), bryozoans (Mendola 2003; Marti et al. 2005), tunicates (Lopez-Legentil et al. 2005; Marti et al. 2005), and sponges (Thompson et al. 1987; Becerro et al. 1995; Page et al. 2005). Fewer studies have examined temporal variation (Turon et al. 1996; Duckworth and Battershill 2001; Marti et al. 2005; Page et al. 2005). Chemical variability has been attributed to several factors such as hydrodynamic characteristics (Duckworth et al. 2004;

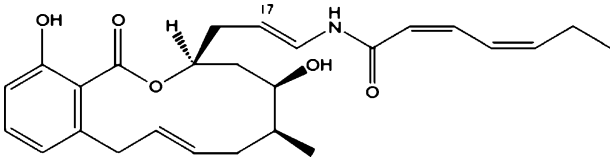

Fig. 1 Chemical structure of the bioactive compound salicylihalamide A

Page et al. 2005), depth (Thompson et al. 1987; Harvell et al. 1993; Page et al. 2005), competition (Maida et al. 1993; Turon et al. 1996), size (Maida et al. 1993; Becerro et al. 1995), and habitat (Becerro et al. 1995).

The primary goal here was to determine whether both morphologies of *Haliclona* sp. produce salicylihalamide A. Secondary to this was to describe the spatial and temporal patterns of salicylihalamide A production in the recently discovered *Haliclona* sp. populations at Hamelin Bay, Jurien Bay, and Bremer Bay, and the ecological implications. This is the first study of the variability of a bioactive compound in a marine sponge from the west coast of Australia.

Materials and Methods

Collection Collections were made haphazardly by SCUBA at each of the four locations (Bremer Bay—34.45°S, 119.38°E; Hamelin Bay—34.20°S, 115.04°E; Rottnest Island—32.00°S, 115.52°E; and Jurien Bay—30.275°S, 115.02°E) along the south western coast of Western Australia (Fig. 2) during the Australian summer (December–February). Winter (June–August) samples were collected only from Bremer Bay because of unfavorable diving conditions at the three other locations. Sponge size was determined before sampling by using an underwater stereo camera to capture a series of stereo images of each sponge (Abdo et al. 2006b). Each set of images was processed in the laboratory to obtain a volume

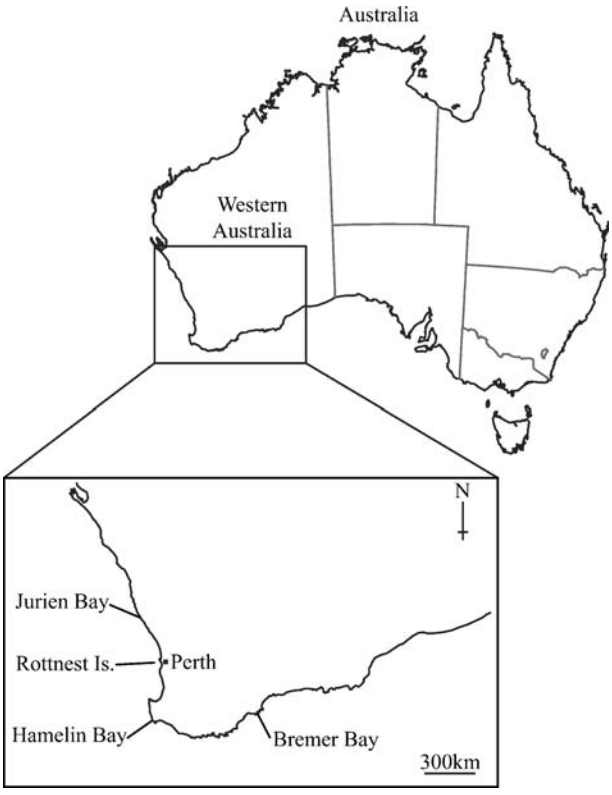

Fig. 2 Study locations along the west coast of Australia. Initially, both morphologies were only known to occur at Rottnest Island but have been found now at Jurien Bay in the north and Hamelin Bay and Bremer Bay to the south. Sponge distribution covers approximately 1,200 km of coastline

estimate for each sponge (Abdo et al. 2006b). Samples (approximately 9 cm^3 in size; N=5, except Rottnest Island where N=6) of both the green and brown morphologies were excised and placed in individual vials and frozen at −20°C. The depth of each sponge, the number of necrotic areas, and the water temperature were also recorded.

Chemical Extraction and Analysis The concentration of salicylihalamide A was determined by using high performance liquid chromatography (HPLC) coupled with ultra violet (UV) detection and mass spectrometry (MS). Each frozen sample (approximately 8 cm^3) was cut into small pieces, placed within preweighed and labeled vials, and freeze-dried for 48 h. The dry weight was recorded (883.29±31.97 mg [mean±s.e.]), and each sample was extracted exhaustively ×3 by addition of 10 ml of ethanol and sonicated for 30 min during each extraction. The supernatant was filtered under vacuum, concentrated in vacuo, freeze-dried, and weighed (67.63±3.45 mg [mean±s.e.]). Samples were dissolved in methanol to give a concentration of 10 mg ml^{-1}. A 160-μl aliquot of each sample was combined with 40 μl (equivalent to 0.5 mg ml^{-1}) of the internal standard, coumarin ($C_9H_6O_2$). For each sample, 40 μl (equivalent to 8 μg μl^{-1} of crude extract) were injected onto a Gemini 3 μ C18 110 Å 50×4.6-mm column (25°C) at a flow rate of 1 ml min^{-1} with a gradient of 50% acetonitrile (ACN): water to 100% ACN over 40 min by using an Agilent 1100 HPLC system (comprising a degasser, binary pump, PDA [for ultra violet detection] and a Gilson 215 Liquid Handler auto sampler/collector). The eluant was directed to a Bruker Daltonics Esquire3000plus mass spectrometer with an Apollo source operating at 40 eV to measure low resolution mass spectral data.

The concentration of salicylihalamide A was quantified by calculating the integral of the peak area at the retention time of 12 min and λ=285 nm (in relation to the integral of the coumarin peak area at 5 min and λ=285 nm) for each sample and converted to a concentration (μg g^{-1} of dry weight) by reference to a standard curve.

Data Analysis Pearson's correlation coefficient (r; Zar 1999) was used to examine correlations between the concentration of salicylihalamide A and water temperature, size, and depth of the sponge. Correlations between water temperature, sponge size, and depth were also examined to ensure that each variable did not influence the other.

The influence of any significant correlations of water temperature, depth, and sponge size with salicylihalamide A concentration was removed with a one-way analysis of covariance (ANCOVA; Zar 1999) to determine if variation in salicylihalamide A concentration occurred among locations (fixed factor, four levels). A two sample t-test was used to examine for variation in the concentration of salicylihalamide A between summer and winter (Zar 1999). For all analyses, data were checked for normality and homoscedascity before analysis, and Bonferonni corrections were applied to account for multiple comparisons (Zar 1999). To determine if the health of the sponge influences the concentration of salicylihalamide A, a two sample t-test was used to compare the salicylihalamide A concentration of healthy (necrotic tissue absent) and unhealthy (necrotic tissue present) sponges.

Results

Differences Between Morphologies Salicylihalamide A was produced by all samples of the green *Haliclona* collected from the four locations and during both summer and winter

seasons at Bremer Bay. The mean concentration of salicylihalamide A within green samples was 10.7 μg g^{-1} (±1.1 μg g^{-1}). The mean yield of salicylihalamide A from the crude extract was 2.83% (±0.28%). Salicylihalamide A could not be detected by either UV or MS in any of the brown samples collected from any location or season (Fig. 3).

Temperature, Volume, and Depth Correlations Water temperature showed an increasing trend in green *Haliclona* from southern to northern locations (Bremer Bay 19.5°C [±0.3°C]< Hamelin Bay 20.1°C [±0.2°C]<Rottnest Island 21.2°C [±0.5°C]<Jurien Bay 22.2°C [±0.4°C]). Salicylihalamide A concentration showed a large, negative correlation (r=−0.703, $P_{\alpha=0.017} < 0.01$) to water temperature in summer (Fig. 4). However, no significant correlation was observed between water temperature and sponge size (r=−0.396, $P_{\alpha=0.017} = 0.075$) or water temperature and sponge depth (r=0.383, $P_{\alpha=0.017} = 0.087$). Interestingly, the difference in mean concentration in the summer between Bremer Bay and Jurien Bay was 5.0 μg g^{-1} with an associated 3°C temperature difference, but the seasonal difference in concentration (5.3 μg g^{-1}) at Bremer Bay was associated with a 1°C temperature change.

Green *Haliclona* sponges ranged in size from 180 to 4,287.5 cm^{-3} with no correlation between sponge volume and salicylihalamide A concentration (r=−0.358, $P_{\alpha=0.017} = 0.111$). No correlation was found between sponge size and the depth (r=−0.002, $P_{\alpha=0.017} = 0.993$). Sponges were collected from depths ranging from 4 to 18 m, and no correlation was observed between depth and concentration of salicylihalamide A (r=0.234, $P_{\alpha=0.017} = 0.306$).

Spatial and Temporal Differences Variability among individuals within a location ranged from 9.0 to 15.9 μg g^{-1} at Bremer Bay; 6.1 to 15.4 μg g^{-1} at Hamelin Bay; 5.1 to 20.6 μg g^{-1} at Rottnest Island; and 5.0 to 13.8 μg g^{-1} at Jurien Bay. Water temperature was the only covariate utilized in the one-way ANCOVA. Salicylihalamide A concentration was influenced by water temperature (Table 1). After accounting for variation because of water temperature, salicylihalamide A differed significantly among all locations (Table 1 and Fig. 5a) except for Hamelin Bay and Bremer Bay (Table 2).

A significant difference (t=3.18, df=10, $P_{\alpha=0.025} = 0.010$) in the concentration of salicylihalamide A was also found between summer (ranging from 9.0 to 16 μg g^{-1}) and winter (ranging from 4.6 to 12.7 μg g^{-1}) at Bremer Bay (Fig. 5b).

Health Influences Only five green *Haliclona* individuals had visible signs of necrosis, and no significant difference (t=0.75, df=19, P=0.462) was observed between healthy and unhealthy sponges.

Discussion

Green *Haliclona* individuals contained salicylihalamide A at all locations and in both seasons at Bremer Bay. The yield from crude extracts in this study (2.83%) was comparable to the 2.55% reported by Erickson et al. (1997) in the initial extraction of *Haliclona* sp. Salicylihalamide A was not detected in any of the brown individuals from the same sites. Given that both color morphologies have similar spicule and skeletal characteristics, this difference in chemical profile may be a useful characteristic in taxonomic classification (Thompson et al. 1987).

Salicylihalamide A concentration was significantly influenced by water temperature, thus probably accounting for some variation among locations. The concentration was also significantly higher in summer than winter in sponges from Bremer Bay. This variation of

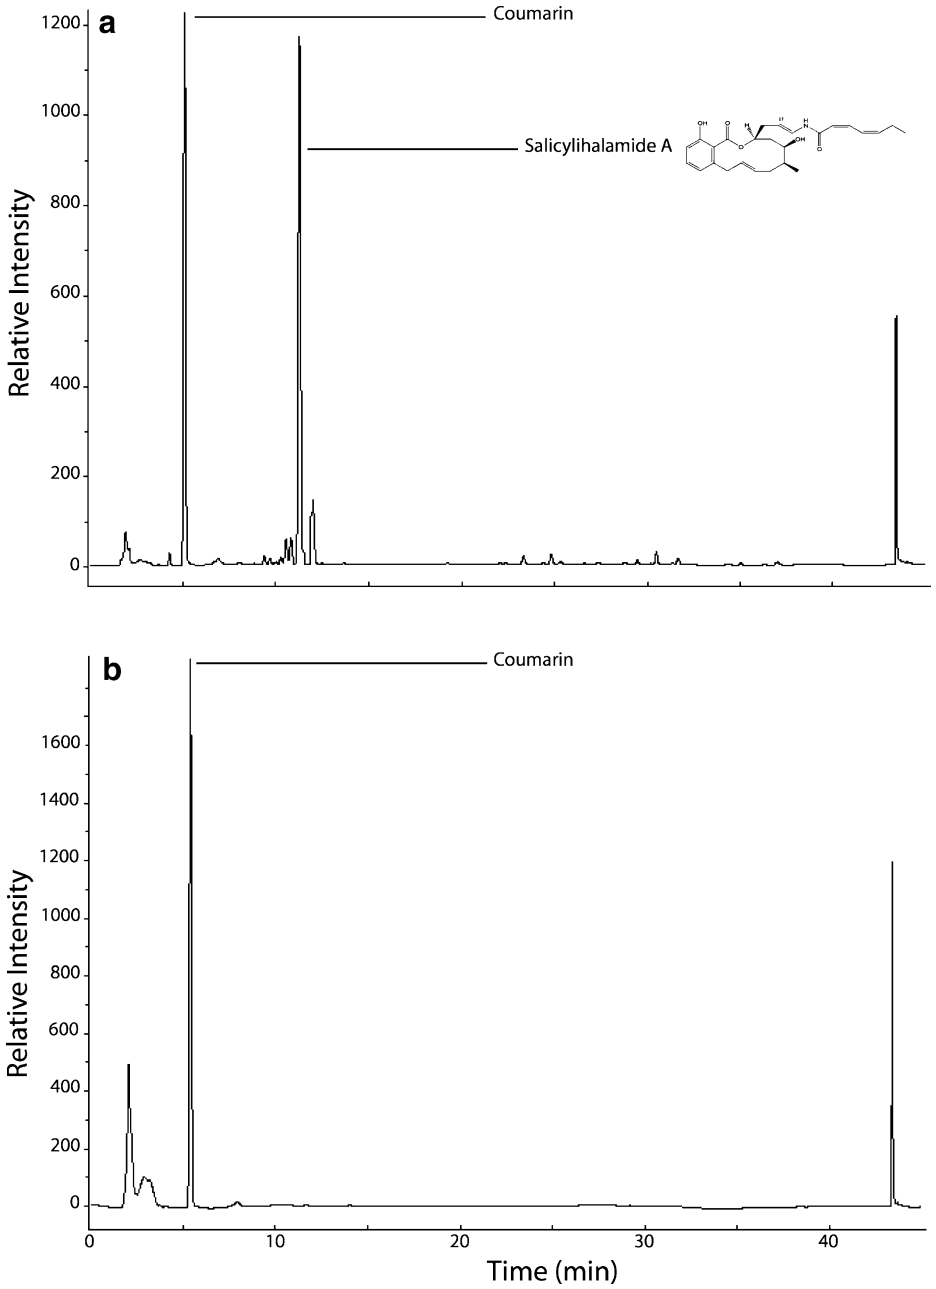

Fig. 3 HPLC chromatographs (λ=285 nm) illustrating the difference in the chemical profiles of **a** green *Haliclona* samples and **b** brown *Haliclona* samples. Salicylihalamide A (at retention time of 12 min) was detected in the green morphology only. Coumarin ($C_9H_6O_2$) was used as an internal standard (at a retention time of 5 min)

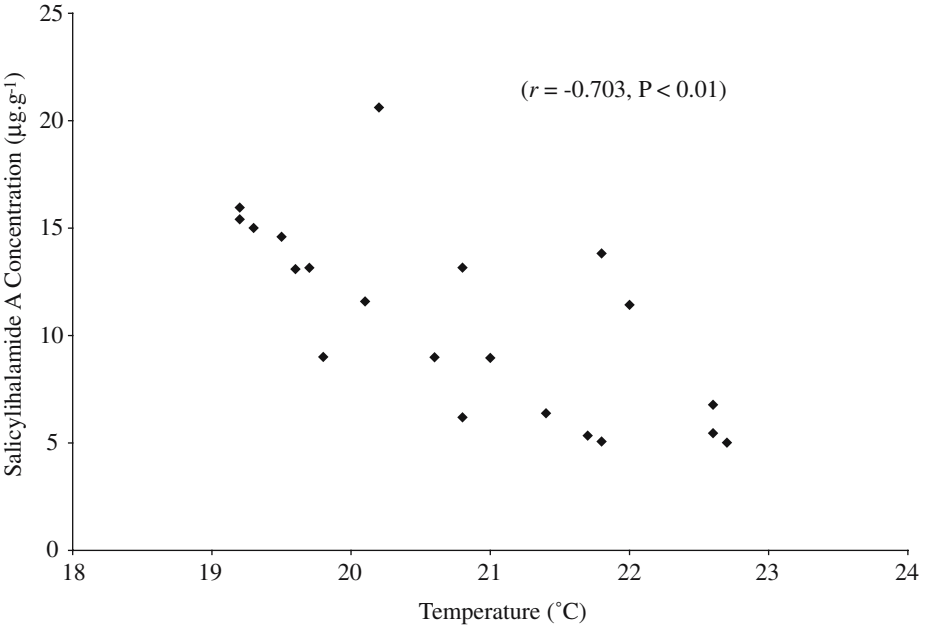

Fig. 4 Correlation ($P<0.017$) between salicylihalamide A concentration and water temperature

salicylihalamide A among locations compares favorably to previous studies where large variability in bioactive compounds has been observed as a result of spatial variation (Thompson et al. 1987; Becerro et al. 1995; Page et al. 2005). Page et al. (2005) found that spatial differences corresponded to a variation in the bioactive compounds produced by *Mycale hentschelli* and that the variation was a result of the environmental differences between locations. This was also evident here, as we found a strong decreasing trend in salicylihalamide A concentration with increasing water temperature. A large environmental gradient occurs along the south west Australian coastline with a 0.5°C rise in water temperature for every degree of latitude (Creswell and Golding 1980), thus resulting in a temperature difference of approximately 3°C between the most northern (Jurien Bay) and southern (Bremer Bay) locations in this study.

Whereas water temperature is an important contributor in the production of salicylihalamide A, other biological or physiological factors, however, also appear to be influencing its production. Salicylihalamide A concentration differed among locations even when the influence of water temperature was removed. The difference in mean salicylihalamide A

Organism size influences the level of bioactivity in sponges (Becerro et al. 1995), with smaller individuals having higher levels of bioactivity presumably as a result of their need for a competitive advantage in obtaining space (Becerro et al. 1995). Becerro et al. (1995) suggested that the sponge *Crambe crambe* may have reached a stand-off with its competitors by reaching an optimal area–perimeter relationship that results in a lower energetic demand for border defense (Becerro et al. 1995; and references within). The production of salicylihalamide A did not correlate to the size of the sponge.

Variation of salicylihalamide A concentrations among locations, beyond the influence of water temperature, may be explained by changes in skeletal spicule mass relative to salicylihalamide A concentration (O'Neal and Pawlik 2002). Differences in spicule or skeletal mass because of environmental influences, such as wave exposure, could be driving the variation in salicylihalamide A concentration.

The temporal variation in secondary metabolite production seen in this study is consistent with that observed for other species (Turon et al. 1996; Duckworth and Battershill 2003; Page et al. 2005). Both Page et al. (2005) and Duckworth and Battershill (2003) found that concentration of bioactive compounds was higher in summer than winter. It was suggested that seasonal variation can occur in response to increased fouling of the sponge surface (Duckworth and Battershill 2001) and to an increase in competitors (Turon et al. 1996) during the summer months. The potential ecological role of salicylihalamide A as an antifoulant is considered unlikely as the green *Haliclona* inhabits low light (irradiance<6 $\mu E\ m^{-2}\ s^{-1}$; Abdo et al. 2006a) overhang habitats and has not been observed to be overgrown by algae (personal observation). Depth-related variability in bioactive compounds has also been related to increased fouling by algae (Thompson et al. 1987); however, there was no correlation observed here between the concentration of salicylihalamide A and depth, further indicating that fouling is unlikely to be influencing production.

Haliclona sp. is a brooding sponge that produces well developed parenchymella larvae and is at the peak of its reproductive period during the summer sampling period of this study. Seasonal changes in bioactive compound production have been related to reproduction in octocorals. Coll (1992) showed that the bioactive compounds were present only during the reproductive season and were confined to the reproductive products. However, Turon et al. (1996) proposed that variation in bioactivity of *C. crambe* decreased with increasing reproductive investment. Future research that investigates whether eggs, embryos, and larvae of green *Haliclona* possess salicylihalamide A would help answer this. It would also be beneficial to sample at all locations during winter and at finer temporal scales, as Page et al. (2005) found site-specific temporal differences in the bioactive compounds of *Mycale hentscheli*.

This study has implications for the future development of salicylihalamide A as a pharmaceutical and for management of green *Haliclona* as an exploitable resource. We revealed a high yield population in Bremer Bay during summer. The consistent production of salicylihalamide A in individuals, regardless of depth or sponge size, suggests that this population could be a target for wild harvest. Caution must be taken, however, if considering wild harvesting as a supply avenue, as salicylihalamide A occurs in relatively low levels within the sponge (0.012% g^{-1} tissue dry weight), and large amounts of biomass would be required for commercial supply.

Acknowledgments The authors are indebted to Linda Heap, Caine Delacy, Dave Gull, and Craig Lebens (Bremer Bay Diving Services) for help during field collections. We also thank the anonymous reviewers for improving this manuscript, and Drs. G. Kendrick, J. McDonald, J. Fromont, and S. Whalan for discussion and comments on the research. Funding for this work was provided by a University of Western Australia (UWA) Small Grant to E. H. and C. B. and UWA University Postgraduate Award to D. A. This research was carried out under Fisheries WA Regulation 179 permit and Fisheries WA who are thanked for assistance with permitting.

Introduction

The North American waterweeds *Elodea canadensis* and *Elodea nuttallii* are invasive submersed macrophytes in Europe. *E. nuttallii* Planch. St. John, in particular, is still spreading over Europe and is found in many waterbodies. Waterweeds are competitive, well adapted to a broad array of environmental conditions (Cook and Urmi-König 1985; Simpson 1990), and contain allelochemicals that are active against competing algae and cyanobacteria (Erhard and Gross 2006).

Although *Elodea* species are often preferred food for waterfowl or crayfish (Lodge 1991; van Donk and Otte 1996), they are avoided by many insect herbivores (Newman 1991 and references therein). *E. nuttallii* is avoided by herbivorous larvae of *Acentria ephemerella* (Pyralidae, Lepidoptera, Denis and Schiffermüller), which cause severe damage to other freshwater macrophytes, such as *Potamogeton* spp. or *Myriophyllum spicatum* L. (Gross et al. 2002). Although Berg (1941) reported feeding of *Acentria* larvae on *E. canadensis* in Danish lakes, a study performed at the Finger Lakes, USA, showed that *Acentria* avoided *E. canadensis* when *M. spicatum* was available, and larvae had a higher mortality on the former (Gross et al. 2001). Avoidance of potential host plants and bad performance is often related to low food quality, i.e., poor nutritional quality, the presence of chemical deterrents or toxins.

In general, nitrogen content is considered the major nutrient determining food quality of plants, and many Lepidoptera prefer plants with the highest nitrogen content (White 1993; Newman et al. 1996). Phosphorus may also limit the growth of Lepidoptera larvae (Perkins et al. 2004). Yet, both *E. canadensis* and *E. nuttallii* have high nitrogen and phosphorus contents (Boyd 1968; Jewell 1971; Newman 1991; Kornijow et al. 1995).

While chemical deterrents are well-known to influence host plant selection and performance of herbivores in terrestrial systems, little is known about similar relationships between freshwater plants and their herbivores. Several aquatic angiosperms contain alkaloids (Ostrofsky and Zettler 1986), and watercress tissue is protected by glucosinolates (Newman et al. 1996), both groups of secondary metabolites known as potent feeding deterrents in terrestrial plants. Hydrolyzable polyphenols present in *M. spicatum* possibly affect the growth of *Acentria* larvae (Choi et al. 2002; Walenciak et al. 2002), but larvae still develop into pupae and adults. Some flavonoids seem to deter aquatic herbivores, e.g., deoxyanthocyanin from the aquatic fern *Azolla pinnata* (Cohen et al. 2002). *Elodea* species contain flavone glucosides (Mues 1983), which might act as feeding deterrents, although they were inactive in allelopathic interactions (Erhard and Gross 2006).

The investigation of chemical defenses against herbivores requires the use of artificial diets (Hay et al. 1998). Filter disks and artificial diets supplemented with pure chemicals or plant extracts have been extensively used to feed terrestrial caterpillars such as *Lymantria*, *Spodoptera*, or *Helicoverpa* (Beninger and Abou-Zaid 1997; Calderon et al. 2001; Simmonds and Stevenson 2001). Diets based on agar have been successfully fed to marine omnivores like amphipods, isopods, or sea urchins (Hay et al. 1994; Cruz-Rivera and Hay 2003). So far, only a few studies have addressed feeding deterrents in submersed freshwater plants, and studies with herbivorous freshwater insects are especially rare (see Dorn et al.

2001). Mostly crayfish have been used in bioassays, as these omnivores feed in a wide variety of laboratory assays (Lodge 1991; Bolser et al. 1998; Kubanek et al. 2001). Thus far, nobody has succeeded in rearing *Acentria* or other aquatic lepidoptera on food other than submersed macrophytes. The larvae avoid all common artificial diets (Choi et al. 2002) that would allow adding antifeedants to their food.

Here, we investigated the performance of neonate and older larvae of *Acentria ephemerella* reared on *E. nuttallii* or pondweeds. We determined content of nutrients and flavonoids in pondweeds and in *E. nuttallii* grown under both high or low light to investigate which factor(s) affect this generalist moth larvae. We also developed a bioassay to test the effect of potential allelochemicals, especially flavonoids, on *Acentria*.

Methods and Materials

Plants *E. nuttallii* was collected in summer or autumn in Lower Lake Constance at the Island of Reichenau and also from a small pond at the campus of the University of Konstanz, Germany. Plants were transported to the laboratory on ice and rinsed with tap water to remove algae and debris. They were shock-frozen in liquid nitrogen and stored at −20°C until lyophilization. *Potamogeton perfoliatus* came from Lower, and *Potamogeton lucens* from Upper Lake Constance. The latter was cultivated in aquaria at 16°C, 30–70 μmol m^{-2} sec^{-1} and at a light cycle of L:D 16:8 hr. Leaves of *P. lucens* were harvested immediately before use in feeding assays.

Larvae Diapausing larvae of *Acentria* aged third to fifth instar were collected in autumn 2003 in Lower Lake Constance. Stems of *P. perfoliatus* containing the overwintering larvae were placed into 1.5-l glass jars with dechlorinated tap water and kept at 4°C in a cooling chamber in the dark. Larvae left their hibernicula after 3–5 mo and were then used in bioassays.

Analysis of Plant Nutrient Content Carbon and nitrogen were measured with an elementar analyzer NCS 2500 (CE Instruments/Thermoquest) with atropine sulfate as a standard (58.8% C, 4.0% N, C:N molar ratio 17:1). Phosphorus was determined with an N/P auto-analyzer after acidic persulfate digestion. Due to low biomass, not all plant samples were available for nutrient analysis, resulting in N=2–10.

Analysis of Plant Chemistry Lyophilized and finely ground plants of *E. nuttallii* were extracted twice in 50% (*v*/*v*) aqueous methanol [1 ml solvent per 10 mg plant dry mass (dm)] for 2 hr each. After evaporation of methanol, the concentrated extract was split into two aliquots. One aliquot was further evaporated to dryness and resuspended in ultrapure water (final concentration 100 mg plant dm ml^{-1}), yielding the crude polar extract that was used in larval bioassays. The second aliquot was adjusted to 2.5% aqueous methanol (*v*/*v*) and fractionated by solid phase extraction (SPE) on a C18 cartridge (2 g sorbens, Phenomenex). After washing with 2.5% methanol, the C18 cartridge was stepwise eluted with 10–100% methanol at 10% intervals, yielding 11 fractions, including the wash fraction. Fractions were evaporated to dryness and resuspended in water (fractions 1–6 that eluted with 10–50% methanol) or 50% methanol (fractions 7–11, eluted with 60–100% methanol). HPLC analysis with a reversed phase C18 LiChrospher column (250×4 mm), a linear gradient with 1% aqueous acetic acid and methanol as solvents, and a photodiode array detector set at 345 nm as primary detection wavelength (details in Erhard and Gross, 2005) showed that

fraction 2 (eluted with 10% methanol) contained flavonoids. This fraction was used in feeding assays. Control extracts and fractionations were performed accordingly, using only solvents but no plant material. Concentrations of luteolin-7-*O*-diglucuronide were calculated from a calibration curve [regression equation: luteolin-7-*O*-diglucuronid (μg)=peak area at 345 nm (A)/5.58 (A μg^{-1}), $R^{2\circ}$=0.99] established with a standard of this compound isolated from *Elodea*. As no pure standards of the glucuronids of apigenin and chrysoeriol were available, we quantified those by their peak areas assuming similar extinction coefficients as for the luteolin-diglucuronide.

Purified metabolites were obtained by extracting 15.5 g fresh *E. nuttallii*, which was homogenized in 250 ml of 50% methanol by using a blender and vigorously stirred over night. After filtration under reduced pressure, the resulting pellet was again treated with 250 ml of 50% methanol and stirred for 2 hr. The solvent was removed under reduced pressure, and the remaining residue taken up in 5 ml of 50% methanol. After centrifugation, the crude polar extract was separated by repeated injections on a preparative HPLC (Gilson 321) using a GromSil 120 ODS-4 column (250×4 mm). Separation of the flavonoids was achieved with a linear gradient of 0.5% aqueous formic acid and methanol starting from 25% methanol to 75% methanol over 30 min. The compounds were identified by two-dimensional NMR techniques and by comparison of the ^{13}C NMR data with the literature (Mues 1983).

Preparation of E. nuttallii-Supplemented Leaves We supplemented *P. lucens* leaf squares with crude polar extract or isolated flavonoids from *E. nuttallii*. Leaves from *P. lucens* were dissected in small pieces of approximately 4×4 mm, omitting the midrib. Leaf squares were placed in 24-well tissue culture plates (two pieces per well) and incubated for 24 hr in aqueous extract, the aqueous flavonoid fraction (100 mg plant dm ml^{-1} each), or the respective controls (400 μl per well). These impregnated leaf squares were used in feeding assays.

The success of leaf supplementation was verified by extracting flavonoids from incubated leaf squares not fed to larvae. Leaf squares were frozen in liquid nitrogen directly after incubation in crude polar extract (0 hr) and 24 hr after application to the inner filter (see below). They were freeze–dried, weighed, and extracted twice for 2 hr with 500 μl 50% methanol in a sonication bath. Aliquots of the extracts were analyzed by HPLC, and we determined the concentration of luteolin-7-*O*-diglucuronide per milligram dry *P. lucens* leaf square to evaluate the effectiveness of supplementation.

Feeding Assays

Performance of First Instar Larvae (Experiment I) In summer 2002, we successfully reared in the laboratory adults that oviposited on *P. perfoliatus* in aquaria. Egg clutches were separated, and neonate larvae hatching from a distinct clutch were divided into four groups, each receiving different diets. The first group was fed *E. nuttallii* (EN) from the campus pond, while two other groups were fed for 3 (PF1) or 5 wk (PF2) *P. perfoliatus*, before receiving *E. nuttallii*. The last group (PF3) got exclusively *P. perfoliatus* (*N*=17–34 per group, for details see Table 1). Larvae were raised in 24-well microtiter plates filled with 2 ml dechlorinated tap water. Larvae received fresh food and water biweekly, and growth was measured by their head capsule width after 3, 5, and 7 wk.

Performance of Older Larvae (Experiments II and III) We performed four no-choice feeding assays, two using *E. nuttallii* shoot fragments or *P. lucens* leaves ("fresh plants", experiments IIa and IIb) and two using supplemented leaves (experiments IIIa and IIIb).

Table 1 Numbers of surviving and dead *Acentria* larvae in the different treatments of experiment I after 7 wk

Treatment		Number (*N*)	Survivors	Dead	
Clutch I	EN	18	0	18	a
	PF1	17	3	14	a, b
	PF2	17	5	12	b
	PF3	17	6	11	b
Clutch II	EN	34	3	31	a
	PF1	34	2	32	a
	PF2	33	11	22	b
	PF3	33	11	22	b

Different letters indicate significant differences at the end of the experiments (χ^2-tests, $P<0.05$).

PF1 Reared on *P. perfoliatus* for 3 wk, then fed *E. nuttallii*, *PF2* reared on *P. perfoliatus* for 5 wk, then fed *E. nuttallii*, *PF3* fed *P. perfoliatus* only, *EN*: fed *E. nuttallii* only

Before all assays, larvae were kept individually in 50-mm glass petri dishes filled with 8 ml of dechlorinated tap water. They were reared on *P. lucens* for 1 d at 16°C in dim light (30 μmol m^{-2} s^{-1}, 16:8 L:D) to make sure that all individuals were actively feeding. After measuring their headcapsule width, larvae were equally distributed to the different treatments (N=13–15 per treatment) to avoid uneven initial headcapsule widths between treatments. Each larva was transferred to a new petri dish filled either with tap water (experiment II) or covered with moist filter paper (Macherey & Nagel, MN615) at the bottom (experiment III). In the latter case, we used two filters: a ring, cut from a 55-mm diameter filter, covered the rim of the bottom, whereas a 27-mm diameter filter was placed in the middle of the petri dish to carry the leaf disk.

As light intensity might influence nutrient composition and content of potential allelochemicals, we tested in two independent experiments whether *Acentria* responds differently to *Elodea* grown under high or low light. Control larvae received *P. lucens*. In experiment IIa (N=13 per treatment), *Elodea* plants were collected from two different sites of the university pond. One site was exposed to full sunlight, whereas the other was in the shade and seldom received full sunlight. Midday light intensities varied between 780 and 1,490 μmol m^{-2} s^{-1} at the sun-exposed site and 107–382 μmol m^{-2} s^{-1} at the shaded site (measured directly under the water surface on five summer days). Water temperature was, in general, 16–18°C, but reached up to 21°C in sun-exposed areas.

Experiment IIb was conducted to determine if light intensity and not other site factors affected eventual differences in plant chemistry or nutrients. We established cultures of pond *E. nuttallii* under controlled conditions in a light chamber. One or two cleaned shoots each were planted in 16 1.5-l glass jars filled with Lake Constance sediment and dechlorinated tap water. After 2 d, plants were divided into two groups. Eight jars were covered with black nylon stockings (20% denier yarn; 154±15 μmol m^{-2} s^{-1}, mean±SD), and the others remained uncovered (544±30 μmol m^{-2} s^{-1}). Water temperature varied between 18.4 and 20.1°C. After 2 wk, plants from both treatments were used as food, and *P. lucens* as control (N=15 per treatment).

To test whether chemicals present in *E. nuttallii* affected feeding behavior, growth, and/or survival of the larvae, *Acentria* were fed in two different no-choice assays either with untreated, control-solvent, crude polar extract, or flavonoid fraction treated leaf squares (N=14 per treatment in both assays). Depending on consumption of the leaves, we prepared new leaf squares every 1–3 d. Together with new food, we also changed the inner filter. Over 20 d,

headcapsule width was measured four times. In addition, the feeding behavior of individual larvae and feeding damage on the leaves was assessed. In experiment IIIa, we only discriminated between damaged and undamaged leaf squares. In experiment IIIb, we distinguished five damage categories: no damage, low consumption corresponding to 1–33% of the leaf, medium (34–66%) and high consumption (67–99%), or whole leaf square consumed.

Statistical Analysis All analyses were conducted with the statistical package JMP IN 5.1 (SAS Institute Inc.), Statistica 6.0 (StatSoft, Inc., Tulsa) or with the software "R", version 2.3.0 (Ihaka and Gentleman, 1996). Nutrient concentrations, flavonoid content, and headcapsule widths were analyzed, whenever possible, by analysis of variance (ANOVA) followed by unequal *N* HSD tests. This test is equivalent to the Tukey HSD test, but considers unequal sample sizes. Homogeneity of variances was tested by using Levene's test, and data were considered normally distributed when Kolmogorov–Smirnov tests resulted in $P>0.05$. When transformation failed to correct for heterogeneity of variances, we used Kruskal–Wallis *H* tests. Individual growth of larvae in experiment IIIa was compared by *t*-test (*E. nuttallii* vs solvent control). Mortality and feeding behavior of the larvae were analyzed by χ^2 contingency tests or Fisher's exact test. In experiment IIIb, we determined the relative proportion of every consumption level for each larva. The relative proportion is calculated as the number of observations of the consumption level divided by the sum of all observations. Differences in feeding behavior of larvae ($N=14$) in the five treatments were analyzed separately for each of the five consumption levels by using Kruskal–Wallis *H* tests. If these revealed significant differences ($P<0.05$) between groups, the data were compared by Nemenyi tests ($k=5$ treatments, $N=14$ replicates; difference in rank sums >293.8 for $\alpha=0.05$).

Results

Nutrient Content Carbon concentrations varied slightly between *Elodea* from the field (36.9 and 35.8% in sun-and-shade-exposed plants) and *P. lucens* (38.7%, one-way ANOVA, $F_{2,13}=4.05$, $P=0.043$), yet pairwise differences were not significant (unequal *N* HSD test, $P>0.05$) (Fig. 1). Nitrogen content in *P. lucens* was lower than in *E. nuttallii* collected in shaded areas (2.3 vs 3.3%; unequal *N* HSD, $P=0.031$). Phosphorus content did not differ among treatments in experiment IIa (one-way ANOVA, $F_{2,13}=3.07$, $P=0.081$).

Elodea grown under high and low light in the light chamber had slightly lower carbon contents than *P. lucens* (37.6 and 36.2% vs 40.7%; unequal *N* HSD, $P=0.039$ and 0.002, respectively). Nitrogen content ranged from 3.4 to 3.7% and did not vary among plants. Phosphorus concentrations were higher in *P. lucens* than in low and high light grown *Elodea* (0.49 vs 0.26 and 0.22%; unequal *N* HSD; $P=0.036$ and 0.006, respectively).

Flavonoid Content Diglucuronides of luteolin, apigenin, and chrysoeriol were present in all *Elodea* samples but not in *P. lucens* (Fig. 2). In some, but not all samples of the latter, a compound with a similar absorption spectrum (λ_{max} at 249, 289, and 329 nm) but a longer retention time was present, indicating the presence of another flavonoid. *Elodea* from the field contained more apigenin- and chrysoeriol-7-*O*-diglucuronides than plants cultured in the light chamber (two-way ANOVA, $F_{1,28}=62.09$ for apigenin and 58.93 for chrysoeriol, $P<0.001$), whereas the luteolin glucuronide did not differ ($F_{1,28}=3.37$, $P=0.077$). In both experiments, flavonoid concentrations were independent of light regime ($P>0.7$).

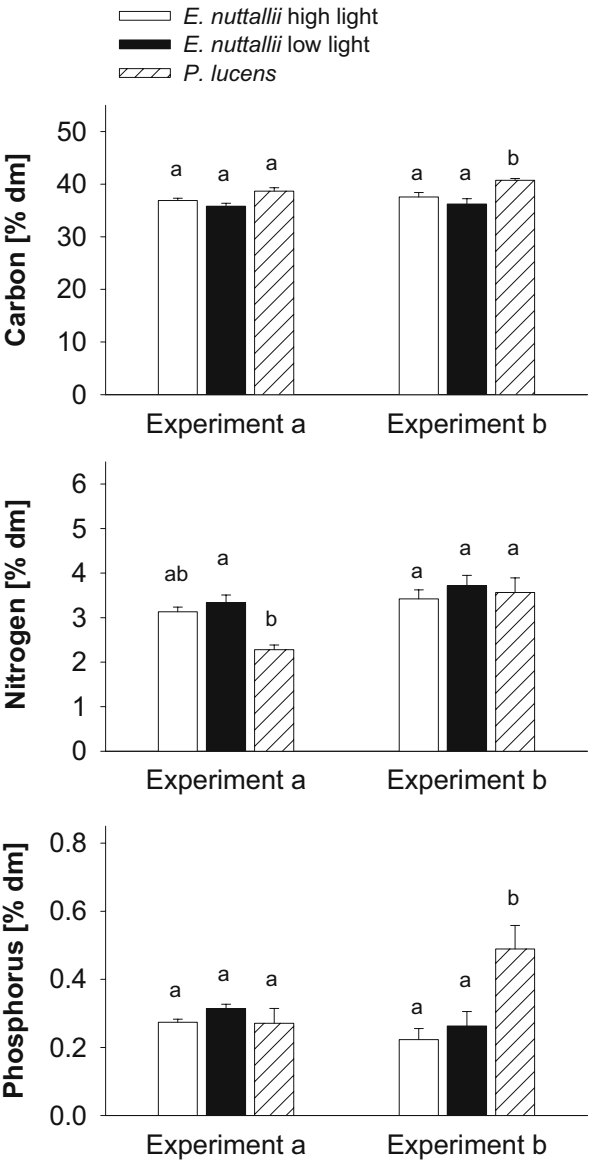

Fig. 1 Nutrient content (% dm) of fresh *P. lucens* and *E. nuttallii* from different light regimes used in growth assays with *Acentria*. In experiment a, *E. nuttallii* was collected in the field. In experiment b, it derived from a laboratory culture. Data represent means+SE (N=2–10). *Different letters* indicate significant differences $P<0.05$

Performance of Neonate Larvae (Experiment I) Neonate larvae of *Acentria* experienced a high mortality (65–100%) during the first weeks after hatching. Significantly more larvae died when fed only *E. nuttallii* compared to those fed first on *P. perfoliatus* for 5 wk and then moved to *E. nuttallii* or those fed only *P. perfoliatus* (Table 1). Furthermore, larvae fed *E. nuttallii* for 7 or 5 wk (EN and PF1) remained smaller than larvae fed most of the time (5 wk) or always on *P. perfoliatus* (PF2 and PF3; unequal N HSD, $P<0.05$ each after two-way ANOVA, clutch I: treatment, $F_{2,59}=3.39$, $P=0.04$; clutch II: treatment, $F_{3,103}=8.67$, $P<0.001$; data not shown).

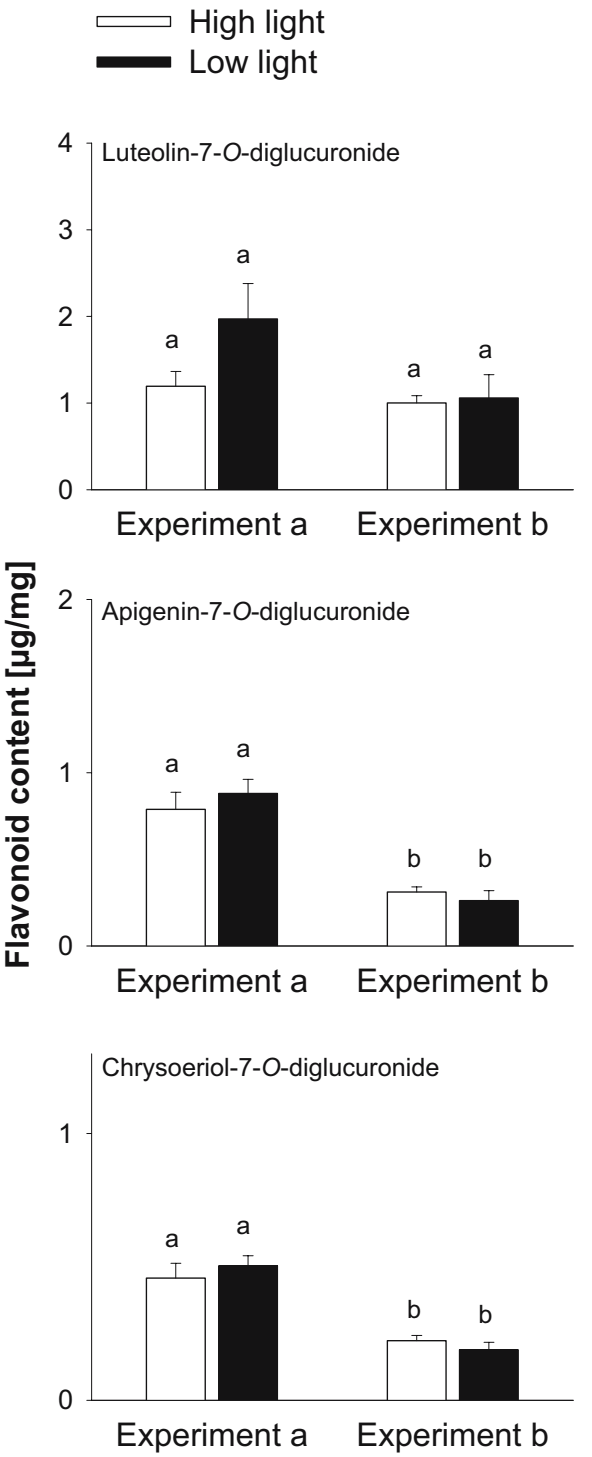

Fig. 2 Content (µg mg^{-1} plant dm) of 7-*O*-diglucuronides of luteolin, apigenin, and chrysoeriol in *E. nuttallii* from different light regimes (high and low light) used in growth experiments with field collected plants (experiment a) and laboratory grown plants (experiment b). Data represent means+SE (N=7–10). *Different letters* indicate significant differences $P<0.001$

Mortality of Older Larvae When reared on fresh plants (experiments IIa and b), none of the larvae fed *P. lucens* died, whereas feeding on *Elodea* grown in high light led to increased mortality (46 and 53%; χ^2-test, P=0.02 and 0.004, respectively; Fig. 3a and b). We observed high fatalities in the first experiment with supplemented leaves (experiment IIIa; Fig. 3c and d), which were mainly caused by escaping larvae. Of the initial 14 larvae, eight fled from the *Elodea* treatment and five from the controls. Four larvae died in the *Elodea* treatment, whereas all control larvae survived, resulting in a significantly increased mortality in the *Elodea* treatment (χ^2=7.337, P=0.007). To prevent escape of larvae in experiment IIIb, we sealed petri dishes with parafilm so that mortality was mainly based on larvae that died in the treatments. Only a few larvae escaped (four from the *Elodea* treatment and one from each of the flavonoid and flavonoid control treatments) due to leaks in the parafilm seal. Similar to experiment IIIa, mortality in the crude extract treatment was marginally increased compared to the other treatments (χ^2=9.333, P=0.053). Flavonoids caused no higher mortality compared to controls (Fig. 3d).

Growth on Elodea Under Different Light Regimes In experiment IIa, larvae fed *P. lucens* increased by 77% in headcapsule width, while those fed sun-exposed and shaded *E. nuttallii* increased by only 18–36%, respectively (Fig. 4a). A two-way ANOVA showed significant food plant and time effects and an interaction of both (plant, $F_{2,163}$=18.672, P<0.001; time, $F_{4,163}$=32.616, P<0.001; plant×time, $F_{8,163}$=3.6, P<0.001).

Similar results were obtained in experiment IIb, where *E. nuttallii* was cultured at low or high light intensity in the laboratory. Both low and high light grown *E. nuttallii* suppressed *Acentria* growth compared to *P. lucens* (Fig. 4b). Here, larvae fed low or high light *E. nuttallii* grew by only 7–15% (both fourth/fifth instar), respectively, and were not significantly different (unequal N HSD, P>0.05). In contrast, larvae reared on *Potamogeton* grew by 39% and were larger than those in both *Elodea* treatments (fifth/sixth instar; $P\leq$0.029). A two-way ANOVA comparing growth after day 12 exhibited significant food plant and time effects but no interaction effect (plant, $F_{2,106}$=37.90, P<0.001; time, $F_{2,106}$=5.05, P<0.001; food×time, $F_{4,106}$=0.32, P=0.867).

Growth of Acentria on Elodea-Supplemented Leaves We compared growth of *Acentria* reared on untreated leaf squares with the growth of larvae fed with leaves incubated in crude polar extract. Starting with day 12, larvae reared on *Elodea*-extract supplemented leaves were smaller than larvae that received control leaf squares (Fig. 4c). Headcapsule width at the beginning of the experiment was 502±54 and 502±51 μm (mean±SE, N=14 each) for treatment and control, respectively. At day 20, larvae reared on untreated leaf squares had reached a mean size of 676±85 μm (N=9), whereas the two remaining larvae fed *Elodea* supplemented leaves had only 557 and 574 μm (N=2). Although these values are outside the 95% confidence interval of the control mean (i.e., 607–745 μm), repeated measures ANOVA (rmANOVA) did not detect any differences between the two groups. As this might be due to the high mortality in the *Elodea* treatment, we compared the individual growth of surviving larvae in the treatments. Headcapsule width of control larvae increased by 176±22 μm (mean±SE), significantly more than that in the *Elodea* treatment (46±21 μm; P=0.028, t-test).

Enrichment of P. lucens with E. nuttallii Extract After incubation in aqueous *E. nuttallii* extract, *P. lucens* leaf squares contained 0.35±0.05% dm (mean±SD, N=3) luteolin-7-*O*-diglucuronide and 0.05±0.004% dm of the other flavonoids (apigenin and chrysoeriol-7-*O*-diglucuronides). When these leaf squares were placed on moist filter paper, most of the

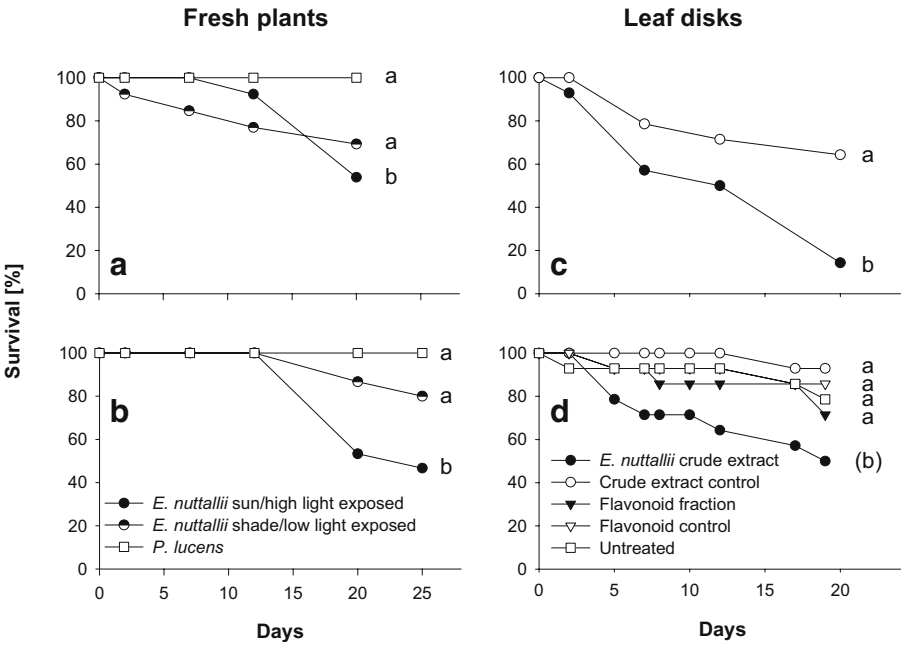

Fig. 3 Survival of *Acentria* on fresh plants (*left panel*) and supplemented *P. lucens* leaf disks (*right panel*) in four independent experiments (initial N=13–15 each). **a** field collected plants, **b** laboratory grown plants, **c** leaf squares supplemented with crude polar extract, **d** leaf squares supplemented with extract fractions as food source. *Letters on the right* indicate significant (P<0.05) groupings among treatments based on χ^2-analyses. *Letters in parentheses* indicate marginal differences (P<0.1)

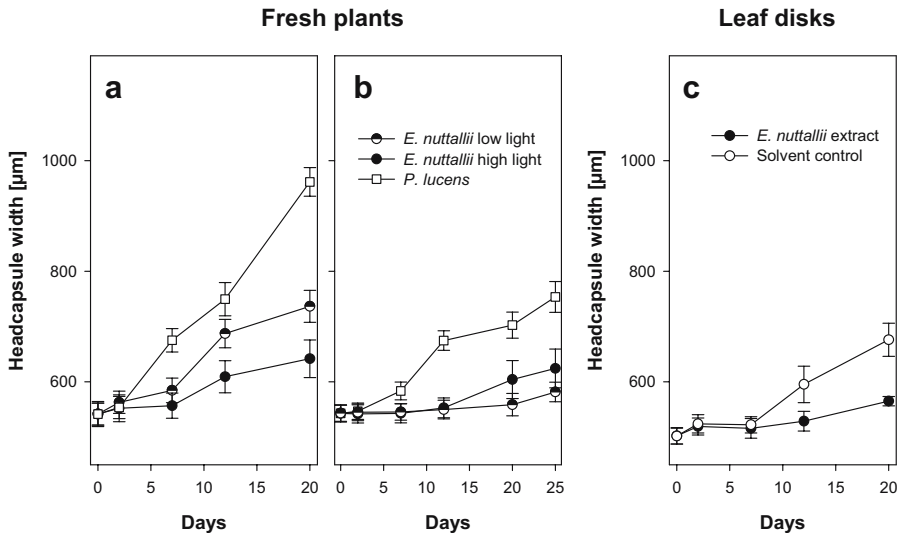

Fig. 4 Growth, measured as headcapsule width (µm) of *Acentria* larvae fed fresh plants from the field (**a**) and from the laboratory (**b**) or supplemented *P. lucens* leaf disks (**c**). N=15 (**a**), 13 (**b**), and 14 (**c**) per treatment at beginning. Data represent means±SE

flavonoids directly diffused into the filter. Only 0.09±0.03% of luteolin and 0.01±0.002% of apigenin/chrysoeriol were found at this time in the leaves, indicating that flavonoids were adsorbed at the surface of *P. lucens*, but were not incorporated into the plant tissue. Amounts detected in the filter paper were 0.8–2.4 and 1.5–2.8 times compared to total leaf squares (luteolin and apigenin/chrysoeriol, respectively). After 24 hr, leaves still contained 0.01±0.007% of the luteolin-diglucuronide, and 0.002% of apigenin/chrysoeriol. At the same time, filter disks had flavonoid contents up to 8.7 (luteolin) and 12.3 times (apigenin/chrysoeriol) higher than the total respective supplemented leaves.

Feeding Behavior of Acentria Larvae fed significantly more often on *P. lucens* soaked in control solvent than on extract treated leaf disks (experiment IIIa, Fisher's exact test, $P<0.001$). In experiment IIIb, we tested whether flavonoids present in *E. nuttallii* influence feeding patterns (Fig. 5). Larvae in this assay exhibited normal feeding behavior that was not different from other assays, but headcapsule widths did not increase at all, even in controls. We observed that larvae were growing, indicated by a visible increase in larval body size. We distinguished the amount of leaf consumed to gain information on larval food uptake. It was striking that larvae did not eat much in all treatments during the first 2 days. Thus, groups did not differ from each other on day 2 (*H*-test, $P=0.458$). After this period, consumption increased in the controls, to a lesser extent in the flavonoid treatment, but not in the crude extract treatment, where until day 10, only two of the offered leaf pieces were damaged (data not shown). In each treatment, except in the crude extract control, some larvae did not eat at all. More larvae showed no consumption in the crude extract and flavonoid treatment ($N=5$ each) than in untreated leaves ($N=2$) and in the flavonoid control ($N=1$). We observed all levels of consumption in every group, but most larvae reared on leaves impregnated with crude polar extract or flavonoids did not feed (86.6±3.7% and 71.1±7.5%, mean±SE, respectively), while total avoidance was less frequent in all three control groups (39.4, 32.5, and 32.4% of untreated, extract, and flavonoid controls, respectively; Nemenyi test $P<0.05$, following *H* test, $H=30.865$, $P<0.001$). In control treatments, larvae consumed significantly more entire leaf pieces (39.6, 41.7, and 49.4%; Nemenyi test $P<0.05$, following *H* test, $H=36.919$, $P<0.001$). A difference in the high consumption level was only visible for the crude extract fed larvae. The proportions of low and moderate consumption ranged between 1.4 and 8.6% and did not differ between groups.

Discussion

Acentria larvae perform better on native pondweed than on the invasive *E. nuttallii*. When reared on suitable food plants, *Acentria* usually has six larval instars until pupation (Gross et al. 2002). Larvae fed *Potamogeton* reached this instar, while those fed *E. nuttallii* had headcapsule widths equivalent to the fourth or fifth instar within the same time span. This indicates that larval development on *Elodea* is delayed. Even if surviving larvae would enter the pupal stage, the prolonged larval development might lead to lower pupal weight, reduced female fecundity, or greater time of exposure to enemies (Price et al. 1980; Haukioja and Neuvonen 1985; Tikkanen et al. 2000).

The impact of *E. nuttallii* on neonate larvae apparently differs from that on older instars after hibernation, which we used in our further experiments. Although there might be exceptions, first instars generally experience higher mortality rates than later instars (Zalucki et al. 2002). Our results with newly hatched larvae show a significant increase in

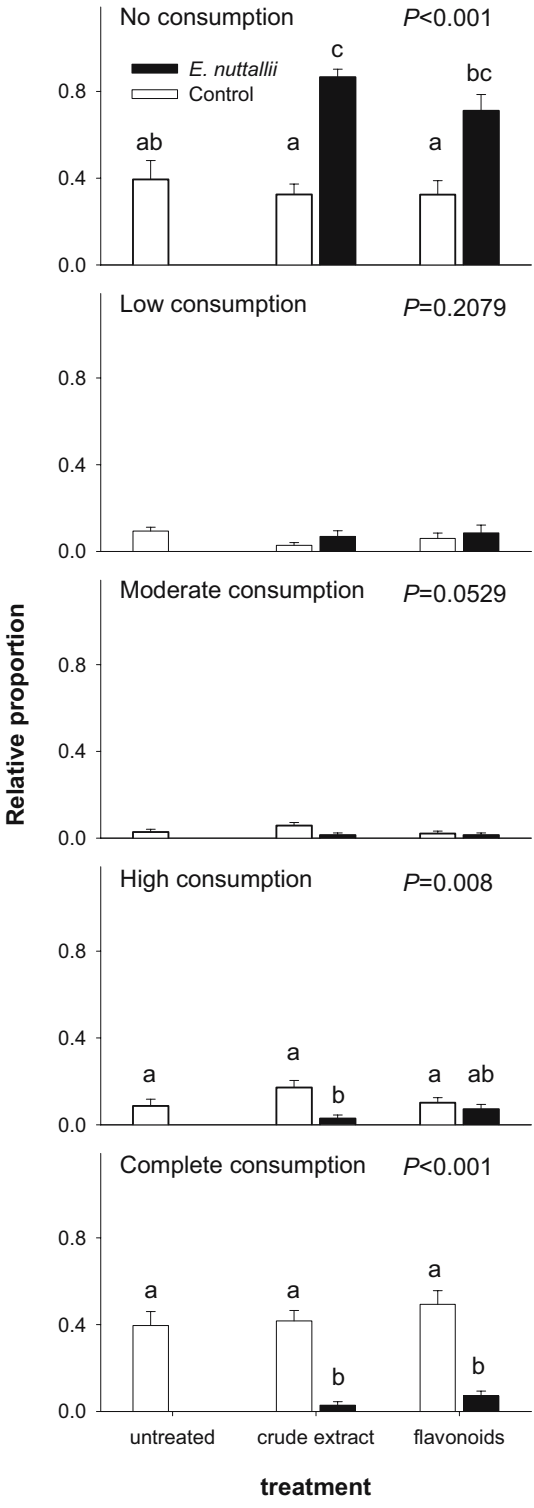

Fig. 5 Proportional contribution [×100%] of different consumption levels among treatments during experiment IIIb. Given are means+SE (N=14 per treatment). *Different letters* indicate significant groupings among treatments (H test followed by Nemenyi test, P<0.05). Levels of feeding damage correspond to 0% (no), 1–33% (low), 34–66% (moderate), 67–99% (high), and 100% (all)

mortality of early instar *Acentria* when fed *E. nuttallii*, ranging between 90 and 100%. In a comparable experiment, *E. canadensis* increased mortality of early instars but only to 50% (Gross et al. 2001). This suggests a more deleterious impact of *E. nuttallii* on the fitness of *Acentria* than *E. canadensis*. A direct comparison of both species in one experiment is needed for final proof.

Structural defenses are most likely not a reason for the poor performance of *Acentria* larvae on *E. nuttallii*, as leaves consist of only two cell layers, and plants were consumed by larvae in our assays. Also, nutritive value did not explain the reduced growth or survivorship of larvae. The average nitrogen content ranged from 3.1 to 3.7% in *E. nuttallii*, comparable to other studies (Newman 1991; Kornijow et al. 1995) and within the range of 1.2 to 4.8% for various submersed angiosperms (Boyd 1968; Jewell 1971; Muztar et al. 1978; Choi et al. 2002).

Cronin and Lodge (2003) measured lower nitrogen levels in freshwater plants grown under high light conditions, but palatability did not differ between treatments. In *M. spicatum*, high light increased nitrogen content (Gross 2003). In our experiments, light had no significant effect on nitrogen content in *Elodea*, and its concentrations did not differ from that in *Potamogeton*. Kornijow et al. (1995) also found low C:N ratios in *E. nuttallii*, and they considered factors other than nutritional value important for herbivores. Also, food plants were never phosphorus limited (Gerloff and Krombholz 1966). Due to the negligible differences in nutrient content in food plants, we consider neither nitrogen nor phosphorus responsible for the bad larval performance.

Our results indicate that allelochemicals in *E. nuttallii* deter feeding by *Acentria* and might inhibit growth of larvae. Crude polar extract and a fraction containing the major three flavonoids from *Elodea* deterred *Acentria* from feeding on *P. lucens* leaves, while untreated or solvent control leaves of *P. lucens* were often completely consumed (Fig. 5). Not many studies have yet investigated chemical defenses in submerged freshwater angiosperms. Many studies have focused on marine macroalgae (Hay 1996; Paul et al. 2006) and emergent or floating-leaved freshwater angiosperms (Bolser and Hay 1998; Dorn et al. 2001; Kubanek et al. 2001; Prusak et al. 2005). These studies often used omnivorous crustaceans as grazers, against which extracts of submersed species have turned out to be inactive (Bolser et al. 1998; Prusak et al. 2005). In contrast, other authors have suggested chemical defenses in submerged freshwater macrophytes against planktivorous *Daphnia*, lepidoptera, and gastropod herbivores based on observed effects and correlations between secondary plant metabolites and feeding activity or changes in behavior (Pennak 1973; Burks et al. 2000; Choi et al. 2002; Cohen et al. 2002; Elger and Lemoine 2005). None of these studies tested isolated chemicals.

The lack of studies establishing evidence for chemical defenses in (submerged) freshwater macrophytes results from methodical problems. Omnivores or shredder herbivores accept various artificial diets (Lodge 1991; Newman et al. 1996; Bolser et al. 1998). The specialized feeding habits of invertebrates challenges the design of suitable artificial diets (Hay et al. 1998). *Acentria* feeds on several species in different freshwater plant families and can thus be regarded as a generalist (Buckingham and Ross 1981). Nevertheless, it consumes exclusively fresh tissue from submerged angiosperms and rejects decaying material or common artificial diets (Choi et al. 2002; D.E. and E.M.G., personal observations).

Acentria larvae did not feed on boiled plant material or other artificial diets (data not shown), and only extract coated fresh leaves could be used in feeding assays. A similar design, in which *Salix* leaves were coated with extracts of several floating-leaved freshwater macrophytes, was used previously in feeding assays with the semiaquatic

lepidopteran *Munroessa gyralis* (Dorn et al. 2001). We tested whether coating of *P. lucens* leaves with *E. nuttallii* extract or fractions would decrease their palatability. The coating of *P. lucens* leaves with *E. nuttallii* extract was not simple. The leaves are thin and do not have a substantial cuticle, which makes them sensitive to organic solvents or wilting. Moist conditions promoted the diffusion of the amphiphilic active compounds in our extracts of *E. nuttallii*. It was necessary to minimize the leaching of extracts into the surrounding medium to make the exposure to active compounds as realistic as possible. The amount of flavonoids enriched in *P. lucens* equaled that of concentrations found in field samples of *E. nuttallii* (0.02–1.2% of plant dm for luteolin-7-*O*-diglucuronide, calculated from values in Fig. 2 and those given in Mues 1983), but flavonoids leached very quickly from the leaves. The inner filter paper prevented the diffusion of the compounds to the outer filter paper, where larvae in *Elodea* treatments spent most of their time. Thus, larvae came in contact with *E. nuttallii* allelochemicals only when they entered the inner filter disk for feeding. Although our method can be further improved, we assume that during feeding on or mining into stems of *E. nuttallii*, *Acentria* would, to some extent, also be exposed to secondary compounds leaching from wounded cells.

E. nuttallii crude polar extracts applied to *P. lucens* leaves had the most deleterious effect on *Acentria*. This treatment reduced survival, growth, and feeding (Figs. 3, 4, and 5). The observed mortality with crude polar extract equaled that of live *E. nuttallii* plants (Fig. 3). The increase in headcapsule width of larvae grown with *E. nuttallii* extract was less than 50% of that of *P. lucens* fed larvae and corresponds to the values observed in the assays with fresh plants (Fig. 4). This corroborates our hypothesis that the negative impact of *E. nuttallii* on *Acentria* is mainly due to chemical defenses. Our results indicate that flavonoids can act as feeding deterrents in *E. nuttallii*, but they do not affect survival (Fig. 3). Corresponding to our results, Beninger and Abou-Zaid (1997) observed a high mortality of *Lymantria dispar* when fed crude extract of jack pine, but not when fed jack pine flavonoids alone. Elliger et al. (1980) found several flavonoids that inhibited growth of *Heliothis zea*, but none of them affected survival. Thus, there must be additional unknown, metabolites present in *E. nuttallii* crude polar extracts that exhibit toxicity or act at least additively or synergistically to flavonoids. Our approach opens the possibility of identifying additional relevant signals in a bioassay guided structure elucidation.

The deleterious effect of *E. nuttallii* extracts on *Acentria* confirms earlier suggestions that *Elodea* spp. might be defended against herbivores (Newman 1991; Kornijow et al. 1995). The natural concentrations of the luteolin-derivative in *E. nuttallii* (0.02–1.2% of plant dry mass, see above) and the other two flavonoids (at least 0.014% for chrysoeriol glucuronide and 0.02% for apigenin glucuronide; Mues 1983) are comparable to the content of structurally related allelochemicals found in other plant species (Beninger and Abou-Zaid 1997). Even though the enrichment of *P. lucens* with *E. nuttallii* extracts yielded concentrations only at the lower range found in field *E. nuttallii*, our observed effects suggest that chemical defense should be relevant under natural conditions. All three flavonoids are also present in *E. canadensis* (Mues 1983; Erhard et al. unpublished results.), which is similarly avoided by the moth (Gross et al. 2001), but they do not occur in *P. lucens* or *M. spicatum* (data not shown), which suffer from severe feeding damage by *Acentria* in the field (Gross et al. 2002). Both the effect of *Elodea* secondary allelochemicals as feeding deterrents and inhibitors of survival and growth might reduce the risk of herbivory on *Elodea*.

Our results show that potential allelochemicals are present in *Elodea* leaves as well as coated *Potamogeton* leaves in low but ecologically relevant concentrations, comparable to concentrations effective in terrestrial systems (Beninger and Abou-Zaid 1997). We thus

assume that the chemical defense in *E. nuttallii* is a powerful trait to protect plants against herbivores and might further strengthen the invasiveness of this species.

Acknowledgments We acknowledge the help of Julia Hoffmann, Nadine Womann, and Manuela Mayer during the feeding assays. Vera Bauke is acknowledged for help during the extraction and purification of flavonoids. Heather Fyson improved the English, and two anonymous reviewers made valuable comments on the manuscript. This study was supported by the German Science Foundation (DFG, project A2 in SFB454 to EMG) and the University of Konstanz (AFF).

Materials and Methods

The amber piece containing the beetle is rectangular, measuring 7 mm long by 4 mm wide by 2 mm deep. The fossil was collected from lignitic seams in sandstone–limestone deposits in the Hukawng Valley in Myanmar. The mine site was located on the slope of the Noije Bum hill about a mile (1.5 km) SSW of the old Khanjamaw mine site and southwest of Maingkwan (26°2′N, 96°36′E). This site is newly mined (D. Cruickshank, personal communication, December 20, 2006) and has been designated as the "Noije Bum 2001 Summit Site." Paleontological findings from this site assigned its age to the Upper Albian (100 Ma BP) of the Early Cretaceous (Cruickshank and Ko 2003). On the basis of spectroscopic and anatomical evidence, the source of Burmese amber from this site was determined to be a member of the Araucariaceae (Poinar et al. 2007). The specimen was deposited in the amber collection of Ron Buckley under accession no. ABS66.

Results

The fossil is approximately 4.5 mm in length, well preserved, complete, and in a clear piece of amber. The beetle is a member of the family Cantharidae and will be described separately. Cuticular vesicles with associated gland reservoirs were extruded from the lateral membrane on each side of the first six abdominal segments (Figs. 1a,b and 2a,c). Secretions were released from the first three vesicles on both sides of the abdomen. By far, the largest deposit (1.4 mm in length) had been released from the extruded vesicle on the right side of the first abdominal segment at the point of contact with a filiform, setaceous, multisegmented antenna belonging to an unknown, alien insect. In this deposit are a number of spherical to subspherical crystal-like bodies ranging from 22 to 34 μm in greatest diameter (Fig. 1c).

Discussion

The extruded vesicles on the fossil soldier beetle are similar in size and shape to those described by Sulc (1949) on a European species of *Cantharis*. Soldier beetles (Coleoptera: Cantharidae) are small- to moderate-sized insects with weakly sclerotized or leathery wing covers. The relatively short-lived adult beetle is active during the day in search of food, which is mainly small insects and pollen from a variety of plants (Dillon and Dillon 1961; Crowson 1981; Daly et al. 1998). Although cantharids are widely distributed today, fossils of this group are unusual, and until the present report the oldest described fossil soldier beetles were from Baltic amber (40 Ma; Spahr 1981; Carpenter 1992). The present discovery more than doubles the previous fossil record.

The structure of the antenna of the potential predator is consistent with those of members of the orders Orthoptera and Blattaria, and the antenna passes through the entire amber piece along the right side of the beetle (Figs. 1a and 2a,b). Members of the above groups that existed at that period and had this type of antennal structure were katydids, crickets, elcanids, and cockroaches, all of which have been reported in Burmese amber (Poinar et al. 2005). This insect probably extended its antennae to investigate the soldier beetle as a future meal. As soon as the beetle detected the intruder's presence, it presumably extruded its abdominal vesicles and emitted defensive secretions (Fig. 3).

The vesicle nearest the area of direct molestation (where the foreign antenna made physical contact with the beetle) deposited the largest amount of secretion. Many insects only discharge defensive droplets adjacent to the area of tactile molestation (Blum 1981), thus conserving secretions. Some of the secretion was deposited on the orthopteroid antenna, whereas the remainder was ejected over the insect's right shoulder (Fig. 1b). A

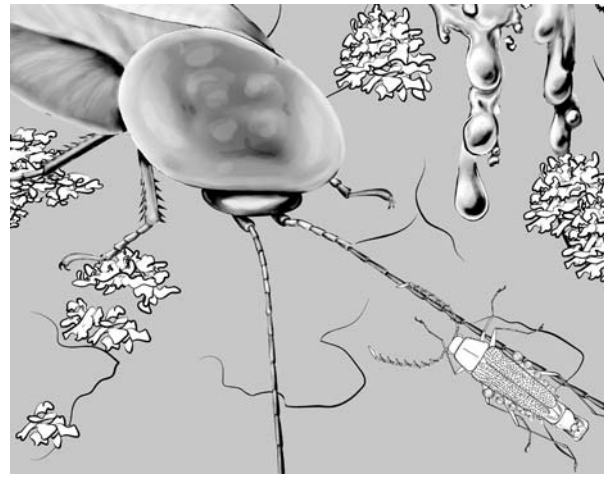

Fig. 3 Proposed scenario on the bark of the resin-producing tree just before the soldier beetle was entombed. In the *upper left* is a blattid with one antenna extended along the right side of the beetle. The beetle is responding by everting six pairs of cuticular vesicles with associated gland reservoirs. A drop of resin in the *upper right* is falling on the beetle. Patches of lichens and moss are growing on the surface of the bark. We portrayed a cockroach as the bearer of the alien antenna because they occur on bark, are omnivorous, and are known from Burmese amber

moment after the beetle released its secretions, it was covered by a flow of resin. Whether the entire predator was also captured is unknown; however, its remaining antenna provides evidence of its presence. This scenario would explain why the preserved beetle was likely employing a defense response, why most of the extruded secretion came from only one everted vesicle, and how some of the secretion ended up on the perpetrator's antenna.

Chemical defense mechanisms have evolved at least 30 times in Coleoptera, including in all members of the Adephaga and in representatives of at least 20 families of Polyphaga (Blum 1981; Dettner 1987). Aside from chemicals produced in specialized glands, distasteful, emetic, or caustic compounds in insect hemolymph are also employed in defense responses (Blum 1981; Dettner 1987). Toxic hemolymph can be released from openings positioned between segments (reflexive bleeding) or via cuticular vesicles extruded from the abdomen and thorax.

Some examples of chemical defense mechanisms involving cuticular vesicles in various families of beetles are listed here. Secretions expelled from extrusive sacs located on the abdomen and thorax of tenebrionid beetles contain benzoquinone, toluquinone, ethylquinone, phenols, aldehydes, and ketones (Tschinkel 1969, 1975a, b). Adult and larval leaf beetles (Chrysomelidae) respond to tactile stimulation by a potential predator by releasing hemolymph with defense compounds (Hilker and Schulz 1994) through cuticular openings positioned along the edges of the thorax and first seven abdominal segments (Pasteels et al. 1988). In disturbed galaerucine (Chrysomelidae) larvae, hemolymph is expelled from extruded dorsolateral vesicles (Bünnige and Hilker 2005). This sticky deposit, which may also contain glandular secretions, can entangle the mouthparts of invertebrate antagonists. After expelling the chemical defenses, these vesicles are retracted back into the body.

Malachiinae (Melyridae) beetles also contain extrusive vesicles located on the abdominal and thoracic segments. Adults of the New Guinea genus *Choresine* contain secondary bioactive compounds called batrachotoxins in their hemolymph, which are apparently expelled through their protruded vesicles located on abdominal segments 1 to 6 and on the prothorax and metathorax (Dumbacher et al. 2004).

It was not possible to identify the crystals in the droplet released by the fossil soldier beetle because any attempted analysis would probably destroy the specimen, but the crystals likely represent defensive chemicals. Soldier beetles of the genus *Chauliognathus* produce certain types of carboxylic acids as well as triglycerides and glyceride esters from

paired exocrine glands located on the thorax and abdomen (Meinwald et al. 1968; Moore and Brown 1978; Eisner et al. 1981; Brown et al. 1988). Diterpenes have also been recovered from members of the genus *Cantharis* (Durvaux et al. 2007). These products seem to be unique to cantharids and could possibly be acquired by feeding on certain types of plants (Blum 1981).

Today, defensive chemicals play an important survival role in insects, but just when beetles began producing toxic compounds in specialized exocrine glands is unknown. The present discovery shows that members of the family Cantharidae had established a chemical arsenal for defense some 100 Ma ago.

Introduction

Carnivorous arthropods are able to use herbivore-induced plant volatiles as cues for their foraging behaviors in many systems that consist of plants, herbivores, and natural enemies (e.g., Dicke 1994, 1999; Turlings et al. 1995; Takabayashi and Dicke 1996; Dicke and Vet 1999). Herbivorous prey are usually under strong selection not to reveal themselves and are difficult for predators to detect. In contrast, information emitted by plants is easier for a carnivorous arthropod to detect because plants have a large biomass compared to that of its herbivores (Dicke and Sabelis 1989; Vet and Dicke 1992; van Loon et al. 2000). The composition of herbivore-induced plant volatiles differs across plant species, cultivars, and herbivore species and is affected by abiotic factors as well (Loughrin et al. 1994; Takabayashi et al. 1994; Turlings et al. 1995; De Moraes et al. 1998; Gouinguene and Turlings 2002; Schmelz et al. 2003). Therefore, carnivores are confronted with variable information about the presence of prey, especially when both they and their herbivorous prey are polyphagous.

The predatory mite *Neoseiulus womersleyi* (Shicha) (Acari: Phytoseiidae), which is a specialist predator of tetranychid mites, is attracted to volatiles emitted from plants infested with prey (Maeda et al. 1999). Because tetranychids are polyphagous herbivores that induce various volatile compositions in different host plants (Van Den Boom et al. 2004), *N. womersleyi* is likely confronted with various chemical cues about the presence of prey on plants. The olfactory response of *N. womersleyi* shows genetic variation and is influenced by an individual's foraging experience with different plant–prey complexes (e.g., Maeda et al. 2001, 2006; Maeda 2006). For example, *N. womersleyi* individuals were attracted to the volatiles from infested plants (tea/kidney bean) that they had previously experienced, but they were not attracted to volatiles of plants (kidney bean/tea) that they had no experience with (Maeda et al. 2006). Because the composition of volatiles differs between tea and kidney beans (Maeda et al. 2006), *N. womersleyi* may have responded to the plant-specific composition of multiple volatiles or to a single specific volatile component.

In the present study, we identified those components in volatile blends emitted from different prey-infested plants (tea and kidney bean) that are attractive to *N. womersleyi* by testing the attractiveness of mixtures of synthetic compounds. The bioassays were conducted after rearing the predatory mites on each plant species.

Methods and Materials

Plants Tea plants (*Camellia sinensis* 'Yabukita') were grown in a plantation at the National Institute of Agrobiological Sciences (Tsukuba, Japan) for 3 yr. During this time, they were fertilized with ammonium sulfate (2.5 g per plant) every 2 mo. We found no *Tetranychus kanzawai* on the tea plants during this period. Because the densities of other herbivores were below detectable levels, no pesticide was sprayed.

Kidney bean plants (*Phaseolus vulgaris* 'Nagauzura') were grown in plastic pots filled with vermiculite and given ample water (no fertilizer) in a climate-controlled room (19±1°C, 50–70% r.h., 16L:8D at approximately 4,000 lx). When the two primary leaves had fully unfolded (about 2–3 wk after germination), the plants were used in the experiments.

Herbivorous Mites The *T. kanzawai* used in this study had been maintained on tea leaves in the laboratory for more than 1 yr (25±3°C, 60–80% r.h., 16L:8D). Current-year branches of tea plants with five to seven leaves were offered to the *T. kanzawai* every 2 wk.

The *Tetranychus urticae* used in this study were obtained from a laboratory culture that had been maintained on kidney bean plants for more than 2 yr (25±3°C, 60–80% r.h., 16L:8D). About 70 kidney bean plants with two fully unfolded primary leaves were offered to the *T. urticae* culture every week.

Predatory Mites We collected *N. womersleyi* from tea plants infested with *T. kanzawai* at Kanaya, Shizuoka prefecture, Japan (34°48′20″N, 138°08′10″E, 200 m a.s.l.) in June 2003. To maintain the predator population with *T. kanzawai*-infested tea leaves, we used an acrylic resin plate (12.5×17×0.2 cm) with 24 holes (6 lines×4 rows, 2.5-cm intervals, 3-mm diameter). The plate was placed on a water-soaked floral oasis (12.5×17×3.5 cm; Nisso Green, Tokyo, Japan) in a plastic box (24×33 cm, 10-cm depth) whose lid had a rectangular aperture (17×26 cm) covered with nylon gauze (0.2-mm mesh). Petioles of tea leaves infested with *T. kanzawai* (10–20 adult females per leaf, as well as other stages) were inserted into the oasis through the holes in the plate. We added 12 new *T. kanzawai*-infested leaves to the culture three times per week. Under these conditions, 40–60 adult female predatory mites were maintained per generation.

To maintain the predators with *T. urticae*-infested kidney bean leaves, we used an acrylic resin plate (12.5×17×0.2 cm) with no holes. The plate was placed on a water-soaked floral oasis in the plastic box described above. Five kidney bean leaves infested with *T. urticae* (30–50 adult females per leaf, plus other stages) were offered to the predatory mites three times per week. Under these conditions, 40–60 adult female predatory mites were maintained per generation.

Olfactometer Experiments The olfactory responses of the *N. womersleyi* were tested in a Y-tube olfactometer (Takabayashi and Dicke 1992) with a 10-cm arm length, 12-cm stem length, and 4-cm internal diameter. Air (2 l/min) cleaned by granular activated charcoal was passed through both arms of the Y-tube olfactometer. We used excised leaves or volatile extracts as odor sources. In experiments with plants, we confined sample plants in a 1-l glass bottle and connected the bottle directly adjacent to the Y-tube. As a control, we used an empty glass bottle. In experiments with extracts or synthetic compounds, 10 μl of hexane-diluted odor sample (see below) were applied to a piece of filter paper (8 cm^2). After evaporation of the solvent, the filter paper was placed in one arm of the Y-tube olfactometer. Another filter paper with 10 μl hexane was placed at the same position in the other arm as a control. Filter papers were changed after five mites had been tested. We confirmed that the olfactory response of *N. womersleyi* was not affected by the sequence (i.e., first to fifth) of tested individuals based on results of preliminary experiments (logistic regression analysis, $P=0.649$, $N=50$).

Fifty *N. womersleyi* individuals (25 individuals/day) were tested for each odor source during the daytime in a climate-controlled room (25±2°C, 50–70% r.h., approximately 1,500 lx). Gravid females of *N. womersleyi* were placed individually in 0.5-ml plastic tubes without prey and water at least 200 min before each bioassay, and each was then individually introduced at the starting point (the downwind end) of a Y-shaped steel wire in the center of the olfactometer. The behavior of each was observed until the mite walked across one of the finish lines established on the upwind ends of the Y-shaped wire. A preliminary examination showed that the mean time to reach the finish line was 102±25 sec (mean±SE, $N=50$).

To account for any unexpected bias caused by the experimental setup, such as the shapes of the Y-shaped glass tube and the steel wire, after every five mites, the arms of the olfactometer were reversed between the sample and control odor sources and the steel wire was replaced. When no odor source was present in the odor-source chamber, predatory

mites were equally attracted to the airflow from both arms of the olfactometer (48% vs. 52%, two-tailed binomial test, $P>0.05$, $N=50$).

Odor Sources to Test the N. womersleyi Reared on T. kanzawai-infested Tea Leaves To investigate the essential components in volatiles of *T. kanzawai*-infested tea leaves that attract *N. womersleyi*, eight odor sources were tested.

(1) *T. kanzawai*-infested tea leaves: To prepare the *T. kanzawai*-infested tea leaves, we maintained five branches of tea plants (each with three leaves) on a water-soaked floral oasis. We introduced five adult females of *T. kanzawai* onto each leaf. This prey density per leaf is commonly observed in tea plantations (e.g., Kawai 1997). After 10 d of the first infestation (25±1°C, 70±5% r.h., 16L:8D at approximately 10,000 lx), the infested tea leaves were used for bioassays. This procedure was the same one used by Maeda et al. (2006). Although Baldwin et al. (2002) reported that excised plant tissues released far more volatiles from both infested and uninfested tissues than was the case for comparable tissues of intact (rooted) plants (corn and lima bean), our preliminary tests confirmed that excised tea branches and rooted plants released similar amounts of volatiles after being infested with *T. kanzawai*.

(2) Uninfested tea leaves: We maintained five branches of tea plants (each with three leaves) on a water-soaked floral oasis. After 10 d of incubation (25±1°C, 70±5% r.h., 16L:8D at approximately 10,000 lx), the branches were used for bioassays.

(3) Extraction of collected volatiles of *T. kanzawai*-infested tea leaves: We confined 5 *T. kanzawai*-infested branches prepared by using the same procedure mentioned above (15 leaves total) in a 1-l glass bottle. We then collected the headspace volatiles for 5 hr with an ORBO-91T adsorbent tube (SUPELCO, Bellefonte, PA, USA) at a flow rate of 100 ml/min of clean air, purified through activated charcoal. The adsorbent tube was washed with 2.0 ml of dichloromethane (environmental analysis grade, Wako Pure Chemical Industries, Osaka, Japan) to extract the volatiles. The sample containing the volatiles was concentrated through evaporation with a rotary evaporator and then diluted with hexane (96% pure, Wako Pure Chemical Industries) to 75 μl. The emission of volatiles by plants is affected by several factors, including prey density, light conditions, and the developmental stage; in this study, however, the condition of the plants did not change during the volatile-collecting period (5 hr). We confirmed that the amount of volatiles did not change over the course of the collection period by comparing the amounts of volatiles emitted during the first, third, and fifth hours. For example, the amounts of (*E*)-β-ocimene, (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), and (*E*,*E*)-α-farnesene (peak area/hr/leaf) did not differ among each period [(35±7, 32±4, and 35±6), (283±43, 263±19, and 294±30), and (925±121, 908±151, and 904±180), respectively, $N=3$]. Therefore, 10 μl of the end product applied on a piece of filter paper included 10 leaf-hr equivalents of volatiles.

(4) Extraction of collected volatiles emitted from uninfested tea leaves: The volatiles of 5 uninfested tea branches (15 leaves total) were collected and concentrated by using the same procedure described above, and 10 μl of the end product included 10 leaf-hr equivalents of volatiles.

(5) Synthetic mixture of volatile compounds of the *T. kanzawai*-induced tea leaf volatiles: Because *T. kanzawai*-infested tea leaves emit significantly larger amounts of (*E*)-β-ocimene, DMNT, and (*E*,*E*)-α-farnesene than do uninfested plants (Maeda et al. 2006), we used these compounds as the herbivore-induced plant volatiles of tea leaves. The quantities of these compounds were tested with an internal standard

method that used dodecane (99% pure, Wako Pure Chemical Industries). An infested tea leaf emitted 19.5 ng of (*E*)-β-ocimene, 98.4 ng of DMNT, and 411.4 ng of (*E*,*E*)-α-farnesene per hr. (*E*)-β-Ocimene (93% pure) and DMNT (95% pure) were synthesized in our laboratory and were identified by ^{1}H (600 MHz) and ^{13}C (125 MHz) NMR analysis (Bruker AVANCE-600, Bruker, Billerica, MA, USA; Matsushita and Negishi 1982; Maurer et al. 1986). (*E*,*E*)-α-Farnesene (>99% pure) was purified from apple pericarp and identified by means of NMR analysis (Pinheiro et al. 1984). We dissolved the three compounds as 10 leaf-hr equivalents in 10 μl of hexane [200 ng of (*E*)-β-ocimene, 1,000 ng of DMNT, 4,000 ng of (*E*,*E*)-α-farnesene].

To test whether each compound is essential for attraction, two of the three compounds were dissolved into hexane (10 leaf-hr equivalents per 10 μl) and were used as attractant as follows:

(6) synthetic mixture without (*E*)-β-ocimene [DMNT and (*E*,*E*)-α-farnesene];
(7) synthetic mixture without DMNT [(*E*)-β-ocimene and (*E*,*E*)-α-farnesene];
(8) synthetic mixture without (*E*,*E*)-α-farnesene [(*E*)-β-ocimene and DMNT].

The eight types of samples were tested by two-choice experiments with hexane (or air) as a control odor source. In addition, we performed a two-choice experiment to test whether the mixture of the three synthetic compounds [(*E*)-β-ocimene, DMNT, and (*E*,*E*)-α-farnesene] and the volatiles collected from *T. kanzawai*-infested tea leaves attracted the predatory mites.

Odor Sources to Test the N. womersleyi Reared on T. urticae-infested Kidney Bean Plants To investigate the essential components in volatiles of *T. urticae*-infested kidney bean plants that attract *N. womersleyi*, nine odor sources were tested.

(1) *T. urticae*-infested kidney bean plants: To prepare the *T. urticae*-infested kidney bean plants, 30 adult females of *T. urticae* were introduced onto each leaf of 5 intact bean plants with two primary leaves (i.e., a total of 300 mites on 5 plants) and reared in a climate-controlled incubator for 10 d (25±1°C, 70±5% r.h., 16L:8D at approximately 10,000 lx). This procedure was similar to that used by Maeda et al. (2006), except for the temperature and infestation period. The plants were reared without excision.
(2) Intact kidney bean plants: Five kidney bean plants, each with two primary leaves, were maintained in a climate-controlled incubator (25±1°C, 70±5% r.h., 16L:8D at approximately 10,000 lx) for 10 d.
(3) Extraction of collected volatiles of *T. urticae*-infested kidney bean plants: We collected the headspace volatiles of *T. urticae*-infested kidney bean plants prepared by using the same method described above. The extract of the collected volatiles was diluted with hexane so that 10 μl of the end product applied on a piece of filter paper included 10 leaf-hr equivalents of volatiles.
(4) Extraction of collected volatiles emitted from intact kidney bean plants: The volatiles of intact plants were collected and concentrated so that 10 μl of the end product included 10 leaf-hr equivalents of volatiles.
(5) Synthetic mixture of volatile compounds of the *T. urticae*-induced kidney bean plant volatiles: Maeda and Liu (2006) showed that *T. urticae*-infested kidney bean plants emit significantly larger amounts of DMNT, methyl salicylate (MeSA), and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (TMTT) than do intact plants. They used a TENAX adsorbent tube. In this study, analysis with an ORBO-91T adsorbent tube

showed that significantly greater amounts of β-caryophyllene also occurred in the infested plant volatiles compared to those of uninfested plants. β-Caryophyllene was found in the headspace of *T. urticae*-infested kidney bean plants by using SPME fiber (Maeda and Takabayashi 2001). Therefore, in this study, we used these compounds (DMNT, MeSA, β-caryophyllene, and TMTT) as the herbivore-induced volatiles of kidney bean plants. The quantities of these compounds were tested with an internal standard method with dodecane. An infested leaf emitted 203.3 ng of DMNT, 14.8 ng of MeSA, 2.7 ng of β-caryophyllene, and 23.4 ng of TMTT. TMTT (92.3% pure) was kindly provided by Dr. Kugimiya of the Center for Ecological Research, Kyoto University. MeSA (98% pure) and β-caryophyllene (89% pure) were obtained from Wako Pure Chemical Industries. We dissolved the four compounds as 10 leaf-hr equivalents in 10 μl of hexane (2,000 ng of DMNT, 150 ng of MeSA, 50 ng of β-caryophyllene, and 250 ng of TMTT).

To investigate the requirement of each compound for attraction, three of the four compounds were used in various mixtures as follows:

(6) synthetic mixture without DMNT (MeSA, β-caryophyllene, and TMTT);
(7) synthetic mixture without MeSA (DMNT, β-caryophyllene, and TMTT);
(8) synthetic mixture without β-caryophyllene (DMNT, MeSA, and TMTT);
(9) synthetic mixture without TMTT (DMNT, MeSA, and β-caryophyllene).

The nine types of samples were tested by two-choice experiments with hexane (or air) as a control odor source. In addition, we used two-choice experiments to test whether the mixture of the four synthetic compounds (DMNT, MeSA, β-caryophyllene, and TMTT) and the volatiles collected from *T. urticae*-infested kidney bean plants attracted the predatory mites.

Statistical Analysis The data from each bioassay experiment were analyzed by using a two-tailed binomial test. The null hypothesis was that predators exhibit a 1:1 distribution over the two odor sources. To test the requirement of each synthetic compound, the degree of attractiveness was compared between a mixture containing all the synthetic compounds *versus* a mixture without one of the compounds (Fisher's exact probability tests).

Results

Response to the Volatile Compounds Emitted from Tea Leaves Tea leaves infested with *T. kanzawai* attracted more than 50% of the predatory mites that had been reared with the *T. kanzawai*-infested tea leaves (74%; two-tailed binomial test, $P<0.001$; Fig. 1), whereas uninfested tea leaves did not attract these predatory mites (two-tailed binomial test, $P>0.05$; Fig. 1). Likewise, the extract of *T. kanzawai*-infested tea leaves attracted more predatory mites (74%; two-tailed binomial test, $P<0.001$; Fig. 1), whereas the extract of uninfested tea leaves did not attract these mites. More than 50% of the predators were attracted to the mixture of (*E*,*E*)-α-farnesene, (*E*)-β-ocimene, and DMNT (74%; two-tailed binomial test, $P<0.001$). In the absence of even one of the *T. kanzawai*-induced volatiles, the mites did not show any preference for the volatiles (two-tailed binomial test, $P>0.05$; Fig. 1). When either (*E*,*E*)-α-farnesene or DMNT was not included in the odor source, the attractiveness of the two-compound mixture was significantly less than that of the three-compound mixture (Fisher's exact probability test, $P=0.004$ and 0.023, respectively). When the extract

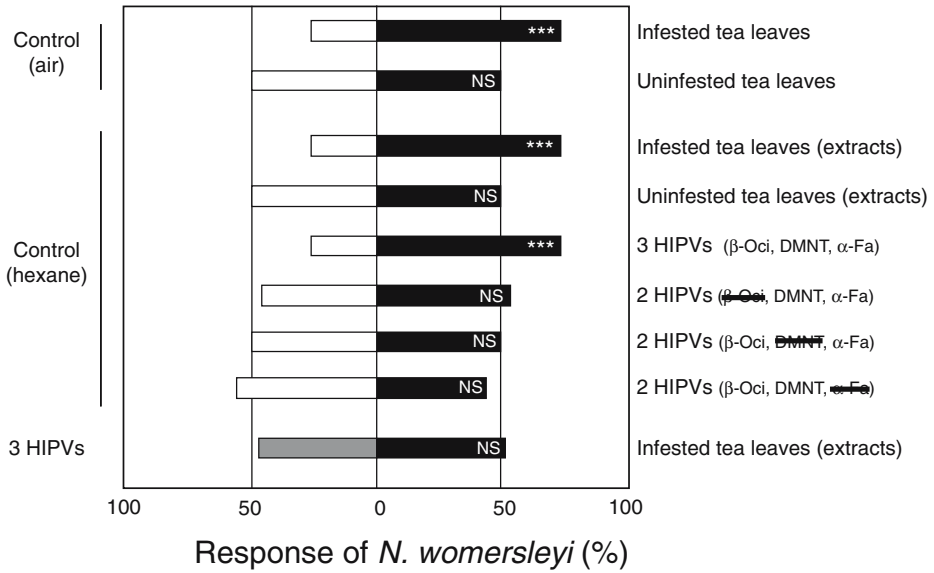

Fig. 1 Responses (%) of *N. womersleyi* to volatiles emitted from *T. kanzawai*-infested tea leaves, uninfested tea leaves, collected volatiles (extracts) from *T. kanzawai*-infested tea leaves, extracts of uninfested leaves, and various combinations of synthetic compounds. The three herbivore-induced plant volatiles (HIPVs) tested were β-ocimene (*β-Oci*), (*E*)-4,8-dimethyl-1,3,7-nonatriene (*DMNT*), and (*E*,*E*)-α-farnesene (*α-Fa*). The upper eight bars show the results of a two-choice test between the sample odors (*black bars*) vs. control odor sources (air or hexane; *white bars*). The bottom bar shows the results of a two-choice test between the collected volatiles from the infested tea leaves (*black bar*) and the mixture of the three synthetic compounds (*gray bar*). ***$P<0.001$

of *T. kanzawai*-infested tea leaves and the synthetic mixture were compared directly, the predatory mites did not show any preference (two-tailed binomial test, $P>0.05$; Fig. 2).

Response to the Volatile Compounds Emitted from Kidney Bean Plants Kidney bean leaves infested with *T. urticae* attracted more than 50% of the predatory mites that had been reared with the *T. urticae*-infested kidney bean leaves (82.0%; two-tailed binomial test, $P<0.001$; Fig. 2), whereas intact plants did not attract the predatory mites. Likewise, *N. womersleyi* showed a significant preference for the extract of the *T. urticae*-infested kidney bean plants (72.0%; two-tailed binomial test, $P<0.01$; Fig. 2), whereas they were not attracted to the extract of the intact kidney bean plants. The mixture of the four *T. urticae*-induced volatile compounds (DMNT, MeSA, β-caryophyllene, and TMTT) attracted significantly more than 50% of these predatory mites (78.0%; two-tailed binomial test, $P<0.001$), and the attractiveness of this odor source was not significantly different from that of the *T. urticae*-infested kidney bean plants or that of the extract of the infested kidney bean plants. However, odor sources lacking any of the volatiles resulted in no preference for the mixture (two-tailed binomial test, $P>0.05$). When DMNT, MeSA or TMTT was excluded from the odor source, the attractiveness of the three-compound mixture was significantly lower than that of the four-compound mixture (Fisher's exact probability test, $P=0.020$, 0.020, and 0.033, respectively). There was no significant preference in the two-choice experiment testing the extract of infested plants and the synthetic mixture (two-tailed binomial test, $P>0.05$; Fig. 2).

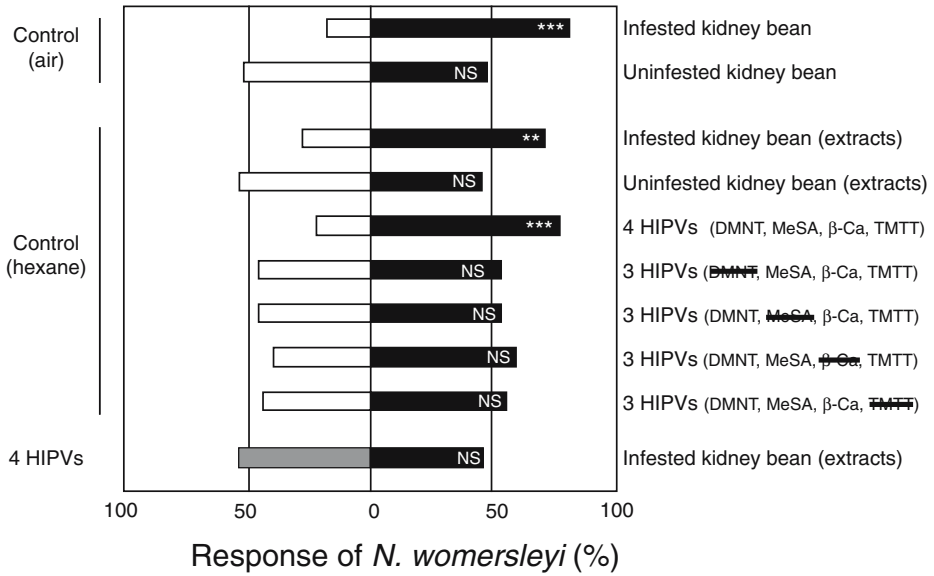

Fig. 2 Responses of *N. womersleyi* to volatiles emitted from *T. urticae*-infested kidney bean plants, intact kidney bean plants, collected volatiles (extracts) from *T. urticae*-infested kidney bean plants, extracts of intact plants, and various combinations of synthetic compounds. The four herbivore-induced plant volatiles (HIPVs) tested were (*E*)-4,8-dimethyl-1,3,7-nonatriene (*DMNT*), methyl salicylate (*MeSA*), β-caryophyllene (*β-Ca*), and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (*TMTT*). The upper nine bars show the results of a two-choice test between the sample odors (*black bars*) vs. control odor sources (air or hexane; *white bars*). The bottom bar shows the results of a two-choice test between the collected volatiles from the infested kidney bean plants (*black bar*) and the mixture of the four synthetic compounds (*gray bar*). ***$P<0.001$; **$P<0.01$

Discussion

The mixture of three synthetic compounds [(*E*)-β-ocimene+DMNT+(*E*,*E*)-α-farnesene, a mimic of *T. kanzawai*-induced tea leaves volatiles] was attractive to *N. womersleyi* that had been reared on tea leaves, but mixtures of any two of these compounds were not attractive. Likewise, the mixture of DMNT, MeSA, β-caryophyllene, and TMTT (a mimic of *T. urticae*-induced kidney bean plant volatiles) was attractive to *N. womersleyi* that had been reared on kidney bean plants, but mixtures of any three of these compounds were significantly less attractive. Therefore, these compounds are the essential attractants among the *T. kanzawai*-induced tea leaves volatiles and *T. urticae*-induced kidney bean plant volatiles, respectively.

In this study, we did not test the attractiveness of a single compound, although Maeda et al. (2006) showed that *N. womersleyi* was not attracted to MeSA alone. In addition, the results of the two- or three-compound mixtures suggest that no single compound tested in this study would attract *N. womersleyi*. Although the effects of other compounds not tested in this study remain unclear, the equal attractiveness of the synthetic mixtures and an equivalent blend of herbivore-infested plant volatiles suggest that the effect of other compounds would be smaller than the three and four tested compounds in the respective plant systems. In the present study, we focused on the essential components of the herbivore-induced plant volatiles that attract the predatory mite. Thus, the synthetic volatiles were tested at a dose equivalent to that produced by the mite-infested plants.

However, as dose-response tests would give us important information, the dose-response tests should be conducted in the future.

Several studies have identified carnivore-attracting compounds from herbivore-induced volatile blends by testing their attractiveness as a single synthetic compound or in a mixture of synthetic compounds (e.g., Whitman and Eller 1992; Scutareanu et al. 1997; Du et al. 1998; Turlings and Fritzsche 1999; Birkett et al. 2003). Only three studies, however, have identified the essential attractants to predatory mites in volatile blends emitted from plants, e.g., lima bean (Dicke et al. 1990a; De Boer et al. 2004; Shimoda et al. 2005). *Phytoseiulus persimilis* (Dicke et al. 1990a) and *Neoseiulus californicus* (Shimoda et al. 2005) showed preferences for several individual prey-induced plant volatile compounds. In another study, *P. persimilis* was attracted to a mixture of several volatiles (De Boer et al. 2004), although that finding could be explained by the attractiveness of a single compound (MeSA). In contrast, our study revealed that *N. womersleyi* showed a preference only for a mixture of several compounds and that the attractiveness could not be explained by a single compound in the mixture.

In nature, plants are usually surrounded by other plants, both conspecifics and heterospecifics. In addition, a single plant may be attacked simultaneously by several herbivore species. Because plant volatile blends are affected by both plant and herbivore species, the predatory mites' environment contains numerous cues. Under such conditions, it would be advantageous for carnivores to be able to distinguish a blend of volatiles emitted from a plant infested by its desired prey (Dicke et al. 2003). De Boer et al. (2004) showed that TMTT alone did not attract *P. persimilis*, but that the presence of TMTT was necessary for *P. persimilis* to distinguish among different volatile blends. Our results also show the importance of several components in a mixture. By using several compounds as cues, *N. womersleyi* should be able to distinguish various blends of volatiles emitted from different plant–prey combinations.

When a specialist predator preys on a monophagous herbivore, the predator may locate its prey by using a specific cue emitted from the plant–prey complex. However, when a predator is a generalist and its prey are polyphagous, the predator must differentiate among and respond to various volatile compounds emitted from the different plant–prey complexes. For instance, the generalist predatory mite *N. californicus* is attracted not only to volatiles from *T. urticae*-infested lima bean leaves but also to volatiles from artificially damaged lima bean leaves, and those from *T. urticae* plus their products such as feces, exuviae, and eggs (Shimoda et al. 2005). In addition, *N. californicus* showed preferences for single synthetic compounds, including (*Z*)-3-hexen-1-ol, (*E*)-2-hexenal, and (*Z*)-3-hexenyl acetate, which are commonly released from various plants even when artificially damaged. These findings suggest that this generalist predatory mite is capable of exploiting a variety of volatile infochemicals that originate from its prey, the prey's host plants, and the interaction between the prey and host plants.

Predators such as *N. womersleyi* and *P. persimilis* prefer spider mites of the genus *Tetranychus*. Because many spider mites are polyphagous (Jeppson et al. 1975), *N. womersleyi* and *P. persimilis* must respond to various spider mite–plant complexes. If several plant species emit a common volatile compound when infested with spider mites, then predatory mites could use the common volatile to find their prey. However, such volatiles may be emitted even when nonprey herbivores attack the plants (Dicke 1999). Therefore, the response to such a general volatile would increase the likelihood of the predator making errors and being attracted to inappropriate herbivores. To avoid making such errors, it would be a better strategy to use more specific infochemicals that originate from their prey–plant complex.

The olfactory responses of *N. womersleyi* and *P. persimilis* have been shown to be affected by their experience (Dicke et al. 1990b; Drukker et al. 2000; De Boer et al. 2005;

Maeda et al. 2006), and the flexibility of the olfactory responses appear to be caused by learning (e.g., Drukker et al. 2000; De Boer et al. 2005). Such an ability to learn would enable predatory mites to respond to specific volatile blends. By focusing solely on these learned blends, however, predators would overlook plants that they have not yet experienced but that may be inhabited by suitable prey. Thus, it would be interesting to examine whether it is better for predators to use commonly emitted volatiles or to learn specific volatile blends. In other words, which strategy is more selectively disadvantageous—being attracted to inappropriate plant–prey complexes or overlooking suitable prey? To answer this question, further investigations of various predators' olfactory response to synthetic volatiles and theoretical studies with mathematical models should be conducted.

Acknowledgments We thank Dr. Junji Takabayashi of the Center for Ecological Research, Kyoto University, and Dr. Norihide Hinomoto of the National Institute of Agrobiological Sciences for the critical review of an early draft of this paper. Dr. Soichi Kugimiya from the Center for Ecological Research kindly provided (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. The authors are grateful to the Chemical Analysis Center, University of Tsukuba, for providing the NMR spectra. This work was supported by the Program for Young Researchers with Fixed-Term Appointments, Special Coordination Funds for Promoting Science and Technology, MEXT, Japan.

Introduction

Interactions among plants, their herbivores, and their pollinators are thought to have led to the diversification of both plants and insects (e.g., Becerra 1997; Farrell and Mitter 1998; Dodd et al. 1999). Historically, studies of plant–herbivore and plant–pollinator interactions have focused either on pollinator attraction to floral traits or herbivore deterrence by plant defenses. However, most plants interact simultaneously with a variety of pollinators and herbivores that could exert reinforcing or conflicting selection pressure on plant traits (Strauss and Whittall 2006; Adler 2007) The study of pair-wise interactions in isolation may not give us an adequate understanding of the costs and benefits of phenotypic traits that mediate interactions with both herbivores and pollinators (Gomez and Zamora 2000; Herrera 2000; Adler et al. 2006).

An increasing number of studies have demonstrated that floral display and rewards may attract antagonists as well as mutualists. For example, wider corollas have made *Polemonium viscosum* flowers more attractive to pollinators but also more vulnerable to ant nectar thieves (Galen and Cuba 2001), and *Ipomopsis aggregata* plants with larger inflorescences attract higher rates of predispersal seed predation (Brody and Mitchell 1997). Hermaphrodites of *Fragaria virginiana* experience more herbivory by the bud-clipping weevil *Anthonomus signatus* compared to female morphs, and this difference is thought to be due to pollen rewards offered by hermaphrodites (Ashman et al. 2004a). Greater nectar rewards in *Datura stramonium* increased oviposition of herbivorous larvae by pollinating hawkmoths (Adler and Bronstein 2004). Therefore, attracting pollinators without also attracting herbivores may be a challenge for flowering plants that require animal pollinators to reproduce.

Scent plays a near-ubiquitous role in plant–insect interactions. Plant volatiles can attract pollinators, provide learning cues for foraging insects, serve as herbivore repellants or attractants, or attract natural enemies of herbivores (De Moraes et al. 1998; Pichersky and Gershenzon 2002; Cunningham et al. 2004; Ashman et al. 2005; Huber et al. 2005). Despite the many ways that scent influences interactions between plants and insects, we know relatively little about how herbivores and pollinators respond to the same scent volatiles. Such information may provide insight into the evolution of the composition, strength, and timing of scent emission. For example, both *Cirsium arvense* and *Nicotiana attenuata* have high floral volatile emission rates during peak reproductive periods that decline after pollination, suggesting a possible cost to emission after pollination is effected (Euler and Baldwin 1996; Theis and Raguso 2005; Theis et al. 2007). However, there are few data to assess the costs and benefits of scent emission in most systems.

Our study addressed the role of floral scent mediating interactions among squash plants, their herbivores, and their pollinators. Most *Cucurbita* species are monoecious, rely on pollinator visitation for reproduction, and are often pollinated by specialist squash bees (Hurd et al. 1974). Several floral volatiles from *Cucurbita* blossoms are attractive to many species of herbivorous cucumber beetles (Andersen and Metcalf 1986; Lampman and Metcalf 1987; Lewis et al. 1990; Metcalf et al. 1995). However, the effect of these volatiles on pollinator attraction is unknown. The goal of this study was to determine whether pollinators and cucumber beetles were attracted to the same floral volatiles to provide a greater understanding of how mutualistic and antagonistic interactions may affect reproductive fitness and selection on *Cucurbita* floral scent.

Methods and Materials

Study System and Site The study was conducted in a butternut squash field located in the town of Dighton, Bristol County, in southeastern Massachusetts, USA (41°49′06.65″ N, 71°07′57.19″ W).

Cucurbita moschata Duchesne (butternut squash, Cucurbitaceae) is an annual broad-leaved vine crop. Plants are monoecious with separate male and female flowers that last for 1 day, opening before sunrise and wilting by early afternoon (McGregor 1976). The scent of male and female *Cucurbita* blossoms attracts *Acalymma vittatum* Fabricius (striped cucumber beetle, Chrysomelidae) (Andersen and Metcalf 1986; Lewis et al. 1990; Metcalf and Lampman 1991; Metcalf et al. 1995; Granero et al. 2004; Ferrari et al. 2006), a specialist herbivore that is responsible for extensive damage to northeastern cucurbit crops (Hoffmann et al. 1996). Leaves and roots of some *Cucurbita* species also produce volatiles that may attract cucumber beetles and other insects (Peterson et al. 1994; Cosse and Baker 1999). However, we focused on floral volatiles because these are most likely to be attractive to pollinators as well as herbivores.

Acalymma vittatum overwinters as adults in diapause that emerge in late spring, feed on cotyledons and new leaves, and then oviposit in early summer. Larvae are specialists on cucurbit roots. The next generation of adults emerges in midsummer and feeds on cucurbit leaves, blossoms, and fruit (Metcalf and Metcalf 1992). Cucumber beetles are often found in cucurbit flowers, where they feed on pollen and floral tissue (Bach 1977; Andersen and Metcalf 1986, 1987; Metcalf and Metcalf 1992).

The squash bee *Peponapis pruinosa* Say (squash bee, Apidae) is one of the most abundant pollinators of squash and pumpkin (Hurd et al. 1974; Shuler et al. 2005). This specialist species collects pollen exclusively from *Cucurbita* blossoms (Hurd et al. 1974). *Apis mellifera* L. (honeybee, Apidae) pollinates cucurbits but does not have a particular affinity (Shuler et al. 2005). Other pollinators that visit *Cucurbita* crops include *Bombus* spp. Latreille (bumblebee, Apidae), various halictid species (*Lasioglossum* spp., *Agapostemon* spp., and Augochlorinae, Halictidae), and *Melissodes bimaculata* Lepeletier (two-spotted miner bee, Apidae) (Shuler et al. 2005).

Treatments Three volatiles, 1,2,4-trimethoxybenzene (T hereafter, Sigma-Aldrich, St. Louis, MO, USA, T68802, 97% pure), indole (I hereafter, Sigma-Aldrich, 13408, 99+% pure), and (*E*)-cinnamaldehyde (C hereafter, Sigma-Aldrich, C80687, 99% pure), are components of *Cucurbita* blossoms that, in combination, were attractive to *A. vittatum* in previous studies and have been used to monitor beetle abundance (Andersen and Metcalf 1986; Lewis et al. 1990; Metcalf et al. 1995). Our purpose was to determine whether these volatiles are also attractive to pollinators to assess whether plants might experience a tradeoff in terms of their ability to attract pollinators while deterring herbivores. The presence and absence of the three volatiles was manipulated in a 2×2×2 factorial design for a total of eight combinations. For each treatment, volatiles were placed separately onto cotton wicks in 20-μl amounts and were applied additively to follow the method of Lewis et al. (1990). Due to its solid state at room temperature, 20 mg of I was dissolved in 20 μl of acetone. Acetone was not used for the other volatiles, which were liquids. Therefore, we used two control treatments, 20 μl of acetone and a dry cotton wick, for a total of nine treatments.

Emission rates vary widely within and among species, and our treatment emission rate is approximately 100-fold higher than what is emitted from various *Cucurbita* on a daily basis (Andersen and Metcalf 1987; Theis, Adler, and Hazzard, personal observation). These rates may be high, but they were selected to mirror those used previously (Lewis et al. 1990). Further, *A. vittatum* attraction had a tightly positive log-linear response to concentrations of both indole and TIC between 0.3 and 30 mg per trap (Lewis et al. 1990). While the slope of the response was higher for TIC than indole, this suggests that beetle response may change in magnitude, but not direction, due to higher concentrations of volatiles. However, similar dose–response curves have not been conducted for *P. pruinosa*. There was 20 μl of volatile

in treatments with a single component (T, I, and C alone), 40 µl of total volatile in treatments with two components (T + I, T + C, I + C), and 60 µl of total volatiles in treatments with all three components (T + I + C). The processing of mixtures of distinct volatiles in the insect brain appears to be close to additive, or even slightly suppressive (Deisig et al. 2006), and so the increase in total volatiles in the combined treatments should not by itself increase attraction.

Trap Design Based on preliminary tests of white, silver, and yellow bowls (Solo Cup, Highland Park, IL, USA) in two sizes (540 ml vs. 4.8 l), we selected yellow (stock no. SPB18), to serve as the trap base because it attracted the most insects (data not shown), which is consistent with previous research using other trap types (Hoffmann et al. 1996). Preliminary trapping indicated that bowl size did not affect insect trapping (data not shown), so the 540-ml bowls were used because they were similar in size to a butternut squash flower. Traps were composed of a bowl with a 20-ml scintillation vial attached to the bottom with silicone-based glue (Permatex, clear RTV silicone adhesive sealant, model 66B, Permatex, Hartford, CT, USA). A 2-ml graduated microcentrifuge tube was placed inside the 20-ml vial. A piece of cotton roll (TIDI Brand, nonsterile, #2-medium, TIDI Products, Neenah, WI, USA) was cut to 3 mm×1 cm and placed into each centrifuge tube. Traps were filled with 520 ml of a soap–water solution (unscented Dawn® soap, Proctor and Gamble, Cincinnati, OH, USA).

Experimental Design Twenty-seven traps were placed in the field on July 26, 2005. Traps were arranged in three blocks, each of which was a row that included one trap in each treatment combination. Traps within blocks were approximately 3 m apart, alternating every other plant, and positioned underneath a broad leaf to protect from rain and mimic flower position. Volatiles were replaced everyday between 1800 and 1900 hours, just before sunset, which allowed us to monitor squash bee pollinators that began to forage before sunrise (Hurd et al. 1974). To avoid bias due to edge or positional effects, traps were moved over one position within the block each day.

Insect Collection and Identification Insects were collected on two separate dates, July 31 and August 4, so that each collection represented multiple days of cumulative insect trapping. Butternut squash plants began to bloom on July 31, reducing the number of pollinators found in traps in the second collection. Insects were cleaned and dried following a protocol from the USDA Bee Biology and Systematics Laboratory (2002). Pollinators were identified to genus using Michener et al. (1994) and to species using Mitchell (1960, 1962).

Data Analysis The number of *P. pruinosa* and *A. vittatum* per trap were used as response variables in separate analyses. Other insects were not caught in sufficient numbers to be analyzed (see "Results" section, "Insect Composition and Abundance" subsection). The two controls (acetone vs. no solvent) were combined into one treatment because there was no difference between them for either insect group ($F_{1,\ 11}<0.1$, $P>0.75$ for *A. vittatum*; no *P. pruinosa* caught in either control). We then determined the effect of T, I, and C as fixed main effects (presence/absence of each), their interactions, block, and collection date on *P. pruinosa* and *A. vittatum* abundance by using separate ANOVAs. Trap was the unit of replication. The number of *A. vittatum* was $\log(x+1)$ transformed to meet assumptions of normality; *P. pruinosa* abundance was normal without transformation. Mean position was used as a covariate for the pollinator analysis but dropped from the beetle analysis because it was not significant. All analyses were performed with SAS v. 9.1.

We expect that synergistic effects of individual compounds will be reflected by significant interaction terms in our ANOVA analysis. However, synergism was defined by Metcalf et al. (1995) as a trap catch that is more than the additive components of the mixture, and they reported the synergistic ratios (SR). SR is the ratio of the mean trap catch of the mixture (minus the control) to the total mean trap catches of each component in isolation (minus the control). We have calculated these values as well.

Results

Insect Composition and Abundance The primary pollinator trapped was *P. pruinosa* (75% of all bees). *Apis mellifera* (3.3%), *Bombus* spp. (1.7%), *M. bimaculata* (6.6%), *Halictus rubicundus* Christ (Halictidae, 1.7%), *Halictus ligatus* Say (Halictidae, 5%), *Augochlorella striata* Provancher (1.7%), and *Lasioglossum* spp. (5%) were also collected from the traps. *Acalymma vittatum* (62.7% of all beetles) was the primary beetle trapped, followed by *Cyclocephala borealis* (northern masked chafer, Scarabaeidae, 34%) and click beetles (Elateridae, 3.3%).

Beetle Attractants Acalymma vittatum was significantly attracted to T and I (Table 1). There were 2.7 times as many *A. vittatum* caught in traps baited with T compared to traps without T, and traps baited with I were 3.3 times more attractive than those without (Fig. 1a). C was not attractive to *A. vittatum*. The effect of the volatiles on *A. vittatum* attraction was additive; there were no significant interactions. However, the combination of TIC trapped twice as many beetles as T + I + C (SR ratio 2.0; Fig. 2a). Other combinations did not appear to be more attractive than the summation of single components (TI vs. T + I: SR ratio 1.2; TC vs. T + C: SR ratio 0.4; IC vs. I + C: SR ratio 0.1; see Fig. 2a for visual comparisons).

Pollinator Attractants Peponapis pruinosa was significantly attracted to T and C, but not to I (Table 2, Fig. 1b). Traps baited with T attracted 2.7 times more *P. pruinosa* than those without T, and traps baited with C were 3.8 times more attractive than those without. There were no interactive effects of any volatiles on pollinator attraction, and the SR ratio was between 0.4 and 1.1 for all volatile combinations (Fig. 2b).

Discussion

We found that each of the three volatiles tested had different effects on the attraction of pollinators and herbivores. (*E*)-cinnamaldehyde was attractive to the pollinator *P. pruinosa* but not the herbivore *A. vittatum*, indole was attractive to *A. vittatum* but not *P. pruinosa*, and 1, 2, 4-trimethoxybenzene was attractive to both (Fig. 1). Because *Cucurbita* rely on pollinators for reproduction (McGregor 1976), the attraction of pollinators has fitness consequences. Furthermore, *A. vittatum* and related diabroticite beetles can have

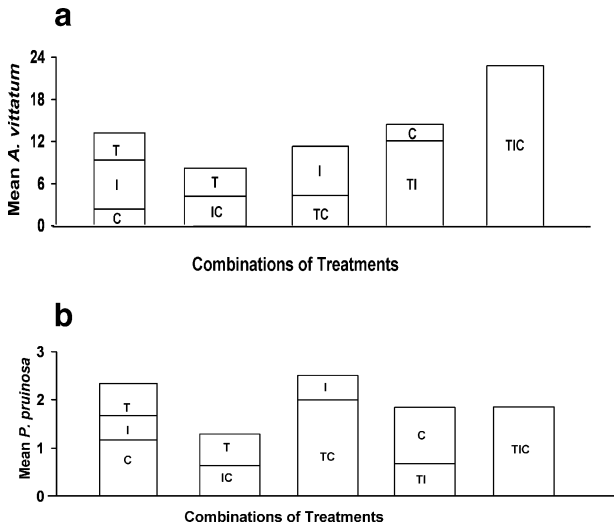

Fig. 2 Number of *A. vittatum* (**a**) and *P. pruinosa* (**b**) caught in traps baited with single volatiles (T, I, or C) as compared to combinations (T + IC, C + TI, I + TC, or TIC together) to illustrate potential synergistic effects

devastating effects on cucurbit growth, reproduction, and survival (Metcalf and Metcalf 1992; Hoffmann et al. 1996). Thus, the attraction of both pollinators and cucumber beetles is likely to have fitness consequences for native cucurbits and implications for crop yield in managed cucurbit systems.

While a growing number of studies have demonstrated that floral display or reward can be costly due to the attraction of antagonists (Brody and Mitchell 1997; Adler and Bronstein 2004; Ashman et al. 2004b; Strauss and Irwin 2004), the current study is one of few to address the role of scent in attracting pollinators compared to herbivores. Similar to our study, specific floral volatiles present in *C. arvense* scent attracted just pollinators, just herbivores, or both pollinators and herbivores (Theis 2006). In addition to having two different corolla shapes, *P. viscosum* has two distinct scent morphs that attract different types of pollinators depending on the presence of floral antagonists (Galen et al. 1987; Galen and Cuba 2001). In areas with low populations of nectar-robbing ants, *P. viscosum* flowers have a wide corolla and a sweet scent that attracts bumblebee pollinators. In areas with high ant populations, flowers have a narrow corolla that deters ants, at the cost of attracting bumblebee pollinators. These flowers emit a skunky scent that attracts fly pollinators that can fit in the narrow corolla.

We found that *A. vittatum* was attracted to 1,2,4-trimethoxybenzene and indole, but not (*E*)-cinnamaldehyde, and that there were no interactive effects of volatiles on attraction. This is contrary to what was observed by Lewis et al. (1990), who found in a field study in Illinois that *A. vittatum* was attracted to indole and (*E*)-cinnamaldehyde, but not 1,2,4-trimethoxybenzene. Similar to their result, we found the combination of TIC to be more attractive than the sum of the parts, with an SR ratio of 2.0. However, our statistical analysis (factorial rather than one-way ANOVA) suggests that this difference is not significant. There are a number of potential explanations for the disparity between our results and those of Lewis et al. (1990). For example, there are many differences in habitat, including microclimate, soil type, and vegetation, between Massachusetts and Illinois. Experimental outcomes can vary over space and time (e.g., Thompson and Cunningham 2002), and the differences between our results and those of Lewis et al. (1990) suggests that this may be the case for the response of *A. vittatum* to *Cucurbita* floral volatiles.

While this research was conducted in an agricultural setting, our results could be relevant to wild cucurbit systems. Native *Cucurbita* species, such as *C. pepo* subsp. *texana* in the southwestern USA, are pollinated by squash and gourd bees of the genus *Peponapis* (Hurd et al. 1971) and are fed upon by *A. vittatum* and other species of diabroticite beetles (Quesada et al. 1995). Pollinators and herbivores could exert different selective pressures on

floral scent, which may influence the evolution of scent composition. Further research could involve manipulative field experiments with *C. pepo* subsp. *texana* in its native habitat to determine if changes in scent volatiles cause appreciable differences in herbivory, pollination, and plant reproduction. Such research should also address the role of scent concentration, which was relatively high in our study, to determine if lower levels that reflect natural blossom emission have similar effects on attraction of both pollinators and herbivores.

Our findings could have important implications for the cucurbit industry. *Cucurbita* fragrance components were not attractive to all visiting specialist insects. For example, we found that only pollinators are attracted to (*E*)-cinnamaldehyde and only herbivores were attracted to indole. The next step would be to determine whether incremental changes in these volatiles lead to differential attraction of pollinators or herbivores. However, there could be unanticipated consequences of a manipulation in volatile levels if these compounds have important functions in other plant parts (e.g., De Moraes et al. 1998). On the other hand, if variation in scent led to increases in pollination or decreases in damage, plant breeders might benefit from selecting plants that produce more (*E*)-cinnamaldehyde or less indole. Decreasing herbivory without the use of pesticides might have the added benefit of limiting damage to local bee populations (Allen-Wardell et al. 1998).

Acknowledgements We thank T'ai Roulston of the Department of Environmental Sciences at the University of Virginia for identifying pollinators, Araujo Farms in Dighton, MA, for the use of their butternut squash field, and S. Halpern, T. Roulston, and two anonymous reviewers for comments on the manuscript. This research was supported by a University of Massachusetts Amherst senior honors research grant awarded by the Commonwealth College to ESA, the National Science Foundation DEB 0542819 to NT, and a Northeastern Integrated Pest Management USDA grant to LSA.

Introduction

The glassy-winged sharpshooter (GWSS) *Homalodisca vitripennis* (Germar), formerly known as *H. coagulata* (Say), is an important insect pest in California. This pest is native to the southeastern USA and northeastern Mexico (Turner and Pollard 1959) and was first introduced to California in the late 1980s (Sorensen and Gill 1996). Since then, GWSS has established throughout much of California including the San Joaquin, Temecula, and Coachella valleys (Purcell and Saunders 1999; CDFA 2005). GWSS is an important vector of *Xylella fastidiosa* (Wells et al. 1987), a xylem-limited plant pathogenic bacterium that causes Pierce's disease (PD) in grapes, leaf scorches in oleanders, almonds, and plums and many other plant diseases (Hopkins 1989; Blua et al. 1999; Purcell et al. 1999; Hopkins and Purcell 2002). GWSS and the pathogens it carries pose a serious threat to the California viticulture industry, as well as to other horticultural crops throughout the state. For example, in the Temecula valley alone, wineries lost 20 to 30% of their vines to PD between 1997 and 2000 (Hix 2001). Currently, there are no effective cures for *X. fastidiosa*-infected plants. Vector control remains the most important strategy for managing PD and other diseases caused by *X. fastidiosa*.

GWSS feeds on xylem fluid of over 100 plant species in at least 37 families (Turner and Pollard 1959; Adlerz 1980; Hoddle et al. 2003; Redak et al. 2004). One of its major crop hosts in California is citrus. High populations of GWSS were shown to cause stress in orange trees, resulting in reduced yield, fruit size, and quality (Hix et al. 2004). In addition, citrus growers have been hampered by state quarantine regulations that restrict movement of bulk citrus produce and nursery stock infested with GWSS into uninfested areas. Furthermore, GWSS may transmit the PD strain of *X. fastidiosa* into citrus plants that may then serve as reservoirs of the bacterium for further acquisition and transmission to grapevines (Bi et al. 2007). It is known that xylem fluid of citrus plants supports growth and development of *X. fastidiosa* when added to culture media (Bi et al. 2007). Improved understanding of the nutritional ecology of GWSS on citrus may help to develop better control strategies.

Numerous studies on nutritional ecology have demonstrated the importance of nitrogen nutrition on survival, growth, and reproduction of phytophagous insects (e.g., Mattson 1980; White 1984; Bi and Felton 1995; Bi et al. 1994, 1997, 2001, 2003, 2005a; Simpson et al. 1995; Joern and Behmer 1997; Blackmer and Byrne 1999). The primary nitrogen nutrients in xylem fluid of GWSS host plants are amino acids and soluble proteins (Andersen et al. 1989, 1992; Bi et al. 2005b). However, xylem fluid is the most dilute food source known for herbivores and requires that strict xylophages such as GWSS engage in exceptionally high feeding rates to acquire sufficient nutrition (Strong et al. 1984; Andersen et al. 1989, 1992). In addition, specialized endosymbiotic bacteria also contribute essential amino acids to their xylem-feeding insect hosts (Wu et al. 2006). In the case of GWSS, two different species of endosymbionts are found compared to one species in phloem feeding insects such as aphids and whiteflies, suggesting a greater requirement for the xylophage to augment incomplete dietary sources through metabolically derived amino acids provided by endosymbionts (Wu et al. 2006). Regardless of the supplemental amino acids provided by endosymbionts, however, complete nutrition for GWSS requires that dietary intake be sufficient to meet demands of growth and reproduction while maintaining energy at adequate levels for host seeking and finding.

As a year-round host in southern California, citrus plays a critical role in the growth and reproduction of GWSS. We previously studied the influence of seasonal nitrogen nutrition fluctuations on the population dynamics of GWSS in citrus (Bi et al. 2005b). In particular,

shifting densities of GWSS adults between lemon and orange trees were correlated to changes in concentrations of certain xylem fluid amino acids on three different occasions during the year-long study. In each case, significant increases in density were associated with positive changes in dietary nitrogen as represented by the free amino acids, not soluble proteins (Bi et al. 2005b). The large fluctuations in amino acid concentrations throughout the annual cycle in both lemon and orange were revealing with respect to how host plants vary temporally in nutritive quality. Coupled with data on shifting densities of GWSS between lemon and orange, the seasonal variability in amino acid concentrations helped to provide greater insight into GWSS movement and host shifts. Previous studies that demonstrated the essential role played by particular amino acids in GWSS ecology (Brodbeck et al. 1990, 1999, 2004; Andersen et al. 1992, 2003, 2005) add support to the conclusion that the observed redistributions between lemon and orange were triggered by changing amino acid concentrations (Bi et al. 2005b).

In addition to occasional shifts among host plants that occur in GWSS feeding ecology, other patterns of GWSS host utilization have been observed but not documented. One of the most prominent of these patterns is the propensity of GWSS adults to feed in higher densities on younger citrus trees relative to older ones. What has not been clear is whether the pattern of higher densities on younger trees has been because of species or varietal differences between the young and old trees rather than to age of the tree itself. We decided to investigate this phenomenon more closely by comparing GWSS densities on a stand of young citrus trees growing adjacent to older trees of the same species and variety. In addition to measuring potential differences in GWSS densities on young vs. old trees, we also were interested in looking for a nutritional basis for such differences. The present study was initiated to determine the influence of seasonal amino acid fluctuations in xylem fluid on GWSS population densities on young and old orange trees.

Methods and Materials

Experimental Plots An orange grove at Newhall Ranch, Piru, Ventura county of California was the site for experiment. Commercially grown young and old orange trees (*Citrus sinensis* var. Valencia grafted on Carrizo) in adjacent blocks were used, separated only by a 3-m access road. The young trees were 6 years old, whereas the old trees were 30 years old. There were more vigorously growing shoots in the young than in the old trees. Twenty trees were randomly selected from each block to monitor GWSS population densities, and 15 of them were used to extract xylem fluid.

Sampling of GWSS A bucket-sampling device (5-gal plastic bucket, with a funneling collecting jar at the bottom, attached to an extendable pole) as described by Castle et al. (2005a) was used to sample both immature and adult GWSS in young and old orange trees. Seven beats were processed with the bucket in each of five directions (360°/5) around the trees. Adults and nymphs in the collecting jar from each tree were transferred to ziplock plastic bags and returned to the laboratory for counting. Population densities of both adult and immature GWSS were monitored on a biweekly basis.

Collection of Xylem Fluid Xylem fluid was used for determination of nutritional quality because GWSS exclusively feeds on xylem fluid (Andersen et al. 1989). Samples of fluid were collected between 6:00 a.m. and 10:00 a.m. on biweekly sampling dates by using a pressure chamber apparatus (Andersen et al. 1989, 1992). One to three terminal shoots from

each tree were used for xylem fluid extraction because these shoots are the preferred feeding sites for GWSS on citrus plants. Upon collection, the xylem fluid was immediately placed on dry ice before final storage in a −80°C freezer. The samples were used for chemical analyses of free amino acids. Xylem fluid sampling was initiated on 3 September 2002 and terminated on 10 September 2003.

Determination of Free Amino Acids Free amino acids were quantified with a Perkin Elmer Applied Biosystem Model 420A PTC derivatizer with an on-line Perkin Elmer Applied Biosystem Model 130A PTC Amino Acid Analyzer. After filtration with a 0.45-μm syringe filter, 20 μl of xylem fluid were reacted with phenylisothiocynate to produce phenylthiocarbamyl (PTC) amino acid derivatives. After derivatization, a methanol solution containing the PTC-amino acids was transferred to a high-performance liquid chromatography system for separation. The PTC-amino acids were separated on a Spheri-5 PTC column (220×2.1 mm), and the PTC chromophore was detected at 263 nm. The buffer system used for separation was 50 mM sodium acetate pH 5.45 as buffer A and 70% acetonitrile/32 mM sodium phosphate pH 6.1 as buffer B. The program was run by using a gradient of buffer A and buffer B with an initial 7% buffer B concentration and ending with a 60% buffer B concentration at the end of the gradient. A standard mixture of known quantities of individual amino acids (Sigma Chemical Co.) was derivatized as above and used for quantification and identification of individual amino acids.

Statistical Analyses A repeated measures analysis of variance (ANOVA; SAS Institute Inc 1989) was used to analyze densities of GWSS during the period when they were present to compare densities on young vs. old trees. Numbers of GWSS adults from bucket-collected samples were $\log(y+1)$ transformed before ANOVA to normalize the data (Little and Hill 1978). Concentrations of individual amino acids in young and old trees during the period when GWSS present or absent were also analyzed by repeated measures ANOVA (SAS Institute Inc 1989). A separate repeated measures ANOVA was conducted on amino acid concentrations during the interval that GWSS was absent. Principal component analysis followed by factor analysis (SAS Institute Inc 1989) was run separately for young and old orange data sets to identify groups of amino acids that exhibited similar dynamical behavior. Outlier analysis by using Mahalanobis distances was applied before factor analysis to eliminate outlying points from the analysis. Individual amino acids with loading values $>|0.7|$ within each factor were grouped, and their annual concentration profiles were presented graphically.

Results

GWSS Densities Differences in GWSS densities relative to amino acid concentrations were evaluated only over the first ten sampling dates when GWSS was present. Beginning with the first sampling on 1 September 2002, higher numbers of adult GWSS occurred on young trees compared to old trees. This difference became increasingly pronounced on each successive sampling date through 22 October 2002 (Fig. 1). After a cold day in early November 2002, GWSS numbers rebounded moderately with consistently higher numbers on young trees compared to old trees through 4 February 2003. After this date, negligible numbers of GWSS (<1 per tree, data not shown) were caught despite conducting the same

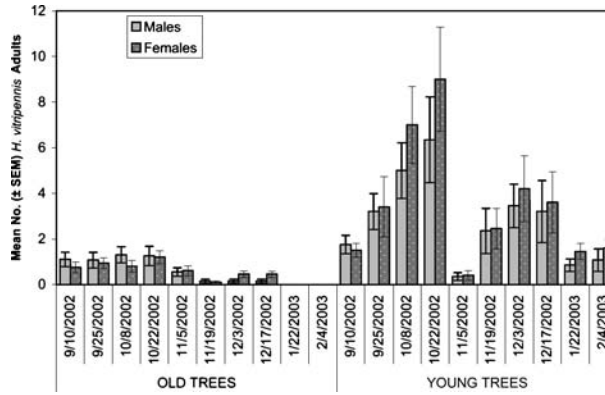

Fig. 1 Mean (±SE) numbers of *H. Vitripennis* adult males and females in young and old orange trees in southern California between September 2002 and February 2003

sampling routine for the remainder of the study. Significantly greater numbers ($F_{(1,28)}=54.45$, $P<0.001$) of adult GWSS occurred on young vs. old orange trees during the September 2002–February 2003 period. Few nymphs were caught during this time (<1 nymphs per tree, data not shown), consistent with previous findings on the phenology of GWSS in citrus (Castle et al. 2005b). There was a slight trend of higher numbers of females on young trees compared to males, with the converse being true for old trees (Fig. 1).

Free Amino Acids Biochemical analyses of xylem fluid sampled from young and old orange trees revealed 19 amino acids present in most samples collected throughout the year. Concentrations of individual amino acids ranged widely relative to one another during either period of the year marked by the presence or absence of GWSS (Tables 1 and 2). Mean concentrations of 12 amino acids including asparagine, serine, glutamine, histidine, threonine, tyrosine, valine, methionine, isoleucine, leucine, phenylalanine, and lysine were significantly higher in young trees compared to old trees during the time that GWSS was present (Table 1). These amino acids together with glycine, arginine, alanine, proline, and cysteine were significantly higher in the next period after the disappearance of GWSS (Table 2). The same was true for the mean totals of nine essential amino acids for insect growth and development that includes isoleucine, leucine, lysine, methionine, phenylalanine, threonine, valine, arginine, and histidine (Taylor and Medici 1966; Brodbeck and Strong 1987; Tables 1 and 2). Similar to previous findings (Bi et al. 2005b), concentrations of proline in orange trees far exceeded any other amino acid with individual sampling date means ranging year-long from 154–463 nmol ml^{-1} in young trees and 99–409 nmol ml^{-1} in old trees (Tables 1 and 2). Apart from double digit mean concentrations of asparagine, glutamine, serine, and threonine occurring during one or both periods, all other amino acids had mean concentrations <10 nmol ml^{-1} (Tables 1 and 2).

Factor analysis revealed commonalities among various amino acids that also were apparent in concentration profiles of amino acids collected over the 1-year period. Separate analyses of young and old orange trees produced rotated loading matrices that included three factors (eigenvalues > 1) for each age category (Table 3). Factor 1 for young trees accounted for 59.6% of the variance in the analysis and contained eight amino acids (asparagine, serine, glutamine, histidine, threonine, tyrosine, valine, and lysine) that had loading values > |0.7|. Another 11.8 and 10.2% of the variance was accounted for by factors 2 (contained aspartic acid, glutamic acid, glycine, and arginine) and 3 (contained leucine and phenylalanine), respectively, for a cumulative 81.6% for all three factors that included

Italicized values denote significantly greater quantities of respective amino acids in comparison of young vs. old trees.

14 amino acids with loading values > |0.7|. For old trees, a cumulative 78.9% of the factor analysis solution was explained by the first three factors that contained a total of 17 amino acids with loading values > |0.7|.

Higher concentrations of total essential amino acids were observed in young trees on nearly all of the 24 sampling dates with differences especially pronounced during fall and late spring–early summer (Fig. 2). The steep rise in the essential amino acids in young trees on the first four sampling dates (2 September–22 October 2002) paralleled the steep rise in GWSS numbers on young trees over the same time period. In contrast, levels of the essential amino acids and GWSS numbers remained flat in old trees during this period. The eight amino acids contained in factor 1 for young trees were characterized by concentration profiles similar to the composite profile for essential amino acids, especially with respect to elevated concentrations in young trees during late spring–early summer (Fig. 3). During the first part of the sampling period when GWSS was present, significantly higher concentrations for all eight amino acids occurred in young trees. However, the age of orange trees was not a significant factor for those amino acids contained in factor 2 for young trees: aspartic acid, glutamic acid, arginine, and glycine (Table 3; Fig. 4). The concentrations of aspartic acid and glutamic acid were similar to one another in young and old trees with reduced concentrations observed from November through April and increased concentrations during warmer months. Peak concentrations for arginine and glycine were observed during early fall with elevated levels occurring as late as 22 January 2003 before declining through late winter–mid spring (Fig. 4).

Italicized values denote significantly greater quantities of respective amino acids in comparison of young vs. old trees.

Concentration peaks that occurred for some amino acids in young trees were often attenuated or absent in old trees. This was most apparent in leucine and phenylalanine in which mid to late October peaks in young trees were missing in old trees (Fig. 5). Peak concentrations of isoleucine and methionine tended to be more tri-modal in young trees than old trees, occurring in fall, early spring, and early summer (Fig. 5). Similar tri-modal profiles, although with greater variation, were also observed for proline and alanine (Fig. 6). Cysteine concentration in young and old trees was the most erratic of any amino acid, being virtually absent from samples on some dates and in relatively high concentrations on surrounding dates (Fig. 6).

Discussion

Successful growth and maintenance of GWSS populations often requires host switching among the many plant species upon which GWSS feeds (Mizell and French 1987; Brodbeck et al. 1999; Redak et al. 2004). At the beginning of this field study in September 2002, GWSS appeared to be relatively abundant in the experimental orchard and surrounding area. In addition, conspicuous numbers were spotted on vegetation in a riparian zone that traversed through the ranch property. Increasing densities of GWSS adults on the young orange trees through the end of October may have reflected host shifting from vegetation outside the orchard. During this same period, however, very little

change in GWSS densities was observed on the old orange trees in spite of their proximity to the young trees. Thus, GWSS adults immigration into the experimental orchard were responding positively to the young trees while showing no net change in densities on the old trees.

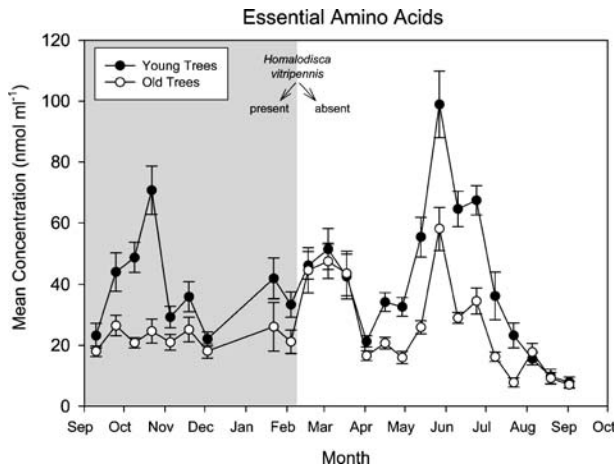

Fig. 2 Mean (±SE) concentrations of the total essential amino acids from September 2002 through September 2003 in young and old orange trees. *Shaded area* represents the period when GWSS was present

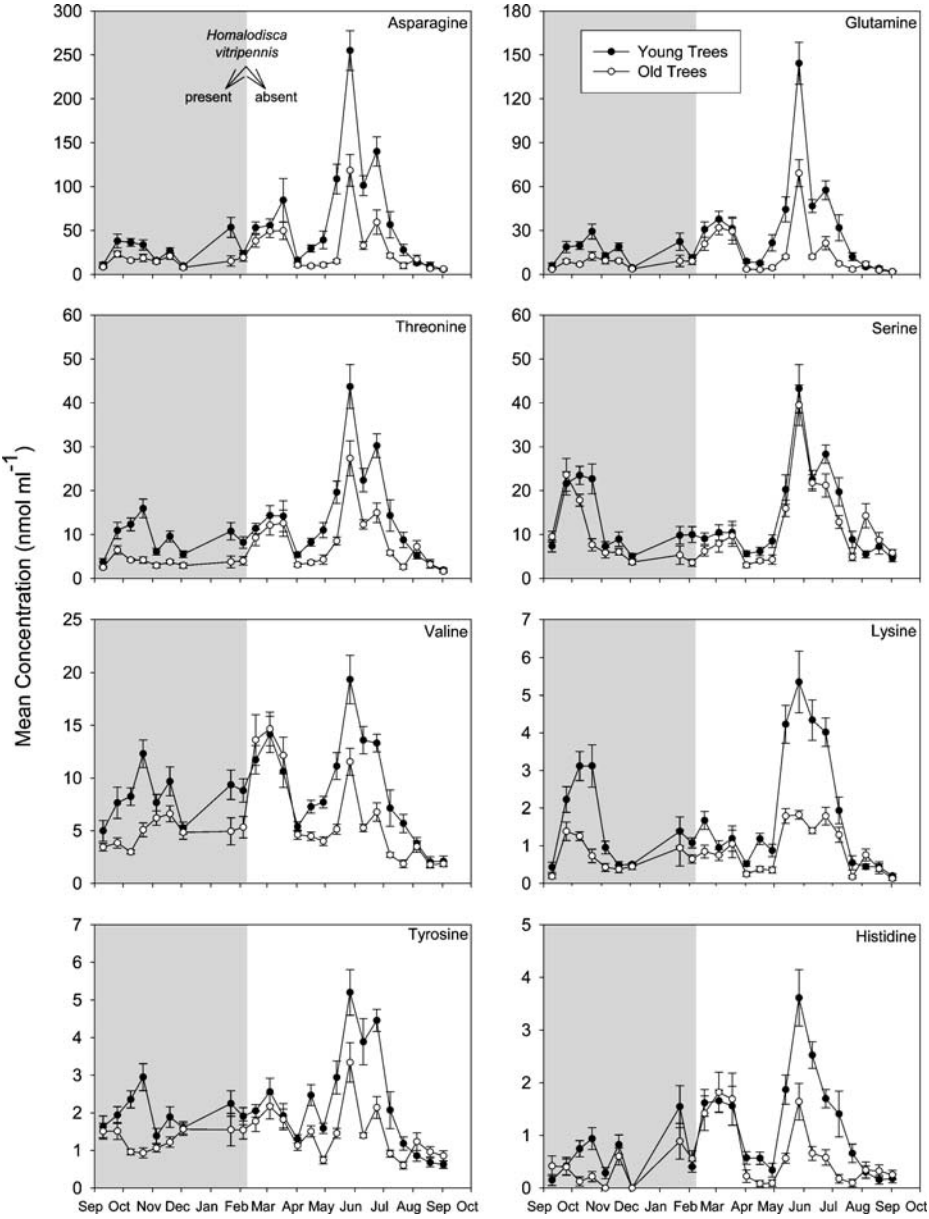

Fig. 3 Annual concentration profiles of eight amino acids from xylem fluid of young or old trees that loaded onto factor 1 in the young tree analysis

At the same time that GWSS adult densities were increasing on young orange trees, concentrations of most amino acids including all nine essential amino acids also were increasing. Importantly, elevated amino acid concentrations observed during the September–October 2002 interval occurred principally in young trees, whereas remaining static or inferior in old trees. Higher levels of asparagine, arginine, proline, glutamine, histidine, threonine, tyrosine, valine, methionine, isoleucine, leucine, phenylalanine, lysine, and serine

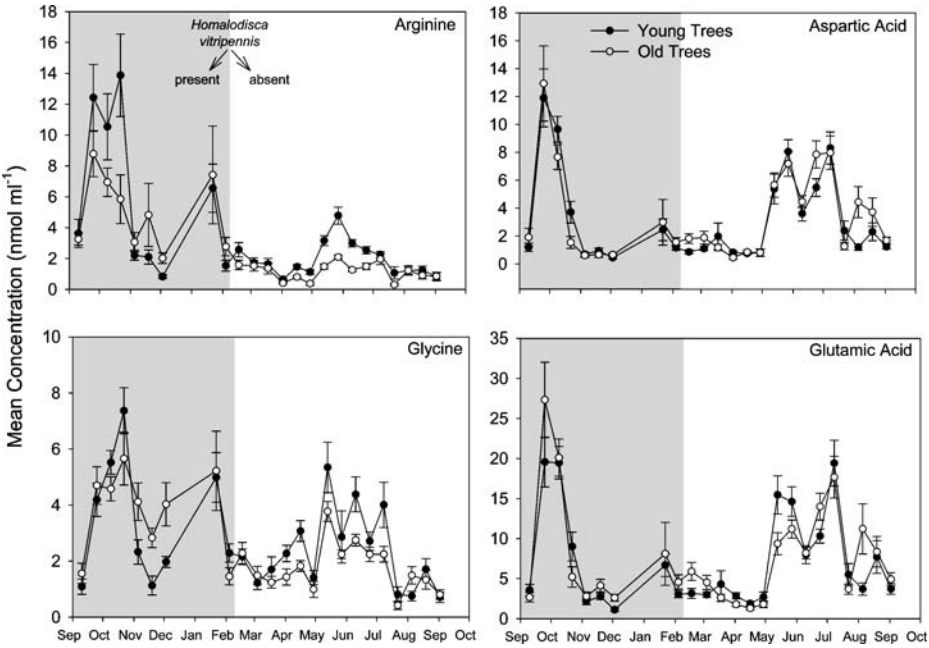

Fig. 4 Annual concentration profiles of four amino acids from xylem fluid of young or old trees that loaded onto factor 2 of the young tree analysis

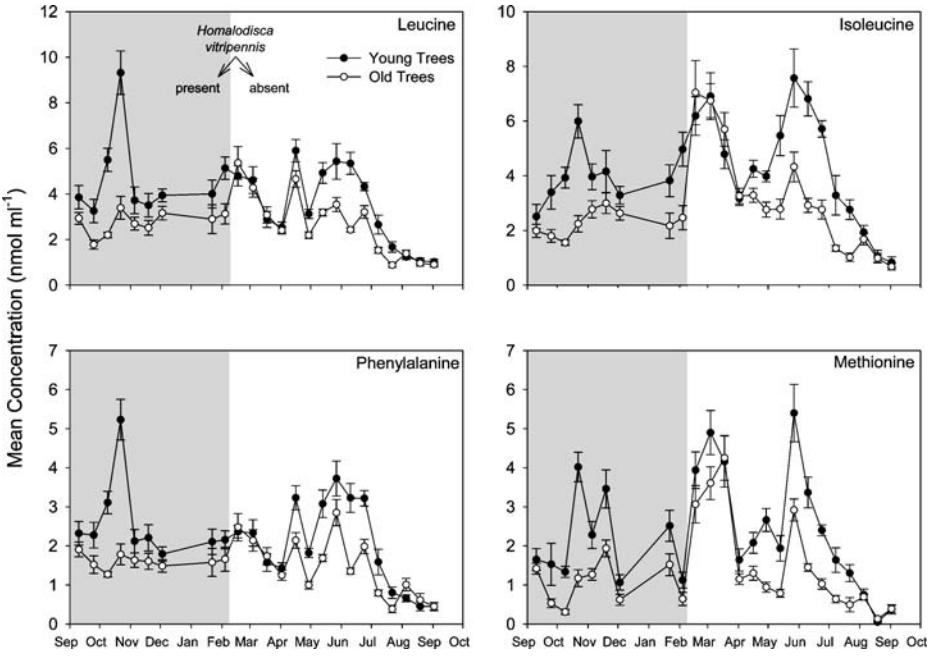

Fig. 5 Annual concentration profiles of four of the ten amino acids from xylem fluid of young or old trees that loaded onto factor 1 of the old tree analysis

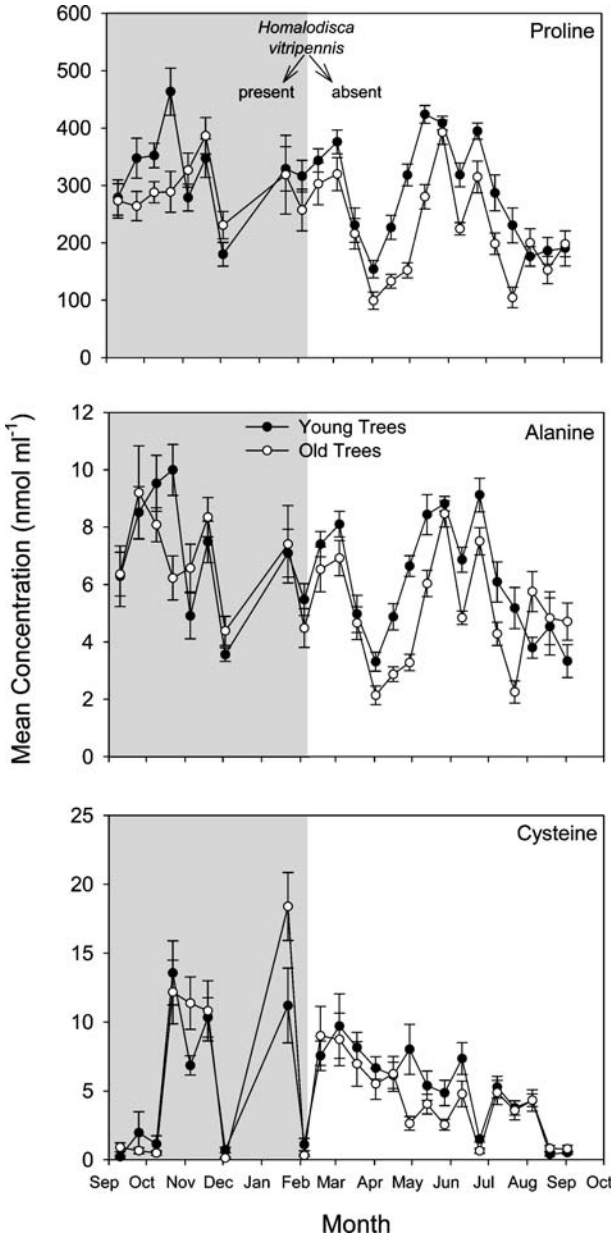

Fig. 6 Annual concentration profiles of proline and alanine from xylem fluid of young or old trees that loaded onto factor 2 of the old tree analysis and of cysteine that did not load into any factor of the young or old tree analyses

were determined in the xylem fluid of young orange trees. Additionally, concentration peaks of glycine, alanine, and cysteine varied between young and old trees, but all 14 remaining amino acids attained significantly higher concentrations in young trees than old trees during the period of GWSS adult recruitment to young trees in fall 2002. Peak densities of GWSS adults were observed on 22 October 2002, after which cooler temperatures and attrition resulted in fewer GWSS adults overall, but with consistently higher numbers remaining in young trees through 04 February 2003. After this date, virtual disappearance of the GWSS

population precluded comparison of GWSS densities on old vs. young trees. However, a similar pattern of significantly higher concentrations of amino acids in young trees compared to old trees continued through the spring and summer seasons before terminating xylem fluid sampling in September 2003.

The propensity of GWSS to feed upon young trees preferentially to old trees observed in this study coincide with general observations of higher GWSS densities found on younger citrus trees rather than older trees. Researchers in California have learned to seek out younger citrus trees for collecting GWSS specimens, but often it is unclear whether species or varietal differences play a role or whether agronomic factors such as fertilization or irrigation regimes potentially affect distribution of GWSS populations. The experimental site in the present study was carefully chosen so as to eliminate most variables other than tree age in terms of GWSS host selection. Both young and old experimental trees were the same variety (Valencia) and under the same irrigation schedule. Their respective positions in adjacent blocks ensured exposure to the same microenvironmental climate. The most significant difference between the young and old trees was the nutritional quality of their xylem fluid as determined by the measurement of 19 amino acids over a 1-year period. The consistently higher concentration of essential amino acids and most of the remaining amino acids in young trees in conjunction with much higher GWSS densities feeding on the young trees strongly support the nutritional superiority of young citrus trees over old trees. The consistently higher densities on young trees also point to the capability of GWSS to locate nutritionally superior trees and exploit them for as long as the nutritional advantage is sustained.

Host switching enables the highly mobile GWSS adults to locate and feed upon nutritionally superior plants. Carbon nutrition may be abundant for GWSS in xylem fluid of host plants such as grapes and citrus because the abundance of GWSS on these plants is not consistently correlated to levels of sugars in the xylem fluid (Andersen et al. 2005; Bi and Toscano, unpublished data), whereas nitrogen nutrition plays a more important role in GWSS host selection (Andersen et al. 2005; Bi et al. 2005b). The primary nitrogen nutrients in xylem fluid of GWSS host plants are amino acids and soluble proteins (Andersen et al. 1989, 1992; Bi et al. 2005b). Soluble protein levels in oranges and lemons did not correspond to shifting GWSS numbers as did amino acids (Bi et al. 2005b). GWSS host selection among *L. indica*, *B. halimifolia*, peach (*Prunus persica*), and plum (*P. salinicia*) was positively correlated with levels of asparagine and glutamine in xylem fluid (Brodbeck et al. 1990). GWSS abundance on grape (*Vitis*) genotypes was correlated to the levels of glutamine, methionine, and phenylalanine (Andersen et al. 2005). We previously reported that GWSS host switching from lemon to orange was closely associated to increase in 12 amino acids in orange including asparagine, glutamine, histidine, threonine, tyrosine, valine, methionine, isoleucine, leucine, phenylalanine, lysine, and glycine (Bi et al. 2005b). Glutamine and asparagine may be ideal host selection cues for generalist feeder GWSS (Brodbeck et al. 1990). These amides are also considered phagostimulants for GWSS (Andersen et al. 1992). Tyrosine and phenylalanine are essential for insect cuticle formation (Bernays and Woodhead 1984). Results in this study provide further evidence that GWSS host selection is dependent upon levels of amino acids in xylem fluid (Andersen et al. 2005).

The drastic decline in GWSS numbers on 5 November 2002 occurred in conjunction with a severe temperature drop. The minimum temperature on that sampling date was below 10°C (data not shown). We noticed that many GWSS had dropped to the ground especially from the young trees, resulting in the lower mean numbers for this sample date. The larger canopies of older trees may provide better protection from cold and other

environmental extremes. Johnson et al. (2006) reported the low temperature threshold for GWSS feeding was 10 and 9.6°C lasting for 12.2 days caused 50% mortality of GWSS. The duration of low temperature in this experiment was relatively short (<12 h). A small portion of the GWSS may be killed directly by the cold and/or the cold resulting starvation may make them more vulnerable to be killed by natural enemies.

The modest decrease in GWSS densities observed from November through December probably represented the decline often observed in insect populations in general during conditions of shorter daylength and cooler temperatures. The sudden disappearance of GWSS after February 4, 2003, however, was unexpected based on the pattern established over the previous 5 months in the experimental orchard or relative to GWSS populations observed in other areas of southern California (Castle et al. 2005b). Area-wide management programs implemented against GWSS in various citrus-intensive regions of southern California have proven effective. The area-wide GWSS management program was initiated in Ventura county in 2003 to protect the shipping nurseries. This program involves treating nurseries and the surrounding citrus groves with soil-formulated imidacloprid (Admire, Bayer CropScience). Imidacloprid is persistent in citrus plants and keeps GWSS in control for 4–5 months (Castle et al. 2005a). There were nurseries with surrounding citrus groves, close to our experimental orchard, treated in early 2003 with imidacloprid. GWSS is extremely mobile with the capacity to move over 1 km in a relatively short time (Blua et al. 1999; Blackmer et al. 2004; Park et al. 2006). It has been noticed that in other areas of California, e.g., in the San Joaquin valley, GWSS numbers on surrounding crops were greatly depressed, although the chemical control program targeting GWSS was applied only to citrus (Park et al. 2006). The disappearance of GWSS after March 2003 in this study (Fig. 1) may be caused by the area-wide GWSS management program.

(Fabaceae) that are pollinated by passerine birds appear to have higher amino acid concentrations than hummingbird-pollinated *Erythrina* species (Baker and Baker 1982b). According to Cruden and Toledo (1977), this may explain why passerine birds defend territories on flowering *Erythrina* trees. In contrast, Gottsberger et al. (1990, 1984) cautioned against attributing too much significance to measured amino acid concentrations because of the likelihood of their leaching from dislodged pollen grains.

Some older publications concerning nectar amino acids were based on semiquantitative techniques, such as ninhydrin staining and comparison with a histidine scale for total amino acid concentrations or thin-layer chromatography for identifying the individual amino acids (Baker and Baker 1973, 1977). With the use of high-performance liquid chromatography (HPLC), more data have become available for amino acids in nectar, including two large surveys of insect-pollinated flowers; 30 species growing in Britain (Gardener and Gillman 2001a) and 73 species from a single plant community in Greece (Petanidou et al. 2006). Information on the nectar amino acids of bird-pollinated flowers is lacking, however, and the study by Baker and Baker (1982b) on *Erythrina* is a good reason to revisit this genus. *Aloe* is another important genus for avian nectarivores (Oatley and Skead 1972). In addition to surveying *Aloe* and *Erythrina* species, I examined other bird-pollinated genera and looked at two potential sources of variation in nectar amino acids: pollen contamination and the variation within and among individual plants.

Methods and Materials

Nectar collection Nectar was collected from plants growing in the field and in cultivation in various locations in and around Pretoria. These included parks, street plantings, private gardens, school grounds, botanic gardens in Pretoria and Johannesburg, and the Suikerbosrand Nature Reserve (SW of Johannesburg). Many species were sampled in the Pretoria National Botanic Garden and the University of Pretoria's Botanic Garden. Where necessary, identifications were confirmed with the curators of herbaria and botanic gardens. Four South American species of *Erythrina* were also included in the survey. A list of collection locations is on file with the author. Only single analyses are presented for many of the species because of cost considerations and, in some cases, availability of plant material.

Nectar samples of approximately 100 μl were collected with care to avoid contamination with pollen or damage to floral tissue and frozen before analysis. Because bird-pollinated flowers produce large volumes of nectar, it was usually possible to collect from single flowers, but sometimes I pooled nectar from different flowers on an inflorescence or raceme. For all nectar samples, sugar concentrations (% *w*/*w*) were measured at the time of collection with a pocket refractometer (Bellingham & Stanley, Tunbridge Wells, UK).

Amino acid analysis The Pico Tag method was used to measure the concentrations of free amino acids with HPLC, by using precolumn derivatization with phenylisothiocyanate (PITC) (Bidlingmeyer et al. 1984). A reversed-phase column (30 cm Pico Tag, Waters) was used for the separation with solvent A being 0.07 M sodium acetate (pH 6.45) with 2.5% acetonitrile and solvent B consisting of 45% acetonitrile, 15% methanol, and 40% water. The gradient used was: 0% B for 14.5 min; direct change to 3% B; 6% B over 9.5 min with a concave gradient; 9% B over 6 min with a convex gradient; 35% B over 20 min linear; kept at 35% B for 10 min; 100% B linear in 30 sec; 100% B for 5 min. Standards (37 amino acids) were included after every six samples. Amino acids were detected at 254 nm with a Waters model 440 UV absorbance detector, and Millenium32 Chromatography Manager

from Waters was used to calculate peak areas. All samples were run in duplicate. Serine and asparagine could not be reliably resolved and have been combined. Large proline peaks on the chromatograms did not show clear separation from 1-methylhistidine, anserine or 3-methylhistidine. Only data for the common protein amino acids are presented: other amino compounds, such as the three just mentioned or hydroxyproline, carnosine, and ornithine, were present only in trace amounts. Note that the total amino acid concentrations will be slightly underestimated because of unresolved peaks.

Effect of pollen on nectar amino acids Three racemes of *Aloe marlothii* were collected from different plants in the same population at Suikerbosrand Nature Reserve. Nectar from each raceme was divided into two 1 ml samples in 1.5 ml Eppendorf© tubes. One served as a control and 5 mg pollen, brushed from freshly dehisced anthers on the same raceme, was added to the other. The pollen–nectar mixture was immediately vortexed and left to stand for 5 min, then filtered through a 0.2 μm filter before the filtrate was frozen for amino acid analysis. Each nectar sample was analyzed twice to estimate the reliability of the data and allow for an error term to analyze the variance in amino acid composition between the pollen and control treatments.

Variability in nectar amino acid composition The deciduous trees of *Erythrina lysistemon* bear scarlet flowers in early spring before the leaves appear. Nectar was collected from four inflorescences on each of six trees in August–September 2005. This is the dry season in Pretoria, and none of the trees was watered. The amino acid composition of each nectar sample was quantified twice to estimate the reliability of the data and allow for an error term to analyze the variance in amino acid composition among the inflorescences.

Statistics Data are expressed as the means±SE. The effect of added pollen on nectar amino acid composition in *A. marlothii* was analyzed using a repeated measures ANOVA with duplicate measures nested within the two treatments (control and added pollen). The relative partitioning of variance within and between *E. lysistemon* trees was analyzed by ANOVA and by calculating repeatability. To quantify the different hierarchical levels of variation in nectar amino acid composition in *E. lysistemon*, separate nested ANOVA were performed for each amino acid using the PROC NESTED procedure of the SAS V 9.1 statistics package (SAS Institute, Cary, N.C., USA). To examine differences in composition independently of the total concentration, the data were adjusted to a total amino acid concentration of 97.5 mM (the mean value for the 24 inflorescences used to examine variability), and reanalyzed. Each analysis contained three sources of variation, nested as follows: *Duplicate* measures (N=2) nested within *Inflorescence* (N=4), which was nested within *Tree* (N=6). The critical level for statistical analyses was set at $\alpha<0.05$ and the significance of the F values was subjected to a sequential Bonferroni correction (Rice 1989). All F values indicating significance are at Bonferroni probabilities. Repeatability±SE was calculated following Becker (1984).

Results

Survey of nectar amino acids in bird-pollinated flowers Among *Aloe* species, high amino acid concentrations were measured in the nectar of *A. marlothii*, but most other species had relatively low concentrations (Table 1). Undetectable amino acids are shown by blank

Amino acid concentrations in mM; sugar concentrations in % *w*/*w*; means±SE if three or four samples analyzed

spaces in Tables 1, 2 and 3 to highlight the limited numbers of amino acids present in the nectars of some plant species. Note that in all tables data for essential amino acids are presented before data for nonessential amino acids.

Some *Erythrina* species had high total amino acid concentrations and a profile that was heavily skewed toward nonessential amino acids: asparagine/serine made a major contribution to the total concentration in *E. caffra*, *E. lysistemon*, *E. latissima*, and *E. crista-galli* (Table 3). Most essential amino acids were present in the nectar of *Erythrina* species, but at low concentrations. Apart from *E. caffra*, *E. lysistemon*, and *E. latissima*, another three southern African species were analyzed: *E. acanthocarpa* and *E. humeana* had high amino acid concentrations, but the value for *E. zeyheri* was low. For the four South American species, nectar amino acid concentrations were lower (and sugar concentrations higher) in the hummingbird-pollinated *E. americana* and *E. flabelliformis* than in *E. crista-galli* and *E. falcata* (Table 3).

In contrast to the *Aloe* and *Erythrina* species, amino acid concentrations were consistently low in the nectar of the other bird-pollinated genera investigated: *Greyia* (all three species of this genus were sampled), *Cotyledon*, *Strelitzia* (two of the three species of the genus), *Schotia*, and *Melianthus* (Table 4). The nectar of four plants of *Greyia sutherlandii* and two of *G. flanagani* contained a single amino acid, valine, at a mean concentration of <1 mM. The nectar of a single plant of *G. radlkoferi* contained only 0.11 mM valine and a trace of leucine (Table 4).

Effect of pollen on nectar amino acids Nectar sugar concentrations in the three *A. marlothii* plants used in the pollen contamination experiment were similar: 9.6%, 10.6%, and 13.7%. Total concentrations of about 50 mM amino acids in the nectar of these three plants

Table 4 Effect of pollen addition on nectar amino acid concentrations in *Aloe marlothii*

Variation in amino acid concentration was analyzed among six different *trees*, four different *inflorescences* per tree and between two different *duplicate* measurements per nectar sample. Nested ANOVA results (*F* values), the proportion of variance explained by each categorical variable (values in parenthesis; %) and repeatability±one standard error (*r*±*SE*) are presented. Significant values (following a Bonferroni correction) are indicated with asterisks. Significance at the 0.001 level could not be detected after Bonferroni correction because SAS only reports significant levels up to 0.0001 (0.0001/15=0.00007).

*$P<0.05$

**$P<0.01$

(Table 5) were higher than the mean value for four other *A. marlothii* plants from different locations (Table 1). Cysteine was absent. Glutamic acid and asparagine/serine were particularly high in these samples, but the addition of pollen had no effect on the amino acids (Table 5). Although an initial mildly significant effect of treatment was detected for ASP and GLY ($P=0.027$ and $P=0.032$, respectively), this did not remain significant for either amino acid following a Bonferroni correction.

Variability in nectar amino acid composition Nectar samples of *E. lysistemon* collected from six different trees showed high and fluctuating levels of glutamine and asparagine/serine, even among inflorescences on a single tree, and also high levels of proline (range 5.6 to 25.6 mM, mean 11.6 mM; data not shown). Total concentrations of amino acids in these nectar samples ranged from 50 to 150 mM with a mean±SE of 97.5±5.5 mM, which is much higher than the mean value for seven other *E. lysistemon* trees shown in Table 3. For the 24 samples from 6 trees used to analyze variability, the nectar sugar concentration measured with a refractometer ranged from 12.9% to 28.0% (mean 18.5%), and the total amino acid concentration was significantly correlated with the sugar concentration: $y=6.147x-16.396$ ($F_{(1,22)}=54.89$; $R^2=0.701$; $P<0.001$). This is to be expected, as both will vary with the water content of the nectar, but note that the amino acids also contribute to the refractometer readings (Inouye et al. 1980).

Because of their absence from more than two thirds of the 24 nectar samples, CYS, GLY, GLU, and TRP were excluded from the analysis. Even when present, these amino acids were barely detectable (e.g., TRP 0.06±0.03 mM; $N=7$) and are probably present in trace

Details as for Table 6, except that concentrations of individual amino acids were adjusted to a total amino acid concentration of 97.5 mM (the mean value for the 24 *E. lysistemon* inflorescences).

*$P<0.05$

**$P<0.01$

amounts only. The nested ANOVA analysis was carried out by using data from both uncorrected and corrected (i.e., absolute and relative) amino acid concentrations. In general, the between-inflorescence proportion of variance comprised most of the variance in nectar amino acid concentrations for both uncorrected (Table 5) and corrected concentrations (Table 6). Indeed, significant variation in the concentration among inflorescences was detected for all amino acids included in the analysis, whereas only a few showed significant between-tree variation (Tables 5 and 6). The between-tree variance for ILE and VAL was no longer significant when amino acid composition was corrected for total concentration. The proportion of variance explained by duplicate measures of the same nectar sample was low (Tables 5 and 6). Although an *F* statistic could not be computed for duplicate measures because of the lack of an error term, the high and significant repeatability of the duplicate measures suggests insignificant variation between them.

Discussion

Flowers pollinated by passerine birds generally have dilute nectars (Nicolson 2002), but some of these have surprisingly high amino acid concentrations. Inflorescences from the six trees used in examining variation in *E. lysistemon* had a mean total amino acid concentration of almost 100 mM, and the nectar of *A. marlothii* used in the pollen experiment had a total concentration of around 50 mM. In contrast, total amino acids in the nectar of 30 insect-pollinated species analyzed by Gardener and Gillman (2001a) ranged from 0.19 to 12.7 mM. Direct comparison with the data of Petanidou et al. (2006) is not possible because these authors expressed amino acids as picomoles per flower.

The distinctive ornithophilous genus *Erythrina* (Fabaceae) has a pantropical distribution and is unusual in including both hummingbird and passerine pollinators. Do my data for the nectar amino acids of *Erythrina* species support the clear pattern demonstrated by Baker and Baker (1982b), using ninhydrin staining read on a spectrophotometer, in relation to bird pollination in this genus? Three of the southern African species, *Erythrina lysistemon*, *E. caffra*, and *E. latissima*, have high amino acid concentrations and are pollinated by a variety of passerine birds, mainly unspecialized nectarivores (Jacot Guillarmod et al. 1979). In the other southern African species analyzed, concentrations vary from <1 mM in *E. zeyheri* to 32 mM in *E. acanthocarpa*. *Erythrina zeyheri* and *E. humeana* are pollinated by sunbirds (Jacot Guillarmod et al. 1979). Pollinators are not known for *E. acanthocarpa*, but sunbirds are likely candidates. Among the South American species, *Erythrina crista-galli* has high amino acid concentrations. Its basal position in the genus (Bruneau 1996) fits with the idea of passerine pollination and high nectar amino acids being ancestral, but field data show it is pollinated by bees and hummingbirds (Galetto et al. 2000). The correlation between nectar amino acid concentration and type of bird pollinator is thus not as strong as postulated by Baker and Baker (1982b), but *E. americana* and *E. flabelliformis* are clear examples of hummingbird-pollinated species with high nectar sugar concentrations and relatively low amino acids.

In nectars of the 16 *Aloe* species analyzed, total amino acid concentrations ranged from low in most species (<10 mM) to high in *A. marlothii* (Table 1). As in the passerine-pollinated species of *Erythrina* (Baker and Baker 1982b), *Aloe* nectar sugars are mainly glucose and fructose (van Wyk et al. 1993). In fact, hexose-dominated nectars are common to all the genera examined in this study (Nicolson 2002). In the case of a 10% pure hexose nectar with a combined concentration of 576 mM glucose and fructose, 50 mM amino acids (as in some individuals of *A. marlothii*) may make a substantial contribution to the refractive index, and this confirms the warning of Inouye et al. (1980) that some nectar sugar concentrations may be overestimated. However, the amino acid contribution to refractive index will be negligible in insect-pollinated flowers with more concentrated nectars and low amino acid concentrations (Gardener and Gillman 2001a).

There are many sources of variation in nectar amino acid composition and concentration. Some nonessential amino acids play a central role in the nitrogen metabolism of plants and make up a high proportion of the amino acids in phloem sap (Douglas 1993; Pate et al. 1985, 1998), so it is not surprising that they also dominate the amino acid profiles in many nectars. In *E. lysistemon*, glutamine, asparagine, and serine together comprised 64% of the total amino acid concentration in nectar of the six trees used to examine intraspecific variation. In nectar of *Impatiens capensis* (Balsaminaceae), glutamine and hydroxyproline, a component of plant cell walls, accounted for most of the intraspecific variability in nectar amino acids (Lanza et al. 1995). Proline comprises almost half the total amino acids in several species of *Nicotiana* (Solanaceae), but the concentrations are low (Kaczorowski et al. 2005). Whereas Carter et al. (2006) considered 2 mM proline in the nectar of ornamental tobacco to be high, proline concentrations averaged 11.6 mM in the 24 inflorescences of *E. lysistemon* used to assess intraspecific variation.

Some differences among studies are caused by differences in methodology. For example, Petanidou et al. (2006) were unable to identify proline or cysteine in the nectars of their large sample (73 species) of eastern Mediterranean plants. Phenylalanine was the dominant amino acid in these nectars, averaging 17% of the total and being especially high in Lamiaceae. Phenylalanine is considered important for bee pollinators in the Mediterranean region (Petanidou et al. 2006), because of its phagostimulatory effect in insects (Gardener and Gillman 2002), but is less evident in other published analyses. Tryptophan was absent from

the nectars of all but one of the 30 plant species analyzed by Gardener and Gillman (2001a), but present in most of those of Petanidou et al. (2006). Additional sources of variation in nectar amino acids include diurnal and seasonal fluctuations in the amino acid composition of phloem sap (Pate et al. 1998; Winter et al. 1992). Growth conditions are also important: Gardener and Gillman (2001b) showed that fertilizer treatment of *Agrostemma githago* (Caryophyllaceae) led to substantial increases in glutamine and proline. Large increases in one or two amino acids will change the relative abundance of all the rest, which is an argument for using absolute rather than relative concentrations. In other studies, Gardener and Gillman (2001a) found composition to be less variable than concentration, and Petanidou et al. (2006) used proportions for their statistical analyses. In *E. lysistemon*, most of the variance in nectar amino acids occurred among inflorescences regardless of whether absolute or relative concentrations were examined. Caution is needed in interpreting my results, as data for 21 out of 36 plant species are based on a single point analysis.

In this study, pollen falling into the nectar was not a source of variation in the nectar amino acids of *A. marlothii*. Confidence in statistical results based on a sample size of three is generally low. However, the use of duplicate analyses in assessing the effect of pollen on amino acid composition controlled for experimental error and, in general, the repeatability of the amino acid analyses for duplicate samples was exceptionally high (Tables 5 and 6). In *A. marlothii*, at least, the results are unlikely to be confounded by pollen contamination during nectar collection. This is in marked contrast to the findings of Gottsberger et al. (1990) who measured dramatic increases in nectar amino acids after pollen addition: 10 pollen grains of *Hibiscus rosa-sinensis* were sufficient to increase the amino acid content of 20 µl of nectar. Although proline remained low after pollen addition to the nectar of *A. marlothii*, it has been reported as the main amino acid released from immersed pollen (Gottsberger et al. 1990; O'Brien et al. 2003). The latter study was in connection with specialized pollen-feeding behavior in *Heliconius* butterflies, but the authors used maize pollen, which bursts when soaked in water or sugar solutions (Human and Nicolson 2003). Whether or not dislodged pollen adds amino acids to nectar may depend on the size and structure of the pollen grains.

There have been only two investigations of the behavioral responses of birds to the inclusion of amino acids in artificial nectar. Neither hummingbirds nor sunbirds selected sugar solutions containing amino acids at low concentrations, and both reduced their feeding rates at higher concentrations (Hainsworth and Wolf 1976; Leseigneur et al. 2007). Among the nonessential amino acids, sunbirds showed no significant avoidance of 15 mM glutamine in 20% sucrose, but did avoid asparagine, serine, and proline at the same concentration (Leseigneur et al. 2007). However, many of the plant species examined in this study produce large volumes of dilute nectar and are visited less by specialized sunbirds than by occasional nectarivores such as bulbuls, starlings, weavers, and mousebirds (Johnson and Nicolson, unpublished data). Moreover, unlike sunbirds, these occasional nectarivores are seemingly undeterred by the bitter taste of some nectars, which is caused by phenolic compounds in the black nectar of *A. vryheidensis* (Johnson et al. 2006) and by unknown compounds, possibly alkaloids, in *E. caffra*. Gardener and Gillman (2002) have drawn attention to the potential contribution of amino acids to the taste of nectar, and it seems likely that the taste of amino acids will be more apparent in dilute nectars. The combination of low sugar and high amino acid concentrations in nectars of some bird-pollinated flowers means that relatively large amounts of amino acids may be ingested in relation to the energy gained, with potential contributions to nitrogen balance of the birds.

Acknowledgments Many people gave permission to sample nectars, and I particularly want to thank the Pretoria National Botanic Garden, Andrew Hankey at the Walter Sisulu National Botanic Garden (Johannesburg), and Veronica Botha who has South American *Erythrina* species in her private garden. Amino acid analyses were carried out by Annette Exley, Department of Biochemistry, University of Pretoria. I am grateful to Braam van Wyk for botanical advice and Luke Verburgt for statistics. This research was supported by the South African National Research Foundation and the University of Pretoria.

and tyrosol were tested in *in vitro* bioassays and showed strong dose-dependent inhibitory effects against *P. ramorum*, *P. cinnamomi*, *P. citricola*, and *P. citrophthora*. These results suggest that phloem chemistry varies in response to pathogen infection in California coast live oak populations and that changes in phloem chemistry may be related to apparently resistant phenotypes observed in the field.

Keywords Sudden oak death · Resistance · *Quercus agrifolia* · Canker · *In vitro* bioassay

Introduction

Phytophthora ramorum Werres, de Cock, and Man in't Veld, the causal agent of sudden oak death (Werres et al. 2001; Rizzo et al. 2002), was first observed killing tanoaks (*Lithocarpus densiflorus*) in Marin County, California in the mid 1990s (Svihra 1999). Since then, the pathogen has been found in 14 coastal counties in California and 1 southwestern county in Oregon. To date, the pathogen has been responsible for widespread mortality of tanoaks, as well as several oak species, including coast live oak (*Quercus agrifolia*), California black oak (*Q. kelloggii*), and Shreve oak (*Q. parvula* var Shrevei) (Garbelotto et al. 2001). The pathogen is known to occur in North America and Europe, and has a wide host range of over 40 plant genera (Rizzo et al. 2005). In the US, the impact of the disease on tanoaks and coast live oaks has been particularly significant with *P. ramorum* in some sites killing 100% of the mature tanoaks and 45% of coast live oaks (McPherson et al. 2005). At such sites, the death of these trees is having a dramatic ecological impact as these species provide food and habitat for animals, serve as fire breaks, and host mycorrhizal networks (Pavlik et al. 1991; Davidson et al. 2005). The destruction of keystone oak species could ultimately lead to reduced biodiversity in these ecosystems and changes in forest composition (Rizzo and Garbelotto 2003).

In oaks and tanoaks, the primary observable symptom of infection is the development of stem cankers that produce a deep red exudate from intact bark (Garbelotto et al. 2001; Rizzo et al. 2002; McPherson et al. 2005). The canker is caused by the pathogen infecting phloem tissue, and frequently extends into the outer portions of the xylem (Rizzo et al. 2002; Brown and Brasier 2007). A black line is usually evident at the margins of the infected areas of the phloem and xylem (Davidson et al. 2003). Other symptoms include brown and white boring dust on the surface of the bark and/or moss caused by ambrosia and bark beetles tunneling into the bleeding cankers (McPherson et al. 2005).

The apparent resistance to *P. ramorum* infection of some individuals within coast live oak populations has been observed in artificial inoculation studies (Dodd et al. 2005; McPherson et al., unpublished data). For example, from artificial branch-cutting inoculation trials, Dodd et al. (2005) found variation (up to eightfold difference in lesion sizes) in susceptibility to *P. ramorum*. In addition, apparent resistance has also been observed in naturally infected forests where a small proportion of infected coast live oaks have survived for extended periods in populations with high mortality levels (McPherson et al. 2005).

Elevated levels of secondary metabolites, specifically phenolic compounds in infected tissue, are often associated with resistance to fungal pathogens in angiosperms (Ostrofsky et al. 1984; Bennett and Wallsgrove 1994). It is possible that these apparently resistant coast live oaks may have increased amounts of phenolic compounds in the *P. ramorum* infected tissue, which are inhibiting the growth of the pathogen. However, no data are available showing changes in secondary metabolites of coast live oaks infected with *P. ramorum*. To date, the majority of studies investigating phenolic chemistry in oak have focused on constitutive wood

and foliage chemistry (e.g., Mammela et al. 2000; Salminen et al. 2004; De Simon et al. 2006).

P. ramorum is a newly discovered pathogen (see review by Rizzo et al. 2005), and there is a need for knowledge concerning the biology of the disease, including a better understanding of the defense responses of oaks infected with *P. ramorum*. We investigated the chemical defense response of California coast live oaks to *P. ramorum* infection by comparing concentrations of the soluble phenolics extracted from healthy and infected trees, and we tested the inhibitory activity of differentially expressed phenolics against pathogenic *Phytophthora* species (including *P. ramorum*) in *in vitro* bioassays.

Methods and Materials

Phloem was sampled from artificially inoculated, naturally infected, and healthy coast live oaks at three different times, December 2004, May 2005, and September 2005 at field sites located in Deer Island, Open Space Preserve (38° 6′ N, 122° 32′ W) and China Camp State Park, Marin County (38° 0′ N, 122° 30′ W), California.

The main goals in the following experiments were to induce cankering (or detect natural cankers) and study the associated host response to the necrogenic activity of the pathogen. Therefore, reisolations of the pathogens were not attempted. Previous studies have shown that *P. ramorum* is the only *Phytophthora* species detected in the cankers produced by using the same inoculation technique and samples cultured from natural cankers found in Marin County (N=44) (McPherson, unpublished data). Furthermore, the appearance of cankers resulting from our inoculations was entirely consistent with the appearance of natural cankers.

The phloem lesions (i.e., the cankers) resulting from artificial inoculations in experiments 1 and 3 covered vertical distances ranging from a few centimeters to over 50 cm (unpublished data). However, exact canker sizes were not measured because, on large stems, the cankers are extremely irregular and the pathogen appears to weave in and out of the phloem (Brown and Brasier 2007). Consequently, cankers are often a collection of smaller lesions with no well-defined edge to the infection, which makes it difficult to accurately measure lesion size.

Set-up for experiment 1: comparison between artificially inoculated and apparently healthy trees Coast live oaks that did not display bleeding cankers or irregular crowns, i.e., that looked healthy, were randomly selected at Deer Island. The diameter at breast height (i.e., approximately 1.5 m above ground) of the selected trees ranged from approximately 28 to 69 cm. The GPS coordinates were recorded for one tree, and the rest of the trees were located in this general area. The trees were then randomly assigned to no treatment (control) and treatment with *P. ramorum*. Each treatment and control consisted of five independent experimental units (trees), for a total of ten trees.

On June 29, 2004, five randomly selected trees were inoculated with *P. ramorum* isolate FOP 10-9-1 with three inoculations per tree at breast height by using a modification of the procedure described by Rizzo et al. (2002). A hole (2 cm diameter) saw was used to remove plugs of bark and phloem tissue down to the sapwood. Five-millimeter agar plugs colonized with an actively growing culture of *P. ramorum* on V-8 agar were placed against the sapwood, and the bark plugs were replaced. Aluminum foil was placed over the wounds, and plugs were held in place with duct tape to minimize contamination and desiccation of cut tissue.

On December 13, 2004, the outer bark over and around the inoculation sites was removed with a hand axe. Samples of inner phloem from the margins of the cankers were harvested, placed in plastic bags, and stored at ambient temperature in the field. Samples of

inner phloem were harvested in the same way from corresponding positions on the trunk of healthy trees. All samples were stored at 4°C upon returning to the laboratory and until extracted.

Set-up for experiment 2: comparison between naturally infected and apparently healthy trees Seven naturally infected trees and five apparently healthy asymptomatic trees were randomly selected for sampling in May 2005 at the China Camp State Park. Trees putatively infected with *P. ramorum* were selected based on symptoms, i.e., the presence of exudate from a canker. Using the same harvesting method described above, phloem was sampled from the active margins of the cankers as well as asymptomatic phloem located at least 60 cm above the cankers on each infected tree (these samples will be henceforth referred to as AFC samples for "away from the canker"). Phloem was sampled from five trees showing no symptoms of *P. ramorum* infection. Samples were placed on dry ice in the field and stored at 4°C upon returning to the laboratory and until extracted.

Set-up for experiment 3: comparison between cankered and noncankered phloem within trees The five uninoculated control trees that were sampled in experiment 1 at Deer Island were used in experiment 3. They had been wounded for sampling on December 13, 2004. These five trees were inoculated with *P. ramorum* (isolate from Jack London State Park, Glen Ellen, California) on June 30, 2005 in areas of the trunk that had not been wounded previously. Phloem samples were collected on September 12, 2005 from canker margins and AFC positions as described for experiment 2. Samples were placed on dry ice in the field, then transported to the laboratory, and stored at 4°C upon returning to the laboratory and until extracted.

Chemical analyses Phloem tissue was frozen in liquid nitrogen and then ground to a powder with a mortar and pestle. Soluble phenolics were extracted with 1 ml of high-performance liquid chromatography (HPLC) grade methanol (Fisher) from 100 mg FW ground phloem tissue for 24 h at 4°C. Particulate matter was removed by centrifugation (5 min at 12,000×*g*). Soluble phenolics were analyzed by HPLC on an Alliance 2690 separation module equipped with an autosampler and a 996 model photo diode array detector (Waters, Milford, MA, USA). A Waters Xterra RP18, 5 μm, 4.6×150 mm column was used. With the exception of a different acidified water–methanol solvents system, the same operating conditions as detailed by Bonello and Blodgett (2003) were performed. Here, 2% formic acid was replaced with 2% acetic acid, and no bases were added to either water or methanol. The photo diode array detector was set to scan between 237 and 400 nm (Bonello and Blodgett 2003), and simultaneous monitoring was performed at 280 nm (flavan-3-ols) and 370 nm (bicyclic coumarin derivatives).

Peak identification and quantification To identify peaks that showed a treatment-dependent behavior, samples within treatments were pooled by combining 50 μl from each sample. The pooled samples were analyzed by HPLC to provide a representative chromatogram for each treatment (Bonello and Blodgett 2003). Nine of these peaks (Table 1) were then analyzed for all individual samples.

UV spectra and retention times of the individual peaks were compared to the following standards: benzoic acid, caffeic acid, catechin, ellagic acid, 4-ethylguaiacol, 4-ethylphenol, gallic acid, ferulic acid, 4-methoxy-4-propylphenol, vanillin, vanillic acid, catechin, taxifolin, tyrosol (Sigma Aldrich, St. Louis, MO, USA), *trans*-4-cinnamic acid, *trans*-4-coumaric acid,

Table 1 Summary of nine phenolic compounds identified in the crude extracts of coastal live oak phloem

Identity (Abbreviated Name, Where Indicated)	RT (min)	Detector Channel for Quantification (nm)
Gallic acid	4.7	280
Tyrosol	7.0	280
Tyrosol-like (TY1)	8.7	280
Catechin	9.5	280
Ellagic acid derivative (EA1)	18.4	370
Ellagic acid derivative (EA2)	19.2	370
Ellagic acid	19.4	370
Ellagic acid derivative (EA3)	21.2	370
Ellagic acid derivative (EA4)	22.6	370

pinosylvin, pinosylvin monomethyl ether (Apin Chemicals, Abingdon, UK), peltatoside, and hyperoside (Extrasynthese, Genay, France).

Gallic acid, tyrosol, catechin, and ellagic acid (see Fig. 1 for structures) were unequivocally confirmed by spiking samples with the respective standards and comparing retention times and UV spectra. These four compounds were quantified by using a four-point regression curve (in a range of 0.005 to 5 mg/ml for catechin, gallic acid, tyrosol, and 0.001 to 1 mg/ml for ellagic acid) constructed with the available standards. Calibration curves with r^2 of 0.99 or better were used. One compound with RT of 8.7 min was identified as a tyrosol derivative based on its UV spectrum, which was similar to that of tyrosol. Similarly, four compounds with RT of 18.5, 19.2, 21.2, and 22.6 min were identified as ellagic acid derivatives based on their UV spectra, which were similar to that of ellagic acid. These compounds, henceforth referred to as TY1, EA1, EA2, EA3, and EA4, respectively, were quantified in terms of tyrosol and ellagic acid equivalents with UV detection at 280 nm for tyrosol and 370 nm for ellagic acid (see Table 1 for a summary of the nine compounds identified and quantified by HPLC).

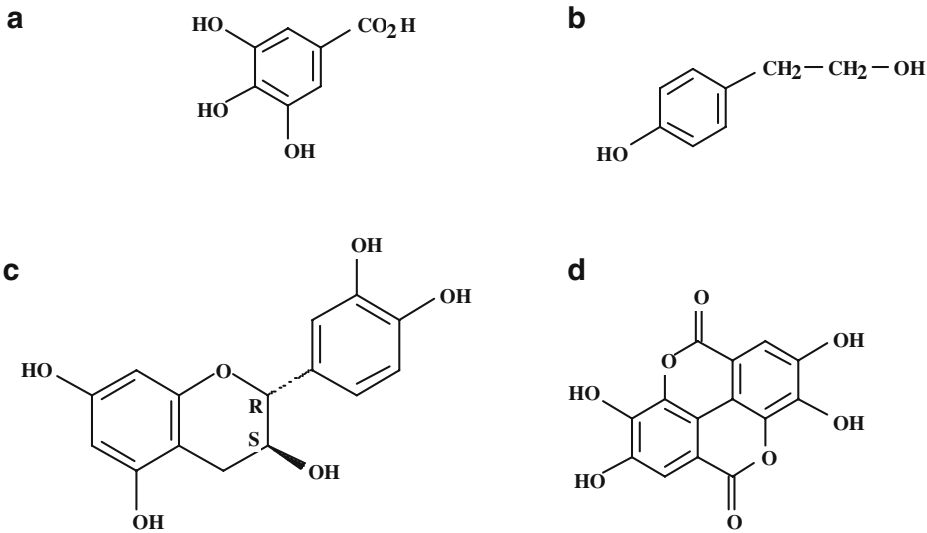

Fig. 1 Structures of the compounds identified in phloem extracts. **a** Gallic acid, **b** tyrosol, **c** catechin, **d** ellagic acid

In vitro bioassay The antifungal activities of gallic acid (2, 3, 6, and 10 mg/ml) and tyrosol (1, 2, 3, and 6 mg/ml) were tested against *P. ramorum*, *P. cinnamomi*, *P. citricola*, and *P. citrophthora in vitro*. Solubility problems prevented us from testing the activity of ellagic acid under the conditions of our assays. For each compound, the concentrations incorporated into dilute frozen lima bean agar (LBA) (Schmitthenner and Bhat 1994) (using the equivalency of 1 ml medium=1 g fresh weight of phloem) were based on the range of concentrations found in the crude extract across all experiments and treatments, i.e., gallic acid, 0.0–5.63 mg/g FW; tyrosol, 0.0–3.25 mg/g FW. In practice, we selected a range of concentrations including approximately twice the highest concentration found in the tissues. This was based on the rationale that individual tissue measurements resulted from the homogenization of tissue that included both necrotic and nonnecrotic areas at the canker margins. Thus, compound concentrations in phloem cells located at the pathogen's invasion front may be underestimated by the "mean" concentration found in the tissue sample analyzed.

Gallic acid changed the medium pH to 3.9, so a corresponding control of LBA, pH 3.9, was used (medium acidified with HCl). Tyrosol did not change the medium pH, so the control for this treatment was unamended LBA (pH=6.7). The same unamended LBA was used as a baseline control in the gallic acid treatment (Fig. 2). In each case, a 3-mm plug of actively growing mycelium was placed onto the center of LBA plate, and mycelial growth (colony diameter) was measured after 4 days incubation at room temperature in the dark. Three replicate Petri dishes/species/chemical/concentration were used. The bioassays with *P. ramorum* were conducted in the laboratory of Dr. David Rizzo at UC Davis.

Statistical analyses For experiment 1, the data on the effect of infection status on concentrations of the identified compounds were analyzed by using multivariate ANOVA. For experiment 2, the data on the effects of infection status and sampling position within trees (canker or AFC, for the infected trees only) on compound concentrations were analyzed with ANOVA by using an unbalanced split plot model with infection status as the whole-plot and sampling position as the subplot. For experiment 3, our data on the effect of sampling position (canker or AFC) on compound concentrations were analyzed with a paired *t*-test. Data from the bioassay were analyzed with univariate ANOVA with compound/concentration and species used as factors. Fisher's least significant difference (LSD) was used to compare the means in all tests. In all analyses, Levene's test was used to examine variance equality, and log or square root transformations were used to eliminate or minimize variance heterogeneity. All tests were conducted using SPSS 11.0 for Windows or MacOS X.

Results

Quantification of Phenolic Compounds

Experiment 1: comparison between artificially inoculated and apparently healthy trees Infected phloem contained greater amounts of gallic acid (20-fold) and ellagic acid (64-fold) than healthy phloem ($F_{1,9}$=32.491, P<0.001; $F_{1,9}$=8.312, P<0.03, respectively). In contrast, infected phloem contained 22% of the catechin and 7% of the EA2, present in healthy phloem ($F_{1,9}$=24.893, P<0.002; $F_{1,9}$=17.048, P<0.002, respectively). Infection status did not affect the concentrations of tyrosol, TY1, EA1, EA3 or EA4 (Table 2).

Experiment 2: comparison between naturally infected and apparently healthy trees As in experiment 1, the concentration of gallic acid was higher in the cankers of infected trees than in

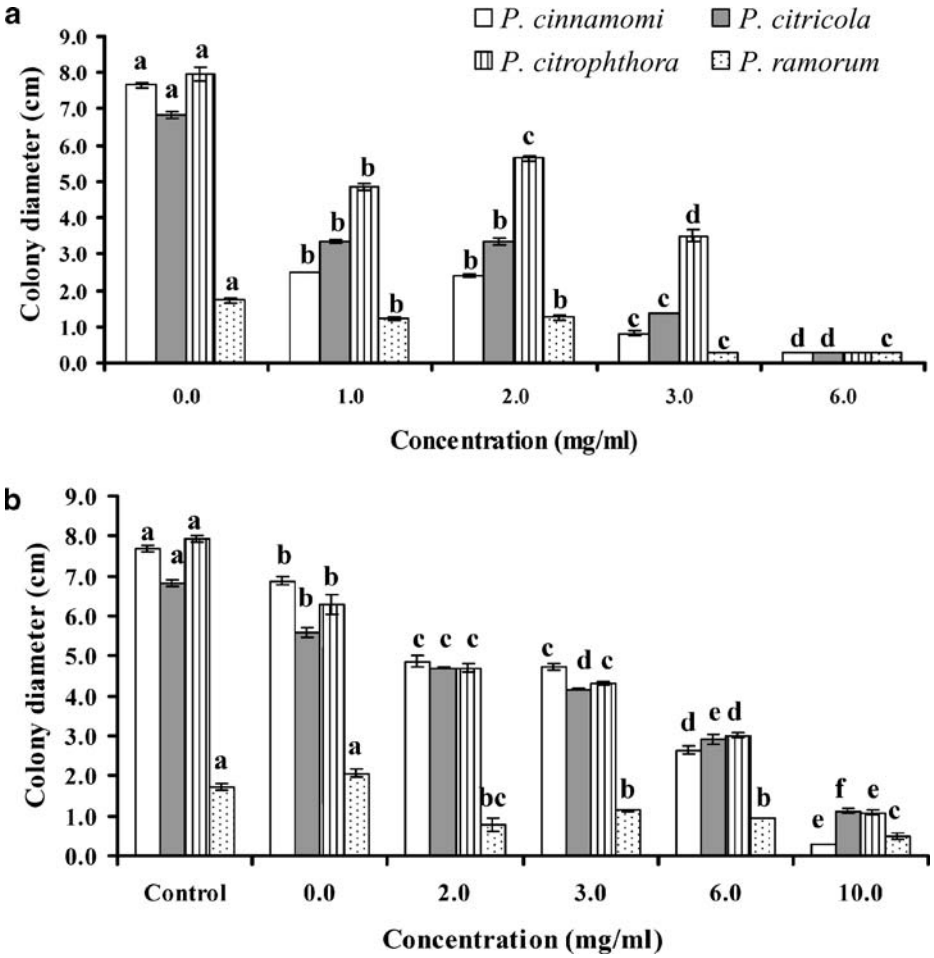

Fig. 2 Effects of tyrosol (**a**) and gallic acid (**b**) on colony growth rates for *P. cinnamomi*, *P. citricola*, *P. citrophthora*, and *P. ramorum*. Each bar represents the mean of three replicates ±1 SEM and includes the diameter of the original inoculum plug (3 mm). Different letters indicate significant differences ($P<0.05$, univariate ANOVA, LSD test) within species only. Species was a significant factor in all ANOVAs, indicating that the four *Phytophthora* species are affected differentially by both treatments. The control for tyrosol (0.0 mg/ml) was used as a baseline and is reproduced as the control bars in **b**

either the phloem of asymptomatic trees (13-fold) ($F_{1,15.9}=28.34$, $P<0.001$) or AFC phloem (10-fold) ($F_{1,8.3}=36.74$, $P<0.001$). AFC and asymptomatic phloem did not differ significantly in gallic acid levels ($F_{1,15.9}=0.01$, $P>0.93$) (Table 3). Ellagic acid was present in greater amounts (4-fold) in cankers of infected trees than in AFC phloem ($F_{1,9.1}=6.14$, $P<0.05$).A trend of greater levels of ellagic acid in infected phloem compared with healthy phloem was also detected ($F_{1,13.7}=3.57$, $P=0.08$). The difference between AFC and healthy phloem was not significant ($F_{1,13.7}=0.84$, $P>0.37$). The concentrations of tyrosol, TY1, catechin, EA1, EA2, EA3, and EA4 were not different among infected, AFC, and healthy phloem (Table 3).

Experiment 3: comparison between cankered and noncankered phloem within trees Tyrosol, catechin, and ellagic acid were found in different amounts in infected and AFC phloem

Table 2 Effect of artificial *P. ramorum* inoculation on the concentration of nine phenolic compounds extracted from the phloem of coast live oak in experiment 1

	Experimental Factors[a]

completely inhibited growth of all four species at the highest concentration, but significant effects could be observed at lower concentrations. *P. citrophthora* appeared to be the least sensitive of the four species to tyrosol. An apparently linear dose response for all four species was observed with gallic acid, although medium acidity also appeared to be a factor (albeit minor) in slowing growth rates for *P. cinnamomi*, *P. citricola*, and *P. citrophthora*, but not *P. ramorum*.

Discussion

Increased concentrations of secondary compounds, especially phenolic compounds, have been reported to occur in the lesion margins of many woody tree species and are generally considered to be implicated in protection against pests and diseases (Hart and Hillis 1974; Woodward and Pearce 1988; Evensen et al. 2000; Viiri et al. 2001, Eyles et al. 2003; Bonello and Blodgett 2003; Blodgett et al. 2007). In the present study, significant differences in phenolic profiles were demonstrated between phloem sampled from the active margins of cankers, healthy phloem from asymptomatic trees, and phloem sampled 60 cm above canker sites in coast live oaks. In particular, five compounds (gallic acid, tyrosol, catechin, ellagic acid, and EA2) were present in differing concentrations in the various treatments. Given that these compounds were present in the healthy phloem as well as in the infected phloem, they are considered constitutive compounds, in contrast to *de novo* produced compounds that are synthesized only in response to a pathogen attack and that would only be detected in infected tissue. This result confirms the lack of evidence, to our knowledge, for phenolics produced *de novo* in response to pathogen attack in oaks.

It should be noted that the production of phenolic compounds was not consistent across all experiments. Specifically, greater amounts of ellagic acid and gallic acid were observed in infected phloem than noninfected phloem in experiments 1 and 2. In contrast, higher amounts of tyrosol and ellagic acid were present in infected phloem than corresponding controls in

experiment 3. It is interesting to note that catechin levels were reduced in infected tissue in two of the three experiments, i.e., experiments 1 and 3. In general, the artificially inoculated trees accumulated more phenolics in response to the infection than the naturally infected trees. We suggest that the artificially inoculated trees, which had been more recently infected with an active pathogen, stimulated a more active host response. As we were unable to determine when the naturally infected trees were inoculated, we cannot speculate on the effect that timing of inoculation has on phenolic production and accumulation. Furthermore, it is possible that other factors such as seasonality (i.e., phenological status) or even the method used to store tissue (room temperature vs dry ice) might have contributed to the observed variability. These factors should be investigated further. The use of controlled branch inoculations to correlate elevated phenolic levels with certain infection characteristics including canker size and host resistance (e.g., Blodgett et al. 2007) may also be helpful.

The soluble phenolic compounds identified in the phloem extracts of infected coast live oak have been implicated as playing key roles in the defense against fungi and herbivores in many woody species including other *Quercus* spp. (Malterud et al. 1985; Pearce 1996; Feucht and Treutter 1999). For example, the durability of some hardwood species against microbes has been directly attributed to the elevated presence of hydrolyzable tannins (Klumpers et al. 1994; Hillis 1999; Barry et al. 2001; Vivas et al. 2004). Hydrolyzable tannins refer to both ellagitannins and gallotannins. The former are esters of hexahydroxydiphenoyl groups with a sugar core and often contain galloyl groups. In contrast, gallotannins consist of a sugar substituted only with galloyl groups (Okuda et al. 1995; Barry et al. 2001).

Hart and Hillis (1972) conducted bioassays with white oak (*Quercus alba* L.) heartwood extracts containing ellagitannins and observed inhibition of the growth of *Poria monticola* Murrill, a wood decay fungus. The capacity of tannins to inhibit the growth of microbes has been credited to the ability of tannins to bind to proteins (Field and Lettinga 1992; Kawamoto et al. 1997) and their antioxidant activity (Okamura et al. 1993; Hagerman et al. 1998). In another study, tyrosol, catechin, and oleuropein were among the main phenolic compounds identified in the stem cortex of olive trees (Del Rio et al. 2003). The stem cortex of olive tree is commonly attacked by a *Phytophthora* sp. causing rot and necrosis, and Del Rio et al. (2003) showed that of the three compounds, tyrosol was the most active growth inhibitor of *Phytophthora* in an *in vitro* bioassay. Of particular note, the greatest antifungal effect was achieved with all three compounds combined. The authors suggested that the increased accumulation of phenolic compounds in the cortex was a defense mechanism of olive plants against the pathogen. Our bioassay results confirmed the toxicity of tyrosol against *Phytophthora* spp., including *P. ramorum*, and indicate that gallic acid also has antimicrobial activity. It is possible that both compounds (and others we have not tested) may have synergistic activities.

In summary, this study demonstrated clear host secondary metabolite responses that may be implicated in the resistance of coast live oak to attack by *P. ramorum*. Further studies involving correlation of compound concentrations with disease resistance *in planta* will be necessary to establish a potential defensive role for any of these compounds. If such a role is established, then some of these compounds could be used as biomarkers in the selection of resistant coast live oak genotypes. These studies, however, are contingent on developing techniques to obtain quantitative measures of host resistance (e.g., based on lesion size as in Blodgett et al. 2007), which are lacking at present in a form that is conducive to concurrent characterization of defense mechanisms.

Acknowledgments The authors would like to thank Nadir Erbilgin, Tom Gordon, Gabriela Ritok-Owens, and Pavel Svihra for the assistance in the field and the lab, David Rizzo for providing the *P. ramorum*

isolates, and Matthew Dileo for conducting the bioassay with *P. ramorum*. Special thanks to Larry Madden for the assistance with the statistical analyses and Duan Wang for conducting the fungal bioassays with *P. cinnamomi*, *P. citricola*, and *P. citrophthora*. Access to research sites was provided by Marin County Open Space District and China Camp State Park. Salaries and research support were provided by state funds appropriated to the Ohio Agricultural Research and Development Center, the Ohio State University, and the U.S. Forest Service (04-CA-11244225-432).

test materials. Few differences in time budgets were observed among aphids exposed to individual components, but synthetic blends and trapped headspace volatiles from PLRV-infected plants resulted in significantly less time spent walking by aphids than synthetic blends and trapped headspace from non-infected controls. Our results indicate that arrestment of *M. persicae* by PLRV-infected plants requires the blend of volatile organic compounds released by these plants and is not produced in response to a single compound.

Introduction

Despite early work that seemed to demonstrate otherwise (Kennedy et al. 1959a, b), olfactory cues can influence aphid responses to host plants (Petterson 1970, 1973; Chapman et al. 1981; Campbell et al. 1990; Nottingham et al. 1991; Pickett et al. 1992; Nottingham and Hardie 1993; Hardie et al. 1995; Petterson et al. 1994; van Giessen et al. 1994; Visser and Piron 1997; Park and Hardie 1998; Quiroz and Niemeyer 1998; Eigenbrode et al. 2002; Jiménez-Martínez et al. 2004). In addition, aphids respond to plant volatiles both in field-trapping experiments and in laboratory olfactometer bioassays (Petterson 1970, 1973; Chapman et al. 1981; Nottingham et al. 1991; Petterson et al. 1994; Quiroz and Niemeyer 1998).

Volatiles released by plants are altered by pathogen infection (Chaudry et al. 1998; Cardoza et al. 2002; Jiménez-Martínez et al. 2004; Huang et al. 2005; McLeod et al. 2005), but the adaptive significance of these changes is obscure. Recent evidence indicates aphids are capable of responding behaviorally to differences in olfactory cues from plants infected with viruses and non-infected control plants (Eigenbrode et al. 2002; Jiménez-Martínez et al. 2004; Srinivasan et al. 2006). The aphid species in these studies are the principal virus vectors, and each aphid species exhibits improved performance on the infected plants, suggesting the patterns are part of co-adaptation between virus and the aphid on which it depends for transmission.

The green peach aphid, *Myzus persicae* (Sulzer) is the principal vector of *Potato leafroll virus* (PLRV; genus Polerovirus; Luteoviridae; Syller 1996). The aphid acquires the virus in a persistent manner, and PLRV particles are associated with the salivary glands of the aphid after acquisition (Harrison 1984). The aphid develops faster, has higher fecundity, and preferentially settles on cultivated potato, *Solanum tuberosum* L., infected with PLRV than on non-infected potato plants (Castle and Berger 1993; Castle et al. 1998). Eigenbrode et al. (2002) showed that preferential colonization of potatoes infected by PLRV by *M. persicae* is influenced by volatile emissions from PLRV-infected plants. They reported that potato plants infected with PLRV produced volatiles that attracted and arrested *M. persicae*. In choice tests with and without contact with the leaf surface, and conducted in darkness, more aphids were located on or near leaflets from PLRV-infected plants than on or near leaflets from plants infected with *Potato virus Y* (PVY), *Potato virus X* (PVX), non-infected controls, or sham-inoculated plants (exposed to virus-free aphids). Volatile organic compounds (VOC) trapped from the plant headspace of PLRV-infected potato plants were more attractive than headspace VOC trapped from healthy plants in a dual-choice bioassay. Similar results were reported by Jiménez-Martínez et al. (2004), studying the response of *Rhopalosiphum padi*, the bird cherry-oat aphid, to wheat plants infected by *Barley yellow dwarf virus* compared with non-infected control plants. More recently, Srinivasan et al.

(2006) showed that *M. persicae* performs better on PLRV-infected hairy nightshade *Solanum sarrachoides* (Sendtner) plants than on non-infected controls, and that both winged and non-winged forms of the aphid show a preference for virus-infected plants.

The specific mechanisms that influence aphid responses to volatile compounds from virus-infected plants have not been investigated. It is possible that one or several of the components elevated by virus infection are specific arrestants for the aphids. Alternatively, the entire blend released by the infected plants may be responsible. The situation is similar to that for changes in plant volatile release following arthropod herbivory (De Moraes et al. 1998; Du et al. 1998; Dicke 1999; Paré et al. 1999; Turlings and Fritzsche 1999; Kessler and Baldwin 2001). Only a few of these studies have examined the importance of, and attempted to isolate, the blends and individual blend components released by herbivore-attacked plants on the responding carnivores. The parasitoid *Cotesia marginiventris* is attracted to a synthetic mixture of 11 major components of the blend emitted by corn plants infested by the parasitoid host, *Spodoptera exigua*. The predatory mite *Phytoseiulus persimilis* is attracted to four chemicals identified in the blend emitted by Lima bean plants infested with their prey, the spider mite *Tetranychus urticaethus* (Dicke et al. 1990).

Eigenbrode et al. (2002) reported that at least 11 headspace volatile components (*cis*-2-hexen-1-ol, *n*-nonane, nonanal, undecane, β-myrcene, (*R*)-(+)-limonene, (−)-*trans*-caryophyllene, (+)-longifolene, α-pinene, β-pinene, and α-humulene) were elevated by PLRV infection but not by PVX or PVY infection or sham inoculation compared with non-infected plants. In this study, we follow up on the report of Eigenbrode et al. (2002) to determine if individual VOC or blends of these compounds that are elevated as a result of PLRV infection elicit significant behavioral and physiological activity in the green peach aphid. Our specific objectives were to: (1) determine arrestment of the green peach aphid to blends of VOC elevated as a result of PLRV infection and those that are produced by non-infected potato plants, (2) determine arrestment of green peach aphid by individual, pure VOC elevated as result of PLRV infection, (3) determine the electrophysiological (EAG studies) response of *M. persicae* to individual VOC compounds, and (4) compare aphid movement rates and time allocated to specific behaviors when exposed to pure individual VOC or blends of these compounds elevated as a result of PLRV infection.

Methods and Materials

Insects The virus-free aphid colony originated from the "OUR" clone (maintained by T. Mowry at the University of Idaho Research and Extension Center in Parma, Idaho) and was maintained on seedlings of *Physalis floridana* Rybd. We tested second- to third-instar apterous aphids from this colony.

Test Compounds *Cis*-2-hexen-1-ol, *n*-nonane, nonanal, undecane, β-myrcene, (*R*)-(+)-limonene, (−)-*trans*-caryophyllene, (+)-longifolene, α-pinene, β-pinene, and α-humulene were purchased from Aldrich (St. Louis, MO, USA). All these VOC were elevated at least twofold without overlapping standard errors about the mean based on trapped headspace of five infected and five healthy plants (Eigenbrode et al. 2002). They are compounds from the fatty acid/lipoxygenase pathway (*cis*-2-hexen-1-ol), 9 and 10-carbon aliphatics (*n*-nonane, nonanal, undecane), monoterpenes ((*R*)-(+)-limonene, β-myrcene, α-pinene, β-pinene), and sesquiterpenes ((−)-*trans*-caryophyllene, (+)-longifolene, α-humulene). Serial dilutions of each compound in paraffin oil (Sigma Chemical Company, St Louis, MO, USA) were prepared to make all doses tested. Compounds were blended in ratios that mimicked ratios

at which they are present in the headspace of PLRV-infected and non-infected potato plants. Various concentrations were tested depending on the experiment.

Doses Each compound was dissolved in paraffin oil to obtain 1,000 mg/ml solutions. Dilutions were done until the desired concentrations were achieved. For the electroantennography (EAG) studies (see below), an intermediate dose of 5×10^{-5} ng per paper leaf model was tested. Individual chemical compounds in emigration bioassays were tested at doses of 4×10^{-7}, 2×10^{-6}, 1×10^{-5}, 5×10^{-5}, and 2.5×10^{-4} ng per paper leaf model. In direct observation studies, a dose of 2.5×10^{-4} ng per paper leaf model was used. Synthetic blends were tested at either 2.5×10^{-4} ng per paper leaf model (representing the concentration present in the headspace of PLRV-infected plants) or 1.25×10^{-4} (representing the concentration present in the headspace of non-infected plants). The synthetic blends were prepared by adding each component at a concentration that approximated that found in natural headspace collections and dissolved in paraffin oil, making a total blend concentration of 100 mg/ml. Dilutions were done until the desired concentrations were achieved. Natural headspace volatiles were also tested at 2.5×10^{-4} ng per paper leaf model (PLRV-infected) and 1.25×10^{-4} (non-infected plants).

Electroantennography Physiological activity of *M. persicae* when exposed to the compounds implicated in aphid responses to infected plants was assessed with electroantennography. EAG was carried out by using a commercially obtained electoantennography system (Syntech, The Netherlands). Each compound was dissolved in paraffin oil to make 1% (*v*/*v*) solution. One hundred microliters of the solution was applied onto an 8× 60 mm strip of Whatman No. 2 filter paper, which was then inserted into a glass Pasteur pipette that was oriented above the antennae of the aphid. The blank control consisted of a strip of filter paper treated only with 100 μl of paraffin oil. The aphid's antennae were attached across electrodes under a microscope. An air stimulus controller (model CS-05b, Syntech) was used for the air and odor delivery. A constant flow (10 ml/sec) of charcoal-filtered and humidified air passed over the antenna through the open end of the glass positioned 15 mm from the antenna. For most experimental procedures, a 2-min interval was maintained between simulations. Serial dilutions of the chemical compounds in paraffin oil were prepared to make an intermediate dose of 5×10^{-5} ng per paper leaf model. The maximum EAG amplitude was measured, the solvent blank response was subtracted, and the results were normalized to the response to linalool. Tests were replicated 10 times. Millivolt potentials for each chemical were averaged and compared to linalool, and the air control and each chemical response was also compared proportionally to linalool.

Behavioral Bioassays

Arrestment Arrestment of the green peach aphid to individual components, to synthetic blends of these components, and to a naturally occurring blend was measured with an emigration rate bioassay. This bioassay measures the rate at which aphids move away from an odor source, and was used previously to detect differential aphid emigration from virus-infected and healthy potato plants (Eigenbrode et al. 2002; Srinivasan et al. 2006). An arena made of a polystyrene 150-mm diam Petri dish was fitted with a false floor of polyethylene screening (mesh size ca. 1 mm) on which aphids could walk freely. One hundred microliters of the test solution were applied onto a filter paper (Whatman No. 2) cut to the approximate size of a potato leaflet (35 mm diam×55 mm length). The solution

was allowed to soak into the filter paper for 2 min and to begin releasing the dissolved test substance before introducing the aphids into the arena. Thirty apterous green peach aphids were placed directly above the paper leaf model on the mesh floor, and the arena was covered. Thereafter, aphid emigration was recorded every 10 min for 50 min. Aphids that left the leaf outline were considered emigrants and were removed and counted at each observation. Controls consisted of only filter paper in a leaf outline. Tests were replicated five times. Aphids were used once and then discarded. Prior bioassays of this nature had been carried out in darkness to avoid visual cues associated with infected vs. healthy plant tissue. The bioassays in the present study were conducted under normal laboratory lighting because all tested materials were visually equivalent. For the individual compounds tested, emigration rates in response to treatments were compared by using analysis of variance (ANOVA) followed by a least significant difference (LSD) means separation procedure (PROC GLM) in SAS (2002–2003). As for the synthetic blends, each treatment was fitted to the model $y = m*(1-\exp(-b*\text{time}))$, where y is the proportion emigrating, m is the maximum emigration, and b is the rate of emigration and time is in minutes. Following model estimation, parameter comparisons were done using full model dummy variable techniques.

Movement Rates and Specific Activities Behavior of individual aphids exposed to test compounds or blends was monitored and recorded to examine the basis of differences in emigration rates. One hundred microliters of the test compound were applied onto Whatman filter paper No. 2 beneath the floor of the arena and allowed to soak in and begin releasing the test compound for 2 min. Afterward, an individual aphid was placed onto the floor of the arena and observed continuously for 5 min. To observe the aphids and record their behavior, a tracking system developed for recording and quantifying animal behavior on artificial or natural substrates was used (Eigenbrode et al. 1989). It consists of an Apple Macintosh computer, a Summagraphics SummaSketch tablet (Summagraphics Corp., Fairfield CT, USA), a boom-mounted dissecting microscope equipped with an ocular crosshair and a mechanical stage manipulator salvaged from a compound microscope. We used this system for the analysis of the behavior of individual aphids when exposed to test compounds or blends. The behaviors of interest were: (1) walk, antenna forward; (2) stop, antenna back; (3) probe taken to describe short stopping periods when the aphid would be seen trying to place its stylet in the walking mesh; (4) walk, antenna back; (5) stop, antennae forward; (6) honeydew taken to describe periods when the aphid would stop and drop honey dew; (7) walk, antennae alternate; and (8) off the arena. Sixty aphids were observed for each of the treatments, and the observation time for each replicate was 300 sec. Wilk's lambda multivariate ANOVA (MANOVA) statistic assessed the significance of treatment effect on all behavioral categories simultaneously, and total time and proportion of time spent in each activity in response to the treatment was compared by using ANOVA followed by a least significant difference (LSD) means separation procedure (PROC GLM) in SAS (2002–2003).

Results

Electroantennography Among the compounds tested, only *cis*-2-hexen-1-ol, α-humulene, (−)-*trans*-caryophyllene, decanal, heptanal, (*R*)-(+)-limonene, and β-myrcene, elicited EAG responses from the aphid's antennae. *Cis*-2-hexen-1-ol and α-humulene elicited the highest

activities, whereas the pinenes and *n*-nonane elicited EAG responses that were lower than the control (Fig. 1).

Behavioral Bioassays

Arrestment

Emigration Rate Bioassays with Individual Compounds Among the VOC elevated as a result of PLRV infection, β-Pinene was a mild arrestant at concentrations of 4×10^{-7}, 2×10^{-6}, and 1×10^{-5} ng per paper leaf model (Table 1). The other compounds did not show any significant differences in the rate of emigration by green peach aphid at the different concentrations (4×10^{-7}, 2×10^{-6}, 1×10^{-5}, 5×10^{-5}, and 2.5×10^{-4} ng per paper leaf model) tested (Table 1).

Emigration Rate Bioassays with Synthetic Blends The synthetic blend that mimicked PLRV infection, and including all the compounds tested individually, was more arrestant to the aphids than either the synthetic blend that mimicked non-infected plants or a blank control (paraffin oil) (Fig. 2). For instance, after the first 10 min, a mean of 16 aphids had emigrated from PLRV mimic synthetic blends paper models compared to a mean of 24 aphids emigrating from paper leaf models treated with non-infected blend of plants (Fig. 2). When emigration data were fitted to the emigration rate model, significant differences were recorded both in the emigration rate (*b*) parameter and the maximum emigration rate (*m*) parameter (Table 2).

Emigration Rate Bioassays with Headspace Volatiles Emigration results with headspace volatiles collected from PLRV-infected and non-infected potato plants showed that green peach aphid is arrested by the PLRV-infected headspace volatiles blend, with fewer aphids emigrating from above paper leaf models treated with the PLRV-infected headspace volatiles compared to aphids emigrating from paper leaf models treated with non-infected headspace volatiles or a blank control (Fig. 3). When emigration data were fitted to the emigration rate model, significant differences were recorded both in the emigration rate (*b*) parameter and the maximum emigration rate (*m*) parameter (Table 3).

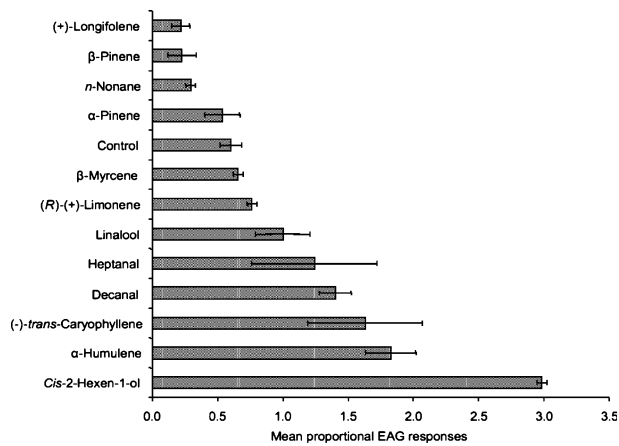

Fig. 1 Mean±SEM proportional mV EAG responses by *M. persicae* to selected VOC elevated by PLRV infection (responses standardized to linalool=1 and control = paraffin oil)

Table 1 Mean cumulative proportion of aphids emigrating when exposed to selected individual volatile organic compounds (VOC) elevated as a result of PLRV infection tested at five concentrations bracketing those present in the headspace VOC of PLRV-infected potato plants

those exposed to a synthetic blend that mimicked non-infected potato plants (walking: $F=6.34$, $P=0.001$; stopping: $F=6.92$, $P<0.001$; probing: $F=3.08$, $P=0.019$), or those exposed to headspace blends collected from non-infected potato plants (Fig. 5). The aphids walked more slowly when exposed to either a synthetic blend made to mimic PLRV infection or pure headspace blend collected from PLRV-infected potato plants compared to either a synthetic blend made to mimic non-infected potato plants or pure headspace blends collected from non-infected potato plants ($F=6.90$, $P<0.001$) (Table 5).

Discussion

The study demonstrates that apterae of green peach aphid, the principal vector of PLRV (Syller 1996), respond to PLRV-infected potato plants preferentially compared to non-infected plants, and that this preference is influenced by volatile emissions from the PLRV-infected plants. These results are consistent with previous findings (Castle et al. 1998; Eigenbrode et al. 2002). Our results show further that a blend of volatiles produced by PLRV-infected plants, which differs in total concentration and relative composition from a blend from non-infected potato plants, is an arrestant for green peach aphid, whereas the individual components of the blend are not arrestants. To the best of our knowledge, this is the first study to demonstrate the importance of blends for *M. persicae* and the first to show the importance of blends vs. individual volatile compounds for eliciting behavioral responses in any aphid species.

In our EAG bioassays, results showed that some of the compounds elevated as a result of PLRV infection were perceived by the aphid's antenna (Fig. 1). There were some differences, however, in the intensity of response to particular compounds. For example, *cis*-2-hexen-1-ol, which is a green leaf volatile (GLV), and α-humulene, which elicits higher activity, whereas the pinenes and *n*-nonane caused EAG responses that were lower than the control. In prior studies, GLVs have elicited activity in EAG to other aphid species and green peach aphid (Hardie et al. 1995; Visser et al. 1996). Similarly, EAG responses to plant volatiles have been reported in several aphid species (Visser and Piron 1995; Visser and Yan 1995; Visser et al. 1996), and there are significant differences between EAG responses among the different aphid species (Hardie and Park 1998).

Most of the behavioral bioassays that investigate the responses of phytophagous insects to host volatiles usually report activity for blends of volatiles rather than for single compounds. For example, Fraser et al. (2003) used a blend of α-terpinene, methyl salicylate, (*E*)-ocimene, benzyl alcohol, decanal, nonanol, phenylacetaldehyde, and geranyl acetone at the same concentration as emitted by tomato foliage to attract *Manducta sexta* in a wind tunnel. They suggested that no single compound serves as a signature compound for host plant selection by the insect. In our system, observed arrestment of the green peach aphid onto PLRV-infected plants evidently requires the blend of VOC released by these plants and is not produced in response to a single compound. In our bioassays that tested individually several compounds elevated as a result of PLRV infection only β-pinene was mildly arrestant (Table 1), whereas none of the other individual compounds were especially active at the tested dose range (Table 1). However, the synthetic blend that mimicked headspace from PLRV-infected plants, and consisted of all compounds tested individually, was arrestant to the aphids compared with a synthetic blend that mimicked non-infected plants or a no-plant control. Response by aphids to these synthetic blends was similar to the response to intact trapped headspace blends from PLRV-infected and non-infected plants. The greater response of green peach aphid to blends of pure compounds than to individual compounds indicates a synergistic mechanism, similar to that observed for semiochemicals in other systems including pheromones, floral scents, and host volatiles (Silverstein and Young 1976; Linn et al. 1986; McLeod et al. 2005). The importance of blends and the sensitivity of insects to specific ratios have also been demonstrated in studies of parasitoid and predator responses to arthropod-feeding-induced release of VOC from plants (Dicke et al. 1990; Turlings et al. 1991).

Our study focused on the principal VOC elevated by PLRV infection and did not consider possible effects of minor components in the blend. At least one study that used herbivore-induced synomones indicates that minor compounds could be important in affecting behavior (Gouinguené and Turlings 2005), and minor components can affect activity of pheromones (Arn et al. 1985). Nonetheless, the activity of our synthetic blends is comparable to that observed with the natural blend trapped from headspace, suggesting we have isolated the most important components required for activity in this system.

Our direct observational data also confirm that activity requires a blend. A few differences in time budgets were observed among aphids exposed to individual compounds, but distinct and significantly different behavioral patterns were observed in aphids exposed to either a synthetic blend that consisted of all individual compounds or headspace volatiles collected from PLRV-infected plants. Over PLRV blends, the aphids spent less time walking, and their mean walking speed was lower than aphids over non-infected blends. In aphids, host plant selection may be divided into four consecutive steps: (1) prealighting behavior, (2) leaf surface exploration and probing of subepidermal tissues, (3) deep probing of plant tissues, and (4) evaluation of the phloem sap (Vargas et al. 2005; Powell et al. 2006). The relative importance of each of these stages may be affected by the degree of host specialization (Bernays and Funk 1999) and by the species studied (Tosh et al. 2003; Vargas et al. 2005). Our results have implications for the second stage in the host-finding behavior of aphids, which involves leaf surface exploration and probing of subepidermal tissues. During this stage, aphids exhibit antennal waving on the plant surface, evidently facilitating detection of odors in the boundary layer close to the plant surface (Hardie and Powell 2000). Differences in emigration, time allocation to walking, and walking speed in our study indicate that the preference for PLRV-infected plants exhibited by the green peach aphid permitted to contact, probe, and feed on potato plants (Castle et al. 1998) is at least in part determined by aphid responses to volatile cues available near the plant surface.

Whether other modalities influence the response of aphids to PLRV-infected plants remains to be determined.

For all our experiments, we used a clonal population of green peach aphid based on a collection made in southern Idaho. Our results with this clone show that the species is capable of responding differently to blends than to pure compounds from host plants. The vast areas planted to potatoes in southern Idaho and the superior quality of PLRV-infected plants for green peach aphid growth and reproduction (Castle and Berger 1993) may have selected for responsiveness to the specific compounds and blends we studied. Responses of other populations of green peach aphid may differ, and the phenomenon should be examined in other green peach aphid clones.

Our results assist in understanding disease spread. Arrestment of the green peach aphid to PLRV-infected plants can increase the probability of virus acquisition promoting further the spread of PLRV, in addition to the observed payoff of increased fitness (Castle and Berger 1993). McElhany et al. (1995) infer from modeling studies that examined effects of preference for infected or healthy plants on pathogen spread, that the rate of pathogen spread depends on the percentage of infected plants, and that rates of pathogen spread would be high when vectors prefer healthy plants. However, their model leaves out other factors such as insect density, insect movement, or the initial numbers of inoculative insects, which may also play a role in rates of pathogen spread. From our study and other studies (Eigenbrode et al. 2002; Jiménez-Martínez et al. 2004; Srinivasan et al. 2006), it is beginning to emerge that volatiles emitted by infected plants contribute to this preference. In the future, it will be important to examine these and other factors that may be causing such preferences and their relative importance in disease spread. Conducting such experiments is time consuming and costly. We thus suggest that these and other factors be incorporated in models to fully understand the consequences of the observed preferences on disease spread.

Introduction

Coupled gas chromatography–electroantennographic detection (GC-EAD) is a widely used procedure for distinguishing insect olfactory stimulants within mixtures of volatile chemicals. Insect antennae are exposed to compounds eluting from a gas chromatograph (GC) while the electrical potential across them is continuously recorded (Arn et al. 1975). Voltage deflections are detected in the antennae coincident with the elution of olfactory stimulants, and stimulants of particular biological importance for the insect, such as pheromones, typically produce relatively larger deflections. The elicitation and comparative strength of antennal responses can be used to assess the likelihood that a particular compound will be found (after further investigation) to have behavioral activity for an insect. GC-EAD has been used effectively by researchers to rapidly screen large numbers of candidate semiochemicals or raw extracts of active material for further evaluation in behavioral experiments, thereby eliminating unnecessary behavioral tests of inactive compounds (Cork et al. 1990; Bjostad 1998).

The utility of EAD data depends greatly upon the quality of the signal detected from the antenna and the signal-to-noise ratio. Noise can be generated within the antennal preparation and apparatus by sources of electromagnetic radiation, changing local electric fields, changes in the quality of electrode contact with the antenna, amplifier noise, as well as movement of the antennae caused by air fluctuations, muscular contractions, or mechanical vibrations conducted through the equipment (Van der Pers 1998). This constant stream of random background noise and spurious electrical perturbations invariably mask some true signals (i.e., potentials presumably arising from stimulated olfactory sensilla), and otherwise compete with them for recognition (Fig. 1). Generally, authors have reported EAD-detected olfactory stimulation without indicating a specific method for discriminating signal from noise. In some cases, authors have stipulated "consistency" or "repeatability" of an EAD spike at specific retention times as evidence for an olfaction-generated signal (Ellner et al. 2001; Nunez et al. 2002). To improve the repeatability of EAD data interpretation, some have employed explicit tests based in the statistical improbability of a random noise spike both exceeding a threshold level and recurring at the same retention time (Zhang et al. 2001; Zhang and Aldrich 2003; Asaro et al. 2004). Such methods gain power through repeated runs of the same compound over the same insect species. However,

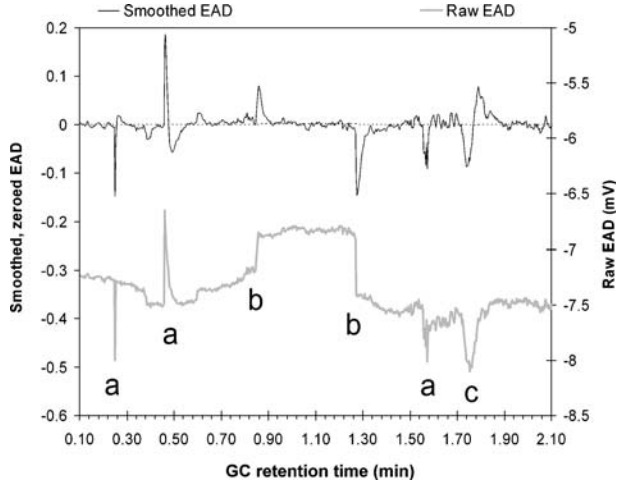

Fig. 1 A composite EAD trace illustrating various types of deflections that may be present. The lower trace is the raw unfiltered EAD trace as it is recorded from the antenna, and the upper trace has had zero-filtering and some smoothing applied. Non-signal "spikes" are shown at locations *a*, baseline shifts are shown at *b*, and an olfaction generated signal is shown at *c*. Smaller random noise perturbations are seen throughout

because these methods discriminate signals using deflection amplitude data alone without considering deflection shape, they may require many data runs to resolve genuine olfactory responses, and they may be ineffective at distinguishing signals when noise-associated deflections are similar in amplitude.

The signal-to-noise ratio in EAD procedures can sometimes be improved with modifications to the associated hardware and antennal preparation technique. For example, the signal-to-noise ratio of an EAD preparation that utilizes a single antenna can be improved by attaching multiple antennae in parallel to the recording electrodes (Park and Baker 2002). In addition, the unique dynamics of olfactory responses can be exploited in the use of filters that discriminate between signal and noise. Voltage deflections produced by antennae exposed to olfactory stimulants have a characteristic shape and duration (or wavelength) that is the product of both the dose/time characteristics of the presented stimulus and antenna physiology (Sullivan and Slone, unpublished data). Consequently, low-pass filters have been incorporated into EAD amplifiers that attenuate short wavelength signals typical of electromagnetic noise while passing the long (i.e., >1–10 sec) wavelengths associated with electrophysiological responses (Guerin et al. 1983; Bjostad 1998; Sasaerila et al. 2000; Leal et al. 2001). The analog EAD signal output is commonly converted to a digital stream for data storage and examination with graphical software. With the data recorded as a series of numbers representing the antennal voltage measured at a fixed interval (e.g., every 0.2 sec), mathematical filters can also be applied to antennogram data sets post-collection to extract antennal response from background noise. Such post hoc methods are available on commercial EAD software and include smoothing algorithms such as moving-average which, like low-pass filters, tend to attenuate noise with shorter wavelengths. However, the shape dynamics of olfaction-generated EAD signals are adequately distinct to allow discrimination based on more precise waveform characteristics; hence, further refinement to such post hoc noise filters is possible. Assuming the concentration of stimulant eluting from the GC is not approaching the saturation point of the olfactory sensillae, EAD output amplitude will covary approximately linearly with the log-transformed concentration of an eluting stimulant (Zhang et al. 2002; Sullivan, unpublished data) or the first integral of the amplitude of the flame ionization detector output. Hence, the shape of the raw olfaction-generated signal closely resembles that of the flame ionization detector (FID) peak. Under normal GC operating conditions (i.e., the column is not overloaded and its temperature is programmed to increase constantly), these peaks should resemble the bell shape of a normal distribution (Fig. 2). Hence, EAD peaks arising from GC-generated stimuli eluting will have an essentially constant wavelength

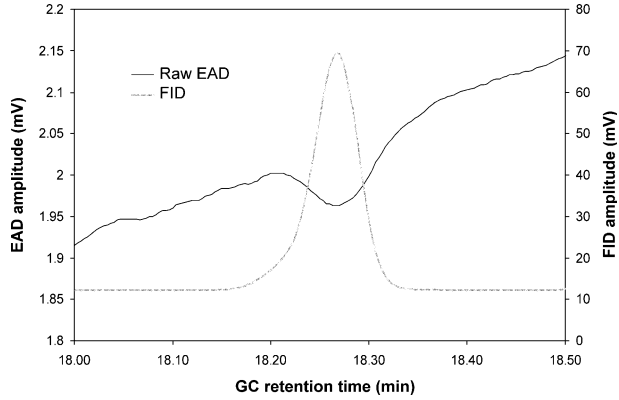

Fig. 2 A GC peak and associated EAD olfaction response superimposed to show the approximate bell shape of each

(i.e., peak width) and a high degree of bilateral symmetry between their left and right slopes.

In this paper, we describe three algorithms that discriminate olfaction-generated signals from noise in EAD data on the basis of either (1) signal amplitude alone, (2) signal amplitude and wavelength, or (3) signal amplitude, wavelength, and symmetry. We then compare the signal-discriminating capacity of the three algorithms to one another and to discrimination methods based on either general visual appearance of EAD traces or retention time consistency of signals. The algorithms are formulated to be applicable to any EAD data sets where voltage changes across antennae are detected with a high-impedance DC amplifier (such as described in Bjostad 1998 and used in EAD systems sold by Syntech, Hilversum, The Netherlands) interfaced with an analog-to-digital converter and data management software that allows the final collected data set to be converted to an ASCII file and examined in a spreadsheet program. PC-based digital data acquisition systems suitable for GC-EAD commonly permit the user to convert recorded data to ASCII format (including data acquisition systems sold by Syntech; SRI Instruments, Torrance, CA, USA; and DATAQ, Akron, OH, USA), so it should be possible for most GC-EAD operators to apply our algorithms to their own data sets. In addition, we have made available on the Internet an Excel spreadsheet that performs all of the calculations.

Methods and Materials

Apparatus Setup and Data Collection EAD data were collected from the antennae of the Nantucket pine tip moth, *Rhyacionia frustrana* (Comstock; Lepidoptera: Tortricidae), the southern pine beetle, *Dendroctonus frontalis* Zimmermann (Coleoptera: Curculionidae), and the parasitoid *Roptrocerus xylophagorum* (Ratzeburg; Hymenoptera: Pteromalidae) using procedures and apparatus described previously (Pettersson et al. 2000; Asaro et al. 2004; Sullivan 2005). Antennae were mounted between two glass electrodes filled with Beadle–Ephrussi ringer solution amended with polyvinylpyrrolidone (Bjostad 1998), and the recording electrode was connected to a high impedance guarded input AC/DC preamplifier (Syntech). Output from the preamplifier was processed by a signal interface box (Syntech IDAC 2/3) that provided optional baseline control of the analog signal. Digitized signal from the FID and the signal interface box were collected at five samples per second with a PeakSimple Chromatographic Interface and PeakSimple software (SRI instruments). Data were collected without the automatic baseline return filter engaged on the IDAC 2/3. The EAD and FID data files were saved in ASCII format and subsequently opened in an Excel spreadsheet as two columns of successive voltage readings from the FID and the EAD [note that for data collected with Electro Antenno Detection software (Syntech 2004), "EAD session" data files (*.ead) can be saved in ASCII format (*.asc) within the "File: Save As" window].

Data Transformation We first applied an exponential zeroing filter to the raw EAD data. Filtrations of the data in this way converted the approximately Gaussian raw EAD signals to "sigmoid" deflections that were essentially identical to the output produced by the analog baseline-return filter present on the SYNTECH IDAC 2/3 signal interface box:

$$Z_t = E_t - E_{t-1} + r \cdot Z_{t-1} \quad (1)$$

where Z=zeroed data, t=sample number, E=EAD data (i.e., voltage recorded from antenna), and r=zeroing rate [related to the time constant (T.C.) on the SYNTECH IDAC 2/3 by $r = 0.37^{\frac{1}{f_s \cdot TC}}$; f_s=sampling rate per second. We set r to a value of $0.8w^{0.05}$ where w is

the width in samples of an average FID peak in the sample run at half its height. This value produced positive and negative deflections in the zeroed EAD data that were similar in amplitude.

We further filtered the zeroed data to remove spurious noise spikes by applying an exponential averager (Lyons 1997):

$$s_t = \alpha_s \cdot Z_t + (1 - \alpha_s) \cdot s_{t-1}, \tag{2}$$

where α_s=weighting factor for smoothing. The purpose of the averaging filter is to pass deflections that occur at the wavelength expected of an olfaction signal (for EAD data, this is the wavelength of the FID peaks) while attenuating the higher frequencies associated with noise. For typical GC-EAD recordings where the FID peak width at half-height is 2–3 sec (10–15 time steps), we found that a value of 0.15 for α_s maximized the difference in amplitude between signal peaks and higher frequency noise, thus allowing for the highest S/N ratio.

We calculated a baseline using a similar exponential averaging function:

$$b_t = \alpha_b \cdot s_t + (1 - \alpha_b) \cdot b_{t-1}, \tag{3}$$

where α_b=weighting factor for the baseline. The baseline is the axis from which we measured height of EAD deflections. Hence, it ideally should attenuate signals with the wavelength expected from olfaction signals while passing lower frequencies, thereby allowing the baseline to follow the average meanderings of the zeroed EAD data and permitting the subtraction of baseline "drift". To achieve this end, we set α_b to 0.001.

Signal Discrimination We transformed the data finally with one of three candidate algorithms designed to "filter out" EAD deflections that did not possess specific distinguishing characteristics of those produced by olfactory stimulants eluting from the GC. Our goal was to design a function whose value (ψ) was large and positive when an olfaction-generated signal occurred at retention time t, and small or negative otherwise.

The first algorithm was the *Peak Height method*. The amplitude of negative EAD deflections from the baseline was measured at time t. This algorithm formalized the process ostensibly used by EAD operators during visual evaluation of graphic EAD output, namely, locating negative deflections in zeroed data that stand out appreciably from the background noise:

$$\psi_{P(t)} = b_t - s_t, \tag{4}$$

The second algorithm was the *Additive method.* In addition to the initial downward deflection of the EAD output, a second positive deflection is generated by the zeroing filter (Eq. 1) when the raw data stream contains a negative-deflecting Gaussian peak of a wavelength similar to the GC peaks. The amplitude of this positive deflection will equal approximately that of the negative deflection when the EAD response possesses the same wavelength (i.e., peak-width) as a GC-generated stimulus (i.e., an FID peak), when r of the zeroing algorithm is set to $0.8w^{0.05}$. Hence, for EAD signals generated by GC-eluting stimuli, that is, "true" olfactory responses, the sum of the amplitudes of a negative deflection occurring at time t and a corresponding positive deflection occurring at time $t+w$ will have a value that exceeds that produced by random background noise comprised of random frequencies:

$$\psi_{A(t)} = (b_t - s_t) + (s_{t+w} - b_{t+w}). \tag{5}$$

This algorithm tends to filter out EAD deflections with either low amplitude and/or inappropriate wavelength, and therefore, was hypothesized to be more accurate at

discriminating signal from noise than the "Peak Height" algorithm (Eq. 4) which discriminated signals by using amplitude alone.

Finally, in the *Minimum method*, we recorded the smallest of the negative and positive deflections of the zero-filtered EAD data stream at the wavelength expected from an olfaction-generated peak as the value of the function:

$$\psi_{M(t)} = \min\left[(b_t - s_t), (s_{t+w} - b_{t+w})\right]. \tag{6}$$

This method discriminated specifically against EAD deflections in the zeroed data where the negative deflection at time t and positive deflection at $t+w$ differed substantially from each other in amplitude: higher function values are generated for peaks with both the symmetry of a Gaussian peak *and* appropriate wavelength. Because this algorithm discriminated peaks based on three diagnostic qualities of olfaction-generated EAD signals (i.e., peak amplitude, wavelength, and symmetry), we hypothesized that this algorithm might result in greater rejection of noise than the two previously described.

Noise Characterization In the absence of compounds eluting from the GC, EAD output had a continuous and predictable noise pattern. The distribution of noise around the baseline was normally distributed. In addition, we found that the individual points had a high degree of positive serial correlation, with first degree correlations typically above 0.8 (Slone and Sullivan, unpublished data). Serial correlation in the data peaks would invalidate traditional statistical techniques by violating the assumption of independence.

Signal and Noise Measurement We defined a "peak" as any location where the following was true:

$$\psi_t = \max\left(\psi_{t-2}, \psi_{t-1}, \psi_t, \psi_{t+1}, \psi_{t+2}\right). \tag{7}$$

By using only the peaks, we reduced the amount of points to process and eliminated the ~0.8 first-order serial correlation present in EAD data (Slone and Sullivan, unpublished data). These peak values were normally distributed around their mean, which allowed us to use conventional statistical techniques.

To categorize each peak as either signal or noise, we first identified sections of the processed EAD run (ψ) where elution of olfactory stimuli from the GC could not have occurred. These sections included retention times both before the solvent peak eluted from the column (but after the initial antenna noise had abated) and after all analytes had eluted at the end of the GC temperature program. We then calculated the mean (μ_n) and standard deviation (σ) of all positive peaks within those sections as an estimate of baseline noise inherent in the entire EAD trace.

Next, a cutoff amplitude was selected to separate true signal peaks above the cutoff from noise peaks below the cutoff. This amplitude was set through a combination of the noise distribution and the desired probability of committing a type I (false identification of noise as signal) error. The experimentwise error probability (α_E; typically 0.05) depended upon the number of peaks in the data set and the probability that any single peak might trigger a type I error (comparisonwise error, α_c). The α_E and α_c values are related by the following equation, functionally similar to the Bonferroni correction (Jones 1984):

$$\alpha_c = 1 - (1 - \alpha_E)^{1/n}, \tag{8}$$

where n is the total number of peaks in the portion of the data stream that is being tested. The cutoff amplitude was calculated by finding the value of the z statistic that satisfied the

following equation of the normal distribution populated with the calculated values of α_c and σ. (e.g., Mendenhall et al. 1990):

$$\alpha_c = \int_{y=z}^{\infty} \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\left(\frac{1}{2\sigma^2}\right)y^2\right], \tag{9}$$

and adding that value to the mean noise level (μ_n). Any peak that had a value greater than (μ_n+z) was categorized as a signal, and all others were rejected as noise.

Performance Testing: Simulation We evaluated the sensitivity and noise-rejection capacity of the algorithms by applying them to simulated EAD data sets that contained a specified amplitude of random background noise and either a simulated olfaction signal (a normally distributed deflection of known amplitude and a width at half-height of w), a spurious, short-duration deflection event (spike), also of known amplitude, or an instantaneous baseline-shift of known amplitude (see Fig. 1). For each simulation, t_{max}=3,000, with 1,000 samples containing only background noise (used for measuring μ and σ of the noise) and 2,000 samples containing background noise plus the simulated signal/spurious event, and each simulation was replicated 20 times The specific tests we performed were as follows:

1. Twenty well-spaced simulated olfaction signals with background noise repeated at several signal/noise ratios
2. Positive and negative simulated spurious spikes randomly generated at a probability of 0.0125 per time step (~25 spikes per run; these spikes were randomly generated to allow for any effects from varied spacing and positive–negative spike interactions). These runs were also repeated with the spikes occurring over a range of amplitudes.
3. Instantaneous positive and negative baseline shifts, randomly generated at a probability of 0.0125 (~25 shifts per run; the shifts were randomly generated for reasons described in 2 above).

Performance Testing: Real Data We applied the algorithms to real data sets and compared their performance. First, we examined EAD runs from *R. frustrana*, *D. frontalis*, and *R. xylophagorum* and then compared FID and EAD traces at retention times where the different algorithms indicated antennal signals.

Second, we applied the algorithms to noisy EAD runs of *D. frontalis* females exposed to analyzed extracts of hindguts of *D. frontalis* males. Eleven electrophysiologically active molecules had been previously identified for this combination of insect and test extract (Sullivan 2005). We processed 17 individual EAD runs using experimental error rates (α_E) from a conservative 2.7e-6 to a liberal 0.9999. For each run, we calculated the baseline noise level and cutoff amplitude using EAD output after the solvent peak, but before the first FID-detectable sample peak eluted from the GC, and again after no further peaks were detected by the FID. We noted the number of signals detected by each algorithm that matched the retention times of the 11 known active molecules and also any signals detected at other retention times. Similarly, we performed 17 replicates with each algorithm where the digital EAD output from two runs selected at random from the 17 *D. frontalis*/hindgut runs were averaged, then 17 replicates of four runs averaged, 17 replicates of eight runs averaged, and finally one replicate of all 17 runs averaged. These runs were all processed with experimental error rates (α_E) of 0.05. This method of averaging multiple EAD runs

from different antennae to improve the signal-to-noise ratio was previously used by Sullivan (2005).

Results and Discussion

Simulation Testing Tests of the three algorithms that used simulated EAD runs revealed the strengths and weaknesses of each, with highly significant performance differences ($P<<0.05$) found among the algorithms in all tests. The Peak Height method was always inferior in finding signals to the other two methods, and the Additive method was significantly better than the Minimum method (Fig. 3). In terms of noise rejection, the Peak Height method was also inferior to the other two methods in cases where the spike amplitude was less than eight times, or the baseline shift amplitude was less than three times, the maximum background noise amplitude (99th percentile of all noise peaks). With very large spikes or baseline shifts, the Additive method rejected less noise than the other methods. The superior method for noise rejection was clearly the Minimum method, which rejected large spikes and baseline shifts five to ten times better than the other methods.

The simulation testing was deliberately designed to highlight marginal cases where olfaction-generated signals were competing with large amounts of background noise. For EAD runs where the amplitude of olfaction-produced deflections stands well beyond the background (i.e., those performed with especially good antennal preparations and more-than-adequate concentrations of stimulants in the test sample), most signals would be easily discerned by any of the algorithms or by eye. However, there are often cases where the amplitudes of some or all of the signals are small, or the number of spurious deflection events in the run are large, and in these situations, the Additive or Minimum methods should provide EAD operators with a powerful tool for improving their ability to discriminate noise from signal. If the operator's goal is to identify all possible signals in a run with the possibility of encountering some false positives, then the Additive method is preferable. If the goal is to minimize errors, then the Minimum method is superior. The discriminatory power of the algorithms can be enhanced several-fold if applied to data from

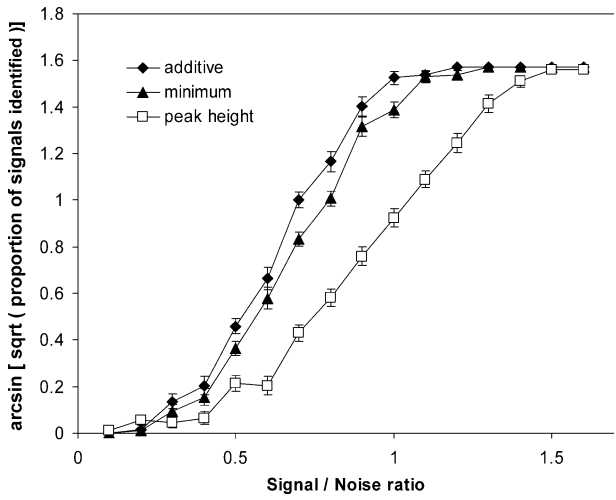

Fig. 3 The proportion of simulated signals that each of the algorithms discriminated is shown as the mean of 20 replications plus standard deviation error bars at each of several signal to noise ratios. An arcsin (sqrt) transformation was used to linearize the proportional results. For S/N ratios <1.5, the Additive method was slightly superior to the Minimum method, and both were far better at discriminating the simulated signals than the Peak Height method. For S/N ratios ≥1.5, all methods discriminated all signals

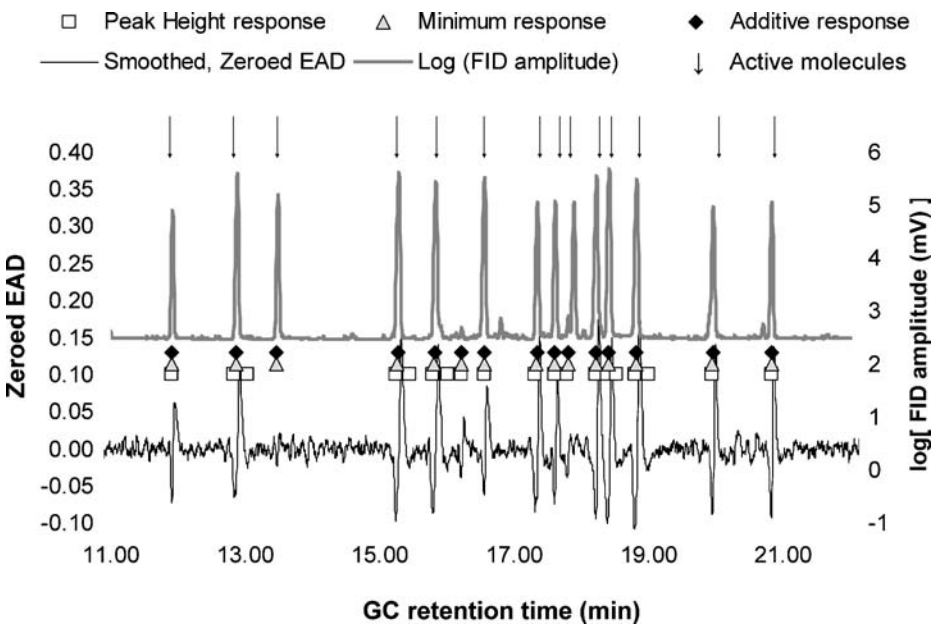

Fig. 4 Zeroed EAD recording of the parasitic wasp *Roptrocerus xylophagorum* (Hymenoptera: Pteromalidae) and the associated GC trace from a mix of host and associated plant odors. The locations of previously determined active molecules (*arrow*) and significant responses (Additive, *diamond*; Minimum, *triangle*; Peak Height, *square*; α_E=0.05) from the three algorithms are shown

multiple GC-EAD runs (replications) because the likelihood that a "false" signal will be registered at the same retention time will become vanishingly small with additional replication. Statistical tests can also be performed on the frequency that signals are detected at a particular retention time to further reject spurious signals and accept only the retention times of active compounds; signals should occur with a greater frequency than predicted by random chance at the retention times of active molecules (Zhang et al. 2001; Zhang and Aldrich 2003; Asaro et al. 2004). The chief contribution of these two algorithms to interpretation of EAD runs is the increase of the effective signal/noise ratio in the data, an improvement which reduces the number of EAD runs necessary for a researcher to accurately discern electrophysiologically active compounds.

Real Data Testing All three algorithms successfully discriminated antennal signals from noise in EAD data from the three orders of insects examined. In an EAD recording of the parasitic wasp *R. xylophagorum* responding to a mix of host and associated plant odors, the Additive and Minimum methods correctly "tagged" all of the active compounds [i.e., compounds whose activity with olfactory sensillae had been demonstrated by statistical analysis of multiple EAD runs (Pettersson et al. 2000; Sullivan, unpublished) in the mixture (Fig. 4)]. The Peak Height method failed to detect one active compound and returned five apparent false positives at the tail end of active compounds. All methods identified a compound at 16.21 min that has not previously been demonstrated as an active molecule. In a rather noisy EAD recording of the southern pine beetle, *D. frontalis*, subjected to the same mix of odors as *R. xylophagorum* above (Sullivan, unpublished), all three methods identified signals at all three retention times of compounds with demonstrated olfactory and/or behavioral activity with this beetle (Fig. 5). Additionally, all three methods identified

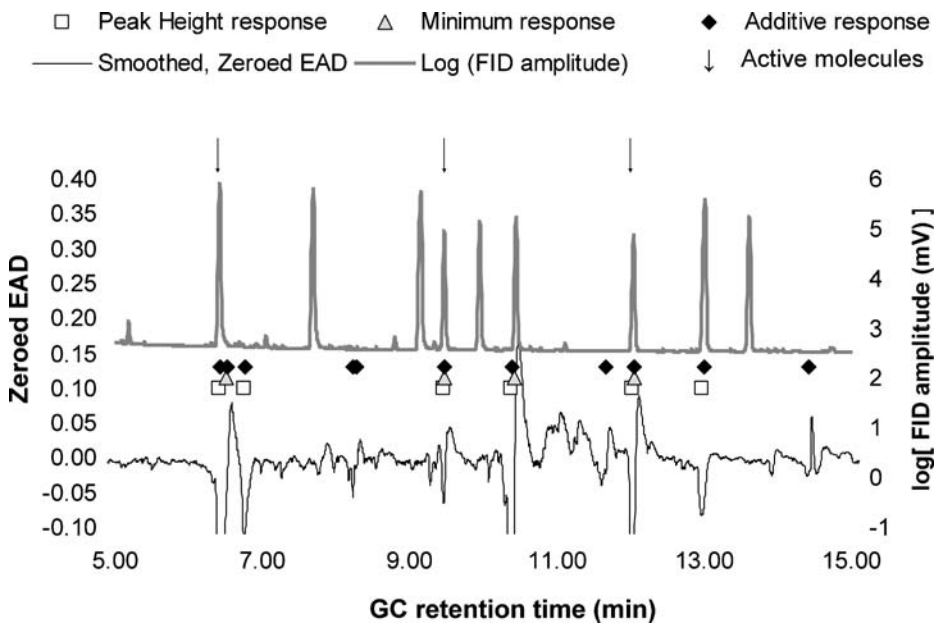

Fig. 5 Zeroed EAD recording of the southern pine beetle, *Dendroctonus frontalis* (Coleoptera: Curculionidae) subjected to the same mix of odors as *R. xylophagorum* in Fig. 6. The locations of previously determined active molecules (*arrow*) and significant responses (Additive, *diamond*; Minimum, *triangle*; Peak Height, *square*; α_E=0.05) from the three algorithms are shown

a rather large peak at approximately 10.50 min associated with the elution of *p*-cymene, although this has not previously been demonstrated to be an olfactory stimulant. While the Minimum method returned no additional positives, the Additive method detected seven additional active retention times that were apparently false positives, and the Peak Height method returned two additional false positives. In an EAD recording of a female Nantucket pine tip moth (*R. frustrana*) exposed to a mixture of host-associated odors (Asaro et al. 2004), all three algorithms correctly identified signals at retention times of seven known olfactory stimulants in the mixture (Fig. 6). The Additive method also detected one additional active molecule at 15.70 min that has not been identified previously as an olfactory stimulant for this insect, and it returned an additional two false positives. The Peak Height and Minimum methods failed to detect two known active molecules, and the Peak Height method returned a single false positive. All algorithms also identified one FID peak at approximately 16.50 min that had not been shown previously to be an active compound.

The replicated EAD runs from *D. frontalis* females that responded to male *D. frontalis* hindgut extract were relatively noisy. In general, approximately half of the retention times associated with electrophysiologically active compounds were identified at α_E=0.05, but with clear differences in performance among the algorithms (Fig. 7). The Additive method consistently identified more "true" signals than the other two algorithms at any α_E level, yet tagged fewer erroneous retention times than the Peak Height method. The Minimum method identified fewer signals than the other methods, but showed greater error-rejecting capability by not tagging any retention times incorrectly at α_E levels$\leq$0.05.

Although the Minimum method had superior error-rejection capacity, the Additive method showed the best overall power by consistently producing the fewest false

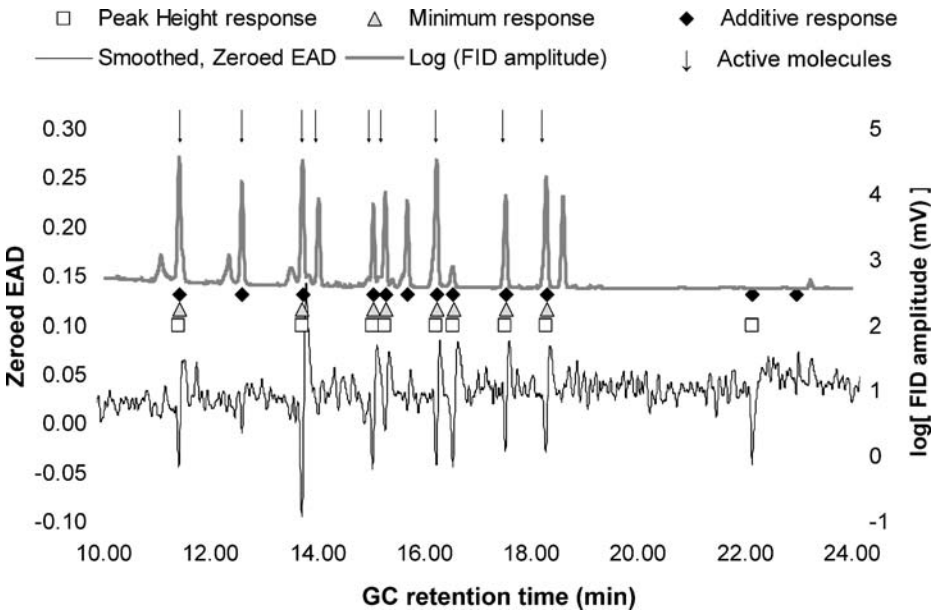

Fig. 6 Zeroed EAD recording of a female Nantucket pine tip moth, *Rhyacionia frustrana* (Lepidoptera: Tortricidae) and the associated GC trace from a mixture of host-associated odors. The locations of previously determined active molecules (*arrow*) and significant responses (Additive, *diamond*; Minimum, *triangle*; Peak Height, *square*; α_E=0.05) from the three algorithms are shown

classifications per correct classification (Fig. 8). The Minimum method had medium overall power, and the Peak Height method had the lowest power with real data sets, returning the highest number of false positives per true response. Algorithm traces for the Additive method also consistently had higher average signal/noise ratios than output from the other algorithms (Fig. 9). Additionally, the Additive method recognized more true olfaction-generated signals than is apparently possible by visually comparing peak heights in EAD

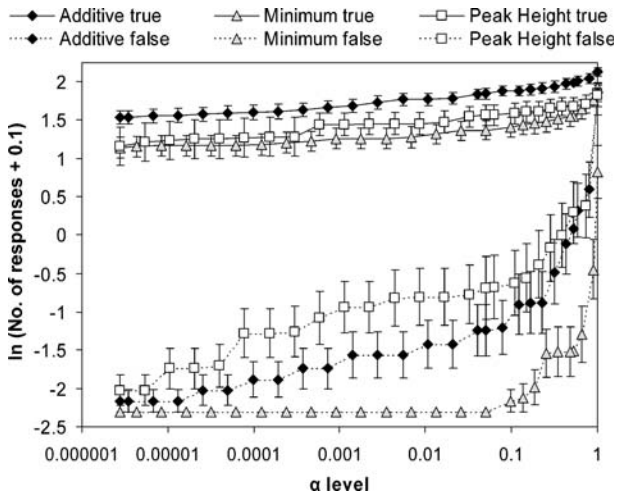

Fig. 7 Average number of true and false significant responses (±1 SD) from 17 southern pine beetle EAD runs produced by each algorithm using a range of experimental error rates (α_E). The numbers of signals found were log(x+0.1)-transformed before averaging to normalize the variances

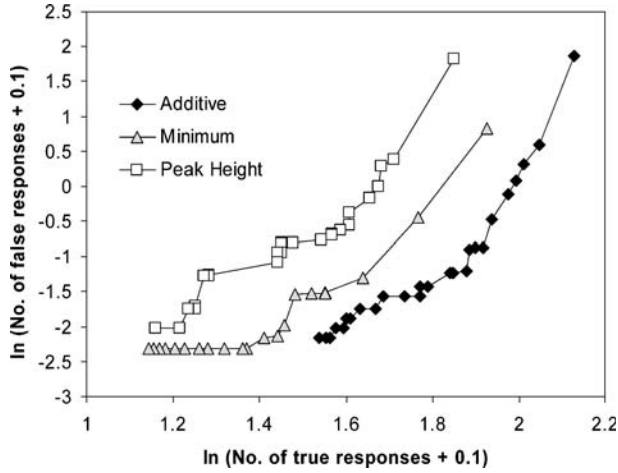

Fig. 8 True vs. false significant responses returned from each algorithm for southern pine beetle EAD runs. Each point shown represents the average of 17 runs evaluated at a different α_E level, ranging from 2.7e-6 (*farthest left*) to 0.9999 (*farthest right*). Points lower and further to the *right* indicate superior performance

traces, as this latter procedure was ostensibly duplicated by the Peak Height algorithm. Thus, our data demonstrate that the Additive algorithm was an effective "amplifier" of olfaction-generated responses in insect-produced EAD traces.

Our analyses of averaged data from randomly selected combinations of EAD replicates showed that greater signal-resolving power and improved noise rejection occurred when the algorithms were applied to averaged data from progressively greater numbers of runs

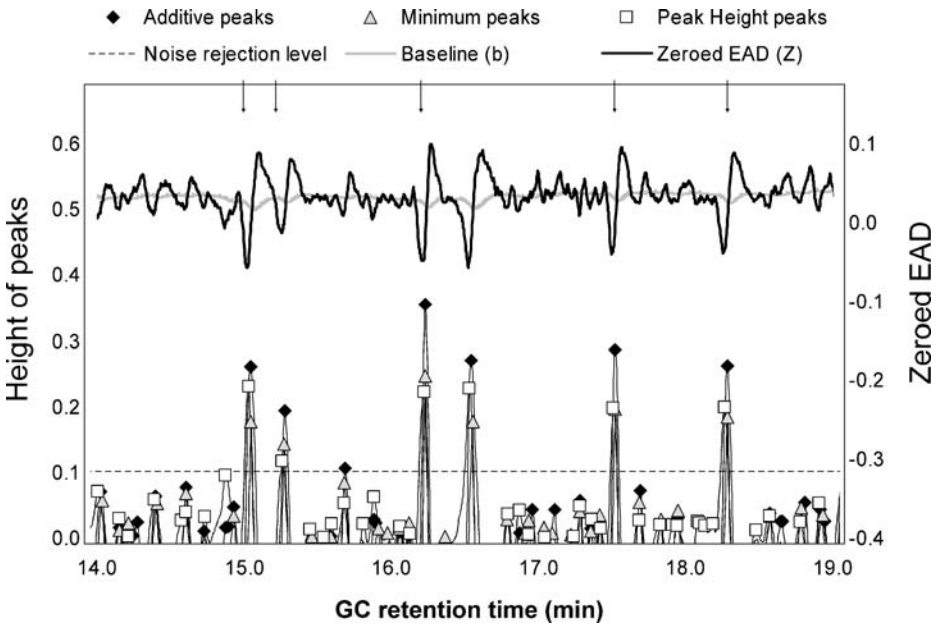

Fig. 9 Output traces (ψ) from each of the algorithms are shown below a section of EAD output from Fig. 6, a female Nantucket pine tip moth, *Rhyacionia frustrana* (Lepidoptera: Tortricidae) responding to a mix of host-associated odors. The output from each method has been standardized so that the mean of the trace is 0, and the noise rejection limit is 0.1. The Additive method amplified EAD olfaction peaks relative to noise peaks more than the Minimum or Peak Height methods

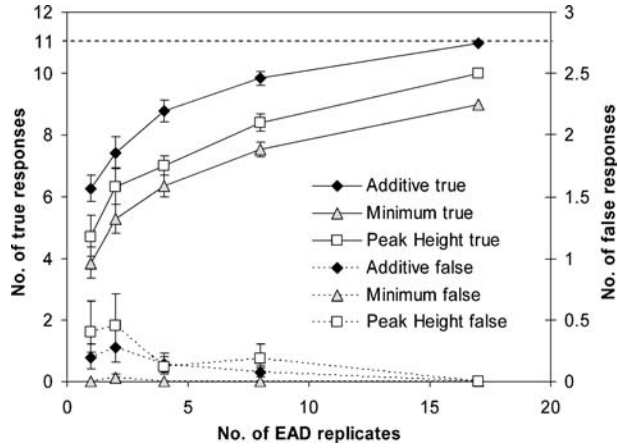

Fig. 10 Results from southern pine beetle EAD run averaging showing increasing numbers of true responses and decreasing numbers of false responses when more runs were averaged. With all 17 runs averaged, the Additive method found all 11 active molecules with no errors. Data were log(x+0.1)-transformed for analysis and back-transformed for display. Note that the true and false responses are displayed on different scales for clarity

(Fig. 10). With α_E=0.05, the Additive method consistently identified the greatest number of retention times associated with active compounds while committing a modest number of errors, and it was the only method to tag the retention times of all 11 active molecules when all 17 runs were averaged. When four or more runs were averaged, the Additive method also consistently identified a location at 22.75 min corresponding to an unknown singly oxygenated monoterpene. Because this was an unknown compound with uncertain biological activity, it was excluded from the analysis and was not counted as either correct or incorrect. The Peak Height method identified a moderate number of active retention times, but it also had the highest number of apparent false positives. The Minimum method identified the fewest signals, but it generally had no false positives. Because the EAD traces of southern pine beetle responding to hindgut extracts were generally noisy, several replicated analyses of averaged run sets were necessary to resolve all 11 active molecules. Nonetheless, the analysis in Fig. 10 demonstrates that both the Minimum algorithm and, to a greater extent, the Additive algorithm can reduce the number of EAD runs necessary for discerning electrophysiologically active compounds.

Applications Our Additive algorithm represents a powerful tool that can be used to enhance the realized signal-to-noise ratio of any GC-EAD system that stores its data digitally. Raw data can be copied into a spreadsheet program, transformed, and then examined using the graphics capabilities of the spreadsheet. We created an Excel 2000 spreadsheet that contains all of the required transformations and calculations. The user pastes raw or pre-zeroed EAD data into a column, selects areas of the data with no eluting molecules to calibrate the noise level, and enters other information about the data collection methodology. Charts on the spreadsheet display the traces and indicate significant impulses found by each of the three methods. This spreadsheet is available as electronic supplementary material (doi:10.1007/s10886-007-9338-6).

In summary, with a novel insect or compound, the optimal use of GC-EAD data for identifying olfactory stimulants is of great importance, as an incorrect identification of a stimulant could lead a researcher seeking behavior-modifying compounds to waste effort on an inactive compound; in contrast, failure to recognize evidence of olfactory stimulation could cause an important behavioral molecule to be overlooked. For antennal preparations of some insect species, the maximum signal level obtainable may be at or below the

background noise level (for example, see Russell et al. 2004). As our Additive and Minimum method algorithms have the capacity for extracting signals that are similar in amplitude to surrounding noise, they should effectively increase the sensitivity of an EAD system and may allow data collection where it would not otherwise have been possible. Additionally, our algorithms and data analysis procedures eliminate the potential for experimenter bias that is inherent in visual evaluation of data sets because the decision of whether a deflection event is a "real" signal or not is made by a uniformly applied mathematical test. By combining these algorithms with replication, high levels of power and discrimination for detecting active molecules in EAD data are provided.

Acknowledgments The bulk of this work was completed at the USDA Forest Service Forest Insect Research facility while the first author was employed there. The authors thank two anonymous reviewers for their thoughtful comments.

geometric isomers of the 2,13-dienal revealed specific attraction to a lure with the (2*E*,13*Z*)-isomer as a main component.

Keywords Sex pheromone · Octadecadienal · Reversed-phased HPLC · APCI-LC-MS analysis · 2,4-Dinitrophenylhydrazone · Lepidoptera · Sesiidae · *Macroscelesia japona*

Introduction

Moths in the family Sesiidae have clear wings and a wasp-mimetic body. Although most of the clearwing moths are diurnal and possibly communicate with visual cues, the females produce a species-specific sex pheromone that attracts males. It is well known that sesiid pheromones are mainly composed of 2,13- and 3,13-octadecadien-1-ols and their acetates (Ando et al. 2004; Ando 2007; El-Sayed 2007). In addition, recent studies have reported 2,13-octadecadienal as a component of sesiid pheromones. For example, Francke et al. (2004) identified the (2*E*,13*Z*)-isomer from *Sesia apiformis*, and we identified the same compound from *Macroscelesia japona* and *M. longipes* (Naka et al. 2007). These structure determinations, however, were reported without any information as to other geometric isomers of the 2,13-dienal. GC-MS analyses of the pheromone extracts were carried out by using only one synthetic compound with the 2*E*,13*Z* configuration as an authentic standard, and chromatographic behaviors of the other geometric isomers have not been reported. Activities of the isomers have never been evaluated in the laboratory or in the field. Studies with all geometric isomers of the 2,13-dienal are necessary to confirm the identification. Furthermore, the Sesiidae includes more than 1,000 species worldwide (Pühringer and Kallies 2004). The diversity of the insects suggests that another possible pheromone component, 3,13-octadecadienal, also might be found in the Sesiidae. Therefore, we synthesized all geometric isomers of the 2,13- and 3,13-dienals and characterized them. Because most isomers of the dienals were unstable to GC conditions, HPLC and LC-MS analyses were used instead. We also reexamined a pheromone extract of *M. japona* to confirm our previous identification. The results of this paper should be useful for unraveling other pheromone systems in the Sesiidae.

Materials and Methods

Instruments ^{1}H and ^{13}C NMR spectra were recorded with a Jeol Alpha 500 spectrometer at 500.2 and 125.7 MHz, respectively, with $CDCl_3$ solutions containing TMS as an internal standard. GC analyses were carried out on an HP-5890 Series II gas chromatograph (Hewlett-Packard, Wilmington, DE, USA) equipped with a flame ionization detector (FID) and a DB-23 column (0.25 mm ID×30 m, 0.25 μm film, J & W Scientific, Folsom, CA, USA). The column temperature program was 50°C for 2 min, 10°C/min to 160°C, then 4°C/min to 260°C. Samples were injected via a cool on-column injector heated at oven temperature plus 3°C after holding at 53°C. The carrier gas was He. GC-MS was conducted in EI mode (70 eV) with an HP5973 mass spectrometer system (Hewlett-Packard) equipped with the same DB-23 column as the GC analysis and a split/splitless injector. The carrier gas was He, and the ion source temperature was 230°C. HPLC analyses were made with a Jasco PU-980 liquid chromatograph equipped with an integrator (System Instrument Chromatocorder 21J), a UV detector (Jasco UV-970, 235 or 210 nm), and an ODS column (Senshu Pak PEGASIL ODS-II, 2.0 mm ID×25 cm; Senshu-kagaku, Tokyo, Japan). As the

eluent, 16 % H_2O in acetonitrile was used at a flow rate of 0.2 ml/min. LC-MS was conducted with a Shimadzu LCMS-2010 equipped with an atmospheric pressure chemical ionization (APCI) interface and the same ODS column and eluent as for the HPLC analysis. The mass spectra were recorded in negative ion mode, and the following parameters were used: APCI temperature (400°C), CDL temperature (250°C), and nebulizer gas flow rate (2.5 l/min).

Chemicals The chemical structures of the 2,13- and 3,13-dienyl compounds are abbreviated as follows: Z=(*Z*)-double bond, E=(*E*)-double bond, number before the hyphen=position of the double bond, number after the hyphen=carbon number of the straight chain, Ald=aldehyde, and OH=alcohol. All geometric isomers of octadecadienals were prepared from the corresponding alcohols, which had been synthesized in our previous study (Naka et al. 2006), by the following oxidation.

Oxidation of Octadecadien-1-ols with (E)-2-Double Bond E2,Z13-18:OH (300 mg, 1.1 mmol) in CH_2Cl_2 (10 ml) was mixed with pyridinium chlorochromate (PCC, 300 mg) and stirred 4 h at room temperature. After addition of hexane (30 ml), precipitates were removed by filtration, and the filtrate was concentrated. The residue was taken up in hexane (30 ml), and insoluble precipitates were filtered off. After evaporation of hexane in vacuo, the residue was chromatographed on silica gel to give E2,Z13-18:Ald (190 mg, 63 %). By the same procedure, E2,E13-18:Ald was obtained from E2,E13-18:OH.

Dess-Martin Oxidation of Other Octadecadien-1-ols Z2,Z13-18:OH (100 mg, 0.38 mmol) in CH_2Cl_2 (1 ml) was added to a solution of Dess-Martin periodinane (Dess and Martin 1991; 500 mg, 1.2 mmol) in CH_2Cl_2 (4 ml) at room temperature. After stirring for 3 h, the mixture was diluted with ether (20 ml), and the resulting mixture was poured into saturated aqueous $NaHCO_3$. The organic layer was separated, washed with water, dried over Na_2SO_4, concentrated in vacuo, and purified by column chromatography with silica gel to give Z2,Z13-18:Ald (75 mg, 75%). By the same procedure, Z2,E13-18:Ald and the four geometric isomers of 3,13-octadecadienal were obtained from the corresponding alcohols. NMR analyses of Z2,Z13-18:Ald and Z2,E13-18:Ald (see Tables 1 and 2) showed trace contamination (~3%) from the corresponding aldehyde with the (*E*)-2-double bond, indicating slight isomerization of the (*Z*)-2-double bond. In the case of the 3,13-octadecadienal, isomerization of the (*Z*)-3- and (*E*)-3-double bonds was barely detectable by NMR analysis.

Derivatization of Octadecadienals with 2,4-Dinitrophenylhydrazine Each isomer (10 μg) of the dienals was separately coated in a glass vial (2 ml) and treated with 2,4-dinitrophenylhydrazine (1 mg) in H_2O (200 μl) at room temperature. After 1 h, the resulting hydrazone derivative was extracted with hexane (400 μl×3). After removal of the hexane, the residue was dissolved in acetonitrile and analyzed by LC-MS. The derivatization was also carried out for a mixture of four geometric isomers (50 ng each) of the 2,13-dienal or 3,13-dienal with a small amount of hydrazine in a similar manner.

Insects and Pheromone Extraction Ten larvae of *Macroscelesia japona* were collected in November in Maibara City, Shiga Prefecture, and kept in a refrigerator at 8±1°C without light for 2 months. They were then placed in a plastic cage at 25±1°C under a 15L:9D photoperiod until emergence as adults (Naka et al. 2007). Abdominal tips of the females that adopted a calling position were excised and extracted with hexane for 15 min.

Field Tests The synthetic lures were tested in two field trials: Takatsuki City (Osaka, Japan) from June 14 to July 8, 2006, and Tsukuba City (Ibaraki Prefecture, Japan) from June 15 to July 1, 2006. A rubber septum (white rubber, 8 mm OD, Sigma-Aldrich, St. Louis, MO, USA) was used as a dispenser of the synthetic lure and placed in the center of a sticky board trap (30×27 cm bottom plate with a cover, Takeda Chemical Ind., Osaka), which was set 1.5 m above the ground.

Results

Synthesis and Structure Confirmation of Dienals E2,Z13-18:Ald and E2,E13-18:Ald were easily synthesized by PCC oxidation of the corresponding alcohols, E2,Z13-18:OH and E2, E13-18:OH. Because the same oxidation of other geometric isomers of 2,13-octadecadien-1-ol and all isomers of 3,13-octadecadien-1-ol did not yield the required aldehydes at all, we examined Dess-Martin oxidation with a periodinate [1,1,1-tris(acetyloxy)-1,1-dihydro-1,2-benziodoxol-3(1*H*)-one] (Dess and Martin 1983, 1991). This reagent had been used in the successful oxidation of alkenols with a double bond in the 2- or 3-position (Schwarz et al. 1986), and we confirmed its efficacy for the oxidation of the 2,13- and 3,13-dienols.

Table 1 shows the ^{1}H NMR data of all geometric isomers of 2,13- and 3,13-dienals, which were synthesized without isomerization of the double bond. The 2,13-dienal could be readily distinguished from the 3,13-dienal by the splitting pattern of the aldehyde proton (1-H). The signal of the 2,13-dienal was a doublet, and that of the 3,13-dienal was a triplet. Additionally,

[a] $J_{1\text{-}2}$

[b] $J_{2\text{-}3}$

[c] $J_{3\text{-}4}$

[d] NMR data of the olefinic and allylic protons from 12- to 15-positions and terminal methyl protons at the 18-position were almost the same as those of the corresponding 2,13-18:Ald

the 2,13-dienal showed two allylic methylene protons (4-H_2) at δ 2.3-2.6 ppm, whereas the 3,13-dienal showed two allylic methylene protons (2-H_2) at δ 3.1-3.2 ppm, at lower field because of the proximity to the carbonyl group. Because chemical shifts of the olefinic protons at the 2- and 3-positions of the 2,13-dienal and at 3- and 4-positions of the 3,13-dienal were different from those at the 13- and 14-positions, the splitting patterns were readily interpretable to indicate configuration of the double bonds at the 2- and 3-positions. Coupling constants between the two olefinic protons of the (*Z*)- and (*E*)-double bonds were ~15.5 and ~11 Hz, respectively. ^{13}C NMR data were also informative in confirming the structures of the synthetic dienals, because many signals were recorded without overlapping (Table 2). The 2,13-dienal was distinguished from the 3,13-dienal by its characteristic allylic carbon (2-C) at δ 43-47 ppm. Because the resonance of the carbonyl carbon (1-C) was affected by conjugation, the positional isomers could be differentiated by comparing the chemical shifts of 1-C. In addition, the chemical shift of each olefinic and allylic carbon at the (*Z*)-double bonds was upfield from that of the corresponding carbon at the (*E*)-double bonds without exception, clearly indicating the geometric configuration of each isomer.

GC Analysis of the Synthetic Dienals The four geometric isomers of each dienal, whose structures and purities had been confirmed by NMR, were analyzed by GC on a DB-23

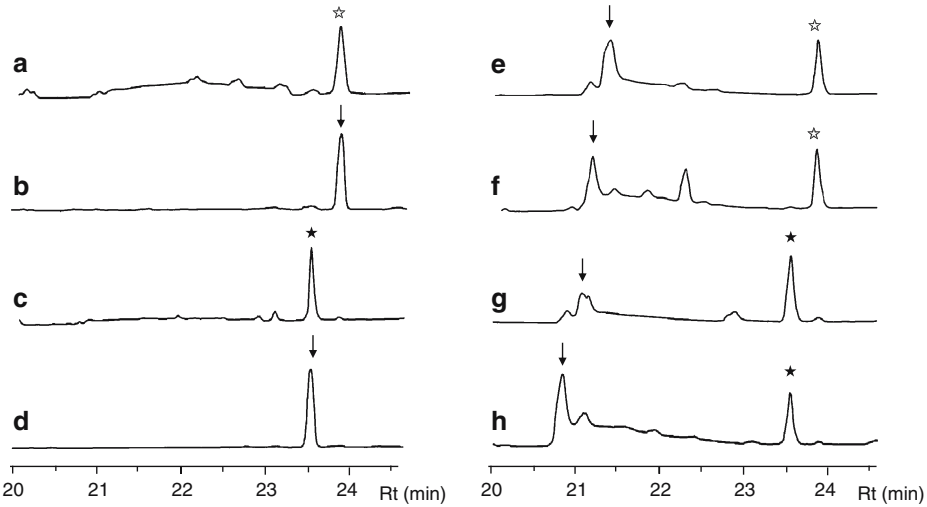

Fig. 1 GC analysis of synthetic 2,13- and 3,13-octadecadienals (20 ng each) on a DB-23 column (0.25 mm ID×30 m) with cool on-column injection; **a** Z2,Z13-18:Ald, **b** E2,Z13-18:Ald, **c** Z2,E13-18:Ald, **d** E2,E13-18:Ald, **e** Z3,Z13-18:Ald, **f** E3,Z13-18:Ald, **g** Z3,E13-18:Ald, and **h** E3,E13-18:Ald. The *arrows* show the compounds that were expected to be detected without any isomerization of the double bonds, and the identifiable isomerized products are indicated by *open stars* (E2,Z13-18:Ald) and *filled stars* (E2,E13-18:Ald)

capillary column with cool on-column injection. The FID chromatograms are shown in Fig. 1, and tentatively assigned retention times (R_ts) are listed in Table 3. On a polar column, an aldehyde usually elutes faster than the corresponding alcohol and acetate. However, R_t of E2,Z13-18:Ald was longer than R_ts of E2,Z13:OH and E2,Z13:OAc (see footnote in Table 3) because of the conjugation of the aldehyde. In this analysis, the observed R_ts of Z2,Z13-18:Ald and E2,Z13-18:Ald were the same (Fig. 1a and b), and those of Z2,E13-18:Ald and E2,E13-18:Ald were also the same (Fig. 1c and d) indicating complete conversion of the (*Z*)-2-double bond into the (*E*)-2-double bond under the GC conditions used. In the case of the 3,13-dienal, each geometric isomer showed a complex chromatogram (Fig. 1e–h). Z3,Z13-18:Ald and E3,Z13-18:Ald produced a recognizable peak at the R_t of E2,Z13-18:Ald (23.86 min), and Z3,E13-18:Ald and E3,E13-18:Ald produced a peak at the R_t of E2,E13-18:Ald (23.53 min), indicating the partial isomerization of the (*Z*)-3- and (*E*)-3-double bonds into the (*E*)-2-double bond. In addition to the peak with the long R_t, each geometric isomer of the 3,13-dienal showed some broad peaks with shorter R_ts (21-22 min) indicating complicated isomerization of the double bond at the 3-position. With reference to the R_ts of the corresponding alcohols and acetates (see footnote in Table 3), we assumed that the peaks indicated by arrows were four geometric isomers of the 3,13-dienal eluted from the GC column that had kept their original structures. If this is the case, the isomers of 3,13-dienal eluted in the order *EE* → *ZE* → *EZ* → *ZZ*. In the course of GC analysis with a split/splitless injector, the (*Z*)-3- and (*E*)-3-double bonds were completely isomerized to the (*E*)-2-double bond.

HPLC Analysis of the Dienals and LC-MS Analysis of Their Hydrazones The synthetic dienals were first analyzed by HPLC with an ODS column. The 2,13-dienal with a conjugated system was perceptible at a ng-level with a UV detector operated at 235 nm (Fig. 2a). Whereas E2,Z13-18:Ald and Z2,E13-18:Ald were not completely separated, a mixture of the four isomers showed four distinguishable peaks. The elution order was *ZZ* → *EZ* → *ZE* → *EE*.

Table 3 Chromatographic behaviors of synthetic 2,13- and 3,13-octadecadienals on GC and HPLC and of their 2,4-dinitrophenylhydrazone derivatives on LC-MS

		R_t (min)		
		Aldehyde		Hydrazone
		GC[a]	HPLC[b]	LC-MS[c]
2,13-Diene	(*Z,Z*)-isomer	23.89[d]	33.2	25.1
	(*E,Z*)-isomer	23.86	36.0	27.6
	(*Z,E*)-isomer	23.53[d]	36.8	26.9
	(*E,E*)-isomer	23.53	39.9	29.5
3,13-Diene	(*Z,Z*)-isomer	21.42[e]	31.6	21.4
	(*E,Z*)-isomer	21.15[e]	33.7	22.8
	(*Z,E*)-isomer	21.08[e]	34.5	22.8
	(*E,E*)-isomer	20.86[e]	36.7	24.4

[a] Retention times (R_ts) on a DB-23 column (0.25 mm ID×30 m, 0.25 μm) using a cool on-column injector. Column temperature: 50°C for 2 min, 10°C/min to 160°C, and 4°C/min to 230°C. R_ts (min) of some corresponding alcohols and acetates were as follows: E2,Z13-18:OH 22.29 , E2,Z13-18:OAc 21.82, E3,Z13-18:OH 21.61, E3,Z13-18:OAc 21.37

[b] R_ts on a ODS column (2.0 mm ID×25 cm). Eluent: 16 % water in acetonitrile. Flow rate: 0.2 ml/min. Detection: UV 235 nm for 2,13-dienal and 210 nm for 3,13-dienal. λ_{max} of four geometric isomers of 2,13-dienal were as follows: Z2,Z13-18:Ald 229 nm, E2,Z13-18:Ald 222 nm, Z2,E13-18:Ald 227 nm, and E2,E13-18:Ald 223 nm

[c] R_ts on an ODS column (2.0 mm ID×25 cm). Eluent: 8% water in acetonitrile. Flow rate: 0.2 ml/min. APCI detected a negative ion at *m/z* 443 ($[M-1]^-$ of hydrazones derived from the aldehydes) in selected ion monitoring mode

[d] Completely isomerized to E2,Z13-18:Ald or E2,E13-18:Ald during GC analysis (see Fig. 1a–d)

[e] Peaks expected to be not isomerized. Samples were mainly isomerized to E2,Z13-18:Ald, E2,E13-18:Ald, and other unknown compounds under the GC conditions used (see Fig. 1e–h)

Although the 3,13-dienals were detected by UV at 210 nm (Fig. 2b), the sensitivity was low and the peaks were broad. The elution order of the four geometric isomers of the 3,13-dienal was the same as that of the 2,13-dienal. Each isomer of the 3,13-dienal eluted faster than the corresponding isomer of 2,13-dienal possessing the same configuration (Table 3). Next, these dienals were analyzed by LC/MS after derivatization with 2,4-dinitrophenylhydrazine using the same ODS column. Each derivative was sensitively detected by negative ion APCI. Fig. 2d and e shows the mass chromatograms monitoring $[M-1]^-$ at *m/z* 443 of the 2,13- and 3,13-dienals, respectively. The hydrazone of Z2,E13-18:Ald eluted faster than that of E2,Z13-18:Ald, and thus, the elution order of the 2,13-dienal derivatives was $ZZ \rightarrow ZE \rightarrow EZ \rightarrow EE$. Hydrazones of the 3,13-dienal exhibited a similar elution order, and the derivatives of E3,Z13-18:Ald and Z3,E13-18:Ald eluted at almost the same R_ts (Table 3). The chromatogram in Fig. 2d was recorded for a 1:1:1:1 mixture of four geometric isomers. However, the peak areas of the hydrazones of Z2,Z13-18:Ald and Z2,E13-18:Ald were smaller than the others owing to partial conversion of the (*Z*)-2-double bond into the (*E*)-2-double bond during derivatization. This derivatization was achieved with the hydrazine dissolved in distilled water at room temperature. The reaction with an acidic aqueous solution of the hydrazine, which was used as a general procedure for various aldehydes, caused easy conversion of the configuration. Further mild conditions for the hydrazone formation were examined, but cooling and dilution of the hydrazine solution did not affect the final ratio of the products. We could not find a set of conditions that prevented the isomerization completely. Isomerization

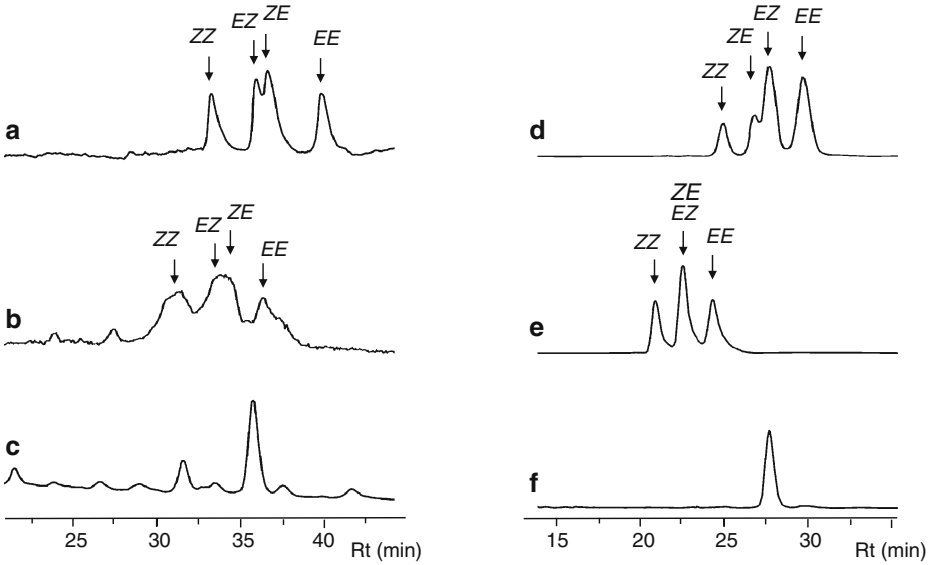

Fig. 2 HPLC analysis of octadecadienals (**a**–**c**, UV absorption) and LC-MS analysis of their 2,4-dinitrophenylhydrazone derivatives (**d**–**f**, mass chromatograms of $[M-1]^-$ at *m/z* 443); **a** a mixture of four geometric isomers of 2,13-octadecadienal (50 ng each, UV 235 nm), **b** a mixture of four geometric isomers of 3,13-octadecadienal (250 ng each, UV 210 nm), **c** a crude pheromone extract of *M. japona* (5 FE), **d** hydrazones derived from the four isomers of 2,13-octadecadienal (50 ng each), **e** hydrazones derived from the four isomers of 3,13-octadecadienal (50 ng each), and **f** a crude pheromone extract of *M. japona* (2.5 FE) treated with the hydrazine. Both analyses used the same column (ODS, 2.0 mm ID×25 cm), eluent (16% H_2O in acetonitrile), and flow rate (0.2 ml/min)

of the double bond at the 3-position to the (*E*)-2-double bond was also observed but was slight, as shown in Fig. 2e.

Reexamination of the Dienal Produced by M. japona Females Previous GC-MS analysis had indicated that a crude extract of abdominal tips from *M. japona* females included an octadecadienal and an octadecadien-1-ol in a ratio of 10:1 (Naka et al. 2007). To confirm the structure of the aldehyde component, a pheromone extract of five female equivalents (FE) was analyzed by HPLC with the ODS column that had been used for the analysis of authentic dienals, operated under the same conditions. As shown in Fig. 2c, the extract included a component with the same R_t as authentic E2,Z13-18:Ald (36.0 min) among other unknown compounds detected at UV 235 nm. Several fractions were recovered, and an aliquot of each fraction was analyzed by GC-MS. This analysis showed E2,Z13-18:Ald only in a fraction that included the component eluted at 36.0 min. The rest of the fraction was analyzed by LC-MS after treatment with 2,4-dinitrophenylhydrazine, and the hydrazone derivative of E2,Z13-18:Ald was detected. Furthermore, another extract (five FE) was directly treated with the hydrazine and then examined by LC-MS. As shown in Fig. 2f, the hydrazone of a dienal was detected at the same R_t as the derivative of E2,Z13-18:Ald (27.6 min) but not at the R_t of the 3,13-dienal. These experiments confirmed that E2,Z13-18:Ald detected by the previous GC-MS analysis was not an artifact from degradation of Z2,Z13-18:Ald or the 3,13-dienal.

Field Attraction of M. japona Males Whereas attraction of *M. japona* males with a lure baited with a 10:1 mixture of E2,Z13-18:Ald and E2,Z13-18:OH was found in our previous

Table 4 Attraction of *Macroscelesia japona* males to traps baited with a binary synthetic lure including 2,13-octadecadienal (2,13-18:Ald, major component) and 2,13-octadecadien-1-ol (2,13-18:OH, minor component)[a]

field tests (Naka et al. 2007), the activity of their geometric isomers had not been evaluated. Therefore, several mixtures combining the insect-produced isomers with other isomers were tested. Thus, E2,Z13-18:Ald (natural major component) was mixed with a geometric isomer of E2,Z13-18:OH as a minor component, and E2,Z13-18:OH (natural minor component) was mixed with a geometric isomer of E2,Z13-18:Ald as a major component. The results are shown in Table 4. The population density of the insects was not high in 2006, but the natural-type lure baited with E2,Z13-18:Ald and E2,Z13-18:OH attracted male moths. In addition to this combination, lures baited with E2,Z13-18:Ald and Z2,Z13-18:OH also attracted some moths. Lures baited with other combinations of aldehyde and alcohol were not attractive.

Discussion

Based on the experiments that used all four geometric isomers of 2,13- and 3,13-octadecadienals as authentic standards, we propose a procedure for the identification of an aldehyde component in pheromone extracts of sesiid moths. Because many lepidopteran sex pheromones are composed of multiple components with different functional groups, and because GC-MS generally detects alcohols and acetates with high sensitivity and without isomerization, a crude pheromone extract should first be analyzed by GC-MS. However, even by using a cool on-column injector, dienal samples with a (*Z*)-2-, (*Z*)-3-, or (*E*)-3-double bond will be partly to completely converted into the isomer with an (*E*)-2-double bond. Isomerization will be complete with a split/splitless injector, giving one peak for the isomerized aldehyde, which might be better than the cluster of peaks obtained with the cool on-column injector for the preliminary examination of the pheromone extract. When an octadecadienal is detected, the procedures described here can confirm the position and

geometry of the double bonds. In our previous experiments with the *M. japona* pheromone, we reduced the aldehyde component with $NaBH_4$ and analyzed the resulting alcohol by GC-MS to determine the double bond position and configuration in the parent aldehyde (Naka et al. 2007). As an alternative approach, the structure determination can be accomplished by HPLC and LC-MS with an ODS column. When the pheromone component is a 2,13-dienal, the configuration of the two double bonds can be directly determined by the HPLC chromatographic behavior monitored at UV 235 nm. In the case of a 3,13-dienal, where a trace amount of the natural pheromone cannot be detected by UV monitoring, APCI-LC-MS analysis of the hydrazone derivative can be used to determine the configuration of the double bonds. Although R_ts of the hydrazones derived from Z3,E13-18:Ald and E3,Z13-18:Ald were almost the same, the configuration at the 13-position of the original compound is determined by the above preliminary GC-MS analysis. During GC analysis, Z3,E13-18:Ald and E3,Z13-18:Ald are expected to be converted into stable E2,E13-18:Ald and E2,Z13-18:Ald, respectively, which are separable on a polar GC column.

In this study, we confirmed the E2,Z13 configuration of the aldehyde secreted by *M. japona* females. In addition to the sesiid species, E2,Z13-18:Ald has been identified from a tineid species, *Tineola bisselliella* (Yamaoka et al. 1985). However, the unstable Z2,Z13-18:Ald has never been reported from pheromone gland extracts, whereas the corresponding alcohol component (Z2,Z13-18:OH) has been identified from some sesiid species, along with E2,Z13-18:OH (Ando 2007; El-Sayed 2007). The homo-conjugated double bond of a 3,13-octadecadienal is also unstable and easily migrates to the 2-position. The 3,13-dienal might be produced by enzymatic oxidation of the 3,13-dien-1-ol, which has been identified from several species as a pheromone component. Interestingly, (*E*)-2-Hexenal and (*Z*)-3-hexen-1-ol are well known as a leaf aldehyde and a leaf alcohol, respectively. Many plants also produce unstable (*Z*)-3-hexenal, another leaf aldehyde, which acts as an attractant to some predatory insects (Shiojiri et al. 2006). It would be interesting to know whether moth species utilize the relatively unstable 3,13-dienal as a sex pheromone. Szöcs et al. (1989) reported that males of two tineid species, *Monopsis rusticella* and *Nemapogon falstriellus*, were attracted by lures that included Z3,Z13-18:Ald. This finding suggests that some lepidopteran species might actually secrete the 3,13-dienal. Conversely, it is possible that the unstable aldehyde attracted the males after isomerization of the (*Z*)-3-double bond. We are now carrying out screening tests with the synthetic dienals to find new attractants for sesiid species in Japan.

Acknowledgement We are grateful to Mr. R. Wakasugi and Mr. D. Wakatsuki in Zoological Laboratory of Meijo University for the collection of *M. japona* and Dr. F. Mochizuki of Shin-Etsu Chemical Co., for supplying some dienyl compounds. This work was supported in part by a research grant from Heart Co. (Tokyo, Japan).

Introduction

The apple hairy moth or Indian gypsy moth, *Lymantria obfuscata* Walker 1865 (Lepidoptera: Lymantriidae), is a periodic pest on various fruit trees (Beeson 1941; Rahman and Kalra 1944; Butani 1979) and forest trees (Mathur 1964; Verma et al. 1979; Chacko et al. 1988) in India. It is found in northern India (Jammu and Kashmir, Himachal Pradesh, Uttar Pradesh, Punjab), northern Pakistan (Chaudhry et al. 1966), and Afghanistan (Schintlmeister 2004), but it is not as widely distributed as previously suggested (Gupta 1992). Reports that it occurs in southern India (Kumar 1974; Misra and Choudhuri 1974) are erroneous and likely based on taxonomic confusion with *Lymantria ampla* Walker 1855 (Ramaseshiah and Ramesh Bali 1987; Chacko et al. 1988; Chacko and Singh 1990). Biology and behavior of *L. obfuscata* are described elsewhere (Beeson 1941; Masoodi 1991).

Lymantria obfuscata and allopatric *L. dispar* cross-mate under laboratory conditions and produce viable hybrids for up to three generations [Victor Mastro, United States Department of Agriculture (USDA), Animal and Plant Health Inspection Service, Otis, MA, USA; personal comm. to PWS]. As might be expected, the sex pheromone of *L. dispar* (disparlure=*cis*-7,8-epoxy-2-methyloctadecane; Bierl et al. 1970) and analogues were shown to attract male *L. obfuscata* (Beroza et al. 1973; Punjabi et al. 1974) and were tested for population suppression (Masoodi et al. 1990).

We tested the hypothesis that the sex pheromones of *L. obfuscata* and *L. dispar* are similar. We report results of laboratory mate acceptance studies with con- and heterospecific pairings of *L. dispar* and *L. obfuscata* and the identification and field testing of sex pheromone components of *L. obfuscata*.

Methods and Materials

Experimental Insects Egg masses of *L. obfuscata* were collected in the Kulu Valley (Kashmir, India) and shipped to the Beneficial Insects Introduction Research Laboratory (BIRL), USDA, Agricultural Research Service, Newark, DE, USA, under USDA importation permit no. 36668. Larvae were reared on *L. dispar* diet (Bell et al. 1981) at 25°C, 60–75% R.H., and a photoperiod of 15L/9D. Late stage larvae of *L. dispar* were obtained from the BIRL culture, which originated from insects collected in Pennsylvania in 1976. These larvae were fed and kept as those of *L. obfuscata*.

Mate Acceptance Studies with Con- and Heterospecific L. dispar and L. obfuscata In replicated laboratory experiments 1–4, a 1- to 3-day-old male *L. obfuscata* or male *L. dispar* (BIRL colony) was paired with a virgin 1- to 3-day-old con- or heterospecific female in 500-cc paper cups (Solo Cup Co., Highland Park, IL, USA) with clear plastic lid

(Table 1). Replicates of all experiments were conducted in the afternoon hours when female moths of both species were calling. For each replicate, we recorded for up to 10 min whether and when a male attempted copulation. Differences between proportions of males attempting copulation were tested by contingency table analysis (χ^2; α=0.05) followed by Tukey-type multiple comparison of arcsin-transformed proportions (Zar 1984).

Laboratory Analyses of Pheromone Gland Extracts Abdominal tips with pheromone gland of calling 1- to 2-day-old virgin female *L. obfuscata* were removed and extracted for 5–20 min in high-performance liquid chromatography (HPLC)-grade hexane. Aliquots of pheromone gland extract and synthetic standards were analyzed by coupled gas chromatographic–electroantennographic detection (GC–EAD) and coupled GC–mass spectrometry (MS), employing equipment and general procedures previously described (Arn et al. 1975; Gries et al. 2002a). In this study, we used a Rose-5 column (30 m×0.25 mm ID×25 μm film; Rose Scientific Ltd., Edmonton, Alberta T6E 5Y5, Canada), splitless injection, a temperature program of 100°C (held 1 min) with a temperature increase of 10°C per min to 280°C, and an injector and detector temperature of 240°C.

General Methods and Instrumentation Tetrahydrofuran (THF), *N*-methylpyrrolidinone (NMP), and hexamethylphosphoramide (HMPA) were dried by standard methods. Oven-dried glassware was assembled hot and maintained under Ar; liquids were transferred by cannula under Ar pressure. Commercial anhydrous LiCl was dried by heating 2 hr at 180°C at 0.01 mm Hg and then stored in a dry box. Commercial anhydrous $MnCl_2$, CuI, and $CuCl_2$ were weighed and stored in oven-dried glassware in a dry box. Infrared spectra were recorded on Perkin-Elmer Paragon 1000 and 1600 FT-IR instruments. Optical rotations were measured on Jasco DIP-1000 and Perkin-Elmer 341 polarimeters. Nuclear magnetic resonance (NMR) spectroscopy of synthetic compounds was conducted on Bruker 300 (at 300 MHz for ^{1}H and 75 MHz for ^{13}C) and Varian AS500 (at 499.77 MHz for ^{1}H and 125.68 MHz for ^{13}C) spectrometers, with chemical shifts reported in ppm relative to TMS (^{1}H, δ 0.00) and $CDCl_3$ (^{13}C, δ 77.00). Elemental analyses were performed with a Carlo-Erba model 1106 elemental analyzer. In one instance, reaction product and unreacted starting material were separated by HPLC employing a Waters LC 625 chromatograph equipped with a Waters 486 variable-wavelength UV-visible detector set at 210 nm, HP Chemstation software (Rev.A.07.01), and a reverse-phase Nova Pak® C18 (3.9×300 mm) column (Waters) eluted with acetonitrile (1 ml/min).

Table 1 Percent of virgin 1- to 3-day-old male *L. obfuscata* or male *L. dispar* attempting to copulate, and mean time elapsed (±SD) before copulatory attempts were made, when paired with a virgin 1- to 3-day-old con- or heterospecific female in laboratory experiments 1–4 (see "Methods and Materials" for details)

Exp. No. (Replicates)	Female	Male	% Males Attempting Copulation[a]	Mean (±SD), Time (min) Elapsed Before Copulatory Attempt
1 (14)	*L. obfuscata*	*L. obfuscata*	93 a	1.38 (0.65)
2 (26)	*L. obfuscata*	*L. dispar*	15 b	1.50 (0.95)
3 (24)	*L. dispar*	*L. dispar*	83 a	1.85 (1.69)
4 (14)	*L. dispar*	*L. obfuscata*	71 a	1.67 (1.32)

[a] Numbers followed by the same letter are not significantly different; contingency table analysis of proportions of responding males (P<0.05) and Tukey-type multiple comparison of arcsin-transformed proportions (Zar 1984).

Source of Test Chemicals (*Z*)-2-Methyloctadec-7-ene (2Me-7*Z*-18Hy) and (+)- and (−)-disparlure were available from a previous project (Gries et al. 2002b). (3*R*,7*Z*)- and (3*S*,7*Z*)-3-Methylnonadec-7-enes (3*R*-Me-7*Z*-19Hy and 3*S*-Me-7*Z*-19Hy) were obtained by de-epoxidation of the corresponding (3*R*,7*R*,8*S*)- and (3*S*,7*R*,8*S*)-*cis*-7,8-epoxy-3-methylnonadecanes (3*R*-me-7*R*8*S*-epo-19Hy and 3*S*-me-7*R*8*S*-epo-19Hy) with triphenylphosphineselenium in dichloromethane (Clive 1978; Gries et al. 2005a).

Syntheses of (3*R*,7*R*,8*S*)- and (3*S*,7*R*,8*S*)-*cis*-7,8-Epoxy-3-methylnonadecanes

*(2'S,3'S)-cis-2',3'-Epoxy-1'-tetradecyl (1S)-10-camphorsulfonate (***2**, Fig. 1) A solution of $MnCl_2$ (3.47 g, 27.5 mmol) and LiCl (2.34 g, 55.0 mmol) in THF (55 ml) was cannulated (Ar pressure) into a 250-ml three-neck flask fitted with a low-temperature thermometer, magnetic stir bar, and pressure-equalizing 50-ml dropping funnel, and cooled to −10°C. A portion (56 ml, 80%) of a THF solution of *n*-decylmagnesium bromide [prepared from 6.09 g (27.5 mmol) of 1-bromodecane and excess Mg] was cannulated in at −10°C, followed by NMP (18 ml, 187 mmol). The mixture was warmed to 0°C, and a solution of $CuCl_2$ (38 mg, 0.28 mmol) and LiCl (24 mg, 0.56 mmol) in THF (4 ml) was cannulated in. (2′*S*,3′*R*)-4′-Bromo-*cis*-2′,3′-epoxy-1-butyl (1*S*)-10-camphorsulfonate (**1**; Aldrich; 3.00 g, 7.87 mmol) was melted *in vacuo* and dissolved in THF (10 ml). The mixture was cooled to −25° C, and the solution of **1** was added dropwise (pot temperature, −25 to −20°C). After 20 min, NMR assay of an aliquot showed complete consumption of **1**. The mixture was poured into Et_2O (100 ml) and saturated aq. NH_4Cl (100 ml). The separated organic layer was washed with H_2O (5×100 ml) and brine (25 ml), dried over Na_2SO_4, filtered, and concentrated. Column chromatography (silica gel, elution with 0–50% Et_2O-hexanes) yielded 3.30 g of impure **2** containing ring-opened alcohol. Most of the diol was removed by Kugelrohr distillation (75°C, <0.1 mm), leaving 2.77 g (79%) of nearly pure material. Purified **2**: mp 24.5–25.5°;

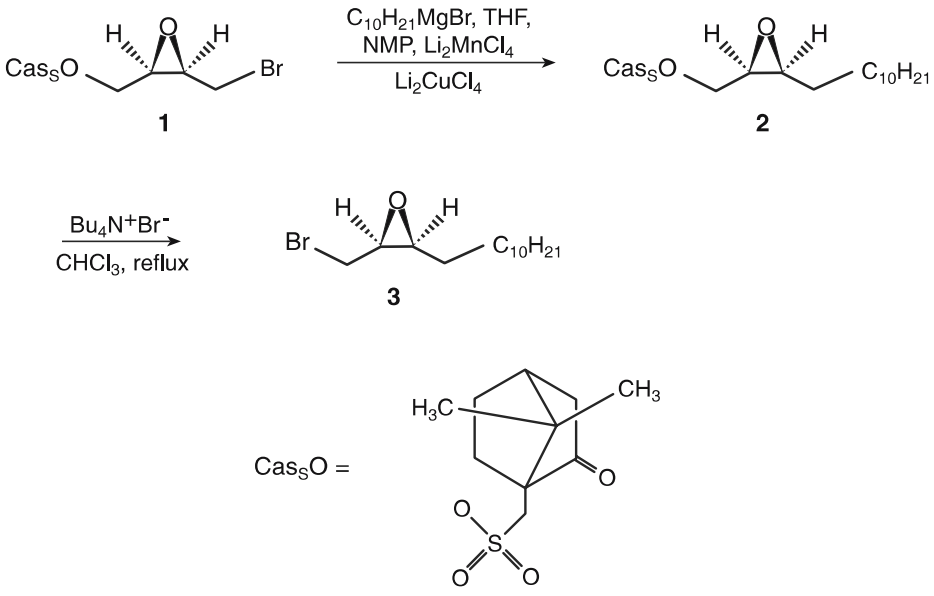

Fig. 1 Scheme for the enantioselective synthesis of (2*S*,3*S*)-1-bromo-2,3-*cis*-epoxytetradecane

$[\alpha]_D^{25} = +37.0°$ (c 2.35, $CHCl_3$); IR (film) 2920, 1747, 1360, 1172, 970 cm^{-1}; ^1H NMR δ 4.49–4.44 (dd, *J*=11.4, 4.2 Hz, 1H), 4.33–4.27 (dd, *J*=11.4, 7.1 Hz, 1H), 3.66 (d, *J*=15.1 Hz, 1H), 3.27 (m, 1H), 3.11 (d, *J*=15.1 Hz, 1H), 3.06 (m, 1H), 2.51–2.35 (m, 2H), 2.14 (t, *J*= 4.5 Hz, 1H), 2.11–2.00 (m, 1H), 1.96 (d, *J*=18.5 Hz, 1H), 1.27 (m, 18H), 1.76–1.30 (m, 4H), 1.12 (s, 3H), 0.89 (s, 3H), 0.88 (t, *J*=7.0 Hz, 3H); ^{13}C NMR 214.2, 68.5, 57.9, 56.7, 53.4, 48.0, 47.2, 42.7, 42.4, 31.8, 29.5–29.3(6), 27.9, 26.8, 26.5, 24.9, 22.6, 19.7, 19.6, 14.0. Anal. calcd. for $C_{24}H_{42}O_5S$ (%): C, 65.12; H, 9.56; found C, 65.27; H 9.85.

*(2S,3S)-1-Bromo-2,3-cis-epoxytetradecane (**3**)* Tetrabutylammonium bromide (13.8 g, 42.6 mmol) and $NaHCO_3$ (200 mg) were mixed with $CHCl_3$ [80 ml, freshly filtered through Al_2O_3; 30 ml of $CHCl_3$ was distilled off (azeotropic removal of traces of water)]. The mixture was heated to 65°C, and a solution of **2** (10.39 g, 23.5 mmol) in $CHCl_3$ (10 ml) was added. The magnetically stirred mixture was kept at 67°C for 10 hr (no **2** detected by NMR analysis), then poured into H_2O (150 ml) and pentane (200 ml). The organic layer was washed (H_2O) and dried (Na_2SO_4–$MgSO_4$). Solvent evaporation afforded a pale yellow oil, which crystallized. Column chromatography (silica gel, elution with 0–1% Et_2O-hexanes) gave 6.6 g (97%) of ~98% pure **3**. Recrystallization (pentane) gave >99% pure material: mp 35.1–35.6°C; $[\alpha]_D^{24.5} = -39.7°$ (*c*=1.9, $CHCl_3$); ^1H NMR δ 3.52–3.50 (m, 1H, H-1), 3.28–3.25 (m, 2H, H-1, H-2), 3.08–3.07 (m, 1H, H-3), 1.55–1.49 (m, 2H), 1.38–1.20 (br m, 18 H), 0.88 (t, *J*=6.6 Hz, 3H); ^{13}C NMR 58.9, 55.6, 31.8, 29.6–28.9(7), 27.2, 26.4, 22.6, 14.0. Anal. calcd. for $C_{14}H_{27}BrO$ (%): C, 57.71; H, 9.34; found C, 57.75; H 9.50.

*(R)-2′-Methylbutyl (1S)-10-camphorsulfonate (**5**, Fig. 2)* In a 500-ml 3-neck flask fitted with a dropping funnel and thermometer, a mixture of dry $MnCl_2$ (20.5 g, 163 mmol) and LiCl (13.8 g, 326 mmol) was dissolved (magnetic stirring under Ar) in THF (200 ml, 1.5 h at 0°C) to give a yellow solution (Cahiez and Marquais 1993). At −5°, 44 ml of 3M MeMgCl (132 mmol) in THF were added dropwise, followed by 108 ml (1.04 mol) of NMP at 0–5°C and then 20 ml of a THF solution of $CuCl_2$ (220 mg, 1.63 mmol) and LiCl (138 mg, 3.26 mmol) at 0° C, to give a brown-yellow solution. A solution of (*S*)-3′-bromo-2′-methylpropyl (1*S*)-10-camphorsulfonate (**4**) (>99% *ee*, Hahn et al., unpublished data; 20.0 g, 54.4 mmol) in THF (60 ml) was added dropwise at 0°C, and the mixture was held at 0°C for 16 hr; NMR analysis showed complete consumption of starting material. The mixture was poured into saturated aq. NH_4Cl and hexanes and the separated organic layer was washed with H_2O (2×100 ml) and brine. Drying over Na_2SO_4 and solvent evaporation left 16.55 g of pale yellow oil. This was dissolved in 1:1 ether/hexane, filtered through silica gel (10 g) and concentrated to leave 15.4 g (94%) of **5** as a colorless oil. Silica gel chromatography (elution with 20% ether/hexane) afforded an analytical sample: $[\alpha]_D^{26} = +36.8°$ (c 5.3, $CHCl_3$); IR (film) 2,965, 1,747, 1,358, 1,170, 963 cm^{-1}; ^1H NMR δ 4.20–4.15 (dd, *J*=9.3, 5.9 Hz, 1H), 4.09–4.03 (dd, *J*=9.3, 6.6 Hz, 1H), 3.60 (d, *J*=15.0 Hz, 1H), 2.99 (d, *J*=15.0 Hz, 1H), 2.57–2.35 (m, 2H), 2.13 (t, *J*=4.5 Hz, 1H), 2.10–2.00 (m, 1H), 1.96 (d, *J*=18.3 Hz, 1H), 1.80 (oct, *J*=6.6 Hz, 1H), 1.70–1.60 (m, *J*=4.8 Hz, 1H), 1.56–1.40 (overlapping m's, 2H), 1.34–1.16 (m, 1H), 1.12 (s, 3H), 0.98 (d, *J*=6.6 Hz, 3H), 0.93 (t, *J*=7.5 Hz, 3H), 0.89 (s, 3H); ^{13}C NMR 214.4, 74.6, 57.8, 47.8, 46.4, 42.6, 42.4, 34.5, 26.8, 26.5, 24.8, 19.7, 19.6, 15.9, 11.0. Anal. calcd. for $C_{15}H_{26}O_4S$ (%): C, 59.57; H, 8.67; found C, 59.79; H 8.72.

*(R)-1-Bromo-2-methylbutane (**6**)* Camphorsulfonate **5** (9.29 g, 30.7 mmol) and vacuum-dried tetrabutylammonium bromide (11.9 g, 36.9 mmol) were heated together to 90–95° C in a Kugelrohr distillation apparatus, starting at 1 atm pressure. The pressure was gradually reduced (needle valve) until bromide **6** began to distill; 3.51 g of 98% pure material was

collected in 0.5 hr. The semisolid pot residue was taken up in H_2O and pentane, and the pentane layer was dried over Na_2SO_4, filtered, and concentrated. Removal of solvent by distillation left another 0.89 g of **6** (total 4.40 g, 95%). Chromatography of a portion (SiO_2 column, elution with pentane) and distillation (bp 119–120°C) afforded an analytical sample: $[\alpha]_D^{20} = -6.50°$ (c 3.4, $CHCl_3$) [lit.: $[\alpha]_D^{20} = -6.66°$ (c 12, $CHCl_3$), Bestmann et al. 1998]; ^{1}H NMR δ 3.38 (dd, *J*=9.8, 5.1 Hz, 1H), 3.32 (dd, *J*=9.8, 6.1 Hz, 1H), 1.77–1.63 (m, 1H, H-2), 1.54–1.41 (m, 1H, H-3), 1.33–1.19 (m, 1H, H-3), 0.99 (d, *J*=6.6 Hz, 3H), 0.89 (t, *J*=7.4 Hz, 3H); ^{13}C NMR δ 41.0, 36.7, 27.5, 18.3, 11.2.

*(R)-1-Bromo-3-methylpentane (**8**) and (S)-1-Bromo-3-Methylpentane (**10**)* The known (*R*)-1-Bromo-3-methylpentane (**8**) was prepared from bromosulfonate **4** by a procedure (Nakamura and Mori 1999) that does not affect the chiral center (Fig. 2). ^{1}H NMR δ 3.50–3.36 (m, 2H, 1-H_2), 1.95–1.83 (m, 1H, H-2), 1.72–1.60 (m, 1H, H-2), 1.60–1.50 (m, 1H, H-3), 1.43–1.30 (m, 1H, H-4), 1.25–1.12 (m, 1H, H-4), 0.89 (d, *J*=6.3 Hz, 3H, 3-CH_3), 0.89 (t, *J*=7.2 Hz, 3H, 5-H_3). (*S*)-1-Bromo-3-methylpentane (**10**; Barrett et al. 1996) was synthesized in a similar fashion from bromosulfonate **9** [the (*R*)-enantiomer of **4**]. For direct comparison, (*S*)-1-bromo-3-methylpentane was also prepared from commercial (*S*)-3-methyl-1-pentanol (TCI America, Portland, OR, USA).

*(3R,7R,8S)-cis-7,8-Epoxy-3-methylnonadecane (**11**)* A solution of (*R*)-1-pentyl-3-methylmagnesium bromide [freshly prepared from 0.60 g (3.96 mmol) of (*R*)-1-bromo-3-

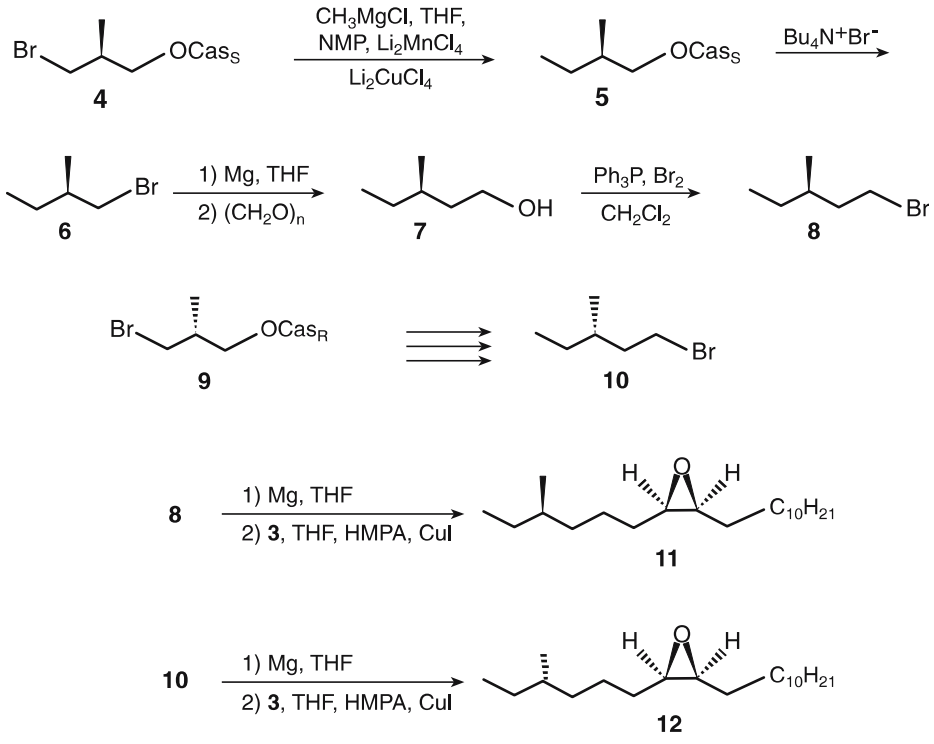

Fig. 2 Scheme for the enantioselective syntheses of (3*R*,7*R*,8*S*)- and (3*S*,7*R*,8*S*)-*cis*-7,8-epoxy-3-methylnonadecane

methylpentane (**8**) and two equiv. of magnesium turnings by refluxing for 3 hr in 6 ml of degassed THF] was added dropwise to a stirred mixture of bromoepoxide **3** (372 mg, 1.28 mmol), CuI (0.073 g, 0.38 mmol), distilled HMPA (2.0 ml, 11.5 mmol), and THF (0.8 ml) at −23°. After 1 hr (no starting bromoepoxide **3** detectable by GC), the reaction mixture was warmed to 0°C and quenched with aq. NH_4Cl solution. The reaction products were extracted with hexane–ether (1:1), and the extracts were washed (water, brine) and dried (anhyd. $MgSO_4$). Solvents and low-boiling by-products were removed *in vacuo*. Flash chromatography (40 g SiO_2, 0–3% ether in hexane) yielded 290 mg (0.98 mmol) of pure epoxide **11** (77%); $[\alpha]_D^{20} = -4.57°$ (c 2.45, $CHCl_3$); IR (film) 2957, 2925, 2855, 1463, 1378, 1088, 909, 828 cm^{-1}; ^1H NMR δ 2.90 (m, 2H), 1.15–1.55 (4 m's, 29H), 0.86 (m, 9H); ^{13}C NMR δ 57.23, 57.21, 36.47, 34.34, 31.91, 29.63, 29.62, 29.56, 29.55(2), 29.42, 29.33, 28.16, 27.83, 26.59, 24.14, 22.67, 19.07, 14.09, 11.35. Anal. calcd. for $C_{20}H_{40}O$ (%): C, 81.00; H, 13.59; found C, 80.73; H 13.70.

*(3S,7R,8S)-cis-7,8-Epoxy-3-methylnonadecane (**12**)* Synthesis of compound **12** was analogous to that of **11**, starting with bromoepoxide **3** and (*S*)-1-bromo-3-methylpentane (**10**) derived from (*S*)-3-methyl-1-pentanol (TCI America). The final product **12** was separated by HPLC from unreacted starting material **3**. The yield (based on recovered **3**) was 40%. Spectral data of **12** were identical to those of **11** $[\alpha]_D^{20} = +6.40°$ (c 0.53, $CHCl_3$); for epoxide **12** derived from (*S*)-1-bromo-3-methylpentane that was produced from bromosulfonate **9**: $[\alpha]_D^{20} = +6.46°$ (c 0.65, $CHCl_3$); anal. calcd. for $C_{20}H_{40}O$ (%): C, 81.00; H, 13.59; found C, 81.30; H 13.35. Spectral data were identical to those of epoxide **11**.

Field Experiments Candidate pheromone components were field tested on the campus of Dr. Y. S. Parmar University of Horticulture and Forestry (Nauni, India; 30°51.52′N, 77° 10.18′E) and in oak stands of the Kandaghat Forest (30°57.27′N, 77°6.82′E) within 30 km of Solan (Himalach Pradesh, India). At 15- to 20-m intervals, sticky 2-l milk carton traps (Gray et al. 1984) were suspended 1.5 m above ground in randomized complete blocks. Traps were baited with a gray sleeve stopper (The West Co., Lionville, PA, USA) impregnated with test chemicals in HPLC-grade hexane.

Experiment 5 tested the two most abundant and antennal stimulatory components 2Me-7*Z*-18Hy and (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadecane [(+)-disparlure] singly at 50 μg each and in combination (50:25 μg) vs. unbaited traps. Because the unbaited control traps did not capture a single insect, they were excluded from follow-up experiments. Considering further that (+)-disparlure and 2Me-7*Z*-18Hy were attractive as single components in experiment 5 and apparently more attractive in combination, experiment 6 explored whether the attractiveness of 2Me-7*Z*-18Hy could be enhanced by either one or both enantiomers of disparlure. Based on synergistic attractiveness of 2Me-7*Z*-18Hy and (+)-disparlure in experiment 6, experiments 7 and 8 explored the optimal binary blend by testing components singly and at various ratios. Experiments 9 and 10 then investigated the potential role of minor candidate pheromone components. Experiment 9 tested whether one or both of 3*R*-Me-7*Z*-19Hy and 3*S*-Me-7*Z*-19Hy enhanced the attractiveness of 2Me-7*Z*-18Hy. The design of experiment 10 was based on the hypothesis that 3*R*-Me-7*Z*-19Hy and 3*S*-Me-7*Z*-19Hy may be effective only in combination with their corresponding *RS*-epoxides; thus, we tested all four components in combination for their effect on the binary blend of 2Me-7*Z*-18Hy and (+)-disparlure.

Trap catch data were subjected to nonparametric analyses of variance (Friedman's test) followed by comparison of means by the Scheffé test (Zar 1984; SAS/STAT 1988). In all analyses, α=0.05.

Results and Discussion

In mate acceptance studies with pairs of con- or heterospecific male and female *L. dispar* and *L. obfuscata*, male *L. dispar* and male *L. obfuscata* made copulatory attempts mainly when paired with a conspecific female (Table 1). Most male *L. obfuscata* paired with a female *L. dispar* also attempted copulation, suggesting that (+)-disparlure produced by female *L. dispar* as a single sex pheromone component was attractive and thus might be a pheromone component also of female *L. obfuscata.* These results further suggested that other volatile constituents present in, or released from, pheromone glands of female *L. dispar* [*cis*-7,8-epoxy-2-methylheptadecane; *cis*-7,8-epoxy-3-methylnonadecane; (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadec-17-ene (Gries et al. 1996, 2005b)] did not antagonize male *L. obfuscata*. Conversely, the few copulatory attempts male *L. dispar* made when paired with female *L. obfuscata* (Table 1) suggested that female *L. obfuscata* emit one or more volatile components antagonistic to male *L. dispar*. We hypothesized that these components were part of the *L. obfuscata* sex pheromone blend and initiated pheromone analysis.

GC–EAD analyses of pheromone gland extract from female *L. obfuscata* revealed eight components that consistently elicited responses from male antennae (Fig. 3). The two most abundant components **C** and **G**, which also elicited the strongest responses from antennae, had GC retention and mass spectrometric characteristics entirely consistent with (*Z*)-2-methyloctadec-7-ene (**C**) and the corresponding epoxide disparlure (**G**). Component **H** had retention indices (RI; relative to alkane standards; Van Den Dool and Kratz 1963) on three GC columns (DB-5: 2140; DB-23: 2459; DB-210: 2422) consistent with those of *cis*-7,8-epoxy-3-methylnonadecane, a trace component in pheromone gland extracts of *L. dispar* (Gries et al.

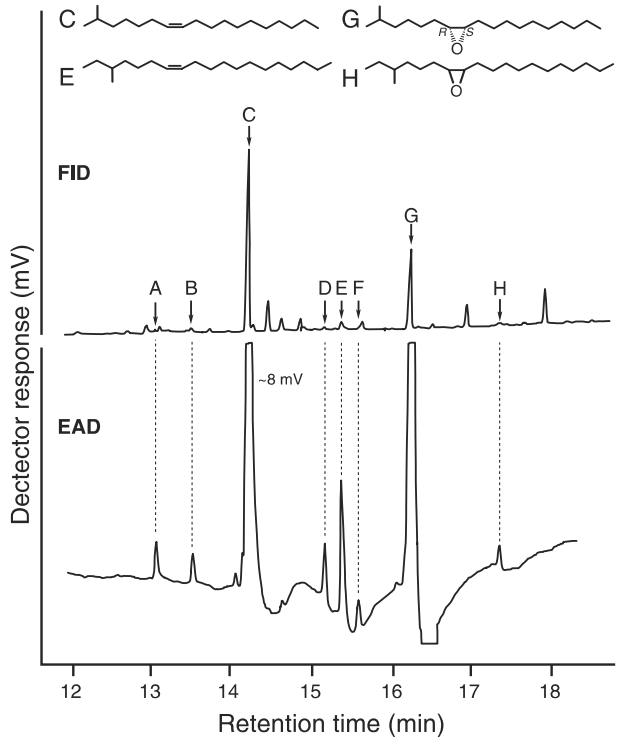

Fig. 3 Representative recording (*N*=6) of flame ionization detector (*FID*) and electroantennographic detector (*EAD*: male *L. obfuscata* antenna) responses to one female equivalent of pheromone gland extract of *L. obfuscata*. Compound identities: *A* unknown; *B* unknown; *C* (*Z*)-2-methyloctadec-7-ene [2Me-7*Z*-18Hy]; D unknown; E (3*R*,7*Z*)- and/or (3*S*,7*Z*)-3-methylnonadecene [3*R*-Me-7*Z*-19Hy and/or 3*S*-Me-7*Z*-19Hy]; *F* unknown; *G* (7*R*,8*S*)-*cis*-7,8-epoxy-2-methyloctadecane [=(+)-disparlure]; *H* (3*R*,7*R*,8*S*)- and/or (3*S*,7*R*,8*S*)-*cis*-7,8-epoxy-3-methylnonadecane [3*R*-Me-7*R*,8*S*-epo-19Hy and/or 3*S*-Me-7*R*,8*S*-epo-19Hy]

1996). Structural assignment of component **H** was indirectly supported by the presence of the corresponding hydrocarbon (*Z*)-3-methylnonadec-7-ene (**E**), which had a mass spectrum and retention indices (DB-5, 1954; DB-23, 1988; DB-210, 1971) entirely consistent on all three columns with those of an authentic standard. Components **A**, **B**, **D**, and **F** occurred in quantities well below FID detection threshold, and their structures are not yet known.

The identification of 2Me-7*Z*-18Hy in pheromone gland extracts of female *L. obfuscata* explains the relatively few copulatory attempts male *L. dispar* made when paired with a female *L. obfuscata* (Table 1). 2Me-7Z-18Hy is a pheromone component of sympatric *L. dispar* congeners [*Lymantria monacha* in Europe (Grant et al. 1996; Gries et al. 1996) and Japan (Gries et al. 2001); *L. fumida* and *L. lucescens* in Japan (Schaefer et al. 1999; Gries et al. 2002b)] which, when added to (+)-disparlure baits, strongly reduces attraction of male *L. dispar* in Europe (Grant et al. 1996; Gries et al. 1996), North America (Cardé et al. 1973) and Asia (GG and PWS, unpublished).

Epoxide **3** was prepared from commercially available epoxide **1** (Gries et al. 2005b; Fig. 1). The conversion of **1** to **2** proceeded in 79% yield. A more convenient procedure, omitting Li_2MnCl_4 and using HMPA and CuI in place of NMP and Li_2CuCl_4, afforded **2** in 67% yield. In the conversion of **2** to **3**, elevated temperature (67°C) is essential to achieve complete reaction in minimal time; the presence of acid/water must be avoided to maximize the reaction rate and minimize product isomerization to a *trans*-epimer of **3**. Byproduct $Bu_4N^+Cas_sO^-$ is easily recovered from the aqueous phase from the reaction workup by evaporation of the water. Synthesis routes to target epoxides **11** and **12** are outlined in Fig. 2. Access to commercially unavailable (*R*)-1-bromo-2-methylbutane (**6**) was gained by chemoselective coupling of CH_3MnCl (Cahiez and Marquais 1993) with bromoalkyl camphorsulphonate (casylate) **4** (crystalline solid; >99% pure; R. Hahn, F. B. Cook, and M.-Y. He, unpublished data) to give the casylate ester of (*R*)-2-methyl-1-butanol (**5**; 94% yield), followed by displacement of casylate by bromide (95%). Bromide **6** and its enantiomer derived from bromo-casylate **9** were converted (Pino et al. 1959 and references therein; Schaefer et al. 1973 and references therein; Bestmann et al. 1998) to known **8** and **10**, respectively. Grignard reagents from the latter two compounds were then coupled with epoxide **3**, to afford **11** and **12**. Additional quantities of 3*S*-Me-7*R*,8*S*-epo-19Hy (**12**) were obtained from commercially available (*S*)-3-methyl-1-pentanol (the enantiomer of alcohol **7**) via bromide **10** (Fig. 2). NMR and IR spectral data and optical rotation values of the final epoxides **12** obtained from the bromides **10** obtained by the two different routes were identical. Spectral data for 3*R*-Me-7*R*,8*S*-epo-19Hy (**11**) are identical to those of its diastereomer **12**. Optical rotation values differed considerably.

In experiment 5, (+)-disparlure and 2Me-7*Z*-18Hy as single-component lures attracted male *L. obfuscata* (Fig. 4). Both components in combination appeared more attractive, but results were not statistically analyzed because many traps were damaged or removed by monkeys. In experiment 6, (+)-disparlure significantly enhanced attractiveness of 2Me-7*Z*-18Hy, whereas (−)-disparlure had neither synergistic nor antagonistic effects (Fig. 4). In experiments 7 and 8, combinations of (+)-disparlure and 2Me-7*Z*-18Hy at blend ratios of 0.5:1, 5:1, 1:2, and 1:10 were of similar effectiveness and more effective than either component alone in attracting male *L. obfuscata* (Fig. 5). The attractiveness of 2Me-7*Z*-18Hy in experiment 9, or 2Me-7*Z*-18Hy plus (+)-disparlure in experiment 10, was not affected by the addition of other candidate pheromone components (Fig. 6).

Laboratory and field data support the conclusion that the sex pheromone of *L. obfuscata* comprises a blend of two synergistic components: 2Me-7*Z*-18Hy and (+)-disparlure. The blend is dissimilar to the single-component sex pheromone (+)-disparlure in populations of European and Asian *L. dispar*. Male *L. obfuscata* and male *L. dispar* also differ in their response to (−)-disparlure. (−)-Disparlure strongly antagonizes attraction of male *L. dispar* to pheromone sources

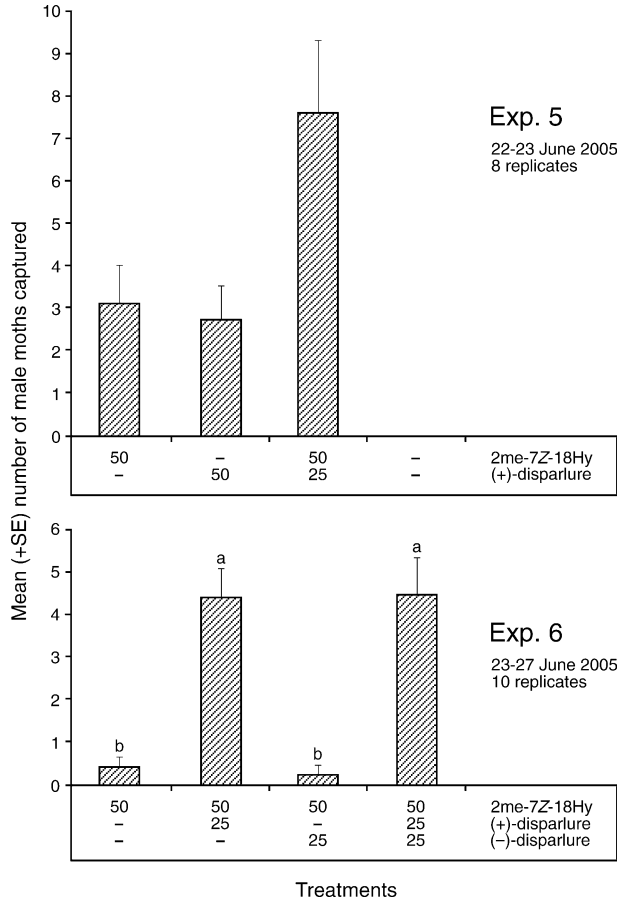

Fig. 4 Mean (+SE) number of male *L. obfuscata* captured per experimental period in experiment 5 (30°51.52′N, 77°10.18′E) and experiment 6 (coordinate data lost, site on road to Pomology research area on campus of Dr. Y. S. Parmar University of Horticulture and Forestry, Nauni, India) in sticky traps baited with candidate pheromone components. Bars in experiment 6 with different letter superscripts are significantly different; nonparametric analyses of variance by ranks (Friedman's test) followed by comparison of means (Scheffé test), $P<0.05$ (SAS/STAT 1988). Compound nomenclature as in caption of Fig. 3

(Klimetzek et al. 1976; Cardé et al. 1977a, b; Miller et al. 1977; Plimmer et al. 1977) but does not affect the behavior of male *L. obfuscata.* The dissimilar sex pheromones of *L. obfuscata* and *L. dispar* and the contrasting response to (−)-disparlure both support taxonomic distinction of *L. obfuscata* and *L. dispar*.

If we consider the presence of congeners a biological factor that shapes the sexual communication signal of individual species (Linn and Roelofs 1995), then the dissimilar sex pheromones of *L. obfuscata* and *L. dispar* could be explained by the contrasting composition of the lymantriid communities they inhabit. None of the congeners *L. monacha*, *L. fumida*, and *L. lucescens* that produce 2Me-Z7-18Hy as a sex pheromone component, with strong antagonism of heterospecific male *L. dispar*, is present in the *L. obfuscata* community. Thus, 2Me-7*Z*-18Hy can be part of the *L. obfuscata* sex pheromone. Similarly, *L. monacha* in sympatry with *L. dispar* purportedly produces (−)-disparlure (Hansen 1984), which enhances the specificity of the communication channel and reduces cross-attraction of male *L. dispar* (Klimetzek et al. 1976; Cardé et al. 1977a, b; Miller et al. 1977; Plimmer et al. 1977). With *L. monacha* absent from the *L. obfuscata* community, male *L. obfuscata* did not evolve to recognize and be antagonized by (−)-disparlure (Fig. 4).

It would now be intriguing to study potential divergence of the *L. obfuscata* sex pheromone in lymantriid communities of different composition, particularly in the Pamir Mountains of Tajikistan where *L. obfuscata* and *L. dispar* may co-occur, as proposed by Schintlmeister (2004).

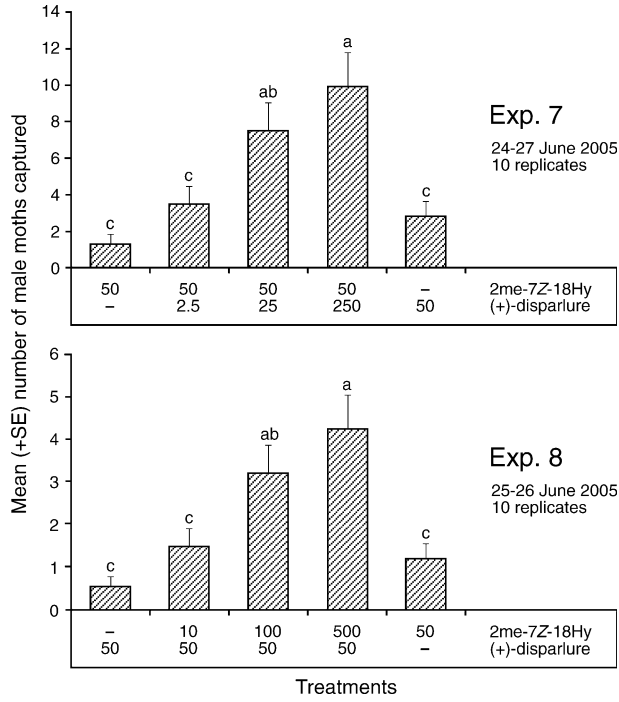

Fig. 5 Mean (+SE) number of male *L. obfuscata* captured per experimental period in experiment 7 (30°57.29′N, 77°6.82′E) and experiment 8 (30°56.98′N, 77°7.27′E) in sticky traps baited with candidate pheromone components singly and in binary combination at different ratios. Bars in each experiment with different letter superscripts are significantly different; nonparametric analysis of variance by ranks (Friedman's test) followed by comparison of means (Scheffé test), $P<0.05$ (SAS/STAT 1988). Nomenclature as in caption of Fig. 3

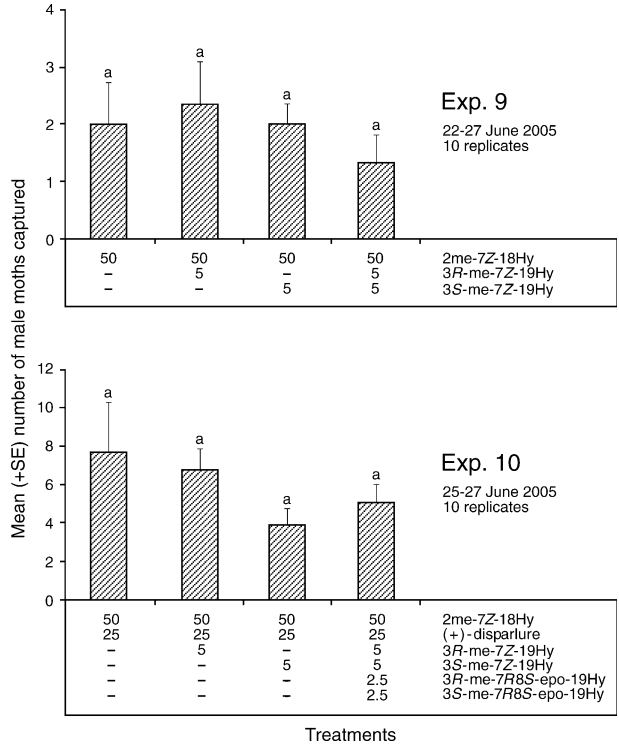

Fig. 6 Mean (+SE) number of male *L. obfuscata* captured per experimental period in experiment 9 (30°51.76′N, 77°10.28′E) and in experiment 10 (near 30° 57.3′N, 77°6.8′E) in sticky traps baited with the binary blend of (+)-disparlure and (7*Z*)-2-methyloctadec-7-ene alone or in combination with other candidate pheromone components. *Bars* in each experiment with the same letter superscript are not significantly different; nonparametric analysis of variance (Friedman's test) followed by comparison of means (Scheffé test), $P<0.05$ (SAS/STAT 1988). Compound nomenclature as in caption of Fig. 3

Acknowledgments We thank Dharam Pal and Ravinder Sharma for field assistance, Girish Sharma and Amit Nath for guidance on use of suitable trapping sites, Devinder Singh for local transportation, Sanjeev Thakur for permission to run field experiments in the Kandaghat Forest Range, Gagandeep S. Hehar for logistical help, T. D. Verma and Prem Raj Gupta for information on *L. obfuscata* biology and behavior, Susan Barth for moth rearing, Mei-Keng Yang for elemental analyses, Stephen Takács for some statistical analysis, Eberhard Kiehlmann for review of the manuscript, and Jocelyn Millar and two anonymous reviewers for constructive comments. The research was supported by a Natural Sciences and Engineering Research Council of Canada—Industrial Research Chair to G.G., with Pherotech International Inc., SC Johnson Canada, and Global Forest Science (GF-18-2007-226; GF-18-2007-227) as industrial sponsors. Insects were maintained in SFU's Global Forest Quarantine Facility, construction of which was completed with financial support from Global Forest Science.

of head and mandibles (for a review see Deligne et al. 1981; Prestwich 1984); (2) evolution of the frontal gland as a unique chemical defense tool in the advanced termite families Serritermitidae, Rhinotermitidae, and Termitidae (Costa-Leonardo and Kitayama 1991); and (3) related behavioral and defensive strategies (Pasteels and Bordereau 1998). Frontal gland defensive secretions of termite soldiers may contain different chemical components, including mono-, sesqui-, and diterpenoid hydrocarbons, alcohols, ethers, ketoaldehydes, fatty acids, macrocyclic lactones, etc. (Prestwich 1978, 1984; Prestwich et al. 1978, 1980; Prestwich and Collins 1980, 1981a, b; Naya et al. 1982; Pasteels and Bordereau 1998; Chen et al. 1999). The deterrent property of such a secretion is often enhanced by the formation of a glue-like material after release that immobilizes enemies (Deligne et al. 1981).

Apart from its defensive role, frontal gland substances can be involved in alarm communication, in more advanced families (e.g., Eisner et al. 1976; Deligne et al. 1981; Pasteels and Bordereau 1998). The role of individual compounds of the secretion in the elicitation of alarm has been confirmed only in a few cases. α-Pinene and limonene in *Nasutitermes rippertii*, 3-carene and limonene in *Nasutitermes costalis* (Vrkoč et al. 1978), and α-pinene in *Nasutitermes princeps* (Roisin et al. 1990) have all been shown to be alarm pheromone components.

The 17 species of the genus *Prorhinotermes* (Isoptera: Rhinotermitidae) form the subfamily Prorhinotermitinae (Quennedey and Deligne 1975). This subfamily, despite many advanced characteristics, also displays several primitive traits, such as a linear ontogeny lacking a true worker caste (Roisin 1988) and a nesting habit without a well-defined centralized nest. These species can be classified as single-site nesters, with colonies located in dead logs and stumps, usually in close vicinity of water sources (e.g., Banks and Snyder 1920; Shellman-Reeve 1997). The distribution of *Prorhinotermes* species is cosmotropical with maximum diversity in Southeast Asia; the species usually live on islands and are found rarely on the mainland. The island distribution is likely a consequence of the ability of these species to cross the open ocean in floating logs or coconuts (Emerson 1955).

In colonies of *Prorhinotermes*, soldiers are abundant, often comprising more than 10% of the population. Soldiers defend the colony interior as well as foraging groups and possess, in addition to slashing falcate mandibles, a voluminous frontal gland. The reservoir of this gland extends over the whole abdomen and can be observed as a transparent sac (Šobotník et al. 2004). (*E*)-1-Nitropentadec-1-ene is the major defensive compound of *Prorhinotermes simplex* (Hagen), *Prorhinotermes inopinatus* Silvestri, and *Prorhinotermes flavus*, the only *Prorhinotermes* soldiers analyzed to date. This chemical is present in high amounts in the body of soldiers (up to 370 μg/individual, ca. one tenth of the average soldier body weight) (Vrkoč and Ubik 1974; Chuah et al. 1990; Kuldová et al. 1999; Šobotník et al. 2004). (3*Z*,6*E*)-α-Farnesene has also been identified in the frontal gland secretion of *P. simplex* soldiers (Naya et al. 1982). It is well accepted that the volatile compounds from this gland serve as an alarm pheromone (Moore 1969).

In this study, we compared frontal gland contents of *Prorhinotermes* species from Neotropical (*P. simplex*), Malagasy (*P. canalifrons* Sjöstedt), and Papuan (*P. inopinatus*) regions to ascertain knowledge about the qualitative and quantitative chemodiversity of this gland secretion.

Methods and Materials

General

Most chemicals were obtained from Sigma-Aldrich or Fluka. (3*Z*,6*E*)-α-Farnesene and (*E*)-1-nitropentadec-1-ene were synthesized earlier in our laboratory (Svatoš and Attygalle

1997; Kuldová et al. 1999). (*E*)-1-Nitroheptadec-1-ene was synthesized from hexadecanal, analogous to the synthesis of (*E*)-1-nitropentadec-1-ene (Kuldová et al. 1999). *Ocimum basilicum* essential oil was purchased from Essential Oil University and lime essential oil from Aldrich.

Quantitative gas chromatography-mass spectrometry (GC-MS) analysis was carried out on a Varian Saturn 2000R ion-trap GC-MS instrument with electron ionization (70 eV). A DB-5 ms fused silica capillary column (30 m×0.25 mm, film thickness 0.25 μm, J & W Scientific) was used for the analyses with the following temperature program: 70°C for 2 min, increased to 200°C at a rate of 20°C per minute, and then to 320°C at 10°C per minute. Splitless injection was used with helium as a carrier gas. Each sample was analyzed ×3, and mean values were calculated for the integrated areas by using calibration curves. The calibration curves were calculated with solutions of different concentration ratios of (3*Z*,6*E*)-α-farnesene, and (*E*)-1-nitropentadec-1-ene to 1-bromodecane.

For identification of compounds, EI mass spectra (70 eV) were recorded on a Fisons MD800 quadrupole MS coupled to a Finnigan Focus GC (Thermo) fitted with a ZB-5 ms capillary column (30 m×0.25 mm, film thickness 0.25 μm, Zebron Phenomenex) that employed conditions as above. Identification was generally based on fragmentation pattern together with comparison of retention indices. However, for the various sesquiterpenes, as well as (*E*)-1-nitropentadec-1-ene and (*E*)-1-nitroheptadec-1-ene, coinjection with standards was also carried out. *Ocimum basilicum* essential oil, containing *trans*-β-bergamotene (Bini et al. 2000), and lime essential oil, containing (*Z*)-γ-bisabolene (Joulain and Koenig 1998), were employed as a source of standards.

Retention indices on both ZB-5 and DB-wax (30 m×0.25 mm, film thickness 0.25 μm, J & W Scientific) columns were obtained by using a mixture of *n*-alkanes (C8–C22) as standards, and methane as an unretained compound. For the ZB-5 column, a temperature program of 60 to 240°C at 3°C per minute, then to 320°C at 20°C per minute, was used, while the DB-wax was kept isothermally at 165°C.

The Fourier transform infrared (FT-IR) spectra were obtained by using a Finnigan GCQ GC interfaced with a Bruker Equinox 55 system (FT-IR resolution, 8 cm^{-1}; light pipe temperature, 200°C), equipped with a DB-5 capillary column (30 m×0.32 mm, film thickness 0.25 μm, J & W Scientific) and an oven temperature program of 70°C for 2 min, increased to 250°C at 10°C per minute. Injection was splitless, and He was the carrier gas.

Insects

Soldiers were removed from mature laboratory colonies of *P. canalifrons* (collected in Réunion in 2001), *P. inopinatus* (collected at Kau Wildlife Area, Madang Province, Papua New Guinea, in 2000), and *P. simplex* (collected in Soroa, Piñar del Rio, Cuba, in 1964). All colonies were kept in permanent darkness at 26±1°C with elevated humidity (>85%). Soldiers that molted from late pseudergate instars were chosen for the analysis. These individuals do not differ greatly in their outer anatomy or size among the three species (Fig. 1).

Extracts of Soldiers

Immediately after removal from the colony, soldiers were frozen at −20°C for 5 min and dissected transversely at the third abdominal segment to open the gland. 1-Bromodecane in hexane (50 μl; 0.554 mg ml^{-1} for *P. canalifrons*, 0.576 mg ml^{-1} for *P. inopinatus* and *P. simplex*) was used to extract single individuals. Ten samples each of *P. canalifrons* and

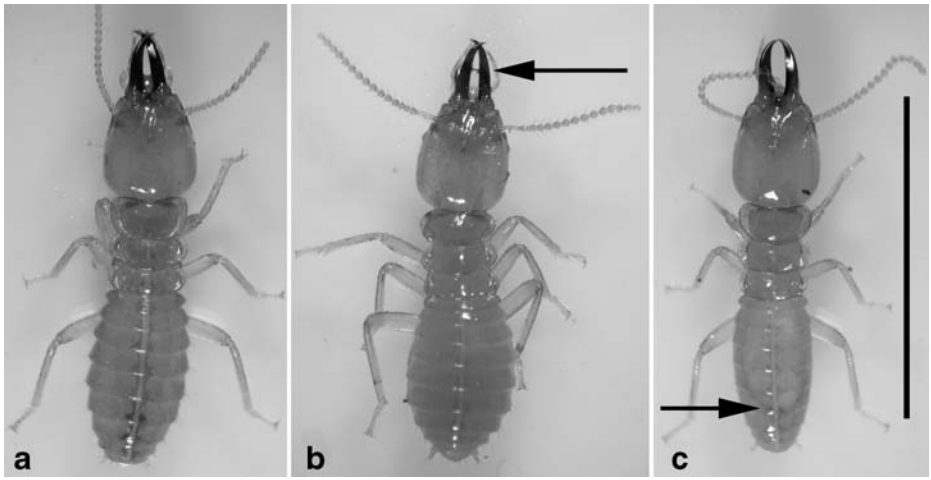

Fig. 1 Soldiers of three *Prorhinotermes* species: **a** *P. canalifrons*; **b** *P. inopinatus* (the released frontal gland secretion between the mandibles is marked with an *arrow*); **c** *P. simplex* (the frontal gland reservoir ending in the seventh abdominal segment is marked with an *arrow*). The *bar* represents 5 mm

P. inopinatus, and three samples of *P. simplex* were prepared. The samples were shaken for 10 min and the extracts were separated from the termites and then stored at −20°C.

Additionally, an extract of 10 *P. canalifrons* soldiers was prepared to establish retention indices of the compounds on a polar column. To confirm the origin of the sesquiterpenes and nitroalkenes, the contents of a *P. simplex* soldier frontal gland were carefully removed with a microcapillary by piercing the body wall at the third abdominal segment and then analyzed by GC-MS.

Results and Discussion

GC-MS analysis of the three species revealed large quantities of (*E*)-1-nitropentadec-1-ene, along with much lower amounts of the homologs, (*E*)-1-nitroheptadec-1-ene, 1-nitrotridec-1-ene, and trace amounts of 1-nitrotetradec-1-ene, 1-nitrohexadec-1-ene, nitropentadecadiene, and nitroheptadecadiene. The composition and relative ratios of the nitroalkenes were similar across the three species. The much lower amounts of the nitroalkenes with an even number of carbon atoms, in comparison to those with an odd number, follows the pattern for hydrocarbons and their derivatives in insect cuticle (Blomquist and Dillwith 1985).

All the nitroalkenes from the frontal gland extracts gave mass spectra similar to that of (*E*)-1-nitropentadec-1-ene with diagnostic ions of $M^{+\bullet}$, $[M–OH^{\bullet}]^{+}$, and $[M–OH^{\bullet}–H_2O]^{+}$ (Table 1), together with *m/z* 30 and 46, corresponding to $[NO]^{+}$, and $[NO_2]^{+}$, respectively. In the mass spectrum of all of the nitro-olefins, a peak at *m/z* 87 was found and assigned to $[C_3H_5NO_2]^{+}$, which originates from α-cleavage of 1-nitro-olefins with the conjugated double bond $RCH{=}CHNO_2$. This assignment of *m/z* 87 was confirmed by analysis of the (*E*)-1-nitropentadec-1-ene standard, which also contained (*E*)-1-nitropentadec-2-ene impurity. No *m/z* 87 was present in the mass spectrum of the latter compound, which eluted prior to nitropentadec-1-ene on the ZB-5 column and which otherwise gave a similar fragmentation pattern. The identity of (*E*)-1-nitropentadec-2-ene was confirmed by GC/FT-IR. In alkenes, the position of the nitro group (a strong electron-withdrawing group), with respect to the

Table 1 Analytical data of nitro compounds from frontal gland of *P. canalifrons* soldiers

Compound	*m/z*: $M^{+\bullet}$, $[M–OH^{\bullet}]^+$, $[M–OH^{\bullet}–H_2O]^+$	RI on ZB-5
Nitrotridecane	229, 212, 194	1,762

RI = retention index

double bond, determines the wavelength of the C–H asymmetrical stretching, C=C stretching, and C–H wagging peaks in the infrared spectrum, thus allowing determination of nitroalkene configuration (Brown 1955). Peaks at 3,043, 1,668, and 968 cm^{-1} in the gas-phase FT-IR spectrum of this compound shifted in comparison with the values found for (*E*)-1-nitropentadec-1-ene (Table 2), indicating the presence of the $-CH=CHCH_2NO_2$ moiety in *trans* configuration.

An attempt to determine the carbon–carbon double bond position in the nitroalkenes from soldiers by chemical ionization ion-trap MS using acetonitrile failed to form any adducts, further supporting the presence of the $-CH=CHNO_2$ moiety in these chemicals. In this method, the ion $[C_3H_4N]^+$, originating from fragmentation of acetonitrile, reacts with a C=C double bond, indicating the position of the double bond (Oldham and Svatoš 1999). However, the $-CH=CHNO_2$ moiety did not react with $[C_3H_4N]^+$ due to the strong electron withdrawing effect of the nitro group conjugated with the carbon–carbon double bond.

The amounts of nitropentadecene in the soldier frontal gland secretions were fairly similar among the three *Prorhinotermes* species, reaching up to 300 μg/individual (Table 3). Apart from the nitroalkenes, we also detected two nitroalkanes (Table 1) at similar amounts in all samples. It has previously been shown that *P. simplex* workers reduce (*E*)-1-nitropentadec-1-ene, secreted by colony soldiers, to 1-nitropentadecane using a specific oxidoreductase (Spanton and Prestwich 1981), thereby detoxifying the defensive compound. We believe that nitrotridecane and nitropentadecane found in our extracts may be detoxification products in soldiers.

Although the nitroalkene content in the frontal gland was similar across the three species, the sesquiterpene hydrocarbon content differed considerably. Soldiers of *P. simplex* contained (3*Z*,6*E*)-α-farnesene, with no other α-farnesene or sesquiterpene isomers detected. *P. inopinatus* soldiers contained two geometric isomers of α-farnesene, (3*Z*,6*E*) and

	152±89	**207±60**	**294±68**

[a] For six individuals only: in three individuals, the level of (3*Z*,6*E*)-α-farnesene was too low for a reliable quantification and in the other it has not been detected

(3*E*,6*E*), while *P. canalifrons* soldiers contained the same two α-farnesene isomers along with smaller amounts of *trans*-β-bergamotene and (*Z*)-γ-bisabolene (Table 4). *P. canalifrons* and *P. inopinatus* differed significantly ($P<10^{-3}$, Mann–Whitney *U* test) in the relative amounts of the two α-farnesenes (Table 3, Fig. 2). The main sesquiterpene in *P. inopinatus* is (3*Z*,6*E*)-α-farnesene with lower amounts of the (3*E*,6*E*) isomer. However, in *P. canalifrons*, the (3*E*,6*E*) isomer was more abundant. The quantity of (3*Z*,6*E*)-α-farnesene in *P. simplex* soldiers was much higher than in soldiers of the other two species (Table 3), in agreement with our earlier report (Šobotník et al. 2004) .

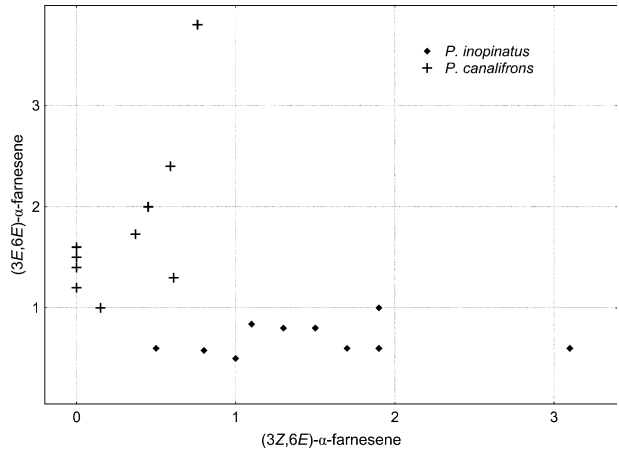

Fig. 2 Quantities (μg/individual) of α-farnesene isomers from the frontal gland of individuals of *P. inopinatus* and *P. canalifrons* soldiers

In comparison to the closely related *Coptotermes* genus, in which the defensive secretion of lactones forms a glue-like material after release (Deligne et al. 1981), the *Prorhinotermes* secretion remains fully liquid. The large amounts of chemicals found in an individual soldier in our analyses are probably sufficient to defeat numerous intruders; for example, 10 μg of nitropentadecene is the LD_{50} for the house fly *Musca domestica* (Kuldová et al. 1999). In addition, the relatively large percentage (10%) of soldiers in a *Prorhinotermes* colony means that large amounts of defensive compounds are available for repelling numerous intruders or even relatively large predators from the colony. Although this may provide good protection for *Prorhinotermes* colonies, it comes at a relatively high price: the use of relatively large amounts of rare nitrogen.

Acknowledgements We are grateful to Christian Bordereau and Alain Robert for providing us with the *P. canalifrons* colony. The *P. inopinatus* material was obtained thanks to a project funded by the US National Science Foundation (DEB-02-11591). We kindly acknowledge Anna-Karin Borg-Karlson for the gift of pure (3*E*,6*E*)-α-farnesene and Erin Walsh for the language corrections. Financial support was provided by the Grant Agency of the Academy of Sciences of the Czech Republic (A600550614), and the Z4 055 0506 project realized in the Institute of Organic Chemistry and Biochemistry, Academy of Sciences of the Czech Republic, Prague.

Introduction

Egg hatching on the Caribbean spiny lobster, *Panulirus argus*, is a highly synchronous event occurring before the ebbing tide, which assists the larvae in being transported by currents to offshore nursery areas (Yeung and Lee 2002). This timing is critical as it ensures that larvae are released at times in which transport is optimal as well as at times that minimize the threat of predation and exposure of larvae to adverse conditions (Forward 1987; Morgan 1995).

Synchrony of larval release among marine crustaceans is mediated by chemical-based communication between the hatching eggs and the ovigerous female (Rittschof et al. 1985, 1989, 1990a, b; Forward et al. 1987; De Vries and Forward 1991a; De Vries et al. 1991; Ziegler and Forward 2007). Pheromones originating from the hatching embryos induce the ovigerous female to perform stereotypical larval release behaviors (e.g., Ennis 1973, 1975; Branford 1978; Moller and Branford 1979; DeCoursey 1983; De Vries and Forward 1991a; Ziegler and Forward 2007). Among spiny lobsters, the female lobster uses her walking legs to probe her egg mass while she rapidly flexes and extends her abdomen, all the while actively beating the pleopods back and forth. During larval release, this vigorous "pleopod pumping" behavior assists in the egg hatching process by compressing the egg mass. Compression of the egg mass helps to break open egg membranes and free the larvae, which then swim into the water column. As more eggs hatch, more pheromone is released, causing the female to pump harder. This positive feedback system leads to a synchronous release of larvae (Forward 1987; Tankersley et al. 2002; Ziegler and Forward 2007).

Previous experiments suggest that chemical cues mediate these behaviors among spiny lobsters. Pleopod pumping activity of ovigerous females with late-stage embryos increases when they are exposed to hatch water (the medium into which larvae have been released; Ziegler and Forward 2007). Solutions of homogenized late-stage embryos and homogenized egg cases also induce larval release behaviors in lobsters with late-stage embryos. These observations suggest that a substance(s) is released at the time of hatching that acts to induce stereotypical pleopod pumping behaviors of the female.

Peptides are effective communication molecules in the marine environment because of their high solubility, high specificity, short half-life, and high signal-to-noise ratio (Rittschof et al. 1992; Pettis et al. 1993; Atema 1995; Decho et al. 1998; Rittschof and Cohen 2004). Small peptides originating from the proteolysis of egg cases may be the compounds responsible for coordinating synchronous release of larvae, as crabs display similar larval release pumping behaviors when exposed to solutions containing specific peptides (Rittschof et al. 1985, 1989; Forward et al. 1987). For the crab *Rhithropanopeus harrisii*, the developing embryos control the exact time of hatching, whereas the female controls the synchrony of hatching (Forward and Lohmann 1983). Ovigerous females exposed to partially identified native peptides or to pheromone analogs will initiate the pumping response, a behavior used to measure pheromone activity (Forward et al. 1987; Rittschof et al. 1989; Pettis et al. 1993).

We hypothesize that ovigerous spiny lobsters will respond to the same peptides that produce a larval release pumping response in brachyuran crabs (Forward et al. 1987; Pettis et al. 1993; Rittschof 1993). We used the stereotypic larval release behaviors of ovigerous spiny lobsters as a biological assay to investigate the chemistry of the substances released upon egg hatching. Measurements of pleopod pumping frequencies in response to various model peptides at several concentrations were used to determine which chemical cues are used by lobsters. These substances are collectively termed "pumping pheromones". We tested a logical series of di- and tripeptides and two oligopeptides: bradykinin, a barnacle settlement pheromone mimic recently implicated as a larval release pheromone (Rittschof

and Cohen 2004); as well as its complement des–Arg^9–bradykinin, which lacks arginine (Arg) at the basic carboxyl terminus. These compounds were chosen based upon the compositional analysis of partially purified native pheromones from previous studies on brachyuran crabs (e.g., Forward et al. 1987; Rittschof et al. 1985, 1989). No peptides were extracted from the lobsters; rather, we evaluated these logical synthetic candidates for activity. We demonstrate that pleopod pumping responses are evoked by peptides, which have a neutral amino acid at the amino terminus and a basic amino acid at the carboxy terminus, suggesting that specific peptides mimic or act as crustacean pheromones. According to the model for egg hatching, trypsin-like enzymes from hatching eggs would break down the egg membrane and cleave these peptides that are released in the water. The parent female senses the chemical, which stimulates her to pump her pleopods, and thus, results in the synchronous release of larvae.

Methods and Materials

Collection and Maintenance of Spiny Lobsters Ovigerous *P. argus* were collected by hand by using SCUBA from coral reefs near the Keys Marine Laboratory on Long Key, FL (24°49.567N, 80°48.884W) from April to August 2006. Lobsters were maintained in individual glass aquaria containing about 75 l of continuously aerated seawater (salinity of 35–36; 27°C) that was filtered to remove particles >5 μm. The water in the aquaria was changed daily at random times, and the lobsters were fed frozen squid and shrimp every other day. A 14:10-hr photoperiod that simulated the ambient light/dark cycle at the time of collection was employed.

Before experimentation, ovigerous females were classified according to the developmental stage of their egg masses. A small group of embryos (N=20) was removed from the egg mass and examined under a dissecting microscope. Only lobsters with embryos that would hatch within 24–36 hr were tested, as female responsiveness to chemical cues that induce larval release behavior increases with embryo maturity. Females with late-stage embryos are more responsive than females with early-stage embryos (Ziegler and Forward 2007).

Peptide Solutions All test chemicals were obtained from Sigma Chemical Company. The peptides used were chosen based on previous studies with brachyuran crabs (e.g., Forward et al. 1987; Rittschof et al. 1989; De Vries and Forward 1991a). These include dipeptides composed of various combinations of neutral, basic, and acidic amino acids (Table 1), as well as several tripeptides and two oligopeptides. According to Rittschof et al. (1985) and De Vries et al. (1991), bioassays that used solitary amino acids alone did not induce pumping in previous studies on brachyuran crabs. Therefore, we did not test individual amino acids.

Test solutions containing peptides were prepared immediately before use in aged offshore seawater (salinity 35), which had been filtered to remove particles >0.5 μm. Previous studies found that aged offshore water lacked chemical cues that induce larval release behaviors (e.g., Rittschof et al. 1985, 1989). A stock solution for each peptide was made at 10^{-4} M and diluted for testing. An aliquot of the peptide solution was mixed into 15 l of filtered offshore water to form the appropriate test concentration.

Pumping Assay The frequency of pleopod pumping upon exposure to the test compounds was used as a bioassay to quantify larval release behavior of the female. The general

Table 1 Pleopod pumping response measurements of ovigerous *P. argus* to dipeptides

Dipeptide	Response Threshold Concentration (M)	Maximum Response (%)	Effective Concentration Range (log units)
Neutral–basic			
Glycine–arginine (Gly–Arg)	10^{-9}	51.8	4

Acid–acid			
Glutamic acid–glutamic acid (Glu–Glu)	No response	–	–

experimental procedure was, first, to place an ovigerous female in a glass aquarium (50.8× 25.4 cm) containing 15 l of filtered (>0.5 μm) offshore seawater that did not contain the test solution. After a 5-min acclimation period, the number of pleopod movements was counted during a 1-min interval. This count is a measure of the *unstimulated* pumping rate. Second, the same lobster was transferred immediately to an identical aquarium with a test solution, and, after 5 min of acclimation, the number of movements in a 1-min period was counted. This second count was the *stimulated* pumping rate. An increase in pleopod pumping rate upon exposure to the test solution was considered a positive response. If pumping activity decreased or stayed the same, the lobster was scored as unresponsive.

For each test solution, a lobster was tested in a series of five or more concentrations, ranging from 10^{-4} to 10^{-12} M. The first solution in the series contained filtered offshore water (concentration=0 M), which served as a control (the unstimulated pumping rate). Lobsters were tested sequentially with the remaining concentrations proceeding from the lowest to highest to minimize the chances of sensory adaptation. Individuals were tested once at each test concentration. Each lobster was placed in filtered seawater (control) for at least 30 min before being retested at the next higher concentration. Preliminary experiments indicated that 30 min was sufficient time between exposures to test solutions for the lobster to return to the same pumping rate as in offshore water (i.e., unstimulated pumping rate). To ensure that test solutions remained active, solutions were remade after eight to ten lobsters were tested.

Pleopod pumping responses to the test peptides were characterized three ways: (1) response threshold concentration, (2) effective concentration range, and (3) maximum percent response (Rittschof et al. 1989). The response threshold concentration is defined as

the lowest concentration of a test substance to evoke a significant increase in pumping rate ($P<0.05$) relative to the pumping rate observed in the control (offshore water). The effective concentration range is the molar concentration range between the response threshold concentrations and the next higher concentration at which the pumping rate returns to the control level. The maximum percentage of response is the highest percentage of lobsters that responded to a test concentration within the effective concentration range (Forward et al. 1987; Rittschof et al. 1989).

The sample sizes for each test solution ranged from 12 to 20. Responses of lobsters to test solutions were compared to control responses (in filtered offshore water) by using a χ^2 test for multiple proportions and a Dunnet-type multiple comparisons test (Zar 1999).

Results

Pleopod Pumping Responses to Dipeptides Pleopod pumping responses by ovigerous *P. argus* to the test dipeptides varied with the amino acid composition of the peptide (Fig. 1). Pumping responses were elicited by all dipeptides with arginine (Arg) at the carboxy terminus (Table 1). Response threshold concentrations ranged from 10^{-6} M for Lys–Arg to 10^{-9} M for Gly–Arg. The maximum percent response ranged from 24.3 to 51.8%, with the greatest number of animals responding to Gly–Arg (Table 1). The effective concentration range for each active dipeptide was at least 2 log units of concentration, and was as high as 4 log units for Gly–Arg. Only dipeptides with a neutral–basic or basic–basic structure were active. No significant pumping responses were observed for any of the other dipeptide combinations tested (Table 1).

The dose-response curves for dipeptides that induced a significant response show a similar trend (Fig. 1). As concentration increases, pumping activity rises from a threshold to a maximum level, then declines at higher concentrations, sometimes to a non-significant level (e.g., Ala–Arg).

Pleopod Pumping Responses to Tripeptides Most of the test tripeptides with Arg at the carboxy terminus produced a significant pleopod pumping response, with the exception of

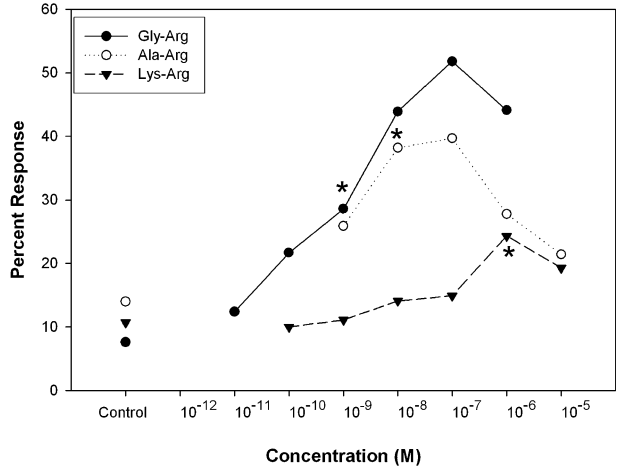

Fig. 1 Percentage of ovigerous *P. argus* responding to dipeptides. Control is the pumping response level upon exposure to filtered offshore water. Lowest concentration at which the pumping response was significantly greater than the controls ($P<0.05$) is indicated by an *asterisk*. ($N=18$ for all test solutions)

Trp–Ile–Arg (Fig. 2). Response thresholds ranged from 10^{-8} M for Gly–Gly–Arg to 10^{-6} M for Pro–Ile–Arg (Table 2). The maximum response ranged from 38.4 to 58.3%, with the highest pumping response observed for Gly–Gly–Arg (Table 2). The effective concentration range for each tripeptides was at least 3 log units of concentration.

The neutral–basic-basic tripeptide Gly–His–Lys also produced a significant pumping response (Fig. 2), with a response threshold of 10^{-4} M and a maximum response of 26.1%, which was the lowest of all tripeptides tested (Table 2). There was no significant pumping response when lobsters were subjected to increasing concentrations of the neutral–neutral–basic tripeptide Gly–Gly–His (Fig. 2; Table 2). These results indicate that neutral-basic amino acid combinations of tripeptides with Arg or Lys at the carboxy terminus are capable of inducing a significant pleopod pumping responses for *P. argus* (Table 2).

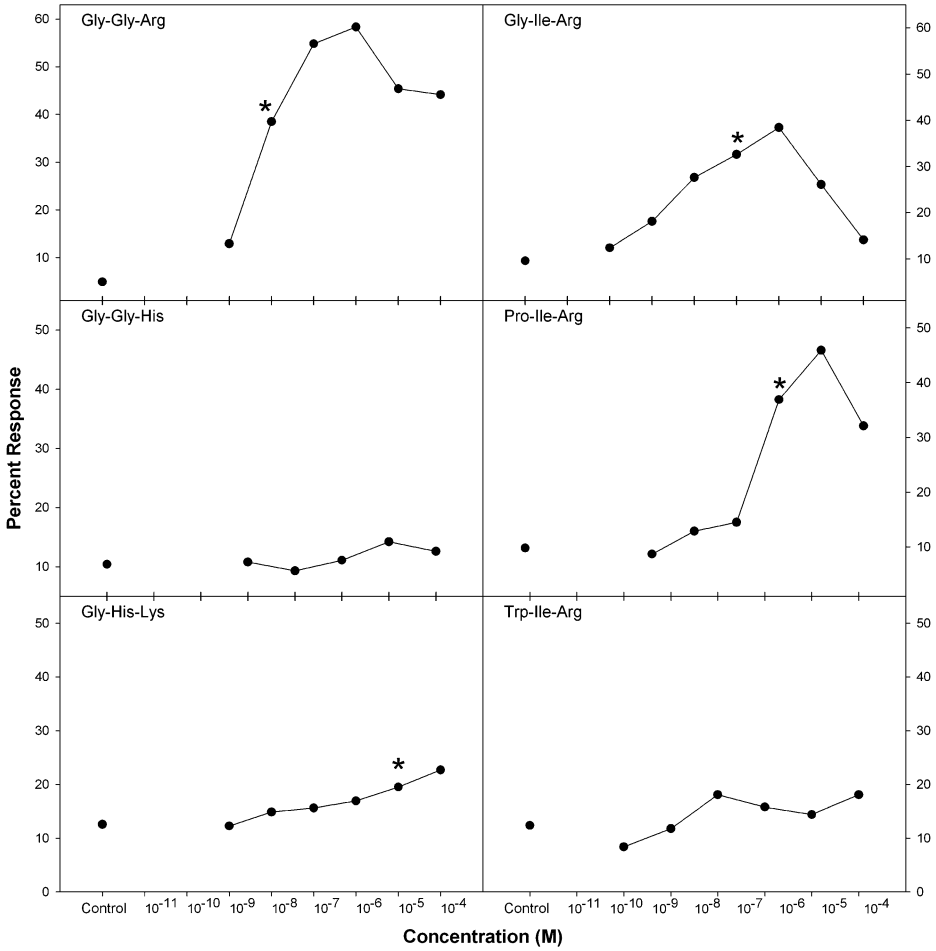

Fig. 2 Percentage of ovigerous *P. argus* responding to tripeptides. Control is the response level upon exposure to filtered offshore water. Lowest concentration at which the pumping response was significantly greater than the controls ($P<0.05$) is indicated by an *asterisk*. ($N=12$ for Gly–Gly–His and Trp–Ile–Arg, $N=14$ for all other test solutions)

Table 2 Pleopod pumping response measurements of ovigerous *P. argus* to tripeptides

Tripeptide	Response Threshold Concentration (M)	Maximum Response (%)	Effective Concentration Range (log units)
Neutral–neutral–basic			
Glycine–glycine–arginine (Gly–Gly–Arg)	10^{-8}	58.3	4
Glycine–isoleucine–arginine (Gly–Ile–Arg)	10^{-7}	38.4	3
Proline–isoleucine–arginine (Pro–Ile–Arg)	10^{-6}	45.9	3
Tryptophan–isoleucine–arginine (Trp–Ile–Arg)	No response	–	–
Glycine–glycine–histidine (Gly–Gly–His)	No response	–	–
Neutral–basic–basic			
Glycine–histidine–lysine (Gly–His–Lys)	10^{-4}	26.1	1

The dose-response curves for tripeptides that induced a significant response show a similar trend (Fig. 2). As concentration increases, pumping activity rises from a threshold to a maximum level, then declines at higher concentrations, but rarely to a non-significant level. An exception is Gly–His–Lys, in which responses modestly increased with increasing concentration.

Pleopod Pumping Responses to Bradykinin Pleopod pumping rate increased when ovigerous lobsters were subjected to increasing concentrations of bradykinin, an oligopeptide with Arg at the basic carboxy terminus (Fig. 3). Pumping rates were not significantly different from the control when lobsters were subjected to increasing concentrations of des–Arg–bradykinin, an oligopeptide without a basic amino acid at the carboxy terminus (Fig. 3). The response threshold for bradykinin was 10^{-7} M, with a maximum response of 52.9% (Table 3). The effective concentration range for bradykinin was over 3 log units of concentration (Fig. 3; Table 3). These data suggest that the

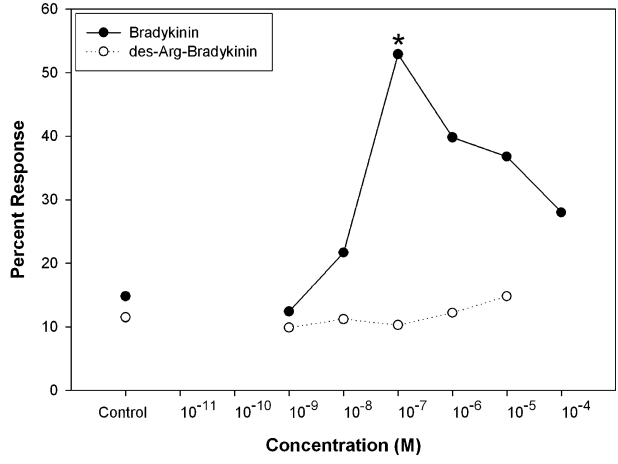

Fig. 3 Percentage of ovigerous *P. argus* responding to bradykinin (arginine at carboxy terminus) or des–Arg–bradykinin (lacking arginine at the carboxy terminus). Control is the response level upon exposure to filtered offshore water. Lowest concentration at which the pumping response was significantly greater than the controls ($P<0.05$) is indicated by an *asterisk*. ($N=20$ for both concentrations)

Table 3 Response measurements of ovigerous spiny lobsters to oligopeptide sequences with a basic carboxyl terminal (bradykinin) or without (Des–Arg^9–bradykinin)

Oligopeptide	Response Threshold Concentration (M)	Maximum Response (%)	Effective Concentration Range (log units)
Bradykinin Arg–Pro–Pro–Gly–Phe–Ser–Pro–Phe–Arg	10^{-7}	52.9	3
Des–Arg^9–Bradykinin Arg–Pro–Pro–Gly–Phe–Ser–Pro–Phe	No response	–	–

oligopeptide bradykinin has the correct chemical format of neutral–basic amino acid combination at the carboxyl terminal, which is capable of inducing a significant pleopod pumping responses for *P. argus* (Table 3).

As the concentration of bradykinin increases, pumping activity rises from a threshold (10^{-7} M) to a maximum level, then declines (Fig. 3). This response pattern was similar to the curves for Gly–Arg, Gly–Gly–Arg, and Pro–Ile–Arg (Figs. 1, 2,and 3).

Discussion

Our model for larval release by the spiny lobster *P. argus* proposes that egg hatching readiness is communicated to the female by the release of peptide pheromones from the embryos (Forward and Lohmann 1983; Rittschof et al. 1985; Ziegler and Forward 2007). These pheromones induce the female to undergo stereotypical behaviors involving rapid movements of pleopods. This physical "pumping" activity assists in the rupture of the egg membranes and the subsequent release of free swimming larvae. Peptides that elicit a positive response are considered to be "active peptides". Our results show that specific peptides were capable of inducing the larval release behavior.

Peptides with Arg or Lys at the carboxy terminus and an adjacent neutral or basic amino acid were capable of inducing a pumping response in ovigerous *P. argus* (Tables 1, 2, and 3). The compounds with the lowest threshold concentration for inducing the pumping response were Gly–Arg (threshold at 10^{-9} M), followed by Gly–Gly–Arg and Ala–Arg (thresholds both at 10^{-8} M). Bradykinin was able to induce pleopod pumping in *P. argus* at a response threshold of 10^{-7} M. This result suggests that increased potency might be achieved by decreasing the length of the peptide. The shortest peptide (Gly–Arg) had the lowest threshold concentration.

In terms of response threshold, peptides with Arg at the carboxy terminus are more active than those containing Lys (Tables 1 and 2). Arg has an additional amino group, and thus, is more basic than Lys. In addition, Lys has a shorter chain length (R group) with a lower pK_a. Such structural differences may explain the differences in response levels. The basic tripeptide Gly–His–Lys produced a significant pumping response (Fig. 3); however, the concentration necessary to produce a significant response was $>10^{-4}$ M. This is quite high in comparison to peptides with Arg. Active peptides containing Lys at the carboxy terminus were able to induce a significant response in the mud crab *R. harrisii*, but only at threshold levels that were higher than amounts possible in the natural pumping pheromones (Rittschof et al. 1985; Forward et al. 1987). Thus, peptides containing Lys at the carboxy terminus may not be used as pheromones for *P. argus*.

The peptides tested that induced significant responses were at similar concentrations to the concentrations predicted for the native pheromones in brachyuran crabs (Forward et al. 1987; Rittschof et al. 1989). The lower threshold for the most active peptides tested (Gly–Arg, Gly–Gly–Arg, Ala–Arg, and bradykinin) ranged from 10^{-7} to 10^{-9} M for *P. argus*. These thresholds are 3–4 orders of magnitude below those peptides used as pheromones by other marine invertebrates such as the sand dollar *Dendraster excentricus* (Burke 1984), the abalone *Haliotis* (Morse 1988), the barnacle *Balanus amphitrite* (now known as *Amphibalanus amphitrite*; Tegtmeyer and Rittschof 1989), and the cnidarian *Cassiopeia andromeda* (Fleck 1998; Walther and Fleck 1998). Thus, sufficient amounts of these peptides could be released by the eggs to serve as pheromones.

The chemical induction of the behavioral response occurs only within a narrowly defined concentration range. Responses typically decline when the concentrations are either more or less that one magnitude from the concentration that evokes the greatest responses (Forward et al. 1987; Rittschof et al. 1989; Browne et al. 1998; Decho et al. 1998). Peptides such as Ala–Arg, Gly–Ile–Arg, and bradykinin are inhibitory at high concentrations. This inhibition may be caused by inhibition at the neural level (Derby and Atema 1988; Rittschof et al. 1989).

These results are consistent with previous studies of chemically induced larval release in crustaceans. The chemical nature of pumping pheromones for brachyuran crabs has been determined to be a heterogeneous group of small peptides containing Arg (Rittschof et al. 1985, 1989; Forward et al. 1987). Behaviorally active peptides have a general structure of a neutral amino acid at the amino terminus (e.g., alanine) coupled to a basic amino acid at the carboxy terminus (e.g., arginine; Forward et al. 1987; Rittschof et al. 1989; Pettis et al. 1993). Other common characteristics of these active peptides include a positively charged R group attached to the carboxy-terminal and a hydrophobic R group attached to the amino-terminal end of the molecule (Pettis *et al.* 1993).

Peptides capable of inducing the pumping response in the crab *R. harrisii* have Arg as the carboxy terminal residue and a neutral amino acid at the hydrophobic residue (Forward et al. 1987). An amino acid analysis of the pumping factors previously indicated that peptides with histidine (His) were not among those associated with *R. harrissi* (Rittschof et al. 1985), although Gly–His–Lys produced a significant pumping response (Forward et al. 1987). This is consistent with our results for *P. argus* in which the tripeptide Gly–His–Lys produced a significant pumping response, whereas Gly–Gly–His did not. These results suggest that His cannot be the carboxy terminal residue in the peptide pheromone.

Although His is a basic amino acid, it contains an imidazole ring structure, and thus, may lack the necessary components to act as a chemical signal in this system. Lys and Arg are more basic amino acids than His. The pK_a values for Lys and Arg indicate that their side chains are always positively charged under physiological conditions. These amino acids are strongly polar, and, as a consequence, can easily be hydrated by the surrounding aqueous environment. Histidine has a pK_a in physiological range and is often incorporated into protein active sites. The imidazole can exchange protons at physiological (neutral) pH, and thus, it often plays a role in enzymatic catalysis (Mathews et al. 1999).

Peptides with Arg or Lys at the carboxyl terminus are produced by trypsin-like serine proteases, which cleave after basic amino acids. Therefore, the pheromones that induce pumping behavior may be generated by trypsin-like serine proteases capable of digesting the membrane around the embryos of spiny lobsters. Trypsin-like activity may result from enzymes released by embryos (Rittschof et al. 1990a, b; De Vries and Forward 1991b). The brachyuran crabs *Neopanopae sayi*, *Uca pugilator*, and *Sesarma cinereum* release proteolytic enzymes near the time of hatching (De Vries and Forward 1991b). These assist

with the breakage of the outer membrane of the egg case, resulting in the emergence of a free-swimming larva. A logical extension of our work is to test the hypothesis that peptide pumping pheromones are created by enzymatic activity (Rittschof et al. 1990a, b).

Results from the present study support the hypothesis that larval release behaviors are induced by active substances (pheromones) composed of small peptides. The active peptides likely have a specific amino acid sequence of neutral–basic and neutral–neutral–basic di-, tri- and oligopeptides. These biologically potent peptides are effective at concentrations from 10^{-4} to 10^{-9}. The results of this study support the conceptual model that larval release in spiny lobster *P. argus* is controlled by pheromones released from hatching eggs that act to induce the stereotypical pumping behaviors of the female, synchronizing larval release.

Releasing larvae in synchrony with the time of slack water before the ebbing tide allows the phyllosoma larvae to enter the water column at a beneficial time for transport by currents to offshore nursery areas for development (Yeung and Lee 2002). This synchronous timing also ensures that larvae are released at times that minimize the threat of visual predation and exposure of larvae to adverse conditions such as low salinity and high temperatures (Forward 1987).

Acknowledgements This material is based in part on research supported by the National Science Foundation grant number OCE-0221099 and ECOHAB grant number NA170P2725, with additional funding from the Oak Foundation. All research was conducted according to the conditions of the FFWCC Special Activities License #05SR-9340. We thank Lonny Anderson, Dr. Mary Alice Coffroth, Todd Hitchins, Matthew Hoxie, Karen Neely, Daniel Poland, and Adrianna Zito for support with lobster collection. Gary Dickinson and Joshua Osterberg provided valuable comments to the manuscript. We also thank Dr. Dan Rittschof for helpful suggestions with the design and analyses of these experiments.

Skin (epidermal) glands, the blood–skin barrier, cloacal glands, feces, and urine have been described as potential sources of pheromones in lizards (Mason 1992). In these animals, epidermal glands, and in particular, the femoral glands (holocrine, tubulo-follicular, sebaceous-type glands) in the femoral and pre-cloacal regions, have received the most attention (Quay 1986; Van Wyk and Mouton 1992; Dujsebayeva 1998). Another type of epidermal gland, the "generation" gland [mostly holocrine secretory cells located in the beta-layer of the epidermis (Maderson 1967; Van Wyk and Mouton 1992)], is also known to occur in the femoral, pre-cloacal, antebrachial (fore-arm), and dorsal epidermal regions in cordylid lizards (Van Wyk and Mouton 1992).

Reports regarding the chemical nature of the material secreted by the epidermal glands of lizards are limited to studies on the femoral and pre-cloacal glands (Alberts 1990; Weldon et al. 1990; Alberts et al. 1992, 1993; Escobar et al. 2001, 2003; López and Martín 2005a, b, 2006). Alberts (1990) reported proteins and lipids as the main components of the femoral secretion of the desert iguana, *Dipsosaurus dorsalis*, in a ratio of 4:1, respectively. The composition of the proteins varied among individuals. These proteins absorb ultraviolet light and may be used to facilitate visual detection of the deposited secretion by conspecifics (Alberts 1990; Alberts et al. 1993). In addition, volatile lipids could also act as olfactory cues for the detection of femoral secretions (Alberts 1990). In male green iguanids, Alberts et al. (1992) found seasonal variations in the lipid composition, but in contrast to the proteins, little individual variation was observed. Volatile lipids in these secretions could have a semiochemical function (Mason and Gutzke 1990; Escobar et al. 2001, 2003).

Alberts et al. (1992) identified a number of lipids, including carboxylic acids and steroid alcohols, in the femoral secretion of the lizard, *Iguana iguana*. Escobar et al. (2001, 2003) reported 49 lipids in 20 *Liolaemus* species. As in other lizard species (Chauhan 1987; Alberts 1990; Alberts et al. 1992), these compounds belong to three main classes, alkanes, carboxylic acids, and steroids. Information on a possible pheromonal role of the epidermal gland secretions of squamates is limited. Variation in the incidence and relative amounts of specific compounds has, nevertheless, been attributed to intraspecific (Alberts 1990; Escobar et al. 2003), interpopulational (Escobar et al. 2003), and interspecific differences (Cooper and Vitt 1986; Escobar et al. 2001).

If one accepts that chemicals in the femoral secretions play a role in the communication of lizards, then this raises the question of whether the major constituents, such as the fatty acids that are almost ubiquitous in nature, are the major semiochemicals of these animals, or whether minor components, perhaps overlooked in the investigations, are involved? To shed more light on this question, we started analyzing lizard secretions by using highly sensitive chemical methods.

The family Cordylidae (girdled lizards) is one of the lesser-known lizard families of the world and is restricted to the southern subcontinent of Africa (Frost et al. 2001). Femoral glands occur on the ventral aspect of the thigh in males, and in some species, also in the females (Mason 1992). The cordylid femoral glands correspond to the tubulo-follicular sebaceous type holocrine glands found in other lizards (Cole 1966; Quay 1986). The so-called sungazer, *Cordylus giganteus*, a large terrestrial girdled lizard, inhabits the Highveld *Themeda* grasslands in parts of the Free State, KwaZulu-Natal, and Mpumalanga provinces of South Africa (Van Wyk 1992; Branch 1998). Both sexes possess femoral glands in the ventral femoral region of the hind legs.

Males also exhibit generation glands as a patch of glandular scales, anterior to the single row of femoral glands. In addition, males have a patch of generation glands on the ventral aspect of the antebrachial (fore-arm) region (Van Wyk and Mouton 1992). The secretions of

these glands were not investigated in the present study. Due to the nature of their grassland habitat, visual communication may be of limited value, and therefore, chemical communication is a possible alternative. *C. giganteus* is also recognized as a species showing high refuge fidelity (Ruddock 2000) in a rather homogenous habitat, further suggesting the use of chemical cues for site recognition.

Here, we describe a comprehensive chemical characterization of the volatile constituents of the femoral gland secretions of *C. giganteus*. For the first time, the chemical properties of the secretions of a lizard species of the family Cordylidae are reported.

Methods and Materials

General

All Pyrex glassware was thoroughly cleaned with water and acetone, and heated to 500°C to remove any residual organic material. Dichloromethane (Fluka, Residue Analysis Grade) was used for extraction of organic material from collected samples. Syringes were cleaned with the same solvent.

Collection and Sample Preparation

Femoral gland secretions were collected from individual adult male and female lizards in a study population on a farm in the Lindley district (Free State Province, South Africa; 28°01′S, 28°05′E) during the months of April 1998 (11 males and 12 females), October 1998 (5 males and 5 females), and January 1999 (5 males and 5 females). Secretions were collected by squeezing plugs of the secretion from the femoral pores on the hind legs of the lizards, by using a pair of forceps. The collected material was transported to Stellenbosch at −10°C and stored at −70°C until processed for analysis.

Organic constituents were extracted with 150 μl of dichloromethane from secretions of individual lizards. The extracts were filtered and concentrated to ca 10 μl by slow evaporation in a nitrogen atmosphere. Samples of 0.2 to 1.0 and 1.0 μl, of the concentrated extracts were used for qualitative and quantitative analyses, respectively.

For the determination of the amount of each chemical in the femoral gland secretion, the secretion (11.44 or 10.89 mg, respectively) of a male or a female lizard was extracted with four portions of 200 μl dichloromethane. The extract was slowly evaporated to dryness in an inert atmosphere at 22°C, and the residual material dissolved in 20 μl of an internal standard solution containing 49 μg of octadecane/ml in dichloromethane. One mircoliter of each of these solutions was used for the analysis by GC.

Analytical Techniques

Gas chromatographic (GC) analyses were performed on Carlo Erba 4160 and 5300 GCs, while the quantitative analysis was carried out with an HP 5890 Series II GC. All instruments were equipped with a flame ionization detector (FID) and split/splitless inlet systems, with the injector and detector at 220 and 280°C, respectively. Helium was used as carrier gas at a linear flow velocity of 28.6 cm sec^{-1}. Glass capillary columns (40 m × 0.3 mm i.d.) were coated with PS-089-OH [silanol-terminated (95%)-methyl-(5%)-phenylpolysiloxane copolymer] at a film thickness of 0.25 μm. Samples were injected in the split mode by using a split ratio of 1:10. The volatile chemicals were thermally focused on the column at a temperature of 30°C, after

which, the column was heated ballistically to 40°C and then programmed at 8°C min^{-1} from 40 to 160°C, followed by 2°C min^{-1} to 280°C (hold 60 min).

Electron impact mass spectra (EI-MS) were acquired at 70 eV on a Carlo Erba QMD 1000 GC-MS instrument, using the same column and conditions as above. For the analysis of steroid derivatives, a mass range of *m/z* 25–550 was selected. An ion source temperature of 200°C and an interface temperature of 250°C were used for all analyses. Some GC-MS analyses were carried out on a Fisons MD-800 instrument using the parameters specified above.

High-resolution GC-MS analyses of an extract from a male sungazer were performed on an AMD Intectra 604 high-resolution mass spectrometer coupled to a Carlo Erba 4160 gas chromatograph using the gas chromatographic parameters specified for the QMD 1000 instrument.

Trimethylsilyl Derivatives

An extract of femoral gland secretion was concentrated in a Reacti-Vial left uncapped in a nitrogen atmosphere to yield approximately 1 mg of solvent-free material. Methoxylamine hydrochloride (5.23 mg, 0.0626 mmol) dissolved in pyridine (50 μl) was added to the material. The reaction mixture was heated in a GC oven for 15 min at 60°C, after which, the solvent was carefully blown off with nitrogen. Trimethylsilylimidazole (75 μl, 0.511 mmol) was added to the reaction product and the reaction mixture heated at 100°C for 2 hr in a capped vial (Thenot and Horning 1972). The sample was concentrated to about 50 μl in a nitrogen atmosphere while the reaction product was still hot. Approximately 2 μl of this solution was used for a GC-MS analysis.

Reference Compounds

Most of the compounds used to confirm the identity of the chemicals of the femoral gland secretions were obtained commercially or were available from previous studies. The following compounds were synthesized.

Dodecyl propenoate (**2**) was synthesized by a transesterification procedure described by Rehberg (1955). Dodecanol (16.3 g, 87.5 mmol) and methyl propenoate (25.0 g, 291 mmol) were refluxed in a nitrogen atmosphere in the presence of *p*-toluenesulfonic acid monohydrate (2.00 g, 10.5 mmol), as catalyst, and hydroquinone (0.350 g, 3.18 mmol) as radical scavenger. After refluxing the reaction mixture for 30 min, the temperature was reduced to 62–63°C, and the methanol/methyl propenoate azeotrope formed in the transesterification reaction distilled off over a period of 4.5 hr. The temperature was increased, and the residual methyl propenoate distilled off at 80°C, yielding dodecyl propenoate (20.654 g, 98% yield) in a purity of 97%. MS (70 eV): *m/z* (%) 168(2), 140(4), 127(9), 125(4), 113(9), 111(13), 97(23), 83(30), 73(32), 69(32), 55(100), 43(45), 41(52), 39(10), 29(28), 27(32).

Dodecyl propanoate (**3**) was likewise synthesized by the Rehberg method from dodecanol and methyl propanoate to give the target compound. MS (70 eV): *m/z* (%) 213 (1), 168(2), 140(4), 130(2), 125(3), 111(12), 97(28), 83(39), 75(73), 57(100), 55(43), 43 (36), 41(31), 39(4), 29(24), 27(5).

Results and Discussion

GC-MS analyses of the femoral gland secretions of male and female sungazers gave total ion chromatograms (TICs) that were qualitatively identical but with some

quantitative differences. A typical total ion chromatogram of an extract of the femoral gland secretion of a female sungazer is depicted in Fig. 1. The extracts of the secretions of both male and female lizards did not contain any early eluting volatile constituents. To rule out the possibility that highly volatile material present in the secretion could have been lost when the sample was concentrated for analysis, GC-MS analysis was repeated by using solventless sample introduction (Burger et al. 1990) of the raw secretion. Results confirmed that the secretion, as collected, was devoid of more volatile compounds commonly present in exocrine secretions and that the constituents of the secretion can be described as semi-volatile.

A total of 173 chromatographic peaks were observed in the GC-FID analyses, but in the GC-MS analyses, only 53 components (Table 1) could be detected with sufficient sensitivity to yield mass spectra suitable for identification. The quantitative GC-FID analyses showed that these 53 compounds constituted more than 90% of the total mass of the detected compounds. The components of the extract were tentatively identified by comparison of their low-resolution electron impact mass spectra with NBS, NIST, Wiley, and the in-house LECUS mass spectra libraries. Further diagnostic information on some tentatively identified steroids was obtained by interpretation of the mass spectra of their

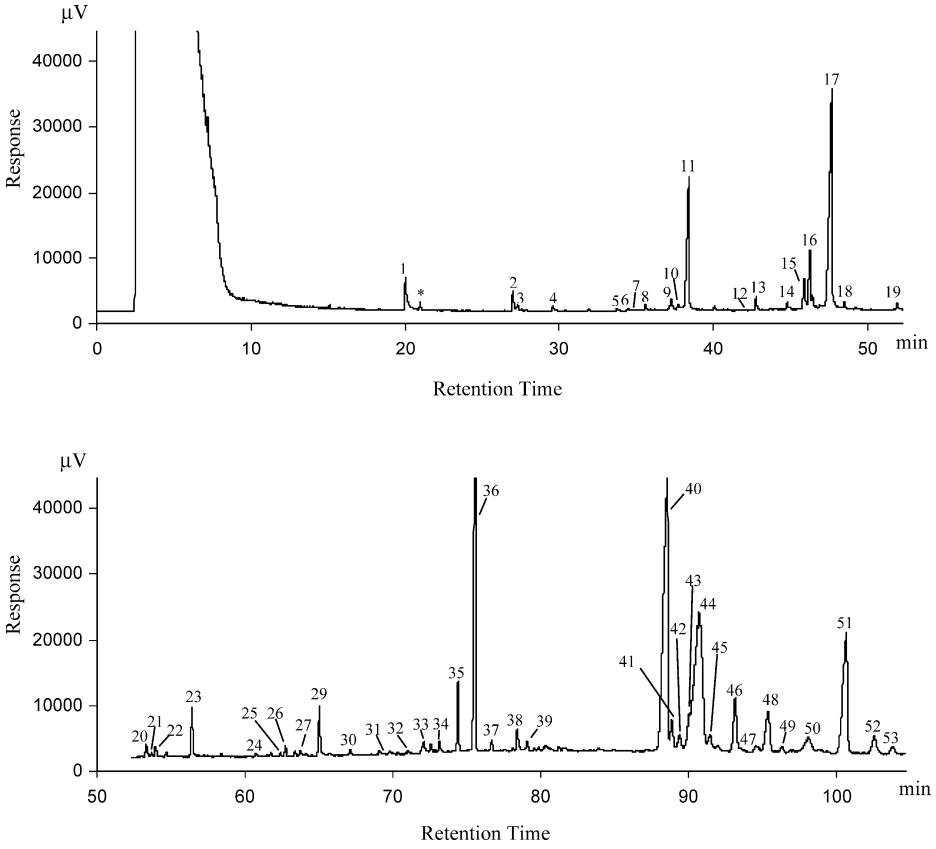

Fig. 1 Total ion chromatogram (FID) of an extract of femoral gland secretion of a female sungazer, *C. giganteus*. *Contaminant

[f] Prominent ions in the mass spectra of unidentified steroids

[g] Ions corresponding to those in the mass spectrum of an unidentified steroid found in the femoral gland secretion of *Podarcis hispanica* (Martín and López 2006b).

trimethylsilyl derivatives, employing published mass spectral data. The structures of most of these compounds were confirmed by gas chromatographic co-elution with authentic reference compounds.

Although a large number of homologous long-chain alkanes were identified in the precloacal secretions of 20 *Liolaemus* lizard species (Escobar et al. 2001, 2003), alkanes have not been found in the secretions of other lizards. The femoral secretion of *C. giganteus* contained only one alkane, pentacosane.

Constituents **1** and **7** were tentatively identified as long-chain alcohols. The molecular mass of long-chain alcohols can normally be established by invoking a characteristic ion at $[M-46]^+$ formed by the loss of a molecule each of water and ethylene. Although constituent **7** was present in such a low concentration that this ion could not be detected, this chemical and constituent **1** were identified by gas chromatographic co-elution with authentic synthetic reference compounds as 1-hexadecanol and 1-dodecanol, respectively. These were the only alcohols identified in the secretions. The femoral secretions of some other species that have been investigated were found to contain up to nine homologous unbranched long-chain alcohols (López and Martín 2005b; Martín and López 2006b).

A series of methyl ketones, comprising 2-heptadecanone (**8**), 2-nonadecanone (**14**), 2-henicosanone (**22**), 2-tricosanone (**26**), 2-tetracosanone (**30**), and 2-pentacosanone (**32**), was identified in the femoral secretion of the sungazer. Previous studies have found C_{13} and C_{19}, C_{15} and C_{16}, C_{16} and C_{19}, and C_{19} ketones in the femoral secretions of, respectively, *Acanthodactylus erythrurus* (López and Martín 2005b), *Lacerta schreiberi* (López and Martín 2006), *Psammodromus algirus* (Martín and López 2006a), and *Podarcis hispanica* (Martín and López 2006b),

The sungazer's femoral secretion contained a single unsaturated C_{17} aldehyde. Martín and López (2006a, b) found only a few aldehydes in the secretions of the species they studied. Aldehydes are oxidized by oxygen to fatty acids in an autoxidation reaction that is promoted by high temperatures and ultraviolet light (Pryor 1966). It is possible that α-tocopherol, a radical scavenger (Fossey et al. 1995) present in the femoral secretion of lizards (e.g., *Lacerta schreiberi*; López and Martín 2006), largely inhibits this reaction.

The secretions contained 19 saturated and unsaturated C_{14}–C_{24} carboxylic acids. Ions characteristic of carboxylic acids are present in low abundance in the mass spectra of constituents **10**, **12**, **28**, and **33**. Based on the available mass spectral information and retention time comparison with other saturated and unsaturated carboxylic acids, these compounds were identified as unsaturated carboxylic acids. However, the position of unsaturation in these acids was not established. Previous investigators (e.g., Alberts et al. 1992) have found carboxylic acids with similar chain lengths in other species, while still other species produce carboxylic acids with a wider range in the number of carbon atoms (e.g., C_6–C_{26} in *Liolaemus* spp; Escobar et al. 2001).

The mass spectrum of constituent **3** contained ions which are typically present in the mass spectra of long-chain alcohols and alkenes. However, comparison of this spectrum with mass spectral libraries provided no conclusive characterization: the main point of divergence being the presence (in **3**) of an abundant ion at *m/z* 75. High-resolution GC-MS analysis revealed that the elemental compositions of this ion and another at *m/z* 57 were $C_3H_7O_2$ and C_3H_5O, respectively, indicating that constituent **3** could be an ester of propanoic acid, possibly dodecyl propanoate. The high-resolution mass spectrum of constituent **2** showed that the prominent ions at *m/z* 73 and 55 were $C_3H_5O_2$ and C_3H_3O, respectively. As polar compounds elute faster than analogous saturated compounds on apolar columns, it was concluded that constituent **2** is the propenoic acid ester analog of constituent **3**. Gas chromatographic co-elution of these two chemicals with synthetic

[f] Cleavage of the D-ring

[g] Cleavage of the C-ring

[h] Does not appear in the mass spectrum, due to the low concentration of the compound

reference compounds confirmed that both of them contain unbranched alkyl moieties, i.e., they are dodecyl propenoate (**2**) and dodecyl propanoate (**3**).

The presence of a relatively large number of steroids, which eluted from the apolar column with retention times between approximately 87 and 105 min, in the femoral secretion of the sungazer suggested to us that these compounds could have a semiochemical function in this animal.

The interpretation of the mass spectra of steroids has been discussed in great detail (Budzikiewicz 1972; Thenot and Horning 1972; Shackleton 1985). Some of the more informative diagnostic ions in the mass spectra of the steroids identified in the femoral secretion of the sungazer and of their TMS derivatives are summarized in Table 2. Using this information and retention time comparison with authentic synthetic steroids, seven steroids were identified in the secretion. Constituent **46** was tentatively identified as 4,4-dimethyl-cholest-8-en-3β-ol. However, the published mass spectral data of this steroid did not correspond well with the mass spectrum of constituent **46**, and therefore, this compound remains unidentified. Another ten steroids could not be identified, some of which are also present and unidentified in other lizards (Martín and López 2006b).

The abundant steroids plus the well-known fixative squalene may function as the major controlled-release carrier materials in the secretion. Escobar et al. (2003) and Alberts (1990) postulated that cholesterol and the protein fraction could serve as controlled-release carrier materials or fixatives for semiochemicals in some lizards. It is also possible that the long-chain esters, hydroxy esters, and lactones (López and Martín 2005a, b, 2006; Martín and López 2006a, b) could have the same function in other lizard species. Lactones, long chain esters, and hydroxy esters were not found in the femoral gland secretion of the sungazer.

Squalene is the major component in the secretions collected from males during April 1998 and January 1999. In the secretions collected from males during October 1998, the component with the highest relative concentration differed among individuals and was squalene, cholest-5-en-3β-ol, or lanost-8-en-3β-ol. The major component in female secretions collected during these three seasons was usually either cholesterol or cholesta-5,7-dien-3β-ol, although in each of these seasons, a different female had octadecanoic acid as the major chemical.

Available information on the role of chemical communication in the social behavior of Cordylid lizard species is limited to a study of the behavior of the Cape girdled lizard, *Cordylus cordylus*, a member of the Cordilidae family, which showed that males and females can discriminate between their own secretions and those of individuals of the same sex (Cooper et al. 1999). Further research is needed to test whether *C. giganteus* individuals respond to femoral gland secretions of conspecifics and, if so, which (if any) of the chemicals identified herein mediate such responses.

Acknowledgements The research was supported by Stellenbosch University and the National Research Foundation, Pretoria, South Africa. Lanral Ruddock is thanked for the collection of secretions.

acknowledged on the grounds of theoretical considerations and empirical demonstrations involving mainly visual- or acoustic-based communication systems (Maynard Smith and Harper 2003). Nevertheless, a growing body of evidence indicates that odors are broadly used in individual, sexual, and species recognition in vertebrates, and may be reliable signals of quality and compatibility (Wyatt 2003).

Birds were once considered to have a poor sense of smell, but more recent findings have modified the knowledge of this subject. Many birds species are sensitive to odors, and actually use olfaction in some behavioral tasks (for a review, see Roper 1999). However, compared to other organisms, information on the production or social use of self-produced odor compounds in birds has been largely neglected. Recent studies suggest that odor may play an important role in mate choice of birds (Zelano and Edwards 2002; Bonadonna and Nevitt 2004; Soini et al. 2007).

Procellariiform seabirds (petrels and albatrosses) have the most highly developed olfactory anatomy and neuroanatomy known in birds (Bang 1966). The first suggestion of the function of this anatomy was for finding food (Grubb 1972), and this was subsequently shown for many petrel species (reviewed by Roper 1999 and Nevitt and Bonadonna 2005a). Odors may also help petrels and albatrosses to navigate when flying across the oceans (Nevitt and Bonadonna 2005b).

Within species, petrels are faithful for life to their breeding colony and to their partner. In many species, pairs breed in underground burrows. Monogamous pairs lay a single egg, and partners alternate parental duties and foraging trips to sea (Warham 1996). Returning from the sea, many burrowing petrel species approach the colony and nest at night (to avoid avian predators, Mougeot and Bretagnolle 2000). Odors play a fundamental role in finding the burrow, and an odor signature of the nest facilitates burrow recognition in the dark (Bonadonna et al. 2003, 2004).

We recently showed that Antarctic prions, *Pachyptila desolata*, were able to recognize their own as well as their partner's odor, suggesting that personal odors may play a role in the nest's olfactory signature. This was the first evidence of individual recognition through odor in a bird species. Moreover, quite unexpectedly, we discovered a pattern of scent discrimination that is well-documented in mammals: Antarctic prions avoided self-odor when presented with the scent of another conspecific (Bonadonna and Nevitt 2004). Such behavior was first reported in mice, and was related to major histocompatibility complex genes (MHC), kin recognition, and inbreeding avoidance (Manning et al. 1992). This could also be the case in petrels, as high phylopatry may expose them to the risk of inbreeding and should select for mechanisms that allow for kin discrimination (Zelano and Edwards 2002).

Even after years of preservation, collected petrel feathers smell distinctive to the human nose (Bonadonna, personal observation). Birds protect and waterproof their feathers by preening them with the products of the uropygial gland (Stettenheim 1972). These products may carry odors that play a role in the behavior of birds (Soini et al. 2007). For example, odors produced by this gland play a role in sexual behavior of domestic ducks, *Anas platyrhynchos* (Balthazart and Schoffeniels 1979; Jacob et al. 1979). In petrels, the products of this gland may be species-specific (Jacob and Hoerschelmann 1982) and may constitute an olfactory signature on petrel feathers.

We hypothesized that feather scents of Antarctic prions constitute an individual olfactory signature, and we predicted that the scents produced by the feathers of the same bird in two different years should be more similar to each other than the scents produced by the feathers of two different birds in the same year. We report the results of our study herein.

Methods and Materials

Feather samples Feather samples were collected on Ile Verte (49°51′S, 70°05′E) in the Kerguelen Archipelago (southern Indian Ocean). The first sample was collected in the 2002–2003 austral summer from 10 pairs of ringed Antarctic prions, *P. desolata*, (20 birds), and again in the 2003–2004 and 2004–2005 austral summers (hereafter called years). We thus obtained feather samples for three consecutive years on seven females and six males (individuals may not survive and pairs may not nest every year, Warham 1996). Fifty to 200 mg of feathers were cut from the duvet around the uropygial gland with steel scissors cleaned in methanol between samples. Feathers were stored in aluminum paper, in a closed plastic bag, and refrigerated. Plastic bags were opened just before chemical analysis.

Chemical analysis Feathers of each sample were weighed and immersed in 4 ml dichloromethane for 24 hr. After this, the feathers were removed, and the solvent allowed to evaporate to 250 μl in a fume hood. Twenty microliters of *n*-dodecane (purity 99.8%, Sigma Aldrich Switzerland) in dichloromethane (200 μg/ml) were added to each extract as an internal standard. The samples were analyzed on a Varian CP3800 gas chromatograph (Varian, Palo Alto, CA, USA), equipped with a flame ionization detector and a Varian CP-Sil 5 CB Low Bleed MS (25 m×0.25 mm, ID, film thickness 0.25 μm) column. The oven was programmed as follows: 50°C for 2 min, 3°C min^{-1} to 100°C, 2.7°C min^{-1} to 140°C, 2.4°C min^{-1} to 170°C, and 10°C min^{-1} to 290°C. An on-column injector at 250°C was used with helium (1 ml min^{-1}) as carrier gas. To determine the identity of compounds, gas chromatography–mass spectrometry was employed using a Varian CP3800 coupled to a Varian Saturn 2000 ion trap mass spectrometer equipped with splitless injection and the same capillary column as above. The scan range of the ion trap was 38 to 350 *m/z*. The oven temperature program was the same as that above except the initial temperature of 50°C was held for 3 min. Total ion chromatograms and mass spectra were recorded in the electron impact ionization mode at 70 eV. Identification of compounds was based on mass spectral fragmentation pattern, using various libraries [Wiley 138 and NBS 75K libraries (McLafferty 1998), NIST98 (Stephen 1998), and the compilation by Adams (1995)], and chromatographic retention index (RI).

Selection of compounds and statistical analyses for comparison of chemical profiles We concentrated our analysis on compounds with retention times between 3 and 40 min in the FID chromatogram, on the basis that compounds with RI of greater than 1,700 on an apolar column do not have sufficient vapor pressure to be perceived by birds. Birds do not have a "wet" nose such as some mammals (e.g., dogs, mice, cats, etc) or a vomeronasal organ (Bang and Wenzel 1985) and, therefore, are likely only to perceive molecules that are borne by an air flow. From the 39 samples, we distinguished 99 different peaks; some were found in most samples, others in only a few. We considered each compound as a distinct dependent variable (99 variables) and each bird in each year (hereafter called bird/year) as a sampling unit (39 units). The data set contained a large number of potential dependent variables compared to the low number of sampling units. Therefore, we reduced the number of compounds (dependent variables) by using two different working hypotheses. Firstly, we hypothesized that the olfactory signature of birds is a bouquet composed of compounds present in all birds in different relative concentrations (Alberts 1992). Compounds of high occurrence (HOC) were selected as follows. We considered the third year profile of a bird (i.e., the profile obtained from the most recent feather sample). We used a compound only if it was present in the third year profile (i.e., the most recent feather sample) of at least 10 individual birds; 28 compounds fulfilled this criterion. Then, for all 13 birds and for each year, we considered the amount of these

compounds (amount=0 if compound was absent) and ran a principal component analysis (PCA; proc PRINCOMP in SAS 8.2) on the correlation matrix. This generated synthetic dependent variables that captured systematic associations among compounds.

Secondly, we hypothesized that the olfactory signature of birds is a bouquet composed of compounds present in a few birds, but with different association patterns, independent of compound concentration (Alberts 1992). Compounds of low occurrence (LOC) were selected as follows. We used a compound only if it was present in the third year profile of, at most, 5 individual birds; 21 compounds fulfilled this criterion. For all 13 birds and for each year, we ran a multiple correspondence analysis (MCA; proc CORRESP in SAS 8.2) on the contingency table to generate synthetic dependent variables that captured systematic presence/absence associations among compounds.

For each synthetic variable from PCA and MCA analyses, we estimated the variance among birds over years and the variance among years with respect to birds. These variances were accounted for in mixed effects linear models (proc MIXED in SAS 8.2) by the random factors "bird" and "year," respectively. An estimate of the residual variance was also provided. The measure of repeatability of the olfactory signature of an individual bird was computed as the ratio of the variance among birds consistent over years (i.e., "bird random effect") to total variance (intraclass correlation coefficient [ICC]). The blend of volatile compounds was considered as an individual olfactory signature if the variance component "bird" differed significantly from zero and if the ICC was higher than 50%. The fixed factor "sex" was also included in the models.

Results and Discussion

Representative chromatograms obtained from extracts of a single bird in each of the 3 yr are given (Fig. 1). The compounds identified in our analyses (Table 1) and used in our PCA and MCA were lipids. This is not surprising, considering that these compounds were probably derived from the uropygial gland, which principally produces waxes and greases to protect feathers (Jacob and Ziswiler 1982). Among the identified volatile compounds are fatty alcohols, fatty aldehydes, and hydrocarbons (Table 1).

Lipids are important as odors of vertebrates (Alberts 1992; Hagelin et al. 2003; Burger 2005), and some of the compounds we identified in Antarctic prions have already been identified as mammalian semiochemicals. For example, alkanes, such as decane and octane, are specific odor compounds from forehead hairs of white-tailed deer, *Odocoileus virginianus* (Gassett et al. 1997) and interdigital secretions of bontebok, *Damaliscus dorcas* (Burger et al. 1999). Aldehydes such as (*E*)-2-hexenal, dodecanal, and nonanal are present in urine of deer mouse, *Peromyscus maniculatus* (Ma et al. 1999) or in bontebok, (Burger et al. 1999), and alcohols such as dodecanol, heptanol, and tetradecanol are present in the preorbital secretion of grysbok, *Raphicerus melanotis* (Burger et al. 1996). Given the structure of these compounds and their function in other vertebrates, it seems likely that these compounds are produced endogenously through the oxidation or reduction of fatty acids. This is consistent with recent findings in other birds such as the dark-eyed junco, *Junco hyemalis* or green woodhoopoe, *Phoeniculus purpureus* (Burger et al. 2004; Soini et al. 2007).

Analysis of the variation in HOC The first three PCA components each accounted for a noticeable percentage (>25%) of the variation in the concentration of each of the 28 compounds selected. These three components represented variation in the concentration of 24, 3, and 1 distinct compounds and accounted for 76%, 8%, 5% of the total variation in

Table 2 Statistical modelling of the variation in 3 synthetic variables derived through PCA analysis from the variation in concentration of 28 HOCs

	Estimated Variance	SE	*P*
PCA first component (1, 2, 3, 4, 6, 7, 8, 9, 10, 11, 13, 14, 15, 17, 18, 19, 20, 22, 23, 24, 25, 26, 27, 28)			
Sex			0.239
Year	2.193	3.714	0.277
Bird	0	Ne	1
Residual variance	19.568	4.678	
Intraclass correlation coefficient=0			
PCA second component (12, 16, 21)			
Sex			0.265
Year	0.050	0.154	0.373
Bird	1.020	0.635	0.054
Residual variance	1.316	0.380	
Intraclass correlation coefficient=0.43			
PCA third component (5)			
Sex			0.315
Year	0.042	0.140	0.382
Bird	0.049	0.230	0.416
Residual variance	1.239	0.358	
Intraclass correlation coefficient=0.04			

For the fixed effect, sex, the *P* value is that associated with an *F* test with 1 degree of freedom for the dependent variable and 24 residual degrees of freedom. For the random effects, year and bird, the *P* value is that associated to a Wald test.

The compounds for which the squared correlation coefficient R^2 with focal PCA component is >0.20 are given in parentheses.

SE: standard error, *Ne*: no standard error estimates could be produced for variance estimates equal to zero.

concentration of compounds, respectively. For these three synthetic variables, the variance estimates for the factors "bird" and "year" did not differ significantly from zero. The variation among birds over years accounted for a small fraction of the total variation with the possible exception of the second principal component (Table 2). It is possible that fatty acids present on feather samples collected in the first 2 yr continued to be modified during preservation, changing the relative quantity of derived "signature compounds". No sex effect was detected for any of the three synthetic variables.

According to these results, variation in the concentration of HOC was not likely to constitute an individual olfactory signature. However, we cannot exclude the possibility that our sampling protocol was not subtle enough to detect differences and that a possible signature of same compounds at different relative concentration exists. More sophisticated individual odor sampling protocols are needed to test this.

Analysis of the variation in LOC The first four MCA dimensions accounted for a substantial percentage (>20%) of the variation in the presence/absence of each of the 21 compounds selected. These four dimensions represented the variation in the presence/absence of 9, 4, 2, and 5 distinct compounds and accounted for 35%, 19%, 10%, and 8% of the total variation in the presence/absence of compounds, respectively. For the first two of these synthetic variables, variation among birds over years ("bird" factor) was statistically significant and accounted for a large fraction of the total variation (Table 3). Identified

Table 3 Statistical modelling of the variation in 4 synthetic variables derived through MCA analysis from the variation in presence/absence of 21 LOCs

	Estimated Variance	SE	*P*
MCA first dimension (29, 33, 34, 35, 36, 37, 46, 47)			
Sex			0.542
Year	0	0.015	0.490
Bird	0.323	0.163	0.024
Residual variance	0.169	0.0499	
Intraclass correlation coefficient=0.66			
MCA second dimension (30, 41, 43, 48)			
Sex			0.634
Year	0	Ne	1
Bird	0.188	0.107	0.040
Residual variance	0.178	0.050	
Intraclass correlation coefficient=0.51			
MCA third dimension (40, 49)			
Sex			0.051
Year	0	Ne	1
Bird	0	Ne	1
Residual variance	0.200	0.047	
Intraclass correlation coefficient=0			
MCA fourth dimension (31, 32, 38, 44, 45)			
Sex			0.716
Year	0.033	0.043	0.221
Bird	0.087	0.057	0.063
Residual variance	0.126	0.037	
Intraclass correlation coefficient=0.35			

For the fixed effect, sex, the *P* value is that associated to an *F* test with 1 for the dependent variable and 23 residual degrees of freedom. For the random effects, year and bird, the *P* value is that associated to a Wald test. The compounds for which the percent variation explained by the focal dimension is >20% are given in parentheses.

SE: standard error, *Ne*: no standard error estimates could be produced for variance estimates equal to zero.

compounds responsible for the statistical difference were isododecane, 3-methylundecanoic acid, (*E*)-2-octenal, and isotridecane for the first synthetic variable, and octane, isopentadecane, (*E*)-2-dodecenol, and tetradecanal for the second synthetic variable. Therefore, we believe that these LOC compounds may constitute an individual olfactory signature repeatable over years (ICC=0.66 and 0.51, respectively) that distinguishes individuals ("bird" effect *P*=0.024 and 0.04, respectively; Fig. 2).

The effect of the sex of the bird was close to being significant for the third synthetic variable (*P*=0.051; Table 3). However, in recent experiments in which odors of male and female birds were presented simultaneously in a Y-maze, neither male nor female Antarctic prions showed any preferences (Bonadonna et al. unpublished data). More work is needed to resolve this discrepancy.

In summary, our results, although preliminary and lacking direct behavioral confirmation for the compounds, suggest the existence of an endogenous individual olfactory signature in Antarctic prions, originating from the uropygial gland: an individual is more similar to itself with regard to volatile compounds, from year to year, than it is to a conspecific. This

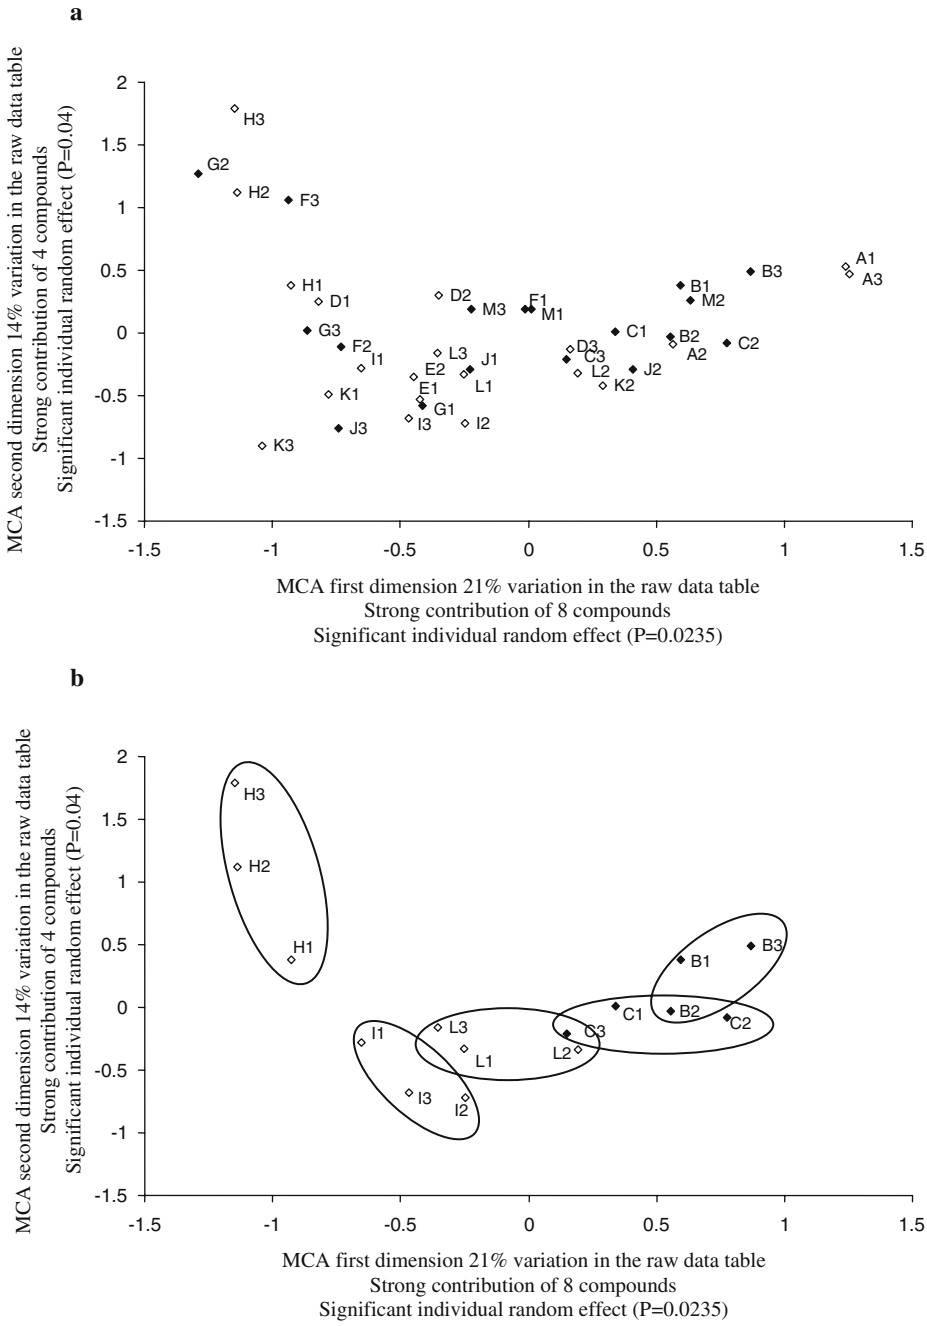

Fig. 2 **a** Volatile compound profile of 13 birds (*letter*) over 3 yr (*number*) as described by 2 synthetic variables derived through MCA analysis from the variation in the presence/absence of 21 volatile LOCs. *Open symbols* represent females; *filled symbols* represent males. **b** Same representation as in **a** but only selected birds are presented to better show clustering

is consistent with behavioral studies on partner-odor recognition (Bonadonna and Nevitt 2004). As this odor is likely endogenous, it might also broadcast the compatibility and quality of a potential mate as previously proposed (Zelano and Edwards 2002). To our knowledge, this is the first demonstration of a putative odor signature in birds.

Acknowledgments This study was supported by the Institut Polaire Français Paul Emile Victor (IPEV, Program no. 354) and performed in adherence to the IPEV/CNRS ethical guidelines. We thank B Buatois for the help with the gas chromatography; Dr. G Nevitt, C Bajzak, and Dr. S Caro for the help in the field; Prof. F S Dobson, Dr. P D'Ettorre, and Dr. M-C Anstett and two anonymous reviewers for the critical review of an earlier draft of the manuscript.

three genotypes. Sinigrin, 4-hydroxyglucobrassicin, and phenylethylglucosinolate were present at significantly higher levels in flowers than in leaves. In response to caterpillar feeding, sinigrin levels in both leaves and flowers were significantly higher than in undamaged plants, whereas 4-hydroxyglucobrassicin leaf levels were lower. Our results show that feeding on flower tissues, containing higher concentrations of glucosinolates, provides *P. brassicae* with a nutritional benefit in terms of higher growth rate. This preference appears to be in contrast to published negative effects of volatile glucosinolate breakdown products on the closely related *Pieris rapae*.

Keywords Herbivory · Lepidoptera · Pieridae · Myrosinase · Isothiocyanates · Nutrition · *Brassica nigra*

Introduction

Most plants are not simply homogeneous resources to herbivorous insects but produce discrete organs with different functions. In addition to the vegetative leaf tissues, plants produce reproductive organs (flowers, seeds) that may exhibit significant differences in levels of both nutrients and defensive secondary metabolites. Specialized guilds of herbivores are known to exploit specific plant structures (Schoonhoven et al. 2005). Flowers and seeds may be attacked by insects that rarely feed on leaf tissues, and vice versa. Other herbivores exhibit more plasticity in food selection and will readily feed on all available parts of the plant. Even the latter herbivore types display some preference for a specific plant structure, presumably as a means of obtaining optimal nutrient intake, limiting competition, or obtaining enemy-free space.

The cabbage white butterflies *Pieris brassicae* L., *Pieris rapae* L., and *Pieris napi* L. are specialized on the plant family Brassicaceae. Interactions between these butterflies and their host plants have been explored in detail, and they have acquired the status of a model system in the field of insect–plant biology (Feltwell 1982; Chew and Renwick 1995; Renwick 2002). Glucosinolates, characteristic of the Brassicaceae, play a crucial role as chemical mediators of these interactions. Adult females of *P. brassicae* and *P. rapae*, as well as their larvae, exploit glucosinolates as token stimuli during selection of host plants for oviposition and feeding (Renwick et al. 1992; van Loon et al. 1992; Moyes et al. 2000; Schoonhoven and van Loon 2002). The majority of *Pieris–Brassica* interaction studies has focused on cultivated forms of *Brassica oleracea* L., which are biennials. Other wild crucifers, such as the annual black mustard, *Brassica nigra* L. (Koch), are reported to be host plants for *P. brassicae* in Europe as well (Harvey et al. 2003). We studied within-plant feeding site location in detail on three genotypes of *B. nigra*. We included the analysis of leaf and flower glucosinolates to assess whether a chemical basis for selection of either plant organ in terms of quality or quantity of these compounds could be determined. In addition, we investigated whether growth rates differed between caterpillars feeding on either leaves or flowers to assess whether the observed preference behavior would confer a nutritional benefit.

Methods and Materials

Plants Seeds of *B. nigra* var. *abyssinica* A. Braun from three early flowering accessions were obtained from the Centre for Genetic Resources (CGN, Wageningen, The Netherlands).

The accessions were: A, CGN06619 (feral population, collected in 1975 from the Peloponesus, Greece); B, Junius CGN06618 (advanced cultivar, collected in 1977 in Germany); and C, Giebra CGN06620 (advanced cultivar, donated in 1965 by the Botanical Garden of the Justus Liebig University, Giessen, Germany). Sowing was done on April 7, 2004, in a greenhouse at 22±2°C and 60±5% RH. Two weeks later, plants were individually transplanted into 1.5-l pots and transferred to another greenhouse compartment on April 30, 2004. This compartment was kept at 22±2°C, 60% RH, natural light supplemented by additional illumination by 500-W SON-T lamps (Philips, Eindhoven, The Netherlands) for 16 hr per day. Flower bud formation and flower opening were recorded daily to determine developmental stage (Harper and Berkenkamp 1975).

Insects *Pieris brassicae* caterpillars were obtained from a laboratory strain established in 2004 and reared on Brussels sprouts (*B. oleracea* var. *gemmifera* cv Cyrus) plants grown in a climatized greenhouse, under the same conditions as given above for *B. nigra* plants. The colony was maintained in a climatized room at 22±1°C, RH 40±5%, and a photoperiod of L16:D8.

Caterpillar Position on the Plant On the first day of an experiment, newly hatched *P. brassicae* larvae were collected from the laboratory culture and taken to the greenhouse. Three caterpillars were placed on the first true leaf below the lowest flowering branch of a plant in growth stage 4.1 (Harper and Berkenkamp 1975). Total numbers of plants used from each accession were A, 8; B, 7; and C, 9. Caterpillar position on the plants was scored each morning in four categories: on a true leaf, on a small leaf in the inflorescence, on a flower, and on the stem. Caterpillar instar stage was recorded daily until the fifth instar was reached. In the late fifth instar, caterpillars that had entered the wandering phase left the plants.

Caterpillar Growth on Leaves and Flowers Three neonate caterpillars were inoculated on each of 20 plants of accession A, on a mature leaf just below the inflorescence. The inoculation took place when plants had just started to flower (growth stage 4.1). Just after caterpillars had molted to the third instar, they were transferred to the lowest branches of the inflorescence on half of the plants. We applied a specially constructed water barrier to prevent caterpillars from migrating from leaves to the inflorescence or vice versa, while not influencing the microclimate around the plant (Fig. 1). Fresh body weights of larvae were determined to the nearest milligram on a Mettler electronic balance at three time points separated by 3-d intervals.

Preparation of Plant Samples for Glucosinolate Analysis Ten seedlings of each of the three accessions were individually transplanted to 1 1/2-l pots. Plants were maintained at 22±2°C, RH 60±5%, during the 16-hr photophase (8 Philips SON-T Agro 400-W sodium lamps) and 8-hr scotophase.

At day 47 after sowing, leaf and flower samples were taken from all 10 plants of each accession. After sampling, five plants of each accession were designated untreated (controls). Three groups of 10 newly hatched *P. brassicae* caterpillars were placed on three leaves of the five treated plants. As soon as the caterpillars had migrated to the flowers, which took place late in the second or early in the third instar (days 5–6), leaves damaged by the caterpillars were sampled. Leaves of a similar age were sampled from the control plants and intact flowers were sampled from both control and treated plants.

The flower and leaf samples were kept in paper envelopes and stored in a −20°C freezer before and after freeze-drying. Samples were freeze-dried in the envelopes for 2 d (Labconco Freedry system). After freeze-drying, the envelopes were sealed in plastic and sent to the laboratory of NA in Denmark for chemical analysis.

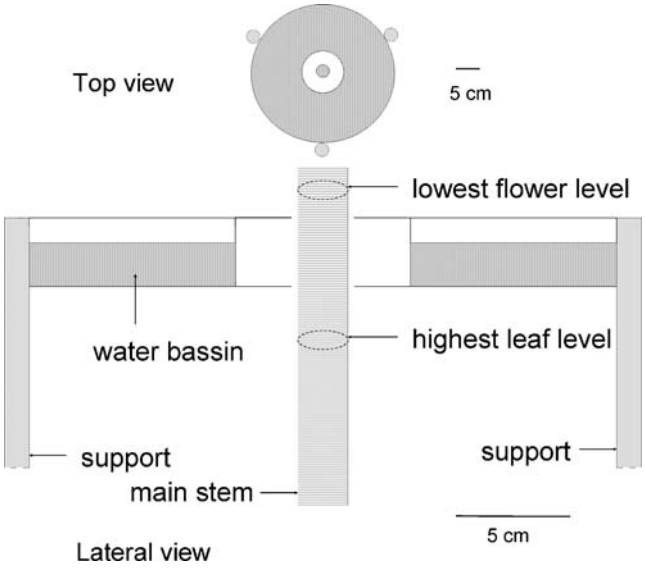

Fig. 1 Schematic drawing (top and lateral views) and dimensions of water barrier applied around the stem of *B. nigra* plants to prevent movement of caterpillars from leaves to flowers and vice versa. A circular water container was manufactured of plastic. The middle circle consisted of a central platform, preventing drowning of caterpillars feeding on the inflorescence in the rare events of falling down or downward migration. In the center of the platform, a hole allowed the main stem to grow through. The platform was put in place around the main stem just below the branch carrying the first flower buds. The circular opening between the central hole and the stem was blocked with soft foam (not drawn)

Determination of Glucosinolate Content Freeze-dried samples were weighed accurately into 10-ml centrifuge tubes (excluding the petiole part of leaves). For samples below 300 mg, the entire sample [27–257 mg dry weight (DW)] was used to avoid errors associated with subsampling, but from a few samples above 300 mg, a representative subsample was taken. Each sample was extracted 3× in 70% boiling aq. methanol with benzylglucosinolate as internal standard. The combined extracts were adjusted to 10.00 ml, of which an amount was applied to an anion exchange column (Agerbirk et al. 2001a). To keep within the linear range of the additional sample preparation steps, the amount of crude extract applied depended on the weight of the sample extracted as follows (DW extracted/volume applied): 25–75 mg/8 ml, 75–150 mg/4 ml, and 150–300 mg/2 ml. Glucosinolates were converted to desulfoglucosinolates (Agerbirk et al. 2007), which were eluted and quantified by high-performance liquid chromatography (HPLC) (Agerbirk et al. 2001a) and identified by comparison of retention times and diode array UV spectra with those of authentic standards (Agerbirk et al. 2001b). A number of unidentified trace peaks with areas typically less than 0.2% of the desulfosinigrin area were ignored. Generally accepted relative response factors were used for calculation of glucosinolate levels based on the HPLC peak areas (at 229 nm, band width 8 nm) of the desulfoderivatives (Wathelet et al. 2004). The recoveries of internal standard in the three extraction series were [mean (SD)] 99% (6%), 97% (13%), and 98% (4%), as compared to HPLC peak areas obtained after application of the internal standard only to DEAE columns in parallel control experiments. Preliminary experiments without the addition of internal standard (comprising both leaf and flower samples from plants both with and without caterpillars feeding) confirmed the absence of benzylglucosinolate as an endogenous glucosinolate in the material, in

accordance with previous reports (Feeny and Rosenberry 1982; Sang et al. 1984), allowing the use of this glucosinolate as internal standard. The identities of all desulfoglucosinolate peaks were confirmed by liquid chromatograph mass spectrometry (LC–MS) of representative samples with an Agilent 1100 Series LC (Agilent Technologies, Waldbronn, Germany) coupled to a Bruker Esquire 3000+ ion trap mass spectrometer (Bruker Daltonics, Bremen, Germany). An XTerra MS C18 column (Waters, Milford, MA, USA; 3.5 μM, 2.1×100 mm) was used at a flow rate of 0.2 ml min^{-1}. The mobile phases were as follows: A, 0.1% (v/v) HCOOH and 50 μM NaCl; B, 0.1% (v/v) HCOOH and 80% (v/v) MeCN. The gradient program was 0 to 4 min, isocratic 2% (v/v) B; 4 to 10 min, linear gradient 2 to 8% B; 10 to 30 min, linear gradient 8% to 50% (v/v) B; 30 to 35 min, linear gradient 50 to 100% (v/v) B; 35 to 40 min, isocratic 100% B. The mass spectrometer was run in electrospray mode, observing positive ions. Mass spectral data were treated with the native DataAnalysis software.

The extraction procedure was somewhat simplified compared to the standard protocol (Agerbirk et al. 2001a, originally optimized for seed extraction), as variable sample weights were accepted, and mechanical homogenization during extraction was avoided. These simplifications were justified by results of initial control experiments: A number of both leaf and flower samples of varying weights (up to 400 mg) were first subjected to the extraction described above. Then, the residue was further extracted for another three times, but this time with mechanical homogenization. In all cases, low relative amounts of glucosinolates (1–16% compared to the first extract) were detected in the extract obtained with mechanical homogenization (with a tendency for increasing percentage with increasing sample weight). Proportional amounts of internal standard were similarly recovered in all the extracts obtained with mechanical homogenization, showing that the internal standard had already been completely mixed with endogenous analytes during the extraction without homogenization. Hence, it was concluded that the ratio of internal standard to endogenous glucosinolates extracted without mechanical homogenization was representative of their initial concentrations.

Statistical Analyses Proportion of days caterpillars spent on different positions on the plant was treated as binomial data. Distributions over the four positions were compared by using the Kolmogorov–Smirnoff test (GenStat release 8.11; Anonymous 2005). Caterpillar weights were analyzed by analysis of variance. The amount (μmol/g DW) of each glucosinolate detected in the leaf and flower samples were analyzed with a generalized linear model after a logarithmic transformation. The effect of time (before and during caterpillar feeding), treatment (undamaged and damaged by caterpillars), plant tissue (leaf and flower), and genotype (accessions) and all possible two- and three-way interactions were investigated (GenStat release 8.11).

Results

Position on the Plant First and second instars fed primarily on leaves, whereas third instars migrated via the small leaves of the flower branches to the flower buds and flowers. Once flower feeding began, no further leaf feeding was observed (Fig. 2). The distribution of caterpillars over the four positions was statistically similar for the three genotypes (Kolmogorov–Smirnoff test, $P>0.05$).

Caterpillars fed in discrete meals two to three times each hour, interspersed with phases without feeding. On a leaf, after termination of a meal, they moved away from the freshly

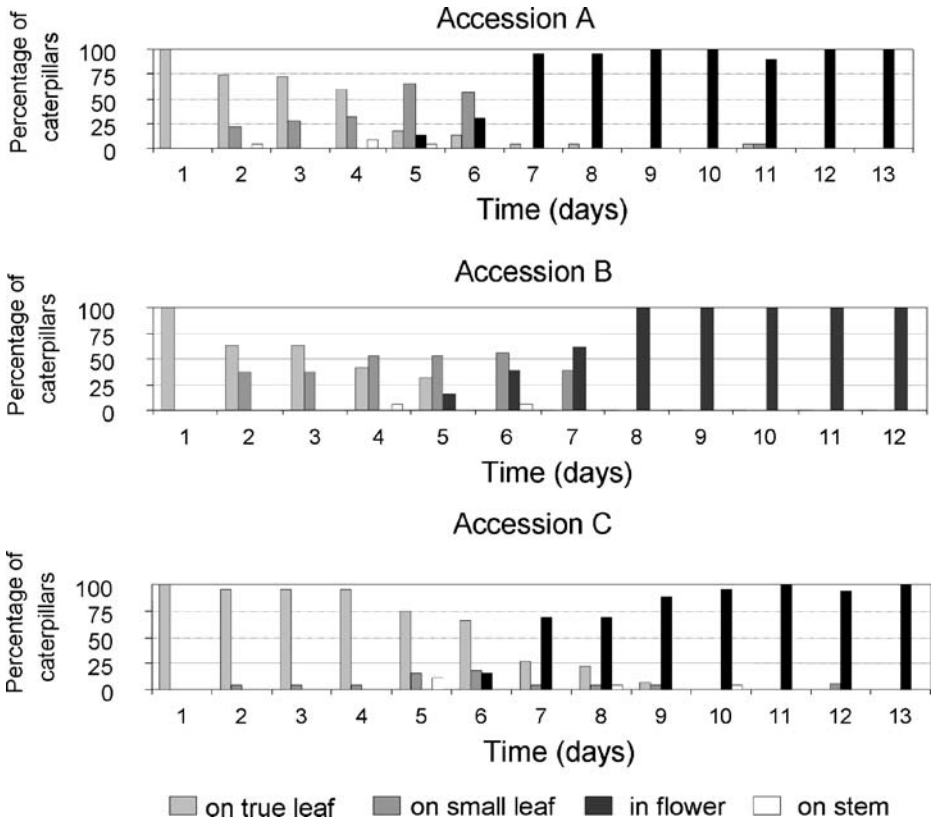

Fig. 2 Frequency distribution of caterpillar position on *B. nigra* plants observed daily over a period of 12–13 d. On day 1, neonates were introduced on a true leaf just below the inflorescence. Four organ positions were distinguished: on a true leaf, on a small leaf in the inflorescence, on a flower, or on a stem in the inflorescence. Percentages are averaged based on three caterpillars per plant for eight, seven, and nine plants of accessions A, B, and C, respectively

damaged wound, after which they rested most of the time elsewhere on the leaf until they moved back to the feeding site. By contrast, in the inflorescence, during a single meal, caterpillars moved from flower to flower along flowering branches. A fifth-instar caterpillar consumed on average 135±21 buds and flowers. When they were not feeding, *P. brassicae* larvae rested on stems immediately adjacent to the flowers.

Caterpillar Growth Caterpillars feeding on flowers of accession A since molting to the third instar had significantly higher fresh body weights on each of the three measuring points (mid-L4 and early and mid-L5 and late L5; Fig. 3) than those that were confined to leaves ($P<0.01$, generalized linear model).

Glucosinolate Levels Five glucosinolates were identified: the aliphatic allylglucosinolate (sinigrin), which occurred in large amounts, and low levels of four aromatic glucosinolates including 2-phenylethylglucosinolate and the three indole glucosinolates indol-3-ylmethyl-glucosinolate (glucobrassicin), 4-methoxyglucobrassicin, and 4-hydroxyglucobrassicin. Despite the minor levels of the identified aromatic glucosinolates, they were quantified

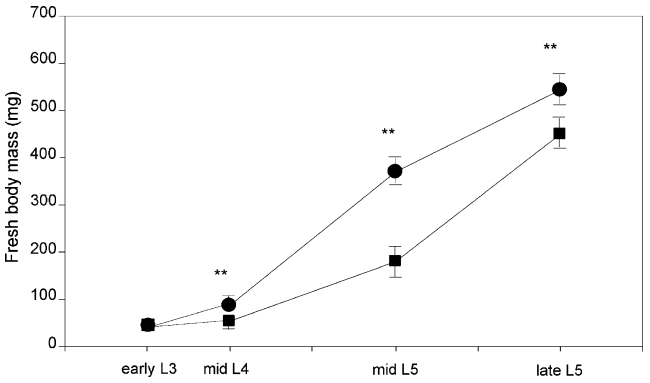

Fig. 3 Fresh body mass of *P. brassicae* on either flowers (*circles*) or leaves (*squares*) of *B. nigra* in mid-fourth, mid-fifth, and late-fifth instar developing on *B. nigra*, accession A. Mean and SEM are plotted for 30 caterpillars

and included in the statistical analyses because of their well established chemosensory influences on *Pieris* species (Schoonhoven and van Loon 2002). No other significant peaks were detected. 2-Phenylethylglucosinolate was either below the detection limit in leaves (accession C) or present at very low levels (range 0.001–0.013 μmol/ g DW). We carefully distinguished the peak with the exact retention time of (desulfo) 2-phenylethylglucosinolate from an unidentified trace peak that was more intense in leaf chromatograms (estimated levels 0.03–0.35 μmol/g DW in leaves, 0.01–0.08 μmol/g DW in flowers), that had a retention time 0.7 min longer than that of (desulfo) 2-phenylethylglucosinolate, and that did not coelute with the authentic standard of 2-phenylethylglucosinolate after spiking.

Genotype and tissue type were the most important factors affecting the levels of identified glucosinolates, and these factors showed a significant interaction (Table 1). No significant interactions were found between treatment and tissue ($P>0.05$ for all glucosinolates). Glucosinolate concentrations have been graphically depicted for accession A in Fig. 4. Sinigrin was by far the most abundant compound in all three genotypes, with levels at least 44 times higher (range 44–305) in leaves and at least 87 times higher (range

Table 1 Results from generalized linear model analysis on log-transformed data of glucosinolate concentrations in two tissue types (leaves and flowers) for three genotypes of *B. nigra*

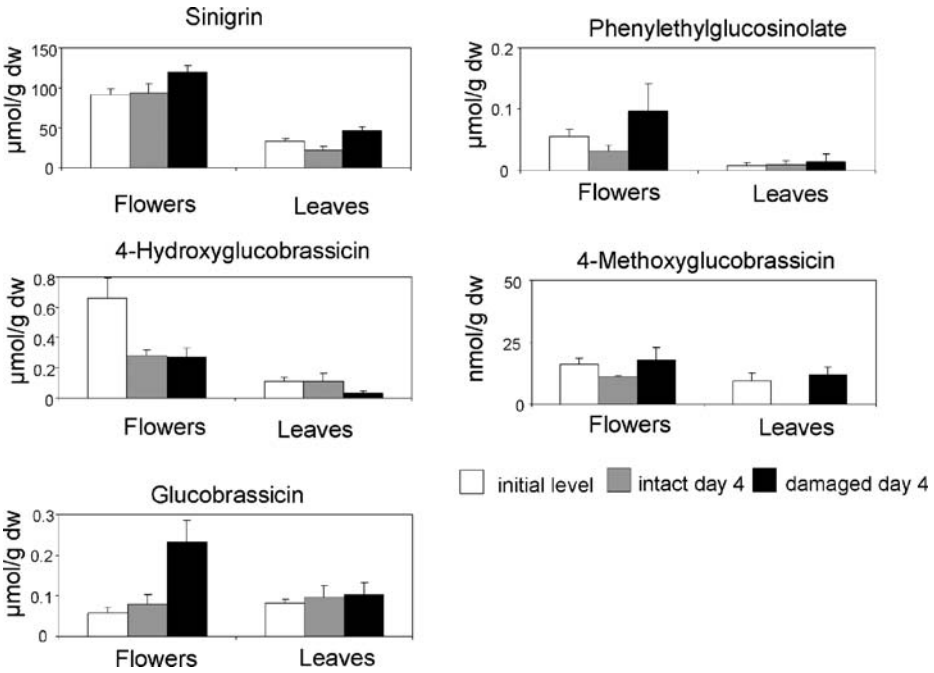

Fig. 4 Concentrations of five glucosinolates (mean + SEM) in leaves and flowers of 10 plants of accession A. For both leaves and flowers, the initial concentration just before treatment, the concentration in leaves or flowers of plants damaged by feeding caterpillars during 4 d, and the concentration determined in leaves or flowers of intact plants 4 d after caterpillars were introduced on the treated plants

87–447) in flowers of any of the three genotypes and treatments than the second most abundant compound, 4-hydroxyglucobrassicin. Sinigrin, 4-hydroxyglucobrassicin, and phenylethylglucosinolate were present at significantly higher levels in flowers than in leaves. Sinigrin levels were ca. fivefold higher in flowers than in leaves. In response to caterpillar feeding, sinigrin levels in leaves were higher than in undamaged plants ($P<0.05$; Table 1). In flowers of accession A (Fig. 4), there was a similar tendency for induction of sinigrin by caterpillar feeding, but such induction was not seen with flowers from the other two genotypes (results not shown). Levels of other glucosinolates showed moderate variations that were not affected by the experimental variables (Table 1, Fig. 4 and results not shown). There was no systematic induction of any indole glucosinolate or of total indole glucosinolates in response to caterpillar feeding (results not shown).

Discussion

Our data show that *P. brassicae* third, fourth, and fifth instars preferentially feed on *B. nigra* flowers. Preference was absolute: although leaf material was available in surplus, caterpillars fed exclusively on flowers. Historically, *P. brassicae* has been commonly considered a folivore (Feltwell 1982), with its impact on plants examined primarily from this perspective. To the best of our knowledge, this is the first detailed study showing that *P. brassicae* larvae preferentially feed on the buds and flowers of its host plant. The status of

P. brassicae as an agricultural pest has invariably resulted in a focus on cultivated, biennial forms of *B. oleracea* in studies of its host plant relationships. We also observed flower and silique feeding under field conditions (Smallegange et al., unpublished results).

The impact of folivores on plants has both direct and indirect effects. Directly, these herbivores reduce the leaf area available for photosynthesis, thereby decreasing the plants' ability to garner resources for defense and reproduction (Marquis 1984; Mothershead and Marquis 2000; Schoonhoven et al. 2005). Indirectly, leaf herbivory can delay flowering (Meyer and Root 1993; Strauss et al. 1996) or can alter developing flowers both physically (Strauss et al. 1996; Lehtilä and Strauss 1999; Mothershead and Marquis 2000) and chemically (Lohman et al. 1996; Karban and Baldwin 1997). This may cause a reduction in plant attractiveness to pollinators or in the efficiency of pollen delivery, resulting in decreased pollination and, subsequently, reduction of seed set and overall fitness of the plant. Florivory, feeding on flowers, has received less attention than folivory or feeding on other vegetative plant parts despite its common occurrence and potentially high impact on plant fitness (recently reviewed by McCall and Irwin 2006). Feeding on flowers causes damage to structures essential for plant reproductive output (Juenger and Bergelson 1997; Adler et al. 2001). Indirectly, petal damage leads to a reduction in pollinator visitation that not only reduces reproductive success but also affects male fitness (via pollen removal) of the plant as well (Karban and Strauss 1993; Krupnick and Weis 1998; Adler et al. 2001). However, the compensatory abilities of plants can partially overcome the impact of floral herbivory (Hendrix 1988; Krupnick and Weis 1998). Removal of reproductive organs as a preferred mode of feeding has evolutionary consequences, as this type of attack is likely to exert a stronger selection pressure than leaf feeding, especially in annual species like *B. nigra*. Although many plant species accumulate higher concentrations of defensive secondary metabolites in reproductive organs than in vegetative organs (Schoonhoven et al. 2005), in *B. nigra*, these higher levels are not sufficient to deter the specialist feeder *P. brassicae*. A putative barrier to florivory by generalist herbivores lies in the higher quantities of secondary plant compounds that are typically found in these organs relative to the levels reported for leaves (Rask et al. 2000; Fahey et al. 2001; Brown et al. 2003; Strauss et al. 2004; this study). The location of high concentrations of defensive secondary plant compounds, including glucosinolates, in reproductive structures is consistent with the optimal distribution of chemical defenses predicted by plant defense theory (Zangerl and Bazzaz 1992; van Dam et al. 1996; Wallace and Eigenbrode 2002; Strauss et al. 2004). Myrosinases, β-thioglucosidase enzymes that convert glucosinolates into products such as isothiocyanates and nitriles, which are volatile in the case of, e.g., sinigrin and 2-phenylethylglucosinolate, occur in different forms in flowers and leaves (Rask et al. 2000). By using headspace techniques, isothiocyanates and nitriles have been reported from mechanically macerated bud samples of several *Brassica* species (Tollsten and Bergström 1988). Phenylacetonitrile was detected in headspace samples of intact *B. rapa* L. flowers (Omura et al. 1999). Benzylcyanide was released in significantly higher amounts from *Brassica napus* L. in midflowering than in bud stage (Jönsson et al. 2005). High levels of isothiocyanates are potentially toxic to both specialist and generalist herbivorous insects (e.g., Li et al. 2000; Agrawal and Kurashige 2003), while even low levels may be detected by specialized sensory receptors and assist specialized herbivores in host plant finding (Renwick et al. 2006).

The growth rate we observed for caterpillars feeding on flowers was remarkable. The feeding site preference of L3–L5 caterpillars presents a case of within-plant selective foraging, the adaptive value of which might be the ingestion of higher nutritional content in flowers, known to act as nutrient sinks, compared to leaves. Nutrient acquisition during the

larval stage can affect pupal survival, longevity, and fecundity of Lepidoptera (Feltwell 1982; Van der Meijden et al. 1984; Metspalu et al. 2003). For example, female pupae of *Tyria jacobaeae* were significantly larger when caterpillars were reared on leaves and inflorescences of *Senecio jacobaea* plants than when reared on leaves only. This is advantageous because large pupae have a higher eclosion success, and it may explain why *T. jacobaeae* females prefer flowering plants for oviposition (Vrieling and de Boer 1999).

Faster growth has often been interpreted as a mortality-reducing factor. It is assumed that by reducing the amount of time that larvae are early instars, when they are most vulnerable to attack by natural enemies, they will experience higher survival (the 'slow-growth–high-mortality hypothesis' sensu Clancy and Price 1987; Benrey and Denno 1997). This has been experimentally confirmed under field conditions for the interaction between *P. rapae* feeding on *B. oleracea* and its predators and parasitoids such as *Cladophora glomerata* (Loader and Damman 1991; Benrey and Denno 1997). However, for other tritrophic interactions, faster growth was associated with higher mortality due to natural enemies (e.g., Clancy and Price 1987). Biere et al. (2002) found that larvae of the moth *Hadena bicruris* exhibit a strong preference for seeds of their food plant, *Silena latifolia*, over leaf tissues. Herbivore development proceeded more rapidly on seeds, and the larvae were less susceptible to parasitism from their main endoparasitoid, *Microplitis tristis*.

Herbivorous insects specialized on glucosinolate-containing plants typically avoid the formation of toxic isothiocyanates by employing specialized detoxifying mechanisms. In the case of *P. brassicae*, this is accomplished by a nitrile specifier protein (NSP) in the gut that changes the products of the myrosinase-catalysed hydrolysis of glucosinolates from isothiocyanates to relatively harmless nitriles (Wittstock et al. 2004), which may be further metabolized before excretion depending on side chain structure (Agerbirk et al. 2006; 2007). Shortly before this mechanism was reported, it was discovered that allyl isothiocyanate, the volatile hydrolysis product of sinigrin, is toxic to the specialist feeder *P. rapae* when feeding on an artificial diet (Agrawal and Kurashige 2003). Assuming a 20% DW in the artificial diet as used by Agrawal and Kurashige (2003), the maximum concentration to which *P. rapae* caterpillars were exposed in their study was 8.5 μmol/g DW. This dose caused significant negative effects on growth rate and inhibited development. In contrast, sinigrin levels in *B. nigra* flowers were more than 10 times higher (Fig. 4) and flowers sustained higher growth rates of *P. brassicae* than leaves, which had average levels of sinigrin two times higher than the corresponding amount of allylisothiocyanate as applied in the artificial diet. Assuming that isothiocyanates were produced in significant amounts during ingestion of glucosinolate-containing foliage by *P. rapae*, an involvement of the glucosinolate–myrosinase system in defense against this specialist species was suggested. *Brassica nigra* plants that had been induced by previous *P. rapae* feeding damage had a 27% increase in sinigrin concentration, but also 43% higher trichome density (Traw and Dawson 2002). Our data confirm the reported induction of sinigrin in leaves upon feeding, but also demonstrate that the magnitude of the induction is minor relative to the difference between leaves and flowers. With the elucidation of the NSP-based mechanism for detoxification of the glucosinolate–myrosinase system, the suggested involvement of the glucosinolate–myrosinase system and defense to specialists now needs to be re-evaluated. Formation of isothiocyanates is to be expected only if the myrosinase activity in the plant is so high that available NSP cannot completely direct the reaction towards nitriles, combined with glucosinolate levels sufficiently high to produce toxic levels of isothiocyanates. The selective foraging on flowers by *P. brassicae* documented here demonstrates that the caterpillars are able to detoxify even high levels of sinigrin, such as those present in *B. nigra* flower tissue. Not only high glucosinolate levels but also high myrosinase activity would be needed to exert toxic effects on *Pieris*

caterpillars, as has been experimentally demonstrated for another glucosinolate-adapted herbivorous insect, *Plutella xylostella* (Li et al. 2000). Glucosinolates occur in cells of all organs of Brassicaceous plants, whereas myrosinases can be found in scattered glucosinolate-free cells. It remains to be examined whether flower buds of different age, flowers, and siliques of *B. nigra* have cells that contain myrosinases. In the related *B. napus* L., expression of the MYR1-gene coding for particular myrosinase isoforms has been demonstrated to occur in all organs investigated, including petals (Falk et al. 1992), although myrosinase was absent in very young flower buds in this species (Andréasson et al. 2001). Myrosinase gene promoters fused to beta-glucuronidase as a reporter showed expression of myrosinase in idioblast myrosin cells in immature and mature seeds and phloem myrosin cells of *B. napus* (Thangstad et al. 2004). Data on headspace composition of inflorescences actually fed upon by *Pieris* spp. are not available. Follow-up studies on the types and quantities of volatile breakdown products emitted by herbivore-damaged flowers are required to quantify myrosinase activity levels in flowers. If these levels are low, the better performance associated with flower feeding might be reconciled with a role of the glucosinolate–myrosinase system in defense against the specialist *P. brassicae*. However, a likely and simple explanation of the better performance associated with flower-feeding may be that the caterpillars are able to efficiently detoxify the glucosinolate–myrosinase defense system in both organs, and that flowers, major nutrient sinks on a plant, are more nutritious than leaves. The fact that early instars did not migrate to flowers may be an adaptation to factors other than nutrient content: leaves are the site of oviposition, are present earlier in the season than flowers, and may provide better refuge from natural enemies for small instars. We have never observed *P. brassicae* or *P. rapae* ovipositing on flowers or flowering stems.

Neither *P. rapae* nor *P. brassicae* sequester glucosinolates for their own defense against natural enemies (Müller et al. 2003), in contrast to what had been published earlier by Aplin et al. (1975). The intensely green, clear regurgitant these caterpillars instantly, and typically, produce when attacked may contain highly concentrated glucosinolate hydrolysis products (nitriles) stored in the foregut. Presence of concentrated glucosinolate hydrolysis products may explain the obvious repellent effect of regurgitant to natural enemies such as *Cotesia* wasps and predators (Brodeur et al. 1996). Consequently, caterpillars may prefer flower tissues that contain high levels of these compounds, thus boosting their defense against both specialist and generalist natural enemies (Soler et al. 2005). Behavioral experiments with parasitoids and predators known to act as common natural enemies of *P. brassicae* (Feltwell 1982) are required to test this hypothesis.

Acknowledgments The authors thank André Gidding, Frans van Aggelen, and Leo Koopman for rearing *P. brassicae*, Unifarm for sowing and planting *B. nigra*, and the CGN (Wageningen, The Netherlands) for supplying *B. nigra* seeds. Matthieu Joosten (Laboratory of Phytopathology, Wageningen University) is acknowledged for freeze-drying the samples. We thank C.E. Olsen for LC–MS analyses and Birgitte B. Rasmussen and Lene K. Petersen for excellent technical assistance. Financial support from Gluds Legat and the Dutch Science Foundation NWO (grant 811.34.006) is gratefully acknowledged.

Introduction

In response to herbivore damage, plants synthesize and release complex blends of volatile compounds that serve as indirect defenses that mediate the attraction of predators and/or parasitoids of the herbivores responsible for the damage (Vet and Dicke 1992; De Moraes et al. 1998; Kessler and Baldwin 2001; Turlings and Wackers 2004; de Boer et al. 2004). Herbivory is not the only factor that induced the release of plant volatiles, even deposition of eggs by herbivorous arthropods may induce volatile attractants (Colazza et al. 2004; Hilker and Meiners 2006).

By releasing volatile compounds after herbivore attack, a plant can affect both predation and oviposition rates, thus influencing control over its herbivore population (Kessler and Baldwin 2001). Volatile compounds may also act as a direct defense by repelling herbivores (Turlings and Wackers 2004, and references therein). However, for some herbivores, plant volatiles represent a complex message that is interpreted according to the biological context, and these compounds may also attract other herbivores and thereby incur ecological costs (Kessler and Baldwin 2002; Heil 2004; Bengtsson et al. 2006; Hori et al. 2006, Srinivasan et al. 2006).

Plant volatiles include isoprenoids, carotenoids, benzenoids, phenylpropanoids, fatty acid derivatives, and amino acid derivatives (Turlings et al. 1998; Ferry et al. 2004; Dudareva et al. 2006). Herbivore feeding and mechanical damage can induce responses in plants that may be either systemic or restricted to the wounded site (Potting et al. 1995). Emission of plant volatiles in response to herbivores, resulting in the attraction of parasitoids and predators, has been documented in many systems, most of which include crop species (Turlings and Wackers 2004).

The potato tuberworm moth, *Phthorimaea operculella* Zeller (Lepidoptera: Gelechiidae), is a major pest in many potato-producing countries. At plant senescence, adult females lay eggs in soil cracks and on exposed tubers (Traynier 1975; Radcliffe 1982). After eclosion, the larvae mine into tubers, leaves, and stems, resulting in significant yield losses (Fenemore 1988). The highest percentage of infestation is found in exposed tubers above ground. This infestation is also a major source of further infestation in storage (Sileshi and Teriessa 2001). Until recently, control of this pest has been achieved with insecticides (Coll et al. 2000), semiochemicals, and natural enemies (Salehi and Keller 2002; Saour 2004). Less attention has been paid to the mechanisms of host-plant location and the tritrophic interactions mediated by compounds released by the plant.

Minute pirate bugs of the genus *Orius* (Hemiptera: Anthocoridae) are important natural enemies of pest insects and mites (Bush et al. 1993), and they are used as biological control agents in many parts of the world (Butler and O'Neil 2007 and references therein). Our field observations in potato crops of Southeastern Brazil show that adults of *O. insidiosus* attack and consume eggs and early instar larvae of *P. operculella* in partially exposed tubers and leaves of potato plants. Preliminary studies on the response of *P. operculella* to potato plants showed that these organisms did not respond to volatiles from the aerial portion of these plants in olfactometer bioassays. We then focused our studies on the behavioral responses of *P. operculella* to exposed potato tubers, to address the question of whether these insects are able to adjust their response to volatiles emitted from tubers with respect to

the tuber induction status. The role of volatiles for the polyphagous predator *Orius insidiosus* (Say) was also examined.

Methods and Materials

Insects and Plant Material Larvae of the potato tuberworm moth *P. operculella* were collected from potato fields at Paranapanema, Sao Paulo State, Brazil. Insects were reared on potato tubers inside plastic containers at 25±5°C and 60±10% relative humidity on a 12:12 hr L/D photoperiod regime. Pupae were sexed and placed in Petri dishes until adults emerged. Adults were maintained in net cages (20×20×20 cm) under the same conditions as larvae and fed with a 10% (*v*/*v*) honey solution. To avoid inbreeding, new larvae were collected regularly from potato fields. To obtain mated females, one newly emerged female and two males were confined together in plastic containers (5 cm high×10 cm diameter) for 5 d. Only females of *P. operculella* were used. Adults of the minute pirate bug *Orius insidiosus* were collected from flowers of *Helianthus annuus* and *Bidens pilosa* (Asteraceae) adjacent to potato fields with high infestation by the potato tuberworm moth, and kept in 10 ml glass vials under same conditions described above. Tubers of *Solanum tuberosum* L. (Solanaceae) cultivar Agata were obtained from the *Instituto Agronômico* (IAC), Campinas, São Paulo state, Brazil.

Olfactometer Bioassays To study the behavioral response of mated and unmated females of *P. operculella* and adults of *O. insidiosus* toward induced and noninduced volatiles of exposed tubers of potato plants, we conducted four-arm olfactometer bioassays (Vet et al. 1983) with the following three treatments:

Treatment 1: one tuber with approximately 400 g was mechanically damaged three times with a wheel cutter (1 cm diam.) over a distance of 3 cm, to mimic the damage caused by the first instars of *P. operculella*; *Treatment 2*: a tuber damaged by 50 first instars of *P. operculella*, which were allowed to feed before testing; *Treatment 3*: one intact tuber.

The bioassays were conducted after 24 hr of damage, to allow tuber penetration by small first instars of *P. operculella* in treatment 2. Each trial consisted of a combination of three treatment sources offered to the insects (mechanical damage, larval damage, and intact), whereas one chamber was kept empty. Treatments were randomly assigned to the arms.

The insects to be tested were introduced individually through the air extraction hole, after which the airflow was immediately started. The olfactometer was rotated every five trials to avoid positional biases not associated with the experimental treatment. After each trial, the apparatus was cleaned with water, and a four-empty-arm bioassay was conducted to evaluate the presence of volatile residuals. The tuber in the chambers was changed after cleaning. The response of each insect was tested for a period of 5 min. Bioassays with *P. operculella* were conducted at night, whereas those with *O. insidiosus* were conducted with fluorescent light, according to the activity pattern known for these insects (Fenemore 1988; Reid and Lampman 1989). The insects were deprived of food for 24 hr before the bioassays. The insect response to volatiles was measured with two variables: (1) the percentage of time spent walking in each odor field, and (2) the final position, which was defined as the odor field where the insect was positioned at the end of the 5-min-period. The total number of insects tested for each bioassay varied from 40 to 60. All treatments were carried out in a room at 25±5°C and 60±10% relative humidity.

Collection and Analysis of Headspace Volatiles Collection of volatiles from tubers was performed by using three different sampling techniques: (1) a push–pull dynamic headspace collection; (2) a static headspace collection that used solid phase microextraction (SPME) (Tholl et al. 2006); and (3) a direct headspace sampling (Millar and Sims 1998). For the pull headspace sampling, the tubers (~400 g) were placed in a glass chamber (20 cm tall× 10 cm diam). Clean humidified air was forced through the chamber, regulated by a flowmeter at 500 ml min^{-1} positioned at the lower part of the chamber. Volatiles were trapped in a glass tube (7.5×0.5 cm) attached to the top of the glass chamber containing 100 mg Super Q adsorbent (80/100 Mesh, Alltech Assoc., IL, USA). The trap was connected to the outlet of the chamber and via another flowmeter to the vacuum compressor. Volatiles were eluted with 100 µl dichloromethane, and 1 µl eluate was injected into a gas chromatograph coupled to a mass spectrometer (GC-MS). Empty chambers were used as a control to extract air volatiles in the three sampling techniques. SPME sampling technique was conducted with a SPME fiber coated with 100 µm of polydimethylsiloxane (Supelco, Bellefonte, PA, USA). The fiber was conditioned for 1 hr in a GC injection port at 250°C and afterward, placed inside the glass chamber above the tubers. After sampling, the fiber was analyzed immediately by GC-MS. Direct headspace sampling was conducted by removing an aliquot of 10 µl of headspace of the plant material placed inside the glass chamber with a gas-tight syringe and injected directly into the GC-MS. All collections were conducted at 25±3°C and 60±10% relative humidity. Each treatment was repeated five times.

Volatiles were characterized by GC-MS-EI on a Hewlett Packard 6890 gas chromatograph system with a fused capillary column (30 m×0.25 mm×0.25 µm, HP-5MS, crossbond 5%-phenyl-95%-dimethylpolysiloxane) directly coupled to a selective mass detector Hewlett Packard 5973. Injector and detector temperatures were 250°C and 280°C, respectively. Injections were made in splitless mode with a constant column flow of 35 cm sec^{-1} helium. The oven was programmed from 35°C min^{-1}, 3°C min^{-1} to 250°C for 40 min. Quantification of methyl jasmonate (MeJA) (see below) was calculated by constructing a calibration curve with known concentrations of synthetic standards, and correlating their peak areas with those of the samples collected from tubers.

Response of Insects to Synthetic MeJA To investigate if the biased preference of mated females of *P. operculella* and *O. insidiosus* to volatiles from undamaged and damaged potato tubers (see "Results") could be explained by differences in the concentration of MeJA, behavioral bioassays were conducted in the four-arm olfactometer with synthetic MeJA 95% [Sigma-Aldrich Co., Steinheim, Germany—a mixture of methyl jasmonate (95%) and two unknown isomers] placed on a rubber septum at the equivalent amount found in the direct headspace sampling of intact tubers (0.001 ng g^{-1} of fresh tuber). A behavioral response curve was built by using as reference the equivalent amount of MeJA (0.001 ng g^{-1}) plus two dilutions and five concentrations with a factor of three (0.0001, 0.0003, 0.001, 0.003, 0.009, 0.027, 0.081, and 0.241 ng g^{-1}). The response to each concentration was analyzed in one chamber of the olfactometer, whereas the other chambers were kept empty, as described by Vet et al. (1983). Treatments were randomly assigned to the arms. The response of the insects was measured by the time spent walking in each odor field.

Statistics As data on percentage of time spent walking in each odor treatment were not normally distributed in the bioassays with tubers, they were analyzed with a nonparametric Friedman test with a multiple comparison analysis for ranked data based on Nemenyi test

(Zar 1999). The number of final positions for each odor treatment was analyzed by using the Cochran *Q* test; pair-wise comparisons of the number of final positions were analyzed with a test for multiple contrasts of data subjected to the Cochran test (Zar 1999). Mean differences of the amount of MeJA among the treatments were analyzed with a one-way analysis of variance (ANOVA). A two-way ANOVA was used to analyze the response (mean time spent in each test odor field) of mated females of *P. operculella* and adults of *O. insidiosus* to synthetic MeJA, with insect species and MeJA concentration as fixed effects. Multiple comparisons were made by using a Tukey HSD test (Zar 1999).

Results

The response of females of *P. operculella* to volatiles of exposed potato tubers was dependent on their mating status and on the induction treatments. For unmated females, the percentage of time spent walking in the different fields failed to show a significant preference for any of the treatments (Friedman test: $\chi^2=5.57$, $df=3$, $P=0.135$). In contrast, mated females showed differences among the treatments (Friedman test: $\chi^2=13.87$, $df=3$, $P=0.003$), preferring to stay longer in the field corresponding to the treatment with intact tubers than in those containing tubers with mechanical damage, larval damage, or clean air (Fig. 1). The number of final positions followed the same pattern, with unmated females showing no significant results and mated females choosing to remain in the field corresponding to intact tubers significantly more than in the other treatments (Table 1).

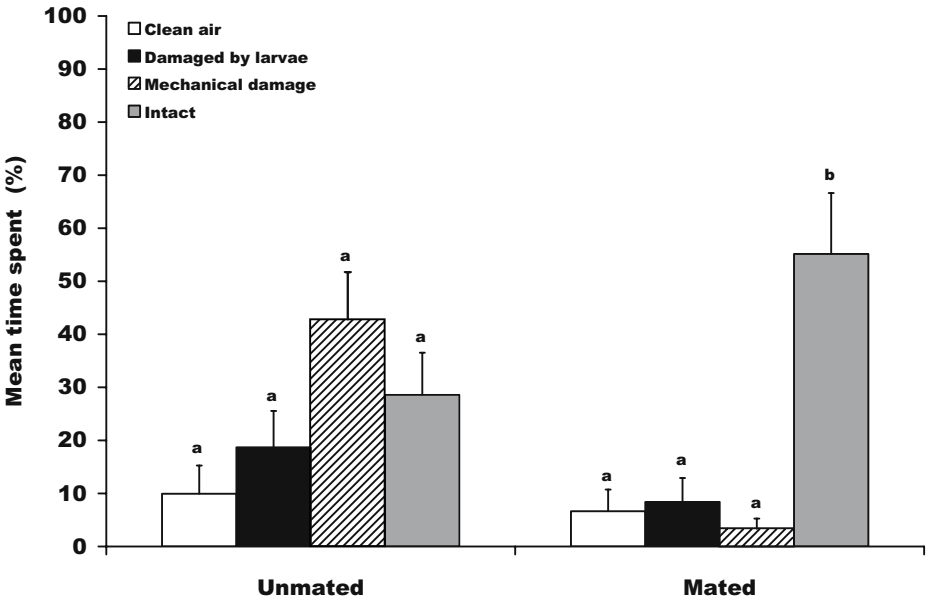

Fig. 1 Response of mated females of *Phthorimaea operculella* to volatiles from differently treated potato tubers. The mean percentages of time spent (±SE) within each field of the olfactometer were recorded for 5 min. Different letters indicate significant differences, evaluated by a multiple comparison test of ranked data based on the Nemenyi test ($P<0.05$)

Table 1 Total number of final positions of *Phthorimaea operculella* females and adults of *Orius insidiosus* to four different odor sources in the olfactometer

Treatments	Insects		
	Unmated *P. operculella*	Mated *P. operculella*	*O. insidiosus*
Clean air	2^a	3^a	1^a
Intact	6^a	11^b	3^a
Mechanically damaged	8^a	3^a	1^a
Damaged by larvae	4^a	1^a	14^b
Cochran Q test	Q=5.61; *N*=40; *df*=3, *P*=0.1320	Q=13.11; *N*=40; *df*=3, *P*=0.004	Q=22.00, *N*=40; *df*=3, *P*<0.001

Different letters in each row indicate significant differences by multiple contrasts for data subjected to the Cochran *Q* test ($P<0.05$, Zar 1999)

Adults of *O. insidiosus* also responded to the volatiles emanating from exposed tubers. The percent of time spent walking was significantly different among the treatments, with the insects staying longer in the field with tubers damaged by larvae than in those with intact or mechanically damaged tubers, or with clean air (Friedman test: $\chi^2=12.12$, $df=3$, $P=0.007$, Fig. 2). The same result was obtained for the number of final positions, which was significantly different among treatments showing that insects responded to volatiles from tubers infested with *P. operculella* larvae over those of intact and mechanically damaged tubers, or clean air (Table 1).

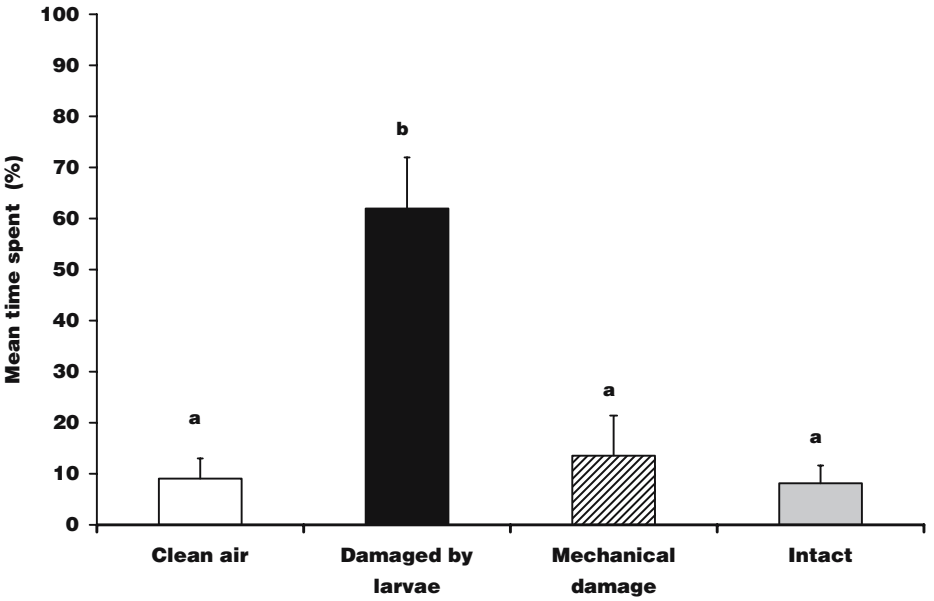

Fig. 2 Response of adults of *Orius indisiosus* to volatiles from differently treated potato tubers. The mean percentages of time spent (±SE) within each field of the olfactometer were recorded for 5 min. Different letters indicate significant differences evaluated by a multiple comparison test of ranked data based on the Nemenyi test ($P<0.05$)

No peaks were detected with either pull or static headspace SPME collection. The analysis of direct headspace of intact and induced tubers showed a mixture of isomers of MeJA [methyl jasmonate (90%) and two unknown isomers (10%)] as the only compounds. Confirmation of this result was made by co-injection with commercially supplied MeJA. MeJA measurements of the headspace from potato tubers were calculated by using a standard curve with five replicates and known amounts of synthetic MeJA injected into the GC-MS. Quantitative significant differences of the mean amounts of MeJA were found among treatments (one-way ANOVA: $F_{2,\ 9}=6.66$; $P=0.017$). Infestation with *P. operculella* larvae for 24 hr resulted in a six- to tenfold increase in the amount of MeJA emitted (0.090 ± 0.006 ng g^{-1} of potato fresh tuber) when compared with tubers damaged artificially (0.002 ± 0.0007 ng g^{-1}) (Tukey test: $P=0.042$), and intact tubers (0.001 ± 0.0003 ng g^{-1}) ($P=0.021$), respectively. There were no differences between the amount of MeJA emitted by intact or artificially damaged tubers ($P=0.890$).

Mated females of *P. operculella* and adults of *O. insidiosus* showed their highest activity on a different range of concentrations of synthetic MeJA (Fig. 3), and the response to MeJA was significantly different between insect species (two-way ANOVA: $F_{1,\ 281}=3.90$; $P=0.040$) and MeJA concentrations (two-way ANOVA: $F_{7,\ 281}=2.62$; $P=0.012$). Moreover, an interaction between species and MeJA concentrations was found (two-way ANOVA: $F_{7,\ 281}=5.53$; $P<0.001$). Adults of *O. insidiosus* showed a stronger response to higher concentrations of MeJA than mated females of *P. operculella*. Maximum range activity of mated moths and the minute pirate bug to synthetic MeJA was observed

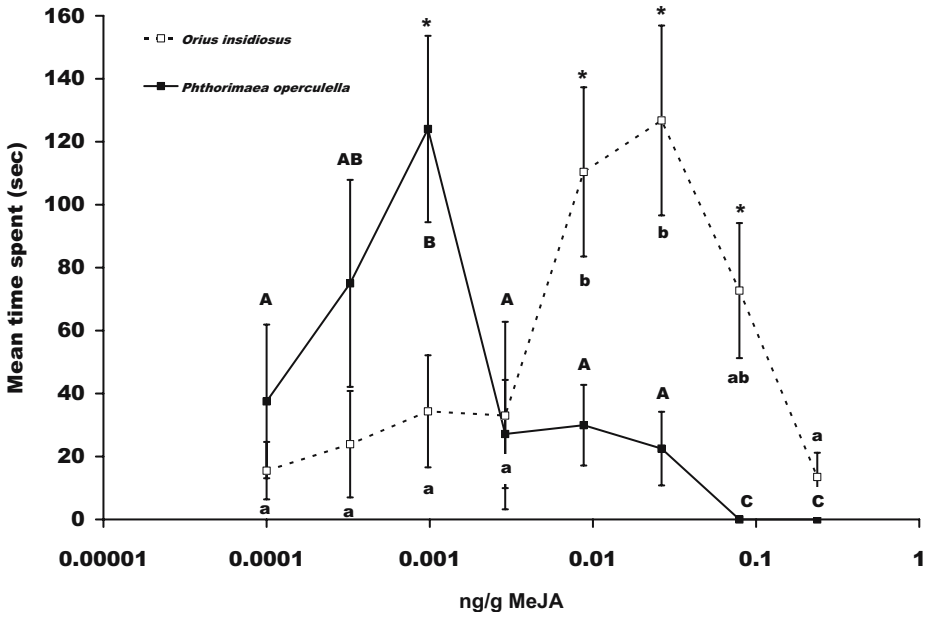

Fig. 3 Activity of mated females of *Phthorimaea operculella* and adults of *Orius insidiosus* to different concentrations of synthetic MeJA. The mean time spent (±SE) within each field of the olfactometer was recorded for 5 min. Differences were analyzed by using a two-way ANOVA. Different letters within each species indicate significant differences (Tukey test; $P<0.05$) among concentrations, being uppercase for *P. operculella* and lowercase for *O. insidiosus*. Asterisks indicate significant differences of each concentration between species (Tukey test; $P<0.05$)

at 0.0003 to 0.001 and at 0.01 to 0.05 ng g^{-1}, respectively, which correspond to the concentrations of intact and infested tubers detected in the direct headspace samplings.

Discussion

When allowed to select between potato tuber volatiles, mated females of *P. operculella* preferred the intact tubers over damaged ones, whereas unmated females showed no response. Several studies have shown that herbivores that forage for suitable food items often use volatiles emitted by host plants as cues (Prokopy and Roitberg 2001, and references therein). The decision to approach, feed on, or oviposit on a plant might depend on: (1) the plant's defense status, (2) the activity of conspecifics, and (3) the mating status of the animal. Thus, the ecological role of these compounds may differ among plant and herbivore species (Bolter et al. 1997; De Moraes et al. 2001; Rojas et al. 2003; Pickett et al. 2003; Heil 2004; Meiners et al. 2005; Tasin et al. 2005; Dickens 2006). The internal state of an animal, such as reproductive stage, also influences its foraging behavior (see Vet and Dicke 1992, for a review). Mated *P. operculella* females might use volatiles from intact tubers to locate a suitable site for oviposition. Several other insect species preferentially oviposit on undamaged rather than damaged host plants in response to volatile cues (De Moraes et al. 2001; Carroll et al. 2006) as at high infestation levels, volatiles released by damaged tubers may indicate: (1) herbivore population densities are already high, and as a result competition among larvae may be high (Prokopy and Roitberg 2001, and references therein); (2) the presence of natural enemies attracted by the volatiles, such as egg parasitoids responding to locally and systemically induced plant volatiles (Meiners and Hilker 1997; Lou et al. 2005); (3) direct plant defenses have already been activated; and (4) a lower nutritional value for their offspring than on intact plants (Bernasconi et al. 1998). Avoidance behavior mediated by induced plant volatiles also has been shown for some herbivorous insects (Meiners et al. 2005; Mehrnejad and Copland 2006). Thus, the effect of induced responses of potato tubers on populations of *P. operculella* and the sensory responsiveness of the females of this insect should be further investigated.

Plants responding to herbivore attack may release large amounts of volatiles into the environment. These play important roles in host location for many predators and parasitoids (De Moraes et al. 1998; Kessler and Baldwin 2001; Lou et al. 2005; Mehrnejad and Copland 2006; Yan and Wang 2006). Some species of *Orius* use plant volatiles in prey-searching behavior (Reid and Lampman 1989; VanLaerhoven et al. 2000; Tillman 2006, Mochizuki and Yano 2007), and our results indicate that *O. insidiosus* can exploit volatiles released by exposed potato tubers infested with larvae in the trophic system considered. The orientation of *O. insidiosus* to plant volatiles induced by larvae-infested tubers supports the hypothesis of Vet and Dicke (1992), who suggested that the ability of natural enemies to distinguish between intact and herbivore-induced plant synomones could increase their searching efficiency.

Regarding the role of MeJA as a mediator of tritrophic interactions, this compound has been found to occur constitutively in some plants and also to be inducible. Amounts of MeJA released by the plant are known to increase according to the extent of the damage (Preston et al. 2004). MeJA is well-known as a phytohormone signaling wounding (e.g., De Bruxelles and Roberts 2001; Howe 2004) and mediating even morphological changes (e.g., Boughton et al. 2005). A direct role of MeJA as cue for predators and parasitoids has not been well described (James 2005; James and Grasswitz 2005). However, our results suggest that it may mediate potato tuber attractiveness to herbivores and their natural enemies. At specific concentrations, MeJA mediates host recognition of the second and

third trophic levels on exposed potato tubers, by influencing *P. operculella* mated females to avoid previously attacked tubers, and by attracting the generalist predator *O. insidiosus* to tubers attacked by *P. operculella* larvae. In addition, the range of active concentrations corresponds with the respective emissions from intact and infested tubers found in headspace samplings.

Volatiles of different cultivars of potato plants attract potato pests (Bolter et al. 1997; Eigenbrode et al. 2002). Nevertheless, apart from being specific for the damaging herbivore species, herbivore-induced synomones may also be plant-specific and cultivar-specific (Takabayashi et al. 1991). To our knowledge, this is the first study of volatiles emitted by infested or intact potato tubers that mediate the interactions between herbivorous insects and their natural enemies.

Based on the results obtained in the laboratory study, we propose the following scenario for tritrophic interactions among potato plants, *P. operculella*, and the polyphagous predator *O. insidiosus*: Mated females of the potato tuberworm moth locate their host and lay egg clutches on intact tubers, which are partially exposed from the soil in older plants. The response of *P. operculella* and *O. insidiosus* to potato tubers is then modulated by MeJA. Mated females may locate a suitable site of oviposition by detecting the low concentrations of this compound emitted by intact tubers. Once the tubers are subjected to feeding by first-instar larvae, the plants release higher amounts of MeJA, thus becoming less attractive to mated tuberworm moth females, but attractive to the polyphagous predator *O. insidiosus*. Both *P. operculella* and *O. insidiosus* might have adapted to associate plant volatiles with the potential presence of suitable host plants or prey. Furthermore, the concentration of MeJA might determine the kind of behavioral response of both the herbivorous and the predatory species.

In South America, cultural practices, such as the type of irrigation and removal of the halum, are known to affect the level of tuber infestation by the potato tubermoth because they affect the exposure of tubers (CIP 1988). Proper implementation of control measures, such as filling soil cracks, affect the ability of adults of the potato tuberworm to oviposit on exposed tubers (Coll et al. 2000). Predation by *O. insidiosus* is restricted to eggs and the first instars of many insects; thus, it may be possible to use *O. insidiosus* against *P. operculella* in biological control programs, and the current study offers evidence to support the potential use of induced volatiles of potato tubers to improve the foraging efficacy of the minute pirate bug.

ZAR, J. H. 1999. Biostatistical Analysis. New Jersey.

grasshoppers and Mormon crickets. A typical bait formulation consists of wheat bran or other solid carrier impregnated with an insecticide. Adding attractants and phagostimulants could result in greater bait acceptance, lure susceptible species to bait particles, and enhance palatability. Such additions to bait formulation make bait treatment more efficacious (Latchininsky and VanDyke 2006).

Vegetable oils have kairomonal attractant properties toward grasshoppers primarily due to the presence of linoleic and linolenic fatty acids (Bomar and Lockwood 1994a). These fatty acids are dietary essentials for grasshoppers and, once volatilized, can be detected by the insects' olfactory receptors (Bomar and Lockwood 1994b). Furthermore, fatty acids may be token stimuli for necrophagic grasshoppers seeking other nutrients, such as proteins, which are abundant in insect cadavers. Due to the presence of these fatty acids, certain vegetable oils used as insecticide carriers can function as "liquid baits" and markedly enhance the efficacy of grasshopper control programs (Lockwood et al. 2001).

The goal of this study was to develop a sensitive and efficient laboratory bioassay method and to apply this approach to identify particular vegetable oils that induce grasshopper attraction and feeding. Such oils may be useful kairomonal adjuvants and/or carriers for acridicide formulations.

Materials and Methods

Fatty Acid Analysis The initial selection of oils for screening was based on considerations of chemical profile, availability to pest managers, and cost. We sought oils with a fatty acid profile similar to that of the grasshopper *Melanoplus sanguinipes* (F.) (Barlow 1964), a common rangeland pest grasshopper, and that were widely available and inexpensive. A literature search and market investigation yielded eight candidate vegetable oils: canola, corn, linseed or flax, olive, peanut, rapeseed, soybean, and sunflower (Table 1). Subsequently, samples of these oils were obtained from available suppliers and analyzed for their actual fatty acid composition as described in Broughton and Wade (2002; Table 2). Lipids were extracted sequentially with chloroform-methanol (1:2, *v/v*), chloroform-saline (1:1, *v/v*), and one part chloroform (2×) following the method of Bligh and Dyer (1959). Chloroform fractions were pooled, evaporated to dryness, and suspended in minimal quantities of chloroform. After extraction, lipids were saponified in toluene and 0.5 mol/l KOH in methanol (8 min at 86°C)

Table 1 Typical fatty acid percent composition of some common vegetable oils (White 2000) as compared to *Melanoplus sanguinipes* adult grasshoppers

Fatty Acid Oil	Palmitic	Stearic	Oleic	Linoleic	Linolenic	Other	Total
Canola	4	2	64	19	9	2	100

**Small amounts of fatty acids like Myristic, Palmitoleic, and Erucic

to liberate free fatty acids, cooled on ice, and acidified with 0.7 mol/l HCl in methanol. Free fatty acids were extracted with hexane (×2), evaporated to dryness, and methylated with ethereal diazomethane. The methyl esters were redissolved in hexane and analyzed by gas chromatography [Hewlett-Packard 5890 gas chromatograph with a DB23 capillary column (0.25 mm× 30 m, J & W Chromatography, Folsom, CA, USA) with hydrogen as the carrier gas]. Fatty acids were quantified by using pentadecanoic acid (NuCheck Prep, Elysian, MN, USA) as an internal standard.

Fatty acid profiles of the oils did not agree exactly with previously published data (Table 1). This is not surprising as fatty acids produced in any one type of oilseed may vary widely with geographic location, soil type, climate, agricultural practices, and even exposure to pesticides (White 2000).

Comparisons among the fatty acid profiles of the vegetable oils and *M. sanguinipes* were based on percent similarity (Kotila 1986). Furthermore, three fatty acids were of particular interest—linoleic, linolenic, and oleic—because they (mostly the first two and, to a lesser extent, the third) are the primary olfactory attractants of grasshoppers (Bomar and Lockwood 1994a, b). Consequently, the oils were ranked according to (1) percent similarity of their fatty acid profiles with *M. sanguinipes*; (2) combined, linolenic and linoleic acid content; and (3) oleic acid content. The ranking of each oil reflected the theoretical expectations of the oil performance as phagostimulants based on previous studies. The final ranking of vegetable oils as grasshopper attractants and feeding stimulants was developed after three sets of laboratory bioassays were performed with the selected oils.

Bioassay The non-diapausing strain of *M. sanguinipes* was selected for laboratory experiments. It is one of the few grasshopper species continuously available in laboratory colonies in the USA, and is a significant component of the rangeland grasshopper pest community (Pfadt 1988). In addition, its fatty acid profile is known (Barlow 1964).

Assays 1 and 3 were conducted on fourth instar nymphs. Nymphs were used in bioassays because the nymphal stage is when control programs generally should be conducted on

rangeland grasshoppers, fourth instar nymphs can be handled without injury, and feeding behavior is more consistent and reliable than in fifth instars (Bomar and Lockwood 1991). Nymphs were raised from eggs provided by the USDA-ARS Northern Plains Agricultural Research Laboratory in Sidney, Montana. Grasshoppers were hatched and reared according to Henry (1985). Assay 2 was conducted on adult insects, with equal numbers of males and females.

Pairs of grasshopper nymphs were used in assays, rather than single individuals. Adult grasshoppers were tested with just one individual per assay chamber. Before testing, all grasshoppers were held without food or water for a period of 4 h. Gladware® brand storage containers (739 ml capacity) were selected as an optimal assay chamber.

Bioassays were developed using a 24-h time period from introduction of the grasshopper(s) to the test chamber until scoring of the results. This amount of time was the minimum necessary to assure that grasshoppers had passed through an entire circadian cycle, an important consideration in context of their feeding periodicity (Lockwood et al. 1996). A longer duration of assay increased the probability that the nymphs would molt into the next instar, thereby invalidating the results. Environmental conditions were standardized at 27±1° C, 14:10 h light/dark, and 30% RH.

Whatman 1 filter paper (55 mm diam) was chosen for assays because it provided a neutral and stable substrate following Bomar and Lockwood (1994a, b). Oils were applied to flat filter paper discs with an airbrush applicator as described by Lockwood et al. (2001). This method allowed oil to be deposited at a rate that simulated aerial field applications of 1 l/ha (0.2 µl per disc) and 10 l/ha (2 µl per disc). However, the airbrush method of applications was not optimal because the oil was evenly applied and subsequent grasshopper feeding on was highly dispersed and not always evident. Often, nymphs would simply scrape the surface of the paper, rather than remove a readily discernible portion of the substrate. This made accurate scoring of the paper feeding difficult.

As an alternative method, the paper discs were folded in half to create a tent-like shape, which made it easy for the insects to grasp and feed on the edges. At each end of the crease, we applied various amounts of canola oil (from 0.1 to10 µl) until we found a volume that would create a visible spot (ca. 1 cm diam) without bleeding over the entire disc surface. A 2 µl drop created a distinct semicircular area for feeding, and in preliminary tests with 20 pairs of grasshopper nymphs, 60% of them removed a detectable portion of the oil-treated paper from the folded disc. In some cases, the nymphs chewed the entire semicircle of oil-impregnated paper, leaving behind only the untreated substrate. The 4 µl of oil per 55-mm filter paper is 20 times greater than the average amount that would be applied to the same surface area via most ultra low volume (ULV) aerial applications (1 l/ha is a typical rangeland ULV rate), but the application method provided an optimal "target" for grasshopper feeding in context of the assay.

A simple binomial approach was used to score insect feeding: Either a detectable (by unaided human vision) portion of the substrate was removed, or it was not. Efforts to generate more refined estimates for substrate removal or to determine whether there was surface scraping eroded the interobserver reliability of scoring.

Previous studies suggested that adding a water source during a feeding assay may decrease grasshoppers' physiological stress and increase their feeding on tested substrates (Bomar and Lockwood 1994a, b). As such, we conducted preliminary tests with a water-soaked cellulose sponges (ca. 3 cm^3) placed in the assay chambers. The oils in this test included 5 vegetable oils (canola, olive, rapeseed, flax, and a 1:1 blend of rapeseed and flax) and crop oil (a paraffinic oil as positive control) by using a pair of 2 µl drops. Data were analyzed by Pearson's chi-square linear-by-linear association with SPSS 14.0 statistical software. Results showed that tests with no water were generally more sensitive to differences among oils

(Table 3). Grasshopper feeding on different oils increase inconsistently, and only in two cases (rapeseed and canola) did the presence of water significantly ($P<0.05$) increase feeding (Table 3). Given that the inclusion of a water-soaked sponge added logistic complexity (i.e., keeping the paper from being wetted), raised humidity to unnaturally high levels in the chamber, provided an alternative, confounding substrate for feeding, and yielded results that obscured differences between the potential feeding stimulants, we chose to conduct our assays with untreated Whatman 1, 55-mm diameter filter paper discs in the absence of a water source.

Three sets of laboratory bioassays were conducted following the standard protocol described above. In the first two sets, unsexed fourth instar nymphs and adult males and females of *M. sanguinipes* were used. Five vegetable oils were applied to filter paper discs: canola, flax, olive, rapeseed, and a 1:1 mixture of rapeseed and flax oils. In addition to the vegetable oils, as a positive control, we assessed an oil that is widely used as an adjuvant in agriculture sprays in the US: crop oil concentrate (United Agri Products brand), which is a paraffinic oil that contains a phosphate ester emulsifier. The third set of bioassays was conducted on fourth instar *M. sanguinipes* nymphs only. Ten vegetable oils were used: canola, corn, flax, olive, peanut, soybean, SoyStick (methylated soybean oil that is a chemically modified derivative of soybean oil often used as a non-ionic surfactant in herbicide sprays), sunflower, rapeseed, and rapeseed-flax 1:1 mix. As positive controls, we used both crop oil concentrate and mineral oil (Safeway brand, U.S.P.). The latter oil was composed of alkanes and cyclic paraffins derived from the distillation of petroleum that makes a colorless and odorless light oil.

In addition to the aforementioned qualities of oils, French rapeseed oil was tested because it was a carrier for an insecticide—Adonis® (a.i. fipronil)—used worldwide for grasshopper and locust control (FAO 2004). Flax oil was also tested in cooperation with Rhône-Poulenc, who was seeking at the time a highly available and economical carrier for other formulations of the insecticide fipronil. Although flax oil is usually not consumed by humans, it is high in linolenic acid.

Statistical Analyses In all three sets of assays, a minimum of ten replicates for each oil were tested in randomized order. The resulting data were analyzed with Pearson's chi-squared linear-by-linear association using SPSS 14.0 statistical software.

Table 3 Phagostimulation assay protocol development trial using 4th instar *M. sanguinipes* grasshopper nymphs. Two-choice tests of vegetable oils with and without water sources in the test arenas

Results

Fatty Acid Analyses Fatty acid analyses of the vegetable oils studied and their percent similarity to *M. sanguinipes* are summarized in Table 2. Flax oil was the most similar to the fatty acid profile of *M. sanguinipes* (85%), followed in order by rapeseed-flax mix (71%), soybean (65%), peanut and rapeseed (56%), canola (54%), corn (53%), sunflower (47%), and olive oils (39%; Table 2). Peanut oil was the only oil to have any measurable quantity of erucic acid, a 22:0 carbon fatty acid. Both canola and rapeseed oils had less than 0.01% erucic acid. The latter was surprising because rapeseed oil typically contains between 25 and 50% of erucic acid (White 2000). As such, the rapeseed oil that we used should be considered as a variety of canola. However, the French rapeseed oil was unbleached and not deodorized, unlike canola or other food-grade vegetable oils tested. Unique to olive oil was the presence of 2% palmitoleic acid (16:1). The stearic acid (18:0) content of flax oil was closest to levels found in *M. sanguinipes* (Table 2). All analyzed vegetable oils lacked myristic (14:0) acid, which made up 1% of the fatty acid profile of *M. sanguinipes*.

Two of the tested oils, flax and sunflower, had higher amounts of linolenic and linoleic acids combined (72% each) than did *M. sanguinipes* (63%; Table 2). The other oils had lower amounts of these oils; olive oil had the least (13%), followed by canola (26%), peanut and rapeseed (29%), rapeseed and flax mix (50%), soybean (58%), and corn (60%).

The highest proportion of oleic acid (80%) was found in olive oil, followed by canola (65%), rapeseed (63%), peanut (52%), rapeseed-flax mix (41%), and corn and soybean (25%; Table 2). Flax oil had the same oleic acid content as *M. sanguinipes* (19%). Only sunflower oil contained a lower proportion (15%) of this fatty acid than the grasshopper.

Bioassays 1 and 2 Results of the first two sets of assays are presented in Tables 4 and 5. The untreated (negative control) papers had no nymphal feeding and a low level of feeding by adult grasshoppers (2 positives out of 60). Relative to the oil-treated papers, there was significantly ($P<0.05$) less feeding on plain paper than expected. The crop oil concentrate (positive control) had 10% feeding by the nymphs and 20% feeding by the adults. The positive control had significantly ($P<0.05$) less feeding than all of the vegetable oils except rapeseed. Feeding between vegetable oils differed from expectations ($P<0.05$). Olive oil was the most phagostimulatory of the oils, being fed on 100% of the time, by both nymphs and adult grasshoppers. Canola and flax had 60% feeding by nymphs and 80% feeding with adults. The rapeseed-flax mix had 50% feeding by nymphs and 70% by adults. Rapeseed oil had a 20% feeding response with nymphs and 70% with adults. Among the vegetable oils, only rapeseed showed significant ($P<0.05$) differences between the feeding of adults and nymphs.

Table 4 Assay 1: phagostimulation trial using fourth instar nymphs of *Melanoplus sanguinipes*

Oil	N	Percent with Feeding Damage	Preference Rank
None	60	0	6
Crop	10	10	5

Flax	10	60	2
Rapeseed+flax	10	50	3
Canola	10	60	2
Olive	10	100	1

Table 5 Assay 2: phagostimulation trial using adult (50% males, 50% females) *Melanoplus sanguinipes*

Oil	N	Percent with Feeding Damage	Preference Rank
None	60	3	5
Crop	10	20	4
Rapeseed	10	70	3
Flax	10	80	2
Rapeseed+flax	10	70	3
Canola	10	80	2
Olive	10	100	1

Bioassay 3 Results of the third set of bioassays are presented in Table 6. The differences among vegetable oil treatments and the negative (untreated papers) and positive (mineral oil and crop oil concentrate) controls were significant ($P<0.01$). The oils could be grouped into those that induced low level feeding (crop 10%, rapeseed 20%, methylated soybean oil 20%); moderate feeding (flax 60%, rapeseed-flax mix 50%, canola 60%, peanut 60%, soybean 60%, and corn 70%); and heavy feeding (sunflower 90% and olive 100%).

Vegetable Oil Ranking The rankings of all studied vegetable oils with regard to three "theoretical" parameters (% similarity to *M. sanguinipes*, linolenic+linoleic acid content, and oleic acid content), as well as the results of three sets of bioassays are summarized in Table 7. Based on these data, the mean rank of every oil was calculated separately for theoretical expectations and for practical application of bioassays, and the oils were categorized accordingly (Table 8). The lowest rank reflected the highest attraction and phagostimulatory properties of oils to grasshoppers. Theoretical expectations resulted in the following ascending rank order: flax, rapeseed and soybean, canola and peanut, corn, rapeseed-flax mix, and, finally, sunflower and olive. Among the oils tested in all three sets of bioassays, olive oil performed best, followed by flax and canola, rapeseed-flax mix and rapeseed. Sunflower, corn, peanut, soybean and methylated soybean oils were tested only in one set of bioassays and corn and sunflower performed well.

Table 6 Assay 3: phagostimulation trial using fourth instar nymphs of *Melanoplus sanguinipes*

Type of Oil	N	Percent with Feeding Damage	Preference Rank
None	120	8	8
Crop Oil Concentrate	10	10	7
Rapeseed	10	20	5
Flax	10	60	4
Rapeseed+Flax	10	50	5
Canola	10	60	4

6	Corn	Canola	Corn Soybean			Rapeseed
7	Sunflower	Olive	Flax			
8	Olive		Sunflower			

Discussion

Our expectations regarding the phagostimulatory properties of vegetable oils were based on two assumptions. First, the oil should have the fatty acid profile similar to *M. sanguinipes*. Second, to enhance feeding, the oil should have a significant amount of the fatty acids "behaviorally active" for grasshoppers (linoleic+linolenic, and oleic), and that are known to induce the insect movement toward a food source (Bomar and Lockwood 1994a, b, c). However, we found that none of the studied oils ranked consistently across all parameters. For example, the fatty acid composition of flax oil was most similar to *M. sanguinipes* (i.e.,

Table 8 Ranking of the tested vegetable oils according to theoretical expectations and results of three laboratory bioassays

Parameter/Rank Oil	Theoretical Expectation				Bioassays		
	Percent Similarity	Linolenic+Linoleic Content	Oleic Content	Mean	No. 1	No. 2	No. 3
Canola	5	6	2	4.3	2	2	4
Corn	6	2	6	4.7	–	–	3
Flax	1	1	7	3.0	2	2	4
Olive	8	8	1	5.3	1	1	1
Peanut	4	5	4	4.3	–	–	4
Rapeseed	4	5	3	4.0	4	3	6
Rapeseed+Flax	2	4	5	3.7	3	3	5
Soybean	3	3	6	4.0	–	–	4
Sunflower	7	1	8	5.3	–	–	2
Methyl. soybean	–	–	–	–	–	–	7

had the highest percent similarity), and had the highest content of linolenic and linoleic acids; however, it had one of the lowest proportions of oleic acid. In contrast, olive oil ranked lowest according to percent similarity and linolenic+linoleic acid content, but had the highest oleic acid content. Summation of the three theoretical parameters produced rankings that placed flax oil with the greatest potential, and olive and sunflower having the least, with the other oils somewhere in between.

There are reasons to be skeptical regarding the "theoretical expectations" criteria. Percent similarity comparisons were made to published data on the fatty acid content of adult *M. sanguinipes* (Barlow 1964). It is not known how close these data were to the actual fatty acid content of the tested insects, among which there were both nymphs and adults. Fatty acid content of oilseeds can vary depending on many different factors: for example, in the case of sunflower oil, even the position of the seed in the seed head matters (White 2000). Most probably, the fatty acid profiles of grasshoppers also vary depending on developmental stage, sex, source of food, etc. Hence, it is not surprising that our bioassay results did not agree fully with theoretical expectations. Despite its lowest "theoretical" rank, olive oil performed consistently and ranked as the best stimulant in all three sets of assays. It was followed by canola and flax, rapeseed-flax mix, and rapeseed oils. The five remaining oils were tested only once and, therefore, do not allow definitive conclusions to be drawn. Among them, sunflower and corn oil appeared to outperform peanut, soybean, and methylated soybean oils.

Laboratory bioassays demonstrate that addition of a standard aliquot of different vegetable oils result in varying degrees of grasshopper feeding on an otherwise neutral substrate. Addition of olive oil stimulated the greatest feeding in all three sets of assays, regardless of age of the tested insects. Furthermore, addition of canola or flax oils markedly enhanced grasshopper feeding. These three oils could be grouped together as best performing grasshopper stimulants. The second group included rapeseed-flax mix and rapeseed oils. Their performance was not as consistent, especially with regard to nymphal feeding. The third group consisted of soybean, corn, peanut, and sunflower oils. Theoretical expectations regarding these oils varied wildly, and results of a single bioassay should be cautiously interpreted as being negative.

Vegetable oils were shown to function as grasshopper attractants (Bomar and Lockwood 1994a, b, c). This quality makes the oils of particular interest when the insecticide to control a grasshopper infestation acts by ingestion (e.g., an insect growth regulator) and is applied with intervening untreated swaths. Such a management option is known as Reduced Agent and Area Treatment (RAAT; Lockwood and Schell 1997; USDA 2002). Since the mid-1990s, RAAT has been widely implemented on extensive areas in more than ten western states in the USA and in Eurasia (Lockwood et al. 2001; Latchininsky 2006). The ideal insecticide carrier would be attractive enough to move the target insect rapidly over tens of meters (the typical width of untreated swaths in RAAT programs) to the source and then phagostimulatory enough to prompt the insect to eat the treated substrate. This latter quality would both enhance the target efficacy of stomach poisons and reduce the impact on non-target arthropod fauna, compared to contact type insecticides. A vegetable oil that is both a kinetic and gustatory stimulant could be an ideal carrier for biological insecticides such as spores of the fungi *Beauveria bassiana* or *Metarhizium anisopliae*. Such a formulation would increase infection rates, as acridids seek out and eat the treated vegetation. Although fungal pathogens act by contact, the infection frequently occurs when spores enter the buccal cavity of grasshoppers along with food (Bidochka et al. 1997). Vegetable oils also may provide some UV protection to the fungal spores (S. Jaronski, *pers. comm.*). If so, this would also reduce the amount of the biological agent needed for control (Chernysh 2004).

Our laboratory bioassays are the first step in the search for an efficient, economical, and available carrier or adjuvant for insecticides used in grasshopper control. To validate our findings and generalize them towards other acridid pest species, other candidate oils need to be evaluated on operational-size plots under field conditions as has already been done with canola oil (Lockwood et al. 2001).

Acknowledgement The authors are indebted to Dr. Kirk A. VanDyke for invaluable assistance with experimental work and comments on the early version of the manuscript. We thank the anonymous reviewers for their comments and suggestions. The research project was funded in part through University of Wyoming, College of Agriculture mini-IPM grant and Wyoming Department of Agriculture WYAG49653 grant.

Introduction

The transition of desert grasslands to shrub-dominated states is detrimental in areas where lands are valued for forage production for livestock. This transition, often accompanied by degraded conditions (e.g., soil erosion, decreased biodiversity, altered spatial complexity), is typically termed desertification (Pickup 1988; Peters et al. 2004) and has complex causes and effects (Reynolds and Stafford Smith 2002; Bestelmeyer 2005). *Flourensia cernua* DC (tarbush) is one shrub that is increasing in dominance at the expense of desert grasslands in the northern Chihuahuan Desert (Buffington and Herbel 1965). Dominance of shrubs in areas grazed by livestock is typically related to their palatability (Leopold 1924). Tarbush consumption by sheep and goats is negatively related to leaf surface concentration of individual terpenes and epicuticular wax (Estell et al. 1994a, b, 1998a). Herbivory/pruning of woody plants during dormancy can cause a reversion to juvenile growth form and increase the proportion of the plant that is current year growth, both of which are typically more heavily chemically defended (Bryant et al. 1991). Swihart and Bryant (2001) compiled 128 studies that examined a wide variety of herbivores and woody plants and found mature plants typically were preferred over juvenile plants. Mature woody plants have been reported to contain less camphor (white spruce; Sinclair et al. 1988), mono- and diterpenes (red cedar; Vourc'h et al. 2002), and total phenolics (13 African tree species; Rooke et al. 2004) than immature plants. Pisani et al. (2001) fed old and new growth from two *Prosopis* species (new growth was from plants that were topped 10 months earlier) and found that goats preferred old growth vs. new growth of *P. caldenia*, and that this difference was not explained by concentration of total phenolics or condensed tannins. No difference in preference for old or new growth was observed for the lesser preferred *P. flexuosa* in their study. Gowda (1997) observed no difference in concentration of total phenolics or condensed tannins in *Acacia tortilis* that were pruned (removal of outer 20 cm of all twigs) vs. intact plants, although physical defense (spine production) increased with pruning. Although several simulated browsing studies exist, few studies have examined effects of complete mechanical biomass removal on secondary chemical content in regrowth of woody species. Rea and Gillingham (2001) measured regrowth of Scouler's willow (*Salix scouleriana*) at different times after mechanical brushing (biomass removal 10–15 cm aboveground) and found tannin content was unaffected or lower than in intact plants. Our objective was to compare chemical profiles of the leaf surface of intact tarbush and regrowth. Our hypothesis was that regrowth would invest resources into defense compounds and contain greater terpene concentrations than intact plants.

Methods and Materials

Study Site The study was conducted on the Jornada Experimental Range in south-central New Mexico, USA. Soils on the site are deep, well-drained, Doña Ana-Reagan association and vary from sandy loam to loam (SCS 1980). The site is gently undulating with 1 to 5% slope. Long-term (1915 to present) mean annual and growing season (July–September) precipitation for the area is 247 and 131 mm, respectively. Long-term mean monthly temperatures for the coldest (January) and warmest (July) months are 6 and 26°C, respectively. Dominant vegetation on the study site is *Scleropogon brevifolius* Phil (burrograss) and tarbush (a deciduous, root-sprouting shrub). Study plants were located in a 7.5-ha paddock within a dense stand of tarbush from which livestock had been excluded for 5 yr before the study.

Sampling Protocol Ninety tarbush plants in the paddock were selected randomly and labeled at the base with an aluminum tag. All above-ground biomass (10 cm above soil surface) was removed at one time with lopping shears from 45 randomly selected plants during winter dormancy and removed from the site. Leaves were collected the following August during active growth from both regrowth and intact controls. Approximately 75 leaves (including petiole) were collected from a minimum of five leaders of current year's growth from each plant. Leaves were sampled from the middle one-third of leaders with forceps, placed on dry ice, and subsequently stored at −20°C.

Laboratory Analyses Five leaves from each sample were extracted in duplicate for 5 min at room temperature in 5 ml of 100% ethanol containing 5 ng/μl of 2-carene (internal standard) with occasional shaking, followed by filtration through a fiberglass (Fisherbrand G8) filter and stored at 4°C. Dry matter was measured in duplicate for each sample (10 leaves per duplicate) at 100°C for 24 hr. Leaf surface volatiles were analyzed by gas chromatography coupled to mass spectrometry, using a Finnigan ion trap mass spectrometer (EI, 70 eV) in conjunction with a Varian model 3400 gas chromatograph equipped with a DB-5 column (30 m × 0.25 mm fused silica capillary column, film thickness 0.25 μm) with helium as carrier gas (1 ml/min), 1 μl injection size, and a programmed (injector temperature 220°C, transfer line temperature 240°C, initial column temperature 60°C, final column temperature 240°C, 3°C/min) temperature run (Adams 1995; Tellez et al. 1997). Identification of volatile compounds was performed by a comparison of mass spectra with authentic compounds when available or literature data (Adams 1995), and by a comparison of their relative retention times with those of authentic compounds or by comparison of their retention indices with those in the literature (Adams 1995). Concentrations of individual compounds were estimated by using the internal standard, and total volatile concentration was estimated from the cumulative concentrations of all compounds within a treatment.

Statistical Analysis Data were transformed to natural logarithms and subjected to univariate analysis of variance to compare mean concentration between resprouts and canopy for each compound and stepwise discriminate analysis to determine a subset of compounds that could discriminate between resprouts and canopy (SAS/STAT® 2002–2003).

Results

Of the 87 compounds present on tarbush leaves, 35 were greater in intact canopy samples and 16 were greater in regrowth samples based on univariate analysis ($P<0.05$; Table 1). The largest components (>100 μg/g of dry matter) were flourensadiol, unknown #1, artemisia alcohol, borneol, β-eudesmol, and unknown #4 for intact tarbush, and flourensadiol, unknown #7, unknown #6, artemisia alcohol, unknown #5, and β-eudesmol for tarbush resprouts (Table 1). Mean concentration of total volatiles on canopy leaves tended to be less ($P=0.062$) than that of regrowth (3642 vs. 4684 μg/g DM).

In the discriminate analysis, nine compounds (α-muurolene, iso-borneol, unknown #6, *p*-cymen-8-ol, unknown #7, sabinene, β-caryophyllene, δ-cadinene, and α-copaene) explained nearly 95% of the variation between canopy and regrowth samples, and α-muurolene alone explained almost 65% of the variation (Table 2). This subgroup was composed primarily of compounds in low concentrations (<20 μg/g of dry matter) with the exception of unknowns #6 and #7.

[a] Compounds were identified using kovats indices and mass spectral libraries; concentrations (± SEM; μg/g DM) were estimated from relative proportions of internal standard (2-carene); *N*=44 and 45 for regrowth and intact plants, respectively. Statistical analyses were conducted on natural logarithms of concentration means.

[b] Total volatiles are the cumulative estimated concentration of all compounds within a treatment.

[c] Tentatively identified based on Adams (1995)

Table 2 Stepwise discriminate analysis of volatile chemicals in intact (control) and resprouted tarbush

Order entered	Chemical	R^2
1	α-muurolene	0.645
2	Isoborneol	0.818

8	δ-cadinene	0.942
9	α-copaene	0.948

Discussion

Concentration of carbon-based secondary metabolites in woody shrub species are well documented to be highly variable and affected by a number of factors, including plant species, class of compound, leaf age, plant age, season of year, induced responses from mechanical damage or herbivory, as well as a host of other environmental factors such as soil nutrients and light intensity (Cedarleaf et al. 1983; Bryant et al. 1991; Gershenzon and Croteau 1991; Powell and Raffa 1999; Massei et al. 2000; Ward and Young 2002). Pruning or herbivory during dormancy may cause woody plants to revert to juvenile growth stage and increase the proportion of current years growth, both of which are typically more chemically defended (Bryant et al. 1991). A number of theories have been forwarded regarding the allocation of plant resources to secondary metabolites, but a common theme is that tradeoffs exist between growth and defense (Herms and Mattson 1992). Young tissue is typically highly defended in slow-growing woody plants in low resource environments that rely predominately on constitutive carbon-based defenses (Bryant et al. 1991). Because regrowth from the crown and roots of shrubs represents a critical tissue that is paramount to survival of the plant, our hypothesis was that it would contain higher concentrations of secondary metabolites. However, our anecdotal observations suggest an alternative hypothesis because tarbush leaves from plants previously cut near the soil surface (roadgrader blading, etc.) are larger and more succulent in appearance, lighter in color, and less resinous and fragrant than leaves from uncut plants (visual observations only), suggesting they might contain lower concentrations of secondary compounds on the leaf surface. Increased palatability of regrowth after browsing has been reported for woody species in some cases (e.g., Danell et al. 1985; du Toit et al. 1990). Tarbush is a deciduous root sprouter, with new growth for both intact plants and regrowth occurring after summer rains. Both tissues were sampled on the same day; thus, leaf age and season were the same for this study, and any differences in leaf chemistry should be caused by the biomass removal treatment. Although plant age could not be specifically addressed, the 90 plants used in this study were fairly uniform in size and shape, and were assumed to be approximately the same age.

Because secondary metabolite concentration is closely related to consumption of shrubs by livestock and wildlife, the amount of defensive chemicals has implications for herbivory. Three of the first nine compounds to enter the discriminant analysis (sabinene, β-caryophyllene, and α-copaene) were unrelated to intake by lambs at concentrations found in tarbush (Estell et al. 1998b, 2000, 2005). Furthermore, none of the compounds tested (N=25) that did affect intake (α-pinene, camphene, caryophyllene oxide, and camphor) at

concentrations present in tarbush (Estell et al. 1998b, 2002) differed for regrowth with the univariate analysis (except camphor, which was inseparable from *trans*-verbenol in the present study). However, the total amount of volatile chemicals (cumulative estimated concentration of all volatiles within treatment) present on the leaf surface tended to differ (P=0.062) between intact and resprouted tarbush (Table 1). Intake of tarbush and other shrubs by ruminants has been related to total volatile concentration (Schwartz et al. 1980; Estell et al. 1994b; Riddle et al. 1996); thus, resprouts might be less palatable for livestock. However, it cannot be ruled out that other individual compounds that differed between intact and regrowth plants could affect palatability.

A number of studies have examined mechanical shrub removal in the context of shrub control and nutritional value (e.g., Kituku et al. 1992; Reynolds et al. 1992), but few report effects on secondary metabolite concentrations. Pisani et al. (2001) and Rea and Gillingham (2001) both reported lower concentrations of phenolics and/or tannins in regrowth of woody shrubs. This response is not completely surprising as these classes of compounds frequently increase in conjunction with structural components associated with maturity. Tannin content of blackbrush acacia regrowth 34 weeks after burning was greater than unburned controls, but honey mesquite and spiny hackberry regrowth tannin content did not differ from controls (Schindler et al. 2004). We are not aware of any studies that have examined terpenes in response to above-ground biomass removal for woody plants. Whereas mowing agronomic crops and pastures is well documented to reduce maturity and improve forage quality, less is known about the effects of altered growth stage in woody species. Our goal was to examine chemical changes associated with altering the vegetative state of tarbush by clipping intact plants and generating resprouts. Lower cumulative concentration of volatile compounds in intact plants than regrowth suggests repsrouts might be less vulnerable to herbivory than intact tarbush. From a practical standpoint, there would appear to be no advantage to altering growth stage as a means to improve tarbush consumption and reduce competition with grasses, although animal studies are needed for confirmation. Our findings support the general observations that young plants are more defended than older plants, in contrast to anecdotal observations mentioned above. Mowing tarbush and grazing the regrowth may not be an appropriate mechanism to promote grasses in tarbush-dominated desertified areas.

despite defensive chemistry being a key plant fitness trait. Its expression across life stages is important in understanding the lifetime evolutionary selection pressures on a plant (Crawley 1997). Lack of a consistent pattern in chemical defense across different life stages may be a response to multiple herbivores. Alternatively, consistent expression of defense across multiple stages may arise if plants suffer attack from a single herbivore across multiple stages or if they utilize a similar suite of defenses to protect themselves against multiple herbivores (Leimu and Koricheva 2006). The investigation of variation in chemical defense within a genetic framework is crucial to interpreting observed variation in an evolutionary context. For example, Rehill et al. (2006) demonstrate variation in chemistry among developmental zones and the genetic basis of variation in developmental trajectories between parental and hybrid cottonwoods. They discuss their results in light of possible competing evolutionary pressures. Such studies are relatively sparse (Barton 2007), particularly in plant/mammal systems. This paper investigated the stability of genetic-based defensive chemistry to mammalian herbivores across life stages of a eucalypt species.

Phenotypic variation in defensive chemistry across life stages may be particularly marked in heteroblastic plant species, of which the species-rich tree genus *Eucalyptus* has many examples (Jordan et al. 1999). Eucalypts are prone to attack by a suite of vertebrate and invertebrate, generalist and specialist herbivores on different foliage types (juvenile and adult; Majer et al. 1997; Hume 1999). However, as in many plant species, the patterns of genetic-based defense across these stages are largely unexplored. Many heteroblastic eucalypts revert from the adult leaf phase to the juvenile phase when coppicing occurs after the main stem bearing the adult leaf type is damaged (Whittock et al. 2003). Coppicing involves re-sprouting from dormant basal buds at the base of the trunk and allows plants to recover from significant foliage loss often due to fire, wind, or herbivory (Vesk and Westoby 2004).

Eucalyptus globulus is a dominant tree in native forests in south-eastern Australia, and is also a major plantation species in temperate regions of the world (Dutkowski and Potts 1999). It exhibits heteroblasty during ontogeny (Jordan et al. 1999), and trees revert to the juvenile leaf phase when coppiced. In Australia, *E. globulus* foliage is consumed by invertebrates and several mammalian marsupial herbivores. Juvenile foliage is accessible to both terrestrial and arboreal marsupials, while adult foliage (present in a taller tree) is only accessible to arboreal marsupials. Juvenile *E. globulus* coppice foliage exhibits significant genetic-based variation in browsing resistance to a terrestrial macropod (*Thylogale billardierii*) and an arboreal possum (*Trichosurus vulpecula*; O'Reilly-Wapstra et al. 2002). There is also a genetic basis to the defensive compounds that confer resistance (O'Reilly-Wapstra et al. 2004). This suggests that mammalian herbivores have played a role in the evolution of population differences in defensive chemicals within this species. However, a key question is whether the same genetic-based differences in defensive chemistry of juvenile coppice foliage are evident across heteroblastic phases (in the adult foliage). Variation or stability in patterns of genetic-based defense across life stages may reflect the potential selective pressures imposed by associated herbivores at different times. In this work, we utilized *Eucalyptus globulus* trees of known genetic pedigree growing in a common environment trial in two different foliage phases (adult and coppice) to address the question of stability of defensive chemistry.

Materials and Methods

Foliage Collection Foliage was collected from a progeny trial situated at West Ridgley (41° 13′S, 145°80′E) in Tasmania, Australia. The field trial was established with open-pollinated

seed collected from 421 trees (families) from 49 localities throughout the natural distribution of *E. globulus* (see Potts and Jordan 1994 and Dutkowski and Potts 1999 for details). These localities were subsequently grouped into a spatial hierarchy of 13 geographic races and 20 subraces by Dutkowski and Potts (1999) based on spatial disjunctions and patterns of quantitative genetic differentiation observed in field trials. These races have subsequently been grouped into three major lineages based on microsatellite markers (Steane et al. 2006). Eight races of *E. globulus* were selected for this study based on their broad geographic distribution (Dutkowski and Potts 1999) and their genetic (Steane et al. 2006) diversity. The trial was a resolvable incomplete block design with five replicates of 23 incomplete blocks, and each family was represented as a two-tree line plot in each replicate. Ten families were randomly selected from the subrace typical of each of these races, and two trees from each family were selected from different field replicates. In autumn 2004, when trees were 15 years old, the 160 selected trees were felled. Leaves of healthy adult foliage were collected across the apical branch of each tree. The two trees per family were pooled to make 80 samples of foliage for chemical analysis. In autumn 2005, 80 coppice samples (ten families from eight subraces) were collected from the coppicing stumps of the previous years' cut trees. In this case, due to variable coppicing, only one individual per family was sampled, and in the few cases where neither tree coppiced (12 out of the 80), a substitute tree from another family from the same subrace was sampled. While the foliage we collected was accessible to herbivores, browsing of plants was minimal, and there is no evidence in the literature of induced chemical responses in eucalypts.

Analysis of Foliar Chemistry We assayed seven constituents in both the adult and coppice foliage. Two formylated phloroglucinol compounds (FPCs; sideroxylonal A and macrocarpal G, the two dominant isomers of these compounds in *E. globulus*) were assayed by high performance liquid chromatography (HPLC) following Wallis and Foley (2005). These compounds have strong anti-feedant properties to mammalian herbivores (Lawler et al. 2000; O'Reilly-Wapstra et al. 2004; Moore and Foley 2005). By using a pure standard of sideroxylonal A, we expressed results for this compound as mg g DM^{-1} (milligrams per gram of dry matter) and results for macrocarpal G are expressed as mg g DM^{-1} equivalents of macrocarpal A (by using a macrocarpal A standard).

Total oils and 1,8-cineole were assayed by gas chromatography-mass spectrometry (GC-MS; O'Reilly-Wapstra et al. 2004). From using a pure 1,8-cineole standard, the concentration of this compound is expressed as mg g DM^{-1}, and total oil is expressed as equivalents of cineole (mg g DM^{-1}). Total phenolics and condensed tannins were assayed with the modified Prussian blue assay for total phenolics (Graham 1992), and the acid butanol assay for condensed tannins (Porter et al. 1986). Foliage for these assays was prepared and extracted following the method outlined in Hagerman (2002). From using a gallic acid standard, the concentration of total phenolics is expressed as mg g DM^{-1} equivalents of gallic acid and, from using a sorghum standard, the concentration of condensed tannins is expressed as mg g DM^{-1} equivalents of sorghum tannin. Nitrogen was determined on air-dried foliage with the sulfuric acid and hydrogen peroxide method described by Lowther (1980) and analyzed colorimetrically on a continuous flow injection analyzer (QuickChem 800; Lachat Instruments).

Statistical Analyses For each chemical constituent, a one factor general linear model (PROC GLM, SAS, version 9.1) was used first to test the differences between adult and juvenile coppice foliage, and second to test the difference among subraces for each foliage type. Due to assumptions of normality and homogeneity, sideroxylonal A and nitrogen were

log transformed, and total oils and 1,8-cineole were square root transformed. Results for subrace analysis for each variable were analyzed separately, with a Bonferroni adjustment to account for multiple tests. Pearsons correlation coefficient was used to determine the relationship between the subrace mean levels of sideroxylonal A and macrocarpal G in the adult and coppice foliage (PROC CORR, SAS).

Results

There were distinct quantitative and qualitative differences in chemical constituents between the adult and coppice foliage samples (Table 1). Coppice foliage had substantially higher levels of most defensive compounds with higher levels of total phenolics ($F_{1,157}$=56.1, P< 0.001), total oils (√ transformed; $F_{1,154}$=494.3, P<0.001), 1,8-cineole (√ transformed; $F_{1,154}$=579.1, P<0.001), and sideroxylonal A ($\log_{10}$ transformed; $F_{1,157}$=219.5, P<0.001) than adult foliage. Levels of macrocarpal G were similar between the two foliage types ($F_{1,157}$=3.8, P=0.061) while there were no condensed tannins detected in the coppice foliage. Nitrogen was higher in the coppice foliage compared to adult foliage ($\log_{10}$ transformed; $F_{1,157}$=923.7, P<0.001).

Table 1 Chemistry (mean±SE) for adult and coppice foliage

		Adult Foliage			Coppice Foliage			Pearson's Correlation	
Variable	Units	Mean (±SE)	F_{df}	P	Mean (±SE)	F_{df}	P	R	P
Sider A	mg g DM^{-1}	2.0 (0.11)	$6.93_{7,77}$	<0.001[a]	6.7 (0.26)	$8.75_{7,79}$	<0.001	0.93	<0.001
Mac G	mg g DM^{-1} Mac A equivalents	7.3 (0.24)	$15.34_{7,77}$	<0.001	6.6 (0.20)	$5.53_{7,79}$	<0.001	0.95	<0.001
Tannin	mg g DM^{-1} Sorghum equivalents	9.3 (0.53)	$11.77_{7,75}$	<0.001	0	N/A	N/A	N/A	N/A
1,8-Cineole	mg g DM^{-1}	3.3 (0.14)	$0.53_{7,74}$	0.808[b]	27.8 (1.30)	$2.75_{7,79}$	0.014	−0.51	0.195
Total oil	mg g DM^{-1} 1,8−Cineole equivalents	7.8 (0.31)	$1.10_{7,74}$	0.399[b]	55.3 (2.68)	$2.20_{7,79}$	0.045	−0.69	0.060
Phenolics	mg g DM^{-1} gallic acid equivalents	15.2 (1.2)	$2.56_{7,77}$	0.021	39.9 (1.24)	$0.57_{7,79}$	0.781	−0.40	0.323
Nitrogen	% DM	1.2 (0.01)	$2.41_{7,77}$	0.029	2.2 (0.04)	0.82	0.573	0.10	0.810

Results are presented of the general linear model analysis of genetic variation at the subrace level within each foliage type. Significance levels for adult foliage are p<0.007 and p<0.008 for coppice foliage (which excludes the tannins) after bonferroni adjustment for multiple tests within foliage types. The Pearson's correlation indicates the relationship between foliage types at the subrace level

Sider A, sideroxylonal A; *mac G*, macrocarpal G; *mac A*, macrocarpal A; *tannin*, condensed tannin; *phenolics*, total phenolics

[a] Log10 transformed

[b] Square root transformed

There were significant differences among the eight subraces in the two FPCs (sideroxylonal A and macrocarpal G) for both the adult and coppice foliage, and condensed tannins in adult foliage, indicating a genetic basis to variation in these defensive constituents (Table 1, Figs. 1 and 2). At the subrace level, there was a strong positive correlation in the two FPCs between adult and coppice foliage (r=0.93, P<0.01; r=0.95, P<0.01 for sideroxylonal A and macrocarpal G, respectively), indicating stability of the genetic differences in compounds across these two markedly different life stages (Table 1, Fig. 1). In contrast, the differences (P<0.001) among subraces in levels of condensed tannins in the adult foliage has no analogue in the coppice foliage. This differentiation in adult foliage was due to the Strzelecki and Eastern Otway subraces having significantly higher levels of condensed tannins than the other subraces studied (Fig. 2).

Discussion

As highlighted by Barton (2007), few studies (but see Rehill et al. 2006) have documented genetic variation in ontogenetic patterns of defensive chemistry. Our study shows clear

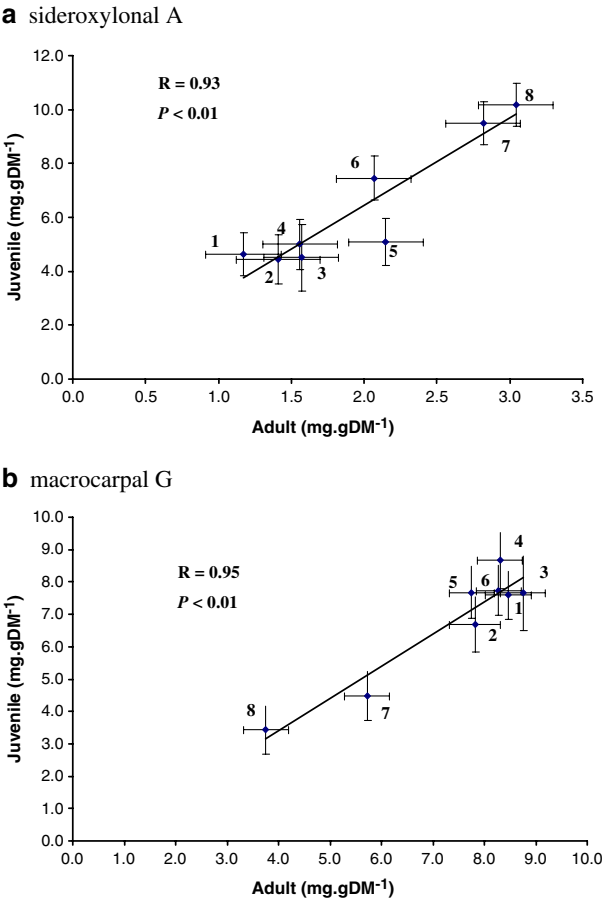

Fig. 1 Association between **a** sideroxylonal A (mg g DM^{-1}) and **b** macrocarpal G (mg g DM^{-1} equivalents of macrocarpal A) in adult and juvenile coppice foliage of *E. globulus*. Subraces are detailed in Dutkowski and Potts (1999) and correspond to: *1* King Island; *2* Southern Tasmania; *3* Eastern Otway Ranges; *4* Western Tasmania; *5* Western Otway Ranges; *6* South eastern Tasmania; *7* Flinders Island; *8* Strzelecki Ranges

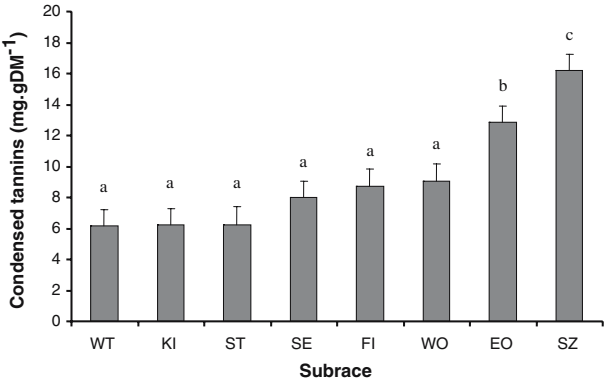

Fig. 2 Variation in condensed tannin levels [least square means (mg g DM^{-1} sorghum equivalents)±SE] of the adult foliage between the eight subraces. Letter that differ indicate significant differences (α=0.05) after Tukey-Kramer adjustment for multiple comparisons. *WT* Western Tasmania; *KI* King Island; *ST* Southern Tasmania; *SE* South eastern Tasmania; *FI* Flinders Island; *WO* Western Otway Ranges; *EO* Eastern Otway Ranges; *SZ* Strzelecki Ranges. a) sideroxylonal A, b) macrocarpal G

variation in the key ecologically important formylated phloroglucinol compounds (FPCs) in both the juvenile and adult foliage types of *E. globulus*. The patterns of variation of the two FPCs among genetically distinct subraces were tightly correlated across life stages, despite changes in the absolute levels of one compound. Our previous research (O'Reilly-Wapstra et al. 2004) and work by others (Moore and Foley 2005) have established the roles of these compounds in conferring resistance to marsupial herbivores that include *T. vulpecula*, the arboreal brushtail possum. The Strzelecki and Flinders Island subraces are differentiated from the other subraces in having higher levels of sideroxylonal A and lower levels of macrocarpal G for both adult and coppice foliage (Fig. 1a and b). A similar pattern has been observed in previous studies of coppice foliage (O'Reilly-Wapstra et al. 2002; 2004).

The FPC compounds are highly heritable (Andrew et al. 2006), and such strong genetic variation provides a platform on which selection can act. Previous research indicates browsing by *T. vulpecula* on young eucalypt plants results in lower reproductive output when the plants reach reproductive maturity, and also that feeding on juvenile coppice foliage provides direct positive selection on sideroxylonal A (O'Reilly-Wapstra et al., unpublished data). The correlated variation in FPCs at the subrace level across life phases may arise from two different scenarios. First, the patterns could be a consequence of adult and coppice defensive chemistry being under the control of the same genes, the differences in expression of which is little modified with life stage. In this scenario, selection through marsupial browsing at either life phase would elicit a correlated response in the other life phase. However, given that *T. vulpecula* feeds on both juvenile coppice (O'Reilly-Wapstra et al. 2004) and adult foliage (Wiggins et al. 2006), it is possible that with geographic variation in browsing pressure from this marsupial, independent selection could result in correlated patterns of genetic variation in chemicals across life history stages, even in the absence of common genetic control.

The strength of selection at different life stages of a plant will be determined in part by the relative fitness costs of having foliage browsed. Coppice re-growth is a response to foliage loss of the main stem, and relative costs of herbivory on the comparatively small biomass of this foliage would be far greater compared to herbivory on a large biomass of adult foliage in a reproductive, mature tree (Swihart and Bryant 2001). In our system,

coppice foliage is susceptible to browsing by two marsupial herbivores (*T. vulpecula* and *T. billardierii*, the terrestrial macropod; O'Reilly-Wapstra et al. 2002), and the levels of most plant secondary compounds (sideroxylonal, total oils, cineole, and total phenolics) were higher in coppice foliage than adult foliage. This supports the idea that allocation of chemical defenses in *E. globulus* is greater in foliage that potentially suffers more browsing pressure and has higher fitness consequences if browsed. This line of thought has been supported in numerous plant/mammalian systems where young foliage in early ontogenetic stages is generally well defended compared to older foliage (review Swihart and Bryant 2001).

There is considerable evidence for the role of tannins in herbivore defense (Harborne 1991 and references within). Tannins, however, also play other roles such as acting as antioxidants (Hagerman et al. 1998) and protecting plants against photo damage (Close and McArthur 2002). In this paper, we found no stability in the expression of condensed tannins between life stages of *E. globulus*. That is, the clear genetic variation observed in the adult foliage was not evident in the coppice foliage because of a lack of tannins in the juvenile phase. In support of this result, coppice foliage in a partner field trial (data not shown) does not contain detectable levels of condensed tannins. Coppice foliage from artificially browsed lignotubers on *E. globulus* seedlings also lacks condensed tannins (O'Reilly-Wapstra, unpublished data). These compounds, however, are present in juvenile seedling and adult foliage in *E. globulus* and other eucalypt species (Macaulay and Fox 1980; Gras et al. 2005), and the defensive function of tannins cannot be discounted (Marsh et al. 2003; O'Reilly-Wapstra et al. 2005). It is possible that the lack of a consistent pattern in condensed tannins across life stages in *E. globulus* may be a response to multiple herbivores (including both mammals and invertebrates) that consume the plant. Specific compounds may be effective against specific herbivores. However, if tannins play a role in defense to mammalian herbivores in this system, we would expect that one of the most vulnerable and highly accessible life stages (coppice) would contain tannins. In addition, our previous work in this system shows that the levels of condensed tannins are phenotypically plastic, particularly when compared to the strongly constitutively stable and highly defensive FPCs (O'Reilly-Wapstra et al. 2005). Such plasticity in tannin levels is evident in other systems (e.g., Aspen, see Osier and Lindroth 2001). These results together may lend support to alternative hypotheses for the role of tannins in the eucalypt system, such as protection against photo damage (Close and McArthur 2002). It is not until the multiple roles of condensed tannins and trade-offs with their production in eucalypts are more fully investigated that we will clearly understand their role in defense against mammalian herbivores.

Acknowledgement Funding was provided to J.O'R-W and B.P. by the Australian Research Council and the University of Tasmania Institutional Research Grant Scheme. We thank Gunns Ltd. and Kelsey Joyce for access to foliage, Robert Barbour, Hugh Fitzgerald, Simone Janney and Noel Davies for aspects of foliage collection and foliage chemical analysis, and an anonymous reviewer for comments on the manuscript.

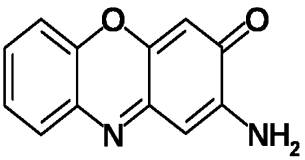
Introduction

Benzoxazinones and their decomposition products (benzoxazolinones and their methyl derivatives) are constitutive naturally occurring allelochemicals of wheat, corn, rye, other members of the Gramineae (Niemeyer 1988), and some non-Gramineae species (Pratt et al. 1995; Baumeler et al. 2000). These compounds serve as plant-defensive metabolites, providing protection from fungi, insects, and invertebrate pests, and they also are allelopathic. Because of their wide spectrum of biological activity, they offer promise for natural controls of pests. The main benzoxazinones produced by maize are 2,4-dihydroxy-7-mcthoxy-2*H*-1,4-benzoxazin-3(4*H*)-one (DIMBOA), and its dimethoxy derivative 2,4-dihydroxy-6,7-dimethoxy-1,4-benzoxazin-3(4*H*)-one (DIM_2BOA), with the former occurring in greater concentrations (Whitney and Mortimore 1959; Klun and Robinson 1969; Corcuera et al. 1978; Copaja et al. 1991; Hedin et al. 1993; Frey et al. 1997; Cambier et al. 2000). These benzoxazinones are present in maize mainly as glycosides, but upon injury from insects or pathogens they are degraded to their unstable and highly toxic agluconic forms, which spontaneously decompose to the corresponding benzoxazolinones, such as MBOA (6-methoxy-2-benzoxazolinone) and BOA (benzoxazolin-2-one) (Niemeyer 1988). Thus, MBOA and BOA are found in plant debris and soil as stable degradation products of DIMBOA and DIBOA, and are considered potentially useful allelochemicals (Fomsgaard et al. 2004).

Maize begins to synthesize and store DIMBOA and DIM_2-BOA as the glycosides once germination is initiated. Many insects, fungi, and bacteria are deterred or inhibited by these benzoxazinoids, resulting in increased plant resistance (Virtanen and Hietala 1955; Wahlroos and Virtanen 1958; Whitney and Mortimore 1959; Klun and Robinson 1969; Couture et al. 1971; Argandona et al. 1980; Givovich and Niemeyer 1991; Hartenstein and Sicker 1994; Koziel et al. 1996; Frey et al. 1997; Hansen 2006). The main fungal inhabitant of maize is the anamorph of *Gibberella moniliformis*, *Fusarium verticillioides* (=*Gibberella fujikuroi* mating population A; syn., *F. moniliforme*). This ascomycetous fungus is consistently found in association with maize throughout the world as a symptomless endophyte (Kommedahl and Windels 1981; Marasas et al. 1984; Bacon and Hinton 1996). The symptomless endophytic association with maize is apparently evolutionarily relevant, as it has been established that *F. verticillioides* and other endophytic fungi detoxify DIMBOA/MBOA and DIBOA/BOA by actively transforming them into the nontoxic components *N*-(2-hydroxy-4-methoxyphenyl) malonamic acid (HMPMA) and *N*-(2-hydroxyphenyl) malonamic acid (HPMA), respectively (Virtanen and Hietala 1955; Zikmundova et al. 2002; Glenn et al. 2003).



Fusarium verticillioides is a nonobligate pathogen; it is not host-specific and has been reported in association with many plant species in addition to maize. It is estimated that 11,665 plant species are potential hosts of *F. verticillioides* (Bacon et al. 1996), although this number may be confounded by historical confusion over current fungal and plant species delimitation and taxonomy. *F. verticillioides* has a long history of being associated with animal toxicosis, and only in this past decade has the etiologic agent been isolated and identified as the fumonisins (Marasas 1996). After this discovery, this class of mycotoxins was established as the cause of equine leukoencephalomalacia, porcine pulmonary edema, and experimental liver cancer in rats. The consumption of maize contaminated with this

fungus is associated with human esophageal cancer and fetal neural tube defects (Voss et al. 1989; Wang et al. 1991; Riley et al. 1993, 1994; Waes et al. 2005). Thus, control of this cosmopolitan fungus on maize is important.

The benzoxazinoids offer protection to the plant from pathogenic attack from non-detoxifying microbes. After the very broad definition of the International Allelopathy Society (Torres et al. 1996), they can be considered allelopathic. However, the ability of fungi to detoxify these or other allelochemicals may allow for an endophytic coexistence with maize, resulting in a competitive advantage for resistant fungi (Glenn et al. 2003). Prior studies established that several species of *Fusarium* are tolerant to the benzoxazinoids (Glenn et al. 2001), and that this tolerance in *F. verticillioides* is in fact caused by the presence of at least two genetic loci, FDB1 and FDB2. Detoxification of the benzoxazolinones requires both loci, and defect at either locus causes sensitivity to the compounds (Glenn et al. 2002). A new transformation product is produced from 2-aminophenol (AP). This product, 2-acetamidophenol (HPAA), was identified as a transformation compound produced by several genetic strains of *F. verticillioides* (Glenn et al. 2003). Several other fungi and bacteria are also known to detoxify this class of compounds (Friebe et al. 1996, 1998; Wieland et al. 1999; Vilich et al. 1999), although genetic mechanisms of detoxification, if any, have not been determined.

Tolerance to the benzoxazinoids by plant pathogens precludes these allelochemicals as control strategies for some pathogens. However, there are several microbial transformation products of BOA that are alleleopathic of which the aminophenoxazine 2-amino-3H-phenoxazin-3-one (APO) (Fig. 1) is stable in soils (Macias et al. 2005). The toxicities of APO compared to other transformation products differ by several orders of magnitude higher than any other benzoxazolinone metabolites (Atwal et al. 1992; Fritz and Braun 2006; Martyniuk et al. 2006).

In a study designed to exploit the natural chemical defenses of corn in combination with the patented endophytic bacterium, *Bacillus mojavensis*, as a biocontrol of *F. verticillioides*, a semiochemical interaction, indicated by the formation of an intense red diffusible pigment, was observed when the two are cultured together on media amended with BOA. The endophytic bacterium has been patented for control of disease on maize, primarily control of the fungus *F. verticillioides* and mycotoxin reduction (Bacon and Hinton 1999). However, the activity of the relatively stable benzoxazolinones on this nontarget endophytic bacterium is not known, and its biocontrol activities might be compromised if it is sensitive to the benzoxazolinones and their decomposition products. As these maize allelochemicals exist in high concentrations early during maize germination (Klun and Robinson 1969) and it is at this time that the biocontrol bacterium, *B. mojavensis*, infects corn seedlings (Bacon and Hinton 1996), the objectives of this research were: to determine the interactive nature of BOA and its final transformation product, APO, on the growth of *B. mojavensis*, and to

2-amino-3*H*-phenoxazin-3-one (APO)

Fig. 1 Structure of 2-amino-3*H*-phenoxazin-3-one (APO), a degradation product of 2-benzoxazolinone (BOA)

determine the *in vitro* antagonistic activity of the bacterium on the biocontrol target *F. verticillioides* cultured in the presence of BOA.

Methods and Materials

Allelochemicals Chemicals used for the transformation analysis were obtained from the following sources: BOA and 2-aminophenol from Aldrich Chemical Co., Milwaukee, WI, USA; MBOA from Lancaster Chemicals, Lancaster, Ca, USA; HPMA was purified and identified after transformation of BOA by RAC826 followed by TLC (Glenn et al. 2003). The identities of these compounds were based on prior analysis and chemical confirmation that used TLC and mass spectrometry procedures reported earlier (Glenn et al. 2003). APO was prepared and chemically characterized by previously described procedures (Macias et al. 2005).

Fungal and Bacterial Strains The strains of fungi used were those that either tested positive for detoxification of BOA or those with defective alleles at loci necessary for detoxification of BOA (Glenn et al. 2002). The *F. verticillioides* strains used consisted of MRC826 (genotype FDB1/FDB2), a wild type for fumonisin production and tolerance to BOA, strain AEG73-A4-1, a tolerant benzoxazolinone phenotype (genotype *Fdb1/Fdb2*) derived from a cross of the wild-type *F. verticillioides* RRC826 with the female fertile AEG 3-1-6 sensitive genotype, and AEG73-A4-2 (genotype *Fdb1/fdb2*), a sensitive benzoxazolinone phenotype derived from this same cross (Glenn et al. 2002). For long-term storage, conidia were frozen at −80°C in 15% glycerol. For routine culturing, spores were streaked onto potato dextrose agar (PDA; Difco Laboratories, Detroit, MI, USA) and incubated at 22°C in the dark. The bacterial strains used were *B. mojavensis* including the patented biocontrol strain RRC 101 (ATCC 55732), and its rifamycin-resistant mutant, RRC112 (Bacon and Hinton 2002). The bacteria were stored as silica gel cultures at −20°C, or 10% glycerol at −80°C, and working cultures were maintained on nutrient agar (Difco Laboratories, Detroit, MI, USA) at 4°C. Inoculum of each strain was prepared from overnight shake cultures grown in nutrient broth (Difco Laboratories, Detroit, MI, USA) at 30°C.

Bacterial–Fungal–BOA Interactions Experiments designed to determine bacterial antagonism to the fungus were assessed on nutrient agar. Antagonism experiments were performed by placing bacterial inoculum prepared from a 24-hr nutrient broth culture (10^4 CFU/ml) either down the center or 2 cm from the edge of each plate, and incubated 2–4 d at 30°C. Plates were then inoculated with a fungal inoculum (10^4 CFU/ml) from a 5- to 7-d-old fungal culture on either or both of the opposite edges of a Petri plate, which was incubated for 7 d at 25°C. The zone of inhibition between the bacterium and fungus was measured on all test medium following earlier procedures (Bacon and Hinton 2002). Radial growth measurements were made 7 and 14 d after inoculation in four directions from the edge of the inoculum to the advancing margin of the colony. Additional observations were made 15 d after inoculations to note any differences in growth responses. Each experiment was repeated at least twice with three replications for each treatment.

Microbial Transformation in Liquid Culture Flasks, 125 ml, containing nutrient broth (50 ml/flask) amended with BOA, 1.0 g l^{-1}, were inoculated with the bacterium prepared from 24-hr nutrient broth cultures (10^6 cell/ml), and incubated on a shaker, 100 rpm, for 24 hr at 25°C. The fungal inoculum (10^4 cfu/ml), which was prepared from 5- to 7-d-old PDA cultures, was added to the BOA-amended nutrient broth immediately after the bacterial

inoculum, placed on the shaker (150 rpm), and incubated for 5–7 d in the dark, and checked for bacterial–fungal interactions indicated by the presence of the red color of APO. Control flasks consisted of nutrient broth with and without BOA or with comparable amounts of ethanol and inoculated either with or without the bacterium or the fungus. Solvent extractions and analyses of liquid media were performed according to Yue et al. (1998). Each experiment was repeated at least twice with three replications for each treatment.

Tolerance of Bacillus mojavensis to BOA and APO Growth rate experiments were used to measure the toxicity of BOA or APO to *B. mojavensis*. Experiments were performed with an automated turbidometer, the Microbiology Bioscreen C Reader (Labsystems, Helsinki, Finland), which was conduced in 100-well sterile microplates. Each well contained 190 µl of nutrient broth, with or without BOA or APO, to which was added 10 µl of bacterial inoculum (10^3 CFU/ml) or fungal inoculum (10^6 CFU/ml). The cultures were incubated at 30°C with constant shaking, and the optical density, OD_{600}, was measured at 30-min intervals over the incubation period of 48–72 hr. The concentrations of BOA used were 1, 0.5, and 0.25 mg/ml. Fungal and bacterial cells from 2-wk-old BOA-amended cultures were removed by filtering through a sterile membrane (0.2 nm), and diluted 50% or 25% with nutrient broth. The dilutions were inoculated with either the fungus or the bacterium. Growth curves and several other plot parameters were generated and analyzed by the software package of the Bioscreen C Reader (Research Express, version 1.00). The specific rates of growth were expressed as a percent reduction over controls that contained no BOA. All experiments were performed in triplicate and were repeated independently. The reported specific rates of growth are averages from two or more experiments, and data were evaluated by analysis of variance and Student's *t* test analyzed by the Analysis ToolPak Microsoft Excel, version 2003 (Microsoft Corp.).

Chemical Transformation of BOA in the Presence of Bacillus mojavensis The interactions of BOA metabolism in the presence of the bacterium and fungi were determined by the thin layer chromatography (TLC) procedure described earlier (Glenn et al. 2001). All strains were grown on 1.0 mg/ml BOA for approximately 7 d, and an agar plug (8 mm diameter) was taken from both the advancing margin of the colony and from within the colony. The agar plugs were then transferred to a TLC sheet (Whatman; silica gel, UV_{254}, aluminum backing), which was heat activated at 50 °C for 10 min before application of the plugs. Plugs were placed on the sheets with the lower surface of the plugs in contact with the silica gel. The contents from plugs were allowed to absorb into the silica gel for approximately 10 sec. Three plugs from each location were placed on the same spot, with drying of the spot between each application with a heat gun, following the procedure of Glenn et al. (2001). Sheets were developed in a saturated chamber containing toluene, ethyl acetate, formic acid (50:40:25, *v*/*v*). Developed sheets were visualized and photographed under UV light by using digital imaging (Alpha Innotech), and R_f values were compared with standards of authentic compound.

The identity of APO resulting from biotransformation of BOA by *F. verticillioides* was indicated by its bright red color (Anzai et al. 1960; Gagliardo and Chilton 1992) and by comparing TLC R_f values with standards, as well as by comparing the absorption spectra with authentic APO after eluting it with methanol from the silica gel (Glenn et al. 2003; Fomsgaard et al. 2004). Further, the confirmation of APO as the decomposition product was based on established published procedures by comparison to a standard of the authentic compound (Macias et al. 2005; Fomsgaard 2006) by using absorption spectroscopy, and gas

chromatography-mass spectroscopy (GS-MS), described earlier (Glenn et al. 2001, 2003; Fomsgaard 2006).

Results and Discussion

The general inhibitory data and growth measurements as well as responses to the fungus by the bacterium are similar to the data described earlier (Bacon and Hinton 2002) and are pictorially shown in Fig. 2a. *B. mojavensis* produces a soluble inhibitory substance on nutrient agar that prevents the growth of *F. verticillioides* from making contact with the

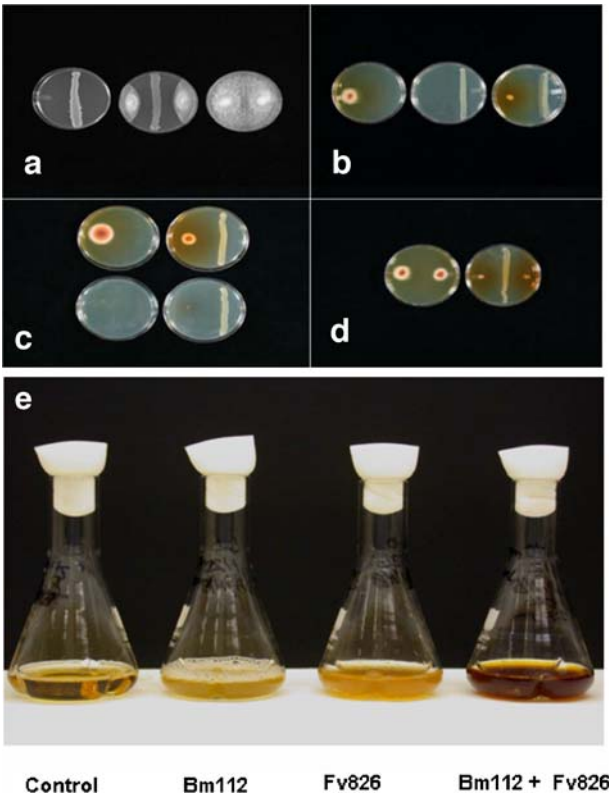


Fig. 2 Culture of *Bacillus mojavensis* RRC102 and *Fusarium verticillioides* MRC826 on nutrient agar with and without BOA. (**a**) Nutrient agar cultures showing zones of inhibition produced by the bacterial inhibitor after 14 d of culture, *center plate*, compared with growth of the fungus cultured alone, *far right plate*. (**b**) Culture of *Fusarium verticillioides* cultured with and without *B. mojavensis* on BOA-amended nutrient agar showing production of *red pigment* (APO), and on the *far right* is a colony of the severely inhibited fungus observed when co-cultured with the bacterium. (**c**). *Top row*, production of APO, the *red pigment*, by *F. verticillioides* (RRC826) with (0.5 cm) and without (1.6 cm) the bacterium *B. mojavensis* (RRC 112); *bottom row*, agar plates showing no growth with and without one of the benzoxazolinone-sensitive genetic strains of *F. verticillioides,* AEG-73-A4-2. (**d**) Production of APO (*red pigment*) in the presence of *F. verticillioides* RRC826 alone (*left*), and with the bacterium (*right*). (**e**) Liquid culture of *B. mojavensis* (*Bm112*) and *F. verticillioides* (*Fv826*) on nutrient broth amended with BOA (1.0 g l^{-1}) resulting in the production of APO during single and dual culture of the organisms (Bm112 and Fv826)

bacterial culture. This inhibitor has been partially characterized as one of the cyclic lipoprotein inhibitors characteristic of this genus of bacteria (Bacon et al. 2005). This bacterium has *in vitro* inhibitory activity to several known maize and other cereal pathogens (Bacon and Hinton 2002), including the ability to reduce the amount of the fumonisin mycotoxins produced by *F. verticillioides* in corn (Bacon et al. 2001). However, the interaction is complex as it was determined that *F. verticillioides* produced fusaric acid, 5-butylpicolinic acid, that is an antibiotic to *B. mojavensis* and other species (Bacon et al. 2006), interfering with the biocontrol potential of bacteria. The *in planta* accumulation of these allelochemicals, to which the *Fusarium* species have been shown to be tolerant (Glenn et al. 2001), is expected to complicate the use of endophytic bacteria for biocontrol work. However, the results of this study indicate that the major benzoxazolinone in maize, BOA, is not toxic to *B. mojavensis*, and that it is transformed in the presence of the bacterium and the fungus, resulting in a product that is further inhibitory to the fungus but not the bacterium. This is in contrast to what the fungus can do alone.

On BOA-amended medium, the inhibitory response observed on nutrient agar is intensified, and greatly restricts the growth of *F. verticillioides* compared to the inhibition observed on media without BOA (Fig. 2b). On BOA-amended medium and in the absence of the fungus, there is no production of the red pigment, even after an extended incubation period of several weeks (data not shown). During an extended incubation, the fungus degraded the BOA, producing radial growth similar to control, which was reported earlier (Glenn et al. 2001). However, on the BOA-amended medium and when both organisms are co-incubated, the red pigment is produced as early as the seventh day of incubation (Fig. 2b,c). Extraction of media, both solid and liquid, determined that this pigment formed in these cultures was APO, based on HPLC, absorption spectra, and biological activity of the compound on *F. verticillioides*. APO was isolated and chemically identified by Gagliardo and Chilton (1992) from nonsterile soil that had been supplemented with BOA. Sensitivity of *F. verticillioides* toward the inhibitory substance produced by *B. mojavensis* was enhanced greatly when cultured on the BOA-amended nutrient agar because of the production of APO. This severe inhibition was not observed on PDA amended with BOA (data not shown), as on PDA the bacterium does not produce the inhibitor. This suggests that the more restricted growth of the fungus is caused by activity of both the accumulation of APO and to the bacterial inhibitor. During an extended incubation period, the growth is still restricted when the fungus is cultured on BOA-amended media in the presence of the bacterium (Fig. 2d), and more severely restricted than when grown in the presence of the bacterium and in the absence of BOA (Fig. 2a).

An intense accumulation of APO, indicated by a large zone of deep red pigment, in the BOA-amended medium appears on media in the presence of the bacterium. The amount produced in the presence of the bacterium appears to be more, and the color is red as opposed to a yellow-red observed in culture without the bacterium (Fig. 2c,d). The inhibition observed by the bacterium (Fig. 2a) compared to that produced in the presence of BOA-amended nutrient agar is greater (Fig. 2b,d). The progeny of the two genetic crosses of *F. verticillioides* do not grow on the BOA-amended medium, and there are no accumulation patterns of the red pigments (Fig. 2c), indicating that fungal growth and activity are required for the production of transformation products from BOA. It is established that the transformation of BOA follows several steps that lead first to 2-aminophenol (AP), which is a microbial transformation product (Nair et al. 1990; Gagliardo and Chilton 1992; Glenn et al. 2002; Fomsgaard et al. 2004), and subsequently microbial transformations or natural oxidative processes lead to the formation of 10 amino-phenoxazinones (Fomsgaard et al. 2004). That *B. mojavensis* is required for the

accumulation of APO is indicated in those cultures that showed a greater intensity of pigment accumulation over cultures that did not contain both the bacteria and fungi, and absent in nutrient broth without the addition of BOA (Fig. 2e). Another maize pathogen, *Gaumannomyces graminis* var. *tritici*, transformed BOA to APO in liquid culture (Friebe et al. 1998), and APO is now known to occur in cultures of several root endophytic fungi of tobacco, including *F. sambucinum* (Zikmundova et al. 2002).

The red color observed on agar media amended with BOA is also produced in nutrient broth by the bacterium-and-fungus mixed culture (Fig. 2e). Most of this color is caused by APO, which is based on its absorption spectrum of extracted media, and R_f values of the red spots on TLC plates (Fig. 3). However, there were other minor products observed on the TLC plates, suggesting the possible presence of related aminophenoxazinones. It is evident that the bacterium does not produce APO when exposed to BOA (lane 10, Fig. 3), and that APO is produced only in the presence of the fungi (lanes 4–9). Further, these data also indicate that this bacterium is not capable of transforming BOA (lane 10, Fig. 3). HPMA, a major decomposition product of BOA, was also obtained in lanes 4–9, but in the culture of the bacterium, lane 10, there was no decomposition product, and only the original BOA remained with intensity similar to the standard, lane 1. However, the intensity of the BOA in lanes 4–9 decreased, indicating transformation by the fungus. Apparently, the tolerant cross, AEG73-A4-1, lane 9, transformed BOA similarly to the pattern identified in the wild-type strain resulting in AP, which is transformed or oxidized to APO and HPMA, and as discussed below to 2-acetaminophenol (HPAA) by strains defective at appropriate genetic loci.

APO was first described as an antifungal substance under the name of questiomycin A, a compound produced from *Actinomycetes*, *Pseudomonas*, and *Waksmania aerate* (Anzai et al. 1960; Gerber and Lechevalier 1964). Gagliardo and Chilton (1992) later reported that APO was more toxic to microorganisms than BOA. The toxicity spectrum for the aminophenoxazinones for those organisms tested is APO>HPMA>BOA (Fritz and Braun 2006). Our study, however, indicated that neither APO nor BOA was toxic to *B. mojavensis* (Fig. 4) at concentrations that occur naturally (Cambier et al. 2000). However, there was a significantly longer lag period at the 25-μg/ml concentration than obtained with the other concentrations (Fig. 4). APO was toxic to *F. verticillioides* when cultured on the BOA-amended agar-based media used here, which suggests that the fungus was not able to

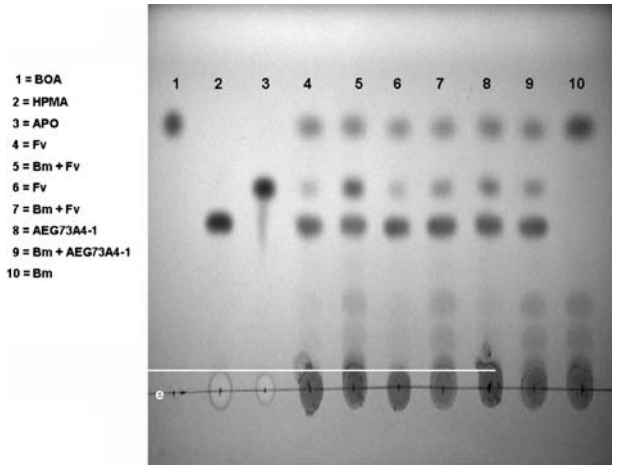

Fig. 3 TLC profiles of BOA and related metabolites obtained from agar plugs placed on silica gel plate showing the transformation products obtained from a 7-d-old culture of *F. verticillioides* MRC 826 (FV) and one of the genetic strains, AEG73-A4-1, cultured alone and in combination with *B. mojavensis* RRC112 (*Bm*); BOA, benzoxazolin-2-one; HPMA, *N*-(2-hydroxyphenyl) malonamic acid; APO, 2-amino-3H-phenoxazin-3-one. The silica gel plates were prepared following the procedure of Glenn et al. (2001)

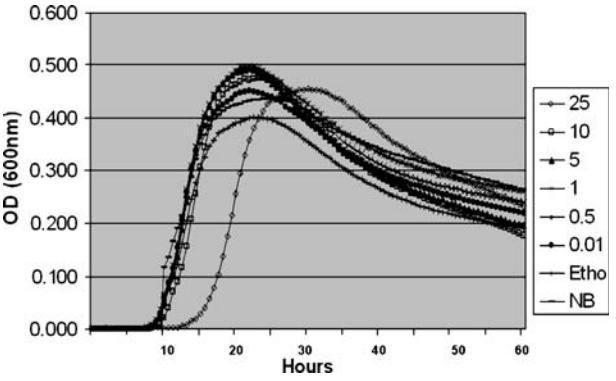

Fig. 4 Effects of APO on the specific rates of growth of *Bacillus mojavensis* RRC101 cultured in nutrient broth amended with different concentrations of APO (μg/ml). APO was solubilized in 100% ethanol (etho) and appropriate dilutions made to nutrient broth (NB); etho, ethanol control, representing the highest amount of APO added to nutrient broth during the experiment and shown for clarity as each dilution contained a comparable ethanol control; NB, nutrient broth controls

detoxify it within the 2-wk observation period. Knop et al. (2007) reported that *F. verticillioides* could utilize APO as a C-source, but indicated that its growth was reduced by 14% when cultured with 1 μM of APO. This concentration was considerably less than that used here and elsewhere (Macias et al. 2005; Martyniuk et al. 2006; Krogh et al. 2006), which are concentrations reported to occur naturally (Martyniuk et al. 2006). Perhaps the growth reduction observed in *F. verticillioides* by Knop et al. (2007) is reflective of the small amount of APO used. However, statistical significance was not assigned to the 14% reduction observed.

We established earlier that *F. verticillioides* was capable of cleaving the oxazolone ring of BOA, producing AP that is oxidized to HPMA or HPAA, and the latter caused primarily by the inactivity of the pathway control by FDB2 (Glenn et al. 2003). It was not established that the two genetic loci have direct relationships to the accumulation pattern observed by strains of *F. verticillioides*. The two strains of *F. verticillioides* genotypes used here represented two genotypes of 24 random ascospore progeny, and each differ in the number of functional alleles at both loci, designated Fdb1 and Fdb2. Tolerant strains have both alleles at both loci, and sensitive strains are defective either at one or both loci, i.e., FDB1/*fdb2* or *fdb1*/FDB2. Significant amounts of HPAA are produced only by strains of the genotype Fdb1/fdb2, thus, AP is not transformed to HPAA by all strains. Further, neither the natural occurrence nor the toxicity of HPAA to other organisms has been examined. In general, however, wild-type strains of *F. verticillioides* and several *Fusarium* species all show tolerance to most metabolites of BOA (Yue et al. 1998; Glenn 2001; Glenn et al. 2001) with detoxification proceeding from BOA or MBOA resulting in the accumulation of HPMA. The primary focus of concern, therefore, is the transformation of AP to either HPMA, a substance not toxic to most naturally occurring strains of *F. verticillioides*, or to APO.

The transformation of AP to the more biologically active APO has relevance, especially at the ecological level. The ability of *F. verticillioides* to detoxify AP into several nontoxic products led to the tentative conclusion by Glenn et al. (2002) that the benzoxazolinones allelochemicals are probably not effective resistance mechanisms against this fungus. However, interactive microbial activity was not considered relevant. As established here and by others (Gagliardo and Chilton 1992; Fomsgaard et al. 2004; Fritz and Braun 2006), however, APO is an important microbial transformation product of AP, although the interactions are perhaps exceeding complexity as observed here and by others (Macias et al. 2005; Knop et al. 2007).

Our interpretation of the results obtained in this study is that the inhibition of growth of *F. verticillioides* by *B. mojavensis* also prevents the efficient transformation of AP by *F. verticillioides* to the nontoxic HPMA, which is summarized in Fig. 5. The fungus in the presence of the bacterium seems capable of hydrolyzing BOA to AP, but then apparently is unable or at least has a reduced capacity for modifying AP to HPMA, resulting in an accumulation of AP that is either converted by the bacterium or spontaneously oxidized to APO. APO is more toxic to a broad range of microbes, including *F. verticillioides*. *B. mojavensis* is able to tolerate APO, thus an environment is created that favors the bacterium. As the effect is observed to occur some distance on culture plates from the bacterium, there is a suggestion for the production of an inhibitory diffusible substance. We speculate that if indeed an inhibitory substance is produced, it would interfere with the enzymatic function of the second genetic locus, FDB2, resulting in the accumulation of APO (Fig. 5). We do not know if this substance is the same as the fungal growth inhibitor produced in media by the bacterium that inhibits the *F. verticillioides* (Fig. 2a).

This is the first report to show that in the presence of a bacterium on BOA-amended medium there is an increased expression of *in vitro* toxicity to a fungus, which usually has the capability to detoxify BOA into decomposition products. Recently, Knop et al. (2007) demonstrated that detoxification of BOA by *F. verticillioides* was greatly reduced in the presence of the herbicide metolachlor. This information along with our data suggests that biotic and abiotic stress can influence the overall allelopathic interaction with the benzoxazolinones. As APO is the major transformation product of AP by most soil microorganisms, the role of APO and its accumulation by a fungal antagonist is highlighted here with several ecotoxicological possibilities. As *B. mojavensis* is an endophyte, the possible endophytic transformation of BOA into APO offers additional benefits. Further, the long-term stability of APO in soil types (Macias et al. 2005) and the suggestion that it might be the final transformation products by organisms in most soil types (Fritz and Braun 2006) are other features that should enhance the use of benzoxalinones combined with tolerant organisms such as *B. mojavensis* as effective biocontrol agents.

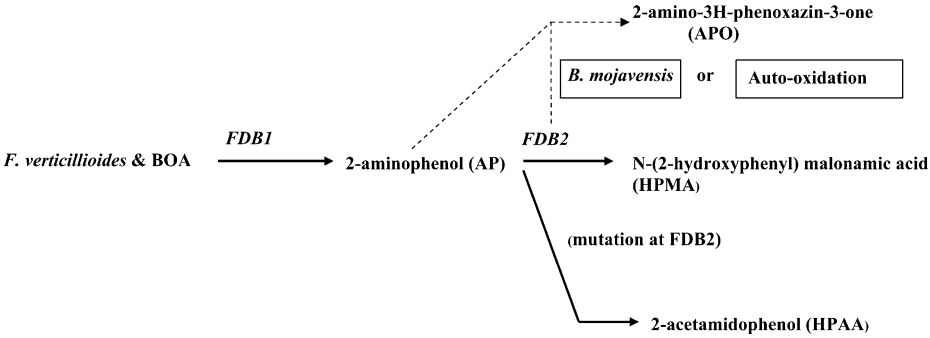

Fig. 5 Theoretical detoxification of BOA by co-cultures of *Bacillus mojavensis* and *Fusarium verticillioides* (modified from Glenn et al. 2003). *F. verticillioides* RRC826 cultured on BOA amended PDA transforms BOA, which involves two functional genetic loci, *FDB1* and *FDB2*, leading to the production of a relatively nontoxic *Fusarium* transformation product, HPMA. However, a mutation at *FDB2* causes the accumulation of a novel product as a result of the acetylation of AP to form HPAA. We theorize that in the presence of the wild-type loci of *F. verticillioides*, *B. mojavensis* interferes with the locus *FDB2*, resulting in an accumulation of APO, which results either from a physical spontaneous oxidation of AP to form APO, or direct transformation by *B. mojavensis* to APO. Under either pathway some HPAA should also accumulate

Keywords *Phragmites australis* · *Spartina alterniflora* · Root exudation · Allelopathy · Gallic acid · Reactive oxygen species · Microtubule

Introduction

Phragmites australis (Cav.) Trin. ex Steudel, known as common reed, is a perennial graminaceous plant that propagates mainly through rhizomes and, at low frequency, through seeds (Coops and Velde 1995). *P. australis* occurs in every state of the United States except Arkansas (probably present but undocumented) and is predominantly seen along the borders of lakes, ponds, and rivers (Harrington 1964). According to archaeological records, it has been present in the United States for at least 40,000 yr and it is considered a native species (Hansen 1978). However, genetic analysis of *P. australis* has shown that the more aggressive exotic European genotype has been introduced and is displacing the native genotype by invading new areas (Blossey 2002; Saltonstall 2002). *P. australis*'s distribution and relative abundance has increased dramatically over the last 150 yr (Saltonstall 2002). Presently, it represents one of the most abundant plant species in the US coastal wetlands and is considered an indicator of wetland disturbance (Blossey 2002).

Exotic plant invasions into a new ecological niche are often dangerous and are known to threaten ecosystems across the world (Mack et al. 2000). Such invading plant species not only compete with native species for space and resources but also often replace the entire native biodiversity leading to the formation of monocultures (DiTomaso 2000). Of an estimated 50,000 species introduced as exotic species, around 10% are plant species that are reported to have escaped from their natural ecosystems (Pimentel et al. 2000). Such introduced exotic plants often turn invasive and result in devastating effects on the ecosystem and account for huge economic losses (Zedler and Kercher 2004). The introduction of an invasive species to a new habitat creates competition for space and resources with native species. Traditionally, introduced species are more aggressive because of the nonavailability of predators in the new habitat and their ability to produce potent allelopathic chemicals (Bais et al. 2003a; Inderjit et al. 2006). *P. australis* is now considered as one of the major invasive species causing considerable negative impact on native biodiversity (Marris 2005). Human activities that lead to ecological disturbances, stresses such as pollution, changes in hydrologic regimes, and increased soil salinity, have all been proposed as causes for the rapid expansion of *P. australis* (Minchinton 2002). In addition, a number of edaphic factors have been suggested (Chambers et al. 2002).

Root allelopathy is one of the factors responsible for the invasive success of many plant species (Callaway et al. 1999; Callaway and Aschehoug 2000; Bais et al. 2003a,b, 2006). Root allelopathy specifically refers to the secretion of phytotoxins through root exudates of one plant species that suppress the growth of other species in the vicinity (Bais et al. 2003a, 2006). The Eurasian native spotted knapweed (*Centaurea maculosa*), one of the most economically destructive exotic invaders of North America, uses root-secreted chemical warfare and displaces other weeds and crops (Callaway et al. 1999; Callaway and Aschehoug 2000). Use of novel biochemical weapons that function as unusually powerful allelopathic agents or as mediators of novel plant–plant and plant–soil microbial interactions is known as the 'novel weapons hypothesis' (NWH) (Callaway and Ridenour 2004; Inderjit et al. 2006). (±)-Catechin, a root-derived toxin secreted by spotted knapweed, has been reported to have broad-spectrum allelochemical activity against a number of plant

species (Bais et al. 2002, 2003a). Leafy spurge (*Euphorbia esula* L.), another exotic perennial weed of Eurasian origin is known to rhizo-secrete jatropane diterpenes and ellagic acid derivatives that suppress other plants in its vicinity (Qin et al. 2006).

Apart from edaphic and environmental factors, allelopathic interaction among salt marsh plants has been suggested as an explanation for the zonation in the marsh exhibited by *P. australis* and other species (Drifmeyer and Zieman 1979). However, their experiments with *P. australis* rhizosphere washings did not inhibit germination of the two salt marsh plant species, *Distichlis spicata* or *Scirpus robustus*. Three triterpenoids (β-amanacin, taraxerol, taraxeron) and a flavone (tricin) have been identified from the aerial portions of *P. australis* (Ohmoto 1969; Kaneta and Sugiyama 1972). In addition, various phytochemicals have been extracted from *P. communis* (an earlier name for *P. australis*) and tested for their anti-algal effect on different algal species (Li and Hu 2005). The screen identified a phytotoxic effect of ethyl-2-methylacetoacetate against the algal species *Chlorella pyrenoidosa* and *Microcystis aeruginosa* (Li and Hu 2005). None of these chemicals has been tested for allelochemical activity on other seed plant species. To the best of our knowledge, no previous studies have isolated and characterized chemicals from root exudates of *P. australis* nor tested them for potential allelochemical activity. Considering the complexity of isolating and characterizing allelochemicals secreted from the roots into the soil, we addressed this issue by establishing an *in vitro* system, whereby *P. australis* secreted allelochemicals into a growth medium.

We systematically examined root secretions from two *P. australis* genotypes for their phytotoxicity, by following a bioassay-driven approach that used the model plant *Arabidopsis thaliana*. We identified a phytotoxic compound, gallic acid, as the phytochemical responsible for the root phytotoxicity of *P. australis*. We also established that the identified compound is a broad-spectrum rhizotoxin, which is effective against a diverse range of plants. Finally, we demonstrated that gallic acid generates elevated levels of reactive oxygen species (ROS) in the roots of the treated plants, thus leading to ROS-mediated microtubule disruption and complete collapse of the root architecture.

Materials and Methods

Plant Material and Chemicals

Arabidopsis thaliana wild type cultivar Columbia (Col-0) seeds were procured from Lehle Seeds (Round Rock, TX, USA); certified seeds of tobacco (*Nicotiana tabacum*) and mustard (*Brassica juncea*) were purchased from Ritchters Herb Specialists (Goodwood, Ontario, Canada). The GFP fusion line for tubulin-specific kinase was obtained from J.Y. Lee, Delaware Biotechnology Institute, Delaware, USA. Lettuce (*Lactuca sativa*) seeds were obtained from W. Atlee Burpee (PA, USA). Seeds of three native grass species (*Poa sandbergii*, *Festuca idahoensis*, *Koeleria macrantha*) were obtained from R.M. Callaway, University of Montana, Missoula, MT, USA. *Spartina alterniflora* seeds were obtained from Environmental Concern, P.O. Box P, 201 Boundary Lane, St. Michaels, MD, USA. Aseptic cultures of *P. australis* P38 and BB were established in tissue culture and were obtained from the *P. australis* genotype collection at the Halophyte Biotechnology Center, College of Marine and Earth Studies, University of Delaware. The aseptic cultures were used for the collection of root exudates and all other *in vivo* and *in vitro* studies. Gallic acid was obtained from Sigma-Aldrich, USA.

Culture Conditions

Seeds were washed in double-distilled water three times and surface-sterilized with 50% commercial bleach (sodium hypochlorite) for 3–5 min for *A. thaliana* and 5–10 min for all the other seeds followed by 3–4 washes in sterile distilled water. Seeds were cultured on Murashige and Skoog's (1962) (MS) solid medium with 3% sucrose, and allowed to germinate for 5–10 d until roots and shoots emerged. They were incubated at 25±2°C under a 16:8 h L/D regime. Plates were illuminated with cool fluorescent light with an intensity of 24 μmol m^{-2} s^{-1}.

Preparation of Root Exudates

P. australis genotypes, P38 and BB, were previously determined to be exotic (haplotype M) and native (haplotype F) genotypes, respectively, according to the methods of Saltonstall (2003). About 40 new plantlets of *P. australis* genotypes P38 and BB were inoculated into 400 ml 3% MS liquid medium in 1 l Erlenmeyer flasks, and the cultures were incubated on a rotary shaker set at 90 rpm at 25±2°C. Cultures were provided with a 16:8 h L/D photoperiod. After 25 d of incubation, the spent medium with the secreted root exudates was collected and freeze-dried in a lyophilizer (Labconco). Lyophilized powder was used as the source of root exudate for all phytotoxicity assays and for high-performance liquid chromatography (HPLC) fractionation. Lyophilized (2.5 g) powder was dissolved in 10 ml of distilled water and filter-sterilized by passing through a 0.45 μm filter (Millipore). The filtered liquid was used as sterile root exudate stock for all *in vitro* phytotoxicity assays.

In Vitro Phytotoxicity Assays

Three- to 5-d-old *A. thaliana* Col-0 and 5- to 6-d-old tobacco (*Nicotiana tabacum*), lettuce (*Lactuca sativa*), mustard (*Brassica juncea*), and smooth cordgrass (*Spartina alterniflora*) seedlings that had been germinated on MS solid medium with 3% sucrose were transferred to 24-well plates containing 1% MS liquid medium with respective treatments of root exudates. The treatments included 10%, 20%, and 30% (*v*/*v*) root exudates of *P. australis* and 50, 100, and 150 μM gallic acid separately. Control cultures did not receive any root exudates. Another control was set up with 30% sterile water to account for the dilution effect, if any. Similarly, the effect of gallic acid (100 μM) was also studied on three grass species (*P. sandbergii*, *F. idahoensis*, *K. macrantha*). A positive control with 100 μg ml^{-1} (±)-catechin, a known rhizotoxin (Bais et al. 2002), was also included for comparison. Cultures were incubated on a rotary shaker set at 90 rpm maintained at 25±2°C. Plants were illuminated with cool white fluorescent light for a 16:8 h L/D photoperiod. All treatments had six replicates, and the experiment was repeated at two independent times. The experiment was terminated at the end of the 10th d, and the observations were recorded as fresh weight in grams.

Identification of Compounds in Root Exudates

For HPLC analysis, 100 mg of the lyophilized powder of the root exudates were dissolved in 500 μl of 2.5 mM potassium phosphate buffer (pH 2.5) and filtered; 30 μl of the filtrate were injected. The major peaks separated on an Altech organic acid column (Prevail, Organic acid, 5 μm; 150×4.6 mm) were collected and assayed for phytotoxicity *in vitro* as

described earlier. Peaks that showed phytotoxicity were collected and resubjected to HPLC analysis and compared with the standard gallic acid peak to match the retention time. 1 μg μl^{-1} stock solution of standard gallic acid was prepared in 2.5 mM potassium phosphate buffer (pH 2.5) and was used for the comparison and estimation of gallic acid in the root exudates by using the peak areas. HPLC was performed in a Dionex HPLC system, equipped with a photodiode array detector. The separation was performed with an isocratic mobile phase of 2.5 mM potassium phosphate buffer (pH 2.5). Similarly, one additional set of separations was done by using a step-wise gradient of methanol and water as the mobile phase on a C_{18} column (Dionex Acclaim®, Polar Advantage II, 5 μm, 120 Å, 4.6× 150 mm). The methanolic fraction was subjected to electrospray ionization–mass spectrometry (ESI–MS) analysis to trace the molecular ion mass peak in the root exudates for confirmation.

Effect of *P. australis* and Activated Charcoal on Growth of *A. thaliana*

Pots of 40-d-old P38 and BB *P. australis* were seeded with about 50 seeds of *A. thaliana*. The germination and establishment of *A. thaliana* plants were monitored. After 6 wk, observations were recorded in terms of the number of *A. thaliana* plants that survived and established in P38 and BB pots. A set of control pots with only *A. thaliana* plants was also set up, and the number of plants surviving after 4 wk was counted, and the data were expressed as percent survival. A similar experiment was conducted with additional pots with 20% (*w*/*w*) activated charcoal (4–8 mesh; from Sigma) in which P38 and BB plants were grown for 40 d and seeded with 50 *A. thaliana* seeds. Germination and establishment of the *A. thaliana* plants were monitored. At 4 wk, pot germination data were collected and presented as percent survival.

Collection of Soil Cores and Extraction of Gallic Acid from *P. australis* Pots and Natural Stands

About 20 plants of each *P. australis* lines P38 and BB were grown in pots containing commercial plant growth soil mix (procured from Miracle-Gro Lawn Products, Marysville, OH, USA) for about 40 d. Then, soil cores (at least six) were drawn from different random spots in the pot by using a cork borer as a sampling device, and they were sectioned into the top 5 cm, middle 5 cm, and bottom 5 cm depths. For each respective depth, 0.5 g samples were taken from the respective sections and mixed to form a representative composite sample. This was done for each pot. One-half gram of each composite sample was extracted separately with 8 ml of 2.5 mM potassium phosphate buffer (pH 2.5). The extract was centrifuged, the supernatant was filtered, lyophilized to dryness, and redissolved in 0.5 ml of 2.5 mM potassium phosphate buffer (pH 2.5) and used for HPLC analysis. Similarly, representative soil samples were collected from the sites of natural *P. australis* stands from four different locations (three from near Lewes, DE and one from near Darien, GA; respective GPS locations of these sites are listed in the legend to figures). The roots and root bits or damaged roots if any in the soil samples were hand-removed to obtain a clean soil sample without any roots for field samples. Damage to roots in pot sampling was avoided by sampling away from the root core zone. Composite samples were prepared by mixing thoroughly the 10 samples collected from the same location, and about 10 replicates of such samples were obtained for analysis. One gram each of the soil sample was extracted in 10 ml of 2.5 mM potassium phosphate buffer (pH 2.5), the extract was centrifuged, and the supernatant was collected, filtered by passing through 0.45 μM filter, and freeze-dried.

The entire freeze-dried powder was redissolved in 400 μl 2.5 mM potassium phosphate buffer (pH 2.5) and used for HPLC analysis.

In Vitro Assay

An *in vitro* germination assay was conducted to test the effect of root exudate of *P. australis* P38, BB (10%, 20%, and 30% *v*/*v*), and gallic acid (50, 100, and 150 μM). Plates containing the respective treatments were prepared by adding root exudates and gallic acid directly to molten MS solid medium with 3% sucrose. The solidified media in the Petri dishes were seeded with 50 each of surface-sterilized *A. thaliana* seeds. Control plates contained only MS medium without root exudates, and the chemicals were also seeded with 50 surface-sterilized *A. thaliana* seeds. The plates were incubated for 5 d, and the number of seeds germinated was counted, and the data expressed as percent survival. Six replicates per treatment were taken, and the experiment was repeated twice.

Imaging for Reactive Oxygen Species

ROS imaging was done by following a slightly modified protocol of Foreman et al. (2003). Briefly, 4- to 5-d-old *A. thaliana* seedlings germinated on MS solid medium with 3% sucrose were transferred to MS liquid medium with 1% sucrose and pretreated with 20% root exudates of *P. australis* BB, P38 genotypes, and 50 μM gallic acid with or without 500 μM ascorbic acid (AsA) for 30 min; controls did not receive either root exudates or chemicals. After 30 min, 2.5 μM 2′,7′-dichlorodihydrofluorescein diacetate (HB_2-DCFDA) dissolved in DMSO (less than 0.001% final concentration) procured from Invitrogen (USA) was added to the cultures and incubated for 30 min at 4°C. Cultures were washed with 0.1 mM KCl, 0.1 mM $CaCl_2$ (pH 6.0). Washed roots were incubated in MS liquid medium with 1% sucrose for another 30 min at 23±2°C. A time point experiment was also carried out by treating the roots with gallic acid with or without AsA (500 μM) from 0 to 40 min. Roots were imaged by using excitation and emission wavelengths of 488 nm and 522 nm, respectively. The images were of 512×512 pixels with 10 scans of 1 s each in a confocal laser scanning microscope (CLSM) detailed in the following section. Images were captured with either a ×10 or ×40 (with water correction) objective on a Zeiss LSM 510 NLO attached to an Axiovert 200M with an automated stage microscope equipped with Zeiss LSM 510 software.

Effect of *P. australis* Root Exudates and Gallic Acid on Root Cell Microtubules and Root Viability

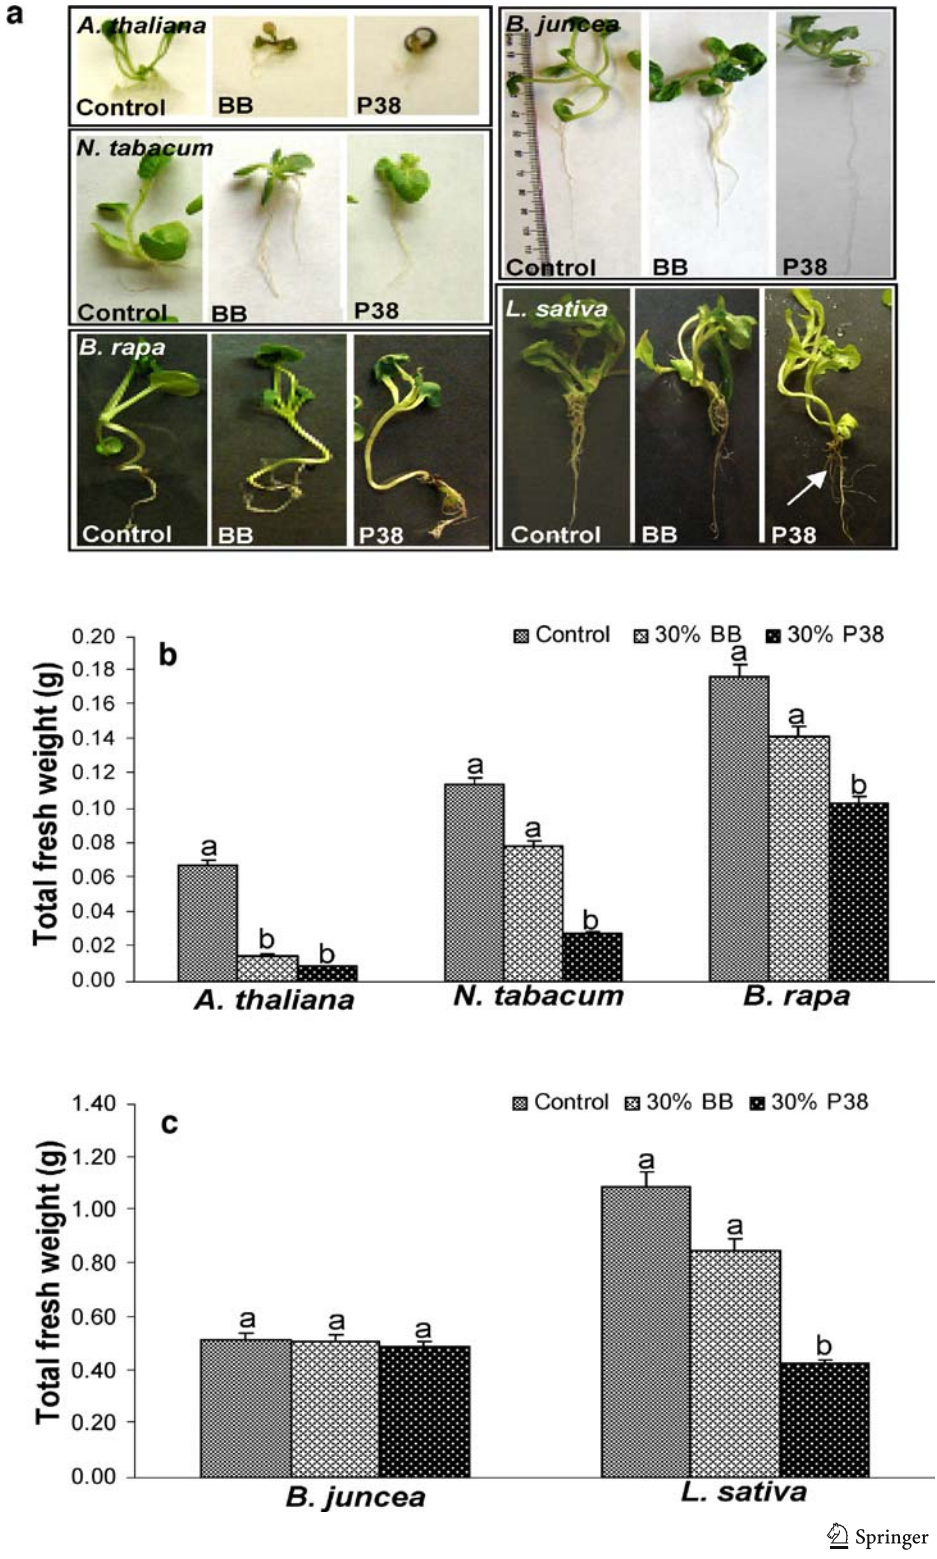
An experiment similar to that of the *in vitro* phytotoxicity assay was set up by using an *A. thaliana* transgenic line that carried a GFP fusion for a microtubule-specific kinase (CTD-PAPK1-GFP). Plants were incubated for 5 h with root exudates (20% *v*/*v*) and gallic acid (50 μM) separately with different treatments. Treatments included gallic acid, gallic acid plus 500 μM AsA, a control without any chemical, and another control with only AsA. Roots were imaged for microtubule arrangement in control and treated plants by using a confocal scanning laser microscope (CSLM). A time point experiment was also conducted with gallic acid treatment with or without AsA and a positive control with H_2O_2 (10 μM). The treated roots were imaged at different time intervals from 0 to 40 min for microtubule architecture. Images were captured with a ×40 objective (water correction lens) on a Zeiss LSM 510 NLO attached to an Axiovert 200M with an automated stage microscope

equipped with Zeiss LSM 510 software. Similarly, a viability assay was also conducted by using the *A. thaliana* plants treated only with root exudates and gallic acid. Roots were visualized by staining with fluorescein diacetate (FDA) and imaged with CSLM.

Effect of AsA on *in vitro* Survival of *A. thaliana*

About 3- to 5-d-old *A. thaliana* Col-0 seedlings germinated on MS solid medium with 3% sucrose were transferred to 24-well plates that contained 1% MS liquid medium with 50, 100, and 150 μM gallic acid with or without 500 μM AsA. Cultures were incubated on a rotary shaker set at 90 rpm maintained at 25±2°C. Plants were illuminated with cool white fluorescent light for a 16:8 h L/D photoperiod. All treatments had six replicates, and the experiment was repeated on two independent occasions unless otherwise mentioned. The experiment was terminated at the end of the 10th d, and the observations were recorded as fresh weight in grams.

Statistical Analysis



Data on total fresh weight of the plants, the number of plants that survived, and persistence of gallic acid in the soil were averaged from two separate experiments and further analyzed for variance using the Microsoft Excel XP version, followed by a Student's *t* test (Sokal and Rolf 1995). The data means were considered significantly different at the probability of $P<0.05$.

Results

P. australis Root Exudates are Phytotoxic

The phytotoxicity assay results show a severe inhibitory effect of the *P. australis* root secretions on the seedling growth of *A. thaliana* (Fig. 1a). Among the other species tested, the severe inhibitory effect was observed for tobacco (*N. tabacum*), turnip (*B. rapa*), and lettuce (*L. sativa*) (Fig. 1a–c). It is surprising to note that the root exudates did not show any significant growth effect on mustard (*B. juncea*) seedlings. There was a highly significant ($P<0.05$) reduction of biomass production, as measured in terms of total fresh weight (Fig. 1b and c). Root death generally started from the root tip continuing progressively toward the central elongation zone (data not shown). The roots turned completely dark by the end of the 10th d after the crude exudate treatment (Fig. 1a). However, the viability staining of the *A. thaliana* roots with FDA post 24-h treatment with root exudates revealed that the roots lost viability by 24 h after treatment at higher concentrations (30%) of P38 root exudates (Supplementary Fig. 1) as indicated by the reduction in the green fluorescence. The effect was more severe in the case of the plants treated with root exudates from exotic line P38 when compared to that of the native BB (Fig. 1; Supplementary Fig. 1).

P. australis Inhibits the Growth of *A. thaliana* Seedlings *in vivo*

The root exudates of *P. australis* demonstrated a severe growth inhibitory effect on *A. thaliana* plants grown *in vitro*. Therefore, we speculated that if the root-secreted component is involved in this process, the effect should also be seen *in vivo*. Hence, to mimic conditions that are more realistic, we grew the *P. australis* plants in pots containing plant growth soil mix. After the establishment of the *P. australis* plants for about 40 d, the pots were seeded with a known number of *A. thaliana* seeds (N=50). Germination and establishment of the *A. thaliana* seeds was studied for 6 wk. In line with our *in vitro* results, 6 wk after seeding, complete inhibition of *A. thaliana* seedling growth occurred in the pots with the exotic *P. australis* line P38 (Fig. 2a and b). *A. thaliana* plants grown with P38 showed 97% mortality (Fig. 2a and b) when compared to control pots, which were seeded with *A. thaliana* plants alone. The results also demonstrate greater mortality of the

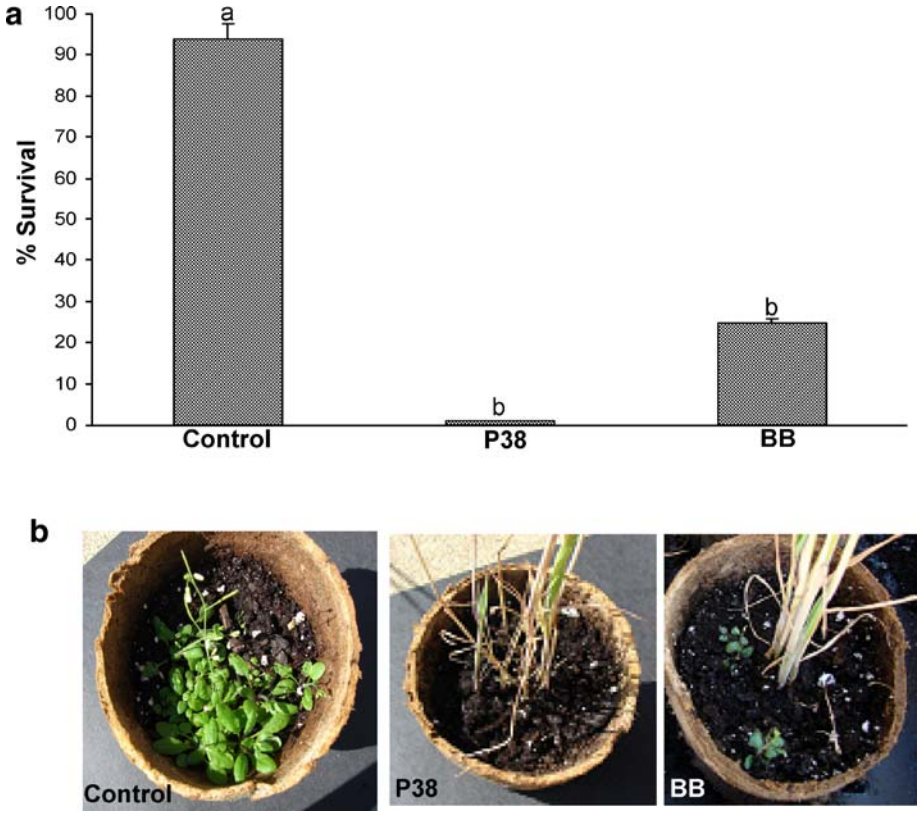

Fig. 2 Effect of *P. australis* (*P38*, exotic; *BB*, native) on the *in vivo* (in pot) germination, establishment, and survival of *A. thaliana* (**a** and **b**). Pots with 40-d-old *P. australis* plants were seeded with a known number of *A. thaliana* seeds. The germination and establishment of the *A. thaliana* seedlings was monitored for 6 wk, and the post 6-wk seeding data are expressed as the % survival (values are presented as the mean±SD, N=4). *Different letters on the bars* are used to indicate means that differ significantly (P<0.05)

A. thaliana plants grown with P38 (exotic) seedlings than those grown with BB (native) seedlings (Fig. 2a and b). These observations together with the *in vitro* results confirm the involvement of a root exudate component in the phytotoxic effect of *P. australis* on susceptible plants.

Application of Activated Charcoal Confirms the Allelopathic Activity

To confirm the involvement of root allelopathy in *P. australis*, we predicted that if we introduced an exogenous component that makes the root-secreted compounds unavailable for plant uptake, it would result in the survival of the susceptible plants. Activated charcoal has been previously reported to act as a sink that adsorbs secreted root exudates, thus making them unavailable for plant uptake (Callaway and Aschehoug 2000; Bais et al. 2003a). Accordingly, we prepared a potting soil mix with 20% activated charcoal, planted *P. australis* plants, and allowed them to grow. After 40 d, the pots with and without activated charcoal were seeded with about 50 seeds of *A. thaliana* each. The germination and establishment of the seedlings was monitored, and the observations were recorded after 4 wk. The post 4-wk results presented in Fig. 3 show a significant recovery of the *A. thaliana* growth in P38 plants with activated charcoal ($P<0.05$) compared to the P38 plants

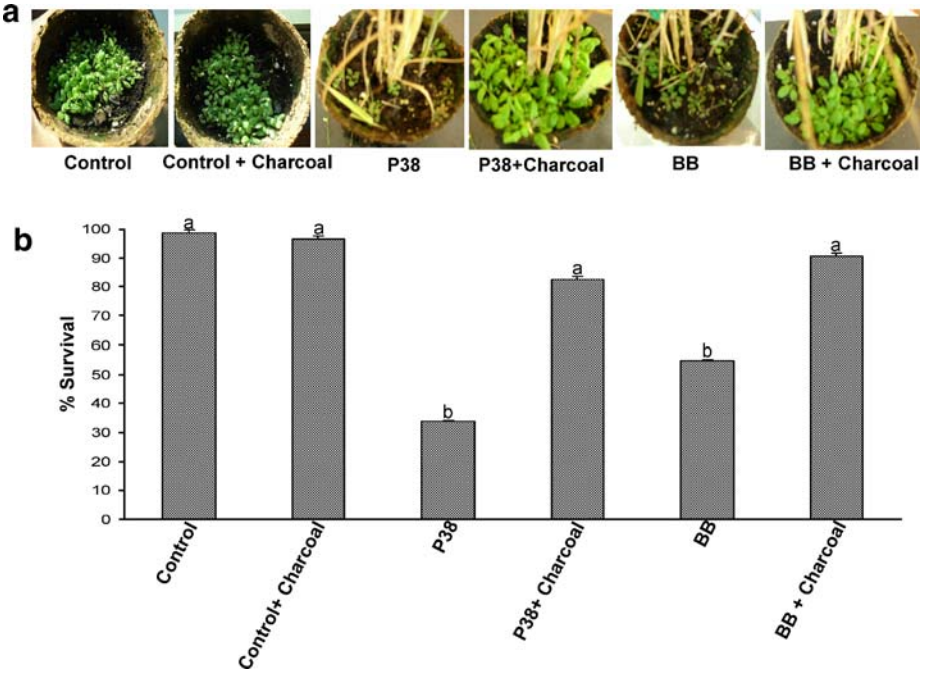

Fig. 3 Effect of activated charcoal (20% *w*/*w*) on the *in vivo* susceptibility of *A. thaliana* to *P. australis*. The pots of 40-d-old *P. australis* grown in plant growth soil mix containing 20% activated charcoal (*w*/*w*) were seeded with 50 *A. thaliana* seeds. The germination and establishment of the seeds was monitored for 4 wk. **a** Shows the more robust and vigorous growth and establishment of *A. thaliana* seedlings in the P38 (exotic) and BB (native) pots with activated charcoal. **b** Shows the plant survival in terms of the number of seeds germinated and established under different treatment conditions (values are presented as the mean±SD, $N=3$). *Different letters on the bars* are used to indicate means that differ significantly ($P<0.05$)

without activated charcoal. It is interesting to note that the *A. thaliana* cocultured with P38 plants with activated charcoal were more robust and fitter than control plants or control plants plus charcoal (Fig. 3). A similar response was also observed with the BB plants. Activated charcoal alone did not have any inhibitory effect on the germination and establishment of *A. thaliana* (Fig. 3). These data confirm that root exudates, in particular, have a role in the allelopathy of *P. australis*.

2,3,5-Dihydroxy Benzoic Acid (Gallic Acid) is the Phytotoxic Compound in the Root Exudates

A previous report suggested the involvement of an anti-algal effect by *P. communis* whole plant extracts (Li and Hu 2005). The authors demonstrated a phytotoxic effect of ethyl-2-methylacetoacetate against the algal species *Chlorella pyrenoidosa* and *Microcystis aeruginosa* (Li and Hu 2005). As our previous results showed the presence of a phytotoxic principle in crude *P. australis* root exudates, we adapted HPLC separations to purify the active compound. Purification and characterization of the active phytotoxic compounds were performed as per the published protocol (Bais et al. 2002, 2003a,b; Stermitz et al. 2003; Qin et al. 2006). We found that the phytotoxic activity was limited to one isolated peak, which was identified as gallic acid by HPLC–MS scans (Supplementary Fig. 2). We also analyzed root secretions by HPLC analysis for the presence of ellagic acid (EA), and ethyl-2-methylacetoacetate (EMA). It is interesting to note that we were able to detect only gallic acid in the root exudates. The later two chemicals were either absent or not present in concentrations detectable by HPLC. The presence of the gallic acid peak was confirmed by comparing the representative retention time with that of the standard gallic acid (Supplementary Fig. 2a and b). The presence of gallic acid was also confirmed by doing an ESI–MS analysis for gallic acid in the root exudates. The ESI–MS molecular ion mass peak for standard gallic acid (Supplementary Fig. 2c) and P38 (Supplementary Fig. 2d) exudates are shown. However, root exudates did not show the presence of a molecular ion mass of either ellagic acid or ethyl-2-methylacetoacetate, as reported earlier for the whole plant extracts (data not shown).

Gallic Acid Inhibits the Growth of *A. thaliana* and Other Species

After the identification of gallic acid in the root exudates, we determined that it is phytotoxic by testing standard gallic acid. The results (Fig. 4a–d; Supplementary Fig. 3) showed a severe phytotoxic effect on *A. thaliana* and other plant species, including the closely associated native species *S. alterniflora* and some of the native upland grass species studied with 100 μM gallic acid as LC_{50} ($P<0.05$). It is interesting to note that gallic acid did not show any phytotoxic effect on the seedlings of rice (*Oryza sativa*) or wheat (*Triticum aestivum*) (data not shown). Mortality of the plant was due mostly to the complete suppression of plant growth as a result of the death of the primary root similar to the effect shown by the *P. australis* P38 root exudates (Fig. 1a). Concomitantly, neither ellagic acid nor ethyl-2-methylacetoacetate showed any growth inhibitory activity or rhizotoxicity on *A. thaliana* plants (data not shown). The toxic effect of gallic acid on *A. thaliana* roots was further confirmed by the complete loss of viability of the treated roots as shown by the FDA staining (Supplementary Fig. 1). The treatment with the 100-μM gallic acid resulted in the complete loss of fluorescence when compared to the untreated control; these data correlated well with the observation of the 100-μM gallic acid as LC_{50} for *A. thaliana*.

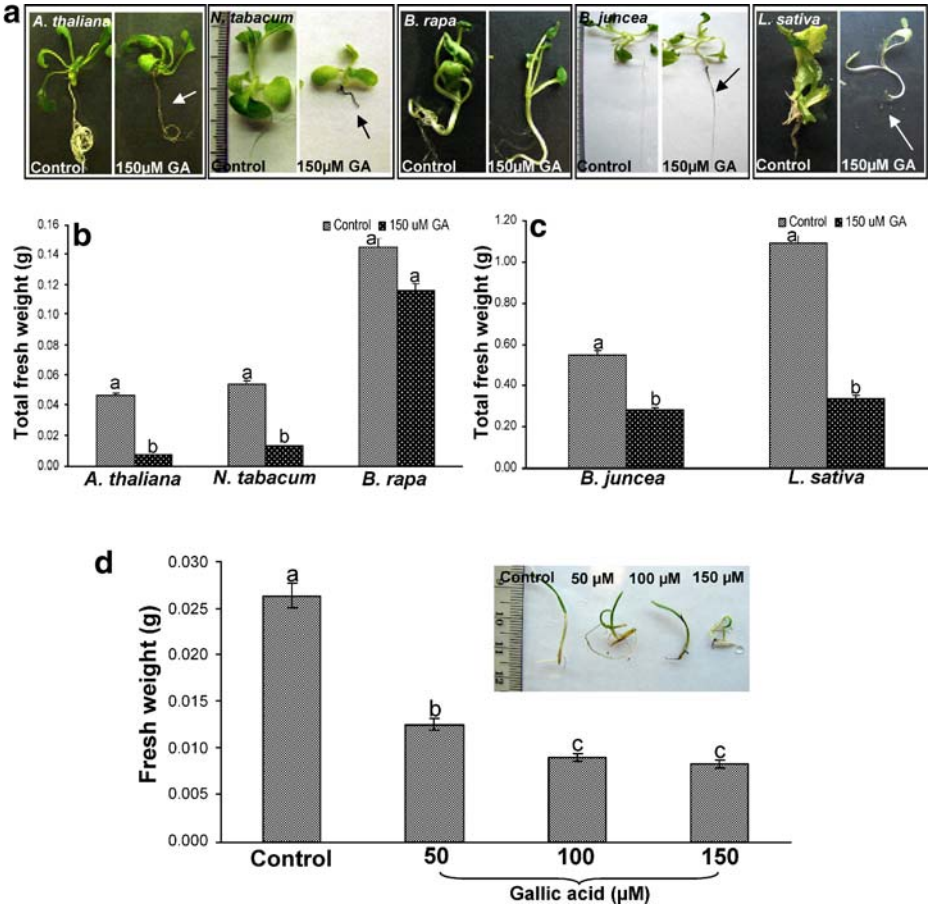

Fig. 4 Effect of gallic acid (*GA*) on the growth and development of *A. thaliana*, *N. tabacum*, *B. rapa* (**a** and **b**), *B. juncea*, *L. sativa* (**a** and **c**), and *Spartina alterniflora* (**d**) on the 10th d after treatment. Gallic acid was dissolved in DMSO and diluted with water to achieve the final concentration of DMSO (less than 0.0001%) and administered (150 μM) to the media containing 3–5-d-old seedlings (see the "Materials and Methods" section). The 24-well plates were subsequently incubated under a 16-h light and 8-h dark photoperiod on an orbital shaker set at 90 rpm at 25±2°C. The data represent the amount of growth inhibition by root gallic acid in terms of severity of killing the roots (**a**; *arrows*) and fresh weight accumulation (values are presented as the mean±SD, $n=6$). *Different letters on the bars* are used to indicate means that differ significantly ($P<0.05$)

Gallic Acid persists in *P. australis* Rhizospheric Soil

As gallic acid is exuded under controlled laboratory conditions, we tested for its presence under realistic rhizospheric conditions. The results (Fig. 5) show the persistence of significantly higher gallic acid ($P<0.05$) in the middle zone (5–10 cm from the top soil) of the pot followed by the top (5 cm) and bottom (10–15 cm from the top soil) zones. In addition, persistence of a significant concentration of gallic acid was also observed in the rhizospheric soils of *P. australis* natural stands from three different locations fringing Delaware Bay near Lewes, DE and one from near Darien, Georgia (Fig 5b, see legend for GPS coordinates). These data further confirm gallic acid as the probable phytotoxic

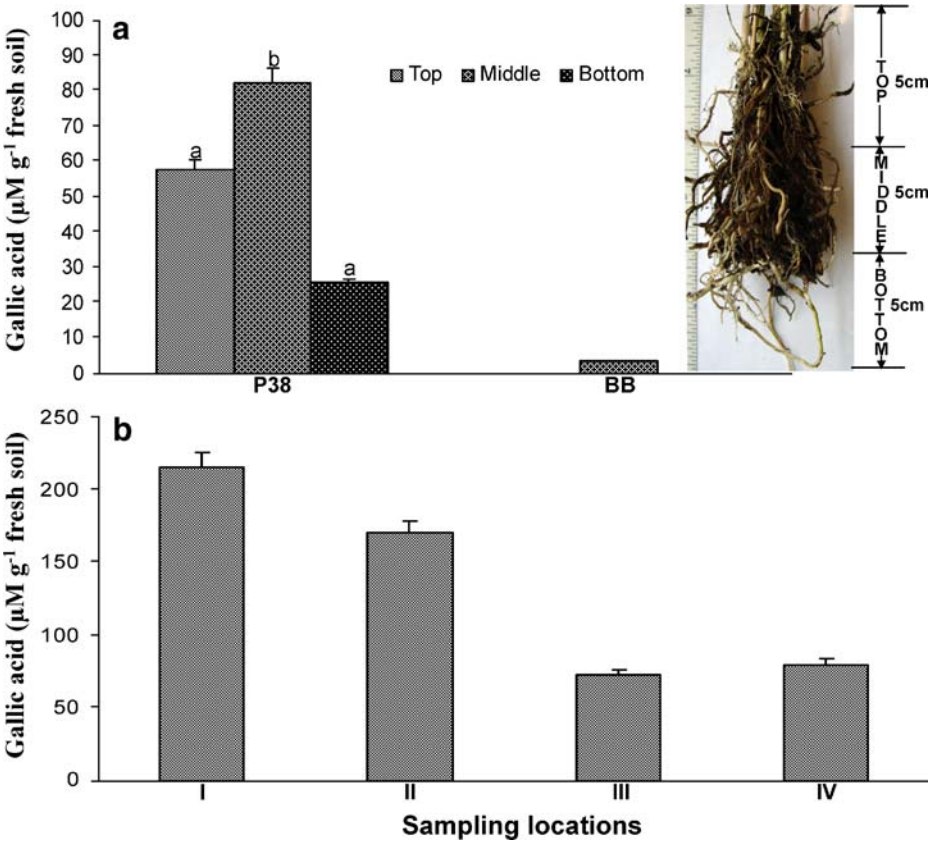

Fig. 5 **a** Secretion and persistence of gallic acid in the rhizospheric soil of *P. australis* (P38=exotic; BB=native) sampled at different depths and estimated by HPLC analysis (see the "Materials and Methods" section). *Inset*: Pictorial depiction of three different depths at which soil cores were collected. *Different letters on the bars* are used to indicate means that differ significantly ($P<0.05$). **b** Gallic acid levels in the soils sampled from natural stands of *P. australis* (all exotic-P38 genotype) from four different locations, three from near Lewes, Delaware [*X*-axis; *I* location I (latitude=38.76604; longitude=75.16674; N38°, 45.9624; W075° 10.0044), *II* location II (latitude=36.78106; longitude=75.15268; N38°, 46.8636; W075° 9.1608), *III* location III (latitude=33.66604; longitude=75.13434; N38°, 47.9624; W075° 11.0044)] and one from near Darien, Georgia [*X*-axis; *IV* location IV ((31° 18′ 43.80″ N, 81° 27′ 26.21″ W)] (values are presented as the mean±SD, $N=10$)

principle secreted through root exudates. It is interesting to note that the data show that *P. australis* plants grown in pots with artificial soil secretes approximately twofold less gallic acid compared to the *P. australis* plants grown in the natural environment. This difference in secretion potential of gallic acid may be because of differences between the edaphic factors in the marsh and the microcosms.

Effect of *P. australis* Root Exudates and Gallic Acid on Germination of *A. thaliana* Col-0 seeds

As most of our phytotoxicity assays involved the use of 5- to 10-d-old seedlings, we questioned whether root exudates and gallic acid have any effect on seed germination. We

studied the germination of *A. thaliana* seeds on root exudates and gallic acid plates. The result (Supplementary Fig. 4) indicates that neither root exudates nor gallic acid appeared to inhibit seed germination. However, root exudates and supplemented gallic acid killed the just emerged *A. thaliana* seedlings (Supplementary Fig. 4a–c). The deleterious effect of root exudates and gallic acid on *A. thaliana* seedlings was concentration-dependent (Supplementary Fig. 4a–c). Furthermore, the seedlings on gallic acid plates initially appeared more robust than controls; this might be an immediate resistance response of the plant to the toxin. However, the seedlings on the gallic acid medium showed severe reduction in root length when compared to control plants, which eventually lead to the death of the plants (Supplementary Fig. 4a and c). These results together suggest that gallic acid functions as a post emergent rhizotoxin. However, there is, of course, also a possibility that root exudates contain additional toxins that kill plants immediately after germination. This needs to be investigated.

Gallic Acid and *P. australis* Root Exudates Generate Elevated Levels of ROS and Disrupt the Microtubule Networks

As gallic acid is a phenolic compound, and such compounds are known to generate ROS (Muzandu et al. 2005), we hypothesized that it might trigger ROS generation in the exudates- and gallic acid-treated roots. To test this hypothesis, we imaged the roots of the wild type *A. thaliana* (Col-0) plants by a fluorescent H_2DCFDA (Foreman et al. 2003) staining method under three different treatments: a control, plus gallic acid, plus both gallic acid and AsA, a strong ROS quencher (Chen and Gallie 2005). Similarly, imaging was also done with the root exudate-treated *A. thaliana* roots. H_2DCFDA is a cell-permeant dye that is activated specifically in response to ROS, and the intensity of fluorescence is proportional to the amount of ROS generated (Foreman et al. 2003). The post 5 h imaging data showed the production of elevated levels of ROS on the roots treated with 50 μM gallic acid when compared to the untreated control *A. thaliana* roots (increased fluorescence in the panel) (Supplementary Fig. 5). The generated ROS was completely quenched when the roots were treated with 500 μM AsA. A similar response was also recorded with *P. australis* root exudates (data not shown). Our goal was to gain insight into the mechanism involved in the phytotoxic role of gallic acid at the cellular level. We suspected that gallic acid-generated ROS and the associated biochemical change on the root surface might result in other downstream processes that lead to the complete collapse of the roots. Considering these aspects, we hypothesized that gallic acid might disrupt the microtubule network of the cell through a ROS-mediated process. To test this hypothesis, we used an *A. thaliana* transgenic line with Col-0 background possessing a GFP-tagged microtubule specific kinase, which specifically labels microtubules. Five-d-old *A. thaliana*-35S: GFP-PAPK1 seedlings germinated on MS solid medium with 3% sucrose were treated with 50 μM gallic acid (the lowest concentration of gallic acid was selected to have a sublethal effect). Post 5 h treated roots were imaged with a confocal microscope. The result (Supplementary Fig. 5) shows that the lowest concentration of the gallic acid used resulted in the complete disruption of the microtubule network. A similar effect was also observed with root exudates (data not shown). With both root exudates and gallic acid treatment, the microtubule assembly appeared to be dismantled and formed localized aggregates of microtubule fibers. However, the effect was reversed when the roots were treated with 500 μM AsA along with 50 μM gallic acid. These data together with the other results suggest that gallic acid acts on the *A. thaliana* roots through ROS-mediated disruption of the microtubule network.

To track the pace of the effect of gallic acid on *A. thaliana* roots, we conducted a time point experiment and imaged the roots for both the generation of ROS and corresponding microtubule disruption. The results showed that by 10 min after treatment, ROS was generated on the root surface and increased further over the time period (Fig. 6a). Correspondingly, the disruption of the microtubule assembly also appeared to be initiated by 10 min, and it reached the maximum level by the 40th min (Fig. 6b). The destruction of microtubules was severe by 40 min, which resulted in the appearance of disassembled microtubules as small florescent specs on the roots (Fig. 6b). To check the involvement of ROS, we used 10 μM H_2O_2 as a positive control and imaged the microtubule network. H_2O_2 is an important ROS and is known also to induce other ROS species (Bolwell et al. 1995). H_2O_2-induced ROS showed a similar and more severe effect than gallic acid and resulted in the complete destruction of the microtubule assembly within 10–20 min of treatment (Fig. 6c). The H_2O_2 at 10 μM showed no inhibitory effect on the roots of *A. thaliana* (data not shown). Treatment of roots with 500 μM AsA along with gallic acid resulted in complete quenching of the gallic acid-generated ROS on the root surface (Fig. 6d). The treatment of roots with AsA along with gallic acid suppressed the negative effect of gallic acid on microtubules and restored the control phenotype of the microtubule network (Fig. 6e). These results established conclusively that gallic acid acts on *A. thaliana* roots through the generation of elevated levels of ROS that lead to destruction of the microtubule assembly and, finally, to the collapse of the root architecture.

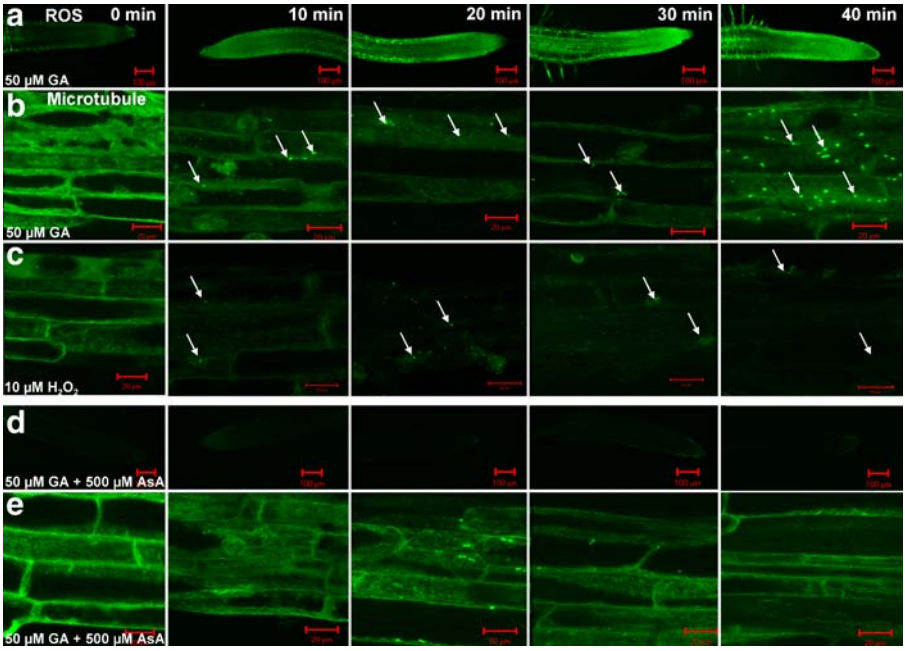

Fig. 6 Induction of root surface reactive oxygen species (*ROS*) by gallic acid (*GA*) (50 μM) (**a**), effect of 50 μM gallic acid (**b**), and 10 μM hydrogen peroxide (**c**) on root cell microtubule architecture over a 40-min time period. Effect of combined treatment of 50 μM gallic acid with 500 μM AsA on root surface ROS generation (**d**) and root cell microtubule architecture (**e**) over a 40-min time period. The images are confocal scanning laser micrographs and each image is representative of the roots of at least six independent plants analyzed and imaged. (Scale bars=100 μM for ROS images and 20 μM for microtubule images). See the "Materials and Methods" section for the details on microscopy and staining methodology

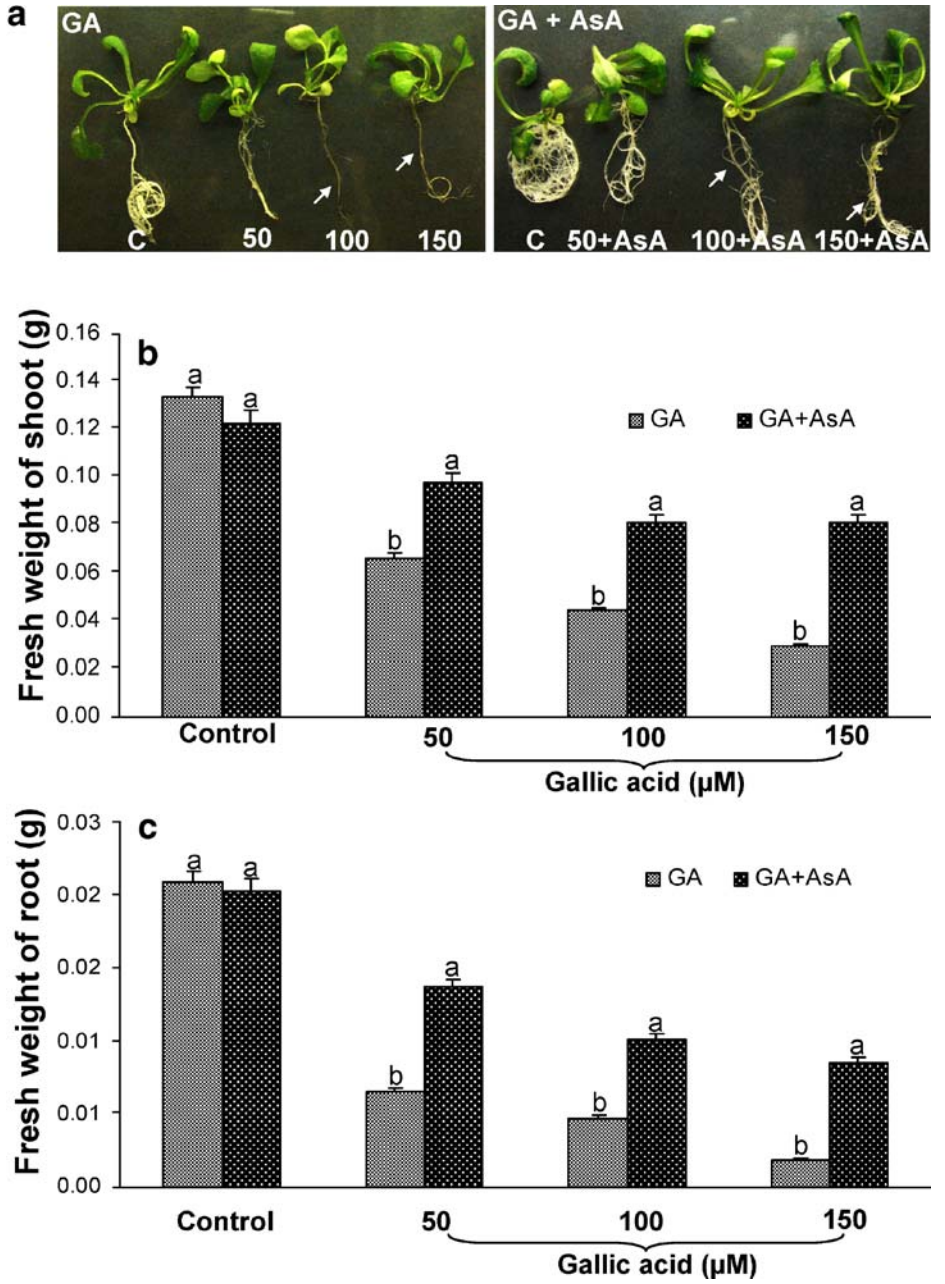

Fig. 7 Role of AsA (500 μM) in the recovery of *A. thaliana* seedlings from gallic acid (GA) (50–150 μM) toxicity *in vitro*. 50–150 μM of gallic acid with or without 500 μM AsA (dissolved in water and filter-sterilized using 0.45 μm filter) were administered to the culture medium holding 5-d-old *A. thaliana* seedlings. The cultures were then incubated under a 16:8 h L/D photoperiod on an orbital shaker set at 90 rpm at 25±2°C. **a** Shows the completely collapsed, killed, and darkened roots of gallic acid-treated *A. thaliana* and the mostly recovered roots when treated with AsA (indicated by *arrows*). **b** and **c** Show the growth and recovery of the *A. thaliana* plants subjected to combined treatment of gallic acid and AsA post 10 d in terms of the production of fresh weight of shoot (**b**) and root (**c**) (values are presented as the mean± SD, N=6). *Different letters on the bars* are used to indicate means that differ significantly (P<0.05)

AsA, a ROS Quencher, Reverses the Effect of Gallic Acid

Our observations presented in the earlier sections established that the phytotoxicity of gallic acid on *A. thaliana* and other species is because of ROS-mediated destruction of the microtubule network of root cells. We verified this by the inclusion of AsA in gallic acid treatment. We set up an experiment that used 5-d-old *A. thaliana* seedlings treated with different concentrations of gallic acid (50–150 μM) with or without AsA (500 μM). The results show that the treatment with AsA resulted in more than 80% recovery from the effect of gallic acid (Fig. 7). The AsA-treated roots appeared normal and similar to the controls when compared to the darkened and dead roots of gallic acid-treated *A. thaliana* (Fig. 7a). Furthermore, greater than 80% recovery in growth in terms of fresh weight of the roots and shoots was observed with the plants treated with AsA along with gallic acid when compared to plants treated with gallic acid alone (Fig. 7b and c).

Discussion

Plant–plant chemical communication and perception strategies are sophisticated but only partly understood. Among the different interactions, the suppressive interaction of a class of chemicals secreted by one plant against neighboring plants (allelopathy) have been implicated in the invasiveness of many exotic weedy species (Callaway and Aschehoug 2000; Bais et al. 2006; Inderjit et al. 2006). *P. australis* is one of the dominant colonizers of U.S. wetland marshes and exhibits invasive behavior by virtually replacing the entire native vegetation in its niche (Lynch and Saltonstall 2002). Genetic analysis of *P. australis* has revealed the introduction of more aggressive genotypes from Europe (Saltonstall 2002). However, in some locations, such as the Lake Superior wetlands, it is the native genotype that is exhibiting invasive behavior, thus complicating the debate over *Phragmites* control if the invader is a native (Wills and Birks 2006). In this communication, through a series of biochemical and cell signalling studies, we report for the first time a root-secreted rhizotoxic compound that is implicated as one of the factors for the invasiveness of *P. australis*. Root exudates of *P. australis* P38 showed strong rhizotoxicity on different tested plants including the model plant *A. thaliana*. The rhizotoxicity observed by both *in vitro* and in pot experiments under greenhouse conditions, supported by increased survival of *A. thaliana* plants in the presence of activated charcoal, indicate the involvement of root exudate-derived allelopathy. Root exudate-mediated allelopathy has been reported in a number of species (Callaway et al. 1999; Callaway and Aschehoug 2000; Bais et al. 2006; Inderjit et al. 2006). Root exudates from *in vitro* grown spotted knapweed (*C. maculosa*) have exhibited phytotoxicity on a number of weedy species including the model plant *A. thaliana* and crops such as wheat (*Triticum aestivum*) and tomato (*Lycopersicon esculentum*) (Bais et al. 2002). In these cases, plants showed wilting symptoms before senescence with reduced shoot and root differentiation (Bais et al. 2002). Similarly, *P. australis* root exudates induced severe rhizotoxicity, leading to the inhibition of root growth with the whole root eventually turning dark and collapsing. Often, such root exudate-mediated toxicity has been attributed to one or a few potential phytotoxins (Bais et al. 2002, 2003b; Stermitz et al. 2003; Qin et al. 2006).

Gallic acid was highly phytotoxic to *A. thaliana* and other plant species tested. It particularly induced rhizotoxicity similar to crude root exudates leading to severe inhibition of root growth and disrupting the total root architecture. Gallic acid, a phenolic compound found in a number of dicot species (e.g., oak, birch, tea, grape, and sumac) (Barman and

Rai 2000; Kraus et al. 2003), is a main constituent of gallotannins. Although, the gallic acid biosynthetic pathway is still debated, it has been shown that gallic acid is synthesized directly from its precursor 5-dehydroshikimate in the leaves of *Rhus typhina* (Werner et al. 2004). Although, the presence of gallic acid has been shown in monocots (Iqbal et al. 2003; Li and Hu 2005), its biosynthetic pathway has not been deduced in these species. It may be because of an altogether different but specific biosynthetic pathway in monocots. The presence of other phenolic acids such as ellagic acid in *P. communis* (former name for *P. australis*) supports this view (Li and Hu 2005). Gallic acid present in the whole plant ethanolic extracts of *P. communis* was negated for any allelopathic effect on two algal species studied (Li and Hu 2005). Ethyl acetate fractions of buckwheat (*Fagopyrum tataricum*) showed the presence of gallic acid and a strong phytotoxic effect on selected plant species (Iqbal et al. 2003). The allelopathic effect of gallic acid has been reported in a number of other species (Weidenhamer and Romeo 2004). In our study, gallic acid showed a severe rhizotoxic effect on the monocot, *S. alterniflora*, a native salt marsh grass often displaced by *Phragmites*, and on the native upland monocot grasses *P. sandbergii*, *F. idahoensis*, and *K. macrantha*, but it is interesting to note that it has no effect on crop species such as rice and wheat (data not shown). The specificity of gallic acid toxicity against various monocot and dicot species should be studied. Its effect on some monocots, including *S. alterniflora*, suggests an allelopathic role in salt marshes. The vast majority of salt marshes overrun by *Phragmites* consist of monocots specifically belonging to the genus *Spartina* (Burke et al. 2002). Our future research will check toxicity on a wide array of both freshwater and saltwater marsh plants.

The phytotoxicity of gallic acid exhibited by the treated roots appears to have been triggered by elevated levels of ROS. This conclusion is supported by the observation that gallic acid treatment resulted in the production of elevated levels of ROS. As the gallic acid treatment caused the collapse of the roots, we suspected that its role was in disrupting the microtubule architecture. Accordingly, we imaged the gallic acid-treated roots of *A. thaliana*-CTD-PAPK1-GFP, a transgenic line carrying a specific GFP tag for visualizing microtubule architecture. This confirmed that increased microtubule disruption was associated with increased ROS levels over a time period. When other plants were incubated with AsA, a ROS quencher and antioxidant (Chen and Gallie 2005), they showed little or no microtubule disruption. Our gallic acid-treated plants exhibited a considerable amount of recovery when incubated with AsA. It is interesting to note that the phytotoxin, (±)-catechin, secreted through the root exudates of *C. maculosa*, was previously shown to trigger a wave of ROS, which led to the Ca^{2+} signaling cascade triggering genome wide changes in gene expression, ultimately to the death of the root system in *A. thaliana* (Bais et al. 2003a; Weir et al. 2003, 2006; Prithiviraj et al. 2007). The phytotoxic effect of gallic acid involved ROS generation and ultimately led to microtubule disruption in the susceptible plant *A. thaliana*. Our results indicate microtubule disruption as the direct effect of ROS generated by gallic acid. However, further studies are needed to establish that genome wide changes upon gallic acid administration lead to gene expression variations corresponding to marker ROS and microtubule genes.

ROS has been implicated in the signaling and induction of various plant processes from pathogenesis (Torres et al. 2002) to various other stimuli such as gravity response, abscissic acid, auxin, gibberellic acid, UV-B light, and nodulation (nod) factors (Zhang et al. 2001; Mackerness et al. 2001; D'Haeze et al. 2003). An important question is how do ROS modify the downstream targets that lead to phytotoxicity? The response reported in the present study might be occurring through ROS-mediated modification of the downstream signaling proteins, thus leading to altered gene expression and cell death. ROS generated by

phenols have been implicated in the microtubule destruction and associated cell death in human cancer cell lines (Makoto et al. 2000). A polyphenol, phenol [1-(2,4-dihydroxyphenyl)-3-hydroxy-3-(4′-hydroxyphenyl) 1-propanone (beta-hydroxy-DHP)], isolated from licorice root (*Glycyrrhiza glabra*) has been reported to inhibit microtubule assembly in human breast and prostate cancer cell lines (Rafi et al. 2002). However, to the best of our knowledge, there are no reports of a plant rhizo-secreted toxin damaging the microtubule network of the root cells of other plants. In future studies, we need to buffer solutions of gallic acid in the bioassay experiments, given that the effect of pH on the toxicity of phenolic acids has been well-established (Staman et al. 2001; Blum and Gerig 2005).

In summary, overall, the step-wise experiments performed and the correlative results reported in the present study indicate that *P. australis* secretes a phenolic compound gallic acid into the rhizosphere. The presence of gallic acid in the soil of coastal *Phragmites* marshes has been confirmed. The rhizo-secreted gallic acid produces an allelopathic effect on the tested plants both *in vitro* and in pot experiments under greenhouse conditions. Furthermore, gallic acid inhibited plant growth through ROS-mediated cell death associated with the destruction of the root microtubule assembly.

L-3,4-Dihydroxyphenylalnine (L-dopa), identified from Mucuna (*Mucuna pruriens* L.) (Fujii 1994), is exuded from the roots, and causes growth inhibition in other species that grow close to the plant. Although L-dopa is the precursor for some alkaloids, lignin, phenylpropanoids, and melanin in plant species, excess exogenous L-dopa suppresses root elongation of some plants (Fujii 1994; Nakajima et al. 1999; Hachinohe et al. 2004). In the melanin synthesis pathway, L-dopa is metabolized to dopaquinone by polyphenol oxidase (PPO, EC 1.10. 3. 1, EC 1.14. 18. 1), and then dopaquinone is transformed into brown-colored melanin and melanin-like compounds via several steps that include oxidation and polymerization (Albrecht and Kohlenbach 1990). The melanin synthesis pathway generates reactive oxygen species (ROS), such as O_2^-, $^1O_2$, H_2O_2, and $OH^\bullet$, and free radical species (FRS; Kruk et al. 1999). Although L-dopa is the effective therapeutic agent for Parkinson's disease, it has been reported that the long-term administration of L-dopa induces cell apoptosis and cytotoxicity (Basma et al. 1995; Lai and Yu 1997; Haque et al. 2003). The neurocytotoxicity of L-dopa is considered to be a result of oxidative damage caused by ROS and/or FRS generated from the melanin synthesis pathway (Graham 1978; Basma et al. 1995; Lai and Yu 1997; Haque et al. 2003).

In suspension-cultured carrot cells, we revealed previously that the main factor of the phytotoxicity of L-dopa was oxidative damage by ROS and/or FRS (Hachinohe and Matsumoto 2005). In L-dopa-treated carrot cells, an accumulation of melanin and an increase of lipid peroxide levels occurred. The growth of the cells was restored by a reduction of the amount of melanin and lipid peroxide by application of antioxidants, ascorbic acid and α-tocopherol. Early studies on the phytotoxicity of L-dopa showed that its action was species-selective (Fujii 1994; Nakajima et al. 1999). We have surveyed the effect of L-dopa on 32 species and found tolerant and susceptible species (Hachinohe et al. 2004). However, the mechanism of the species-selective phytotoxicity of L-dopa remains obscure.

The aim of this study was to elucidate the mechanism of species-selective phytotoxicity of L-dopa. The involvement of ROS/FRS in the phytotoxicity of L-dopa was examined in barnyardgrass (*Echinochloa crus-galli* L.) and lettuce (*Lactuca sativa* L.), tolerant and susceptible species, respectively. Additionally, the activity of PPO, a key enzyme of the melanin synthesis pathway, was compared between the species.

Methods and Materials

Growth Conditions and Bioassay Seeds were sown on an aluminum mesh tray covered with cheesecloth and set in a plastic box (310×220×50 mm) that contained distilled water. The water level was adjusted to keep seeds wetted until germination. They were kept in a growth chamber under 25:20°C, 12:12 h L/D conditions. Germinated seeds of 1-day-old lettuce and 4-day-old barnyardgrass were used for bioassays. Ten uniformly germinated seeds of each species were set in a plastic box (60×60×100 mm) that held 200 ml of 0.5% agar culture medium (pH 6.0) containing L-dopa. In addition, ascorbic acid or α-tocopherol was added to the medium to determine the recovery effects of the antioxidants from phytotoxicity of L-dopa on lettuce. Plants were kept in the growth chamber under 25:20°C, 12:12 h L/D conditions for 5 days, and their root lengths were measured with a ruler. Each treatment was conducted with three boxes, and the experiment was repeated three times.

Determination of Lipid Peroxidation Lipid peroxide was determined with the thiobarbituric acid (TBA) test (Velikova et al. 2000). Plant root tissue (500 mg) was homogenized in a

Table 1 Effect of L-dopa on the root growth of barnyardgrass and lettuce

Plants	Root Length (% of Control)				
	10^{-7} M	10^{-6} M	10^{-5} M	10^{-4} M	10^{-3}M
Barnyardgrass	103.7 (8.77)	88.4 (4.90)	89.7 (0.60)	98.2 (18.79)	12.2 (1.12)*
Lettuce	99.0 (3.00)	98.9 (2.20)	29.1 (3.28)*	19.8 (0.35)*	8.9 (0.49)*

Root lengths of untreated control in lettuce and barnyardgrass are 52.5±0.9 mm and 40.7±2.1 mm, respectively. Numbers in parentheses are the ±SE of the mean (N=5).

*P<0.01, a significant preference between control and L-dopa treatment

0.1% (*w*/*v*) trichloroacetic acid (TCA) solution (5 ml) with a pestle and a mortar. The homogenate was centrifuged at 10,000×*g* for 20 min, and 0.5 ml of the supernatant was added to 1 ml of 0.5% (*w*/*v*) TBA in a 20% TCA solution. After the mixture was incubated for 30 min at 98°C, the reaction was stopped by cooling on ice. The sample was centrifuged at 10,000×*g* for 5 min, and the absorbance of the supernatant was measured at 532 nm. The value for non-specific absorbance at 600 nm was subtracted. The amount of thiobarbituric acid reactive substances (TBARS) was calculated with an extinction coefficient of 155 mM^{-1} cm^{-1}.

Spectrophotometric Assay of Melanin Total melanin content was determined at 1, 3, and 5 days after treatment according to Wakamatsu and Ito 2000. Plant root tissue (50 mg) was homogenized in 5 ml of a 90% (*v*/*v*) Soluene-350 solution and solubilized completely at 100°C for 30 min. After cooling, the absorbance at 500 nm was determined with synthetic melanin used as a standard.

Enzyme Extraction and Enzyme Assay A PPO assay was performed according to Vaughn et al. (1988). Root tissue (500 mg) of barnyardgrass and lettuce growing in agar culture medium for 5 days was homogenized with 5 ml of 0.1 M sodium phosphate buffer (pH 7.0) that contained 0.1% Triton X-100. The homogenate was centrifuged at 12,000×*g* for 20 min at 4°C, and the supernatant was used as a crude extract. PPO activity was determined spectrophotometrically by following the conversion of L-dopa to dopaquinone at 490 nm. The reaction medium consisted of 50 mM sodium phosphate buffer (pH 7.0), 100 mM

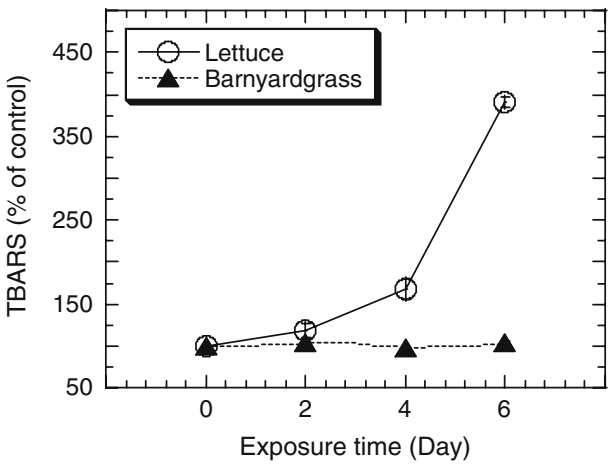

Fig. 1 Effect of L-dopa on lipid peroxide formation in barnyardgrass and lettuce. Concentration of L-dopa was 10^{-4} M. *Bars* indicate ±SE of the mean (N=3)

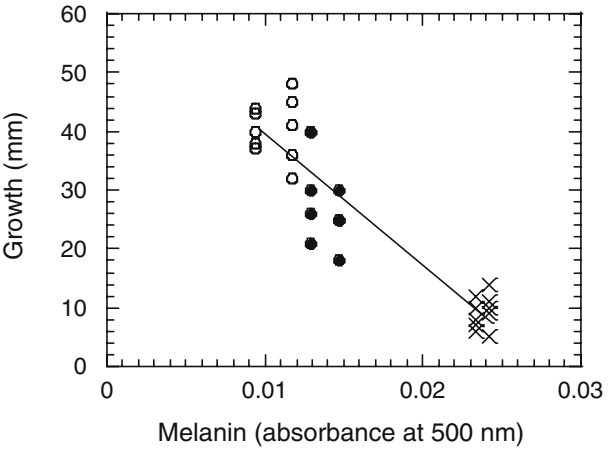

Fig. 2 Relationship between melanin content and elongation in root of lettuce treated with L-dopa for 3 days (r^2=0.85, $F_{1, 28}$=152.8, P<0.001). *Open circle* Control, *filled circle* 10^{-5} M L-dopa, *ex sign* 10^{-4} M L-dopa

L-dopa, 0.15% SDS, and 2,800 U/ml catalase. All assays were conducted in triplicate, and experiments were repeated at least three times.

Statistical Analysis Data were analyzed with Statcel (OMS, Saitama, Japan) and tested for normality and homogeneity of variances (F test or Bartlett test) followed by ANOVA or simple linear regression analysis. Differences between treatments were determined by Fisher's PLSD test, Scheffé's test, Student's t test, or Welch's t test.

Results

The growth suppression by L-dopa differed remarkably between barnyardgrass and lettuce. Root lengths of 10^{-4} M L-dopa-treated plants were approximately 100 and 20% of untreated controls of barnyardgrass and lettuce, respectively (P<0.004, Table 1).

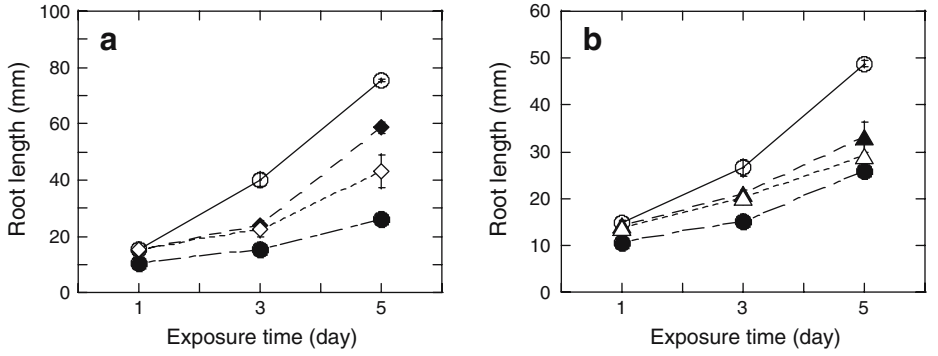

Fig. 3 Effects of ascorbic acid (**a**) and α-tocopherol (**b**) on the growth of lettuce root treated with L-dopa. *Open circle* control, *filled circle* 10^{-5} M L-dopa, *open diamond* 10^{-5} M L-dopa+10^{-8} M ascorbic acid, *filled diamond* 10^{-5} M L-dopa+0.5×10^{-7} M ascorbic acid, open *triangle* 10^{-5} M L-dopa+10^{-7} M α-tocopherol, *filled triangle* 10^{-5} M L-dopa+0.5×10^{-6} M α-tocopherol. A one- way ANOVA was performed: ascorbic acid at 3 days ($F_{3, 8}$=28.47, P<0.001), ascorbic acid at 5 days ($F_{3, 8}$=117.07, P<0.001); α-tocopherol at 3 days ($F_{3, 32}$=35.37, P<0.001), α-tocopherol at 5 days ($F_{3, 32}$=36.60, P<0.001)

Table 2 Effect of antioxidants on the formation of lipid peroxide and melanin in root of lettuce treated with 10^{-5} M L-dopa

Treatment	TBARS (nmol/g F.W.)	Melanin (μmol/mg F.W.)
Control	1.35 (0.10)a	24.0 (0.88)a
Dopa	2.43 (0.20)b	26.4 (0.57)b
Dopa + ascorbic acid	2.06 (0.01)ab	21.4 (0.40)ab
Dopa + α-tocopherol	1.95 (0.06)ab	20.8 (0.16)a

Concentrations of ascorbic acid and α-tocopherol were 0.5×10^{-7} M and 0.5×10^{-6} M, respectively. Numbers in parentheses are the ±SE of the mean (N=3). A one-way ANOVA was performed: TBARS ($F_{4,\ 10}$=137.57, P< 0.001), melanin ($F_{4,\ 10}$=49.37, P<0.001). Means followed different letters differ significantly at P=0.05

The amount of lipid peroxide in L-dopa-treated root of barnyardgrass and lettuce was determined (Fig. 1). The increase of TBARS induced by L-dopa was remarkable in lettuce, reaching 3.8-fold of non-treated control, but little increase was detected in barnyardgrass throughout the exposure period. Regression analysis showed that the content of lipid peroxide in plant roots correlated with the degree of growth inhibition (r^2=0.67, $F_{1,\ 10}$=20.4, P<0.05; data not shown).

Treatment with 10^{-4} M L-dopa for 5 days resulted in greater melanin content, 104 and 270% of non-treated controls in barnyardgrass and lettuce, respectively (data not shown). The amount of melanin accumulated in lettuce root correlated with the growth inhibitory activity of L-dopa (Fig. 2).

The antioxidants ascorbic acid and α-tocopherol reduced the growth inhibition of lettuce roots caused by L-dopa (Fig. 3). Ascorbic acid was more effective than α-tocopherol in suppressing phytotoxicity. Root lengths of lettuce seedlings were rescued up to 80% of the untreated controls when 0.5×10^{-7} M ascorbic acid was included with 10^{-5} M L-dopa. Moreover, melanin accumulation and lipid peroxide formation returned to the same levels as the control in the antioxidant-treated lettuce (Table 2). Catalase and superoxide dismutase (SOD) were not as effective as ascorbic acid or α-tocopherol (data not shown).

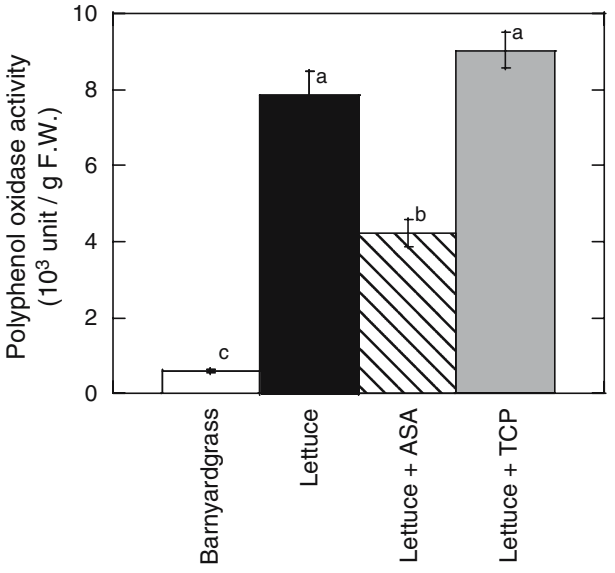

Fig. 4 Activity of polyphenol oxidase in roots of barnyardgrass and lettuce, and the effects of antioxidants on the enzyme activity of lettuce. Concentrations of ascorbic acid (*ASA*) and α-tocopherol (*TCP*) were 0.5×10^{-7} M and 0.5×10^{-6} M, respectively. *Bars* indicate±SE of the mean (N=3). A one- way ANOVA was performed ($F_{3,\ 8}$= 79.64, P<0.001). *Bars* labeled with *different letters* are significantly different (P=0.05)

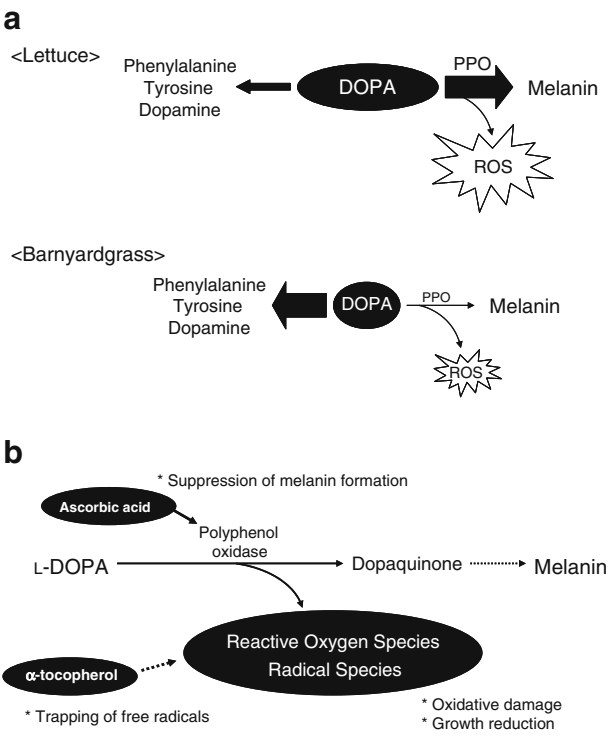

Fig. 5 Proposed mechanism of phytotoxic action (**a**) and selectivity (**b**) of L-dopa

A significant difference in oxidation of L-dopa by PPO between barnyardgrass and lettuce was detected in the roots, with the activity being much greater in lettuce (Fig. 4). The antioxidant effect on PPO activity differed; ascorbic acid suppressed PPO activity in lettuce root extracts but α-tocopherol did not.

Discussion

ROS/FRS cause oxidative damage to membrane lipids and, probably, result in growth inhibition or cell death. Previous work on L-dopa action revealed ROS/FRS involvement in its toxicity on cultured animal cells (Graham 1978; Basma et al. 1995; Lai and Yu 1997; Haque et al. 2003). ROS/FRS are also involved in the phytotoxic action of L-dopa in carrot cells (Hachinohe and Matsumoto 2005). The greater increase of lipid peroxide detected in the roots of lettuce compared to barnyardgrass suggests that the amount of ROS/FRS generated by L-dopa is greater in lettuce, and that the species-selective phytotoxicity of L-dopa between barnyardgrass and lettuce may be attributed to the difference in ROS/FRS generation.

L-Dopa is metabolized to catecholamine, phenylpropanoids, and melanin in plant cells (Pattison et al. 2002). Metabolism to nontoxic amino acids such as phenylalanine or tyrosine is considered to be the detoxification pathway (Nakajima et al. 1999). We previously reported that L-dopa metabolism to phenylalanine or tyrosine is higher in barnyardgrass than in lettuce (Hachinohe et al. 2004). The greater melanin accumulation observed in the roots of lettuce indicates that there is a difference in the activity of L-dopa metabolism in the two species. This difference might account for the species-selective

phytotoxicity. Regression analysis showed that the amount of accumulated melanin correlated with the L-dopa growth inhibitory effect, and melanin synthesis is considered to play a role in L-dopa phytotoxicity.

There are several reports that indicate that the cytotoxicity of L-dopa is reduced by catalase, SOD, ascorbic acid, and α-tocopherol (Parson 1985; Basma et al. 1995; Haque et al. 2003). Ascorbic acid or α-tocopherol both restored the growth of carrot cells treated with L-dopa (Hachinohe and Matsumoto 2005). In this study, ascorbic acid and α-tocopherol also reduced L-dopa phytotoxicity and prevented the formation of melanin and lipid peroxides in the susceptible lettuce species. From the results, we presume that the phytotoxic mechanism of L-dopa on lettuce is a result of oxidative damage by ROS/FRS generated from the conversion to melanin (melanin synthesis pathway). Excess ascorbic acid, however, caused stronger growth suppression and accelerated the formation of lipid peroxide (data not shown). This adverse effect could be caused by the formation of ascorbate radicals that function as oxidants. Antioxidative enzymes, catalase and SOD, did not reduce phytotoxicity, possibly because these macromolecules may not have been taken up through the cell membranes (Buckley et al. 1987; Beckman et al. 1988).

PPO, a copper protein widely distributed in the terrestrial plant species (Sherman et al. 1991), is a key enzyme that regulates the melanin synthesis pathway because it catalyzes a reaction converting L-dopa to dopaquinone (Pattison et al. 2002). Our study showed that PPO activity was significantly higher in lettuce than in barnyardgrass, suggesting that the melanin synthesis pathway is more active, with greater amounts of ROS/FRS and melanin generated. Thus, the difference in PPO activity between the two species is likely to be one of the factors conferring the species-selective phytotoxicity. The antioxidants, ascorbic acid and α-tocopherol, had different effects on lettuce PPO activity. Ascorbic acid may inhibit the melanin synthesis pathway through direct suppression of PPO activity, leading to the reduction of ROS/FRS formation and phytotoxicity. α-Tocopherol, in contrast, is thought to scavenge the ROS/FRS directly, so that while oxidative damage of L-dopa decreased, it caused little effect on PPO activity.

We propose a general mechanism for the phytotoxicity of L-dopa in plant roots, as well as an explanation for its selectivity (Fig. 5). Phytotoxicity of L-dopa in plant roots is due to oxidative damage caused by ROS/FRS generated from the melanin synthesis pathway. The mechanism of species-selective phytotoxicity is likely because of differential PPO activity (Fig. 5a). Furthermore, the mechanism for the alleviation of phytotoxicity might be different between ascorbic acid and α-tocopherol (Fig. 5b).

Introduction

Males of most moth species locate mates by following a plume of sex pheromone upwind to a calling female. In wind tunnel studies, the structure of the pheromone plume is important in mediating how the responding insect orients during upwind flight to the pheromone source (Mafra-Neto and Cardé 1994, 1995; Vickers and Baker 1994). In the field, pheromone is carried downwind in turbulent eddies, which range in size from centimeters to several meters (Murlis and Jones 1981; Murlis et al. 1992). Most male moths that orient to a pheromone source in a wind tunnel require an intermittent chemical signal that mimics turbulent odor plumes in nature to orient and fly upwind (Kennedy et al. 1980; Willis and Baker 1983; Baker et al. 1985). A combination of self-steered counterturning and odor-triggered upwind optomotor anemotaxis, which is induced by the plume structure, is thought to control a moth's upwind trajectory to the pheromone source (Mafra-Neto and Cardé 1994). The integration of these two mechanisms is modulated "moment-to-moment" by the interception of individual odor pulses comprising the fine-scale structure of turbulent plumes (Mafra-Neto and Cardé 1994, 1995, 1996; Vickers and Baker 1994). Male almond moths, *Cadra cautella*, fly faster and straighter to more turbulent odor plumes than to continuous narrow "ribbon" plumes and also locate the sources of turbulent plumes more frequently than they do ribbon plumes (Mafra-Neto and Cardé 1994). However, males of *C. cautella* are also capable of orienting upwind in a homogeneous cloud of pheromone (Justus and Cardé 2002).

Until recently, the release of chemical stimuli in wind tunnel experiments on insect flight behavior relied mainly on the passive evaporation of volatile chemicals from a lure, usually made from a filter paper or rubber septum. Although the dose applied to these lures is specified, the rate of release is influenced by many factors such as vapor pressure, chemical affinity to the substrate used, the kind and amount of solvent used in application, temperature, airflow over the dispenser, and time. It can be difficult or impossible at very low doses to establish the ratio and emission rates of chemicals released from such traditional lures.

A piezo-electric sprayer system has been developed as a solution to many of the problems associated with traditional lures. The piezo-sprayer system allows the precise release of chemical stimuli as an aerosol (El-Sayed et al. 1999b). The system consists of a drawn glass capillary tip, with an opening of 10–50 μm i.d., which is vibrated at ultrasonic frequency (~120 or ~300 kHz) by a piezo-ceramic disk (El-Sayed et al. 1999b; Skals et al. 2003). This disperses the solution in micro-droplets, producing an aerosol, which evaporates completely within 5 cm of the tip. This system provides benefits over passive release systems because by controlling the exact composition of the pheromone solution used, the release rate of each component within the solution can be defined.

The plume structure generated by these piezo-electric sprayer systems has not previously been documented, and little is known about how the plume structure from such systems is likely to affect flight orientation behavior of insects that orient to the odor plume. The physical configuration of the piezo-sprayer is likely to have large and varied effects on plume structure. To our knowledge, there have been 16 published studies that have used this piezo-sprayer system, 14 laboratory studies (El-Sayed et al. 1999a, b, 2001; El-Sayed 2004; Pettersson et al. 2001; Plepys et al. 2002; Coracini et al. 2003; Skals et al. 2003; Svensson et al. 2004; Trimble et al. 2004; Olsson et al. 2005a, b; Tasin et al. 2006a, b) and two field studies (El-Sayed and Byers 2000; El-Sayed and Trimble 2002). Both field studies gave a clear description of the physical configuration of the piezo-sprayer. Of the 14 laboratory studies, five provided descriptions of the physical configuration of the piezo-

sprayer (El-Sayed et al. 1999b, 2001; Pettersson et al. 2001; Plepys et al. 2002; Skals et al. 2003), and the remaining studies cited previous papers, but provided no indication as to whether the piezo-sprayer configuration was the same as in the papers cited. Four of the papers describe housing the piezo-sprayer inside a cylinder and that uses a distal screen/mesh over the downwind end of the cylinder (El-Sayed et al. 1999b, 2001; Plepys et al. 2002; Skals et al. 2003), but only two of these give measurements of the cylinder diameter and length (El-Sayed et al. 1999b, 2001). None describe the size or shape of the openings in the mesh or their density. All of these factors are likely to affect the plume structure of the odor plume released by the piezo-sprayer, which, in turn, could have effects on orientation of insects flying to the source.

In this study, we used a fast response miniature photoionization (miniPID) detector to perform detailed analyses of the fine-scale structure of a plume generated by a piezo-electric sprayer set up in one of four different physical configurations of the piezo-sprayer in a wind tunnel. Furthermore, we investigated the upwind flight behavior of male *C. cautella* to female sex pheromone released at different concentrations from two different physical configurations of the piezo-sprayer.

Methods and Materials

Wind Tunnel The wind tunnel used was typical of many used to study insect orientation to odors and is described by Justus et al. (2002a). Briefly, it was constructed from 3-mm-thick clear polyacrylic Lexan® bent into an arch-shape and connected to a 1-m-wide frame to create a symmetrical semi-cylinder 3 m in length with a center height of 1 m. The floor was constructed from 10-mm-thick clear Plexiglas® sheets. The wind speed was set to 50 cm/s by regulating two variable output fans, one on the input and one on the exhaust. Air was exhausted out of the building from a semicircular-shaped portion of the tunnel, with a straight base, straight sides, and an arched top, measuring 60 cm wide at the base by 60 cm high at the center of the arch and 30 cm high at the sides before the arch curved, which was located in the center at the base of the tunnel. The remaining air was recirculated into the room. $TiCl_4$ smoke was used to visualize the plume from the piezo-sprayer to ensure a large enough area of the tunnel was exhausted so that all of the pheromone-contaminated air was removed from the room. A 150-mm-thick aluminum honeycomb (Hexcel®, 15-mm diameter cells) was used downwind of the upwind fan to reduce turbulence in the tunnel. On one side of the tunnel, there were two oblong openings, 270 mm from the upwind and downwind ends, to allow access. Openings were covered with clear polyvinyl sheets so that airflow was not disturbed during recordings. The tunnel was housed in a room with a controlled environment of 26–28°C and 50–80% R.H.

Sprayer for Release of Ethanol and Pheromone A piezo-electric sprayer system, described by El-Sayed et al. (1999b), was used to produce an aerosol from both pure ethanol for plume detection and analysis experiments and synthetic pheromone diluted in ethanol for moth flight bioassays. The system consisted of a drawn glass capillary tip, with an opening of 10–50 μm i.d., which was vibrated at ultrasonic frequency by a piezo-ceramic disk. This created an aerosol that evaporated completely within 5 cm downwind of the tip. A disk producing a frequency of about 120 kHz was used for recordings of plume structure. A motor-driven syringe pump (CMA/Microdialysis, Carnegie Medicine AB, Stockholm, Sweden) was used to deliver the odorant solution via 0.12-mm i.d. tubing to the capillary tip at a rate of 10 μl/min. This allowed precise known release rates and ratios to be calculated.

In trial behavioral experiments, moths responded negatively (usually by failing to orient along the plume) to the frequency of sounds emanating from this 120-kHz piezo-ceramic disk. Pyralid moths are sensitive to ultrasound within this frequency range, and some species produce and respond to ultrasound within this frequency range during mate orientation and courtship (e.g., Spangler et al. 1984; Trematerra and Pavan 1995). Therefore, a modification to the piezo-sprayer, described by Skals et al. (2003), was used for behavioral experiments. The modified system used a smaller, thicker piezo-ceramic disk, which produced a frequency of about 300 kHz, beyond the hearing range for pyralids (see Connor 1999 for review). Trials indicated that the plume structure did not vary between the two types of piezo disk. We confirmed that the 300-kHz piezo-ceramic disk did not produce ultrasound within the hearing range of moths, using an UltraSoundGate 116 USB hard disk recording system, in combination with an externally polarized Ultra-SoundGate CM16 condenser microphone with a CMPA preamplifier module (Avisoft Bioacoustics, Berlin, Germany), which has a frequency range of 10–180 kHz.

For experiments of plume structure analysis, four different piezo-sprayer configurations were used: (1) sprayer alone; (2) sprayer encased in the center of an 80-mm diameter by 120-mm-long cylinder made of 1-mm-thick polyethylene, with the capillary tip positioned 50 mm from the downwind end of the cylinder, and the downwind end covered by either (a) a 1.6-mm steel mesh, or (b) a 3.2-mm steel mesh, or (c) a 5-cm circular baffle, 70 mm upwind of the sprayer tip. For all configurations, the sprayer was mounted on a stand consisting of a square Plexiglas® base plate, 60×60×4 mm, which had a hole (6.4-mm diameter) drilled in the center of the square. A Teflon® tube, 80 mm in length by 6.4 mm in diameter was inserted into the hole in the base plate, and an 83-mm-high black plastic holder, to mount the capillary tip and the piezo disk, was inserted into the top end of the Teflon® tube. This resulted in the capillary tip being mounted 167 mm above the tunnel floor.

Measurement of Air Velocity around the Piezo-Sprayer Air velocity was measured around the four different piezo-electric sprayer configurations with a Barnant Tri-Sense anemometer (Barrington, IL, USA), at the following locations in relation to the piezo disk: (1) 10 cm upwind; (2) 3.5 cm upwind; 3) 10 cm downwind; (4) 5 cm lateral; (5) 10 cm lateral; (6) 5 cm above; and (7) 10 cm above.

Plume Detection and Analysis The plume structures produced by the four piezo-sprayer configurations were measured with a fast-response photoionization detector (miniPID; Aurora Scientific, Aurora, Ontario, Canada) with a frequency response rate of 330 Hz and a detection threshold of 100 ppb propylene. This miniPID sensor is sensitive to any substance with an ionization potential equal to or below approximately 10.6 eV. Ethanol was used to form the aerosol released from the piezo-sprayer (ionization potential 10.6 eV), and it was also the solvent used to dilute the pheromone in behavioral experiments. Hexane, a more commonly used solvent for dilution of pheromones, was not detectable by the miniPID. In addition, in previous experiments with the piezo-sprayer (P. Witzgall, personal communication) and also in behavioral trials for these experiments, hexane inhibited moth orientation upwind.

The sensor was mounted on a computer-controlled traverse, as used in Justus et al. (2002a), with movement in the longitudinal (x), horizontal (y), and vertical (z) axes. This allowed the miniPID to be placed within the wind tunnel with a precision of 0.25 mm. The sampling rate of the miniPID was set at 1,250 cm^3 min^{-1} through an inlet needle with a 0.076-cm internal diameter. The miniPID controller has three gain settings (1, 5, and 25) and a potentiometer for adjusting the baseline signal level. Noise measured from the probe

running in the tunnel without the piezo-electric sprayer was less than 1 mV rms at the lowest gain setting.

For all piezo-sprayer configurations, measurements of plume structure were taken at 100, 200, and 400 mm from the tip of the vibrating glass capillary. This region near the source is of particular importance because it is within this range that a moth appears to alter its flight behavior as it approaches the odor source (Murlis and Bettany 1977; Murlis et al. 1982; Willis and Baker 1994). The output signal from the sensor was recorded for durations of 15 sec at 3-mm intervals, for a 12×12-mm square at the core of the plume, for a total of 25 recordings, which were then averaged to give mean values for the plume core. The center point of the 12×12-mm square was directly in line with the capillary tip of the piezo-sprayer. Additionally, recordings of 15-sec duration were made every 3 mm along the vertical and horizontal axes within the cross-section of the plumes. A duration of 15 sec is standard for these kinds of experiments (Justus et al. 2002a). Blank recordings, where the piezo-sprayer was turned off, were recorded approximately every 20 recordings, to acquire a baseline. The analog voltage signals from the miniPID were digitized and logged on a computer by using a GemAcq-4data acquisition system (Gemini Enterprises, UK). The sampling frequency was set at 100 Hz (this is sufficiently high to resolve structure perceived by a moth's central nervous system, which has been recorded to have a maximum frequency response of the order of 10 Hz (Christensen and Hildebrand 1988; Vickers et al. 2001), and the full voltage span of 5 V was digitized at 12-bit resolution. Data are presented as voltages to give a relative measure of concentration, which is comparable between recordings. In subsequent statistical analyses (see below), a discrimination threshold of 0.014 mV rms (approximately four times the root mean square noise determined by inspection of recordings) was used to reject noise.

Statistical Analyses of Plume Structure Statistics were calculated by averaging the 25 recordings made within each 12×12-mm core along each plume's axis at the three distances downwind. The characteristics measured for each 15-sec sample of the sensor signal were as follows: (1) relative conditional mean concentration (conditional averages are those formed from ensembles of data taken when signal is present, for example, see Mylne and Mason 1991); (2) intermittency (defined here as the probability of zero signal, $1-\gamma$, the proportion of time for which concentration was below the noise threshold, following the convention of Murlis and Jones (1981) and Jones (1983); and (3) peak-to-conditional-mean ratio (the ratio of the highest registered value in a sample to the overall conditional mean of the sample; this eliminates the influence of intermittency on the conditional mean). Each of these parameters was tested for normality using a Ryan–Joiner test, and none was found to be normally distributed. As a result, all parameters were log-transformed and tested again to confirm they were normally distributed. Analyses of variance (ANOVAs) were run on these log-transformed parameters for both within plumes at various distances from the source and among plume types. All statistical tests were performed using Minitab v.14. For measures of intermittency, both horizontally and vertically through the plume, trend lines were fitted using a four-parameter sigmoidal curve.

Insects Cadra cautella were reared on a diet of poultry laying mash, rolled oats, brewer's yeast, and glycerin (Mafra-Neto and Cardé 1995). Insects were reared at about 27°C, with a 16L:8D light regime and 50–60% R.H. Last instar larvae were sexed, and males were isolated in plastic cups (163 ml), filled one third full of the above diet, until eclosion. Eclosed males were transferred once daily to 30×30×30-cm plastic screened cages. All individuals used in experiments were between 2- and 4-d-old.

Moth Flights to Sprayer Male *C. cautella* were flown to two of the different piezo-sprayer configurations, the sprayer alone and the sprayer with an upwind baffle. These two configurations were chosen because the sprayer alone was the simplest configuration and because in plume structure analysis, the upwind baffle showed the greatest variation from the sprayer alone in a number of the variables recorded. Synthetic pheromone in the natural 13:1 ratio (Allison and Cardé 2006) of the two major components, (9*Z*,12*E*)-tetradecadienyl acetate (Z9E12-14:Ac) and (*Z*)-9-tetradecenyl acetate (Z9-14:Ac), was formulated in ethanol to produce four concentrations of pheromone, which, when released by the piezo-sprayer at 10 μl/min resulted in release rates of 1, 10, 100, or 1,000 pg/min of Z9E12-14:Ac. On a single day, ten moths were flown to each of the four different release rates, for one of the piezo-sprayer configurations, and this was repeated over 4 d, giving a total of 40 moths being flown to each pheromone concentration for each piezo-sprayer configuration. The same experiment was then repeated over another 4 d for the other piezo-sprayer configuration. It was not possible to conduct experiments for the two different configurations on the same day with the same cohort of moths, because of technical and temporal problems associated with switching between configurations, which is especially complicated when using the approximately 300-kHz piezo system because it is extremely sensitive and time-consuming to set up within the moths 2-hr flight period. The order of release rates being tested on each day was decided by using a Latin square design.

All experiments were conducted in the first 2 hr of the scotophase. A male *C. cautella* was chosen at random and held in a small wire cage with one open face kept covered in the odor plume at the downwind end of the tunnel. When the male initiated wing fanning, the open face was uncovered, and the male was allowed to fly upwind. For each male flown, the following behaviors were recorded: (1) activation (wing fanning and walking in the wire cage); (2) taking flight; 3) upwind flight; (4) oriented flight (upwind flight to within 30 cm of the piezo-sprayer); and (5) landing at the source. The landing substrate was larger for the upwind baffle configuration, given that it included the 5 cm circular baffle upwind of the source. Additionally, the time taken from takeoff to reach the source for successful flights was recorded. In experiments with the upwind baffle configuration, the baffle was changed between each change of pheromone concentration.

The tunnel floor was covered with white fabric, and 5.4-cm-diameter red dots were randomly distributed but evenly spaced at 30 circles per square meter to provide non-directional visual cues. All experiments were conducted at about 26°C. Two lateral banks of 25 W, clear red lights (Philips Colortone®) on each side of the room illuminated the ceiling and provided a diffuse light of 7–10 lx in the wind tunnel. Two Sanyo VCB-3512T monochrome CCD cameras (shutter speed 1/100 sec) were mounted around the wind tunnel; one at the side (with a 75-mm lens) and one above the wind tunnel (with a 4.8-mm lens), to record the moths' flight and behavioral responses.

For both configurations tested, responses within each of the behavioral parameters to each of the four pheromone concentrations for each of the 4 d of testing were first subjected to a heterogeneity *G* test. If not significant, they were then pooled and compared using a series of pooled *G* tests for goodness of fit (Sokal and Rohlf 1995). The time taken to reach the source was tested for normality using a pair of Shapiro–Wilk tests for the two piezo-sprayer configurations and then compared with a pair of ANOVAs. Statistical tests were performed using SPSS v. 15. It was not appropriate to make statistical comparisons of moth behavior between the two piezo-sprayer configurations because tests of different configurations could not be performed on the same day with the same cohort of moths.

Results

Air Velocity around Piezo-Sprayer The presence of the sprayer alone in the wind tunnel reduced the 50 cm/sec air velocity in the wind tunnel (Table 1). Relative to the measurements made around the sprayer alone, air velocities around the other piezo-sprayer configurations were higher at 10 cm upwind and at both 5 and 10 cm both laterally and dorsally of the piezo disk, but were lower at 3.5 cm upwind of the piezo disk and 10 cm downwind of the piezo disk. Furthermore, from observing the data, air velocities appeared to be reduced more for the upwind baffle configuration at 3.5 cm upwind and 10 cm downwind, and air velocity also appeared to increase more for the upwind baffle at 5 cm dorsally than for the two mesh configurations.

Plume Structures of the Different Piezo-Sprayer Configurations Representative traces of typical relative ethanol concentrations over a 15-sec period at the core of the plume are shown in Figs. 1, 2, 3, 4. There was discernible variation among the different piezo-sprayer configuration in both the amplitude and periodicity of the signals. In general, concentrations declined as the distance from the piezo-sprayer increased; however, for the coarse mesh sprayer configuration, the concentration of the signal at 200 mm from the source was greater than at 100 mm before decreasing again by 400 mm from the source (Fig. 3). The relative ethanol concentrations decreased at different rates with different configurations likely because of variations in the plume size from each configuration as the plume was carried downwind.

In measurements of the 12×12-mm plume core, the conditional mean concentrations varied between piezo-sprayer configurations at 100 mm (ANOVA, $F_{3,91}=315$, $P<0.001$), 200 mm (ANOVA, $F_{3,96}=178$, $P<0.001$), and 400 mm (ANOVA, $F_{3,96}=520$, $P<0.001$) downwind from the source. Furthermore, conditional mean concentrations also varied among the different distances downwind of the source for each of the individual piezo-sprayer configurations: sprayer alone (ANOVA, $F_{2,72}=37.8$, $P<0.001$); fine mesh (ANOVA, $F_{2,72}=358$, $P<0.001$); coarse mesh (ANOVA, $F_{2,67}=9.04$, $P<0.001$); and upwind baffle (ANOVA, $F_{2,72}=654$, $P<0.001$; Fig. 5a).

Table 1 Air velocity recordings measured using an anemometer, around a piezo-electric sprayer alone in a wind tunnel, and air velocity measurements from around three other piezo-sprayer configurations, relative to the air velocities recorded when the sprayer alone was in the tunnel

Distance from Piezo-Electric Sprayer	Piezo-Electric Sprayer Configurations			
	Sprayer Alone	Cylinder and Fine Mesh	Cylinder and Coarse Mesh	Upwind Baffle
	Air Velocity (cm/sec)	Air Velocity Relative to the Velocities Measured for the Sprayer Alone (cm/sec)		
10 cm upwind	49	+6	+5	+7
3.5 cm upwind	42	−9	−3	−29
10 cm downwind	40	−13	−7	−26
5 cm lateral	40	+13	+10	+14
10 cm lateral	40	+12	+10	+11
5 cm dorsal	42	0	+4	+9
10 cm dorsal	42	+3	+3	+4

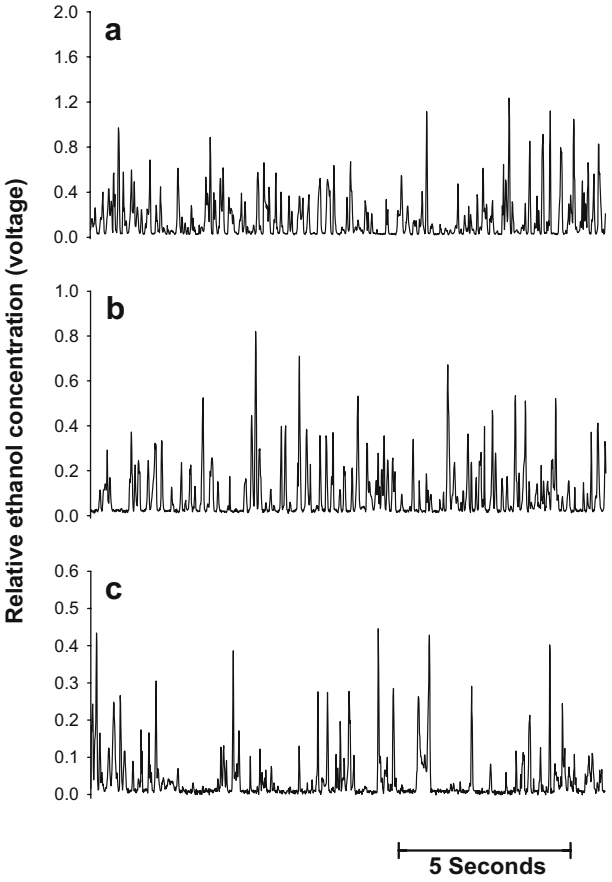

Fig. 1 Representative traces of ethanol concentration at the center of the plume of the piezo-electric sprayer alone, collected using a photoionization detector at three distances downwind of the plume source of the piezo-electric sprayer, in a wind-tunnel: **a** 100 mm; **b** 200 mm; and **c** 400 mm. Each trace represents 15 sec

The fine mesh configuration had significantly higher conditional means than all other piezo-sprayer configurations at both 100 and 200 mm downwind of the plume source (Fig. 5a). These differences in conditional means may be explained by the fact that the fine mesh configuration greatly reduced the air velocity through the cylinder, but increased the airflow around the edges of the cylinder (Table 1), suggesting a pocket of slower moving air in the downwind wake where ethanol concentrations could have built up. This would also explain the fact that at 400 mm downwind, the conditional mean concentrations in the air, which had more time for mixing, were closer to the conditional means of the other piezo-sprayer configurations. The upwind baffle produced similar air velocity changes to the fine mesh (Table 1), but the conditional mean concentrations for these two piezo-sprayer configurations were dissimilar (Fig. 5a). This may be because the diameter of the upwind baffle (50 mm) was smaller than that of the mesh covered cylinder (80 mm) and the baffle was further away from the miniPID detector than the mesh of the cylinder. Therefore, at all measurement points downwind of the source, there was a greater distance for mixing of the air plume behind the upwind baffle configuration than behind the fine mesh configuration.

The coarse mesh configuration had a lower conditional mean concentration at 100 mm from the plume source than at 200 mm. The 25 individual measurements made at 100 mm, of the 12×12-mm plume core, showed that the measurements in the dorsal region of the

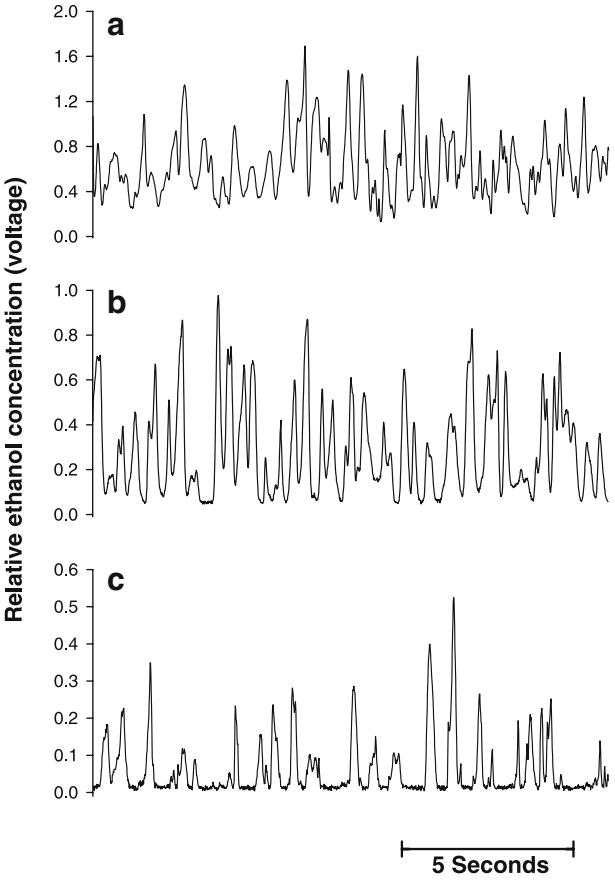

Fig. 2 Representative traces of ethanol concentration at the center of the plume of the fine mesh piezo-electric sprayer configuration, collected using a photoionization detector at three distances downwind of the plume source of the piezo-electric sprayer, in a wind-tunnel: **a** 100 mm; **b** 200 mm; and **c** 400 mm. Each trace represents 15 sec

plume were higher than the measurements in the ventral region of the plume, suggesting that at this distance, the speed of the plume core decreased for this configuration likely because of differences in the air flow around this configuration, which did not occur for the other configurations. Furthermore, lateral and vertical dissections of the plumes showed that the plume for the coarse mesh was narrowest (Fig. 6c and g), and, therefore, the measurements made of this plume were most likely to miss the plume core.

Intermittency at the plume core varied among piezo-sprayer configurations at 100 mm (ANOVA, $F_{3,96}=57.0$ $P<0.001$), 200 mm (ANOVA, $F_{3,96}=38.2$, $P<0.001$), and 400 mm (ANOVA, $F_{3,96}=36.3$, $P<0.001$) downwind from the source. Furthermore, intermittency values also varied among the different distances downwind of the source for each of the individual piezo-sprayer configurations: sprayer alone (ANOVA, $F_{2,72}=110$, $P<0.001$); fine mesh (ANOVA, $F_{2,72}=5040$, $P<0.001$); coarse mesh (ANOVA, $F_{2,72}=3.13$, $P=0.05$); and upwind baffle (ANOVA, $F_{2,72}=265$, $P<0.001$; Fig. 5b). Generally, intermittency values increased with distance from the source for all configurations (Figs. 1, 2, 3, 4), and, therefore, the closer to the source the measurements were made, the less intermittent the plume was. The exception was the coarse mesh configuration where intermittency decreased with distance from the piezo-sprayer. This may be because of the plume dropping and being narrowest for the coarse mesh configuration.

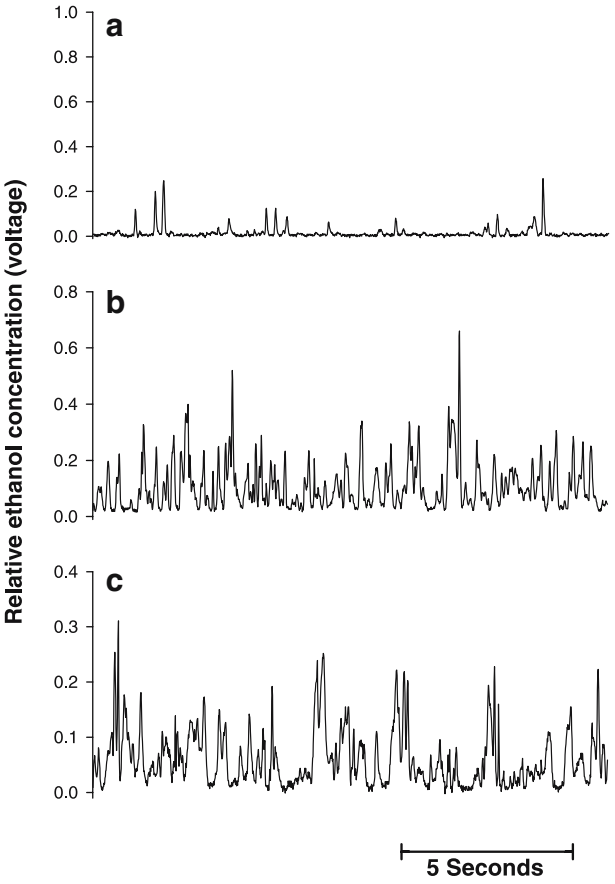

Fig. 3 Representative traces of ethanol concentration at the center of the plume of the coarse mesh piezo-electric sprayer configuration, collected using a photoionization detector at three distances downwind of the plume source of the piezo-electric sprayer, in a wind-tunnel: **a** 100 mm; **b** 200 mm; and **c** 400 mm. Each trace represents 15 sec

Intermittency values at both 100 and 400 mm from the source, for all configurations, from the cores of the plumes to their edges showed a general trend, with intermittency values being low at the plume center and increasing with increasing distance, i.e., the probability of a zero signal increased with distance from the plume center (Fig. 6). Additionally, the width and height of plumes varied greatly between configurations (Fig. 6). In general, at both 100 and 400 mm from the source, the coarse mesh resulted in the narrowest plume (Fig. 6c and g), and the upwind baffle resulted in the broadest plume (Fig. 6d and h).

The ratio of peak to conditional mean concentration gives a measure of signal fluctuation; a larger ratio indicates a greater contrast between the peak amplitude and the conditional mean. The ratio of peak to conditional mean concentration at the plume core varied among piezo-sprayer configurations at 100 mm (ANOVA, $F_{3,89}=57.6$, $P<0.001$), 200 mm (ANOVA, $F_{3,96}=55.6$, $P<0.001$), and 400 mm (ANOVA, $F_{3,96}=55.5$, $P<0.001$) downwind from the source. Furthermore, the ratio of peak to conditional mean concentrations also varied among the different distances downwind of the source for each of the individual configurations: sprayer alone (ANOVA, $F_{2,72}=49.0$, $P<0.001$); fine mesh (ANOVA, $F_{2,72}=43.0$, $P<0.001$); coarse mesh (ANOVA, $F_{2,65}=4.86$, $P=0.011$); and upwind baffle (ANOVA, $F_{2,72}=15.30$, $P<0.001$; Fig. 5c). These data indicate that for the

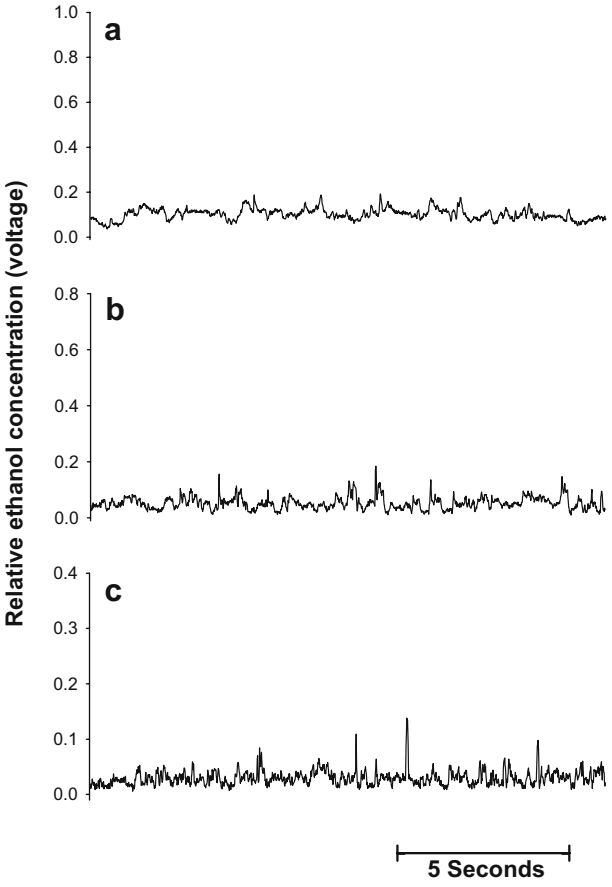

Fig. 4 Representative traces of ethanol concentration at the center of the plume of the upwind baffle piezo-electric sprayer configuration, collected using a photoionization detector at 3 distances downwind of the plume source of the piezo-electric sprayer, in a wind-tunnel: **a** 100 mm; **b** 200 mm; and **c** 400 mm. Each trace represents 15 sec

sprayer alone, coarse mesh, and upwind baffle configurations, signal fluctuation decreased with distance from the source; however, for the fine mesh, the reverse was true. In general, the sprayer alone produced the most fluctuating stimulus intensity in the plume and the upwind baffle the least.

Moth Flights In experiments with both the sprayer alone and with an upwind baffle, high levels of early stage behavioral responses were observed, with nearly all moths tested activating and initiating flight and a large proportion flying upwind along the odor plume (Fig. 7). In the experiments with the sprayer alone configuration, there were no significant differences in the numbers of individuals performing activation, flight, or upwind flight among the different pheromone release rates. However, there were differences in the number of individuals completing oriented flight between the 100 pg/min and 1,000 pg/min release rates (G_1=7.95, P<0.01) and in the number of individuals landing between the 100 pg/min and 1,000 pg/min release rates (G_1=5.82, P<0.05; Fig. 7a). With the 100 pg/min pheromone release rate, more males performed oriented flight and landing than for any of the other release rates. In comparisons between the mean times from takeoff to landing of moths, there were no differences among pheromone release rates (Table 2).

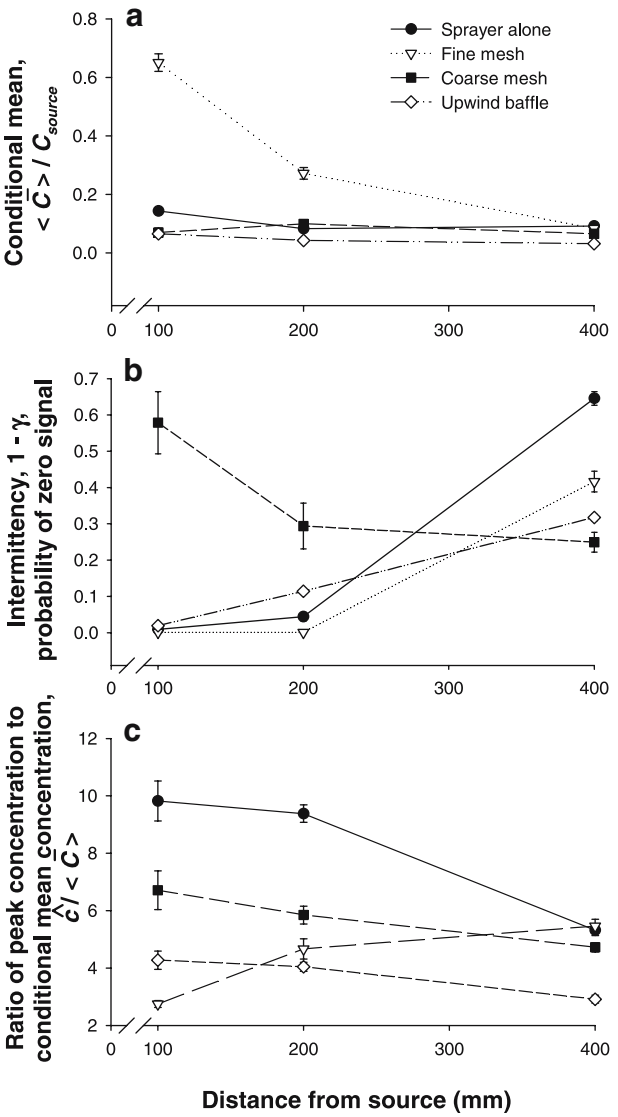

Fig. 5 Mean recordings collected using a photoionization detector from the 12×12-mm core of plumes emitted from four piezoelectric sprayer configurations at three distances downwind from the plume source for: **a** conditional mean concentrations (±SE; N=25); **b** intermittency values, $1-\gamma$ (±SE; N=25); and **c** peak-to-conditional-mean ratios (±SE; N=25)

In experiments with the upwind baffle configuration, there were no differences in the numbers of individuals performing either activation, flight, or upwind flight between different pheromone release rates. However, there were differences in the number of individuals completing oriented flight between the 1 and 1,000 pg/min (G_1=9.66, P<0.01) and the 10 and 1,000 pg/min release rates (G_1=11.28, P<0.001). In addition, there were differences in the number of individuals landing between the 1 and 1000 pg/min (G_1=4.72, P<0.05), the 10 and 1,000 pg/min (G_1=7.95, P<0.01), and the 10 and 100 pg/min release rates (G_1=4.28, P<0.05; Fig. 7b). With the 10 pg/min pheromone release rate, more males performed upwind flight, oriented flight, and landing than for any of the other release rates. In comparisons between the mean times from takeoff to landing of moths, there were no differences between pheromone release rates (Table 2).

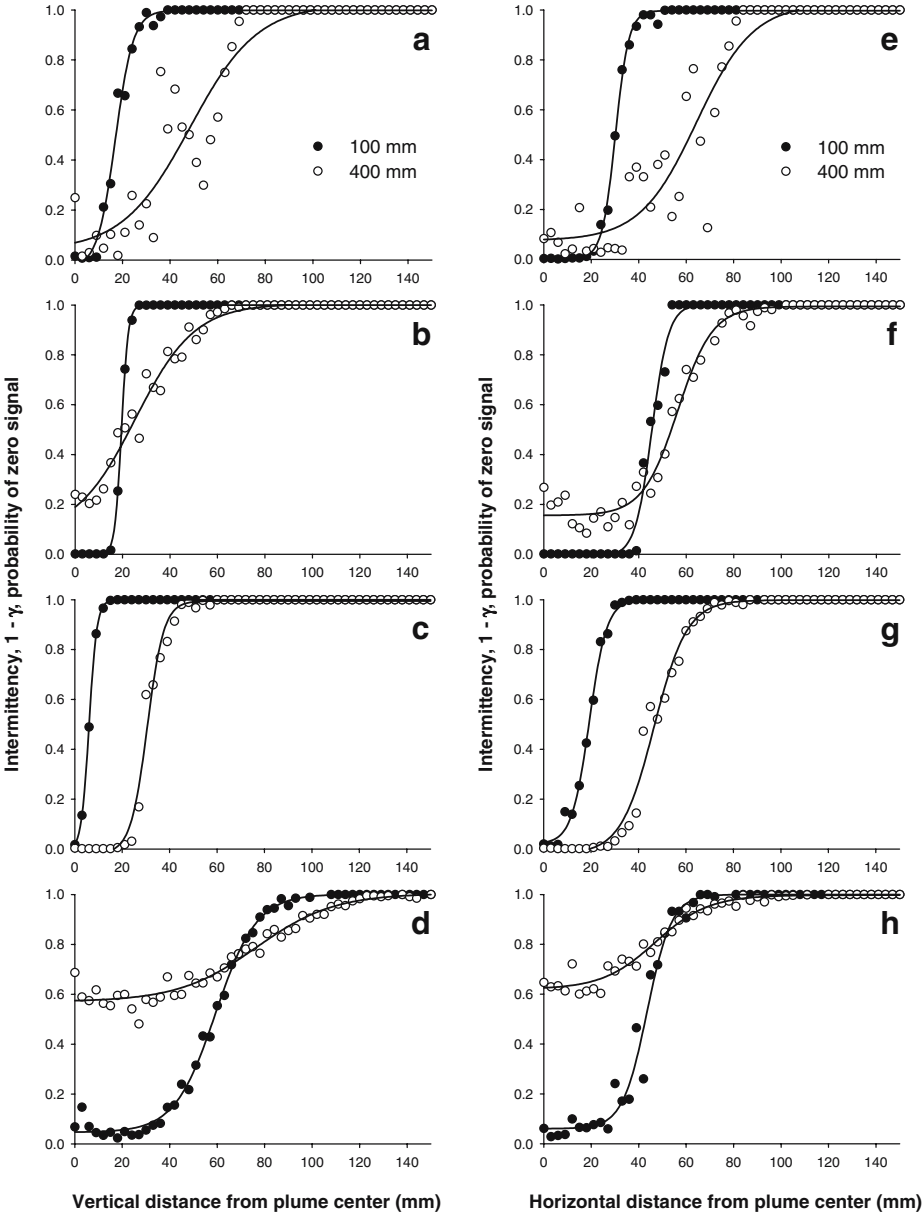

Fig. 6 Intermittency values, $1-\gamma$, recorded using a photoionization detector through four different plumes from the four piezo-electric sprayer configurations, measuring from each plume's axial center moving towards its edge, both vertically upwards through the plume: **a** sprayer alone; **b** fine mesh; **c** coarse mesh; and **d** upwind baffle, and laterally through the plume: **e** sprayer alone; **f** fine mesh; **g** coarse mesh; and **h** upwind baffle (N=25). All trend lines are fitted using a four-parameter sigmoidal curve

Tests for the two configurations could not be conducted on the same day with the same cohorts of moths because of the time taken to set up the apparatus. Therefore, it would not be valid to make statistical comparisons between moths tested with the two different piezo-sprayer configurations. Moreover, the visual cues presented by the two configurations may

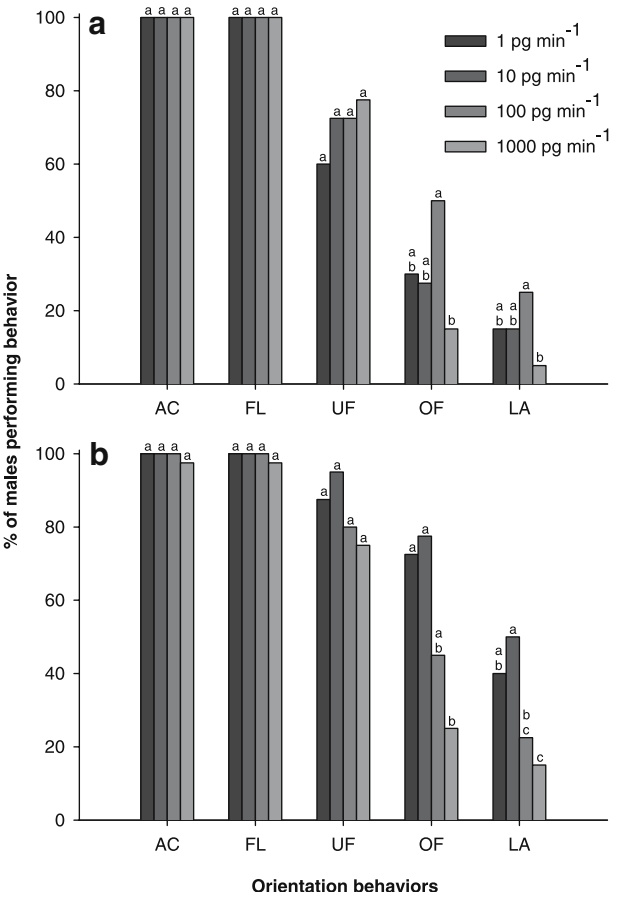

Fig. 7 Flight responses of *C. cautella* to four different release rates of a 13:1 blend of Z9E12-14:Ac and Z9-14:Ac diluted in ethanol from a piezo-electric sprayer system with either: **a** the sprayer alone (N=40) or **b** sprayer with an upwind baffle configuration (N=40). Orientation behaviors are as follows: *AC* Activation, *FL* flight, *UF* upwind flight, *OF* oriented flight, *LA* landing. For each configuration, differences between letters within a behavioral category represent a significant difference at $P<0.05$

have influenced later behaviors, especially propensity to land. Although it was not statistically valid to compare the results between the two sprayers, visual comparisons of the data were made to assess whether any discernable trends could be identified. These comparisons suggested differences among configurations in the level of response and attraction of moths, in close orientation and landing (Fig. 7), in the time taken to reach the source by moths, with moths flying more directly to the upwind baffle (Table 2), and in the level of behavioral responses by moths to the different pheromone release rates, with moths

Table 2 Mean time from takeoff of *Cadra cautella* moths to landing at the source, in seconds (±SE), for two different piezo-electric sprayer configurations, with four different release rates for each configuration

	Piezo-Sprayer Configuration							
	Sprayer Alone				With Upwind Baffle			
Pheromone release rate (pg/min)	1	10	100	1,000	1	10	100	1,000
Mean time from takeoff of moth to landing (sec±SE)	49.5±4.3	51.3±9.3	42.3±7.9	27.0±3.0	20.0±3.1	30.3±6.1	18.1±4.4	23.5±5.1

attracted more strongly to the upwind baffle configuration at lower pheromone concentrations (Fig. 7). The upwind baffle had a significantly lower conditional mean than the sprayer alone at all distances from the piezo-sprayer (Fig. 5a), a broader horizontal and vertical expanse than the sprayer alone (Fig. 6a,d,e, and h), and was significantly more intermittent in the core at 100 and 200 mm from the source, but significantly less intermittent at 400 mm from the source (Fig. 5b).

Discussion

Measurements of the plume structures generated by a piezo-sprayer indicated that the physical configuration of the experiment altered the plume's amplitude and periodicity. At each of the distances downwind from the source, significant differences were found in all of the plume variables among each of the four configurations. Furthermore, in comparisons between results for each of the three distances downwind from the source, separately for each of the different piezo-sprayer configurations, there were significant differences between each of the distances in every comparison made for each of the plume variables measured (Fig. 5), indicating that both configuration and distance from source had significant effects on plume structure. Justus et al. (2002a) demonstrated similar findings in wind tunnel studies in which they compared the effects of changing the configuration of an odor release system, which produced either a stream or a puff of odor from the tip of a glass pipette, resulting in significant changes to all aspects of the plume structure.

Furthermore, our results demonstrated that even minor changes to the configuration of the piezo-sprayer resulted in major changes to the resultant plume structure. For example, with the piezo-sprayer encased in an open-ended cylinder with a distal mesh over the downwind end of the cylinder, changing the distance between the wires in the distal mesh from 1.6 to 3.2 mm resulted in differences between all measures of plume structure (Figs. 2, 3, 5, and 6). This configuration of piezo-sprayer has commonly been used in behavioral experiments (El-Sayed et al. 1999b, 2001; Plepys et al. 2002; Skals et al. 2003); however, in those experiments, the distance between the wires, or any other measures of the structure of the mesh used, were not reported.

In the behavioral experiments, changing the release rate of pheromone had significant effects on the proportion of individuals performing both oriented flight and landing behaviors for both configurations tested (Fig. 7). These results were in agreement with previous studies, which demonstrated that the concentration of pheromone released modulated moth orientation behavior (e.g., Cardé and Hagaman 1979; Keunen and Baker 1982; El-Sayed et al. 1999b). In flight bioassays, more moths landed on the sprayer alone configuration when the pheromone release rate was set to 100 pg/min than to any of the other release rates, whereas for the upwind baffle configuration more moths landed when the release rate was set to 10 pg/min (Fig. 7). Similarly, El-Sayed et al. (1999b) demonstrated that 100 pg/min was the optimal release rate of the major pheromone component for attraction of the grapevine moth, *Lobesia botrana*, when using a piezo-sprayer operating at 120 kHz.

Differences in the fine structure of a pheromone plume have more influence on the flight pattern of *C. cautella* males than a 1,000-fold range in pheromone dose (Mafra-Neto and Cardé 1995). In the present tests, moths responded more strongly to different release rates from the two different sprayer configurations, suggesting that these differences may be caused by differences between the plumes from the different configurations. Furthermore,

from visual comparisons of the data, there appeared to be other differences in behavioral responses of moths between configurations (Fig. 7, Table 2). However, before any conclusions can be drawn about the effects that differences in plume structure can have on flight behavior, these bioassays must be confirmed with fully comparable experiments, where flights to both configurations are tested on the same day with the same cohort of moths, to eliminate any daily bias and any variation in moth response between days.

The levels of behavioral responses in this experiment, specifically landing, were lower than demonstrated in previous experiments with *C. cautella* flying to pheromone applied to a filter paper lure using an almost identical configuration of an upwind baffle (Mafra-Neto and Cardé 1995). In the filter paper lure experiments, a wide range of pheromone concentrations were used, likely to encompass similar concentrations as used in the current experiments. Furthermore, the pheromone components were applied to the filter paper in the same ratio as used in the current tests and, therefore, because of the similar size and volatility of the two pheromone components, it is likely they were released from the filter paper in a similar ratio to which they were applied to the filter paper, making the results of these previous tests comparable to the current experiments. With the filter paper lure, landing percentages ranged from about 70% to about 82% for a variety of pheromone doses in comparison to the 15 to 50% of moths landing for the upwind baffle configuration in the tests reported here. This trend has also been demonstrated in previous studies. For example, males of the codling moth, *Cydia pomonella*, only landed at the source 53±5.7% of the time in piezo-sprayer experiments with a release rate of 50 pg/min of synthetic (*E*,*E*)-8,10-dodecadien-1-ol (codlemone; El-Sayed et al. 1999a) in comparison to about 80% of the time in experiments that use a traditional rubber septum lure, with a release rate of about 40 pg/min (McDonough et al. 1993). However, El-Sayed et al. (1999a) demonstrated an 82±3.4% codling moth landing response to a 100 pg/min release rate. Similarly, landing responses of males of the Brazilian apple leafroller, *Bonagota cranaodes*, were low for both synthetic pheromone blends (ranging from 7–34%) and female gland extracts (57%; Coracini et al. 2003). However, high levels of response to pheromone have been obtained with the piezo-sprayer. For example, the pyralid moth *Plodia interpunctella* exhibited high percentages of source landing to a four-component pheromone blend (Svensson et al. 2004). Similarly, the tortricid *L. botrana* showed frequent (about 80%) landing responses to a three-component pheromone blend (El-Sayed et al. 1999b). It is difficult to compare landing rates or other behaviors in these different trials because plume structures would have varied with the lure type and sprayer configuration.

Because the peak of responses to the piezo-sprayer occurred at 10–100 pg/min, it is likely that the concentrations used in the present experiments were optimal and, therefore, it is unlikely that this was the reason for lower responses to the piezo-sprayer than to traditional lures. The piezo-sprayer used in these experiments used a high frequency of ultrasound (about 300 kHz; Skals et al. 2003) above that to which moths are known to respond (Connor 1999). Furthermore, in previous studies where similar responses were obtained, tortricid moths were used (e.g., Coracini et al. 2003; El-Sayed 2004), which are not known to possess hearing organs. Therefore, it is unlikely that ultrasound was the cause of differences between responses to the piezo-sprayer and traditional lures. Our experiments demonstrate that the plume structures from the piezo-sprayer system were analogous to those produced by more traditional pheromone release systems (Justus et al. 2002a) to which good levels of attraction have previously been recorded (e.g., Justus et al. 2002b).

The lower responses of moths to the piezo-sprayer system may be a result of the solvent released by the piezo-sprayer, which typically uses a flow rate of 10 μl/min. In addition, it has been suggested that ethanol has fewer negative effects on flight behavior than hexane

(P. Witzgall, personal communication), and in our own experiments with the piezo-sprayer, *C. cautella* responded less strongly and landed fewer times at the source when hexane rather than ethanol was used, further suggesting that the solvent affected moth flight and orientation behavior. Solvent had no discernible effect on the orientation of *L. botrana* to a piezo-sprayer (El-Sayed et al. 1999b). However, these latter results may not be applicable to all moth and insect species. Furthermore, the vapor pressure of the solvent and/or pheromone used may affect the plume dynamics of the plume released by the sprayer, which may have a resultant effect on moth orientation behavior.

This study demonstrates that the physical setup of the piezo-electric sprayer in a wind tunnel has significant and unpredictable effects on both the amplitude and periodicity of the odor-plume signal produced. Care must be taken when deciding what release rate to use in relation to the configuration of the piezo-sprayer because this is likely to affect the behavioral responses evoked. Furthermore, differences in the plume structure produced by the piezo-sprayer affect the in-flight orientation behavior of male moths, which could affect how strongly they respond to pheromone. These conjectures require confirmation with dedicated experiments. It is also clear that in the future, care must be taken when designing, describing, and interpreting experiments that utilize the piezo-electric sprayer technology.

Acknowledgments We thank Kris Justus and Amy Sage for help with the experimental setup. T. Berhane supervised colony maintenance. This work was supported by Paramount Farms, Inc. and the California Pistachio Commission. We thank Brad Higbee of Paramount Farms for his interest in this project and his suggestions. We are especially grateful to Ashraf El-Sayed for providing much useful advice on setting up piezo-sprayer systems.

pheromone-mediated mating of parasitoids and even fewer cases where the sex pheromones have actually been identified (Eller et al. 1984, Kainoh et al. 1991; Swedenborg and Jones 1992; Swedenborg et al. 1993; Syvertsen et al. 1995).

Previous work on the pheromone-mediated mating of the aphid parasitoid, *Aphidius nigripes* (Ashmead) (Hymenoptera: Braconidae), reported a diel periodicity in mating. This was modulated by two female pheromones, one that stimulated male upwind flight from a distance, and a second, short-distance one, present in the cuticle of the female (McNeil and Brodeur 1995; Marchand and McNeil 2000). The short-distance component stimulates male courtship behavior when the male is in close proximity to the female but does not elicit upwind flight. Furthermore, there was a significant and permanent reduction in pheromone production after mating (McNeil and Brodeur 1995).

To determine whether the patterns observed hold true for other species in the genus, we undertook a study of the pheromone-mediated mating behavior of *A. ervi* Haliday. *A. ervi* is a solitary endoparasitoid that was introduced in the 1960s into North America from Europe as a biocontrol agent for the pea aphid [*Acrythosiphon pisum* (Harris)] (González et al. 1978), where it is now also found attacking the alfalfa aphid, *Macrosiphum creelii* in certain regions (Michaud and Mackauer 1994). More recently, it has been introduced as a biological control agent into South America and Australia (Schwörer and Völkl 2001). Some research has been done on the foraging behavior of *A. ervi* females (Du et al. 1998; Schwörer et al. 1999; Guerrieri et al. 2002), and on the acceptance of various larval stages as hosts (Sequeira and Mackauer 1994). However, few studies have been conducted on the reproductive biology of this species. Mackauer (1969) compared *A. ervi*'s mating behavior to two other parasitoid species that attack the pea aphid, whereas Battaglia et al. (2002) studied antennation behavior of males during courtship. In this paper, we present: (1) a description of *A. ervi* mating behavior that is mediated by female sex pheromones, and (2) the results from laboratory and field experiments, performed to test the hypotheses that like *A. nigripes*, age and mating status affect both female production of, and male receptivity to, sex pheromones.

Methods and Materials

Insects *Acrythosiphon pisum* and *A. ervi* colonies were established by using material provided by Agriculture Canada. Parasitoids used in these experiments came from mummies collected from aphid-infested broad bean plants, *Vicia faba* L., reared at room temperature (~24°C), under natural light conditions (>15 h light per day).

Newly formed mummies were collected, isolated in individual gelatin capsules, and observed daily for emergence. Each day, the adults were sexed; males and females were placed in separate plastic holding cages with a 20% sucrose solution, and insects were held until needed. In all cases, unless specifically stated, naive virgins of known age were used in all assays.

McNeil and Brodeur (1995) found little evidence of either male or female age affecting the *A. nigripes* male response to extracts of the short-distance pheromone. The absence of age effects was somewhat surprising given that there are significant age-related changes in both the production of, and response to, sex pheromones in Lepidoptera (see McNeil 1991 and references therein). However, the experimental design of the field trials in McNeil and Brodeur (1995) did not allow for a direct assessment of female age effects on the long-distance pheromone. Therefore, in the current study, we included age as a factor in several

of the experiments to test the hypothesis that age would affect both female attractiveness and male responsiveness to pheromones in parasitoids, as reported for moths. We also varied the time of day at which certain assays were conducted to test the hypothesis that mating success, at least in part, was associated with a diel periodicity of both female production of, and male response to, the short-distance pheromone.

Mating Behavior

A newly emerged virgin (<24 h) male and female were paired to observe the behaviors displayed during courtship and copulation. The duration of the pursuit phase, antennation during courtship, and the time spent in copula were measured. To develop an ethogram, 217 naive couples were observed and terminated after 6 min, if mating did not occur, as the probability of copulation was low after 3 min (Mackauer 1969). Observations were made at room temperature between 0700 hours and 1000 hours, as *A. ervi* generally mates in the morning (Mackauer 1969) and, unless specifically stated, all experiments were carried out during this same time period.

In addition the following mating experiments were conducted, to determine:

1. if age affected mating success, by comparing the incidence of mating and time to mate in pairs consisting of a newly emerged virgin male or female with either a newly emerged or 8-day-old member of the opposite sex.
2. the effect of mating status on subsequent mating, by pairing a 1-day-old virgin male or female with a 1-day-old individual of the opposite sex that was either a virgin or that had previously mated on the day of emergence. In the case of females, an additional experiment was carried out, where the incidence of mating of 1-day-old virgins was compared with that of similarly aged females mated <2 h before being paired with 1-day-old virgin males.
3. if there is a diel periodicity in mating activity by comparing mating in pairs of virgin males and females set up at 0800 hours and 1800 hours on the day of emergence.

Twenty-five couples were observed in each experiment and the assays carried out over several days to account for any daily variability due to atmospheric conditions (Marchand and McNeil 2000).

Bioassays with Cuticular Extracts

To establish the optimal extraction time, a preliminary experiment was carried out by soaking newly emerged females in 300 µl of methylene chloride for periods between 180 and 720 s. The 540 s extract gave the highest level of male response (wing fanning behavior) and shortest reaction time following the introduction of the source, so this extraction time was used for all subsequent experiments. Unless specifically stated, all extracts were prepared soon after the lights-on period. Each extract was prepared by using three virgin females, as McNeil and Brodeur (1995) showed that there could be considerable variability in male response to extracts of individual *A. nigripes* females.

Each assay was carried out by using 3 µl [0.01 female equivalents (FE)] placed on a 0.38-cm^2 filter paper disk. All experiments, testing 10 individual 24- to 48-h-old naive virgins, were run between 0700 hours and 1000 hours and replicated three times. The extracts were tested on consecutive days, thereby minimizing any possible daily or atmospheric pressure effects that have been reported in other studies (Lanier and Burns 1978;

Steinberg et al. 1992; Roitberg et al. 1993; Marchand and McNeil 2000). The solvent was allowed to evaporate, and the disk was then introduced into an 8-dr glass shell vial containing a 24- to 48-h-old virgin male parasitoid. Two variables were measured, the proportion of males that responded and the time to respond to the stimulus. Males were considered responsive if they exhibited rapid wing-fanning, the first step in the courtship behavior (Decker et al. 1993; McNeil and Brodeur 1995), within 60 s of exposure to the stimulus.

The following experiments were carried out to determine:

1. the origin of the cuticular pheromone, by comparing the response of 1-day-old virgin males to extracts from the abdomen and the remainder of the body of 1-day-old virgin females.
2. the degree of inter-female variability, by comparing responses to extracts of 10 different <1-day-old virgin females.
3. if there is a diel periodicity in both female production of, and male responsiveness to, the pheromone. The responses of 1-day-old virgin males to female extracts from 1-day-old virgin females, prepared at 0700 hours and 1800 hours, were tested at both 0700 hours and 1800 hours.
4. if female age affected the concentration of pheromone present, by comparing the response of 1-day-old males to extracts from 0-, 2-, 4-, 6-, 8-, 10- and 12-day-old virgin females.
5. if the responsiveness of males was age dependent, by comparing the response of 0-, 2-, 4-, 6-, 8-, and 10-day-old virgin males to a standard pheromone extract from 1-day-old virgin females.
6. to what extent mating affected both attractiveness of, and receptivity to, the cuticular pheromone. To determine attractiveness, the response of 1-day-old virgin males to extracts from 24- to 48-h-old virgin and mated (24 h earlier) females was compared. For receptivity, the responsiveness of 24- to 48-h-old virgin and mated (24 h before) males to an extract from 1-day-old virgin females was compared.

Field Trapping

In all experiments, sticky Delta traps were installed at 10 m intervals, 30 cm above the crop canopy, in an alfalfa plot at Agriculture Canada in London, Ontario. A plastic cylindrical cage (8 cm long and 4 cm diameter), with both ends covered with an open mesh cloth to allow air circulation, was suspended from the roof of each trap. The cages contained a female, with a 20% sugar water solution as a food source or, in the case of controls, just sugar water. All trials were carried out over a 24 h period, starting at 1300 hours, and the number of males captured in each trap was recorded. All parasitoids caught in the sticky traps were collected, sexed, and identified by using the key of the hymenopterous parasites of the pea aphid found in eastern North America (Mackauer and Finlayson 1967). A subsample of those identified as *A. ervi* was sent to Agriculture Canada for confirmation.

The following experiments were carried out, to determine:

1. the level of inter-female variability. Twelve newly emerged females and three controls were randomly distributed along a trap line, and the number of males caught by each female was determined over a 3-day period. Each day, the number of males captured was counted and they were removed, and the position of each trap was re-randomized, to account for any possible effects of trap location.

2. the effect of female age on pheromone production by comparing the attractiveness of newly emerged, 5- and 10-day-old virgin females. Three females in each category and three controls were tested each day. The experiment was replicated four times.
3. if mating affected pheromone production. The attractiveness of 2-day-old females mated on day 1 was compared with that of 2-day-old virgins. Six individuals of each mating category and three controls were tested each day. The experiment was replicated four times.

Statistical Analyses

In the laboratory assays, the proportion of males responding was analyzed by using a chi-square test (α=0.05). For male reaction time as a function of either male or female age, a one-way ANOVA was used, whereas in all other assays, a *t* test was used. For the field trials, the number of males captured in traps containing live females was analyzed by one-way ANOVA.

Results

Mating Behavior

The sequence of events leading to copulation is shown in Fig. 1. In the absence of females, males move actively around the arena, waving their antennae in various directions with their wings held over their abdomen. However, when a female is detected, the male increases walking speed and starts wing fanning. Initially, there are distinct wing fanning bouts, but this behavior becomes almost continuous by the time he contacts the female. The male mounts the female from the back or the side and aligns along her body axis. He advances and places his antennae between those of the female, rapidly moving his own from side to side and making repeated contact with her antennae. This antennal stroking is a prerequisite to successful copulation and probably involves a male contact pheromone present on his antennae that influences female mate choice (see Battaglia et al. 2002). If the female is receptive, she stops moving, raises her abdomen, and positions her antennae laterally, where they remain immobile for the duration of mating. Once the female takes the acceptance position, the male moves backwards and curves his abdomen downwards. Once the genitalia are locked, the female remains completely immobile. Initially, the male continues to slowly antennate the female's antennae/head, but in the final seconds of mating he stops and places his antennae, immobile, above his head. Mating terminates when the female starts walking forward, at which time the male dismounts. Unreceptive females often fly or walk away upon first contact. However, if the male succeeds in mounting an unreceptive female, she continues to move her antennae, flit her wings, lower her head, curve her abdomen forward between her legs, and push the male with her hind legs. About 70% of males tested were successful in mounting the female (Fig. 1), and about 80% of those subsequently succeeded in mating (Fig. 2). If a male was unsuccessful on the first attempt after he mounted the female, he often persisted with antennal stroking, which may occur before or after the first attempt to engage her genitalia. However, the probability of success on subsequent attempts decreases considerably (Fig. 2). Unsuccessful males dismount and move away.

There is a significant effect of both male and female age on male responsiveness (number of males wing fanning, time to wing fanning, number of males attempting to mate)

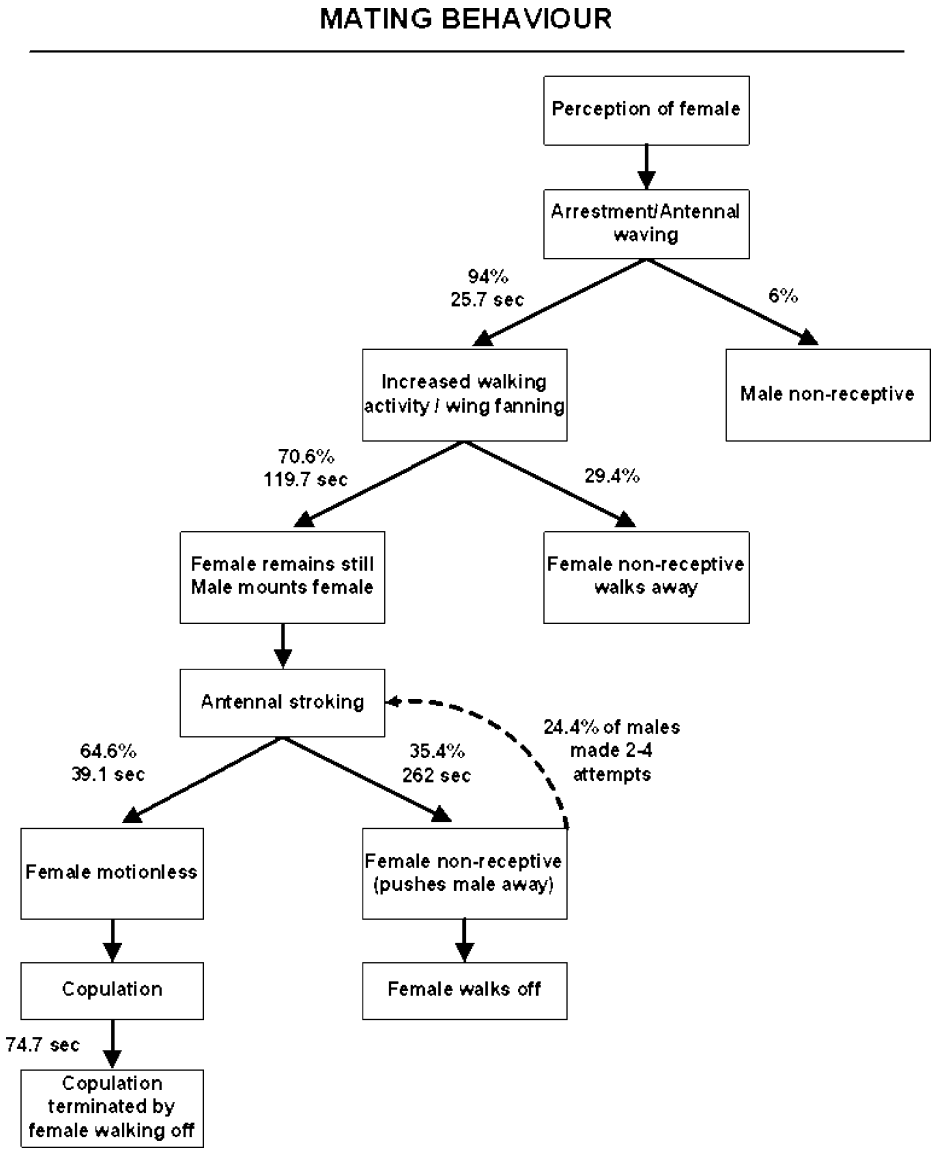

Fig. 1 A flow chart of mating behavior of male *Aphidius ervi* (*N*=217). Percentages indicate the proportion of virgin individuals, <24-h-old, displaying each behavior and the mean duration (in seconds)

and mating success of *A. ervi* (Table 1). There was also a significant effect of time of day on some aspects of male responsiveness and mating success (time to wing fanning, number of males attempting to mate, and number of males succeeding in mating; Table 1). The highest response level and shortest time to respond, as well as incidence of successful mating, were observed with pairs made up of newly emerged adults. Responsiveness and mating success declined, and the time to respond increased, when older males or females were tested, as well as when the bioassays were carried out at the end of the afternoon rather than soon

*Significant at $P<0.05$

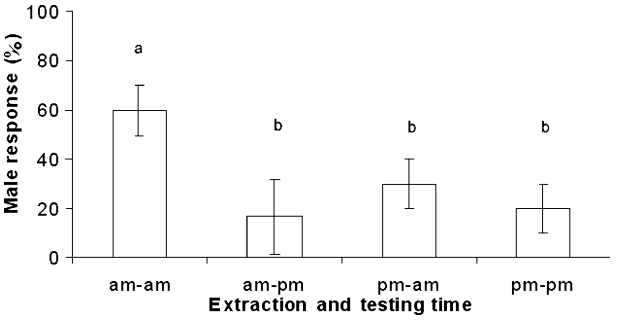

Fig. 3 The proportion of *Aphidius ervi* males (N=30) responding at 7 A.M. and 6 P.M. to 3 μl (0.01 FE) of methylene chloride extracts from 0 to 24-h-old virgin females at the same hours (Mean ±SEM). On the χ-axis, the first value for each trial indicates the time the female extract was made and the second is the time that males were tested. *Bars with different letters* indicate significance at P<0.05

after lights-on (Table 1). The duration of mating varied in the different assays, but no consistent pattern was evident.

Mating, even 2 h before, significantly reduces female attractiveness, as assessed by several indices of male response (Table 1). When males attempted to mate, females generally moved away, exhibited wing flitting and curving of the abdomen forward between her legs. Thus, there was a low incidence of re-mating (Table 1). In no-choice situations, the mating success of previously mated males did not differ significantly from that of similarly aged virgins. It did, however, take significantly longer for them to react to the stimulus, but the mating duration was not significantly different (Table 1).

Bioassays with Cuticular Extracts

The extracts of virgin females elicited a strong wing fanning response from males, whereas the whole body extract of a male did not (90 vs 0%). The source of pheromone appears to be in the abdomen, as abdominal extracts elicited higher responses (mean±SE) than those of the head/thorax (66.7±5.8 vs 6.7±11.6%; χ^2=23.254; df=1; $P<0.001$). However, when males responded, the mean reaction time was similar regardless of the origin of the extract (t=2.307; df=20; P=0.144; data not shown). The proportion of males responding to individual female extracts varied, but these differences were not significant (χ^2=12.329; df=9; P=0.195; data not shown), and mean reaction time was similar for all females (F=1.379; df=9,101; P=0.207; data not shown).

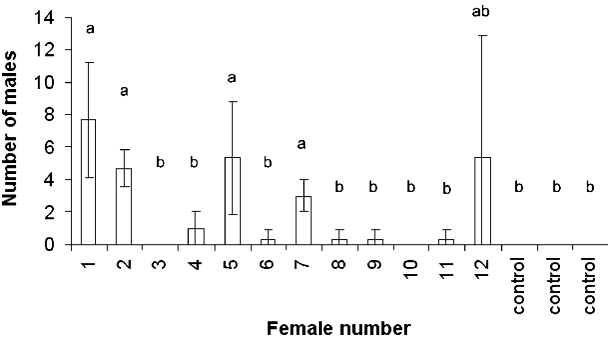

Fig. 6 Evidence of individual variability in the attractiveness of newly emerged virgin *Aphidius ervi* females under field conditions in London, Ontario (Mean±SEM). *Bars with different letters* indicate significance at $P<0.05$

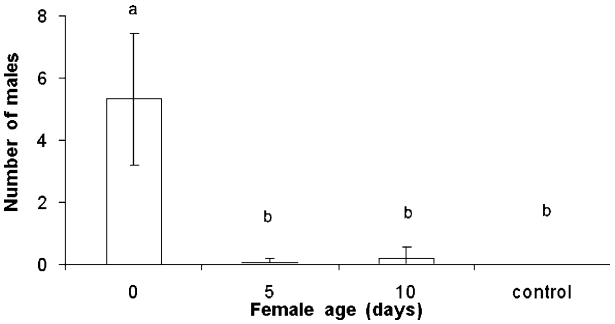

Fig. 7 The effect of age on the attractiveness of virgin *Aphidius ervi* females under field conditions in London, Ontario (Mean± SEM). *Bars with different letters* indicate significance at $P<0.05$

The percentage of males that responded changed depending on the time of day when the female extract was prepared and the time when the assays were carried out ($\chi^2=16.175$; $df=3$; $P=0.001$; Fig. 3). These results suggest a diel periodicity in both female production of the short-distance sex pheromone and the male's receptivity. However, for those males that did respond, their response time did not differ significantly, regardless of the time the extracts were taken or the time the assays were carried out ($F=0.568$; $df=3, 34$; $P=0.640$).

The responsiveness of 24 h-old males to extracts of differently aged virgin females changed with age ($\chi^2=65.455$; $df=6$; $P<0.001$; Fig. 4a), with a noticeable decline occurring with females >6-day-old. This is associated with an increase in time to wing fan, with females >8-day-old ($F=2.533$; $df=6, 114$; $P=0.024$; Fig. 4b). Similarly, male age affected responsiveness to a standard virgin extract, both with respect to the percentage that responded ($\chi^2=19.945$; $df=5$; $P=0.001$; Fig. 5a) as well as the time to respond ($F=3.487$; $df=5, 123P=0.006$; Fig. 5b), and this was due to males >6-day-old.

Extracts from mated females were less attractive than those of similarly aged virgin females (6.6±5.8 vs 86.7±5.8%; $\chi^2=38.571$; $df=1$; $P<0.001$), but as seen in the mating trials, the mean reaction time of those males that responded was unaffected (26.7±22.1 vs 25.6±17.8 s; $t=0.008$; $df=26$; $P=0.929$). In contrast, previous male mating history did not affect the level of response (73.3±5.8 vs 86.7±11.6%; $\chi^2=1.667$; $df=1$; $P=0.197$) or the time to respond (23.8±17.0 s vs 28.6±15.3 s; $t=0.123$; $df=46$; $P=0.727$) to a standard female extract.

Field Trapping

The mean number of males captured per day (ranging from 0 to 8) indicates that there is considerable inter-female variability in the long distance pheromone produced by newly emerged virgins ($F=3.500$; $df=14, 30$; $P=0.002$; Fig. 6). Furthermore, there was a decline

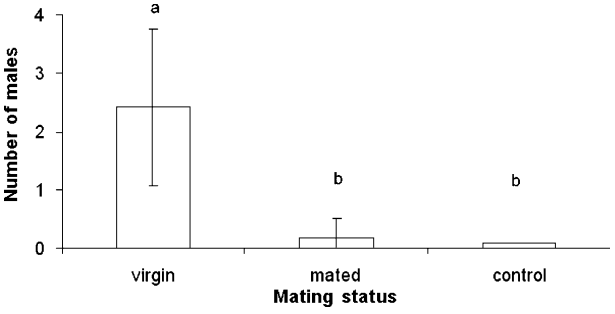

Fig. 8 The effect of mating on the attractiveness of *Aphidius ervi* females under field conditions in London, Ontario (Mean±SEM). *Bars with different letters* indicate significance at $P<0.05$

in the attractiveness of virgin females with age (F=10.014; df=3, 56; P<0.001; Fig. 7). Mating also reduced female attractiveness, with mated females capturing fewer males than virgins of the same age (F=6.092; df=2, 54; P=0.004; Fig. 8).

Discussion

The mating behavior of *A. ervi* is similar to that of *A. nigripes*, with female pheromones modulating attraction and courtship behavior (McNeil and Brodeur 1995; Marchand and McNeil 2000), and with both short- and long-distance pheromones. The short-distance pheromone affecting courtship (wing fanning and attempted copulation) is located in the female abdomen and, as suggested for *A. nigripes*, the low levels of response observed to head/thorax extracts may result from female grooming behavior (McNeil and Brodeur 1995). In both species, the production of, and response to, the short-distance pheromone shows diel periodicity, being maximal in the morning. In *A. ervi*, this periodicity was also evident in the mating assays, with the number of attempted and successful matings being significantly higher in the morning than in the afternoon. Similarly, there was evidence of diel periodicity associated with the long-distance pheromone in *A. nigripes*, as the majority of males captured in traps baited with virgin females occurred between 0600 hours and 1000 hours (McNeil and Brodeur 1995). Mating early in the morning would be quite advantageous for small insects like *A. ervi*, as the cool temperatures and high relative humidity reduce the risk of desiccation. Furthermore, the generally calmer wind conditions at this time of day would be good for foraging males, as flight is inhibited by winds >1 m/s (Marchand and McNeil 2000; McClure and McNeil unpublished data).

A number of parameters affect female production/emission of sex pheromones in *A. ervi*. For example, field trials provide evidence of individual variability in the production of the long-distance pheromone although, while variation was observed, there were no significant differences in the laboratory bioassays that tested the short-range pheromone. A similar pattern of individual variation between females was noted for *A. nigripes*, in field (McNeil and Brodeur 1995), as well as in wind tunnel experiments where female body size (related to the size of the host) played a significant role (Cloutier et al. 2000). There was a significant effect of age on long-distance attraction by *A. ervi* females, presumably due to a decline in pheromone production as reported for the age-related decline in pheromone production in virgin *Helicoverpa zea* females (Teal et al. 1990). There was also a decline in male responsiveness to short-range pheromone as a function of female age, but only to extracts from individuals >6 day-old, similar to the non-significant trend observed for *A. nigripes* (McNeil and Brodeur 1995). The results of this study support the hypothesis that female age affects pheromone production in parasitic Hymenoptera, especially the long-distance one that stimulates male upwind flight.

It would also appear that females of *Aphidius* species are generally monandrous and that repeated matings are rare (results of this study, McNeil and Brodeur 1995). Thus, a post-mating decline in pheromone production (pheromonostatis) is not surprising, and has previously been suggested for other parasitoids (Van den Assem 1986). This phenomenon has generally been studied in Lepidoptera (e.g., Raina et al. 1994; Ramaswamy et al. 1996; Marcotte et al. 2003, 2005), and Diptera (e.g., Ottiger et al. 2000), and the length of the female refractory period may be related to a number of factors, including the quality of the male ejaculate (see Kingan et al. 1993, 1995; Fan et al. 1999a,b; Delisle and Bouchard 1995; Delisle and Hardy 1997; Marcotte et al. 2005). Few *A. ervi* females re-mated, and as

it was only observed in those that had mated 24 h earlier, re-mating was possibly the result of an unsuccessful first mating or due to a low quality mate.

There appear to be fewer, or less-pronounced, changes in the responsiveness of *A. ervi* males to the female short-distance pheromone. There is a decline in responsiveness by males >6 day, which could be the result of reduced sensitivity of peripheral pheromone receptors and/or the integration at the level of the central nervous system (see Hansson 1999). Furthermore, the mating success of 8-day-old males that do respond to the sex pheromone is significantly lower than for 1-day-old individuals, possibly associated with the production of male infochemicals involved in female mate choice (Battaglia et al. 2002). However, while the responsiveness of young, previously mated *A. ervi* males is significantly slower than similarly aged virgins, previous mating history does not affect acceptance by females in a no-choice situation. Whether this is true in a competitive situation, or when older virgin males are involved, remains to be determined. Furthermore, even if females did not discriminate the longer response time of previously mated males, this could result in them being out-competed by virgin conspecifics.

Additional research is required to better understand the causes of the observed changes in the emission of, and response to, sex pheromones in *A. ervi*, as well as to determine to what extent they impact reproductive success. Furthermore, we need to know how factors such as temperature, wind speed, and humidity affect the pheromone-mediated communication system. The information generated would not only add to our basic understanding of insect reproductive biology, but could help determine the optimal conditions for parasitoid release and their effective deployment in pest management programs. Furthermore, the chemical composition of these pheromones must be elucidated if one wishes to test their potential in "push–pull" management strategies (Pyke et al. 1987; Miller and Cowles 1990; Khan et al. 2000; Nalyanya et al. 2000).

Introduction

Pheromones form the mechanistic basis of the organization of foraging in termites, which is the most significant factor affecting their social evolution as emphasized by Traniello and Leuthold (2000) in their review of behavior and ecology of foraging in termites. Termite trail-following pheromones are relatively well known for the Rhinotermitidae and Termitidae of the 'separate life type' (Abe 1987), i.e., for species in which workers forage outside the nest or move from one nesting site to another. In these termites, trail pheromones elicit recruitment and orientation (Traniello 1982; Traniello and Leuthold 2000). Their major component is either an unsaturated straight chain C12 alcohol or a diterpene hydrocarbon (Pasteels and Bordereau 1998; Wobst et al. 1999; Peppuy et al. 2001a, b; Robert et al. 2004; Sillam-Dussès et al. 2005).

In contrast, little is known about those termites that feed on wood in which they also nest ('one-piece life type'; Abe 1987) and, a priori, may have less need for a trail pheromone, but some species of the one-piece nesting termite *Prorhinotermes* may leave their nests (Roisin et al. 2006). The first trail-following pheromone of termites was nonetheless demonstrated in a 'one-piece life type' dampwood termite, *Zootermopsis nevadensis*, (Lüscher and Müller 1960; Stuart 1961), and originally identified incorrectly as hexanoic acid by Hummel and Karlson (1968) and Karlson et al. (1968). The true pheromone structure was recently identified as 4,6-dimethyldodecanal (Bordereau et al. 2006), which is chemically different from trail pheromones of more advanced termites. According to Stuart (1963, 1967, 1969), trail pheromones of the 'one piece life type' termites possibly should be considered more as alarm signals eliciting excitation and recruitment for the defense of the colony. The sternal gland secretion also may have other functions, such as a fungistatic activity (Rosengaus et al. 2004).

In the framework of an evolutionary study on the strategies of chemical communication in termite foraging, the behavioral and chemical properties of sternal gland secretions were investigated in basal termites. The sternal gland, a small ectodermal abdominal gland, is the only glandular source for trail pheromones (Noirot 1969).

We report here the results obtained on *Mastotermes darwiniensis*, which represents the most basal lineage among extant termites, although it exhibits a mixture of primitive and advanced characters, especially with the presence of a true worker caste. *Mastotermes darwiniensis*, endemic to northern Australia, is a unique living representative of a family of termites distributed worldwide in the past. Its phylogenetic relationships with the subsocial cockroach *Cryptocercus* often have been emphasized, but they remained controversial (Thorne 1990, 1991; Nalepa 1991; Grandcolas 1996; Grandcolas and Deleporte 1996; Nalepa and Bandi 2000; Nalepa and Lenz 2000; Lo et al. 2000, 2003; Eggleton 2001) until Inward et al. (2007) showed from a molecular phylogenetic study that *Cryptocercus* is indeed the sister group of termites. *Mastotermes darwiniensis* is the only extant termite whose workers possess three sternal glands located on sternites 3–5. All other termites possess only one sternal gland located on the fourth or fifth sternite. The architecture of its subterranean nest is not well known, but colonies typically feed on multiple trees over extensive areas, requiring extensive subterranean galleries (Miller 1993; Goodisman and Crozier 2002). This termite is, therefore, of an intermediate ecological life type, suggesting

that it might use a trail pheromone. However, a trail pheromone has not been demonstrated previously in this basal termite. Colonies of *M. darwiniensis* in natural woodlands are relatively moderate in size, but huge colonies composed of several million individuals can be found in disturbed habitats, such as urban areas, plantations, and the like, where they may cause severe damage (Hill 1942; French 1986).

We also extended our study to two other basal termites with uncertain phylogeny, *Porotermes adamsoni* (Termopsidae, Porotermitinae) and *Stolotermes victoriensis* (Termopsidae Stolotermitinae; Emerson 1942, 1947; Kambhampati and Eggleton 2000). There are only three species of Porotermitinae in the world; their present geographical distribution (Chile, South Africa, Australia) suggests a Gondwanian origin from the Triassic period. *Porotermes adamsoni*, a unique representative of Porotermitinae in Australia, is considered a relict species. This dampwood termite from south-eastern Australia, generally considered as a 'one-piece ecological life type' termite, although, according to Nkunika (1988), its pseudergates are able to build subterranean galleries and can move from one piece of wood to another. Its colonies are composed of a few thousand to tens of thousands of individuals (Mensa-Bonsu 1976; Lenz 1994). *Stolotermes victoriensis* shares much of its range with *P. adamsoni* in mountainous regions of south-eastern Australia. Its phylogenetic position remains controversial. Although generally considered a basal termite, the configuration of the genitalia would indicate a closer relation of Stolotermitinae with Kalotermitidae, Rhinotermitidae, and Termitidae rather than with Termopsinae and Hodotermitidae (Klass et al. 2000). *Stolotermes victoriensis* is also a 'one-piece life type' termite with pseudergates. Its colonies are composed of a few hundred small individuals.

Thus, the principal objectives of this research were threefold: (a) to investigate whether trail pheromones were present and secreted from the sternal glands in the basal termites *M. darwiniensis*, *P. adamsoni*, and *S. victoriensis*; (b) to identify, synthesize and confirm by bioassay any trail pheromones arising from such studies; and (c) to correlate these results with termite phylogeny.

Materials and Methods

Insects

Mastotermes darwiniensis termites were collected in the field in Australia (Darwin in the Northern Territory and Townsville in Queensland), or were reared in the laboratory in Canberra (ACT) and in Dijon (France). The termites used in Canberra were collected in the Northern Territory and reared in metal drums in climate-controlled rooms (30°C, 90% RH). Most termites used in Dijon came from a colony founded in Australia and taken in 1973 to the Federal Institute of Testing of Materials (BAM) in Berlin (Germany; M. Lenz) and maintained in Dijon since 1999 (28°C, 80% RH). Incipient colonies founded in Darwin in 1999 from swarming imagos, then reared in Dijon, were also used. Workers of *M. darwiniensis* are of large size (9–10 mm long). They possess three sternal glands, of about 0.006 mm^3 for the first two, and a maximum of 0.001 mm^3 for the third.

Porotermes adamsoni termites were collected from stumps or logs of *Eucalyptus* in the Brindabella Mountains near Canberra. They were used in Canberra for trail-following bioassays shortly after collection, or later in Dijon where they were maintained in a climate-controlled room (26°C, 60% RH). Pseudergates of this species also are of large size (8 mm long) and their unique sternal gland is well developed (about 0.03 mm^3).

Stolotermes victoriensis is a termite colonizing wet and decayed logs in southeastern Australia. Pseudergates are 6.5 mm long, and the volume of their sternal gland is about 0.001 mm^3. The termites were collected in the Brindabella Mountains near Canberra, and then maintained in Dijon until use.

Pheromone Extracts

The pheromone was extracted by using two procedures. (a) Whole bodies or sternal glands of workers or pseudergates were immersed in different purified solvents (pentane, hexane, dichloromethane, or methanol) for 12 h at 4°C. After removing workers or glands, extracts were stored at −20°C until used for bioassays or chemical analyses. Sternal glands were prepared by dissecting the glands from cold anesthetized individuals under a stereomicroscope with microscissors and forceps. They were extracted in 2 ml of solvent for 500 glands. (b) Cold anesthesized termites were artificially induced to expose their sternal glands under a stereomicroscope by stretching the abdominal segments with a forceps. A Supelco 65 μm-fiber for solid phase microextraction (SPME) was gently rubbed on the sternal glands. Different types of fibers were tested; the polydimethylsiloxane/divinylbenzene type gave consistently best results. Surface chemicals from 30 individual termites were accumulated on the fiber before thermal desorption. Controls were carried out by rubbing other intertergal membranes or tergites with the same type of SPME fiber. The fiber was desorbed in the injection port of a gas chromatograph for 3 min for gas chromatography (GC) and gas chromatography-mass spectrometry (GC-MS) analyses.

Fractionation of extracts of sternal glands of *M. darwiniensis* and *P. adamsoni* was carried out by preparative GC (Hewlett-Packard HP 6890 GC) connected to a Gerstel preparative fraction collector, using an HP5 capillary column (30 m×0.32 mm ID) (0.25-μm film thickness). The GC effluent was trapped in 120-μl glass U-tube traps cooled in liquid nitrogen. Fractions were collected from a total of 150 individuals, the SPME fiber being desorbed in the GC after rubbing the sternal gland of 30 individuals. The biological activity of fractions was tested in trail-following bioassays.

Cuticular Hydrocarbons

Cuticular hydrocarbons were obtained by extracting 100 workers in 5 ml hexane for 1 h at 4°C, then purifying the extract on silica gel columns (hexane elution).

Chemical Analyses

GC and GC-MS analyses were carried out with a 5973N Mass Selective Detector coupled to a 6890 gas chromatograph (Agilent Technologies, Palo Alto, CA, USA) fitted with a split-splitless injector and a DB™-Wax column (30 m×0.32 mm ID, 0.5 μm film thickness, J&W Scientific, Folsom, CA, USA) or an Equity 5 column (30 m×0.32 mm ID, 0.25 μm film thickness, Supelco). Columns were heated from 40 to 240°C at 5°C min^{-1}. Helium was used as carrier gas at a constant velocity of 37 cm/s. The temperature of the injector was set to 250°C. The column was interfaced directly to the ion source of the mass spectrometer through a heated transfer line maintained at 250°C. Electron-ionization (EI) mass spectra were obtained at 70 eV with the instrument scanning from *m/z* 29 to 450, and the source maintained at 230°C.

Positive chemical ionization (PCI) mass spectra were generated with ammonia as reagent gas (PCI-NH_3). The instrument was scanned from *m/z* 60 to 300 in a 0.7 s cycle.

Quantification of the Pheromone

Because SPME is not a satisfactory quantitative method of extraction, the quantity of pheromone was estimated from a comparison of GC peaks of the pheromone present in sternal gland extracts and of the standard. Due to the limited biological material available in France, the measurements were made on two extracts of 500 sternal glands in *M. darwiniensis* and 100 sternal glands in *P. adamsoni* and *S. victoriensis*. Therefore, it was not possible to use statistical analyses. These qualitative estimates were then compared to the data from the trail-following bioassays.

Synthesis of (*E*) and (*Z*)-2,6,10-Trimethyl-5,9-undecadien-1-ol

Racemic (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol [containing 1.5% (*Z*)-isomer] was prepared by way of the Darzens condensation of geranylacetone (Fluka, Sydney) with ethyl chloroacetate followed by hydrolysis of the intermediate ester, thermal decarboxylation, and $LiAlH_4$ reduction of the resultant aldehyde, as adapted from the method of Kulesza and Gora (1969). (*Z*)-2,6,10-Trimethyl-5,9-undecadien-1-ol [containing 2% (*E*)-isomer] was prepared similarly from nerylacetone (Fluka, Sydney).

Trail-Following Bioassays

Bioassays were carried out either in Canberra with termites freshly collected from the field or in Dijon with laboratory-reared termites. All bioassays were performed in climate-controlled rooms (30°C, 80% RH) under red light. The orientation activity elicited by extracts was assayed with two types of bioassays.

(a) Trail extracts were tested with a 'Y open field' trail-following bioassay on Whatman no.1 filter paper discs (15-cm diameter), with a 120° angle between each branch. On the Y stem (3 cm) and one of the Y branches (7 cm), an artificial trail was drawn with a microliter syringe containing 1 μl of extract per cm of trail. Another extract or solvent as a control was deposited under the same conditions on the base and the other branch of the Y. One termite was placed inside a holding chamber consisting of a small plastic vial (55 mm ID), with the 2-mm wide opening being located at the base of the Y. The distance traveled by the insect on the trail was measured. The activity threshold for an extract was defined as the minimum concentration that elicited termites to travel a mean distance of more than 3 cm, the maximum response being 10 cm. Each termite and each trail were used only once to prevent any effects from behavioral conditioning or trail reinforcement.

(b) Trail extracts were also tested with a 'T maze' bioassay. T-shaped artificial trails were drawn on a Whatman no.1 filter paper and covered with a T tunnel formed in a perspex block laid on the filter paper disc. The T base was 3 cm long, and the branches 6 cm long. The termites were thus guided by the tunnel and had the choice between the left and the right branches.

Exploratory Behavior of a New Environment

The behavior of termites while exploring a new environment was observed by using an 'open field' design: a piece of wood containing a few hundred individuals was deposited at

the center of a sheet of filter paper (40×60 cm) covering the bottom of a plastic container. Observations of termites exploring their surroundings were made under red light.

Statistical Analyses

Results of trail-following bioassays in the open field design were analyzed with a *t* test, whereas those in the T-maze were analyzed with a Kruskall-Wallis or χ^2 test. In this latter case, results were considered significantly different when choices were ≥21/9 for N=30 (significance set at 0.05).

Results

Exploratory Behavior and Trail-following Pheromone

Mastotermes darwiniensis On a clean arena, workers of *M. darwiniensis* explored their environment individually and in tandem and were never seen moving in single file as do termites known for secreting a trail pheromone (Fig. 1a). Moreover, in an open field

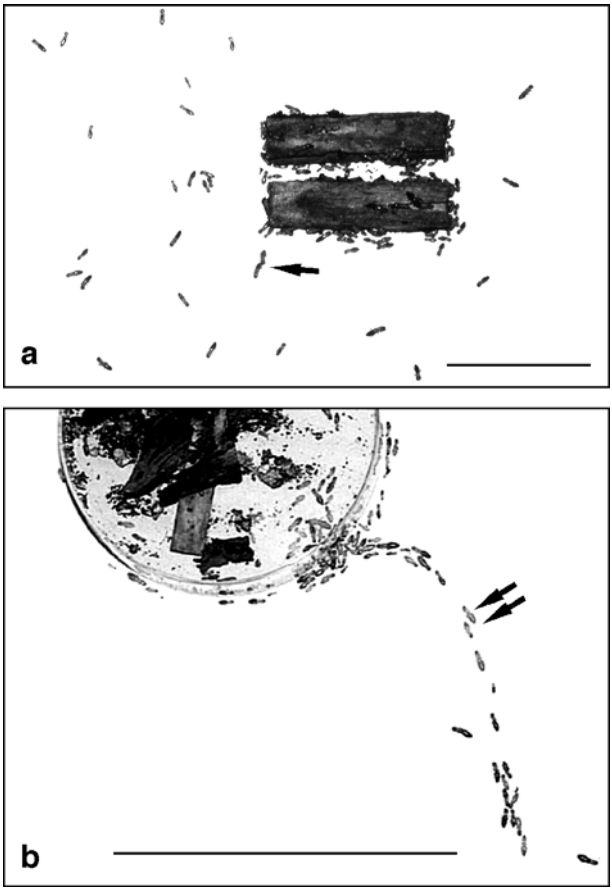

Fig. 1 **a** Exploratory behavior of termites in a new environment. Deposited at the center of a clean container, workers of *M. darwiniensis* scatter over the whole surface and explore their environment individually or in tandem (*arrow*) (scale bar=10 cm). **b** Under the same experimental conditions as for workers of *M. darwiniensis*, pseudergates of *P. adamsoni* explore their environment in single files (*double arrows*), showing the use of a trail pheromone and mass recruitment (scale bar=10 cm)

situation, workers were unable to follow artificial trails made from extracts of whole workers or sternal glands, irrespective of the solvent used for extraction. Even at a concentration of five sternal glands/cm of trail, trail-following did not reach the activity threshold of 3 cm (mean±SD: 1.9±0.5 cm, N=30). These observations raised doubts whether *M. darwiniensis* was secreting a trail-following pheromone. However, T-maze bioassays (Table 1) showed that the workers of *M. darwiniensis* were able to distinguish a trail used by nestmates from a control trail. When given a choice between a control trail and a trail previously followed by at least 50 nestmates, workers preferentially chose the previously used trail, indicating that workers actively or passively mark the substrate when moving.

Workers of *M. darwiniensis* also were able to follow an artificial trail made of hexane extracts of whole workers of at least five individuals/cm of trail in a 'guided' context, indicating a chemical origin of the 'marking' (for 30 tests, 28 choices for the trail made from worker extracts, 2 choices for the control trail made from hexane). Moreover, when given a choice between a trail made with extracts of whole workers without sternal abdominal segments and a trail made from sternal glands 3–5, workers preferentially chose the trail made with sternal gland extracts (26 choices out of 30 tests). In contrast, a trail consisting only of cuticular hydrocarbons of workers was not followed (for 30 tests, 18 choices for the trail made from cuticular hydrocarbons at a concentration of 1 worker equivalent/cm, 19 choices at a concentration of 5 worker equivalent/cm). These results suggest that *M. darwiniensis* secretes a trail-following pheromone from its sternal glands as do other species of termites.

Extracts of sternal gland 4 were about five times more active than those of sternal gland 3 (Table 2). This result was confirmed with a choice test between trails made from extracts of sternal gland 4 and sternal gland 3, at a concentration of 1 gland/cm; workers clearly preferred the trail with the sternal gland 4 extract. Trail-following was not observed for extracts of sternal gland 5, probably due to its very small size.

Porotermes adamsoni In contrast to the individual exploratory behavior of *M. darwiniensis*, pseudergates of *P. adamsoni* explored a new environment in single file with individuals following each other closely (Fig. 1b). This behavior suggested the use of trail pheromone. In contrast also to *M. darwiniensis*, pseudergates of *P. adamsoni* were able to follow artificial trails in an open field situation, secreting a very active trail pheromone from their abdominal sternal gland. The biological activity threshold of trails made from sternal gland was 10^{-2} gland/cm (mean±SD: 7±0.7 cm, N=30). Trail-following was optimal at 10^{-1} and 1 gland/cm (mean: 10 cm, n=30, and reduced at higher concentrations (5 sternal gland/cm; mean±SD: 7.5±0.5 cm, N=30). This bell-shaped dose-curve or concentration-response is characteristic of pheromones.

Table 1 Results of a T-maze trail-following bioassay. Workers of *M. darwiniensis* are able to recognize a trail previously used by at least 50 nestmates. (S: result statistically significant, NS: result statistically non significant, N=30)

	Sternal gland 4 vs hexane	28 vs 2 (S)	–	–	26 vs 4 (S)
	Sternal gland 3 vs Sternal gland 4	7 vs 23 (S)	–	–	–

Extracts of sternal gland 4 (active at 0.1 Weq/cm) were at least five times more active than extracts of sternal gland 3 (active at 0.5 Weq/cm)

S, result statistically significant, *NS*, result statistically non significant, *Weq*, worker equivalent, *N*=30

Stolotermes victoriensis Pseudergates of *S. victoriensis* also followed artificial trails in the open field bioassay. Bioassays showed that the sternal gland was the only glandular source of the trail pheromone. Optimal trail-following was elicited at a concentration of 10^{-1} gland/cm of trail.

Interspecific trail-following bioassays between *M. darwiniensis*, *P. adamsoni*, and *S. victoriensis*

Interspecific trail-following bioassays showed positive responses between *M. darwiniensis*, *P. adamsoni*, and *S. victoriensis*. In a T-maze bioassay, workers of *M. darwiniensis* followed an artificial trail made from extracts of sternal glands of *P. adamsoni* pseudergates (Table 3). Moreover, when given a choice between trails prepared from extracts of *M. darwiniensis* or *P. adamsoni* sternal glands, workers of *M. darwiniensis* preferentially chose the trails of *P. adamsoni* (Table 3).

Pseudergates of *P. adamsoni* always chose the *P. adamsoni* trail when given a choice between *M. darwiniensis* and *P. adamsoni* sternal gland extract trails (Table 3). However, in 'open field' assays, they were able to follow artificial trails made of *M. darwiniensis* sternal gland but to a lesser degree than their own trails (Table 4).

In T-maze bioassays, pseudergates of *S. victoriensis* were not able to distinguish a trail of *Mastotermes* sternal gland extract from their own (Table 3), and in an open field assay, they followed a *Mastotermes* trail better than their own (Table 4).

In sum, these results suggest the presence of a trail-following pheromone component common to *M. darwiniensis*, *P. adamsoni,* and *S. victoriensis*.

Table 3 Interspecific trail-following in a T-maze bioassay

	Number of Individuals Following Each Trail				
Tested Species	Hexane	*P. adamsoni*	*M. darwiniensis*	*S. victoriensis*	χ^2
M darwiniensis	5	25	–	–	S
M. darwiniensis	–	24	6	–	S
P. adamsoni	–	30	0	–	S
S. victoriensis	–	–	17	13	NS

Workers of *M. darwiniensis* were able to follow trails of sternal gland extracts of *P. adamsoni* and that they preferentially chose trails made from extracts of *P. adamsoni* rather than their own trails

Pseudergates of *P. adamsoni* preferred their own trails to trails of *M. darwiniensis*. Pseudergates of *S. victoriensis* followed their own trails and trails of *M. darwiniensis* without preference (concentration of trails: five sternal glands/cm; *N*=30)

S, result statistically significant; *NS*, result statistically non significant

Table 4 Results of interspecific 'open-field' trail-following bioassays

	0	–	–	6.9±1

Pseudergates of *P. adamsoni* and *S. victoriensis* were able to follow trails of sternal glands of *M. darwiniensis* (N=30, Concentration of trails: five sternal glands/cm)

Chemical Nature of the Trail Pheromone

The existence of a compound common to the three species was confirmed by GC-MS after SPME of the surface of the sternal glands (Fig. 2). It was present in relatively high quantities in *P. adamsoni*, and in lesser amounts in *M. darwiniensis* and *S. victoriensis*, where it was detected only by selected ion monitoring to increase sensitivity. Moreover, it partly co-eluted with another compound in *M. darwiniensis*, but its presence was confirmed in two samples of 500 dissected sternal glands.

For *M. darwiniensis* and *P. adamsoni*, the accumulated SPME extracts of the sternal gland surfaces of 150 individuals were separated into three fractions by preparative GC. Fraction F1 from retention times 3 to 29.40 min comprised the most volatile compounds; fraction F2 from RT 29.40 to RT 29.60 min contained only the common compound specific to the sternal gland surface; fraction F3 from RT 29.60 to RT 48 min contained the less volatile compounds, essentially cuticular hydrocarbons from C23 to C28 for *M. darwiniensis*, and from C22 to C30 for *P. adamsoni.* Results in Table 5 show that workers of *M. darwiniensis* followed only the

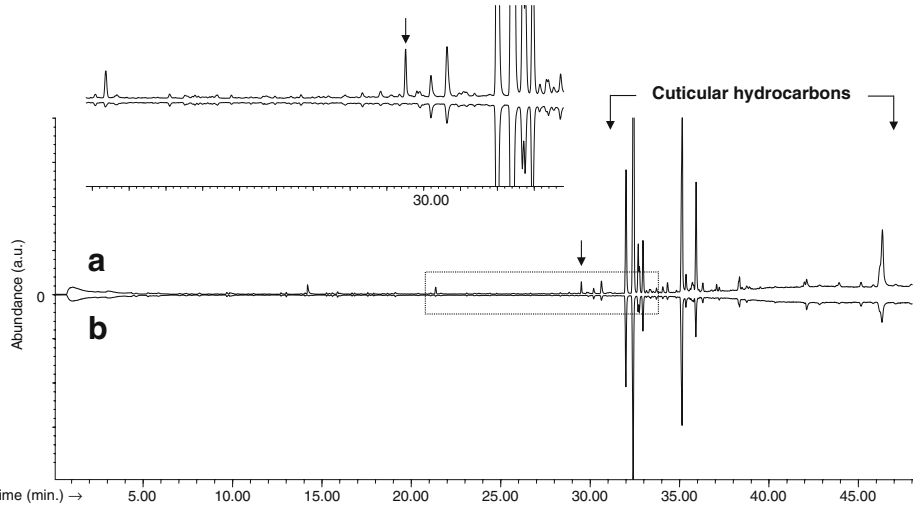

Fig. 2 Comparison of the GC profiles of SPME extracts of (*a*) the surface of sternal gland 5, and (*b*) the extra-glandular abdominal integument of 50 pseudergates of *P. adamsoni*. The majority of peaks are common to both surfaces and correspond to cuticular hydrocarbons from C22 to C30. However, the peak marked by an arrow (RT 29.5 min) is specific to the glandular surface. Detail of the window in the upper part of the figure

trails made of fraction F2 prepared either from *M. darwiniensis* or from *P. adamsoni*. Trail-following was better with trails made from the *P. adamsoni* fraction F2.

In the same manner, pseudergates of *P. adamsoni* followed only the trails made from fraction F2 of the *M. darwiniensis* sternal gland extracts (Table 5). In open field bioassays with trails made of sternal gland extracts of *P. adamsoni*, only the trails made with fraction F2 were active in eliciting trail-following in pseudergates of *P. adamsoni* when tested at the concentration of 10^{-1} ng/cm. They were also the most active when tested at higher concentration (5×10^{-1} ng/cm), eliciting maximal trail-following, but it was noted that at this concentration, fraction F3 containing the cuticular hydrocarbons was also active (Table 5).

The common sternal gland compound of the three species had a retention index (RI) of 2161 on a polar DB-Wax column, and a RI of 1593 on a nonpolar Equity 5 column. Its EI mass spectrum (Fig. 3) suggested a terpenoid structure similar to that of 3,7,11-trimethyl-6,10-dodecadien-1-ol (Bergström et al. 1968). The molecular ion M^+ of *m/z* 210 was confirmed by positive ion chemical ionization (PCI/NH_3), which displayed an MH^+ ion of *m/z* 211. These results suggested that the compound might be the norsesquiterpene homolog of 3,7,11-trimethyl-6,10-dodecadien-1-ol, i.e., 2,6,10-trimethyl-5,9-undecadien-1-ol, which was confirmed by the synthesis of the molecule. The synthetic (*E*)-isomer of 2,6,10-trimethyl-5,9-undecadien-1-ol possessed the same EI mass spectrum and RI (RI 2163 on DB-Wax, and 1598 on Equity 5) as the natural compound. The (*Z*)-isomer was resolved clearly from the (*E*)-isomer (RI 2137 on DB-Wax, and 1572 on HP5). No trace of (*Z*)-2,6,10-trimethyl-5,9-undecadien-1-ol was detectable in extracts of *M. darwiniensis* and *P. adamsoni*.

Biological Activity of Synthetic (*E*) and (*Z*) Isomers of 2,6,10-Trimethyl-5,9-undecadien-1-ol

Mastotermes darwiniensis (*E*)-2,6,10-Trimethyl-5,9-undecadien-1-ol elicited significant trail-following at a concentration of 1 ng/cm of trail, whereas trail-following was reduced beyond a concentration of 100 ng/cm (Table 6). Surprisingly, similar results were obtained

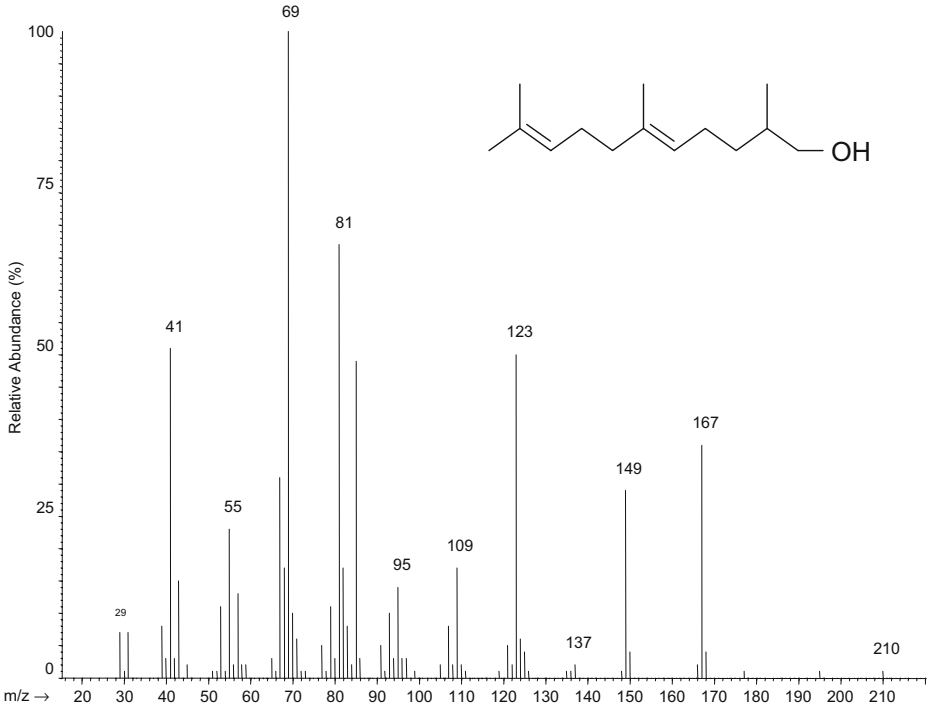

Fig. 3 EI mass spectrum of the compound specific to the sternal gland surface, identified as (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol

with the (*Z*)-isomer for the threshold activity, but higher concentrations of this isomer did not induce a reduction in trail-following. Thus, with the (*Z*)-isomer, we did not obtain the classical bell-shaped curve of responses in relation to pheromone concentration. In addition, a mixture of the two isomers was more active than the (*E*)-isomer, the activity threshold being obtained from 10^{-2} ng/cm.

Table 6 Choice of trails made with synthetic (*E*)- and (*Z*)-isomers, and a mixture of both isomers of 2,6,10-trimethyl-5,9-undecadien-1-ol for *M. darwiniensis* (T-maze trail-following bioassays)

Concentration	(*E*) Isomer Hexane	(*Z*) Isomer Hexane	(*E*)+(*Z*) Isomers Hexane
10^{-3} ng/cm	54/36 NS (n=90)	57/33 NS (n=90)	26/34 NS (n=60)

S, result statistically significant; *NS*, result statistically non significant

Porotermes adamsoni For this species, the isomers were tested in open-field bioassays (Fig. 4). With the (*E*)-isomer, we obtained an activity threshold at 10^{-2} ng/cm, optimum trail-following at 10^{-1} ng/cm, a reduction in trail-following beyond 1 ng/cm, and no response at 1 μg/cm. With the (*Z*)-isomer, the activity threshold was only reached at a concentration of 1 ng/cm and a concentration of 100 ng/cm elicited extensive trail-following. A mixture of both isomers elicited trail-following similar to that obtained with the (*E*)-isomer alone, with an activity threshold at 10^{-2} ng/cm, optimal trail-following between 10^{-1} and 1 ng/cm, and a reduction in trail-following beyond 10 ng/cm.

Stolotermes victoriensis The activity of synthetic (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol could not be tested with this species, due to the death of the colony maintained in France.

Quantification of (*E*)-2,6,10-Trimethyl-5,9-undecadien-1-ol in Sternal Gland Extracts

For *M. darwiniensis*, the quantity of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol was estimated to be about 20 pg per individual. This was confirmed with bioassays: artificial trails made from five sternal glands/cm were more active than trails of 10 pg of synthetic (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol/cm, as active as those of 100 pg/cm and less active than those of 1 ng/cm (Table 7).

For *P. adamsoni*, the quantity of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol was estimated by GC analysis to be about 700 pg/individual, 35 times more than in *M. darwiniensis*. Bioassays confirmed this result. Trails made of five sternal glands/cm were more active than trails of 1 ng of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol/cm, as active as trails of 3.5 ng/cm, and less active than those of 10 ng/cm (Table 7).

For *S. victoriensis*, the quantity of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol was estimated to be 4 pg/individual, five times less than in *M. darwiniensis* and 175 times less than in *P. adamsoni*. This was confirmed by trail-following bioassays. Pseudergates of *S. victoriensis* were not able to distinguish their own trails of 5×10^{-1} sternal gland/cm from

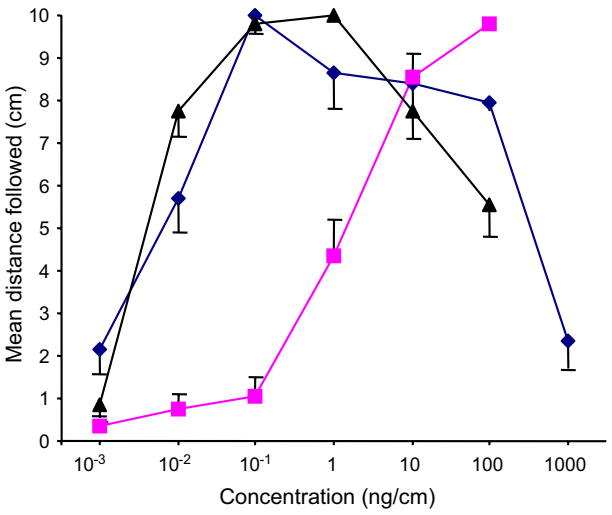

Fig. 4 Trail-following activity of synthetic (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol (—◆—), (*Z*)-2,6,10-trimethyl-5,9-undecadien-1-ol (—■—), and a mixture of both isomers (—▲—) for pseudergates of *P. adamsoni* ('open-field' trail-following bioassay, *N*=30)

Table 7 Comparison of the trail-following activity of trails made from sternal gland extracts (*M. darwiniensis* or *P. adamsoni*), and synthetic (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol

Trail	Sternal Gland/cm	(*E*)-2,6,10—Trimethyl-5,9—undecadien-1-ol (ng/cm)					χ^2 test
Trail concentration	5	10^{-2}	10^{-1}	1	3.5	10	
Number of choices for *M. darwiniensis*	28	2	–	–	–	–	S
	11	–	19	–	–	–	NS
	7	–	–	23	–	–	S
Number of choices for *P. adamsoni*	24	–	–	6	–	–	S
	17	–	–	–	13	–	NS
	4	–	–	–	–	26	S

Results confirm the quantitative estimation of about 20 pg of pheromone per worker in *M. darwiniensis*, and 700 pg of pheromone per pseudergate in *P. adamsoni*

S, result statistically significant; *NS*, result statistically non significant; $N=30$

trails of 10^{-1} sternal gland of *M. darwiniensis*/cm (17 choices for the *S. victoriensis* trail, 13 choices for the *M. darwiniensis* trail, $N=30$).

Whereas the quantity of trail pheromone in individual sternal glands of *P. adamsoni* was 175 times greater than in *S. victoriensis*, it was not possible in the present study to evaluate the quantity of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol in their natural trails by direct measurement.

Discussion

The major roles of the trail-following pheromones in termites are recruitment and orientation. For example, in species of the 'one-piece life type', the pheromone alerts and recruits termites to repair a breach in the nest; in species of the 'separate life type', it also induces recruitment and orientation of foragers outside the nest (Traniello 1982; Hall and Traniello 1985; Traniello and Leuthold 2000). However, we have shown for 'separate life type' species (Pasteels and Bordereau 1998; Wobst et al. 1999; Peppuy et al. 2001a, b) and in this study for the 'one piece' species *P. adamsoni* that both ecological types were able to orientate on artificial trails in an open field experiment. Under the same experimental conditions, the situation was shown to be different for *M. darwiniensis*, which showed no tendency to follow open field trails, independent of the solvents used for extracting the pheromone or the concentration of the trail. Furthermore, whereas pseudergates of *P. adamsoni* form single files of individuals to explore a new environment, just as do workers of 'separate life type' species, workers of *M. darwiniensis* explore the same new environment individually or in tandem. Therefore, the first aim of our study was to know whether the most ancestral extant termite, *M. darwiniensis*, secreted a trail-following pheromone.

Our observations showed that workers of *M. darwiniensis* use a trail-following pheromone secreted from their sternal glands. However, this termite remains the only known species in which a trail pheromone alone does not elicit orientation. Thus, in addition to a trail pheromone, this termite requires a physical constraint, such as a tunnel or gallery, to guide its movement. The question then arose as to whether this unique situation was due to the intrinsic behavior-eliciting properties of the pheromone or to other specific termite behavior. Results obtained with *P. adamsoni* showed that the nature and the

concentration of the pheromone were not responsible for this special behavioral trait of *M. darwiniensis*. Thus, *P. adamsoni* used the same trail pheromone as *M. darwiniensis*, and it was readily able to follow artificial trails made from sternal glands of *M. darwiniensis* in open field assays, whereas the same trails were not followed by workers of *M. darwiniensis*. The unique exploratory behavior of *M. darwiniensis* workers that forage individually or in tandem but not in single file might represent a specific stage in the evolution of the recruitment strategies in termites. Indeed, according to Traniello and Leuthold (2000), mass recruitment might have evolved in social insects from a communication of tandem running type. The ancestral function of the sternal gland in termites, that is the secretion of semiochemicals that mediate the tandem running of swarming imagos at the time of the nuptial promenade, would have evolved in derived species to induce mass recruitment and orientation of foragers. The unusual formation of worker tandems as observed in *M. darwiniensis* during exploratory behavior, therefore, supports this evolution.

Our observations also highlight the uniqueness of *M. darwiniensis* regarding the glandular source of its trail pheromone. Whereas for all other termite species the trail pheromone is secreted by only one sternal gland, it is secreted by at least two sternal glands (sternal glands 3 and 4) in *M. darwiniensis*, which is the only termite known to possess three sternal glands (Noirot 1969). Extracts of sternal gland 4 were much more active than those from sternal gland 3, whereas extracts from sternal gland 5 had minimal activity. Therefore, *M. darwiniensis* might represent an intermediary taxon in a regressive evolution from lost ancestors with numerous metameric glands to the present species of termites that possess only one sternal gland located on sternite 4 or 5. The higher secretory activity of sternal gland 4 of *M. darwiniensis* is significant, given the position of the sternal gland on sternite 4 in the other basal termite families Termopsidae and Hodotermitidae.

The identification of the trail-following pheromone of the ancestral termites *M. darwiniensis, P. adamsoni,* and *S. victoriensis* was the second major aim of our study. We first showed that these three species secreted the same trail pheromone, which was identified as the norsesquiterpene alcohol (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol. This is a new structure for termite trail pheromones. Until now, only unsaturated C12 aliphatic alcohols and a C20 hydrocarbon have been identified as termite trail pheromones: (3*Z*,6*Z*,8*E*)-3,6,8-dodecatrien-1-ol in numerous Rhinotermitidae and Termitidae (Matsumura et al. 1968; Tokoro et al. 1989, 1991; Laduguie et al. 1994; Pasteels and Bordereau 1998; Wobst et al. 1999), (3*Z*,6*Z*)-3,6-dodecadien-1-ol in *Ancistrotermes pakistanicus* (Termitidae Macrotermitinae; Robert et al. 2004), (*Z*)-3-dodecen-1-ol in several Termitidae (Peppuy et al. 2001a, b), and the diterpene hydrocarbon neocembrene in the Rhinotermitidae, Prorhinotermitinae (Sillam-Dussès et al. 2006), and in the Termitidae, Nasutitermitinae (Birch et al. 1972; MacDowell and Oloo 1984).

(*E*)-2,6,10-Trimethyl-5,9-undecadien-1-ol is known in the perfumery industry for its aromas of lemon and lily of the valley (Gora and Antczak 1980) but has never been identified previously in animals. However, an isomer of this compound, (*E*)-4,6,8-trimethyl-7,9-undecadien-5-ol, is secreted from sexual glands of female *Cryptocercus punctulatus* (Le Quéré et al. 1991) and *C. kyebangensis* (Grandcolas et al. 2001), subsocial cockroaches considered as sister taxa of *M. darwiniensis* (Eggleton 2001; Lo et al. 2003). Furthermore, a similar compound, 3,7,11-trimethyl-6,10-dodecadien-1-ol, is secreted by numerous species of bumblebees as a signal sex pheromone, and ants as a trail-marking pheromone (Francke and Schulz 1999; Luxova et al. 2004).

The biosynthesis of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol probably arises from mevalonate or farnesyldiphosphate (Prestwich 1981; Luxova et al. 2004; Hojo et al. 2007), whereas C12 alcohol pheromones probably arise from fatty acid biosynthesis,

especially from linoleic acid or oleic acid (Francke and Schulz 1999; Morgan 2004; Robert et al. 2004). The trail-following pheromone of *M. darwiniensis* and the Termopsidae *P. adamsoni* and *S. victoriensis* therefore represents a new chemical class of pheromones in termites.

The question arose as to whether (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol was the sole compound of the trail pheromone or only its major compound. The pheromones of insects are generally composed of blends, and several observations suggested the existence of multicomponent pheromones in termites (Kaib et al. 1982; Traniello 1982; Hall and Traniello 1985; Pasteels and Bordereau 1998; Traniello and Leuthold 2000; Peppuy et al. 2001a, b). In *M. darwiniensis* and *P. adamsoni*, (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol was the only specific compound detected from the surface of the sternal glands by SPME analysis. The GC fraction containing only (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol was also the only fraction that elicited trail-following. These data suggested that the trail pheromone of *M darwiniensis, P. adamsoni*, and *S. victoriensis*, is comprised solely of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol. Nevertheless, trail-following bioassays performed at high concentrations showed that the GC fraction following that of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol and containing cuticular hydrocarbons also elicited trail-following, although to a lesser degree. This could be explained by the presence of an additional undetected component of the trail pheromone, but not by the presence of the (Z)-isomer of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol that is more volatile than the (*E*)-isomer. We also demonstrated that cuticular hydrocarbons from workers were inactive in eliciting trail-following in *M. darwiniensis*. More likely, it is the result of a tailing peak of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol, as has been observed previously for dodecatrienol or dodecenol after preparative GC in termite species that secrete these compounds as a trail pheromone (Peppuy et al. 2001a; Bordereau, unpublished results).

For *M. darwiniensis*, the activity threshold of synthetic (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol was obtained from 1 ng/cm of trail, i.e., in the high value range known for the activity of termite trail pheromones (Pasteels and Bordereau 1998; Sillam-Dussès 2004). However, this threshold might be dependent on the absolute configuration of the compound, as has been demonstrated previously in insects (Mori 1998) and especially in bumblebees for 3,7,11-trimethyl-6,10-dodecadien-1-ol (Luxova et al. 2004). The chirality of (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol in *M. darwiniensis* has not yet been determined. For *P. adamsoni*, (*E*)-2,6,10-trimethyl-5,9-undecadien-1-ol elicited trail-following from 10^{-2} ng/cm of trail, a threshold typical of many other termite trail pheromones, for example with dodecenol in Macrotermitinae (Peppuy et al. 2001a; Sillam-Dussès 2004).

The third contribution of our study concerns phylogeny. Although chemical communication in termites appears to be highly conserved (Pasteels and Bordereau 1998; Sillam-Dussès 2004; Sillam-Dussès et al. 2006), our study on trail pheromones of ancestral termites highlights some novel phylogenetic data. First, female adults of the subsocial cockroach *Cryptocercus*, a sister taxon of *M. darwiniensis* (Inward et al. 2007), secrete an isomer of the trail pheromone of *M. darwiniensis* from their tergal glands. This would support the phylogenetic relationships between cockroaches and termites, although it also could be a simple phenomenon of convergence because these isomers might arise from different metabolic pathways. Second, whereas the position of the Termopsidae remains controversial from morphological and molecular phylogenetic studies (Eggleton 2001), we showed that the only extant representative of the Mastotermitidae, *M. darwiniensis*, secreted the same trail pheromone as the representatives of two subfamilies of the Termopsidae (Porotermitinae and Stolotermitinae). This supports a basal position of Termopsidae (Thompson et al. 2000) and that the Termopsidae would be socially the most

primitive termites (Thorne and Carpenter 1992; Thorne 1997; Thorne and Traniello 2003). Our results also confirmed the basal position of Stolotermitinae, in contrast to the recent morphological study of Klass et al. (2000) that suggested relationships between Stolotermitinae and Kalotermitidae, Rhinotermitidae and Termitidae. Moreover, our study indicates a heterogeneity within the Termopsidae with the Porotermitinae and the Stolotermitinae in one group and the Termopsinae in the other. Thus, the Termopsidae might not be monophyletic.

The chemical nature of trail pheromones of termites separates the basal termites Mastotermitidae, Termopsidae, and Hodotermitidae with C14 or C18 trail pheromones from the other families (Kalotermitidae, Serritermitidae, Rhinotermitidae and Termitidae) that secrete C12 or C20 trail pheromones (Sillam-Dussès 2004; Sillam-Dussès et al. 2006). This aspect deserves to be studied in other taxa.

Acknowledgement CB is grateful to Theodore Evans, Sil Ruenko, Patrick Gleeson (CSIRO Entomology, Canberra), Michael Neal, Brian Thistleton (Department of Primary Industries, Darwin), and John Holt (James Cook University, Townsville) for hospitality, assistance with termite collections, and discussions on *M. darwiniensis* biology. He also thanks Daniel Fouquet (CIRAD, Montpellier, France) for the gift of the *M. darwiniensis* colony initially established in 1973 at the BAM (Berlin, Germany). The authors thank the Australian authorities for the export permits Nos. PWS P20012196 and WT 2002-29397.

Introduction

The box tree pyralid, *Glyphodes perspectalis*, (Lepidoptera: Crambidae) is distributed in much of Asia, including throughout Japan, Korea, China, and India (Inoue et al. 1982). In Japan, the seriousness of damage to box trees, *Buxus microphylla* Sieb. et Zucc., caused by this pest has increased considerably (Kamizumi 1975; Maruyama and Shinkaji 1987, 1991, 1993; Maruyama 1992, 1993). Insecticide application has been used to control the box tree pyralid in parks and tree-lined streets in Japan. However, such control is complicated by the multiple generations of this pest that occur each year. For example, the Tokyo-Chiba population has three generations per year, with the adults appearing from mid-May to late June, from late July to late August and from late August to mid-September (Maruyama and Shinkaji 1987). If a synthetic pheromone for this insect were identified, it could be used to time insecticide applications more effectively, or it could be used as a possible control agent (e.g., mating disruption) by itself. We, therefore, undertook this study to identify the sex pheromone of this species.

Methods and Materials

Insect G. perspectalis larvae were collected at RIKEN, Saitama Prefecture, Japan, in 2005 and reared on box tree leaves. The insects were kept at 25°C under a 16:8 photoperiod. After emergence, females and males were separated and provided with 5% honey solution as food.

Preparation of Pheromone Extracts Ovipositor tips were excised with a pair of micro-scissors from 2- to 6-d-old virgin female moths, 3–6 hr into the scotophase. The tips were extracted in hexane for 15 min at room temperature. Extracts were placed in screw cap vials and stored at −20°C until analysis.

Chemicals Authentic (*Z*)-11-hexadecenal (Z11-16:Ald), (*E*)-11-hexadecenal (E11-16:Ald), and (*Z*)-11-hexadecen-1-ol (Z11-16:OH) were obtained from Pherobank (Wageningen, The Netherlands). Gas chromatography (GC) analyses showed these compounds to contain <0.1% of the corresponding geometric isomers.

Gas Chromatography GC analysis was conducted by using a DB-23 (30 m×0.25 mm ID, J&W Scientific, Folsom, CA, USA) and an HP-5MS (25 m×0.25 mm ID, Yokokawa Hewlett-Packard, Tokyo, Japan) column with a Shimadzu GC-17A gas chromatograph equipped with a flame ionization detector (FID) and a splitless injector system. Helium was used as the carrier gas. The DB-23 column temperature was set initially at 100°C for 2 min and then increased to 250°C at 5°C min^{-1}; the temperature of the detector and injector was 250°C. The HP-5MS column temperature was initially set at 150°C for 2 min and then increased to 260°C at 10°C min^{-1}.

Gas Chromatograph-Electroantennographic Detection Gas chromatograph-electroantennographic detection (GC-EAD) analysis was performed by using an Hewlett-Packard 5890 Series II GC equipped with an HP-5MS column. The GC had splitless injection and used helium as carrier gas. The oven temperature was held at 100°C for 2 min and then increased to 250°C at 5°C min^{-1}. The effluent from the column was split at a 1:1 ratio between the FID and

EAD. Humidified air (21°C) delivered the GC effluent to the antennal preparation that was connected to an amplifier via Ag–AgCl electrodes immersed in 0.1 M KCl.

Gas Chromatography-Mass spectrometry Gas chromatography-mass spectrometry (GC-MS) analyses were conducted with a Hewlett-Packard 5972 MSD coupled to a Hewlett-Packard 5890 series II gas chromatograph equipped with splitless injection and an HP-5MS column. The column oven temperature was held at 100°C for 2 min and then increased to 240°C at a rate of 10°C min^{-1}. Electron ionization MS was conducted at 70 eV.

Dimethyl Disulfide Derivatization Reaction of monounsaturated components with dimethyl disulfide (DMDS) was performed to determine double bond positions. Crude extracts were dissolved in 50 μl of hexane, and added to 50 μl of DMDS and 10 μl of iodine solution (60 mg in 1 ml of ether). The reaction was carried out in Teflon-lined screw vials, overnight at 40°C. After this, 200 μl of hexane, and 50 μl of $Na_2S_2O_3$ solution (5% in distilled water) were added. The extracts were dried with anhydrous Na_2SO_4 and concentrated for GC-MS analysis.

Laboratory Bioassays Laboratory bioassays were conducted in a screen cage (32×40×30 cm) under the same conditions as described above. A filter paper strip (2×4 cm), impregnated with 2 μl of a hexane solution containing a synthetic pheromone blend, was suspended 5 cm below the center of the top screen. Ten virgin males, 2–6 d after emergence, were released into the cage 3–6 hr into the scotophase. The total number of contacts of males, claspers extruded, with the treated filter paper was recorded for 5 min. Each bioassay was replicated four to ten times. The blend ratio of, Z11-16:Ald, E11-16:Ald, and Z11-16:OH in the treatments was 5:1.25:1, and the amount of Z11-16:Ald 100 ng/female. The differences among the mean numbers of contacts of males per replicate were tested by a Tukey–Kramer test. Significant differences are reported at $P<0.05$.

Field Bioassays Field bioassays were conducted in Box tree, *B. microphylla*, fields at RIKEN, Saitama Prefecture, Japan, May 20–August 20, 2006. Sticky traps (Sumika-Takeda Agrochemical Co., Ltd., Tokyo, Japan) were baited with grey halo-butyl isoprene blend elastomer septa (West Company, Singapore), which were renewed every month. Two traps of each treatment were used, with approximately 10 m as the distance between traps. The blend ratio of compounds, Z11-16:Ald, E11-16:Ald, and Z11-16:OH tested was 5:1.25:1, and the amount of Z11-16:Ald was 0.5 mg/septum. Traps were checked every 10 d for numbers of males. After checking, the sticky inserts were renewed, and trap positions moved. For statistical analysis, the number of males caught at each trap at each time of checking was transformed to $(X+0.5)^{1/2}$, and the differences among the means of catches each check (i.e., every 10 d) were tested by a Tukey–Kramer test. Significant differences are reported at $P<0.05$.

Results

GC-EAD Two major peaks were observed on the EAD trace of ovipositor extract of virgin *G. perspectalis*,; these corresponded with peaks (designated A and B) on the FID chromatogram (Fig. 1).

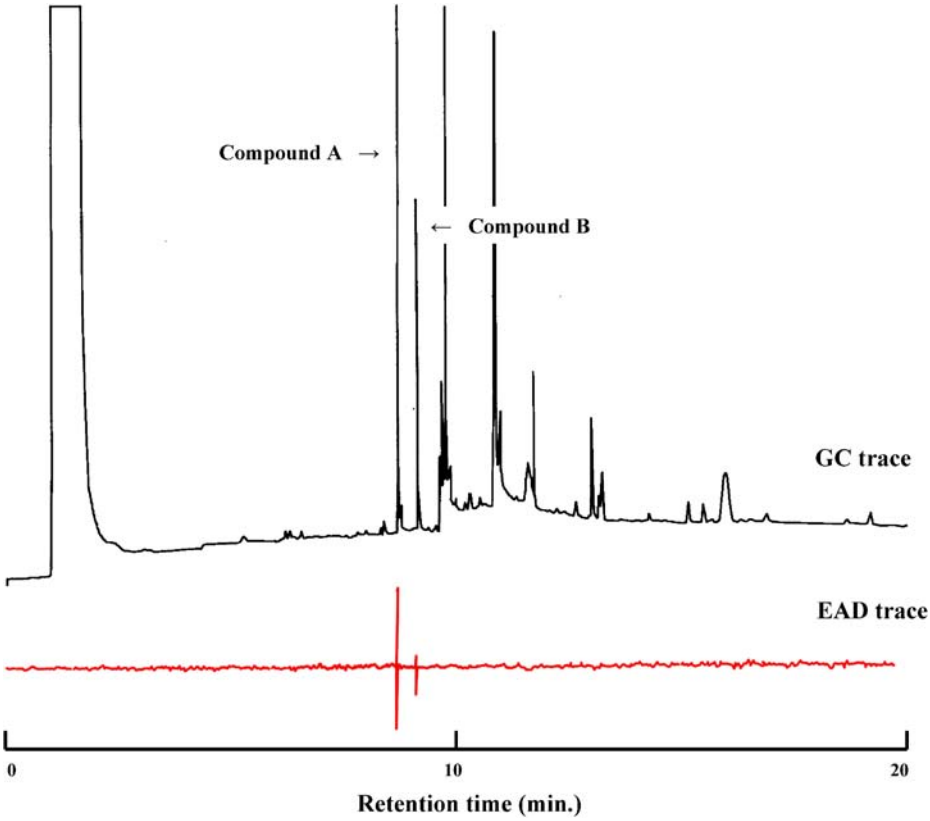

Fig. 1 Gas chromatograph-electroantennogram detection analysis of crude ovipositor extract of virgin *G. perspectalis* females using a male antenna. Compound A = (*Z*)- and (*E*)-11-hexadecenal, Compound B = (*Z*)-11-hexadecenol

Chemical Analyses GC-MS analysis of the crude extracts on the nonpolar HP-5MS column showed Peak A to have a mass spectrum characteristic of hexadecenal, containing *m/z* 238 (M^+, 1.0%), *m/z* 220 (M^+-18, 4.2 %), and *m/z* 55 (base peak, 100%). Peak B gave a mass spectrum characteristic of 11-hexadecen-1-ol, containing *m/z* 222 (M^+-18, 3.4%) and *m/z* 55 (base peak, 100%).

Mass spectral analysis of the DMDS reaction products showed the presence of two DMDS adducts (*m/z* 332) of hexadecenal derivatives. The mass spectrum indicated that both adducts had a double bond at the 11-position, based on fragment ions at *m/z* 332 (M^+), *m/z* 215 (A^+), *m/z* 117 (B^+), and *m/z* 61 (base peak). GC-MS analysis of the DMDS reaction products also showed the presence of an 11-hexadecen-1-ol derivative with a double bond at the 11-position, based on *m/z* 334 (M^+), *m/z* 217 (A^+, base peak), and *m/z* 117 (B^+).

The retention times of the three compounds on the polar DB-23 column coincided with those of synthetic Z11-16:Ald (13.73 min), E11-16:Ald (13.46 min), and Z11-16:OH (15.71 min). Similarly, on the nonpolar HP-5MS column, the retention times of the two peaks coincided with those of synthetic Z11-16:Ald (8.89 min), E11-16:Ald (8.89 min), and Z11-16:OH (9.82 min). The three compounds were, therefore, identified as Z11-16:Ald,

E11-16:Ald, and Z11-16:OH. The ratio of these three compounds in the crude extract was roughly 5:1.25:1, respectively, and the total amount approximately 100 ng/female.

Laboratory Bioassays In the laboratory bioassay that tested the three compounds, only Z11-16:Ald elicited significant responses from males (Fig. 2). The level of response to this compound was not significantly different from the level of response to crude extract. The addition of E11-16:Ald to Z11-16:Ald, Z11-16:OH to Z11-16:Ald, or Z11-16:OH to a mixture of Z and E11-16:Ald, gave no significant change in response compared to that to Z11-16:Ald alone (Fig. 2).

Field Bioassay The mixture of Z and E11-16:Ald, at the natural ratio, gave trap catches that were significantly higher than those in control traps (Fig. 3). However, the major compound, Z11-16:Ald, alone was not attractive to males in the field. The addition of Z11-16:OH to the mixture of Z and E11-16:Ald resulted in a significant depression of trap catches relative to the two component blend.

Discussion

On the basis of GC-EAD, GC, and GC-MS analysis, as well as DMDS derivatization, three compounds were identified in the pheromone gland of female *G. perspectalis*, namely, Z11-16:Ald, E11-16:Ald, and Z11-16:OH. In laboratory bioassays, Z11-16:Ald alone showed significant attractiveness to males. However, in field trials, this compound alone baited in traps did not elicit catches of male *G. perspectalis*. Instead a mixture of Z11-16:Ald and E11-16:Ald was required for significant trap catches (relative to the control). Furthermore, addition of Z11-16:OH to the two component blend resulted in a decreased trap catch of males, but in

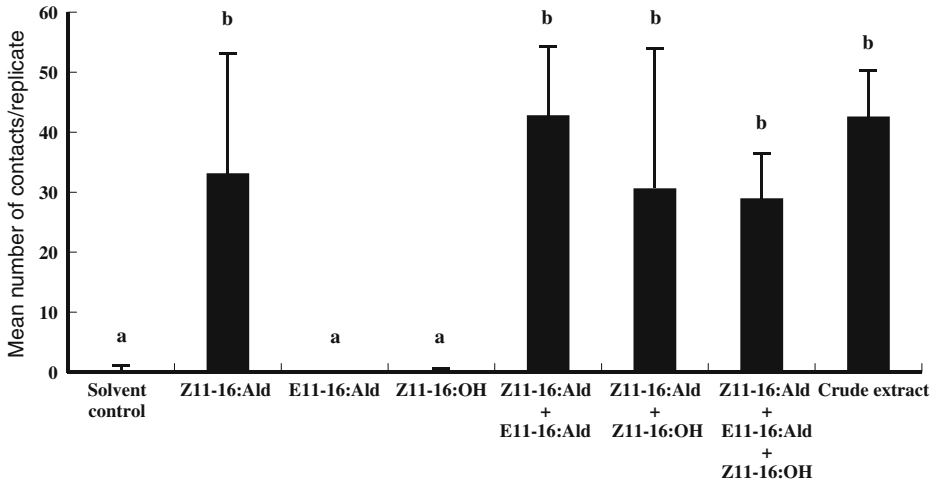

Fig. 2 Laboratory bioassay testing the responses (mean number of contacts/replicate) of male *G. perspectalis* to various treatments. Each treatment, consisting of ten males, was replicated four to ten times. Means with the same letter are not significantly different at $P<0.05$ (Tukey–Kramer test). *Bars* represent standard error of the means

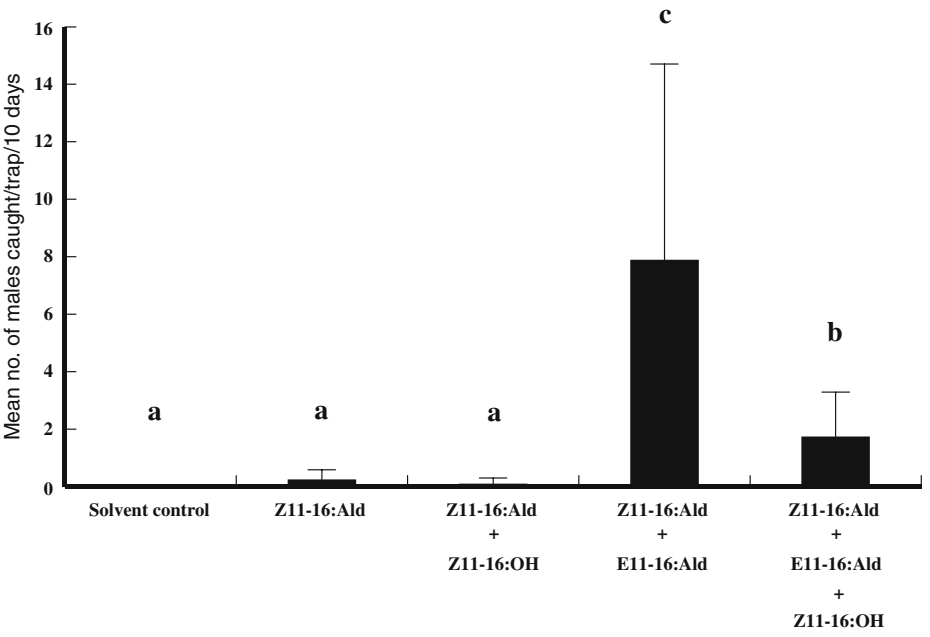

Fig. 3 Field catches of male *G. perspectalis* in traps baited with various chemical treatments. *Values followed by the same letter* are not significantly different at $P<0.05$ (Tukey–Kramer test). *Bars* represent standard error of the means

the laboratory bioassay, no antagonistic effect of the alcohol was found. These inconsistencies between the field and laboratory bioassays are likely due to the limited flight space in the cage not requiring males to maintain sustained upwind flight after activation by the respective blends.

Based on the field and laboratory bioassays, we conclude that the blend of Z11-16:Ald and E11-16:Ald in a ratio of roughly 5:1.25 comprises an attractive sex pheromone blend for *G. perspectalis*. Given the antagonistic effect of Z11-16:OH in the field trials, it seems likely that this compound is a biochemical precursor of the major component Z11-16:Ald (Bjostad et al. 1987; Jurenka and Roelofs 1993) and is not actually released by female *G. perspectalis*.

It is known that eight species of Crambidae utilize Z11-16:Ald as a sex pheromone component, including *Agriphila straminella* (Booij and Voerman 1984), *Catoptria permutatella* (Booij and Voerman 1984), *Chilo partellus* (Nesbitt et al. 1979; Hansson et al. 1995), *Chilo suppressalis* (Nesbitt et al. 1975; Tatsuki et al. 1983), *Chrysoteuchia topiaria* (Kamm and Mcdonough 1980), *Diatraea grandiosella* (Hedin et al. 1986), *Parapediasia teterrella* (Clark and Haynes 1990), and *Tehama bonifatella* (McDonough et al. 1982). However, none of these species utilize the opposite geometric isomer (E11-16:Ald), found in *G. perspectalis*, but rather utilize a positional isomer as a minor component. In another *Glyphodes* species, the mulberry pyralid, *G. pyloalis*, the major component of the female-produced sex pheromone has been identified as (*E, E, Z*)-10,12,14-hexadecatrienyl acetate (Seol et al. 1987, Honda et al. 1990). It is well-established that taxonomically related species of moths may utilize common sex pheromone components (Tamaki 1976). However, this trienic compound appears to have no direct structural relationship to the *G. perspectalis* compounds, except for the length of the carbon chain, even though the two

species are congeners. Studies on the sex pheromones of other *Glyphodes* species are warranted to determine what compounds, if any, are common in this genus.

Acknowledgements We are grateful to Sankei Chemical Co., Ltd. (Tokyo, Japan) and West Company (Singapore, Republic of Singapore) for supplying the rubber septa.

Planococcus minor and the closely related mealybug, *Planococcus citri* (Risso), are similar morphologically (Venette and Davis 2004). In a study that tested the synthetic sex pheromone of *P. citri* (Bierl-Leonhardt et al. 1981) in Taiwan, Tu et al. (1988) reported that some mealybugs thought to be *P. citri* were not attracted to synthetic sex pheromone. These unresponsive mealybugs were later identified as *P. minor* (Tu et al. 1988).

The sex pheromones of two *Planococcus* species, *P. citri* and *Planococcus ficus* Signoret, have been identified and are used for management of these pests (Moreno et al. 1984; Millar et al. 2002; Walton et al. 2006). Considering the importance of *P. minor* as a pest, identification of its sex pheromone would also be useful. We report in this paper the identification of the sex pheromone of *P. minor* as (*E*)-2-isopropyl-5-methyl-2,4-hexadienyl acetate.

Methods and Materials

Insects Mealybugs, originally collected from star fruit (*Averhoa carambola* L.) in the central area of Taiwan, were reared on pumpkins, *Cucurbita moschata* Duch. Poiret, at 25±1°C, 70±5% relative humidity under a photoperiod of 12L:12D. The identity of the species was confirmed by Dr. Doug Miller and colleagues at the United States Department of Agriculture in Beltsville, Maryland, USA.

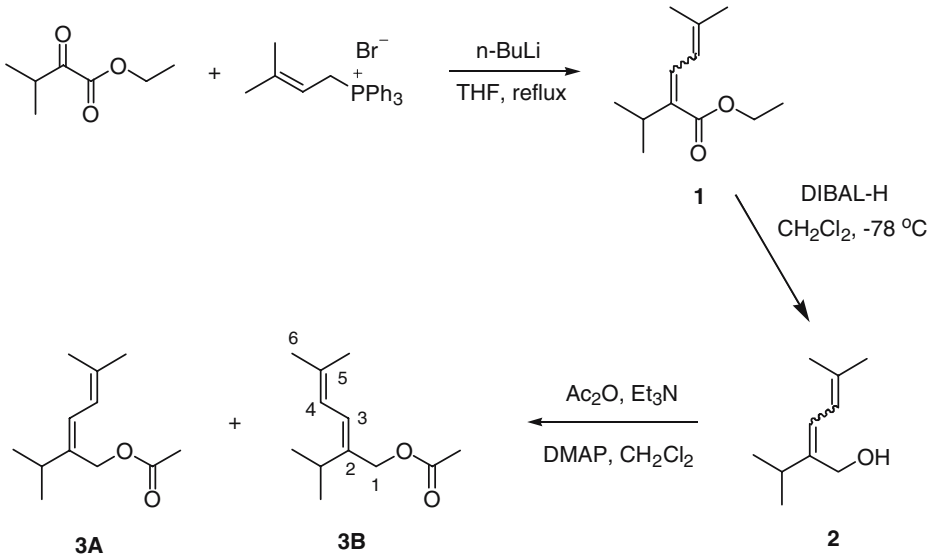
Pumpkins infested with ovisacs (60–70 ovisacs per pumpkin) were placed on a shallow plastic pan in a walk-in incubator. After 16 to 20 d, male nymphs of *P. minor* were separated by the method of Negishi et al. (1980) and Arai (2000). Briefly, male nymphs were allowed to crawl off the pumpkins and pupate on paper towels that covered the pumpkins. The paper towels were then placed in a container (21.5 cm ID.×6.5 cm in depth) in an incubator, and adult males allowed to emerge. Adult males, 2–3 d after emergence, were used in bioassays. Virgin females, after the last molt, were transferred to a new pumpkin with a fine paintbrush so as to prevent any mating with males that had not moved onto the paper towels. Each pumpkin was infested with about 1000–2000 females. Females were used for collection of pheromone 5–7 d after the final molt.

Collection of Pheromone Extract Pumpkins infested with virgin females were placed in a 30×30×30 cm^3 chamber, with purified air passing through the chamber. Because the males' responses to females were strongest during the first 2 hr of the photophase (Hwang and Chu 1987), the headspace volatiles were collected for the first 4 hr of the photophase on a tube (2.5 cm×8 mm ID) of Porapak-Q held in place with glass wool plugs. A total of 10,000–40,000 female-day equivalents (hereafter, FDE) of sex pheromone was collected in each tube. Aerations of uninfested pumpkins served as controls. Chemicals adsorbed on the Porapak-Q were extracted with pentane.

Analysis of Pheromone Extracts Extracts were analyzed by gas chromatography-mass spectrometry (GC-MS) with a ThermoQuest Trace GC interfaced to a Finnigan Trace mass spectrometer (electron impact ionization, 70 eV). The GC oven was held at 40°C for 1 min, then programmed at 10°C min^{-1} to 250°C. DB-5MS, DB-1, and DB-23 columns (all 30 m×0.25 mm ID, J & W Scientific, Folsom, CA, USA) were used for analyses. The injection was splitless, with helium as carrier gas. NMR spectra were recorded on Bruker Avance 300 and Bruker DRX500 spectrometers. High-resolution mass spectra (HRMS) were recorded on a JEOL JMS-700 mass spectrometer.

Isolation of Pheromone High-performance liquid chromatography (HPLC) was employed to isolate the sex pheromone by using an ECOM® Beta 10 Gradient Pump (Prague, Czech Republic), a silica gel column (250×4.6 mm, 5 μm, LDC/Milton Roy, Riviera Beach, FL, USA), a Rheodyne Model 7125 injector, and a DAD230 photo diode array detector (set at 200–650 nm) (ChromTech, Singapore). Extracts from collections of infested and uninfested pumpkins were eluted with a solvent gradient of pentane and diethyl ether (1.0 ml/min), starting with 100% pentane for 5 min, and then decreasing to 85% pentane over 75 min with a concomitant increase of diethyl ether. Fractions were collected every minute with a fraction collector. Fractions were concentrated under a stream of nitrogen and analyzed by GC-MS.

Hydrolysis of the Unknown The fraction containing the unknown (ca. 1 μg) was dissolved in 300 μl of ethanol, and two drops of 1 N NaOH were added. The reaction mixture was kept in a water bath at 35°C for about 30 min before 1 N HCl was added to neutralize the solution. The product was extracted with hexane. The hexane solution was dried by passage through a short plug of anhydrous $MgSO_4$. After concentration under a stream of nitrogen, the product was analyzed by GC-MS.



Hydrogenation of the Unknown One microgram of the isolated unknown was reduced in a septum-capped vial by catalytic reduction with 5% Pd on carbon and a balloon of H_2. After about 30 min, the reaction mixture was filtered through powdered $MgSO_4$ to remove the catalyst. The filtrate was analyzed by GC-MS.

Chemicals Triphenylphosphine, ethyl 3-methyl-2-oxobutyrate, 1-bromo-3-methyl-2-butene, *n*-butyl lithium (*n*-BuLi), tetrahydrofuran (THF), dimethylaminopyridine (DMAP), triethylamine, and acetic anhydride were obtained from Sigma-Aldrich Co. (Milwaukee, WI, USA). Diisobutylaluminum hydride (DIBAL-H) was from Strem Chemicals, Inc. (Newburyport, MA, USA), and 2-isopropyl-5-methylhexyl acetate was purchased from Tokyo Kasei Kogyo Co., Ltd. (Tokyo, Japan).

Laboratory Bioassay A turntable olfactometer (Tashiro et al. 1969) was used with the modifications described below. The turntable was set up in a room with lighting of 940± 120 lx and temperature at 25±2°C, and rotated at 0.67 rpm to reduce any positional effects. Fifteen to 20 sticky traps (6×6 cm^2) were placed on the wheel of a 2-m-diameter turntable, with treatments or controls placed at the center of the sticky traps. Males to be used in bioassays were kept in the dark from 17:00 of the previous day until 09:00 the day of the bioassay, with bioassays carried out during the first 4 hr of the photophase. Males (300–500 for each replicate) were released from a glass dish (20 cm i.d.) in the center of the turntable. Pieces of Parafilm-wrapped pumpkins (1.5×1.5×1 cm), with only the pumpkin skin exposed, were put in a plastic tube (3 cm i.d.×1.5 cm deep) as neutral controls. Pumpkins wrapped in the same way as the neutral controls but infested with 20 females were used as positive controls.

Synthesis of 2-Isopropyl-5-methyl-2,4-hexadienyl acetate (3) The geometric isomers **3A** and **3B** were synthesized as shown in Scheme 1. Details of the procedure are described below.

Preparation of (3-methyl-2-butenyl)Triphenyl phosphonium Bromide A mixture of triphenylphosphine (2.62 g, 1 mmol) and 1-bromo-3-methyl-2-butene (1.49 g, 1 mmol) was

Scheme 1 Synthesis of geometric isomers **3A** and **3B**

refluxed overnight in dry toluene (30 ml) under N_2. After cooling, the precipitate was filtered and washed with toluene. The crystalline product was dried under vacuum to give the phosphonium salt (4.11 g, yield 100%) as a white solid: mp 236–237°C (mp 235–236°C, Armesto et al. 1995). ^{1}H NMR ($CDCl_3$, 300 MHz): δ 1.26 (3H, d, J=4.2 Hz), 1.64 (3H, d, J=6.0 Hz), 4.62 (2H, m), 5.12 (1H, m), 7.88–7.64 (15H, m).

*Preparation of Ethyl 2-isopropyl-5-methyl-2,4-hexadienoate (***1***)* *n*-BuLi (1.6 M, 6.3 ml, 10 mmol) was added slowly to a solution of (3-methyl-2-butenyl)triphenylphosphonium bromide (4.11 g, 10 mmol) in a 40-ml dry THF under N_2 at 0°C, until the solution turned deep red. The reaction mixture was brought to reflux. Ethyl 3-methyl-2-oxobutyrate (1 g, 6.9 mmol in 10 ml of dry THF) was added slowly and the mixture refluxed for another 15 hr. Water (10 ml) was added to the cooled reaction mixture and then 10% aqueous NH_4Cl to neutralize the solution. The mixture was extracted with ether (20 ml×3), and the ether extracts dried with anhydrous $MgSO_4$, filtered, and concentrated. Purification of the residue on a silica gel column (hexane–CH_2Cl_2 3:1) afforded a 1.3:1 mixture of stereoisomers of ethyl 2-isopropyl-5-methyl-2,4-hexadienoate (**1**, 0.71 g, yield 72%) determined by ^{1}H NMR spectroscopy. ^{1}H NMR spectrum ($CDCl_3$, 300 MHz) gave two sets of closely related signals: δ 1.10 (7.8H, d, J=6.9 Hz), 1.20 (6H, d, J=6.9 Hz), 1.31 (3.9H, t, J=7.2 Hz), 1.33 (3H, t, J=7.2 Hz), 1.82 (3.9H, s), 1.84 (3.9H, s), 1.88 (3H, s) 1.89 (3H, s), 2.79 (1.3H, septet, J=6.9 Hz), 3.03 (1H, septet, J=6.9 Hz), 4.12–4.29 (4.6H, m), 6.21 (1H, d, J=12.0 Hz), 6.52 (1.3H, d, J=12.0 Hz), 6.56 (1.3H, d, J=12.0 Hz), 7.31 (1H, d, J=12.0 Hz). The ^{13}C NMR spectrum gave 24 resonances, as expected for the mixture of two geometric isomers: δ 14.0 (2×C), 17.8, 18.4, 20.8 (2×C), 21.8 (2×C), 26.4, 26.6, 27.0, 31.4, 59.6, 59.7, 120.1, 121.9, 129.3, 133.0, 134.1, 135.5, 140.6, 143.6, 167.9, and 168.3.

*Preparation of 2-Isopropyl-5-methyl-2,4-hexadienol (***2***)* DIBAL-H (20% in hexane, 3.6 ml, 4.0 mmol) was added to a solution of the 1.3:1 mixture of ester **1** (294 mg, 1.5 mmol) in CH_2Cl_2 (15 ml) at −78°C under N_2. The reaction mixture was stirred for 30 min and then quenched with −78°C MeOH. Celite (1 g) and $Na_2SO_4{\cdot}10H_2O$ (1 g) were added and the

suspension warmed to room temperature and stirred for another 2 hr (Takano et al. 2001). Filtration and concentration of the resulting mixture, followed by flash chromatography on silica gel (CH_2Cl_2), gave a 1.3:1 mixture of the geometric isomers of alcohol **2** (217 mg, 94%) as a colorless oil. ^{1}H NMR ($CDCl_3$, 300 MHz): δ 1.08 (13.8H, d, J=6.9 Hz), 1.78 (7.8H, s), 1.82 (6H, s), 2.49 (1.3H, septet, J=6.9 Hz), 2.99 (1H, septet, J=6.9 Hz), 4.16 (2H, s), 4.24 (2.6H, s), 6.23–6.07 (4.6H, m). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 18.1 (2×C), 21.4 (2×C), 21.9 (2×C), 26.4, 26.5, 28.1, 33.8, 59.4, 64.3, 119.9, 120.1, 121.1, 122.2, 135.7, 135.9, 143.2, 144.0.

*Preparation of 2-Isopropyl-5-methyl-2,4-hexadienyl acetate (***3A** *and* **3B***)* To a solution of compound **2** (123 mg, 0.8 mmol) in CH_2Cl_2 (10 ml) was added acetic anhydride (204 mg, 2.0 mmol), triethylamine (202 mg, 2.0 mmol), and 4-dimethylaminopyridine (1.3 mg, 0.01 mmol) at room temperature. The solution was stirred for 30 min and then quenched with water. The reaction mixture was extracted with CH_2Cl_2 (10 ml×3). Extracts were combined, dried over $MgSO_4$, filtered, and concentrated *in vacuo* (Takano et al. 2001). Purification on a silica gel column afforded compound **3** (139 mg, 89%) as a mixture of two isomers. The mixture was separated by HPLC, with the same gradient program as that used for isolation of pheromone from the aeration collections, collecting fractions every 0.25 min. Compound **3A** gave a ^{1}H NMR ($CDCl_3$, 300 MHz) spectrum as follows: δ1.07 (6H, d, J=6.9 Hz, 2-CH(CH_3)$_2$), 1.79 (3H, s, 5-CH_3), 1.82 (3H, s, H-6), 2.07 (3H, s, 1-OCOCH_3), 2.44 (1H, septet, J=6.9 Hz, 2-CH(CH$_3$)$_2$), 4.72 (2H, s, H-1), 6.08 (1H, d, J= 11.7 Hz, H-4), 6.29 (1H, d, J=11.7 Hz, H-3). ^{13}C NMR ($CDCl_3$, 75 MHz) of compound **3A**: δ18.2 (5-*C*H$_3$), 21.1 (1-OCO*C*H$_3$), 21.8 (2-CH(*C*H$_3$)$_2$), 26.5 (C-6), 33.8 (2-*C*H(CH$_3$)$_2$), 61.1 (C-1), 120.0 (C-4), 124.4 (C-3), 136.9 (C-5), 138.3 (C-2), 171.3 (1-O*C*OCH$_3$). MS (m/z; %): 196 (5, M$^+$), 121 (100); HRMS m/z 196.1462 [M]$^+$ (calculated for $C_{12}H_{20}O_2$ 196.1463); UV (CH_2Cl_2) λ_{max} (log ε) 248 (4.9) nm. Compound **3B** ^{1}H NMR ($CDCl_3$, 300 MHz): δ1.07 (6H, d, J=6.9 Hz, 2-CH(CH_3)$_2$), 1.79 (3H, s, 5-CH_3), 1.82 (3H, s, H-6), 2.07 (3H, s, 1-OCOCH$_3$), 3.01 (1H, septet, J=6.9 Hz, 2-CH(CH$_3$)$_2$), 4.60 (2H, s, H-1), 6.08 (1H, d, J= 11.7 Hz, H-4), 6.23 (1H, d, J=11.7 Hz, H-3). ^{13}C NMR ($CDCl_3$, 75 MHz): δ 18.2 (5-*C*H$_3$), 21.2 (1-OCO*C*H$_3$ and 2-CH(*C*H$_3$)$_2$), 26.5 (C-6), 28.1 (2-*C*H(CH$_3$)$_2$), 66.6 (C-1), 119.8 (C-4), 125.1 (C-3), 137.3 (C-5), 137.6 (C-2), 170.9 (1-O*C*OCH$_3$). MS m/z (%): 196 (5, M$^+$), 121 (100); HRMS m/z 196.1460 [M]$^+$ (calculated for $C_{12}H_{20}O_2$ 196.1463); UV (CH_2Cl_2) λ_{max} (logε) 248 (4.4) nm. Neat compound 3 gave diagnostic IR absorptions at 1707 (C=O), 1637 cm^{-1} (C=C).

Results

Analysis Comparison of the extracts of volatiles from mealybug-infested and uninfested pumpkins revealed one significant insect-produced compound, which was isolated as a single component of the fraction eluting at 50 min by HPLC. The Kovats Indices (KI) of this unknown were 1687 on the DB-23 column, 1347 on the DB-1 column, and 1350 on the DB-5MS column. In the bioassay, a 100-ng sample of the isolated compound attracted a mean (N=6) of 25.3 male mealybugs, whereas 20 females attracted a mean (N=6) of 3.2 male mealybugs, suggesting that the unknown was active. The mass spectrum of the compound (Fig. 1) showed significant fragments at m/z (%): 43 (18), 69 (7), 91 (13), 93 (18), 105 (13), 121 (100), 123 (11), 136 (16), with a small molecular ion at 196 (5). The presence of significant peaks at m/z 43 ($CH_3C{\equiv}O^+$) and 136 (M^+-CH_3COOH) and the

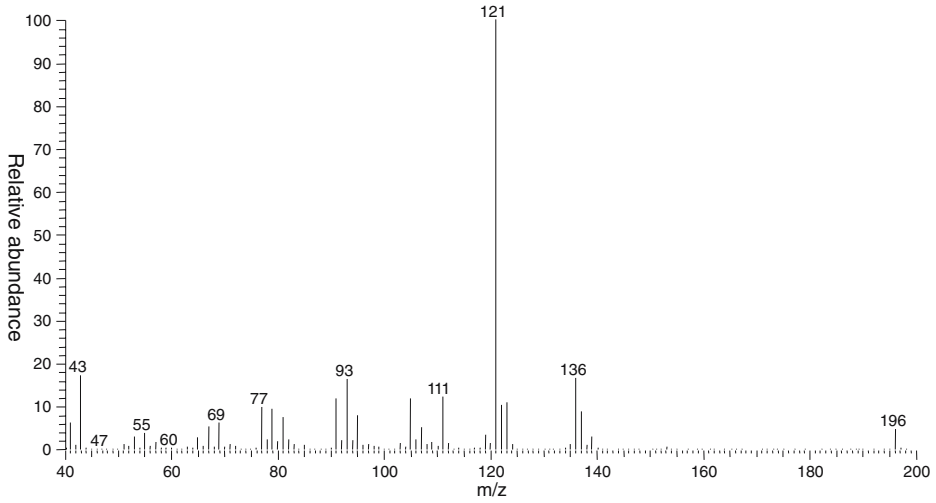


Fig. 1 EI mass spectrum (70 eV) of the active component in pheromone collections from female *Planococcus minor*

absence of other prominent fragmentations between *m*/*z* 196 and 136, suggested that the unknown was an acetate ester. After base hydrolysis, a compound with molecular weight *m*/*z* 154 was found in the reaction mixture. The mass spectrum (Fig. 2) of the hydrolyzed product showed fragment ions with *m*/*z* (%): 43 (34), 55 (38), 69 (34), 93 (46), 111 (100), and 123

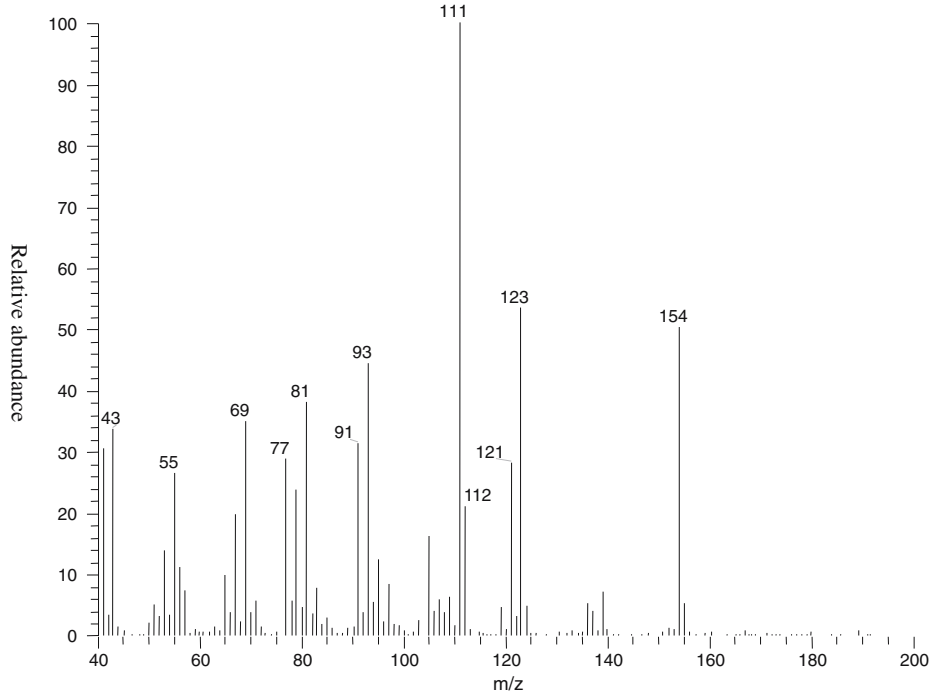

Fig. 2 EI mass spectrum (70 eV) of hydrolyzed active component in pheromone collections from female *Planococcus minor*

(54), and a molecular ion of 154 (50). The molecular weight of the hydrolyzed product was 42 mass units less than that of the unknown, supporting our hypothesis that the unknown was an acetate ester.

The mass spectrum (Fig. 3) of the hydrogenated product showed fragment ions with *m*/*z* (%): 43 (100), 61 (8), 69 (96), 84 (58), 97 (38), 112 (11), 140 (14), and 157 (6). Comparison of the mass spectrum of the hydrogenated product with the NIST mass spectral database suggested a possible structure for the hydrogenated product as 2-isopropyl-5-methylhexyl acetate. This was confirmed by comparing the GC retention time and the mass spectrum of the hydrogenated compound from the insect with that of an authentic standard. These results indicated that the unknown had a carbon skeleton of 2-isopropyl-5-methylhexyl acetate with two sites of unsaturation.

HPLC collection yielded about 3 μg of the unknown from 37,000 FDE of crude extract. The ^{1}H NMR spectrum of the unknown showed signals at δ 1.79 (3H, s), 1.82 (3H, s), 2.07 (3H, s), 4.60 (2H, s), 6.08 (1H, d, J=11.7 Hz), and 6.23 (1H, d, J=11.7 Hz). The six-proton singlet at δ 1.79 and 1.82 (two allylic methyl groups), typical acetyl protons (δ 2.07), oxygenated methylene protons (δ 4.60), and two vinylic protons mutually coupled with a coupling constant of 11.7 Hz, suggested a skeleton of 2-substituted-5-methyl-2,4-hexadienyl acetate. In addition, an isopropyl moiety was revealed by the signals at δ 1.07 (6H, d, J=6.9 Hz) and 3.01 (1H, septet, J=6.9 Hz). On the basis of the above, the unknown compound was identified as 2-isopropyl-5-methyl-2,4-hexadienyl acetate.

Synthesis The stereochemistry of the unknown compound was determined by a non-stereoselective synthesis followed by separation of the (*Z*)- and (*E*)-2-isopropyl-5-methyl-2,4-hexadienyl acetates (**3A** and **3B**). Thus, Wittig reaction between ethyl 3-methyl-2-

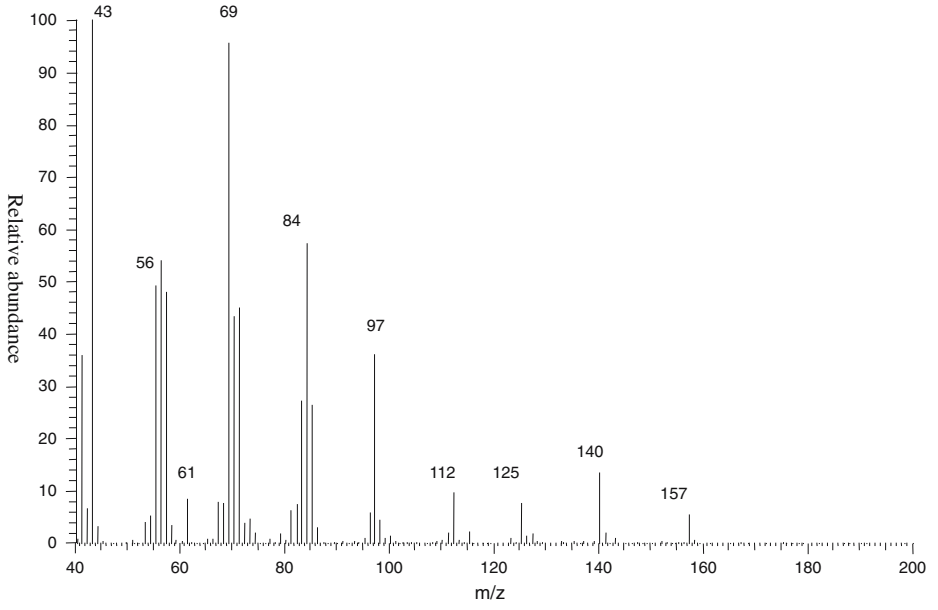

Fig. 3 EI mass spectrum (70 eV) of the hydrogenation product of the active component in pheromone collections from female *Planococcus minor*

oxobutyrate and the ylide from (3-methyl-2-butenyl)triphenylphosphonium bromide (formed by addition of *n*-BuLi) produced an isomeric mixture of **1** in a 1.3:1 ratio. GC-MS analysis of the mixture indicated that the two components had KIs of 1639 and 1651, respectively, on the DB-23 column. The two compounds exhibited similar mass fragmentation patterns, with fragments of *m/z* (%) 81 (28), 91 (21), 107 (49), 123 (100), 135 (12), 153 (25), 181 (28), and a molecular ion at 196 (41). Reduction of compound **1** with DIBAL-H yielded alcohols **2**, with KIs of 1691 and 1733, respectively, on the DB-23 column. The two isomers gave similar mass fragmentation patterns, with *m/z* (%) of 69 (40), 81 (34), 91 (36), 93 (42), 111 (100), 125 (55), and 154 (M^+, 53). The mixture was acetylated to produce the acetates **3** as a (*Z*)- and (*E*)- mixture with KIs of 1666 and 1687, respectively, on the DB-23 column. Compound **3A** eluted at 49.6 min and compound **3B** eluted at 50.3 min from the silica HPLC column. The KI, mass spectrum, and ^{1}H NMR data of compound **3B** were the same as that of the active compound isolated from the insect extracts. The stereochemistry of **3A** and **3B**, and the full assignment of ^{1}H and ^{13}C NMR signals, were obtained from 2D-COSY, NOESY, HMQC, and HMBC spectra as described below.

In **3A**, HMBC correlations were observed between C-1 (δ 61.1) and the proton at δ 6.29, as well as C-1 and the methine proton (δ 2.44) of the isopropyl group, indicating that the more downfield vinylic proton at δ 6.29 was H-3. In addition, the 2D NOESY NMR spectrum of **3A** (Fig. 4) indicated that the vinylic proton with a chemical shift of δ 6.08 had

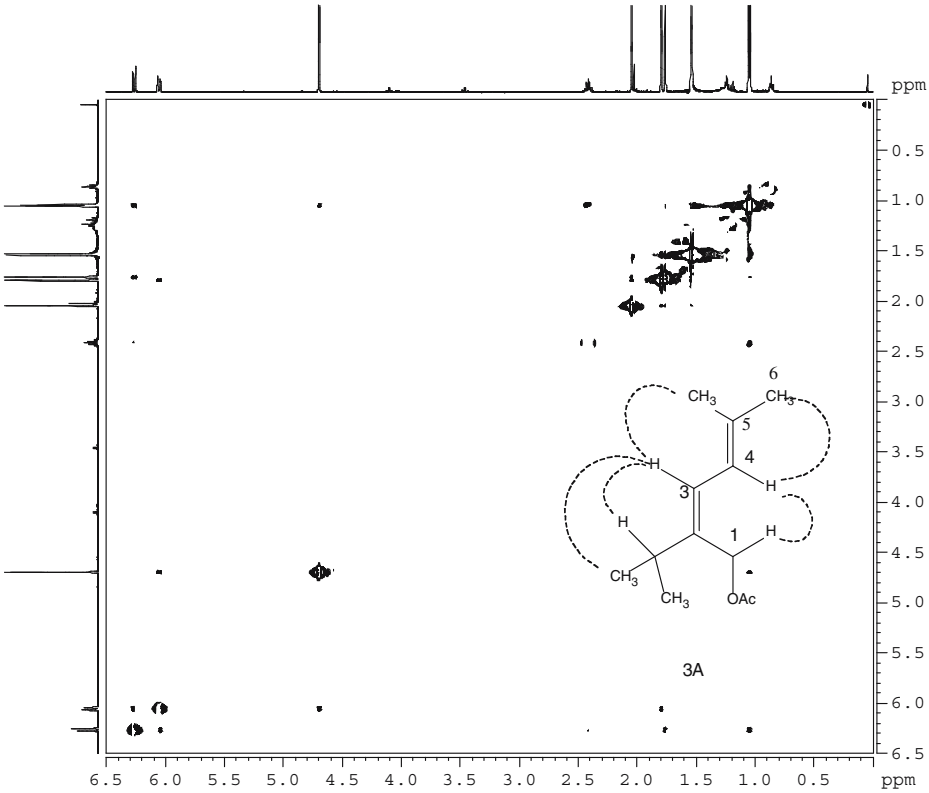

Fig. 4 2D-NOESY NMR spectrum and the key NOE correlations (shown with dashed curves) of compound **3A**

cross couplings with H-1 (δ 4.72) and H-6 (δ 1.82). The vinylic proton with a chemical shift of δ 6.29 had cross coupling with the isopropyl group (δ 1.07 and δ 2.44) and the 5-methyl group (δ 1.79). These NOE correlations suggested the configuration of the double bond in this isomer was *Z*. Thus, the structure of compound **3A** was assigned as (*Z*)-2-isopropyl-5-methyl-2,4-hexadienyl acetate. The NOE effects are summarized in Fig. 4.

Similarly, in **3B**, HMBC correlations were observed between C-1 (δ 66.6) and the proton at δ 6.23, as well as C-1 and the methine proton at δ 3.01 of the isopropyl group, suggesting that the more downfield vinylic proton at δ 6.23 was H-3. In addition, the 2D NOESY NMR spectrum of **3B** (Fig. 5) indicated that the vinylic proton with chemical shift of δ 6.08 had cross couplings with the methine proton (δ 3.01) of the isopropyl group and H-6 (δ 1.82), but not with the methyls of the isopropyl group; presumably, the two methyl groups were turned away from the vinyl proton because of steric repulsion. These data indicated that the alkenyl group (C4-C6) was *cis* to the isopropyl group. The vinylic proton with a chemical shift of δ 6.23 had cross couplings with the 5-methyl group (δ 1.79) and H-1 (δ 4.6). Thus, the downfield vinyl proton must be *cis* to the methylene proton. Thus, the structure of compound **3B** was assigned as (*E*)-2-isopropyl-5-methyl-2,4-hexadienyl acetate. The NOE effects are summarized in Fig. 5.

As a result of the matching NMR spectra, KIs on GC, and mass spectra, the pheromone of the mealybug *P. minor* was identified as (*E*)-2-isopropyl-5- methyl-2,4-hexadienyl acetate.

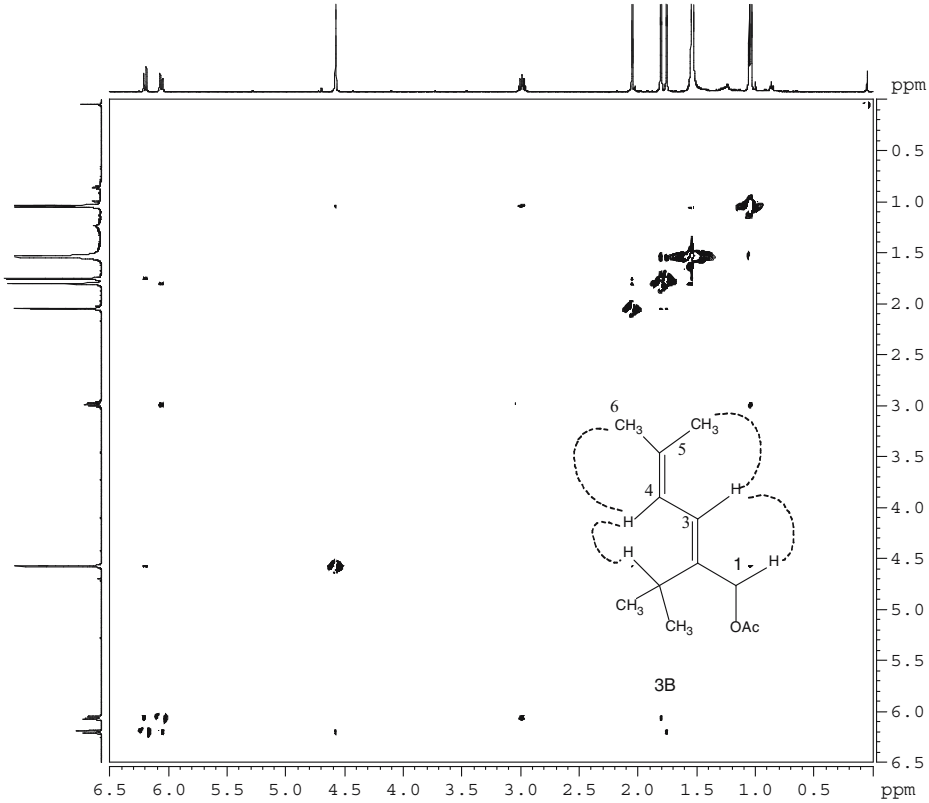

Fig. 5 2D-NOESY NMR spectrum and the key NOE correlations (shown with dashed curves) of compound **3B**

Table 1 Number of male mealybugs attracted to various treatments

Treatment	No. of Males Attracted (mean ± S. D.); N=6
Synthetic compound 3B (*E*) isomer[b] (150 ng)	91.2±19.3 a[a]
Compound isolated from mealybug volatiles (100 ng)	25.3±19.1 b
20 females on pumpkin	3.5±2.8 c
Mixture of synthetic 3A (*Z*) isomer[b] (82 ng) and 3B (*E*) isomer (58 ng)	3.2±2.6 c
Uninfested pumpkin	0 c

[a] Means followed by the same letter are not significantly different at the 5% level (Duncan's multiple range test).
[b] 2-isopropyl-5-methyl-2,4-hexadienyl acetate

Bioassay of Synthetic Pheromone The results for bioassays of the synthetic materials vs. the compound from volatiles of female mealybugs, live females, and controls are shown in Table 1. Synthetic (*E*)-2-Isopropyl-5-methyl-2,4-hexadienyl acetate was more attractive ($P<0.05$) to male mealybugs than any of the other treatments. Interestingly, the other stereoisomer appeared to antagonize attraction, with the mixture of isomers (59% of 3A [*Z*-isomer] and 41% of compound 3B [*E*-isomer]) being unattractive (i.e., not significantly different from the number attracted to the uninfested pumpkin control) to males.

Discussion

We identified the sex pheromone for the passionvine mealybug, *P. minor*, a major pest of economically important crops. Male mealybugs were attracted to the (*E*) isomer of 2-isopropyl-5-methyl-2,4-hexadienyl acetate. That male bugs were attracted in greater numbers to the pure (*E*)-isomer, rather than to a mixture of (*E*)- and (*Z*)-isomers, suggests that a stereospecific synthesis of the (*E*)-isomer will be required for practical use of this pheromone.

The structure of the sex pheromone compound of *P. minor* represents another example of the irregular terpenoid motif of the sex pheromones of pseudococcid species. The sex pheromone of *Pseudococcus viburni* (Millar et al., 2005) is a monoterpene incorporating a cyclopentane unit. The sex pheromones of *Pseudococcus cryptus* (Arai et al. 2003) and *P. citri* (Bierl-Leonhardt et al. 1981) are monoterpenes with a cyclobutane moiety. The sex pheromone of *P. ficus* (Hinkens et al. 2001) is an acyclic monoterpene with the same basic carbon skeleton as the compound we identified here. All of these species appear to use single components as attractants.

Further work will seek to develop a stereospecific synthesis of (*E*)- 2-isopropyl-5-methyl-2,4-hexadienyl acetate, as well as determine optimum doses and longevity of synthetic pheromone lures.

Acknowledgment The authors thank Penny Gullan of the University of California, Davis for preliminary identification of the species and Doug Miller and his colleagues at the US Department of Agriculture in Beltsville, Maryland, USA for confirming the species identity. The authors thank Jocelyn Millar of the University of California, Riverside for suggestions on the synthesis of the pheromones.

Introduction

All cat species (Felidae) use their urine for communication (Macdonald 1985; Asa 1993; Mellen 1993; Ogata and Takeuchi 2000) and have two distinct patterns of behavior when depositing fluid from the urinary tract. These are *normal urination*, during which, the animal squats on the ground and releases a stream of urine, and *spray marking*, whereby urine is ejected by the animal while it stands with its hindquarters towards the target and its tail lifted vertically. The precise direction of spray varies with the species, and adult males typically spray at a higher rate than females, although adult females of most species also spray mark (Schaller 1972; Macdonald 1985; Mellen 1993; Brahmachary and Singh 2000). In both tiger, *Panthera tigris*, and lion, *P. leo*, the fluid released comprises normal urine mixed with a whitish lipid precipitate, which is also present in the bladder. The average total lipid content of the marking fluid of tiger is 1–2 mg/ml of urine (Poddar-Sarkar 1996), and as much as 20 g of lipid a day is excreted (Hewer et al. 1948). When released during normal urination, the lipids do not leave marks on the ground. When sprayed on vertical objects, however, the lipids of tiger urine stick to the surface and in time turn into a dark viscous deposit with a distinct odor (Smith et al. 1989). Odors of tiger marking fluid may last up to 3 weeks and, when fresh, can be detected up to 3 m away (Smith et al. 1989). Marking fluid from lions does not leave the same black long-lived deposit of lipids as that from tigers (Anderson and Vulpius 1999), whereas no lipids have been found in urine from cheetah, *Acinonyx jubatus*, leopard, *P. pardus*, or puma, *Felis concolor* (Asa 1993).

Intact male domestic cats, *Felis catus*, frequently spray urine that has a characteristic species-specific aroma onto vertical objects, although the locations and rates of marking vary between studies (Macdonald 1985). Felinine, a sulfur-containing amino acid (2-amino-7-hydroxy-5,5-dimethyl-4-thiaheptanoic acid), has been identified in the urine of several members of the Felidae including the domestic cat (Datta and Harris 1951, 1953; Westall 1953; Hendriks et al. 1995a) where urinary felinine concentration is positively correlated to blood plasma testosterone concentration. Intact males produce the greatest amount of urinary felinine (122 μmol kg^{-1} d^{-1}) compared with 41, 36, and 20 μmol kg^{-1} d^{-1} in castrated males, intact females, and castrated females, respectively (Hendriks et al. 1995b). Felinine is present in the urine from 6 mo of age (Tarttelin et al. 1998) and is detectable in the urine, kidney, and bladder (Hendriks et al. 2001). It is present in the blood as a precursor tripeptide, γ-glutamylfelinylglycine, which is a glutathione analog. Felinine production is gender-linked and is believed to be synthesized in tissues other than the kidney (Rutherfurd et al. 2002). The biological role of felinine is still unclear, but it is a urinary component involved in domestic cat spray marking. It is likely that it degrades to another compound or compounds that give rise to the distinctive "tom cat" urine odor (Hendriks et al. 1995a). Felinine has also been detected in the urine of ocelot, *F. pardalis*, Indian leopard cat, *F. bengalensis* (Datta and Harris 1951), and bobcat, *F. rufus* (Datta and Harris 1953). However, reports differ for leopards (Datta and Harris 1953; Roberts 1963), and felinine has not been found in the urine of other members of *Panthera* (Hendriks et al. 1995a; W. H. Hendriks, personal communication). Chemical signals among non-domestic cats appear to be more complex than those of the domestic cat. More than 50 different volatile compounds have been identified from lion urine, with no two individuals having exactly the same chemical composition (Anderson and Vulpius 1999). Seven compounds were found in most individual lions tested (male and female), whereas urine from males contained much more 2-butanone than that from females. Of the compounds found in only-male samples, none was detected in all males. Thus, it is unclear whether one or more of these compounds provides a male-specific signal.

Many healthy mammals exhibit an obligatory proteinuria (Monroe et al. 1989), and there is evidence that some of these proteins have a function in communication. More than 100 protein components have been identified in rat urine, including signaling proteins, enzymes, and pheromone binding proteins (Thongboonkerd et al. 2003). Cauxin (carboxylesterase-like urinary excreted protein) is a novel 70 kDa protein that is excreted in the urine of the domestic cat (Miyazaki et al. 2003), bobcat, *Lynx rufus*, and lynx, *L. lynx*, but, as yet, has not been detected in the urine of any other genus of Felidae (Miyazaki et al. 2006a). It is expressed in the epithelial cells of the straight proximal tubules and secreted from the renal tubular cells into the urine (Miyazaki et al. 2006a). Cauxin shares 40% sequence identity with a group of mammalian carboxylesterases that hydrolyze ester, thioester, and amide bonds. It is the main urinary protein of healthy male and female domestic cats, and intact males have higher levels of cauxin in their urine relative to neutered males, females, or cats of 3 mo or less (Miyazaki et al. 2003). Intact males excrete approximately 0.5 mg cauxin per milliliter of urine, decreasing by more than 90% after castration (Miyazaki et al. 2006a). Recently, Miyazaki et al. (2006b) provided evidence for the activity of this protein as a peptide hydrolase, acting on the dipeptide felinylglycine and releasing felinine into the urine. This raises the possibility that cauxin is an important component of sexual signaling in domestic cats and possibly other Felidae, functioning to control the expression of felinine in urine scents. In this study, we report the further characterization of cauxin from both domestic cats and a number of species of big cats. In marked contrast to previous studies (Miyazaki et al. 2006a), we provide proteomic-based evidence that cauxin is expressed by *Panthera* species, which are not thought to produce felinine or its precursors. This suggests that the esterase/peptidase might have other roles in the elaboration of urinary scents in this group of cats.

Methods and Materials

Urine samples from 13 mature intact domestic cats (five male and eight female; aged from 6 mo to 15 yr) were collected by cystocentesis, free catch, or by free collection from the floor. Urine samples from one individual of each of five species of mature male non-domestic cats (Asiatic lion, *Panthera leo persica*; Sumatran tiger, *P. tigris sumatrae*; Persian leopard, *P. pardus saxicolor*; jaguar, *P. onca*; and clouded leopard, *Neophilis nebulosa*) and one mature Asiatic lioness were collected by catheterization during a routine health check at Chessington World of Adventure, Surrey, UK. Samples were centrifuged to remove cell debris and stored at −20°C until required.

Urine protein content was measured using the Coomassie plus protein assay (Perbio Science UK Ltd., Tattenhall, UK). Creatinine levels were also determined to correct for urine dilution using a modification of the Jaffe method of analysis (Cook 1971). Before gel electrophoresis, samples from domestic cats were concentrated, and low molecular weight compounds were removed by acetone precipitation. To each sample, a fivefold volume of acetone was added and incubated for 1 hr at −20°C, centrifuged, 5,000×*g* for 5 min, the supernatant removed, and the pellet resuspended. Urine samples from big cats were treated with StrataClean™ Resin (Stratagene®, Hycor Biomedical Ltd., Edinburgh, UK), which binds and concentrates the protein in the sample and removes non-protein impurities. The resin was added to each sample, vortexed for 1 min then centrifuged at 5,000×*g* for 5 min. The supernatant was removed, the pellet washed with distilled, deionized, water and resuspended.

One-Dimensional Gel Electrophoresis Samples (10 μg) of the urine were electrophoresed through a 12% polyacrylamide gel according to previously documented methods (Laemmli 1970). A 12% resolving gel was prepared and allowed to polymerize before overlaying with a 4% stacking gel. Samples were incubated for 30 min at 37°C in either a reducing (Tris–HCl, 0.125 M; SDS, 0.14 M; glycerol 20% *v*/*v*; dithiothreitol, 0.2 mM and bromophenol blue, 0.03 mM) or non-reducing buffer before loading. The proteins were electrophoresed at a constant potential of 200 V until the dye front had progressed to the bottom of the gel. Gels were stained with Coomassie blue (Bio-Safe™, BioRad, CA, USA).

Two-Dimensional Gel Electrophoresis Before loading onto IPG strips, pH 3-10L (GE Healthcare UK Ltd., Little Chalfont, UK,) each sample (300 μg protein) was treated with StrataClean™ Resin. The resulting pellet was resuspended in buffer containing CHAPS (4% *w*/*v*), 7 M urea, 2 M thiourea, 20 mM dithiothreitol, and ampholytes (0.5% *v*/*v*) and incubated at room temperature for 1 hr. After centrifugation, the supernatant was separated in the first dimension on an IPGPhor unit (AP Biotech Pharmacia). In-gel rehydration (150 Vh at 30 V, 300 Vh at 60 V, 20°C) was followed by isoelectric focusing (500 Vh at 500 V, 1,000 Vh at 1,000 V, and 48,000 Vh at 8,000 V). The focused IPG strips were equilibrated in 50 mM Tris–HCl, pH 8.8, containing 6 M urea, 30% (*v*/*v*) glycerol, 2% (*w*/*v*) SDS, and a trace of bromophenol blue. Dithiothreitol (10 mg/ml) was present as a reducing agent for the initial equilibration, and iodoacetamide (25 mg/ml) was present in the second equilibration step. The proteins were electrophoresed through a linear 12.5% acrylamide gel, and the gels were stained using Coomassie blue (Bio-Safe™, BioRad).

In-Gel Trypsin Digest Gel plugs containing protein from areas of interest were excised, and the proteins were subjected to in-gel tryptic digestion and peptide extraction using a MassPrep™ digestion robot (Waters, Manchester, UK). Briefly, excised gel plugs were placed in distilled deionized water (50 μl) before addition of ammonium bicarbonate (50 μl, 100 mM) and acetonitrile (50 μl). This liquid was removed, and the gel piece was treated with destain solution [10 μl of 50% (*v*/*v*) acetonitrile, 50% (*v*/*v*) 100 mM ammonium bicarbonate]. The protocol included a second cycle of reduction and alkylation. The gel plug was dehydrated in acetonitrile and then rehydrated with 25 μl of trypsin (3 ng/μl) in buffer. After digestion (5 hr), tryptic peptides were extracted from the gel matrix by addition of 30 μl of 2% (*v*/*v*) acetonitrile/1% (*v*/*v*) formic acid. Peptides (1 μl) were mixed with matrix (1 μl) [α-cyano-4-hydroxycinnamic acid saturated solution in a 1:1:1:1 by volume of ethanol, acetonitrile, trifluoroacetic acid (0.4%), and distilled deionized water], and the resultant 2 μl was spotted onto the MALDI target. ACTH (adrenocorticotropic hormone, M=2,464.20), 1 μl of 1 μg/ml stock was used as an external lockmass standard.

MALDI-ToF Mass Spectrometry Peptides were analyzed by using a matrix-assisted laser desorption ionization time of flight mass spectrometry (MALDI-ToF MS) mass spectrometer (M@LDI™, Waters) over the *m/z* range of 1,000 to 3,500 thompsons. The mass spectrometer was calibrated with 2.5 pmol each of bradykinin (MW=903.47), neurotensin (MW=1,671.92), ACTH (MW=2,464.20), and insulin β-chain (MW=3,493.65). Typically, a residual error of ±0.05 ppm was obtained. The mass accuracy of spectra could be further improved by internal standardization with the major trypsin autolysis peak ($[M+H]^+$=2163.057 thompsons). Proteins were identified from their peptide mass fingerprint by manual searching using a locally implemented MASCOT server (ver 1.9, http://www.matrixscience.co.uk) against the Swiss-Prot http://expasy.org/sprot/) or MSDB http://csc-fserve.hh.med.ic.ac.uk/msdb.html/) databases. The initial search parameters

allowed a single missed tryptic cleavage, obligatory (fixed) carbamidomethyl modification of cysteine residues, variable oxidation of methionine, and an *m/z* error of ±250 ppm. The taxonomic search space was restricted to Mammalia. Before MALDI-ToF MS analysis, residual contaminants were removed if necessary from exotic cat samples using ZipTip® C18 tips (Millipore, Hertfordshire, UK).

Electrospray Ionization Mass Spectrometry Electrospray ionization mass spectrometry (ESI-MS) and tandem mass spectrometry (ESI-MS/MS) were performed on a Q-ToF Micro instrument (Waters-Micromass) fitted with a nanospray source. The electrospray was created from a silver-coated glass capillary with a 10-μm orifice (Presearch, Hitchin, UK) held at a potential of +2,000 V relative to the sampler cone. Before ESI-MS/MS, peptides were separated by reversed phase high-performance liquid chromatography on a Dionex Ultimate system. The unit was fitted with a PepMap C18 column (LC packings), 15 cm×75 μm, bead size 3 μm and pore size 100 Å. Before separation, aliquots (10–20 μl) of sample digest were taken up into the injection loop of the Dionex Famos autosampler and desalted in-line using a Dionex Switchos apparatus fitted with a 5 mm× 300 μm C18 pre-column. The pre-column was initially equilibrated in 0.2% (*v*/*v*) formic acid at 30 μl/min. Peptides were then loaded and washed for 3 min at the same rate, after which, the trap and downstream PepMap column were developed with 90% acetonitrile/0.2% formic acid, introduced as a linear gradient of 0–50% in 30 min at 0.2 μl/min. The column eluant was monitored for UV absorbance at 214 nm in an in-line flow cell before being introduced into the mass spectrometer. The initial quadrapole analyzer was set to allow the transmission of selected precursors into the gas cell. The masses of the resulting fragment ions were then measured by the ToF analyzer. Precursor spectra were acquired between *m/z* 400 and 1,500 at a scan/interscan speed of 2.4/0.1 sec. Product ion spectra were acquired between m/m 100 and 2,000 at a scan speed of 1.0/0.1 sec. Raw product ion spectra were deconvoluted using the MaxENT algorithm within the Mass Lynx software. Interpretation of product ion spectra and the determination of peptide sequences were facilitated by the PepSeq module within Mass Lynx. Peptide sequences were searched using the National Center for Biotechnology Information basic local alignment search tool (BLAST). The search was limited to Mammalia; no other parameters were limited.

Results and Discussion

Urine samples from a range of domestic cats each contained multiple proteins distributed between 5 and 300 kDa (Fig. 1a). The overall pattern of bands from one-dimensional gel electrophoresis was similar among individuals, and there was no pronounced difference between males and females. Prominent bands were evident at a mobility corresponding to a molecular weight of approximately 66 kDa, but other bands were also present. To determine the identity of these protein bands, small plugs of gel (1 mm^2) corresponding to each band were recovered, instilled with trypsin, and the resultant tryptic peptides were recovered and analyzed by MALDI-ToF mass spectrometry (peptide mass fingerprinting, results not shown) and electrospray ionization mass spectrometry. This permitted the identification of several of the bands. Predominant urinary proteins included uromodulin (Tamm-Horsfall glycoprotein) present as a diffuse band at 120 kDa and transferrin at approximately 75 kDa. The most intense band in almost every sample migrated at approximately 67 kDa, and might have been anticipated to be serum albumin—urinary

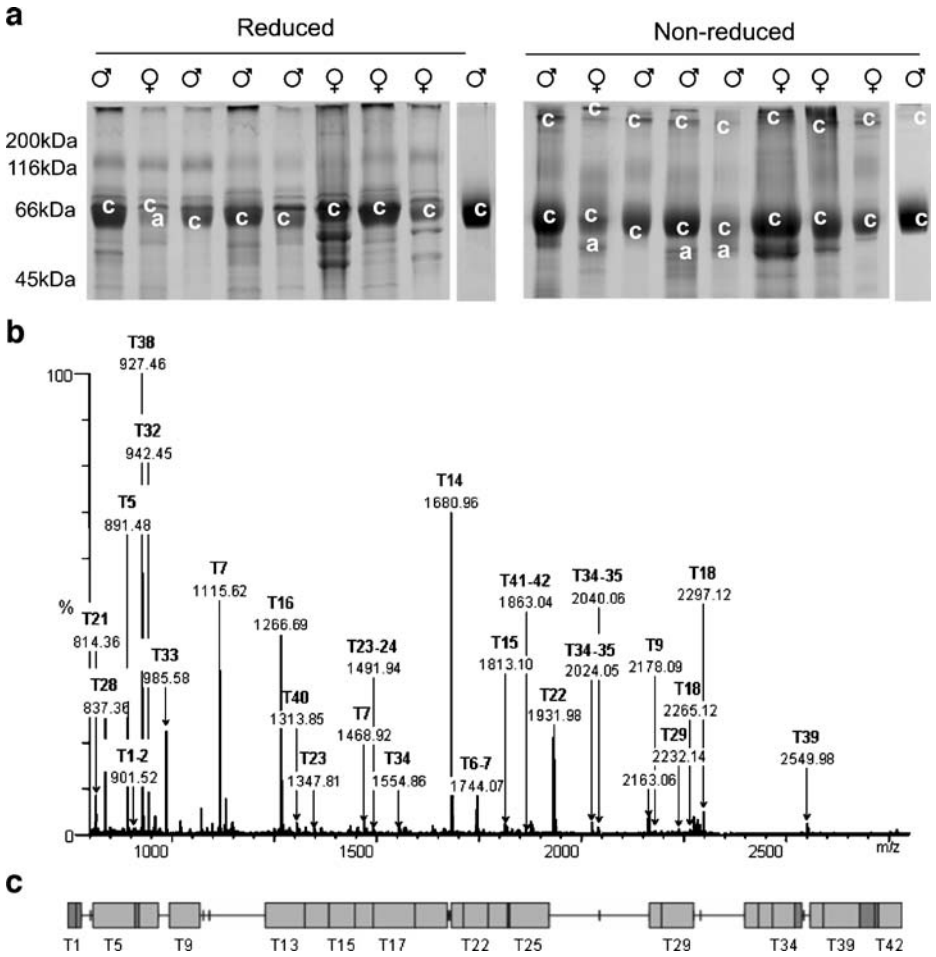

Fig. 1 Analysis and identification of urinary proteins from the domestic cat, *Felis catus*. Proteins in urine samples from adult male and female domestic short hair cats were resolved by reducing and non-reducing one-dimensional SDS-PAGE (**a**). Protein bands in the highly stained region of 60 kDa were excised and subjected to gel digestion before MALDI-ToF mass spectrometry. The proteins identified as cauxin (*white c*) and albumin (*white a*) are indicated on the gel. The mass spectrum of the band identified as cauxin is presented (**b**), and each tryptic peptide from the MALDI-ToF spectrum is highlighted in the peptide map (**c**)

serum albumin is a common observation in renal dysfunction. However, peptide mass fingerprinting revealed a complex series of tryptic peptides that matched with a very high score to the protein cauxin (Entrez Protein ref. BAC22577). Some peptides were also consistent with the presence of feline serum albumin, but it is likely that most of the protein in this band is cauxin. Cauxin is a single polypeptide chain 67 kDa, but exists in part as disulfide-linked multimers. When urine samples were resolved in non-reduced gels, a new series of bands migrating from 300 to 350 kDa was resolved. MALDI-ToF analysis of these bands confirmed that each of them contained tryptic peptides from cauxin. In contrast, albumin, which does not exist as disulfide-linked multimers, remained at a position on the gel approximating 60 kDa. The multiple high-mass cauxin bands might reflect N-linked glycosylation, as the sequence contains four potential glycosylation motifs

(Asn-X-Ser/Thr). Alternatively, the different bands could reflect disulfide-linked association between differentially proteolyzed subunits. Further evidence for cauxin being the predominant protein at the 66 kDa region of the gel was derived from two-dimensional gel electrophoresis (results not shown). After separation, a major protein staining area, smeared over the pI region from 3.5 to 5.8, was identified as cauxin. A smaller, more intense discrete spot, at pI 4.7, was identified by peptide mass fingerprinting as serum albumin.

The tryptic peptide fragments were subjected to *de novo* peptide sequencing (Fig. 2). Peptides were resolved by C18 reversed phase capillary chromatography, and specific peptides were fragmented by collision-induced decomposition. The product ion spectra were then used to direct manual peptide sequencing. Thirteen peptides were sequenced this way. These peptide sequences provide unambiguous confirmation that the protein is cauxin. One tryptic peptide in particular was readily and repeatedly sequenced ($[M+H]^+$=1,115.6 *m/z*) as PALPWNDFR, a sequence that explains all of the mass of the peptide (predicted $[M+H]^+$=1,115.56). This sequence was significant for two reasons. First, the equivalent tryptic peptide expected from cDNA sequencing was *QPK*PALP*G*NDFR (Miyazaki et al. 2003). The glycine residue (G) in this cDNA sequence is at variance with other reported cauxin-like sequences from several species, from which, the consensus *P*x*P*xxx*W* is evident (Ecroyd et al. 2006), and the peptide sequence obtained here corrects a previously reported anomaly possibly because of a cDNA sequencing error. The DNA sequence used to derived the previously published cat sequence was CCC[GGG]AATGACTTCCGA; for tryptophan (W) to be coded for in the same sequence, the DNA sequence would have to be CCC [GGA]AATGACTTCCGA, a single base shift near a region of potential GC compression. The second significant feature of this peptide is that it has nominally been generated by tryptic proteolysis, from the primary sequence context—KQPK[*palPWNDFR*]NAT—trypsin is not generally considered to be capable of cleaving peptide bonds in which the amino acid C-terminal to the scissile bond is proline (Olsen et al. 2004). Thus, the most likely explanation is that cauxin is trimmed by additional N-terminal processing possibly related to the secretion into urine. The proximal tubule of the kidney is replete with exo- and

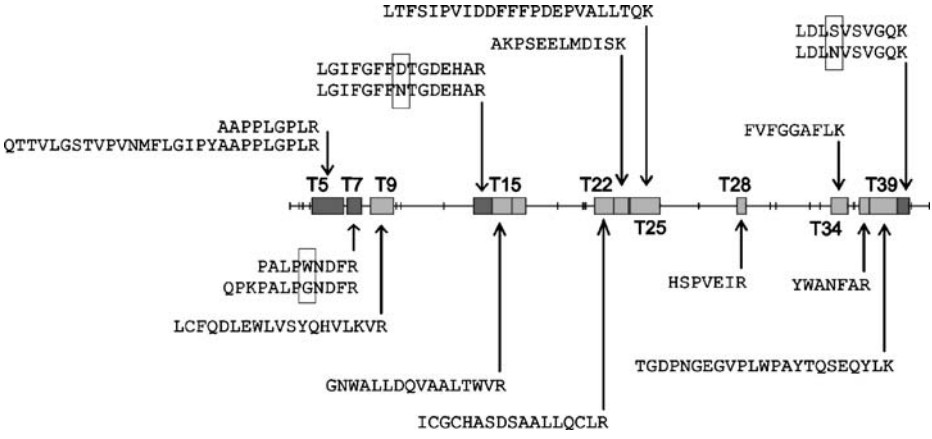

Fig. 2 *De novo* peptide sequencing of tryptic peptides of cauxin from the domestic cat, *F. catus*. Tryptic peptides from an in-gel digest of a band identified by peptide mass fingerprinting as cauxin were resolved using nanoflow reversed phase chromatography, fragmented by tandem mass spectrometry, and the product ion spectra were interpreted manually to obtain the peptide sequence data. The peptides for which sequence data were obtained are highlighted on the peptide map, and peptides that differed from the published sequence are highlighted (this study, top line, previously published sequence, accession number BAC22577)

endopeptidases that could be responsible for this processing. This processing must be partial, however, as we also found clear sequence data for an additional peptide that was derived from cauxin and that was N-terminal to the sequence PALPWNDFR. The multiple bands on non-reducing gels are also indicative of mass heterogeneity in cauxin subunits.

Cauxin has the signature motifs and overall sequence that places it in the class of carboxylesterases (Miyazaki et al. 2003). Although the function of cauxin is not known, it has been suggested that it is responsible for the elaboration of the strong scent of feline in urine used in territorial marking (Miyazaki et al. 2006b). Urinary scent marking is a feature of many members of the Felidae, and accordingly, we examined urine samples from a number of species of big cats for the presence of cauxin, including Asiatic lion, Sumatran tiger, jaguar, Persian leopard, and clouded leopard. In all instances, urine samples were obtained from intact adult males. In all of the male cats, a band corresponding in mass to cauxin was evident, although in several of the samples, the presence of urinary serum albumin migrating at approximately the same position on the gel made identification of cauxin more difficult (Fig. 3). However, when the gels were run under non-reducing conditions, high-mass complexes were evident (Fig. 3a), and these yielded tryptic peptides that could be sequenced readily by tandem mass spectrometry. Multiple peptides were analyzable, which, interestingly, were the peptides cognate to those seen in the domestic

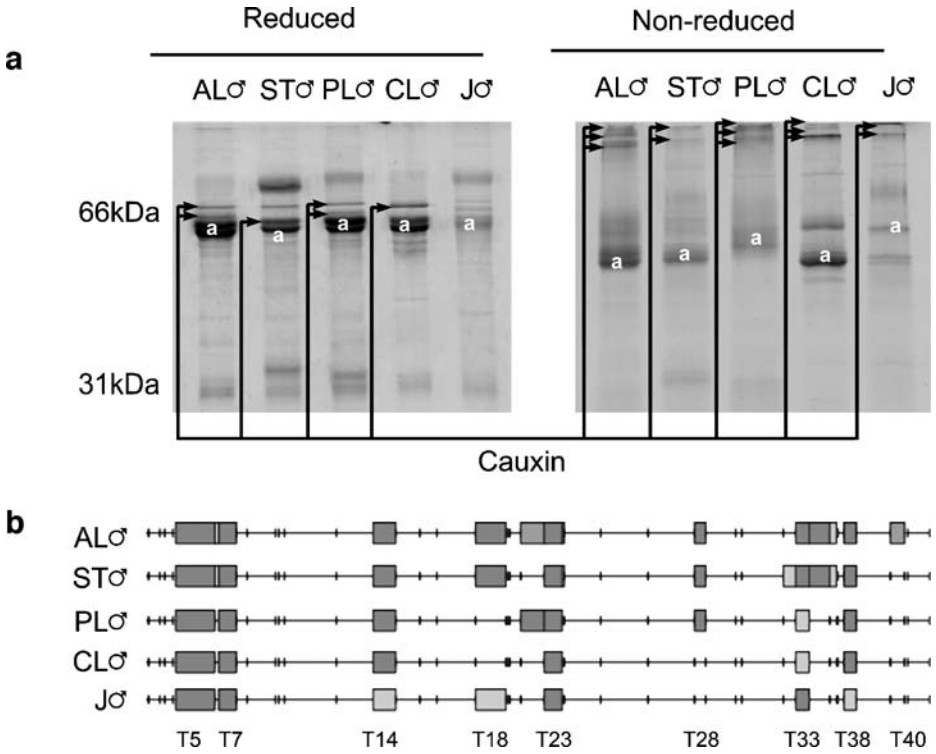

Fig. 3 Analysis and identification of male urinary proteins from the Asiatic lion (*AL*), Sumatran tiger (*ST*), Persian leopard (*PL*), clouded leopard (*CL*), and jaguar (*J*). Proteins in urine samples were resolved by reducing and non-reducing one-dimensional SDS-PAGE (**a**). The proteins identified as cauxin and albumin (*white a*) are indicated on the gel. Major protein bands were excised and subjected to in-gel digestion before peptide mass fingerprinting and the peptides observed by mass spectrometry are highlighted (**b**)

cat. This implies that these were similar peptides that yielded strong ion currents and good fragmentation data irrespective of the source (Fig. 4). Although multiple peptides were sequenced for each of the big cats, there were remarkably few amino acid changes within the big cats, or indeed, when compared to the domestic cat, from which, we infer a high degree of conservation of structure, activity, and function for this protein (Fig. 5). Equally intriguing, the unusual tryptic peptide PALPWNDFR, previously discussed, was present in all big cat samples, implying a similar pattern of N-terminal processing or unusual tryptic cleavage in different species (Fig. 5). The sequence of cauxin from each of the big cats is noticeably similar to that of the domestic cat. We compared this degree of sequence similarity with that obtained for serum albumin also present in urine samples (Fig. 6). For

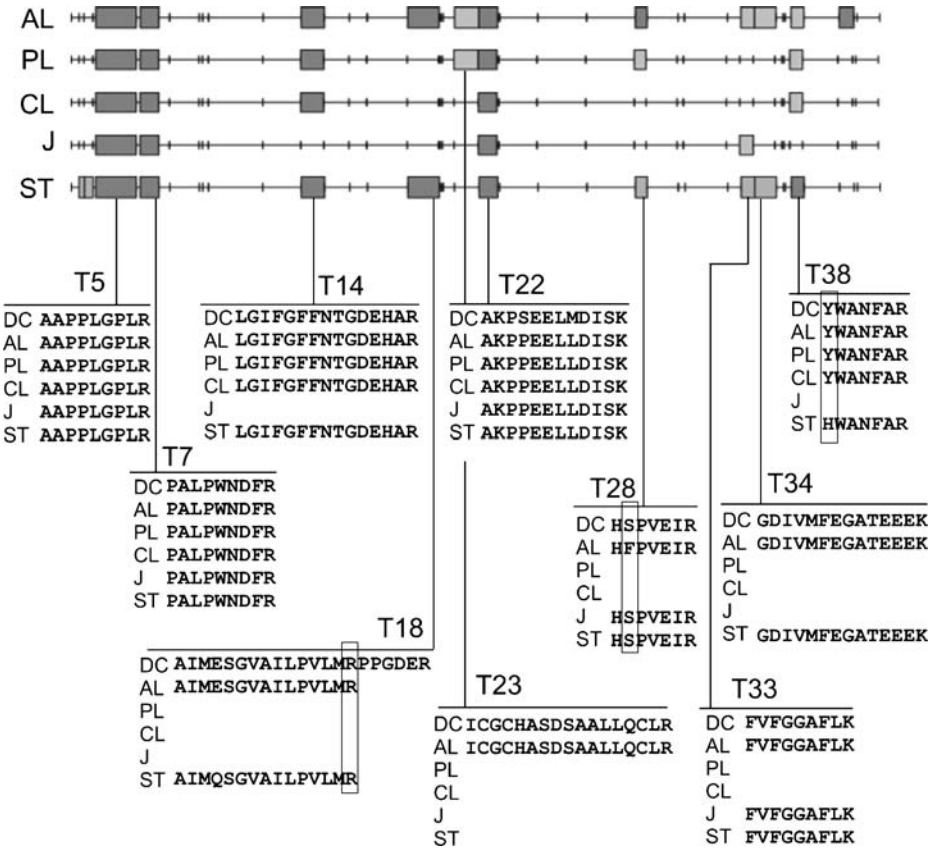

Fig. 4 De novo peptide sequencing of tryptic peptides of cauxin from big cats. Urine samples from five big cat species were resolved on SDS-PAGE (abbreviations as Fig. 3; *DC* domestic cat). Tryptic peptides from an in-gel digest of the band identified by peptide mass fingerprinting as cauxin were resolved using nanoflow reversed phase chromatography, fragmented by tandem mass spectrometry, and the product ion spectra were manually interpreted to obtained peptide sequence data. The peptides for which sequence data were obtained are highlighted on the peptide map. Most peptides had the same sequence as those for the domestic cat, but where peptide sequences differed from the domestic cat in at least one of the big cat species, the amino acid differences are *boxed*. For tryptic peptide T18 from the Asiatic lion (*AL*) and the Sumatran tiger (*ST*), the termination of the sequence at the arginine residue, which in domestic cat is extended to include a non cleavable ArgPro sequence, is presumptive evidence for an amino acid change at that position

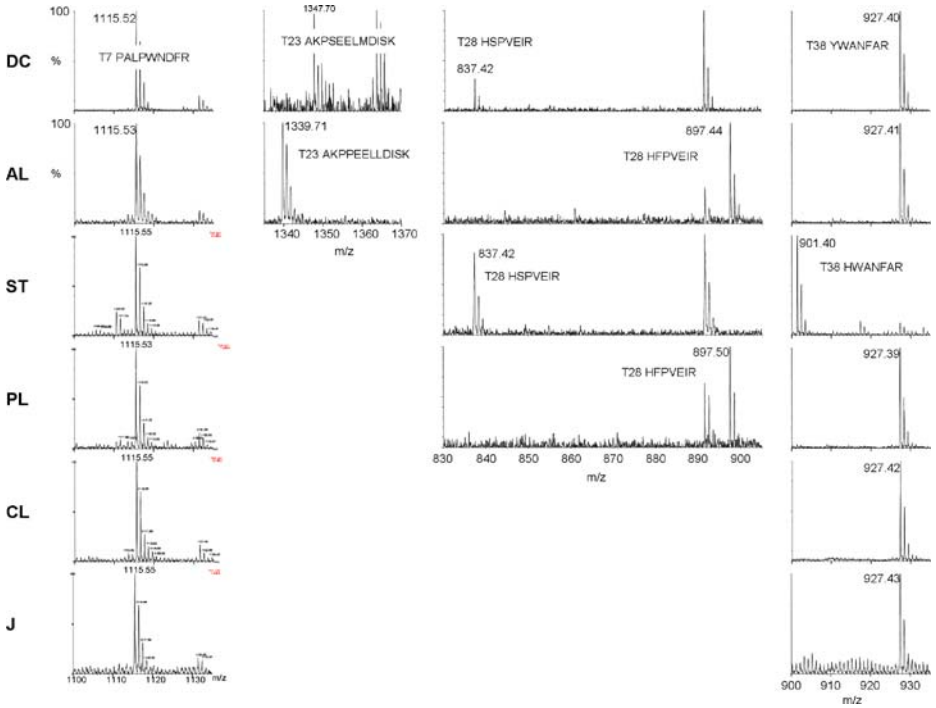

Fig. 5 Identification of polymorphic peptides in cauxin species for big cat species. Urine samples from five big cat species were resolved on SDS-PAGE (abbreviations as Fig. 3, *DC* domestic cat). Tryptic peptides from an in-gel digest were sequenced by tandem mass spectrometry, and for selected peptides where different sequences were obtained for big cats, the corresponding $[M+H]^+$ ion from MALDI-ToF mass spectrometry is shown, together with the corresponding ion that confirms the amino acid change. Additionally, the atypical tryptic fragment PALPWNDFR was observed in all six cat species, and the MALDI-ToF mass spectrum for that specific $[M+H]^+$ ion is included in the *left hand* column

domestic cat, a total of 50 tryptic peptides were identified, covering approximately 66% of the sequence. For the Asiatic lion, 34 tryptic peptides derived from albumin were identical to the domestic cat (covering 58% of the sequence); the corresponding figures for the clouded leopard and the jaguar were 38 (63% coverage) and 36 (51% coverage), respectively. In both the Sumatran tiger and the Persian leopard, we identified 43 (64% coverage) and 39 (59% coverage) tryptic peptides, respectively, but for two peptides (Sumatran tiger) and three peptides (Persian leopard), single amino acid changes were observed. The degree of sequence conversation in serum albumin is high and reflects the relatedness of these species. It is, therefore, not surprising that cauxin has a similar degree of conservation, but this also implies that mechanisms of sexual selection are not driving species-specific evolution of this protein.

The expression of cauxin by several *Panthera* spp. was unexpected, as a previous study had reported that cauxin was not present in urine samples (Miyazaki et al. 2006a). By contrast with the intact domestic male cat (Fig. 1, and Miyazaki et al. 2003); the band intensity of cauxin in these big cats was substantially lower. The protein-based evidence for the existence of cauxin as a urinary component is substantial: identification based on peptide mass fingerprinting, which requires a high degree of sequence conservation among the species under investigation and a model species for which a database entry already

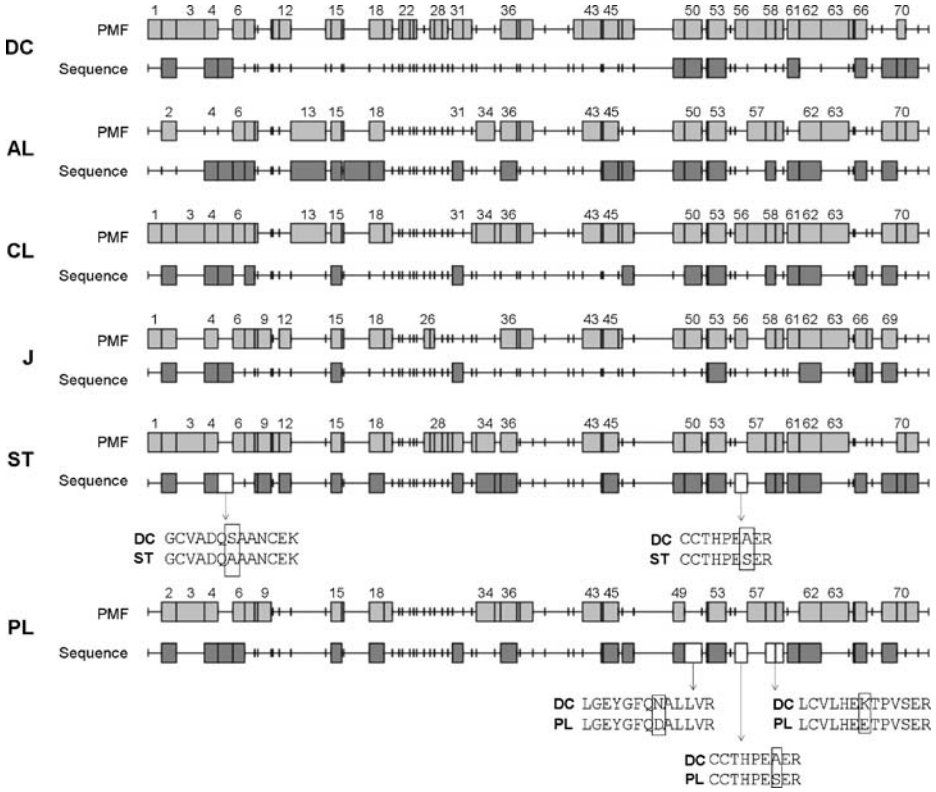

Fig. 6 Sequence homology of albumin in domestic and big cat species. Urine samples from five big cat species were resolved on SDS-PAGE. Tryptic peptides from an in-gel digest of a band putatively identified as serum albumin were used to confirm the identity of this protein. Peptides matched by mass alone (peptide mass fingerprinting) are highlighted as *boxes* in the PMF row for each species (abbreviations as Fig. 3). Additionally, selected peptides were resolved by nanoflow reversed phase chromatography, fragmented by tandem mass spectrometry, and the product ion spectra were manually interpreted to obtained peptide sequence data (row marked 'Sequence'). Where peptide sequences were identical to those for the domestic cat, no additional information is provided, but where sequence differences were observed, the changed sequence and the corresponding sequence for albumin from the domestic cat are *aligned*, with differences *boxed*

exists, and *de novo* peptide sequencing, which can be used as a probe in BLAST searches. In contrast, the previous investigation was based on Western blotting, with an antibody to a C-terminal peptide of cauxin in the domestic cat (SVGQKLKEQEVEFWMNTIVP, spanning tryptic peptides T40 to T42). It is possible that this peptide might not be so highly conserved in the big cat species, and thus, Western blotting might yield weaker signals, which would be exacerbated by the much lower level of expression of cauxin in the big cats.

It is likely that the role of cauxin in the domestic cat is not to act as a carboxylesterase, but as an amidase that catalyzes the hydrolysis of the dipeptide 3-methybutanol-cysteinylglycine to glycine and the cat-specific amino acid felinine. Felinine and its degradation products are putative pheromones (Miyazaki et al. 2007), and the role of cauxin in elaboration of the pheromone from a precursor peptide is enigmatic. What then of the expression of the homologous enzyme in big cats? Neither felinine nor its precursors are present in urine of the Pantherinae (Hendriks et al. 1995a; W.H. Hendriks, personal

communication), and the role of cauxin in these species, albeit in reduced amounts, remains enigmatic. It is possible that the cauxin homolog acts as an amidase, but with different precursor molecules. However, some cats express urine that is replete with complex fatty acyl esters, and alternative substrates should be considered. It is clear that the pheromone/enzymology axis of cats is at the beginning of a new and fascinating phase of development.

Introduction

Chemical defenses are widely distributed in insects and play a crucial role for their protection against attack by predators (Spencer 1988; Trigo 2000; Ruxton et al. 2004). They can act in a direct way on the predator by inflicting pain or poisoning, or indirectly by association with aposematism (Ruxton et al. 2004). Although many of the defensive chemicals of phytophagous insects are toxins sequestered directly from the host plant on which the larva or adult feeds (Duffey 1980; Rowell-Rahier et al. 1991; Nishida 2002), insects can also synthesize *de novo* their own toxins (Pasteels et al. 1992; Mardulyn et al. 1997; Feld et al. 2001; Hartmann et al. 2004; Soe et al. 2004). We are beginning to understand the importance of diversity in defense chemistry. For instance, differences in chemistry between mimetic species may promote learning by predators (Skelhorn and Rowe 2005). Variation in the levels of defense within a species (resulting in the phenomenon of automimicry) is often associated with costly forms of defense (Bowers 1992; Fordyce et al. 2006). Much less is known about the sources of intraspecific variation in the composition of defense chemistry. For sequestered compounds, there is evidence for geographical variation in both the concentration and composition of defenses, often associated with shifts in host-plant use (Kopf et al. 1998; Moranz and Brower 1998; Wahlberg 2001). However, when the defense chemicals are synthesized by the insects themselves, the level of variation and its ultimate explanation still remain unknown. In this study, we examined the extent to which (1) environmental conditions and (2) genetic inheritance modify the composition of the defense secretion in an alpine leaf beetle.

The phytophagous genus *Oreina* Chevrolat (Coleoptera: Chrysomelidae) includes 25 species found throughout the mountain regions of Europe with some incursions into the lowlands and into western Siberia. Most are oligophagous on either Apiaceae or Asteraceae. Four species feed on both families and have been considered as polyphagous, whereas monophagy seems scarce but does exist (*O. gloriosa* on *Peucedanum ostruthium*, for instance) (Jolivet et al. 1986).

Chemical defense is a widespread strategy in Chrysomelidae and is found in all *Oreina* species (with the exception of *O. melanocephala*; Dobler et al. 1996). Adults use active secretion with exocrine glands situated on the pronotum and the elytra, whereas larvae (which lack exocrine defensive glands) stock chemicals in their body (Dobler and Rowell-Rahier 1994). All species that feed on Apiaceae presumably synthesize cardenolides autogenously from ubiquitous plant sterols as shown in closely related chrysomelids (Pasteels and Daloze 1977; Van Oycke et al. 1987). A few *Oreina* species that feed on Asteraceae also sequester pyrrolizidine alkaloid (PA) N-oxides from their host plants, whereas one species (*O. cacaliae*) has lost the ability to produce cardenolides (Dobler et al. 1996). The production of cardenolides seems to be the ancestral character shared with many other species of Chrysomelinae, with PA sequestration having evolved in just a few species of *Oreina*.

In this study, we focused on *Oreina speciosa*, which feeds on several genera of Apiaceae and produces only autogenous cardenolides. We aimed to determine the extent of geographical variation in defense chemistry and whether variation in the cardenolides secreted by *O. speciosa* is related to environmental conditions and/or is genetically inherited. The species can be found throughout Europe in the Alps, the Jura, the French Massif Central, the Balkans, and the Vosges. With at least 38 different components in its secretion (Rowell-Rahier and Pasteels 1994), *O. speciosa* possesses the most complex blend in the genus *Oreina*. Moreover, a comparison of two populations showed differences in their cardenolide profiles (Rowell-Rahier and Pasteels 1994).

A few studies—focused on quantitative genetics—have measured genetic and phenotypic variation of chemical defense in beetles (Eggenberger and Rowell-Rahier 1992; Holloway et al. 1993). Although a considerable part of the variation seems to be genetically determined (e.g., the average heritability of the concentration of 16 secretion compounds in *O. gloriosa* was estimated to be 0.45; Eggenberger and Rowell-Rahier 1992), environmental differences among locations (climate, food quality, predation pressure) are also likely to contribute to the diversity. However, to our knowledge, no studies have tested for a relationship between genetic divergence, environmental conditions, and the composition of chemical defenses.

Therefore, we aimed to determine whether the composition of defense secretions is genetically inherited or shaped by the environment. We analyzed the blend of cardenolides in populations of *O. speciosa* across Europe and correlated this variation with the genetic structure among populations and environmental differences among sites.

Methods and Materials

Collection of beetles and ecological data Sampling of *O. speciosa* was carried out in 2005 at 18 sites in France, Italy, Switzerland, Slovenia, and Croatia (Table 1), covering the Balkans (late June), the Jura (late July), the French Massif Central (mid August), and the Alps (throughout the collecting period, until late August). The latitude, longitude, and altitude of all sites were registered with a global positioning system receiver. The type of habitat was described in each site according to (1) the kind of adjacent vegetation (megaphorbiae or grasslands), (2) the dominant tree species in the surrounding forest (larch [*Larix decidua*], beech [*Fagus sylvatica*] or fir [*Abies alba*]), and (3) the presence/absence of a stream nearby. The host plants on which the beetles were collected were also recorded. Based on these observations, two distance matrices were constructed by using the "R Package for Multivariate and Spatial Analysis" version 4 (Casgrain and Legendre 2001). A habitat distance matrix was created by computing the Jaccard indexes among sites based on the three factors described above (Jaccard 1900). A host-plant distance matrix was derived from the Jaccard indexes based on host-plant sharing.

After collecting their defensive secretions (see below), the beetles were determined by examination of morphological traits under a binocular microscope (Lohse and Lucht 1994). They were then put separately in 1.5-ml labeled Eppendorf tubes containing pure ethanol and stored at −20°C.

Collection of defense secretions Defensive secretions of freshly field-collected beetles were collected from each population. To get enough liquid for analysis, secretions from 5 to 10 insects were pooled. Secretions were obtained by holding the beetles under a binocular microscope and gently tapping on the elytra with forceps until they secreted drops from both sides of the prothorax. Drops were collected with a glass microcapillary and immediately placed in a tube containing approximately 1 ml of methanol. The tubes were stored at −70°C to avoid degradation.

Chemical preparation of samples and chromatographic analysis After crushing the microcapillary with a micropestle, samples were centrifuged for 10 s at 9,000 rpm (5,970×*g*) to eliminate glass fragments, and the liquid was transferred into new tubes. The solutions were concentrated under a nitrogen flow to a final volume of approximately 200 μl. Sample analyses were carried out with the reverse phase-high performance liquid

[a] Number of cardenolides detected.

chromatography (RP-HPLC) method coupled to mass spectrometry (MS). Characteristics of both devices and analysis conditions are described below. (1) RP-HPLC: Agilent 1100 series LC (Agilent Technologies, Basel, Switzerland); G1379A degasser; G1312A binary pumps; G1313A autosampler; G1316A column compartment; G1315A diode array detector; reverse phase C18 column (Lichrospher® 250×4 mm, 5 μm, 100 A [MERCK, Darmstadt, Germany]); reverse phase-18 guard column Lichrocart® 4-4 [MERCK,

Darmstadt, Germany]; flow rate of 0.45 ml/min; solvent system of deionized water and acetonitrile (CAN, HPLC grade) gradient over 60 min (with acetonitrile increasing from 15% to 42% over 36 min, from 42% to 100% over 4 min, remaining isocratic at 100% for 10 min, decreasing from 100% to 15% over 1 min; remaining isocratic at 15% for 9 min); injection volume of 10 μl; UV detection at 220 nm. (2) MS: Agilent 1100 series LC/MSD trap (Agilent Technologies, Basel, Switzerland); ESI (ElectroSpray Ionization) source in negative mode; modified ionization parameters (dry temperature at 325°C, nebulizer (N_2) at 45.0 Ψ, dry gas at 8 l/min, capillary voltage at 3.5 kV); ion optic voltages with a RF amplitude of 150 Vpp, −160 V at the capillary exit and −40 V at the skimmer; specific trap parameters (trap drive at 74 V, scan from 200 to 1,200 *m*/*z* [mass-to-charge ratio of ions], maximum accumulation time at 150 ms); multiplier voltage at 1.8 kV and dynode voltage at 7.0 kV.

Chromatograms were integrated by using the "automatic integration option" of the Agilent Chemstations software (Agilent Technologies, Basel, Switzerland). To consider only those peaks corresponding to cardenolides, peaks with a maximum falling below 219 nm or above 221 nm were excluded (the butenolide lactone ring characterizing cardenolides absorbs at 220 nm). The MS was used to corroborate this selection by the presence of fragments typical of cardenolides, which also allowed the precise identification of some of the compounds as the same or similar to those previously detected in *O. gloriosa* (Eggenberger and Rowell-Rahier 1993). Peaks in different samples with a retention time difference of less than 0.2 min were considered to be the same cardenolide, confirmed by their identical set of fragments in the MS. To standardize the minimum at which a cardenolide was considered present, the height of each peak was divided by the mean height of all peaks within each sample, and only those greater than a minimum fixed value of 0.1 were taken into consideration. The HPLC–MS analysis was performed twice for each sample, giving the same cardenolide matrix. A final presence/absence matrix of cardenolides based on their retention times in all sampled sites was obtained after removing invariable peaks. Based on these data, a similarity matrix was created by computing the Jaccard indexes between sites using the "R Package for Multivariate and Spatial Analysis" version 4 (Casgrain and Legendre 2001). To later compare matrices at the individual level (as genetic distance matrices were computed at the individual level and not at the population level, see below), the "population information" was duplicated among individuals from the same sites to build an individual-based distance matrix in which the two individuals from each site showed the same cardenolide and environmental distance patterns.

DNA extraction, PCR amplification and gene sequencing Total genomic DNA was extracted from two individuals per site, using the DNeasy® Tissue Kit (Qiagen, Hilden, Germany). Extraction was performed using 4–6 legs of each individual. Three mtDNA genes were amplified using insect universal primers: *16s ribosomal RNA* (LR-N-13398 and LR-J-12883 from Simon et al. 1994), partial *cytochrome oxidase I* (*COI*) (C1-J-1751 and C1-N-2191 from Simon et al. 1994) and partial *cytochrome oxidase II* (*COII*) (modTL2-J-3037 and modC2-N-3661 from Mardulyn et al. 1997). Gene amplification was carried out in a standard 30 μl PCR reaction including: 3 μl of 10X PCR buffer (Promega, Madison, WI, USA), 3 μl of a $MgCl_2$ solution (25 mM), 3 μl of dNTPs (1.5 mM), 0.5 μl of forward and reverse primers (10 mM), 0.3 μl of Taq DNA polymerase (Promega, Madison, WI, USA), 3 μl of extracted DNA, all made up to 30 μl with purified MilliQ water. The PCR reactions were run in a TGradient thermocycler (Biometra, Goettingen, Germany) with the following program: initial denaturation at 93°C for 1 min 30 s; 35 cycles comprising

denaturation steps at 93°C for 1 min 30 s, annealing steps at 45°C (*16s rRNA*, *COI*) or at 53°C (*COII*) for 1 min, extension steps at 72°C for 2 min; and final extension at 72°C for 8 min. The PCR products were purified with the QIAquick PCR Purification Kit (Qiagen, Hilden, Germany) following the manufacturer's protocol. Sequencing was carried out by Macrogen (Seoul, South Korea). They performed sequencing with both forward and reverse primers with the three genes under BigDyeTM terminator cycling conditions, purifying the reacted products by using ethanol precipitation, and running them using an Automatic Sequencer 3730XL (Applied Biosystem, Foster City, USA).

Phylogenetic reconstruction and genetic distance matrix 16s rRNA, COI, and COII sequences were reconstituted based on the forward and reverse sequences using Chromas Pro 1.33 (Technelysium, Helensvale, Australia). For *16s rRNA*, alignment was carried out with ClustalW 1.4 (Thompson et al. 1997). For *COI* and *COII*, alignment was trivial as all sequenced fragments were of the same size. We performed partitioned Bayesian analyses (Jordal and Hewitt 2004; Nylander et al. 2004) on the combined data set of the sequences for the three genes. All analyses were performed on a computer cluster at the Bioportal, University of Oslo, using MrBayes version 3 (Ronquist and Huelsenbeck 2003). For each defined partition (one partition per gene sequenced), the best-fit substitution model was determined by using Modeltest 3.06 (Posada and Crandall 1998) through the Akaike information criterion (AIC) selection model (Posada and Buckley 2004), using separate starting NJ Jukes–Cantor-based trees for each partition. In MrBayes, distinct parameters were, therefore, used *a priori* for each partition defined under the previously Modeltest-determined best-fit substitution models. Four Metropolis-coupled chains with incremental heating in four distinct runs of 1,000,000 generations were performed, discarding the first 200,000 generations (burn-in) in each. One tree was saved every 100 generations, and a consensus tree was built by adding all compatible groups. Based on this consensus tree, additive tree distances (Sattath and Tversky 1977) between units were computed using Darwin version 5.0 (Perrier et al. 2003) to infer a genetic distance matrix between individuals computed from the partitioned multigene Bayesian analysis. To our knowledge, only Bayesian methods allow genes to be considered to be evolving independently (i.e., with different evolutionary models) in one single analysis. The phylogenetic hypothesis is then used to determine a multipartition mtDNA distance matrix. This would not have been possible using classical distance, parsimony, or likelihood methods, which do not allow partitioned analyses.

Combined analyses Distance matrices based on (1) cardenolide composition, (2) genetic distances, (3) habitat distances, and (4) host-plant distances were compared by performing Mantel tests (a total of six tests) using the R package followed by Bonferroni correction.

For the two comparisons that were significant (cardenolide composition with genetic distance and with host-plant use), tests were made on the individual compounds and hosts. The Mantel test between host-plant distance and cardenolide distance was repeated while sequentially removing individual host plants and also with each plant species alone to test which were important. To look at the role of individual cardenolides, an ANOVA was performed in JMP (2003) with pairwise genetic distance as the response and each cardenolide peak as a factor (1 when shared and 0 when not). A similar analysis was carried out with host-plant use as the response, based on the Jaccard index between populations. Furthermore, a regression was performed to test if the number of peaks in the cardenolide blend was related to the number of host plants within a site.

Finally, UPGMA analysis (complemented with NJ and maximum likelihood analyses) was used to construct a tree based on the cardenolide composition distance matrix to investigate the overall pattern of grouping among sites. We used the "R Package for Multivariate and Spatial Analysis" (Casgrain and Legendre 2001) for UPGMA tree reconstruction, the restdist module (from the PHYLIP package; Felsenstein 2004) for Nei–Li-based NJ reconstruction, and the restML module (from the PHYLIP package; Felsenstein 2004) for maximum likelihood analysis.

Results

Variability in the genetic and chemical data Our analysis revealed a total of 50 cardenolides, of which 14 were found in all populations. Two substances were detected in only one population, whereas four were present in all populations except one. The number of cardenolides per population varied between a maximum of 42 (FR13) and a minimum of 19 (FR9) (Table 1). However, 2/3 of the populations contained between 30 and 38 cardenolides. On average, pairs of populations shared 66% of their cardenolides, with a maximum (85%) shared between IT1 and VS8 and a minimum (41.8%) between FR9 and FR13.

The genetic analysis yielded a total of 1,510 bp among the three mtDNA genes: 503 bp for *16s rRNA* (8 informative sites among 14 polymorphic sites), 447 bp for partial *COI* (34 informative sites among 44 polymorphic sites), and 560 bp for partial *COII* (30 informative sites among 43 polymorphic sites). This amount of variation—with the proportion of polymorphic sites ranging from 2.5% (ribosomal RNA) to 10% (coding genes)—is common in insect mtDNA at the intraspecific level (Simon et al. 1994). Sequences were deposited in GenBank (accession numbers EF635121 to EF635217). The best-fit substitution models for each of the three genes were determined by Modeltest as follows. *COI*: transitional model (TIM) with gamma parameter and proportion of invariable sites; *COII*: transversional model (TVM) with gamma parameter and proportion of invariable sites; *16s rRNA*: transversional model with equal base frequencies (TVMef) with proportion of invariable sites. The phylogenetic tree obtained by Bayesian inference (not shown) presented a log(likelihood) equal to −3,817.8 and corresponded to the following parameters: (1) *COI* transition rates: Rmat(A–C)=0.126168, Rmat(A–G)=0.2801, Rmat(A–T)=0.0320, Rmat(C–G)=0.1747, Rmat(C–T)=0.3599, Rmat(G–T)=0.0271; *COI* estimated base frequencies: p(A)=0.4239, p(C)=0.1299, p(G)=0.0945, p(T)=0.3517; *COI* gamma parameter: shape=0.0547; *COI* proportion of invariable sites: 0.8636; (2) *COII* transition rates: Rmat(C–G)=0.0349, Rmat(C–T)=0.3477, Rmat(G–T)=0.0302; *COII* estimated base frequencies: p(A)=0.3049, p(C)=0.2005, p(G)=0.1305, p(T)=0.3642; *COII* gamma parameter: shape=14.7693; *COII* proportion of invariable sites: 0.7671; (3) *16s rRNA* transition rates: Rmat(A–C)=0.0517, Rmat(A–G)=0.3449, Rmat(A–T)=0.1454, Rmat(C–G)=0.0116, Rmat(C–T)=0.4303, Rmat(G–T)=0.0161; *16s rRNA* proportion of invariable sites: 0.7216.

Geographical variation The UPGMA clustering of populations based on the Jaccard matrix of cardenolides shows strong, but not perfect, geographical structure (Fig. 1). There was broad-scale east–west division: Balkan and eastern Alpine populations (HR2, HR4, Slo2, Slo9, Slo10) fell with those from the Rhone Valley in the Swiss Alps (VS4, VS5, VS6, VS7), whereas populations from the south–west Alps (FR13, FR14, IT1, VS8)

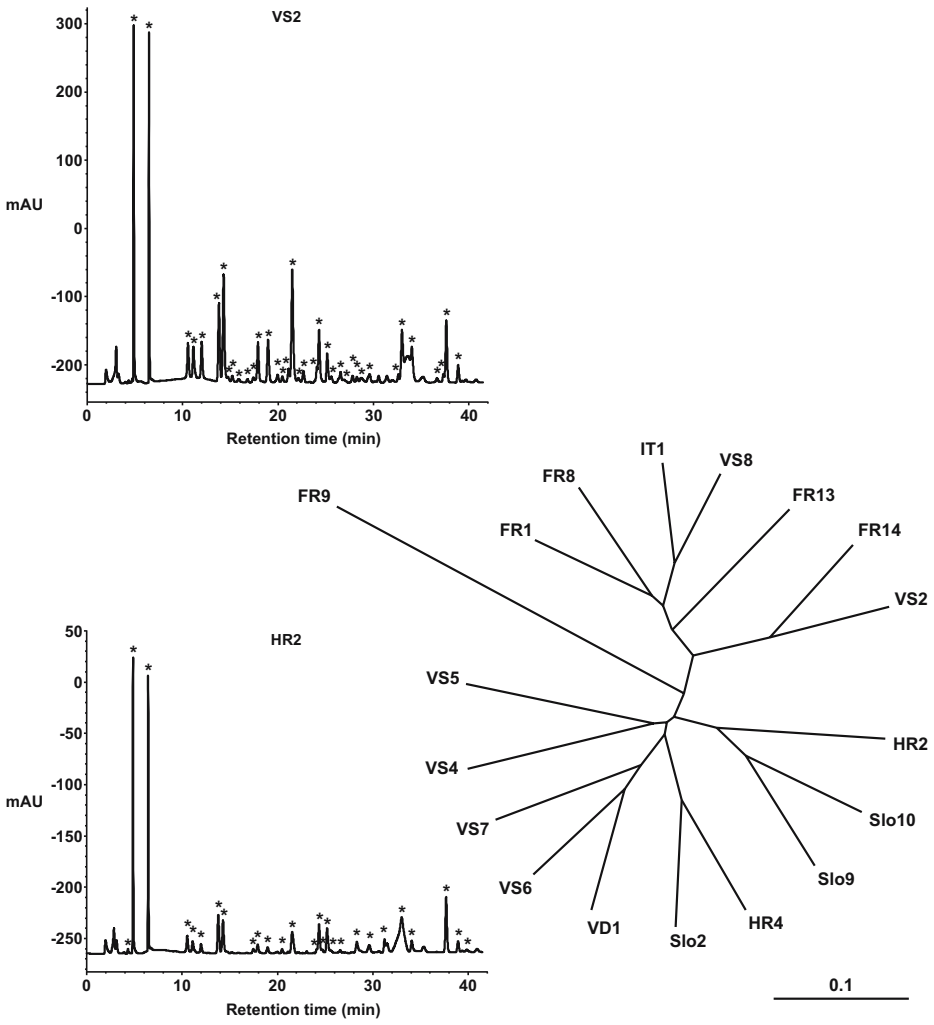

Fig. 1 HPLC traces of defensive secretion of *O. speciosa* from two populations (with each cardenolide peak shown by an *asterisk*) and UPGMA clustering of populations based on their cardenolide composition. Abbreviations for the populations are the same as in Table 1

clustered together with one population from the Jura (FR1) and one from the Massif Central (FR8). Some populations fell in unexpected positions (VD1 and VS2), and FR9 was found at the end of a long branch. The main two-cluster topology remains when performing other analyses such as Nei–Li-based NJ and maximum likelihood (not shown) with the exception of the position of FR9, which sometimes switches between clusters.

Influence of environmental factors and genetics on the overall cardenolide blend Of the six Mantel tests, only that between cardenolide distance and host-plant distance and that between cardenolide distance and genetic distance were significant after Bonferroni's correction (Table 2). The significant effect of host plant on cardenolide composition was not the result of a correlation between the number of host plants and the number of

Table 2 Results of Mantel tests for the pairwise distance matrices

	Cardenolides	Habitat	Host Plants	Genetic Distance
Cardenolides		P=0.075	P=0.006[a]	P=0.005[a]
Habitat	r=0.165		P=0.021	P=0.108
Host plants	r=0.299[a]	r=0.222		P=0.033
Genetic distance	r=0.224[a]	r=0.076	r=0.128	

[a] Significant after Bonferroni's correction.

cardenolides in the blend (linear regression, $F_{1,\ 16}$=0.736, P=0.404). When plants were tested individually, only *Heracleum sphondylium* had a significant Mantel correlation with the cardenolide composition (r=0.166, P=0.049), whereas the correlations for *Angelica sylvestris* and *Seseli libanotis* were marginally nonsignificant (Table 3). The importance of these three plants was confirmed by removing them sequentially from the overall Mantel test between host plant and cardenolide composition. The correlation remained significant when one or two of these plants were removed, but disappeared when removing all three.

Influence of genetics and host plants for each cardenolide separately Nine cardenolides were significantly correlated with genetic distance (Table 4). In contrast, despite the fact that the whole blend of cardenolides was strongly correlated with host-plant use, there were no such correlations at the level of single cardenolides. Nevertheless, simply observing the presence/absence of cardenolides in populations revealed one pattern. Three cardenolides (RT=17.9, 19.0 and 21.6) were present in all sites except one, Puy de Dôme (FR9). This was the only population in our study where *O. speciosa* feeds on *S. libanotis*, and also the only population that lacks both *H. sphondylium* and *P. ostruthium* (Table 1).

Discussion

Autogenously synthesized chemical defense in *O. speciosa* showed considerable geographic variation: 36 out of 50 cardenolides varied in this sample of 18 populations, and no two populations showed the same cardenolide profile. Some of this variation is associated with genetic divergence, with a significant relationship for the overall blend and for nine of the 36 variable cardenolides when tested separately. This is clearly not evidence

Table 3 Results from Mantel correlations between the cardenolide distance matrix and matrices based on individual host plants

of a direct link between divergence at mitochondrial DNA and shifts in chemical defense. Instead, mtDNA serves as a marker of the level of divergence (assuming that mtDNA variation reflects the overall genomic variation) between what are probably strongly isolated populations (Margraf et al. 2007). More genetically divergent populations have probably experienced longer or stronger isolation and, therefore, a greater opportunity for the composition of their defense secretions to diverge by natural selection or genetic drift.

The host plant, a key element of the environment for herbivorous insects, was also important for the expression of some cardenolides. Such an influence of host-plant use is new and intriguing for insects that produce substances *de novo*. In other systems with sequestered compounds, there is a direct link between the host plants on which the insect feeds and the chemical profile of their defense secretions (Malcolm et al. 1989; Kopf et al. 1998; Moranz and Brower 1998; Wahlberg 2001; Verdon et al. 2007). For autogenously produced cardenolides, however, the relationship was unexpected. It is probably explained by the fact that cardenolides are synthesized from plant sterols (and possibly from other compounds such as sugars) that vary between plant species and provide an initial source of variation.

Those cardenolides that could be explained neither by genetic inheritance nor by the tested environmental factors must be the consequence of other sources of variation, such as geographical differences in plant chemistry, phenotypic plasticity, cyclic variation (e.g., seasonal cycles [Fordyce et al. 2005]), other biotic or abiotic environmental pressures (e.g., temperature), or simple random processes. Antagonistic or synergistic interactions between genetic and environmental factors could also explain the fact that many substances did not show a simple correlation with single phylogenetic or environmental distances.

The evolutionary forces driving this intraspecific polymorphism are clearly complex, involving both genetic and environmental influences. Divergence among populations is in part influenced directly by host-plant use, but may also be under natural selection depending on the level of predation or type of predators encountered. Genetic drift is likely to contribute, perhaps if the overall level of cardenolide defense is fixed but the individual

components are free to vary. There also seem to be constraints acting, with 14 of the components invariable across populations.

The number of cardenolides found within each population was remarkable, with between 19 and 42 compounds present. These secretions were pooled samples from 5 to 10 beetles, but because most of the variation in defense within *Oreina* populations is quantitative rather than qualitative (Eggenberger and Rowell-Rahier 1992), individuals are likely to possess the full blend of cardenolides typical of a population. The compounds varied in the number of sugars and the identity of both the sugar and aglycone components (Table 1). The complexity may have a functional explanation, if a blend is more efficient in promoting predator learning or deterrence. It could also simply be a result of the process of synthesis, with a mixed diet providing variation in the initial sterols and the inclusion of by-products and precursors in the secretion further increasing its diversity.

The geographical coherence of cardenolide composition was also striking. Populations were clustered into broadly eastern and western groups (consisting of an E-Alps/Balkan/Rhone valley group and a SW-Alps/Jura/Massif Central group, Fig. 1). This is not a result of host-plant use through host shifts or intraspecific variation in host chemistry, for the plants show no such structuring and are thoroughly mixed throughout the distribution (Table 1 with the one exception of *Seseli libanotis* found only at FR9). It is also not related to differences in the mean altitude of the two groups (Table 1), and so probably not influenced by current climatic conditions. It may be a product of the shared evolutionary history of populations, with two main clusters possibly corresponding to two different Pleistocene refugia and subsequent migration. Similar large-scale structuring is seen in other alpine insects and plants (Schönswetter et al. 2005; Schmitt et al. 2006; Margraf et al. 2007), and future phylogenetic work will test if the different lineages within *O. speciosa* present a biogeographic signal compatible with the history of climatic oscillations in Europe. The revelation of this east/west split shows the value of extending chemosystematics to the use of chemical markers at the intraspecific level. Although chemical defense based on cardenolides is typical of several lineages within the subtribe Chrysolinina to which *Oreina* belongs, there is sufficient variation within a species to group populations and investigate the interaction between their current ecology and evolutionary history.

Acknowledgments The authors wish to thank Matthias Borer for help during fieldwork, Eliane Abou-Mansour for help with chemical analysis, and the National Centre of Competence in Research (NCCR) Plant Survival for funding chemical and genetic analyses.

Introduction

Numerous plant traits may reduce the impact of damage by herbivores on plant fitness. These defensive traits may be expressed constitutively or may be induced following herbivory. Responses induced after damage by herbivores include changes in plant nutritional quality, the induction of defensive proteins and other allelochemicals, and the release of complex blends of volatile organic compounds (VOCs; reviewed by Karban and Baldwin 1997; Walling 2000). In many cases, VOCs may serve as cues that aid the discovery of herbivore-damaged plants by the natural enemies of those herbivores (reviewed by Arimura et al. 2005; Dudareva et al. 2006; D'Alessandro and Turlings 2006). The production of many induced VOCs is mediated, at least in part, by the jasmonic acid signaling pathway, and in many cases, VOC production similar to that caused by herbivore damage can be induced simply by exposing plants to jasmonic acid or its methyl ester, methyl jasmonate (MeJA) in the absence of herbivores (Hopke et al. 1994; Dicke et al. 1999; Degenhardt and Lincoln 2006). Induced VOC production has been studied primarily in cultivated species. Although the study of VOCs in cultivated species has logistical advantages, it is difficult to draw strong inferences on the evolution and maintenance of VOC production on cultivated species because the plants, herbivores, and their natural enemies are often far removed from their evolutionary context.

This study addressed induced VOC production in a native, undomesticated plant species. Sacred datura, *Datura wrightii* Regel (Solanaceae), produces two leaf trichome phenotypes that differ in their susceptibility to herbivorous insects. One phenotype is densely covered by short, non-glandular trichomes and feels velvety to the touch (hereafter the velvety phenotype), whereas the other phenotype is less-densely covered with glandular trichomes that secrete glucose esters and aliphatic acids, and these leaves feel sticky to the touch (hereafter the sticky phenotype; van Dam and Hare 1998a). Trichome phenotype is governed by a single locus and is inherited in a Mendelian fashion, with the allele for the glandular phenotype dominant over the nonglandular phenotype (van Dam et al. 1999). Within Southern California, the region in which this work was conducted, these two trichome phenotypes occur sympatrically, and the frequency of the sticky phenotype varies from 0 to 82% among populations (Hare and Elle 2001). For several of the herbivores that feed on *D. wrightii*, including whiteflies, leafhoppers, and flea beetles, the sticky phenotype is more resistant to attack (Hare and Elle 2002). In contrast, the chrysomelid beetle, *Lema daturaphila* Kogan & Goeden (Coleoptera: Chrysomelidae), appears unaffected by the presence of glandular trichomes (Hare and Elle 2002), and the mirid bug, *Tupiocoris notatus* Distant (Hemiptera: Miridae), specializes on the sticky phenotype (van Dam and Hare 1998b). *Lema daturaphila* is the primary herbivore of *D. wrightii* in Southern California (Hare and Elle 2002).

A number of generalist predators are associated with the herbivores of *D. wrightii*, including the damsel bug *Nabis americoferus* Carayon (Hemiptera: Nabidae; or possibly *Nabis alternatus* Parshley), the big-eyed bug *Geocoris pallens* Stål (Hemiptera: Lygaeidae), larval lacewings *Chrysoperla* spp. (Neuroptera: Chrysopidae), and the jumping spider *Habronattus pyrrithrix* Chamberlin (Araneae: Salticidae; Gassmann and Hare 2005). All of these species were less effective in suppressing *Lema daturaphila* or *T. notatus* when the herbivores were on plants of the sticky phenotype rather than on plants of the velvety phenotype (Gassmann and Hare 2005). *Lema daturaphila* is also parasitized by *Conura delumbis* (Hymenoptera: Chalcidae) and *Myiopharus infernalis* (Diptera: Tachinidae). These two widespread parasitoids have been collected from other populations and subspecies of *Lema daturaphila* (e.g., Puttler 1966), but relatively little else is known about them.

Datura wrightii shares with other solanaceous species the ability to produce elevated levels of proteinase inhibitors (PIs) and polyphenol oxidase (PPO) in response to treatment with MeJA, and induced levels of these defensive proteins in *D. wrightii* are similar to induced levels of PIs and PPO in cultivated tomato, *Lycopersicon esculentum* and potato, *Solanum tuberosum* (Hare and Walling 2006). PI and PPO levels were similarly inducible in the two trichome phenotypes of *D. wrightii*, but trichome morphology itself was not (Hare and Walling 2006).

Relatively little is known of the VOCs produced by *Datura* species. Fraser et al. (2003) reported the presence of several compounds in headspace collections from *D. wrightii* in Arizona that elicited electroantennogram activity in female *Manduca sexta*, and the presence of these compounds may serve as oviposition attractants for *M. sexta*. These compounds included (*Z*)-3-hexenyl acetate, (*Z*)-3-hexenyl propionate, nonanal, decanal, linalool, phenylacetaldehyde, methyl salicylate, geranylacetone, benzyl alcohol, (*E*)-nerolidol, and six unknowns. These plants presumably expressed the velvety phenotype because the sticky phenotype is not known to occur in Arizona (Mira and Bernays 2002), and these plants also were undamaged (Fraser et al. 2003) and presumably uninduced.

The goals of this study were to better understand the induced responses of *D. wrightii*. The first objective was to determine if *D. wrightii* produces VOCs in response to damage by *Lema daturaphila* and/or treatment with MeJA. The second objective was to determine if there might be genetic variation in VOC production among a series of genetic lines of *D. wrightii*. The final objective was to determine if sibling plants within lines that differed in the expression of trichome phenotype might also differ in VOC production.

Materials and Methods

Plants Seedlings were used from eight genetic lines that originated from crosses between a randomly selected pollen donor expressing the velvety phenotype and a heterozygous pollen acceptor expressing the sticky phenotype from four local populations. The plant populations and their characteristics are fully described in Hare and Elle (2004). Two populations, Bell Canyon and Ortega Flats, were from the Santa Ana Mountains from a relatively high-rainfall "mountain" habitat of *D. wrightii*. Two other populations were from the relatively drier Riversidian Sage Scrub habitat. One of these was on the campus of the University of California, Riverside (UC), whereas the other was on an undeveloped land within the city of Moreno Valley, California (MV). Two velvety pollen donors were selected from each of the four populations. Originally, each of the eight pollen donors was crossed to each of three different sticky pollen acceptors; one acceptor was from the same population, whereas another was from a different population in the same habitat, and the third was from a population in a different habitat. The original pollen donors were propagated vegetatively and continue to be maintained in 14 l pots in the greenhouse and repotted annually. The lines used in this experiment were third-generation backcross progeny of heterozygous sticky progeny backcrossed to their original velvety pollen parent. The expected ratio of adult heterozygous sticky to homozygous recessive velvety sibs within each of the three families derived from each of the eight original pollen donors is 1:1, and sibs within families are expected to be at least 93.75% similar after three generations of backcrossing.

Two batches of seeds of third-generation backcross progeny were germinated in the spring and fall of 2006 in a greenhouse equipped with high-pressure sodium lamps providing supplemental illumination for 16 h/day so that mid-day light intensities averaged

1,250±39 μmol m^{-2} s^{-1} PAR illumination (N= 5 readings) at plant height. Greenhouse temperatures ranged between 15° and 35°C. Plants were maintained under these conditions for about 3 months until trichome differentiation was complete (van Dam et al. 1999). One group of plants was used to determine if feeding by *Lema daturaphila* induced VOCs in *D. wrightii*, whereas the second was used to determine if treatment with MeJA also induced VOCs.

Collection of Volatiles Although it would have been simpler to collect the volatiles from detached leaves, Schmelz et al. (2001) showed that detached leaves of maize emitted greater quantities and different blends of VOCs than did leaves attached to their plants. To avoid such potential artifacts, volatiles were collected nondestructively from intact plants. Plants were 30–50 cm tall and had produced 10–15 leaves. After plants had completed trichome differentiation, they were brought to the laboratory and nondestructively aerated for 24 h in a plant growth room [16:8 photophase/scotophase, 26°C day and 20°C night temperatures with light intensity of 293 (±29 SE, N=5) μmol m^{-2} s^{-1} PAR illumination at plant height]. Aeration chambers were made from polyester cooking bags (unprinted 45× 55 cm bags, Terinex, Bedford, England) largely as described by Stewart-Jones and Poppy (2006). Swagelok® fittings with polytetrafluoroethylene (PTFE) ferrules were inserted in two slits in the bags, one for an air inlet and the other for an air outlet. Fittings were sealed to the bags with stainless-steel hose clamps. Bags were then flushed with about 40 l of compressed air (Medical grade) that was filtered through activated charcoal. Preliminary studies showed virtually no residual volatile compounds from new, flushed bags.

A bag was placed over a whole plant, excluding senescing leaves, and secured with a twist-tie around the stem. Intake and exhaust flow rates were regulated with flow meters (Aalborg, Orangeburg, NY, USA). PTFE tubing was used upstream of the adsorbent trap, and polyvinylchloride (PVC) tubing was used downstream. Compressed air, as above, flowed into the bag at 600 ml/min. After the bag was loosely inflated, air was exhausted through an adsorbent trap at the same rate with a house vacuum. VOCs were adsorbed on traps made of glass tubing and filled either with activated charcoal (10 mg) or Super-Q (25 mg, Alltech, State College, PA, USA). Preliminary experiments showed similar performance of the two adsorbents. At the termination of the aeration, traps were wrapped in aluminum foil, labeled, and stored at −20°C for extraction later that day.

Sampling procedures were developed to give highest priority to detect differences in VOC production between trichome phenotypes. Groups of four plants (two pairs of sticky and velvety sibs) were aerated at a time. The experiment was arranged in three blocks, with each block containing one of the three families from each of the original eight pollen donors, and each block of plants was aerated in succession. Within blocks, families from different pollen donors were selected at random for aeration. These procedures were adopted to avoid confounding potential variation in the inducibility of plants from different genetic lines with potential age-related differences over the 24-day VOC collection period.

Insect Damage Treatment After plants were aerated the first time, they were placed in a single cage and 15–20 second, and third instars of *Lema daturaphila* were placed on each of the plants. Larvae were allowed to feed for 24 h, then the leaf area removed was assessed (Hare and Elle 2002), and larvae were removed. Plants were returned to a separate greenhouse with similar conditions as the first. After an additional 48 h, plants were returned to the laboratory and aerated once again for 24 h with clean bags and traps. Preliminary studies showed relatively little VOC induction until 2–3 days after insect damage. To control for potential variation in the number of leaves aerated, aerated leaves

were removed from the plant, dried to a constant weight at 80°C, and the dry weight was recorded. This information was used to calculate the release rate of VOCs per unit of leaf mass (see below). Care was taken to ensure that exactly the same leaves were aerated before and after treatment. A total of 48 plants (8 genetic lines×3 families within each line×2 trichome phenotypes) were aerated before and after insect damage.

MeJA Treatment After these plants were aerated before MeJA treatment, they were returned to a separate greenhouse with similar rearing conditions and treated with a suspension of 8 mM MeJA (Bedoukian Research) in 0.1% Tween 20 (Sigma). This rate is typical of those used in previous studies (e.g., Boughton et al. 2005), and preliminary studies showed that this rate provided a response similar to that caused by insect damage (see "Results") without causing any visible injury to plants. Leaves of plants were sprayed just to run-off (10–15 ml per plant). Plants remained in this greenhouse for 72 h, after which they were returned to the laboratory and aerated once again for 24 h by using fresh bags and traps. At the end of the aeration, traps were removed and extracted, and leaves were collected, dried, and weighed as above. Only 44 plants were aerated because sibs from 2 families (out of 24) grew atypically slowly and were not sampled.

A slightly different collection apparatus was used to sample quantities of (*E*)-β-caryophyllene produced by the original male parents of test plants. For these plants, volatiles were collected from plants in the greenhouse with methods similar to those that Kessler and Baldwin (2001) used to collect volatiles from plants in the field. Rigid polyethylene terephthalate extraction chambers were made from soft drink cups (Solo Cup, Highland Park, IL, USA., model TP16 cups and DL626 lids) that enclosed a single full-sized leaf of a plant. Ambient air was drawn through the cups for 24 h with a 12-V battery-powered vacuum pump (Gast Mfg., Benton Harbor, MI, USA) powered by a deep-cycle marine storage battery, and the volatiles were adsorbed on a Super-Q trap, as above. A manifold was used to draw air through 16 lines at a time at a mean (±SE) flow rate of 680±23 ml/min per line. Fifteen plants were sampled at a time, and the 16th line was connected to an adsorbent trap attached to an empty chamber ('blank') to quantify and control for ambient volatiles in the greenhouse. Extractions were made on five clonal individuals of each original pollen donor before and after treating the whole plant with MeJA, then waiting 72 h as above. In each case, a young but full-sized leaf was extracted, and the sampled leaf was subsequently removed, dried, and weighed.

Volatiles Analysis Volatiles were eluted from the traps with CH_2Cl_2 that contained 4 ng/μl of *n*-bromoheptane as an internal standard. Activated charcoal traps were eluted with 60 μl, whereas the Super-Q traps were eluted with 150 μl. Extracts were stored in 200 μl vials sealed with PTFE closures and stored at −20°C. One micro liter of each extract was analyzed on a Hewlett-Packard 5890 Series II gas chromatograph (Agilent Technologies, Avondale, PA, USA) with a flame ionization detector with a DB-5 column (60 m, 0.25 mm ID, 0.25 μm film thickness, J & W Scientific, Folsom, CA, USA). Injector and detector temperatures were 200 and 250°C, respectively. Injections were made in splitless mode with a column flow of 25 cm/s with helium as the carrier gas. The oven was programmed from 40 to 250°C at 5°C/min with a hold at the final temperature for 5 min. To confirm identifications, selected samples were analyzed with a Hewlett-Packard 6890 GC coupled to a Hewlett-Packard 5973 mass selective detector, and the mass spectra and retention times of compounds were matched with those of authentic standards. Most standards were obtained from Sigma-Aldrich and subsidiaries. Samples of (*E*,*E*)-4,8,12 trimethyl-1,3,7,11 tridecatetraene (hereafter TMTT), (*E*)-4,8,dimethyl-1,3,7 nonatriene (hereafter DMNT), and (*E*)-β-ocimene were kindly provided by Dr. J. G. Millar. Peak quantification was made by

using Agilent ChemStation software, and the detected volatiles were quantified based on comparison of their peak height with those of the internal standard. Quantities of volatiles released are expressed in units of ng per mg leaf (dry wt) per hour.

Statistical Analyses Because volatiles were collected from plants before and after feeding by insects or application of MeJA, the appropriate analysis was a repeated measures analysis with each plant as a 'subject.' Such an analysis provides relatively good control for variation within treatments to detect differences between treatments. Because the response variables are likely correlated, it is inappropriate to analyze each by univariate methods. Instead, a 'multivariate analysis of variance (MANOVA)-protected ANOVA' approach was used in which the group of VOCs was first analyzed by MANOVA, and then ANOVAs were carried out on the individual VOCs only if the MANOVA was statistically significant (Scheiner 2001). Repeated-measure MANOVAs were carried out with trichome phenotype, genetic line, and treatment and their two-way and three-way interactions as fixed effects and plants within trichome phenotype by genetic line combinations as the repeated, random 'subjects' effect using PROC GLM of SAS (SAS Institute 2000). Because of the unequal sample sizes in the MeJA experiment where two of the lines had only two families instead of three, the univariate analyses were carried out by using a restricted maximum likelihood method (PROC MIXED of SAS), which is more robust than PROC GLM with unequal sample sizes. The (log +1) transformation and the arcsine square root transformation were applied to quantitative and proportional data, respectively, so that the residuals would be normally distributed.

Results

Seventeen compounds generally were found in plants induced by insect feeding or treatment with MeJA. Most of these compounds were also found in the volatiles of uninduced plants but at lower concentrations (Table 1). By far, the most abundant compound in plants induced either by feeding by *Lema daturaphila* or MeJA treatment was (*E*)-β-caryophyllene. Although methyl salicylate, geranylacetone, phenylacetaldeyde, and benzyl alcohol were reported from the volatiles of *D. wrightii* in Arizona (Fraser et al. 2003), these compounds were detected, at best, only occasionally and in trace amounts in this study. A number of hexenyl esters also occurred in a few samples in trace amounts. Methyl jasmonate and jasmone were detected from MeJA-treated plants, but not from insect-damaged plants. Because these two compounds likely are artifacts of MeJA treatment, they were deleted from all analyses. With the exception of (*Z*)-3-hexenyl acetate, none of the 'green leaf volatiles' was detected in either experiment. Most of these compounds usually are produced immediately after damage occurs, and their production may have ceased before aerating plants 48 h after insect damage had been terminated.

Larvae of *Lema daturaphila* removed about 10–15% of available leaf tissue during the 24-h feeding period. The quantities of leaf area consumed were ignored in the calculation of VOC production in undamaged plants. This is likely a conservative error in the analysis because it would slightly overestimate the VOC production of undamaged plants, thus making it more difficult to detect increases in VOC production due to insect feeding. Feeding damage was sufficient to cause an increase in the quantities of VOCs overall (MANOVA, Wilks' λ=0.096056, F=10.00, ndf=16, ddf=17, P<0.001). VOC production also varied among genetic lines, (MANOVA, Wilks' λ=0.000069, F=3.64, ndf=112, ddf=119.6,

[a] Tentative identification based upon mass spectrum

$P<0.001$) and due to the interaction between insect feeding treatment and genetic line (MANOVA, Wilks' $\lambda=0.002718$, $F=1.59$, *ndf*=112, *ddf*=119.6, $P=0.006$). Thus, the change in VOC production due to insect damage itself varied among genetic lines. Feeding by *Lema daturaphila* increased the production of the individual compounds, (*Z*)-3-hexenyl acetate ($F_{1,\ 32}=25.53$, $P<0.001$), limonene ($F_{1,\ 32}=22.92$, $P=0.001$), (*E*)-β-ocimene ($F_{1,\ 32}=71.84$, $P<0.001$), linalool ($F_{1,\ 32}=7.79$, $P=0.009$), DMNT ($F_{1,\ 32}=8.84$, $P=0.006$), unknown sesquiterpene 1 ($F_{1,\ 32}=4.43$, $P=0.043$), (*E*)-β-caryophyllene ($F_{1,\ 32}=142.8$, $P<0.001$), α-bergamotene ($F_{1,\ 32}=34.41$, $P<0.001$), α-humulene ($F_{1,\ 32}=60.51$, $P<0.001$), β-selinene ($F_{1,\ 32}=56.38$, $P<0.001$), and TMTT ($F_{1,\ 32}=8.63$, $P=0.006$, Table 1). The quantities of (*Z*)-3-hexenyl acetate ($F_{7,\ 32}=4.21$, $P=0.002$), limonene ($F_{7,\ 32}=2.37$, $P=0.045$), DMNT $F_{7,\ 32}=6.43$, $P<0.001$), unknown sesquiterpene 2 ($F_{7,\ 32}=4.76$, $P<0.001$), (*E*)-β-caryophyllene ($F_{7,\ 32}=6.98$, $P<0.001$), α-humulene ($F_{7,\ 32}=4.18$, P=0.002), and β-selinene ($F_{7,\ 32}=3.37$, $P=0.008$) also differed overall among genetic lines. Interactions between genetic line and insect damage were significant for (*E*)-β-ocimene ($F_{7,\ 32}=2.32$, $P=0.049$), α-humulene ($F_{7,\ 32}=2.67$, P=0.027), and unknown sesquiterpene 4 ($F_{7,\ 32}=2.52$, $P=0.034$), indicating that the increase in the production of these compounds after insect damage varied among genetic lines.

The patterns of variation may be summarized simply by focusing upon the proportion of (*E*)-β-caryophyllene, the most abundant compound, and total VOC production. The percent of the total blend that was (*E*)-β-caryophyllene varied due to treatment ($F_{1,\ 32}=54.21$, $P<0.001$) and genetic line ($F_{7,\ 32}=3.42$, $P=0.008$). After insect damage, the proportion of (*E*)-β-caryophyllene ranged from a low of 17.9% in the UCV9 line to a high of 59.2% in the OFV6 line (Fig. 1). Total VOC production differed significantly only due to insect treatment and genetic line ($F_{1,\ 32}=84.7$, $P<0.001$ and $F_{7,\ 32}=2.59$, $P=0.031$, Fig. 2). Total volatile production increased after insect damage by 3.9-fold in the OFV6 line to 16.2-fold in the OFV8 line.

MeJA-treated Plants The application of MeJA increased the production of volatile compounds overall (MANOVA, Wilks' $\lambda=0.030085$, $F=22.76$, *ndf*=17, *ddf*=12, $P<0.001$). Volatile production also varied among genetic lines (MANOVA, Wilks' $\lambda=0.000020$, $F=3.154$, *ndf*=119, *ddf*=88.2, $P<0.001$) and due to the interaction between MeJA treatment and genetic line (Wilks' $\lambda=0.000453$, $F=1.67$, *ndf*=119, *ddf*=88.2, $P<0.006$). The significant interaction shows that the responses to MeJA also differed among genetic lines. Application of MeJA increased the emission of (*Z*)-3-hexenyl acetate ($F_{1,\ 28}=10.84$, $P=0.003$), limonene ($F_{1,\ 28}=5.35$, $P=0.028$), (*E*)-β-ocimene ($F_{1,\ 28}=99.06$, $P<0.001$), linalool ($F_{1,\ 28}=8.06$, $P=0.008$), DMNT ($F_{1,\ 28}=4.54$, $P=0.042$), unknown sesquiterpene 2 ($F_{1,\ 28}=10.92$, $P=0.003$), (*E*)-β-caryophyllene ($F_{1,\ 28}=342.94$, $P<0.001$), α-bergamotene ($F_{1,\ 28}=19.1$, $P<0.001$), α-humulene ($F_{1,\ 28}=175.9$, $P<0.001$), unknown sesquiterpene 3 ($F_{1,\ 28}=11.1$, $P=0.002$), β-selinene ($F_{1,\ 28}=74.54$, $P<0.001$), and TMTT

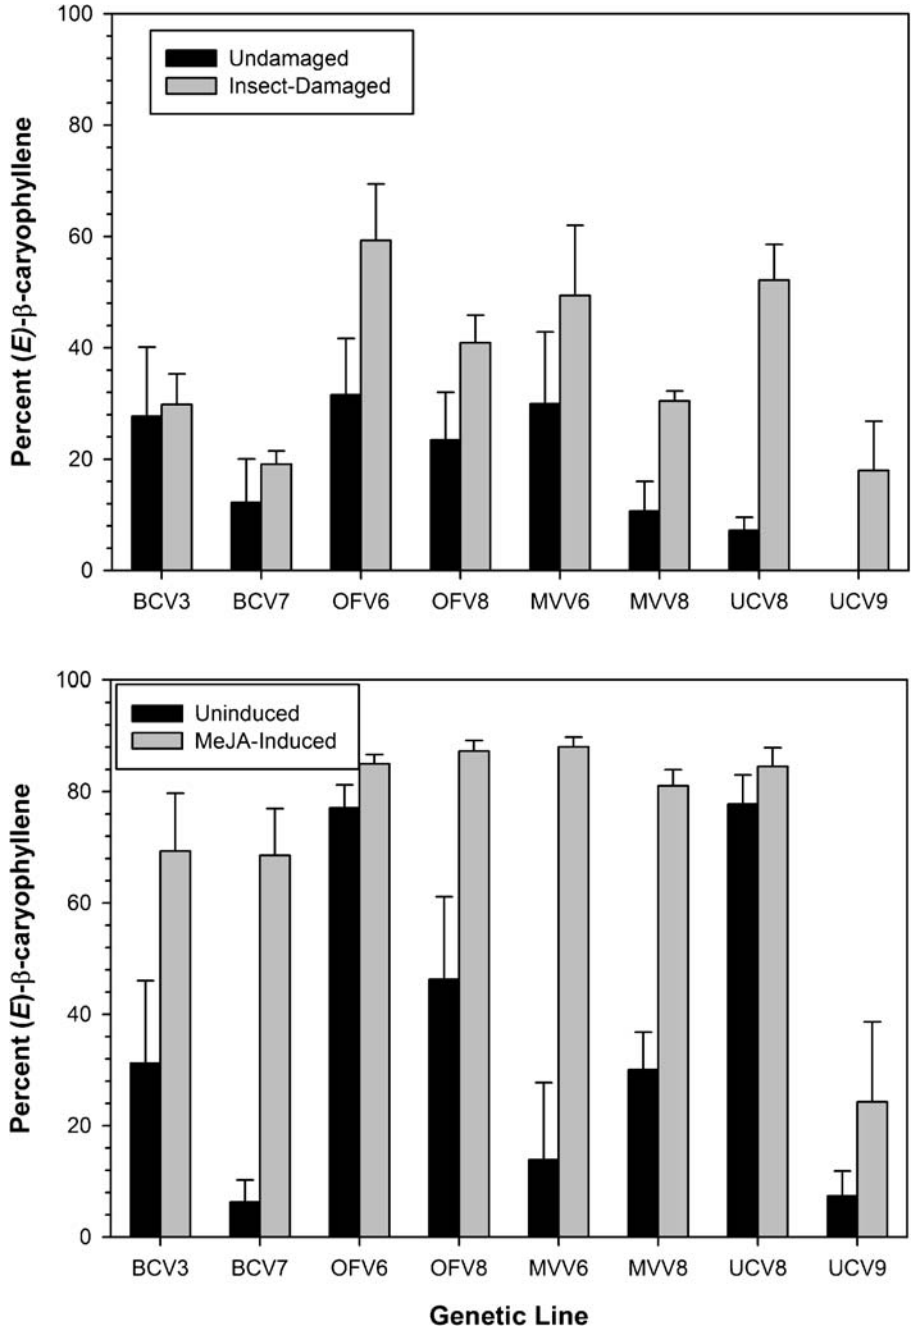

Fig. 1 Mean percent (+SE) of (*E*)-β-caryophyllene in the VOC blends of families from different genetic lines of *D. wrightii* pooled over trichome phenotype. Values are shown both before and after damage by *Lema daturaphila* (*upper plot*) or treatment with MeJA (*lower plot*)

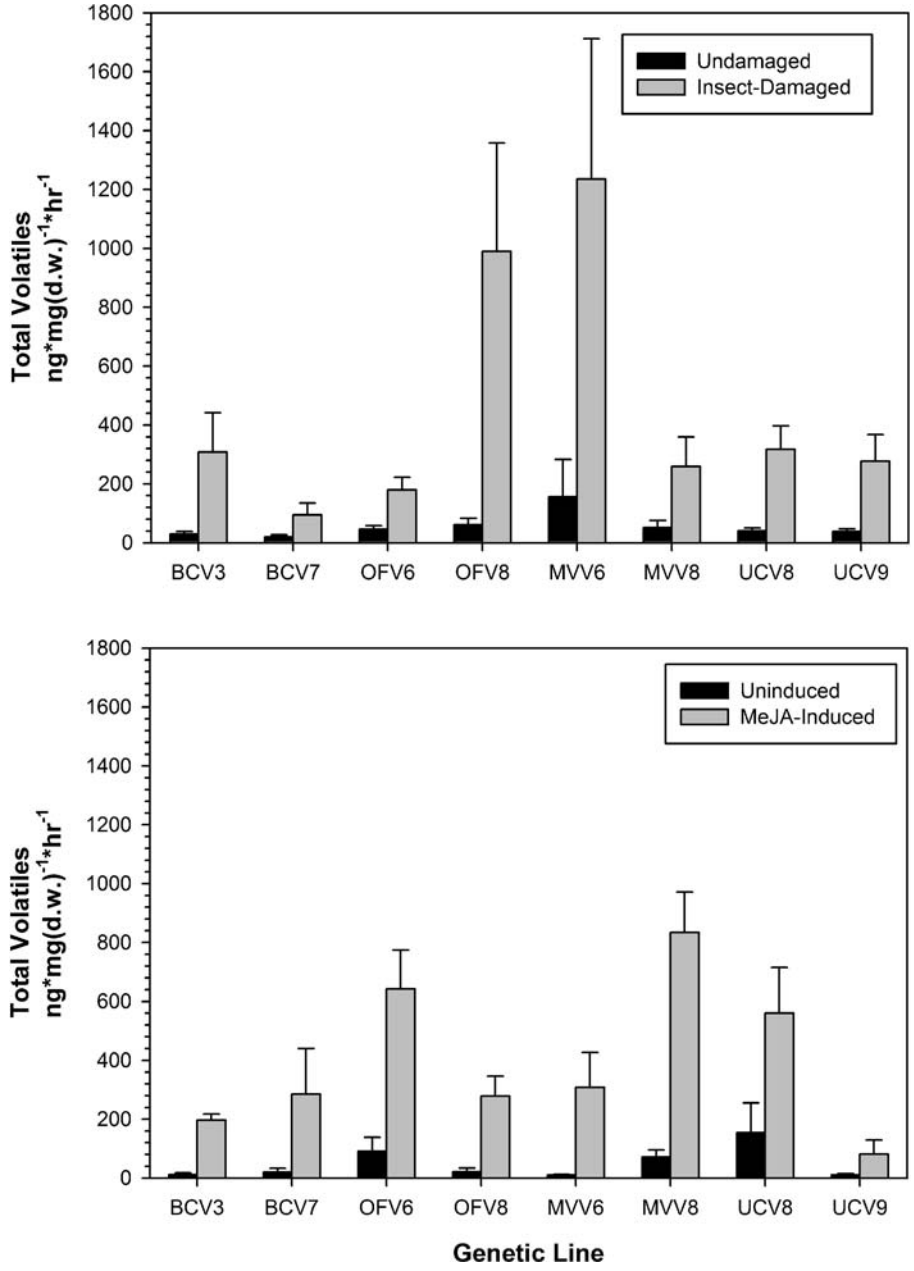

Fig. 2 Mean (+SE) total VOC production by different genetic lines of families from *D. wrightii* pooled over trichome type. Values are shown both before and after damage by *Lema daturaphila* (*upper plot*) or treatment with MeJA (*lower plot*)

($F_{1,\ 28}$=17.08, P<0.001, Table 1). The quantities of limonene ($F_{7,\ 28}$=12.73, P<0.001), (*E*)-β-ocimene ($F_{7,\ 28}$=4.39, P=0.002), decanal ($F_{7,\ 28}$=2.59, P=0.034), unknown sesquiterpene 1 ($F_{7,\ 28}$=10.10, P<0.001), unknown sesquiterpene 2 ($F_{7,\ 28}$=14.59, P< 0.001), (*E*)-β-caryophyllene ($F_{7,\ 28}$=6.58, P<0.001), α-bergamotene ($F_{7,\ 28}$=4.28, P<

0.003), α-humulene ($F_{7, 28}$=3.19, P=0.013), unknown sesquiterpene 3 ($F_{7, 28}$=10.85, P< 0.001), β-selinene ($F_{7, 28}$=3.64, P<0.007), nerolidol ($F_{7, 28}$=4.86, P=0.001), TMTT ($F_{7, 28}$= 4.71, P=0.001), and unknown sesquiterpene 4 ($F_{7, 28}$=3.12, P=0.014) also differed among genetic lines. Interactions between MeJA treatment and genetic line were statistically significant for the production of (*E*)-β-ocimene ($F_{7, 28}$=4.51, P=0.0018), (*E*)-β-caryophyllene ($F_{7, 28}$=5.33, P<0.001), and α-humulene ($F_{7, 28}$=2.79, P=0.025).

The percent (*E*)-β-caryophyllene differed due to MeJA treatment ($F_{1, 28}$=133.0, P< 0.001), genetic line ($F_{7, 28}$=8.31, P<0.001), and the interaction between genetic line and MeJA treatment ($F_{7, 28}$=9.12, P<0.001, Fig. 1). In the plants treated with MeJA, the percent of the total blend of volatiles that was (*E*)-β-caryophyllene ranged from 24.3% in the UCV9 line to 88% in the MVV6 line. Total volatile production differed significantly only between MeJA treatments ($F_{1, 28}$=255.2, P<0.001) and among genetic lines ($F_{7, 28}$= 4.41, P=0.002). Total VOC production increased from 3.6-fold in the UCV8 line to more than 32-fold in the MVV6 line (Fig. 2).

There was no significant variation due to trichome type nor due to any statistical interactions involving trichome type in the MANOVA analyses of either experiment (all $P \geq$ 0.13). Sibling plants differing in trichome type produce similar VOCs (Table 1).

Relationship between Parents and Offspring in (E)-β-Caryophyllene Production Although the same range of volatiles was collected from parents as offspring, for simplicity, only the relationship between parents and offspring for the most abundant volatile, (*E*)-β-caryophyllene, was analyzed and presented. The variation among genetic lines in their production of (*E*)-β-caryophyllene after treatment with MeJA in the backcross progeny was related to the variation in MeJA-induced parents (b=1.108, P=0.04, Fig. 3).

Discussion

Datura wrightii produces an array of terpenoids in response to damage by *Lema daturaphila*, its primary herbivore, or after treatment with MeJA. The amount of increase varied from 3.6- to over 32-fold among *D. wrightii* genotypes. In some cases, VOC production of some lines after insect damage or MeJA treatment was lower than the production of VOCs by other lines before damage or MeJA treatment. By far the most abundant compound was (*E*)-β-caryophyllene, and the proportional concentration of this compound in the total VOC blend after insect damage varied from 17–59% among genetic lines. Previously, PIs and PPO activity were shown to be inducible traits of *D. wrightii*, but the activities of these defensive proteins were independent of trichome phenotype. Similarly, in this study, inducible VOC production also was independent of trichome phenotype.

Variation in the production of VOCs has been studied primarily in cultivars of agricultural crops, including maize (Hoballah et al. 2004), cotton (Loughrin et al. 1995), rice (Lou et al. 2006), carrot (Nissinen et al. 2005), pear (Scutareanu et al. 2003), gerbera (Krips et al. 2001), and cruciferous crops (Bukovinszky et al. 2005). Variation in VOC production also is known in laboratory mutants of other species such as tomato (Thaler 2002) and lotus (Ozawa et al. 2000). In an analysis of 31 maize hybrid lines, for example, there was about 70-fold variation in the quantity of volatiles emitted and in the odor profile; in some cases, the quantities of odors emitted by undamaged plants of one line were higher than quantities emitted by damaged plants of other lines (Degen et al. 2004), as was the case in *D. wrightii*. The significance of such variation in VOC production among cultivars

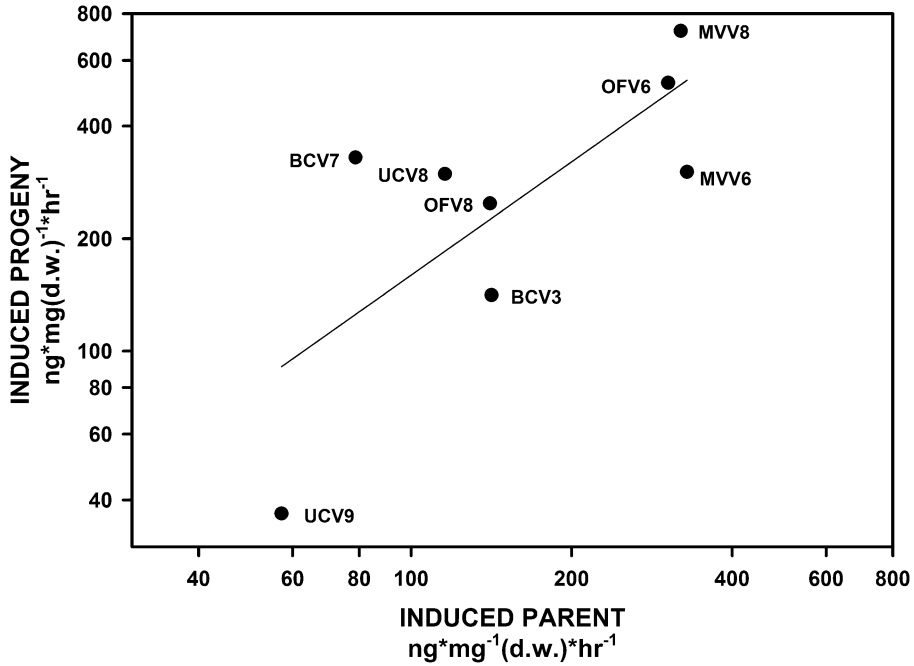

Fig. 3 Relationship between the production of (*E*)-β-caryophyllene by the original male parents of each genetic line and the family means of their third-generation backcross progeny. The regression line (slope= 1.108, intercept=−0.067) is statistically significant at $P=0.045$

is difficult to evaluate. Although some natural enemies may show differential attraction to the odors of particular cultivars in the laboratory (Krips et al. 2001; Hoballah et al. 2002; Bukovinszky et al. 2005), only rarely has it been shown that the more attractive cultivars actually benefit from enhanced biological control in the field (Lou et al. 2006).

Relatively little is known about the extent of genetic variation in VOC production of non-cultivated species, although such variation has been reported among five species and subspecies of teosinte, the ancestors of cultivated maize (Gouinguene et al. 2001). In that study, up to eightfold quantitative variation was noted among the five accessions, and qualitative differences, as indexed by the proportion of three major sesquiterpenes, were also observed. To date, the significance of such variation in VOC emissions among teosintes for suppressing the natural enemies of teosinte's native herbivores in its natural, ancestral environments remains unknown.

Another example of variation in VOC production in natural populations involves three populations of *Nicotiana attenuata* in the American southwest. Halitschke et al. (2000) compared two populations in Utah and found that they differed in their production of (*E*)-β-ocimene, linalool, and *cis*-α-bergamotene. Additionally, a population of *Nicotiana attenuata* in Arizona produced no induced VOCs (Glawe et al. 2003). Although the ecological significance of variation in VOC production between the two Utah populations remains unclear (Halitschke et al. 2000), the primary way in which the Arizona population may cope with absent or reduced induced defenses against its herbivores may be through increased competitive ability (van Dam and Baldwin 2003).

The MeJA experiment was performed to standardize the level of induction and, therefore, is the more accurate induction treatment to investigate potential differences in

induced VOC production among genetic lines. The significant, positive relationship between production of (*E*)-β-caryophyllene between male parents and backcross offspring suggests that the quantitative differences are inherited, although the experimental design was not appropriate to calculate formal estimates of genetic heritability for any plant population. Nevertheless, these data suggest that more detailed experiments to quantify the heritability of VOC quantities and blends within these populations could be worthwhile.

Although the MeJA and insect damage experiments were performed at different times and may not be directly comparable, it appears that feeding by *Lema daturaphila* and MeJA treatment have similar effects on the production of VOCs by *D. wrightii*. Both cause a substantial increase in the production of most compounds, although by far the greatest increases were in the production of (*E*)-β-caryophyllene. Damage by *Lema daturaphila* may cause relatively greater increases in the production of (*Z*)-3-hexenyl acetate, (*E*)-β-ocimene, DMNT, and β-selinene (Table 1). Differences in the volatile blends from MeJA-induced plant compared to insect-damaged plants may not be surprising if plants generally respond differently to insects than to MeJA. Such differences have been reported previously in other systems (Dicke et al. 1999; Degenhardt and Lincoln 2006; Rodriguez-Saona et al. 2006), and induction by insect damage generally results in a more complex blend of volatiles compared to induction with MeJA or JA alone, as was observed in the present study.

These results suggest numerous questions for further study on the evolution and maintenance of direct and indirect defenses against herbivores in *D. wrightii*. First, given the substantial quantitative and qualitative variation in VOC production of *D. wrightii*, do plants that produce either a greater quantity of VOCs, or a particular VOC blend, attract a greater number or diversity of natural enemies? If so, does such differential attraction result in differences in plant fitness? Is there additive genetic variation for total VOC production and odor profile? If so, and if differential attraction of natural enemies results in differential fitness, then is there natural selection on plants for the production of particular VOC blends? Alternatively, if plants producing different levels or blends of VOCs fail to differentially attract natural enemies, then the observed variation may merely reflect neutral variation, perhaps the result of stochastic processes such as genetic drift or founder effects within these relatively small plant populations (Hare and Elle 2004).

The answers to these questions will require detailed behavioral studies in both the laboratory and field on the natural enemies of *D. wrightii*'s herbivores. It seems unlikely that all of those species of natural enemy would respond similarly to variation in VOC production. In other systems, different herbivores induce the production of different VOC blends, and the different blends attract different, specialized parasitoids (e.g., De Moraes et al. 1998). Variation among herbivore-induced blends may matter less to generalist parasitoids (e.g., Yan and Wang 2006). Variation in VOC blends may be of even less relevance to *G. pallens*, which preys upon *Manduca* spp. and flea beetles (Kessler and Baldwin 2001, 2002), as well as *T. notatus* and *Lema daturaphila*, and is the predominant predator in Southern California populations of *D. wrightii* (Gassmann and Hare 2005). The fact that this species can be attracted to plants or sticky cards baited with single compounds (Kessler and Baldwin 2001; James 2002) suggests that only one or a few key components within a blend may be required to attract this important predator. The ecological importance of qualitative variation in the composition of VOCs emitted by *D. wrightii* genotypes after damage by *Lema daturaphila* may vary among different natural enemy species that attack *Lema daturaphila*.

The fact that sticky and velvety sibs produce similar VOC blends and quantities but differ in their suitability for foraging by resident natural enemies (Gassmann and Hare

2005) adds an interesting complication when coupled with prior observations that the frequency of plants with glandular trichomes varies widely among Southern and Central California populations (Hare and Elle 2001). If there is natural selection for VOC production, then the intensity of selection may vary among populations based upon the relative importance of direct defense against herbivores via glandular trichomes compared to indirect herbivore defenses mediated by VOC production. Selection for VOC production may be stronger in populations with a high frequency of plants that express nonglandular trichomes and weaker in populations with a high frequency of plants that express glandular trichomes. *D. wrightii* offers a rich system to investigate the ecological significance of variation in induced VOC production under natural conditions.

Acknowledgments I thank M. Haight and L. Christensen for assistance in the laboratory, J. G. Millar for assistance with the GC-MS analyses, and J. G. Millar and J. D. Allison for comments on a previous draft of the manuscript. This work was supported by the National Science Foundation under Grant no DEB 0414181 to J. D. Hare.

antinutritional compounds, protein or nutritional constituents, leaf toughness, thorns, spines, or trichomes (Karban and Baldwin 1997). Following damage, plant nutritional quality may decrease or the concentration of secondary compounds, physical defenses, or volatile emissions may increase (Green and Ryan 1972; Karban and Baldwin 1997; De Moraes et al. 1998). In many cases, induced changes reduce subsequent herbivory and act as plant defenses (Carroll and Hoffman 1980; Karban and Baldwin 1997; Agrawal 2000). It is thought that induced defenses are less costly than constitutive ones because they are only activated after herbivory (Agrawal 2000; Strauss et al. 2002). Plant defense theory predicts a trade-off between induced and constitutive defenses (Koricheva et al. 2004).

Induced responses to herbivory have been demonstrated multiple times for leaf-chewing insect herbivores (Green and Ryan 1972; Carroll and Hoffman 1980; Malcolm and Zalucki 1996; Karban and Baldwin 1997), but less is known about the effects of phloem-feeding insect herbivores on induction. Because phloem-feeders do not remove leaf tissue per se, defenses induced by phloem feeders may differ from those induced by leaf chewers (Martel and Malcolm 2004). Induction by phloem feeders has been documented in a number of plant species (Gianoli and Niemeyer 1997; Gianoli 2002; Martel and Malcolm 2004; Sauge et al. 2006). In addition to variation among herbivore guilds, there is also variation among closely related plant species (Martel and Malcolm 2004; Cardoza et al. 2005). For example, previous work within *Asclepias* found evidence for cardenolide reduction and induction in high cardenolide species, but no change in cardenolide concentrations in species that lack constitutive defenses (Martel and Malcolm 2004). Similarly, interspecific variation in response to leaf-chewer herbivory has been documented in a number of genera including *Lupinus* and *Gossypium* (Thaler and Karban 1997; Vilarino et al. 2005).

In laboratory experiments, we measured changes in plant quality induced by varying densities of the milkweed–oleander aphid, *Aphis nerii*, on four species (*Asclepias incarnata*, *Asclepias syriaca*, *Asclepias tuberosa*, and *Asclepias viridis*). Specifically, we measured changes in defensive chemical concentrations (cardenolides), foliar nitrogen and carbon, and plant biomass. Plant defense theory predicts that species with high constitutive cardenolide concentrations will not exhibit induction, while species with low levels are more likely to (Karban and Baldwin 1997; Koricheva et al. 2004). We expected *A. tuberosa* (low constitutive cardenolides) to exhibit the highest degree of cardenolide induction, followed by *A. syriaca* (medium constitutive cardenolides), and we did not expect cardenolide induction in either *A. viridis* or *A. incarnata*.

Methods and Materials

Study System Asclepias is composed of predominately herbaceous perennials with a wide geographic distribution (Woodson 1954), and most produce a milky, cardenolide-laden latex when damaged (Malcolm 1991). Cardenolides, or cardiac glycosides, are a group of cardiac-active steroids that are bitter-tasting and toxic in high doses. They have many negative effects on herbivores, even in those species adapted to feed on them (Brower et al. 1984; Malcolm 1989, 1991; Malcolm and Brower 1989; Zalucki et al. 2001a). Their bitter taste combined with potential toxicity has implicated cardenolides in defensive use by plants against herbivores, parasites, and pathogens (Malcolm and Zalucki 1996; Agrawal and Malcolm 2002; Agrawal and Fishbein 2006).

There is much variability in cardenolide concentrations within and among milkweed individuals and species (Nelson et al. 1981; Malcolm 1991; Agrawal and Fishbein 2006)

and both qualitative and quantitative variation among *Asclepias* species (Malcolm et al. 1989; Malcolm 1991). Species also vary in carbon and nitrogen concentration, trichome density, specific leaf area, and water content (Agrawal 2004).

Aphis nerii Boyer de Fonscolombe (Hemiptera: Aphididae) is an aposematic, phloem-feeding specialist of milkweed, *Asclepias* spp., and oleander, *Nerium oleander* L. (Apocynaceae). It undergoes parthenogenetic reproduction for most of its life cycle, and sexual morphs are only produced under cold-day, long-night conditions (Takada and Miyazaki 1993).

Laboratory Experiments In August 2003, three *A. nerii* individuals were collected from geographically distinct locations (Atlanta, GA; Augusta, GA; and Gainesville, FL). Each is referred to as a separate clone. An aphid colony was initiated from one individual from each location, leading to three lab colonies. Separate colonies of these clones were kept at low densities on *A. syriaca* in the growth chamber.

Experiments were conducted in a temperature- and light-controlled walk-in growth chamber. Metal halogen grow lights on timers (16:8 hr, L–D) provided heat and light, and daytime and nighttime temperatures were 34±2.4 and 24±0.48°C, respectively. *Asclepias* seeds (Butterfly Encounters) were grown in Farfard 3B soil with 0.5 g of Osmocote time-release fertilizer (14:14:14, N–P–K) and watered as needed. Genotypes were unknown. Seedlings were grown in small pots (8 cm diameter); however, they were not root bound. Plants were randomly assigned to treatments and rotated daily to homogenize any environmental gradients within the growth chamber. Four species, *A. tuberosa*, *A. viridis*, *A. incarnata*, and *A. syriaca*, were chosen to represent a range of plant quality traits. They vary in foliar carbon and nitrogen concentrations, trichome density (Agrawal 2004), and cardenolide content (Malcolm et al. 1989; Agrawal 2004), as well as in their life history strategies. The rank order from lowest to highest cardenolide contents are *A. tuberosa* (negligible), *A. incarnata* (low), *A. syriaca* (moderate), and *A. viridis* (high) (M.D. Hunter, unpublished data). These four species were previously studied in a set of field experiments (Helms et al. 2004).

The identical experimental design was repeated on each of the four *Asclepias* species (*A. tuberosa*, June 2004; *A. viridis*, July 2004; *A. incarnata*, October 2004; and *A. syriaca*, November 2004). Because of time and space limitations, we could not examine all species concurrently. Thus, comparisons among plant species should be treated with caution. However, photoperiod, temperature, and other environmental conditions remained constant in the growth chamber over the course of all experiments. For each experiment, three aphid densities (1, 25, and 50 aphids per plant, and 0 aphids on controls) were established on 1-mo-old *Asclepias* seedlings that were grown in the chamber prior to the start of each experiment. Fifty aphids per seedling is approximately 250–500 aphids per gram DW plant tissue, which is at the high end of natural aphid densities in our system (Helms et al. 2004). Higher aphid densities, for example, 75 aphids per plant, kill *A. viridis* and *A. tuberosa* seedlings before the experiment concludes. At the start of the experiment, all seedlings were 4 wk old, approximately the same size (10–15 cm in height), and composed of a single stem bearing 6–10 leaves. Initially, five adult apterae aphids were placed on all plants, except controls, and left to reproduce overnight. Adult aphids were removed, and their offspring were thinned to the assigned density with a paintbrush. If necessary, offspring were moved from low- to high-density plants. This was repeated for all three clones, except for the experiment on *A. syriaca*, for which only the Emory and Florida clones were available. Each density by clone combination was replicated seven times, and each plant was caged (including controls). Cages were

constructed from 710-ml Ziploc containers and organza netting over wire frames. Initial cohorts were allowed to develop and reproduce. Once they started reproducing, all offspring were removed daily to keep densities constant. This continued until all aphids died (29±1 d), meaning that the size of each initial aphid population decreased over time.

For each plant species, seven individuals were harvested at the start of the experiment on the same day that the aphids were put on the plants (control A), and seven other plants served as controls throughout the experiment and received no aphids (control B). We chose these controls instead of measuring the same plants twice to avoid any induction caused by early leaf sampling on young plants.

Plants were harvested at the end of the experiment after all aphids had died. Each plant was cut at the stem base and rinsed with deionized water to remove honeydew. Plants were freeze-dried and weighed with a Mettler balance to determine above-ground plant biomass, then ground and homogenized. From each individual, a subsample (~2–3 mg) was analyzed for carbon and nitrogen and another subsample (~50 mg) for cardenolides (methods below). We analyzed the entire above-ground plant because aphids colonized both stems and leaves.

Plant Chemistry For carbon and nitrogen analysis, ground samples were weighed in tin capsules with a Mettler UMT2 microbalance (Mettler Toledo, Greifensee, Switzerland) and analyzed with a Carlo Erba NA 1500 CHN analyzer (Carlo Erba, Milan, Italy). Cardenolides were analyzed by using methods modified from Malcolm and Zalucki (1996). Briefly, ground samples were extracted with methanol and analyzed with high-performance liquid chromatography (HPLC). Peaks were detected by diode array at 218 nm, and absorbance spectra were recorded from 200 to 300 nm with digitoxin as the standard. Peaks with symmetrical absorption maxima between 217 and 222 nm were recorded as cardenolides (Malcolm and Zalucki 1996). Total cardenolide concentration was calculated as the sum of all individual cardenolide peaks.

Statistical Analyses Given that experiments were run sequentially, data from each plant species were analyzed separately. Total cardenolide concentration, plant biomass, and plant foliar nitrogen and carbon were compared among treatments by using two-way ANOVAs with aphid density and clone as main effects. Residuals were checked for normality, and data were transformed when necessary. *Asclepias viridis* biomass data were log transformed. Tukey's honest significant difference tests were conducted to compare among treatment means.

Neither aphid clone nor the interaction between aphid clone and aphid density was significant for any of the plant response variables measured for any of the plant species studied. Therefore, subsequent analyses were done by pooling the three aphid clones together within each density category. This allowed us to compare the three aphid density treatments with control B plants (no aphids). We reran the analyses for total cardenolide concentration, plant biomass, and foliar nitrogen and carbon by using a one-way ANOVA with aphid density (0, 1, 25, or 50 aphids per plant) as the main effect.

In addition to the response of total cardenolide concentration to variation in aphid density, we were interested in the response of individual cardenolide compounds. A MANOVA was used to analyze all individual peaks concurrently, and this was followed by separate univariate ANOVAs for individual peaks. Subsequently, *P* levels were adjusted downward because of multiple comparisons that used standard (nonsequential) Bonferroni methods (Sokal and Rohlf 1995).

Results

Milkweed species varied in their responses to aphid herbivory in general, and specifically to increases in aphid density. Because aphid clone had no effect on any of the response variables measured, we only report comparisons among the four density treatments (0, 1, 25, and 50 aphids per plant).

Aphid density influenced total cardenolide concentration in only one species. As density increased, total cardenolide concentration in *A. viridis* decreased (Fig. 1a $F_{3,62}$=5.86, P=0.001). There was a 43% reduction in cardenolides between the low- and high-density treatments. However, there was no difference between total cardenolide concentration of controls and *A. viridis* plants that experienced aphid herbivory. Eighteen individual cardenolide compounds were detected by HPLC in *A. viridis* (MANOVA Wilk's lambda $F_{54,135}$=1.83, P=0.003). However, only three of these (identified as peaks 17, 12, and 2) were influenced by aphid density (Fig. 1b: peak 17 $F_{3,62}$=9.54, P<0.001; peak 12 $F_{3,62}$=5.21, P=0.003; peak 2 $F_{3,62}$=5.56, P=0.002) with concentrations generally declining at the highest aphid densities.

In *A. syriaca*, overall cardenolide levels were more than an order of magnitude lower than those in *A. viridis* (average *A. syriaca* cardenolide concentration 0.22±0.04 mg/g). There was no effect of aphid density on total cardenolide concentration (data not shown, $F_{3,43}$=0.15, P=0.927), nor on any of the four individual cardenolide compounds detected (MANOVA Wilk's lambda $F_{12,106}$=0.82, P=0.63; individual ANOVA were all nonsignificant, data not shown). No cardenolides were detected in *A. tuberosa*, and cardenolides were detected in only one *A. incarnata* individual (that received 50 aphids per plant).

The effect of aphid density on plant growth (measured as above-ground biomass accumulation) varied among plant species (Fig. 2). As aphid density increased, plant biomass accumulation decreased by 58% on *A. viridis* ($F_{3,62}$=20.63, P<0.001). On *A. incarnata*, plants receiving the high-density treatment accumulated 24% less biomass than those receiving the low-density treatment ($F_{3,59}$=6.70, P=0.001). However, there was no difference in above-ground biomass accumulation between controls and treatment plants under Tukey's honestly significant difference (HSD) test. There was no effect of aphid

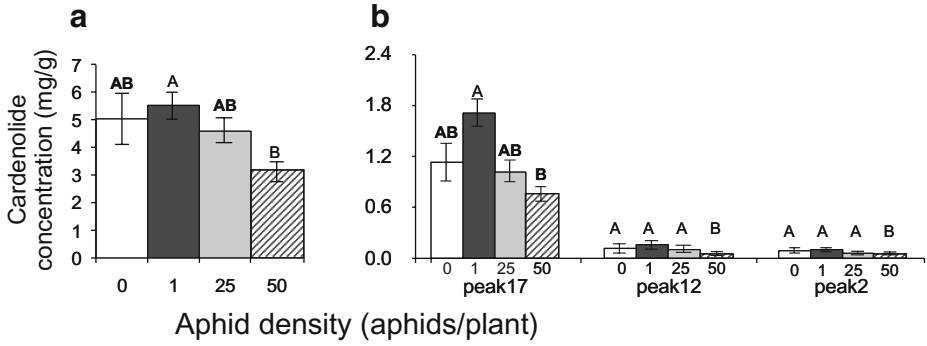

Fig. 1 The effect of increasing *A. nerii* density on **a** total cardenolide concentration and **b** individual cardenolide compounds in *A. viridis*. *White bars* are controls (0 aphids per plant), *dark gray bars* are the low density treatments (1 aphid per plant), *light gray bars* are 25 aphids per plant, and *striped bars* are 50 aphids per plant. There were no significant differences among the three aphid clones, so values were pooled in each density category. Values are means (N=7 for control, N=21 for all other density treatments) ±1 standard error. Different *letters* above *bars* represent significant differences among treatment means

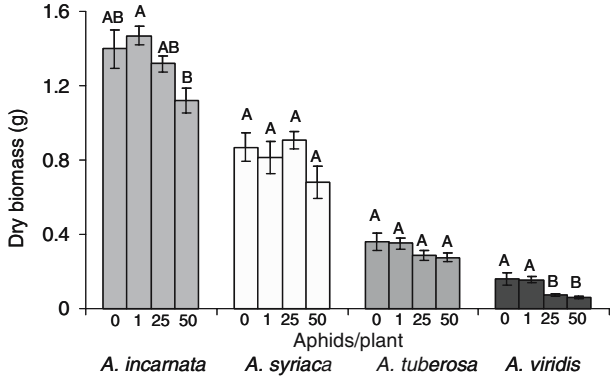

Fig. 2 The effect of increasing *A. nerii* density on final above-ground dry biomass of four *Asclepias* species: *A. incarnata*, *A. syriaca*, *A. tuberosa*, and *A. viridis*. Data from three aphid clones were pooled because there was no effect of clone on biomass accumulation. *Bars* are means of 21 plants (14 for *A. syriaca*) ±1 standard error except for controls (0 aphids per plant), which are means of 7 plants. Different *letters* above *bars* represent significant differences among treatment means within each plant species

herbivory on biomass accumulation of *A. syriaca* ($F_{3,43}$=1.60, P=0.203) or *A. tuberosa* ($F_{3,64}$=1.83, P=0.151).

Asclepias viridis individuals that received the highest aphid density treatment had 15% less foliar nitrogen than control individuals (Fig. 3: $F_{3,65}$=3.49, P=0.021). On *A. incarnata*, there was a trend towards increased foliar nitrogen concentration as aphid density increased ($F_{3,63}$=3.30, P=0.026), but none of the treatments was significantly different from the control under Tukey's HSD test. Aphid herbivory did not influence plant foliar nitrogen in either *A. tuberosa* ($F_{3,62}$=0.57, P=0.636) or *A. syriaca* ($F_{3,44}$=1.56, P=0.212).

Asclepias incarnata individuals that received the high-aphid-density treatment had 3% less foliar carbon than both control plants and plants that only had a single aphid on them (Fig. 4: $F_{3,63}$=4.77, P=0.005). Aphid density did not influence foliar carbon concentrations in any of the other three plant species (*A. tuberosa* $F_{3,62}$=0.28, P=0.840; *A. viridis* $F_{3,65}$= 1.77, P=0.162; *A. syriaca* $F_{3,44}$=1.14, P=0.343).

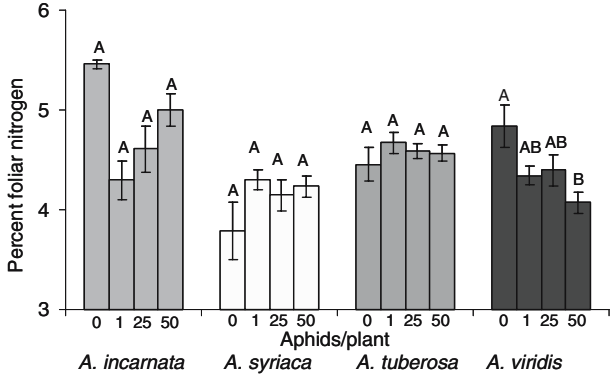

Fig. 3 The effect of variation in *A. nerii* density on foliar nitrogen of four *Asclepias* species: *A. incarnata*, *A. syriaca*, *A. tuberosa*, and *A. viridis*. Data from three aphid clones were pooled because there was no effect of clone on foliar nitrogen concentrations. *Bars* are means of 21 plants (14 for *A. syriaca*) ±1 standard error except for controls (0 aphids per plant), which are means of 7 plants. Different *letters* above *bars* represent significant differences among treatment means within each plant species

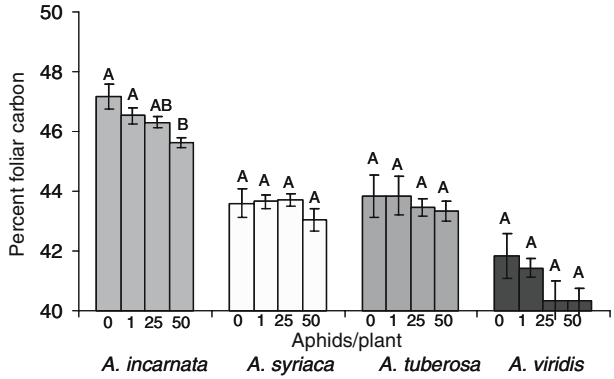

Fig. 4 The effect of variation in *A. nerii* density on foliar carbon of four *Asclepias* species: *A. incarnata*, *A. syriaca*, *A. tuberosa*, and *A. viridis*. Data from three aphid clones were pooled because there was no effect of clone on foliar carbon concentrations. *Bars* are means of 21 plants (14 for *A. syriaca*) ±1 standard error except for controls (0 aphids per plant), which are means of 7 plants. Different *letters* above *bars* represent significant differences among treatment means within each plant species

Table 1 shows plant quality data for the 1-mo-old (control A) seedlings that were harvested at the start of the experiment (before aphids were added), and for control B seedlings that were harvested at the end of the experiment. Interestingly, 4-wk-old *A. incarnata* seedlings had cardenolides present in low concentrations, while older plants expressed no cardenolides. Additionally, cardenolide concentrations increased in *A. viridis* but decreased in *A. syriaca* as plants aged. Foliar nitrogen concentrations decreased as *A. syriaca* and *A. tuberosa* seedlings aged, but foliar carbon concentrations stayed constant between young and old seedlings for all four plant species.

Discussion

There was significant variation among the *Asclepias* species in their responses to aphid herbivory and variation in aphid density. We found no evidence for a trade-off between constitutive and induced cardenolide defenses. None of the species studied exhibited cardenolide induction. *Asclepias viridis* was the only species to show an aphid-induced change in cardenolide concentration, which declined with increasing density (Fig. 1).

Table 1 Biomass, total cardenolide concentration, percent foliar nitrogen, and percent foliar carbon for control A seedlings (collected at the start of the experiment) and control B seedlings (collected at the end of the experiment) of four *Asclepias* species

	Biomass (g)[a]		Total Cardenolide Concentration (mg/g)[a]		Foliar Nitrogen (%)[a]		Foliar Carbon (%)[a]	
	A	B	A	B	A	B	A	B
A. incarnata	0.12±0.02	1.40±0.10	0.23±0.03	0	5.97±0.32	5.45±0.04	43.28±0.27	47.17±0.43
A. syriaca	0.12±0.22	0.87±0.78	0.50±0.23	0.20±0.06	6.16±0.16	3.78±0.28	44.24±0.21	43.60±0.50
A. tuberosa	0.05±0.01	0.36±0.05	0	0	5.54±0.20	4.46±0.17	43.58±0.45	43.83±0.70
A. viridis	0.02±0.01	0.16±0.01	2.98±0.56	5.02±0.89	4.86±0.22	4.84±0.21	40.22±0.55	41.83±0.74

[a] Values are means of seven plants ±1 standard error

Similarly, *A. viridis* foliar nitrogen concentrations declined with increasing density (Fig. 3). Both *A. viridis* and *A. incarnata* exhibited a decrease in final plant biomass with increasing density (Fig. 2). In contrast, aphids had no effect on the growth, nutritional quality, or defensive chemistry of either *A. syriaca* or *A. tuberosa*.

Previous research found that high *A. nerii* density induced cardenolide expression in *A. curassavica* but not in *A. incarnata* (Martel and Malcolm 2004). Martel and Malcolm (2004) found essentially no constitutive or inducible cardenolide defenses in *A. incarnata*, and we found no evidence for cardenolide induction in either of the low cardenolide species examined here (*A. incarnata* and *A. tuberosa*). These species may be defended by other compounds not measured here, such as pregnane glycosides (Warashina and Noro 2000).

The results of Martel and Malcolm (2004) for *A. curassavica* make an interesting comparison with our results for *A. viridis*, because both are high-cardenolide plant species. In *A. curassavica*, cardenolide concentrations decrease at low aphid densities, and then increase as density increases (Martel and Malcolm 2004). We observed no similar increase in cardenolide concentrations at high aphid density on *A. viridis* (Fig. 1a). Our plants were all young seedlings, and Martel and Malcolm (2004) used older plants. It is possible that aphid cardenolide induction or suppression varies with plant age, as has been shown for other plant species (Boege and Marquis 2005). It is also possible that there is much variation among *Asclepias* species in responses to aphid herbivory, such that *A. viridis* and *A. curassavica* simply respond differently to aphid attack.

We observed reduced growth of *A. viridis* and *A. incarnata* at high aphid density (Fig. 2). Because these experiments were run on small, young seedlings, we cannot make any generalizations about the impact of aphid herbivory on larger plants. In addition to causing a decrease in biomass accumulation, high aphid density led to a small decrease in *A. incarnata* foliar carbon concentrations (Fig. 4). While these results were statistically significant, we doubt that a 3% reduction in foliar carbon concentration is ecologically relevant for a plant like *A. incarnata* that typically grows in full sun.

Individual cardenolides differ in both their polarity and influence on herbivores (Malcolm and Zalucki 1996; Zalucki et al. 2001a, b), so it is not surprising that individual compounds respond differently to aphid attack. In *A. viridis*, only a subset (3 of 17) of cardenolide compounds declined significantly under aphid herbivory (Fig. 1b). An examination of the response of individual compounds will likely provide greater insight into plant responses to herbivory than measurements of total concentrations.

Mechanical damage to *A. syriaca* induces cardenolide expression after 24 hr, but then cardenolide concentrations drop to constitutive levels after 148 hr (~6 d) (Malcolm and Zalucki 1996). We collected plants approximately 29 d after each experiment started. If there was rapid cardenolide induction and a subsequent decay, we would have been unable to detect it. *Asclepias syriaca* may induce cardenolides in response to a simulated leaf-chewer, but not to phloem-feeder, damage.

Aphis nerii is a specialist of milkweed and oleander that can sequester cardenolides for defense against natural enemies (Malcolm 1989, 1991; Agrawal and Malcolm 2002). Some researchers have documented no difference in population growth between aphids feedings on high- and low-cardenolide plants (Groeters 1993; Martel and Malcolm 2004), while others have shown a negative impact of cardenolides on aphid maximum population growth (Agrawal 2004). Another milkweed specialist, the monarch butterfly, is negatively impacted by high levels of cardenolides (Zalucki et al. 2001a), so specialist herbivores are not necessarily immune from the defenses of the plants that they specialize on.

Assuming that the benefit to a specialist herbivore of sequestering cardenolides outweighs the negative impact of ingesting cardenolides, then from the plant's perspective,

cardenolide induction in response to herbivory by a specialist herbivore would be counterproductive. Increased cardenolide levels could actually benefit the herbivore and harm the plant because higher cardenolides would allow the specialist herbivore to be better protected from natural enemies. This is known as the lethal plant paradox (Malcolm and Zalucki 1996; Fordyce 2001). By not inducing cardenolides under aphid attack, all four *Asclepias* species avoid benefiting the cardenolide-sequestering herbivore at their own expense. Additionally, by reducing cardenolide concentration, *A. viridis* may reduce the cardenolide concentrations sequestered by *A. nerii* and thus lower the aphid's defense against natural enemies. Future work will compare sequestration of cardenolides under different aphid densities and examine variation in aphid predation and parasitism rates.

We have previously reported the results of aphid population growth on these plant species (Zehnder and Hunter 2007) and it is interesting to relate those dynamics to the plant quality traits measured here. *Aphis nerii* exhibits density-dependent survival, fecundity, and alate production on all four *Asclepias* species. However, density-dependent responses are strongest on *A. viridis* and weakest on *A. incarnata*. *Asclepias viridis* has the highest cardenolide concentrations of all the species we examined, and it also has the lowest biomass after 7 wk of growth. Our current results suggest that the density-dependent reductions in *A. viridis* cardenolide and nitrogen concentrations may be related to the density-dependent vital rates exhibited by *A. nerii*. However, changes in cardenolide, nitrogen, and carbon concentrations do not seem to be responsible for the density-dependent response of *A. nerii* on *A. incarnata*, *A. tuberosa*, or *A. syriaca*.

In summary, we found that changes in *A. nerii* density led to changes in plant chemistry and biomass, although not as we had predicted. *Asclepias* species with low constitutive levels of cardenolides did not exhibit higher levels of induced defenses than species with high constitutive defenses. In no case did increased aphid density lead to increased cardenolide expression. As aphid density increased, *A. viridis* cardenolide concentrations, biomass, and foliar nitrogen decreased. For *A. incarnata*, increased aphid density led to a decrease in plant biomass. Aphid density did not affect any measured trait of either *A. tuberosa* or *A. syriaca*. Our results highlight that congeneric plant species may respond differently to the same levels of herbivore damage.

Myrmicinae) ants obligatorily colonize *Macaranga* and harvest its pearly secreta or food bodies as their main food source. The ants benefit the host plants by patrolling to exclude herbivores (Fiala et al. 1989; Fiala and Maschwitz 1990, 1992a, b). In obligate *Macaranga–Crematogaster* myrmecophytisms, neither party can survive in the absence of the other because they are highly specialized and dependent upon each other (Fiala and Maschwitz 1990; Fiala et al. 1999).

In contrast with other myrmecophytes from the American and African tropics, *Macaranga* is unique in having highly species-specific relationships with ants: one *Macaranga* species harbors one ant species principally, and one ant species interacts with a narrow range of *Macaranga* species (Fiala et al. 1999). Phylogenetic studies have noted the possibility of cospeciation in *Macaranga–Crematogaster* interactions (Itino et al. 2001; Quek et al. 2004), although partnerships of myrmecophytisms in other regions are less specific and appear to be determined by habitat segregation and colonization types, rather than cospeciation (Ward 1991; Davidson and McKey 1993; Yu and Davidson 1997). Moreover, *Macaranga* is ecologically unique among myrmecophytes in that multiple species of obligate myrmecophytes commonly coexist in similar microenvironments on a small spatial scale (Davies et al. 1998; Itioka et al. 2000); nevertheless, the species specificity is maintained (Itino et al. 2001).

The key factor that regulates specific partnerships is the wide variety of *Macaranga* defense strategies. There is interspecific variation in antiherbivore defense by symbiont ants, and ant aggressiveness differs among sympatric *Macaranga* species (Itioka et al. 2000). In addition, *Macaranga* species have different nonant defenses, i.e., physical and chemical defenses that complement ant defenses (Nomura et al. 2000). This suggests that different *Macaranga* species, including obligate myrmecophytes, have different strategies in terms of the balance between ant and nonant defenses. In contrast, the species complex of herbivores that feed on *Macaranga* and predators that feed on the symbiont ants also differ among *Macaranga* species (Itino and Itioka 2001). This is likely to be addressed by differences in defense strategies among *Macaranga* species. For example, *Macaranga* that tend to be attacked by specialist gall-forming flies are well-defended—both chemically and physically, whereas other *Macaranga* species that harbor the most aggressive ants have soft stems and leaves and suffer high levels of damage from birds that forage on the symbiont ants (Nomura et al. 2000; Itino and Itioka 2001). Each ant species is predicted to show its own specific aggressive behavior toward specific enemies in the mutualistic system between a *Macaranga* species and its symbiont ant.

When the host tree is injured, workers of the symbiont ant species immediately move from their nests inside the hollow stems to the surface of the plant and show aggressive behavior (Itioka et al. 2000). In addition, as in the *Cecropia* myrmecophytism (Agrawal 1998), aggressive behavior of symbiont ant workers is induced not only by damage to the host plant, but also by damage to neighboring myrmecophytic trees. This indicates that ant workers can recognize damaged areas, and that cues are released from the damaged host plant that stimulate aggressive behavior by the ants. Moreover, if ant workers inhabiting adjacent undamaged plants respond to damage-induced cues, the cues may provide useful information that enables the ants to recruit promptly for defense against a possible herbivore attack. Thus, in *Macaranga* myrmecophytisms, ant aggressive behavior would be induced not only by damage to the host tree, but also by damage to other *Macaranga* trees. Therefore, we examined whether damaged *Macaranga* leaves induce aggressive behavior in ant workers that inhabit a neighboring tree.

If ants respond equally to the damage of adjacent *Macaranga* trees regardless of tree species, ant defense induced by damage to adjacent trees would not be very effective because the aggressive ant behavior is considered to be enemy-specific. Unnecessary

frequently induced aggressive ant behavior may impose excessive costs on the ant colony, and subsequently, require the host tree to produce greater food rewards. If so, the cost–benefit balance of ant defense would be disrupted. Therefore, if symbiont ants on *Macaranga* myrmecophytes can distinguish between cues from conspecific and heterospecific host trees, they may avoid costly and ineffective responses to cues from adjacent *Macaranga* trees. Thus, we examined whether symbiont ant workers on *Macaranga* myrmecophytes show differential responses and aggressive behavior to artificial damage on adjacent *Macaranga* trees depending on tree species.

One possible cue that induces aggressive behavior in symbiont ants is volatile chemicals emitted from the injured area of the host plant. Many plants emit volatile compounds as an inducible response to herbivore damage that attract natural enemies of herbivores (Vet and Dicke 1992; Paré and Tumlinson 1999). Thus, we examined whether leaf volatiles emitted by injured *Macaranga* are species-specific, and therefore, may be used as chemical cues to induce ant defense.

Methods and Materials

Study site and materials The study site was located in a mixed dipterocarp forest in Lambir Hills National Park, Miri, Sarawak, Malaysia (4°2′ N, 113°50′ E; 60 m above sea level). The details of the study site were described by Yumoto and Nakashizuka (2005). More than ten myrmecophytic species of *Macaranga* occur at the site. We investigated four *Macaranga* species: *M. bancana* Miq., *M. beccariana* Merr., *M. trachyphylla* Airy Shaw, and *M. winkleri* Pax. & Hoffm. These are all obligate myrmecophytes inhabited by species-specific *Crematogaster* ants. The *Crematogaster* species inhabiting the four *Macaranga* species were classified morphologically and by mtDNA sequences (Itino et al. 2001), although the species have not been described. All experimental *Macaranga* trees were <2 m in height and were occupied by mature ant colonies. Field experiments and leaf volatile compound collections were conducted in August, September, and November 2004.

Assessment of ant defensive aggression To investigate whether the intensity of defensive attacks by resident ant workers stimulated by volatiles from injured leaves is specific to the host *Macaranga* species, a field assessment of ant aggressive behavior was conducted in at least ten randomly chosen trees of each of the four *Macaranga* species. The second leaf from the top of a different *Macaranga* tree was collected. A piece (1 cm^2) was cut from the leaf and held close to the second node of an experimental *Macaranga* tree by using forceps and without moving the tree. Leaf pieces were cut and used within 5 min of leaf collection. The numbers of ant workers that aggregated on the second node (recruits), climbed on the forceps or the experimenter's hand (climbers), and/or bit the experimenter's hand (biters) during a 90-sec period were recorded. For ants inhabiting the four *Macaranga* species, eight host leaf pieces were offered separately. For ants inhabiting *M. bancana*, a total of 20 nonhost leaf pieces (8 of *M. beccariana*, 8 of *M. trachyphylla*, and 4 of *M. winkleri*) were offered. For ants inhabiting *M. beccariana*, a total of 20 nonhost leaf pieces (8 of *M. bancana*, 8 of *M. trachyphylla*, and 4 of *M. winkleri*) were offered. For ants inhabiting *M. trachyphylla*, a total of 20 nonhost leaf pieces (7 of *M. bancana*, 8 of *M. beccariana*, and 5 of *M. winkleri*) were offered. For ants inhabiting *M. winkleri*, a total of 12 nonhost leaf pieces (4 of *M. bancana*, 4 of *M. beccariana*, and 4 of *M. trachyphylla*) were offered. When ants in a single experimental tree were examined more than once, we carried out experiments at intervals of at least 2 d, and leaf pieces were offered in randomized order to

eliminate influence by previous experiments. Forceps were rinsed with *n*-hexane between experiments to remove previous plant chemicals.

For each type of behavior within an ant species (represented by their host species), we compared the numbers of ants that responded among the *Macaranga* species by using Kruskal–Wallis tests, and compared the numbers of ants that responded between conspecific host leaf pieces and nonhost leaf species (pooled data) by using Mann–Whitney *U*-tests. For each type of behavior, Kruskal–Wallis tests were used for comparisons of the numbers of ants that responded among the ant species, and Steel–Dwass tests for multiple comparisons.

Chemical analysis of volatile leaf compound Volatile compounds emitted from injured young leaves were obtained by using headspace adsorption to examine differences in the chemical characteristics of the volatile compounds. The first three or four leaves were collected from the top of five randomly chosen trees per species for *M. bancana*, *M. beccariana*, and *M. winkleri*, and six randomly chosen trees of *M. trachyphylla*. The leaves were shredded into approximately 2-cm squares. We recorded the fresh weight of each set of leaves and then placed them into sampling bottles. The inlet of sampling bottles was connected via Tygon tubing to a purge bottle that contained activated charcoal and an air pump. The air was purified by the activated charcoal and pumped into the sampling bottle. Volatiles in the sampling bottle were adsorbed onto 50 mg of TENAX-TA (80–100 mesh; GL Sciences, Tokyo, Japan) in a glass tube (inner diameter [ID]=3 mm; length=16 cm] that was connected to the outlet of the sampling bottle. The air flux was maintained at 150 ml min^{-1} for 150 min. Empty sampling bottles were used as control.

The volatiles trapped in the TENAX-TA were eluted with 1 ml of diethyl ether. Each eluate was condensed to about 5 μl under N_2 flow, dissolved in 200 μl of hexane that contained 200 ng of *n*-eicosane as an internal standard, and 2 μl of each sample were analyzed. Analyses were performed with a GC-17A gas chromatograph and a QP5050A mass spectrometer (Shimadzu, Kyoto, Japan) equipped with a DB-WAX glass capillary column (J & W Scientific, 0.25 mm ID, 30 m length, 0.25 μm film thickness). Helium was used as the carrier gas. The injector was operated in splitless mode for 0.75 min. Oven temperature was programmed as follows: 40°C for 1 min, raised at 3°C min^{-1} to 90°C, to 200°C at 10°C min^{-1}, and then to 240°C at 20°C min^{-1}. Detected peaks were identified by comparing them with mass spectra in the NIST21, NIST27, NIST107, and NIST147 databases. Identification of each compound was further confirmed by comparison of both mass spectrum and GC retention data with those of authentic standards whenever possible. Peaks that were also detected in controls and those with extremely low intensity from only one individual of a species were omitted. Relative peak intensity was calculated as the ratio of the peak area to the peak area of the internal standard. Relative amounts of compounds in a sample were determined as relative peak intensities equivalent to 10 g (fresh weight) of leaves. Based on the relative amounts of compounds, compositions among *Macaranga* species were compared by using two-way repeated-measures ANOVA. For each compound, we compared the relative amounts among *Macaranga* species with one-way ANOVA. Statistical analyses were performed with JMP version 6.0J (SAS institute).

Results

Ant aggressive behavior induced by injured leaf pieces The number of ant recruits differed among *Macaranga* species, except for ants inhabiting *M. winkleri* (Fig. 1). The number of

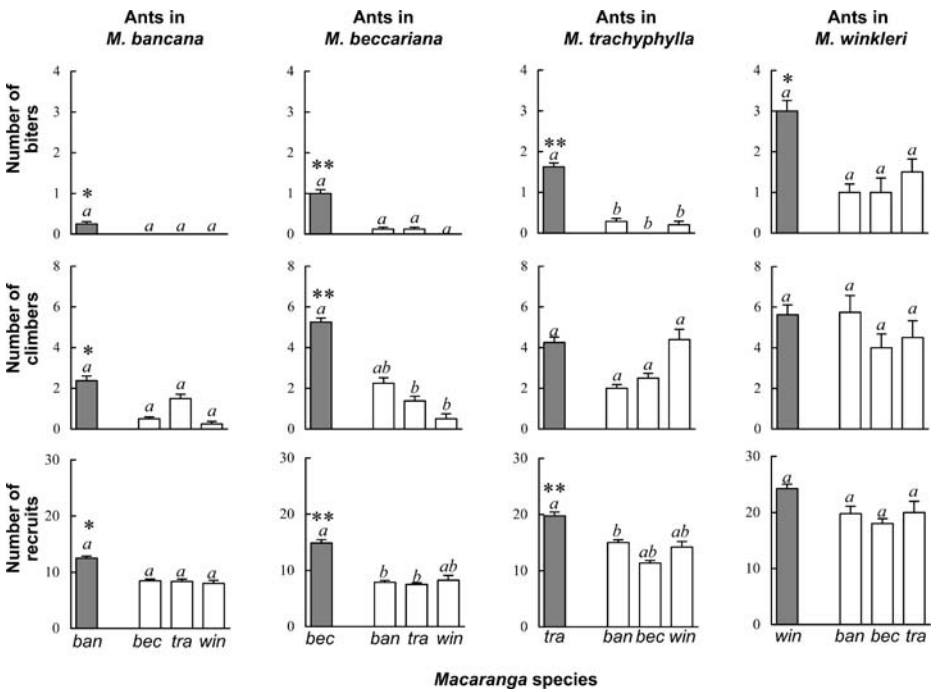

Fig. 1 Intensity of ant defensive aggression (mean number of ants±SE) for three types of aggressive behavior: recruiting, climbing, and biting against a leaf piece cut from another tree of *ban*: *M. bancana*, *bec*: *M. beccariana*, *tra*: *M. trachyphylla*, or *win*: *M. winkleri*. *Gray columns* mean ant responses when host conspecific leaf pieces were offered, and *open columns* mean when nonhost leaf pieces were offered. *Different alphabetical letters* indicate a significant difference in ant response among *Macaranga* species (Steel–Dwass test, $P<0.05$). *Asterisks* above the gray columns indicate significance in ant responses between the offers of host and nonhost leaf pieces (*$P<0.05$, **$P<0.01$, Mann–Whitney *U*-test, see detail in the text)

ants inhabiting the other three species that arrived at host leaf pieces was higher than the number that arrived at nonhost leaf pieces (Mann–Whitney *U*-test: adjusted $Z=-3.047$, -3.331, and -2.775; $P=0.002$, $P<0.001$, and $P=0.006$ for ants inhabiting *M. bancana*, *M. beccariana*, and *M. trachyphylla*, respectively). The number of biters differed among *Macaranga* species only for ants that inhabited *M. beccariana* and *M. trachyphylla* (Fig. 1), although the number of biters that arrived at host leaf pieces was higher than the number that arrived at nonhost leaf pieces in all *Macaranga* species (Mann–Whitney *U*-test: adjusted $Z=-2.279$, -3.470, -4.316, and -2.138; $P=0.023$, $P<0.\ 001$, $P<0.001$, and $P=0.032$ for ants inhabiting *M. bancana*, *M. beccariana*, *M. trachyphylla*, and *M. winkleri*, respectively). In contrast, the number of climbers differed among *Macaranga* species for ants inhabiting *M. bancana* and *M. beccariana* (Fig. 1), which arrived at host leaf pieces in higher numbers than at nonhost leaf pieces (Mann–Whitney *U*-test: adjusted $Z=-2.330$, -3.387; $P=0.020$, $P<0.001$ for ants that inhabited *M. bancana* and *M. beccariana*, respectively).

When host leaf pieces were offered, there were significant differences in the number of recruits and biters among the four *Macaranga* species (Kruskal–Wallis test: adjusted $H=14.790$, $P=0.020$ for recruits; $H=16.885$, $P<0.001$ for biters; $H=6.314$, $P=0.097$ for climbers). When nonhost leaf pieces were offered, there were differences in all three types

of behavior among the four *Macaranga* species (Kruskal–Wallis test: adjusted H=39.186, 19.363, and 26.049 for recruits, climbers, and biters, respectively; P<0.001 for all).

Chemical composition of leaf volatile compound We detected a total of 18 compounds in headspace collections from injured leaves of the 4 *Macaranga* species. Although the four species shared ten compounds, the remaining eight were restricted to one or two species. A total of 17 compounds were identified. The only remaining trace compound showed relatively low similarities with mass spectra in the libraries, and thus could not be identified (Table 1). Of the 18 compounds, the amounts of 9 'green leaf volatiles' (GLVs), including hexane alcohols, aldehydes, and esters, which were major and common components in all *Macaranga* species, did not differ significantly among species. In contrast, the amounts of three monoterpenoids differed significantly among the *Macaranga* species—two sesquiterpenoids were found only in or in the largest amount in *M. trachyphylla*, although the differences in amounts were not significant. Among the four remaining compounds, only nonanal was significant in amount, although all four compounds were restricted to one or two *Macaranga* species (Table 1). The composition of the 18 volatile compounds varied among the *Macaranga* species (two-way repeated-measures ANOVA, df=51, F=1.686, P=0.005).

Table 1 Average relative amounts of the volatile compounds detected from cut leaves of the four *Macaranga* species

Average proportion (in %) are shown in parentheses.

The compounds are listed in order of programmed-temperature retention indices (PTRI) relative to *n*-alkanes on DB-WAX.

All compounds were identified by comparison with authentic standards, except for one compound for which mass fragments are listed with the inferred molecular ion first (*) followed by the base peak and other fragments in order of intensity.

Discussion

In field experiments, ant workers on *Macaranga* trees showed aggressive behavior when a cut leaf piece was placed onto the stem of the tree. We offered leaf pieces carefully so as not to disturb the trees or give physical signs to the resident ants. Moreover, the ants could not recognize the leaf pieces visually from inside the hollow stems. Nevertheless, resident ants immediately emerged from the internodes and aggregated around the offered leaf pieces. Therefore, it is unlikely that ants used visual or physical cues to recognize offered leaf pieces. Rather, it seems more likely that leaf volatile compounds were used as chemical cues for defensive attack because volatile compounds are remotely perceivable and only occur when leaves are wounded. The ants themselves may emit volatile compounds—e.g., alarm pheromones, in response to plant damage, which may recruit other defenders. However, in field experiments, we offered leaf pieces when no ants were present on the tree surface. The aggressive behavior was not observed before starting the experiments in the absence of cut leaf pieces, even when neighboring *Macaranga* trees were close. Thus, at least for initial defenders, aggressive behavior may be induced by volatile compounds emitted from leaves that are mechanically wounded. Ant aggressive behavior in response to volatiles from injured leaves of neighboring *Macaranga* trees would be adaptive as a preemptive defense against herbivores on adjacent *Macaranga* trees.

Ant aggressive behavior differed among the four *Macaranga* species. *M. winkleri* harbored the most aggressive ant species, followed by *M. trachyphylla* and *M. beccariana*; *M. bancana* was the least aggressive species. This pattern of ant aggressiveness is attributed to differences among *Macaranga* species in resource allocation strategies with respect to specific enemy fauna (Itioka 2005). For example, *M. winkleri*, which has a relatively high dependence on symbiont ants for its antiherbivore defense, may profit greatly by recruiting preemptive ant defenders. Ants were recruited on trees of all four *Macaranga* species, even when leaf pieces of nonhost species were offered. Thus, ant recruitment may be induced by volatile compounds common among the leaves of at least these four *Macaranga* species.

In addition, there were intraspecific differences in the intensity of aggressive behavior: resident ant workers showed higher aggressiveness in response to host leaf pieces than to nonhost leaf species. Biting was the most definitive defensive attack behavior, and the number of biters was higher when host leaf pieces were offered than when nonhost leaf pieces were offered in all four *Macaranga* species. This suggests that ant workers can distinguish among injured *Macaranga* species, thereby determining their level of aggressiveness.

Chemical analyses verified that the composition of volatiles emitted from injured leaves was specific to each *Macaranga* species, and that several minor compounds were specific to one or two *Macaranga* species. Of the ten compounds that were detected in all four *Macaranga* species, nine were common GLVs. GLVs consist of a blend of saturated and unsaturated hexane alcohols, aldehydes, and esters, and may provide useful information regarding plant wounds to symbiont ants because GLVs are emitted immediately in response to mechanical plant cell damage (Galliard 1978; Pichersky and Gershenzon 2002) and in predominant amounts from cut leaves (Table 1). A certain number of ant workers showed aggressive behavior in response to nonhost leaf pieces, especially aggregating and climbing behavior (Fig. 1), presumably as a response to GLVs. The other 9 of 18 compounds were detected from 1 or 2 *Macaranga* species only, or in different amounts from all 4 *Macaranga* species, although many of these compounds occur in a wide range of plants. These species-specific compounds may play a role in inducing higher symbiont ant aggressiveness, e.g., the higher number of defenders in the partner ant species.

The level of ant aggressive behavior in the field experiment may have been induced by chemicals emitted from the first defenders that recognized leaf pieces. For example, ants inhabiting *M. winkleri* were the most aggressive, regardless of *Macaranga* species, presumably because their defensive behaviors are strongly controlled by pheromone perception. However, in terms of biting behavior, ants inhabiting *M. winkleri* responded in larger numbers to host than to nonhost leaf pieces (pooled nonhost data). This difference in biting intensity behavior in ants inhabiting *M. winkleri* implies that they could distinguish among leaf species. Wounded *M. winkleri* leaves emitted nonanal, which was not detected in the other three species, as well as a large proportion of (*E*)-2-hexen-1-ol and a small proportion of (*Z*)-3-hexen-1-ol, in contrast to the other three species. Undamaged leaves of *Macaranga* do not emit these green leaf alcohols or nonanal (Jürgens et al. 2006). Thus, the composition of volatile compounds may provide information for ants to distinguish whether or not a wounded plant is a host. If ants distinguish among the blends of volatile compounds emitted by wounded *Macaranga* leaves, aggressiveness may also differ among leaf pieces of nonhost species; however, we did not detect patterns between volatile composition and ant aggressiveness. However, this is not surprising if each ant species is specialized to respond to a small number of host-specific key compounds, such as nonanal in the *M. winkleri* symbiosis. To determine which compounds induce ant behaviors, further electrophysiological studies are required. We conclude that ant workers on *Macaranga* species recognize plant volatiles, including GLVs, as signals that elicit their preliminary orientation and aggregation to the injured area of host plants. They likely then discriminate minor and specific compounds to elicit critical defensive responses such as biting.

This process is important for the maintenance of the species specificity of *Macaranga–Crematogaster* mutualisms. Host-plant selection by foundress ant queens based on chemical cues plays a role in maintaining species specificity (Inui et al. 2001). *Macaranga* seedlings have species-specific nonvolatile surface chemicals that are used by foundress queens to recognize their partner plant species. In addition, the species-specific glaucous surface structure of *Macaranga* stems is a structural barrier preventing colonization of nonpartner ant species (Federle et al. 1997) and may also play a role in the maintenance of species specificity. However, these chemical and structural factors do not completely enforce species specificity during the colonization process because some *Macaranga* seedlings are colonized at low frequencies by foundress queens of nonpartner ant species (Murase et al. 2002; Jürgens et al. 2006). Because species specificity is well maintained in obligate myrmecophytic *Macaranga* trees occupied by mature ant colonies, there must be mechanisms that work after colonization to exclude such 'errors' in the establishment of specific pairs. The efficiency of ant defenses may be one mechanism that reinforces species specificity. Because differences in the intensity of ant defenses have been recognized as differences in allocation to defense strategies among *Macaranga* species (Itioka 2005), *Macaranga* trees colonized by mismatched, less aggressive ants would not survive herbivory, and those colonized by mismatched, more aggressive ants would not produce sufficient rewards to maintain the resident colony. Thus, the specific response of resident ants to host damage would be important for plant survival of herbivory, and consequently, for the survival of the resident ants on the plants.

Overall, our results suggest that *Macaranga* leaf volatiles are important chemical cues used by resident ant workers in guarding their host tree. This response to chemical cues may be a mechanism that gives rise to well-adapted biotic ant defense in species-specific *Macaranga–Crematogaster* associations, and by extension, sympatric cospeciation between ants and plants.

Introduction

Volatile organic compounds (VOCs) emitted by plant–herbivore interactions are of importance for host or prey location by parasitoids and predators of phytophagous insects (e.g., Vinson et al. 1987; Dicke et al. 1990a, b; Turlings et al. 1995; Karban and Baldwin 1997). More than 1,000 VOCs are involved in such interactions (D'Alessandro and Turlings 2006), and in a single plant–herbivore complex 30–50 VOCs are frequently detected by chromatographic analysis. Some entomophagous arthropods are able to discriminate between minor qualitative or quantitative differences among this vast number of compounds, and use these differences as reliable cues to find hosts or prey. For example, sprouts infested by *Plutella xylostella* emit 10 additional VOCs compared to uninfested sprouts that emit 49 compounds. These qualitative differences are perceived by the parasitoid wasp *Diadegma semiclausum* that prefer the odor of infested plants (Bukovinszky et al. 2005). Among the myriad of VOCs identified, some are common and emitted in many plant arthropod interactions, whereas others are highly specific to a particular interaction. It is generally admitted that in tritrophic interactions that involve a carnivorous species specialized toward a particular phytophagous insect, the VOCs used by foragers are highly specific (Vet and Dicke 1992; Steidle and Van Loon 2003). Nevertheless, there is growing evidence that some specialist insects also use general cues such as β-farnesene (Mumm and Hilker 2005), methyl salicylate (de Boer and Dicke 2004), or green leaf volatiles (Whitman and Eller 1992). To understand how individuals use the cues of their environment in a way that can lead to an optimized foraging strategy (Bernays 1996), it is crucial to unravel how predators and parasitoids are able to use more or less specific compounds as reliable foraging cues. However, most studies that examine the effects of VOCs on the behavior of parasitoids or predators have been carried out in laboratory conditions (e.g., Vinson et al. 1987; Dicke et al. 1990a; Turlings et al. 1995; Sabelis et al. 2001; de Boer and Dicke 2004). Field studies are scarce (but see De Moraes et al. 1998 or Kessler and Baldwin 2001), and direct evidence for the potential of synthetic VOCs as field attractants for beneficial insects has only recently been obtained (James 2003, 2005).

Delia radicum, the cabbage root fly, is an economically important pest of cabbage crops (Finch 1989). Females lay their eggs in small clusters in the immediate vicinity of stems of Brassicaceae plants. Larval development takes place inside the roots, where larvae dig galleries while feeding, leading to root decay when infestation is heavy. A large part of egg and larval mortality in *D. radicum* is caused by predation by several species of carabidae and staphylinidae (Wishart et al. 1956; Hugues 1959; Coaker and Williams 1963; Luff 1987; Wright et al. 1960; Mowat and Martin 1981).

In this study, we investigated VOCs used in the field by the main natural enemies of *D. radicum* that are naturally found in cole crops (Finch 1989): small carabid beetles belonging to the genus *Bembidion* and the rove beetles *Aleochara bilineata* and *A. bipustulata* (Coleoptera : Staphilinidae). In both cases, adults are predators of *D. radicum* eggs and larvae, but the staphilinid larvae also develop as parasitoids of *D. radicum* pupae (Fuldner 1960). The two Aleochara species have been suggested previously as potential biological control agents against *Delia antiqua*, a pest of Alliaceae plants (Tomlin et al. 1985; Finch 1989). Whereas carabid beetles are generalist predators, *A. bilineata* and *A. bipustulata*, because they are also parasitoids of *D. radicum*, are more specialized. However, despite their close morphology and biology, the two staphilinids differ in host ranges. Whereas *A. bilineata* is a specialist of phytophagous and saprophagous Anthomyiidae dipterans, *A. bipustulata* has a wider host range, parasitizing not only Anthomyiidae species but also coprophagous and necrophagous non-Anthomyiidae dipterans. This difference in specificity should translate into a different use of volatile cues.

Only a few studies have examined the role of VOCs in host-finding behavior of *D. radicum* predators. In laboratory conditions, by using a Y-tube olfactometer, Royer and Boivin (1999) showed that volatiles coming from host-infested plants, as well as odors from larval frass and hydrosoluble volatiles coming from the larval tegument, were attractive to *A. bilineata* adults. However, the volatiles involved were not precisely identified. Another study highlighted the role of onion in mixed-crop strategies to improve the presence of *D. radicum* natural enemies, *A. bilineata*, *A. bipustulata*, and carabid beetles (Uvah and Coaker 1984). Nevertheless, it was unclear whether the observed effects were caused by onion volatiles or by confounding effects like the presence of additional resources. Finally, two field studies have revealed the ability to increase *A. bipustulata* catches in brassica plots that contain mustard seed meal (Ahlström-Olsson and Jonasson 1992; Riley et al. 2007). Which compounds, among the 14 identified in the natural odor source, could be responsible for this attraction was not specified.

To unravel the foraging cues used by *A. bilineata*, *A. bipustulata* and carabid beetles, to locate *D. radicum*, we first analyzed in the laboratory the VOCs emitted by the rotten part of *Brassica napus* roots that were heavily infested by *D. radicum* larvae. Then, by using an original bioassay designed for ground-dwelling beetles, we analyzed in the field the attractive effect on *D. radicum* natural enemies of various concentrations of the main VOC found compared to the odor emitted by naturally infested roots.

Methods and Materials

Natural Odor Source Infested roots used for the chemical analysis of volatiles and for the bioassays were obtained from our *D. radicum* rearing facility at the University of Rennes (France). Infestations were carried out in a controlled room (21±1°C, 60% RH, 16L:8D photoperiod). To obtain heavily infested material, swede roots (*Brassica napus* var. napobrassica) were placed on a bed of oven-dried sand in a glass plate and then put in 1× 1×1 m Plexiglas™ cages that contained a few hundred *D. radicum* adults. After 3 d, the plates containing the roots harboring many eggs were removed and placed into an insect-proof empty cage. *D. radicum* larvae were left to develop in the roots for 3 wk before the material was used in the experiments. The high level of infestation chosen corresponds to what can be found in the field after the first emergence peak of the flies.

Identification of Major Compounds Emitted by Heavily Infested Roots Three grams of the rotten part of heavily infested roots were put into a 30-ml glass vial closed with aluminum foil. Five repetitions of samples taken from different roots were carried out. Volatile sampling was obtained by inserting a solid-phase micro-extraction (SPME) fiber (1 cm long, 100 μm polydimethylsiloxane coating, SUPELCO 57300-U) through the aluminum sheet into the free space of the vial, where it was maintained for 15 min. Qualitative analysis was carried out with a Perkin–Elmer GC AutoSystem gas chromatograph (GC) coupled to a Perkin–Elmer Turbomass quadrupole mass spectrometer (MS). The GC column was a SGE BP1 capillary column (length 25 m, inner diameter 0.32 mm, film thickness 0.5 μm). The SPME fiber was inserted into the GC injector for thermal desorption in splitless mode for 2 min, and the split flow was adjusted to 30 ml/min. The injector was maintained at 250°C. The GC oven remained at 50°C for 2 min, then raised to 300°C at 5°C/min; helium was used as a carrier gas at a constant flow rate of 1 ml/min; the transfer line to the MS was thermostatted at 280°C, and the ion source at 180°C. MS spectra were recorded from 30 to 500 amu per 0.6 sec in the electron ionization mode at an electron energy of 70 eV

and a filament emission of 200 μA. Identification of molecules was carried out by using the internal NIST library, our personal library, and was confirmed by using pure standards when possible.

Quantitative Measurement of Dimethyl Disulfide (DMDS) All volatiles were collected by using a static headspace method. Headspace consisted of a 1-l airtight closed glass jar. A hole in the middle top of the jar permitted us to insert a SPME fiber for volatile sampling and the pure molecule dilutions for calibration. To allow odor concentration into the headspace, this hole was filled up with patafix™. Odors were sampled during 10 min, with the SPME fiber (same reference as above) at room temperature (24±1°C).

Quantitative measurements were carried out with a Perkin–Elmer GC-FID AutoSystem gas chromatograph (GC) equipped with a flame ionization detector (FID). The GC column was a Perkin–Elmer PE-5ms (5% diphenyl dimethylpolysiloxane) capillary column, (length 20 m, inner diameter 0.18 mm, film thickness 0.18 μm). SPME injection and oven program were the same as described for the GC-MS used in the qualitative analysis.

For calibration, a constant quantity of 1 μl of solution that contained DMDS diluted in paraffin oil was inserted with a Pipetman™ through the hole of the jar, and deposited on a small piece of filter paper maintained inside the jar with Patafix™. As soon as the droplet was deposited, the hole was closed for 5 min, permitting the volatile to evaporate before SPME sampling. The net quantities of DMDS used for calibration were: 1, 0.5, 0.1, 0.05, 0.03, and 0.01 μl. For each of these volumes, the measurement was repeated three times with new prepared solutions. Calibration measurements were conducted over the whole period of chemical analysis. The results showed a strong correlation between the FID peak area and the volume of DMDS used (peak area=8×10E-07 μl DMDS; R^2=0.9726).

Quantity of DMDS Emitted by Heavily Infested Roots Infested roots were weighted and placed in the jar 1 hr before volatile sampling to allow odor concentration to build up. After this period, the quantity of DMDS emitted was measured as described above. Quantities emitted were expressed in nanoliters of DMDS produced per gram of fresh product per hour (nl g^{-1} hr^{-1}). Measures were repeated on five different roots.

Quantity of DMDS Emitted by Field Traps Two microliters of DMDS diluted in 18 μl of paraffin oil were deposited on a 1-cm^2 piece of filter paper inside the trap (see trap description below). Traps were opened in the same way as in the field bioassay and kept 1, 5, or 24 hr on a work surface under an extractor at room temperature (24±1°C). After this period, traps were placed into the 1-l jar and left to emit for 1 hr before SPME sampling. Measures were repeated on three different traps.

Field Bioassays Bioassays were conducted on a 20×40 m broccoli plot in the experimental field station of La Rimbaudais in Saint Meloir des Ondes (48.65°N, 1.9°W), Brittany, France, in the heart of an important zone of cabbage production. Broccoli plants (*Brassica oleracea Italica* var. monopoly) were 8 wk old at the time of the experiment. Experiments were carried out on June 28 and 29 and July 4, 2006 under sunny weather (mean temperatures of 18.5, 18.3, and 22.5°C).

Setup The setup consisted of a rectangular grid of 90 equally spaced mini-pitfall traps arranged over nine rows of culture with 10 traps per row (spacing between and among rows was 80 cm, Fig. 1). Accordingly, the position of each trap in the setup could be identified

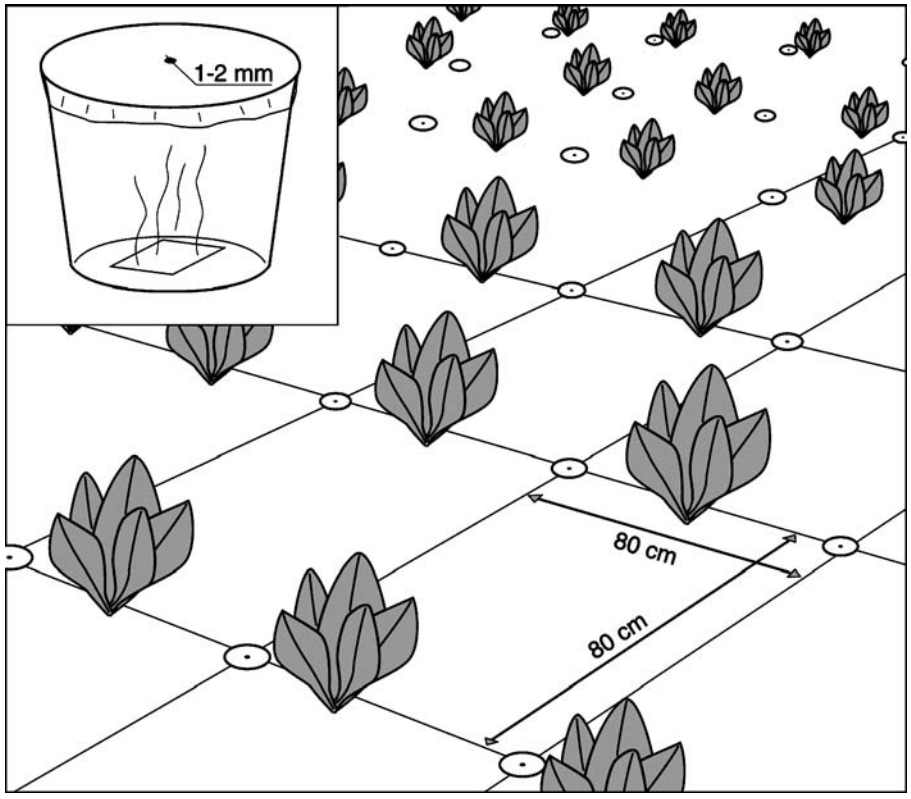

Fig. 1 Diagram showing the traps used to catch *Aleochara bilineata*, *A. bipustulata*, and carabid beetles of the genus *Bembidion* and their disposition in the field bioassays. A rectangular grid of 90 equally spaced traps was arranged over nine rows of broccoli plants with 10 traps per row (spacing between and among rows was 80 cm)

by its row number (1–9) and its column number (1–10). The location of the setup in the parcel was changed for each date the experiment was carried out.

Traps were made of 35-ml plastic cups (33 mm high, 40 mm upper diameter, P100 Solocup™). They were filled with odor sources in the field station's lab as follow: 1 g of the rotten part of an infested rutabaga root (R) or 20 μl of DMDS diluted in paraffin oil at the concentrations of 0% (C), 0.1% (D002), 1% (D02), 10% (D2), and 100% (D20), corresponding to a net quantity of 0, 0.02, 0.2, 2, and 20 μl of DMDS. As soon as an odor source was added, the cup was hermetically sealed with a piece of parafilm™. The 15 traps per treatment were randomly spatially distributed on the grid by using the internal function "sample" of R. Traps were placed in the field between 12:00 A.M. and 1:00 P.M. so that the upper part of the cup would be flush with the soil surface. After 1 hr, traps were carefully opened by piercing the piece of Parafilm™ in the middle with a precision forceps. Holes made this way were about 2 mm in diameter and permitted both odor diffusion and insect trapping. To limit variations caused by diel activity cycles, trapping was allowed for a 24-hr period without any perturbation in the field plot.

In parallel to the setup described above, a transect of 10 pitfalls (10 cm diameter) filled up with 50% alcohol and water, placed perpendicular to rows inside the parcel, was used to

monitor sex ratios of *A. bilineata* and *A. bipustulata* in the field. These pitfalls will be referred to as "control pitfalls" in the "Results" section.

Recovery of Trapped Insects Traps were brought to the lab for insect recovery. For each trap, we noted the treatment and position of the trap (row, column) as well as the number, species, and sex (determined with the presence of the male parameres, i.e., male genital apparatus) of *A. bilineata* and *A. bipustulata*, the number of other staphylinids, carabids, other coleopterans, dipterans, arachnids, and extra information such as dead individuals. All collected insects were grouped by date and treatment and conserved in alcohol for further investigation.

Statistical Analysis Statistical analyses were done with R software (R Development Core Team 2006). The numbers of trapped insects were analyzed with general linear model (GLM) statistic using the numbers of individuals caught in each trap. The distribution of the data was consistent with a Poisson distribution, and the linking function "log" was chosen for these GLMs. Factor effects were analyzed with the function "anova.glm" of R, using a chi-squared test, on a complete model that contained the following effects: treatment (i.e., the five concentrations of DMDS: C, D002, D02, D2, and D20, and R), date, treatment × date interaction, row, column. Numbers of individuals belonging to the same taxon trapped in different odors were compared with an analysis of contrast, using the function "esticon" of the package "doBy" (Højsgaard 2004).

The goodness-of-fit of each model was assessed by a graphical observation of the quantile randomized residuals (Dunn and Smyth 1996), plotted against the normal distribution quantiles (normal probability plot) by using the function "qqnorm" (Becker et al. 1988). Quantile randomized residuals were calculated using the function "qresiduals" from the R package "statmod" (Smyth 2005). The use of randomized quantile residuals instead of residuals *per se* was more appropriate because of: (1) the use of a Poisson family for the GLM fit, and (2) the fact that there were only a few possible values for the response (typically 0, 1, 2, 3) (Dunn and Smyth 1996). For all the GLMs used, graphical representations revealed a good fit between the randomized quantile residuals and the normal probability plot. Furthering the analysis of the residuals, we made for each response at each date a spatial representation of the simplest model residuals over the set up. This representation permitted us to locate any spatial structuration of the residuals that would have revealed a non-independence of the number of insects caught in traps located close together.

Finally, to avoid all possible bias caused by interference inside a taxon (like aggregation behavior), all GLM analyses were carried out again in the presence/absence of analyzed taxa in each trap by using a binomial link function. The results (not shown) are similar to those obtained when using insect counts, thus supporting the conclusions presented herein.

Results

Identification and Quantification of Volatiles The gas chromatograpy–mass spectrometry (GC-MS) analysis of volatiles trapped with SPME revealed a relatively simple profile essentially composed of sulfides (Fig. 2). The main volatile compound identified was dimethyl disulfide (DMDS). Other compounds such as dimethyl trisulfide, dimethyl tetrasulfide, 2-4-5-trithiahexane, and 2-4-dithiapentane were found in smaller amounts, sometimes as traces, or not at all, depending on the sample.

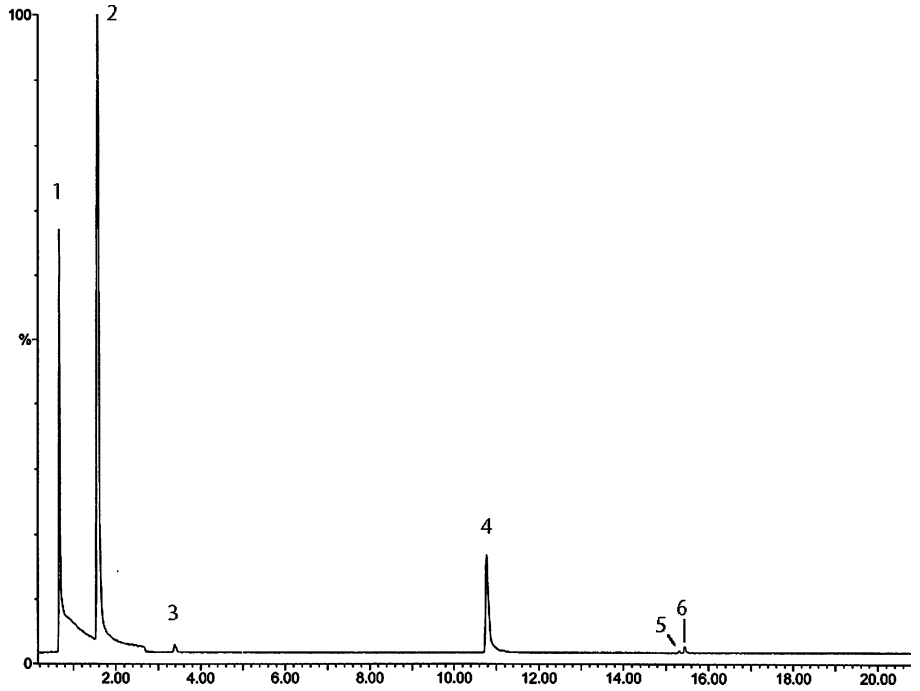

Fig. 2 Typical chromatogram of odors emitted by the rotten part of *Brassica napus* roots heavily infested by *Delia radicum* larvae. 1: SPME injection artifact; 2: DMDS; 3: 2-4-dihiapentane; 4: 2-4-5-trithiahexane; 5: unknown compound; 6: dimethyl tetrasulfide. Refer to the text for details

Among these volatiles, we chose to work with DMDS for several reasons: (1) In all cases, DMDS appeared to be one of the major compounds; (2) As an end product of tissue degradation and because of the high content of sulfur-containing compounds in this genus (notably all glucosinolates), DMDS is likely to be emitted by all attacked Brassicacae roots, regardless of the species infested. Thus, it could be a reliable marker of the presence of *D. radicum*.; (3) DMDS is known as an end product of Alliaceae tissue degradation (Auger et al. 1989b) and could be emitted by these plants also when attacked by *D. antiqua*, a host and prey of both staphilinids studied in this paper.

The quantitative measure of DMDS in infested roots revealed a highly variable concentration. The quantity of DMDS emitted per gram of fresh product in 1 hr, measured on six samples ranged from 0.5 to 38.2 nl, with a mean of 11.2 nl g^{-1} hr^{-1}.

Quantity of DMDS Emitted by the Traps The quantity of DMDS emitted by the traps we used decreased with time. With an initial volume of 2 µl pure DMDS inside the trap, the quantity emitted during the first 6 hr after opening was in the same range as what was emitted by 1 g of infested roots: 38.5±13.2 nl/hr (±SE) between the first hour and the second hour, down to 8.0±0.86 nl/hr (±SE) between the fifth hour and the sixth hour. After 24 hr, only traces were recovered.

Insects Caught in the Traps The 270 traps caught a total of 473 arthropods distributed as follows: 123 *A. bipustulata*, 83 *A. bilineata*, 68 other staphylinids, 155 carabid beetles, 26 other coleopterans (essentially Halticinae), 11 dipterans (all belonging to the genus *Delia*),

one ant, six Arachnids, plus hundreds of springtails (Hexapoda: Collembola) that were not taken into account. Of these arthropods, 32.8% were caught in the traps that contained infested roots, whereas only 6.6% were caught in control traps. The remaining 60.6% of individuals trapped were divided among the traps that contained one of the four DMDS concentrations. For each treatment, a certain number of traps did not catch any of the species we were interested in (N=33, 26, 15, 11, 24, and 12 for T, D002, D02, D2, D20, and P, respectively).

A. bilineata A total of 83 *A. bilineata* adults were caught (0.31±0.06 per trap). The treatment effect was highly significant (Table 1, Fig. 3). Traps containing 0.02 or 0.2 μl of DMDS did not catch more *A. bilineata* than control traps. Traps containing 2 or 20 μl of DMDS caught a higher number of *A. bilineata* than control traps and were not significantly different from each other. Traps that contained infested root caught more *A. bilineata* than all the other treatments (Fig. 3).

The row and column effects were both significant, but without any obvious general pattern (none of the internal or the external rows or columns was responsible for this effect). This observation was consistent with the spatial representation of residuals that did not reveal any structuration.

Although odorous traps captured more females (N=48) than males (N=33), the sex ratio was not biased (*binomial test*, P=0.120), and did not differ from that obtained from control pitfalls for the same week (58 females and 44 males, *Chi-square* test between attractive traps and control pitfalls: χ^2=0.030; 1 *df*, P=0.861).

A. bipustulata A total of 123 *A. bipustulata* adults were caught (0.46±0.05 per trap). The treatment effect was highly significant (Table 1, Fig. 4). Traps that contained only 0.02 μl of DMDS did not catch more insects than control traps, whereas traps that contained 0.2, 2, and 20 μl of DMDS or traps that contained infested roots did. Traps with 2 μl of DMDS caught a higher number of insects than other DMDS concentrations and were not significantly different from traps that contained infested roots.

The influence of the date was significant for *A. bipustulata* (43 individuals caught between June 28 and 29, 52 between June 29 and 30, and 38 between July 4 and 5). As for *A. bilineata*, there was no effect of the interaction between the date and the treatment.

Table 1 General linear model (treatment + date + row + column + treatment × date) results summarizing the effect of the different factors on the number of *Aleochara bilineata*, *A. bipustulata*, and carabid beetles caught per trap

	A. bilineata			*A. bipustulata*		Carabid beetles	
	df	Deviance	P(>|Chi|)	Deviance	P(>|Chi|)	Deviance	P(>|Chi|)
Treatment	5	80.47	< 0.001	44.16	< 0.001	40.77	< 0.001
Date	2	5.72	0.06	7.46	0.024	20.04	< 0.001
Row	24	64.54	< 0.001	32.05	0.126	28.08	0.26
Column	27	57.80	< 0.001	31.50	0.251	55.88	< 0.001
Treatment × Date	10	9.56	0.48	17.36	0.067	14.38	0.16

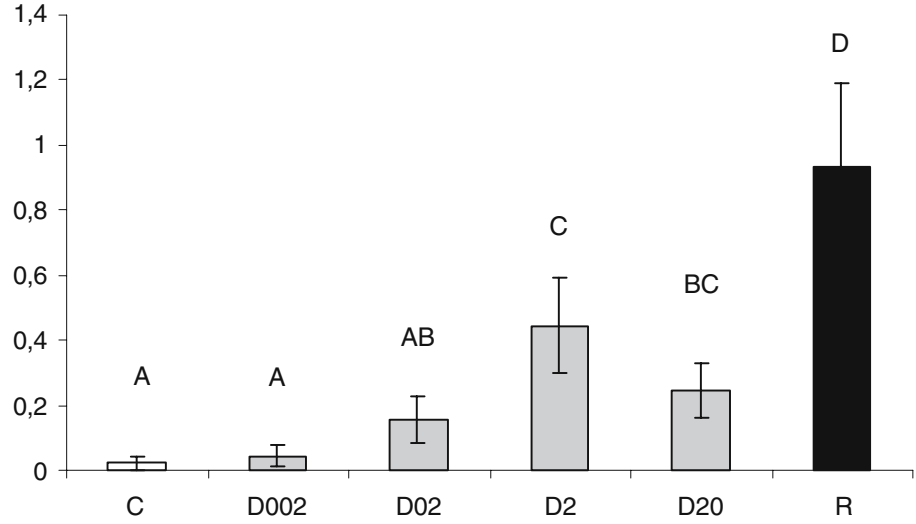

Fig. 3 Mean number of *Aleochara bilineata* caught per trap for each treatment ± SE. (C: control; D002: 0.02 µl DMDS; D02: 0.2 µl DMDS; D2: 2 µl DMDS; D20: 20 µl DMDS; R: rotten part of infested root). Different letters indicate a significant difference between treatments. α=0.05

The row and column position of the traps had no effect (Table 1), in agreement with the spatial representation of residuals.

Sex ratios in the odorous traps were biased toward females (74 females and 49 males, *binomial test*, P=0.030), but this was not caused by odors as a similar bias was observed in control pitfalls for the same week (control pitfall: 81 females and 56 males, *Chi-square* test between attractive traps and control pitfalls, χ^2=0.002; 1 *df*, P=0.965).

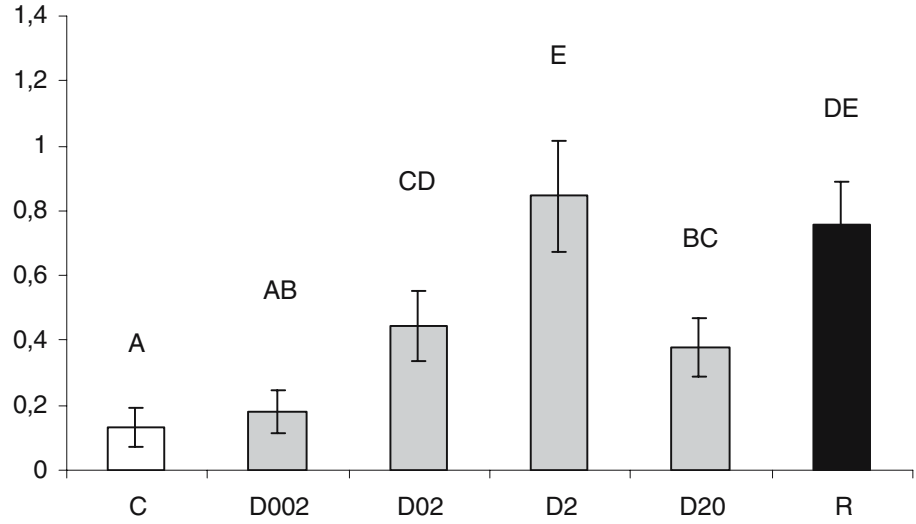

Fig. 4 Mean number of *Aleochara bipustulata* caught per trap for each treatment ± SE. (C: control; D002: 0.02 µl DMDS; D02: 0.2 µl DMDS; D2: 2 µl DMDS; D20: 20 µl DMDS; R: rotten part of infested root). Different letters indicate a significant difference between treatments. α=0.05

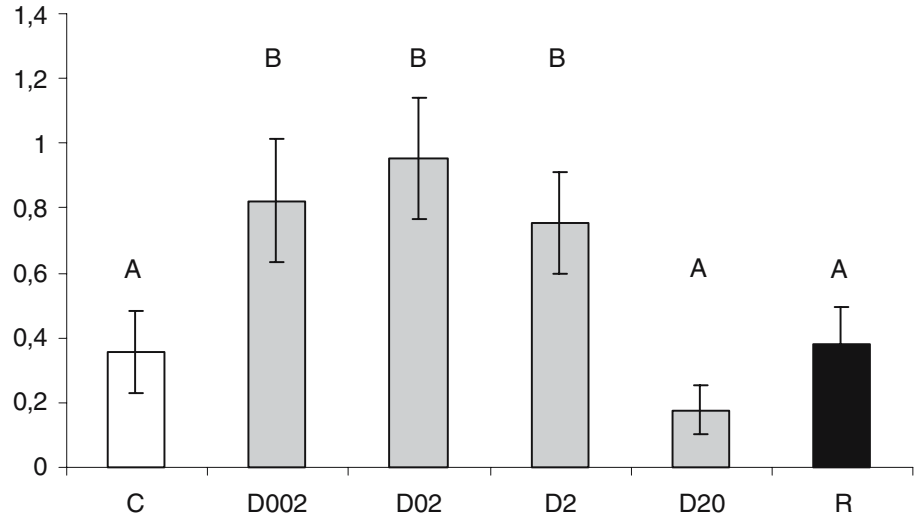

Fig. 5 Mean number of carabid beetles caught per trap for each treatment ± SE. (C: control; D002: 0.02 μl DMDS; D02: 0.2 μl DMDS; D2: 2 μl DMDS; D20: 20 μl DMDS; R: rotten part of infested root). Different letters indicate a significant difference between treatments. α=0.05

Carabid beetles A total of 155 carabid adults was caught (0.57±0.06 per trap). All were identified *a posteriori* as *Bembidion tetracolum* (*N*=91) or *Bembidion lampros* (*N*=62) with the exception of one *B. quadrimaculatum* and one *Microlestes minutulus*. The treatment effect was highly significant (Table 1, Fig. 5). Surprisingly, the traps with the highest concentration of DMDS (20 μl) or naturally infested root odor had no significant effect on carabids, whereas traps with lower concentrations (2, 0.2 or even 0.02 μl of DMDS) caught more carabid beetles than control traps.

The influence of the date was highly significant, particularly because of the twice lower number of insects caught on July 4–5 (*N*=27, compared to *N*=67 and *N*=61 captured on June 28–29 and 29–30, respectively). Nevertheless, there was no effect of the interaction between the date and the treatment.

The column effect was significant, although the row effect was not. As in the case of *A. bilineata*, however, no obvious pattern appeared. Furthermore, the observation of the spatial representation of residuals revealed no structuration.

Discussion

Field bioassays revealed the ecological importance of DMDS in the orientation behavior of the main predators of *D. radicum* eggs and larvae. This compound, frequent in sulfur-containing plants, was emitted in large amounts by brassica roots heavily infested by *D. radicum*. Our results show that DMDS attracts the staphylinids *A. bilineata*, *A. bipustulata,* and the carabids *Bembidion tetracolum* and *B. lampros*. Concentration of the pure molecule seems to play a role, influencing the response of the different predators. To our knowledge, this is the first field study that demonstrates that the concentration of one monomolecular odor influences the orientation behavior of different arthropod predators that belong to the same guild. These results shed new light on the use of general cues by foraging insects, and

could also be helpful for enhancing biological control of *D. radicum*, which feeds on open field crops.

To date, the role of DMDS as a carnivorous insect attractant has been shown only in two tritrophic complexes. The first involves cabbage plants (*Brassica oleracea* spp. *capitata*), the phytophagous lepidoptera *Plutella xylostella*, its specialist parasitoid wasp *Cotesia plutellae*, and a generalist predator, the lacewing *Chrysoperla carnea* (Neuroptera) (Reddy et al. 2002). The second involves leek (*Allium porum*), the phytophagous specialist microlepidoptera *Acrolepiopsis assectella*, and its parasitoid wasp *Diadromus pulchellus* (Dugravot and Thibout 2006). In the first study, Reddy et al. (2002) found DMDS in the frass of *P. xylostella* that was attractive to *C. plutellae* and *C. carnea* in a Y-tube olfactometer setup. In the second, the parasitoid wasp *D. pulchellus* was attracted by a blend of odors coming from attacked leeks (that emit thiosulfinates) and odors of *A. assectella* larval frass (Dugravot et al. 2005; Dugravot and Thibout 2006), the latter material being known to emit a high concentration of DMDS (Auger et al. 1989a). Although DMDS appears to be present in interactions that involve sulfur-containing plants and their associate herbivorous species, little is known about its importance as a cue at the third trophic level (i.e., predators and parasitoids). This study is the first carried out in field conditions that demonstrates such a role for this molecule.

As an end product of sulfur-containing tissues, DMDS is likely emitted by all Brassicaceae infested by *D. radicum*, regardless of plant species. Interestingly, it is also an end product of Alliaceae (Auger et al. 1989b), which are frequently grown in the same geographical zones as cole crops and are attacked by *D. antiqua*, another important host (and prey) of both staphylinids studied here. Accordingly, the positive response of *A. bilineata* and *A. bipustulata* toward DMDS could allow them to locate two of their major preys and hosts (i.e., *D. radicum* and *D. antiqua*) regardless of the infested plant involved. Assessing attractiveness of DMDS in *Allium* crops would confirm this hypothesis.

The main difference we found between the two staphylinid species was their reaction toward the full blend of volatiles emitted by *Brassica napus*-infested roots. Whereas *A. bilineata* showed a preference for this more natural and complete odor, *A. bipustulata* was as much attracted by 2 μl of DMDS as by the natural odor source. One hypothesis is that the more specific the resource, the more specific the cues used to locate this resource should be (Vet and Dicke 1992; reformulated by Steidle and Van Loon 2003). Because *A. bipustulata* is more generalist than *A. bilineata*, notably in that its larvae can parasitize pupae of coprophagous and necrophagous flies, it could benefit from using a general cue like DMDS. Indeed, DMDS is not only emitted by decaying plant tissues that contain sulfur, but also by *any* decaying tissue that contains sulfur. Therefore, DMDS is most likely present in the microhabitat of the coprophagous and necrophagous hosts of *A. bipustulata*, thus making it a good general indicator of prey for this *Aleochara* species. It is notable that the "carrion" smell emitted by the inflorescence of some Araceae, which rely on necrophagous insects for pollination, consists mainly of dimethyloligosulfides (i.e., DMDS or dimethyl trisulfide) (Kite and Hetterschieid 1997). The presence of DMDS in decaying carrion could also explain why pure DMDS attracted carabid beetles (which, as generalists, are also necrophagous), while DMDS-containing odors of naturally infested roots did not.

The difference of attractivity of DMDS found between staphylinids and carabids could highlight the importance of the concentration of a cue in the environment for its use by foraging insects. Indeed, widespread volatile cues apparently lacking specificity could have informative properties that guide specialists to their specific resource based on the concentration of the volatile. In our experiments, the responsiveness of the different taxa toward the nonspecific cue DMDS went from a response to a wide range of concentrations

for the generalist carabid beetles to a response to a narrower range of concentrations (close from what is emitted by the natural odor source) for the more specialist *A. bilineata*. Whereas carabid beetles responded to three of the four concentrations tested, *A. bilineata* responded to only two. The dose–response curve of the two staphylinid beetles shows the strongest response centered around what we found to be the natural quantity of DMDS emitted by an infested root, whereas the dose–response curve for carabid beetles seems wider and centered on the lowest concentration of the molecule. These findings are in accordance with the higher specialization of *A. bilineata* and *A. bipustulata* toward *D. radicum*, in comparison with the carabid beetles.

Associative learning (Vet and Dicke 1992; Dicke et al. 1990a; Takabayashi et al. 2006) or the presence/absence of a particular background odor (Bell 1990; Mumm and Hilker 2005; De Boer and Dicke 2006) could also play a role in attraction toward a nonspecific chemical cue like DMDS. Indeed, predators in a cabbage field could learn by experience that DMDS is often associated with sites where prey can be found. Also, DMDS could only be used when it is part of a full blend of decaying root odor. The extent to which learning or background odors may influence the response of the predators studied herein to different concentrations of DMDS remains to be investigated.

Because of the decreasing rate of volatile emission in our traps, and because of possible differences in the diel activity rhythms of the different predators, it remains possible that the different species caught in the same treatment were faced with different DMDS concentrations when trapped. To avoid this potential bias, future experiments should use a method that ensures the regular diffusion of odors, or work on a shorter time period. Another potential bias that could have influenced the distribution of the different species among the treatments is interference between these species. It is notable that carabid and staphylinid beetles were found in different traps most of the time. However, even if such avoidance occurred, the number of traps was high enough to allow the species to avoid each other without limiting their choice for their preferred treatment. In fact, for each treatment an important number of traps did not catch any insect.

In spite of the potential bias, the setup gave precise and reproducible results. GLM statistics permitted a clear discrimination between the different treatments, even with a low number of insects caught per trap. Furthermore, spatial analysis of residuals allowed checking the validity of assumptions, like the local character of attraction and the independence of data between two adjacent traps. Indeed, neither the effects of the row and columns where the traps were placed nor the spatial representation of residuals revealed any differentiation between the margins and the center of the setup (which could have been the case if individuals had been attracted from outside the setup). Likewise, there was no spatial structure of the residuals (i.e., spatial aggregation of smallest or highest residuals near a particular treatment) as would have been found if traps had influenced each other. Because of its high selectivity, the number of simultaneous comparisons allowed, and the power of the statistical analysis that can be conducted, this setup seems effective in testing local attraction for small ground-dwelling beetles (smaller than 3 mm) in realistic field conditions.

The use of our understanding of the chemical ecology of tritrophic interactions to enhance biological control practices is a motivating approach. To date, only the studies of James (2003, 2005) have shown the possibility of using synthetic VOCs for this purpose. By adding general cues such as methyl salicylate or *cis*-3-hexen-1-ol in plots, the number of flying beneficial arthropods caught in sticky traps increased. The results presented in this paper are the first that show attractivity of beneficial ground-dwelling beetles toward a synthetic odor in the field. Attractiveness of DMDS toward the main natural enemies of *D. radicum* could be useful for biological control. However, before DMDS can be used in the

field, we need to define precisely the conditions under which it is attractive to predators and how it will influence their efficiency to control *D. radicum* populations. Ongoing lab and field experiments should give us such information.

Acknowledgments The authors thank the staff of the experimental station of La Rimbaudais, Saint-Méloir-des-Ondes, France, for providing experimental fields; Romain Rouchet for help on the field experiment; Yannick Outreman and Manuel Plantegenest, Agrocampus, Rennes, France, for advice on statistical analysis; Roxina Soler, NIOO-KNAW, Heteren, The Netherlands, for useful comments on a previous version of the manuscript. This work was supported by a PhD grant to A. Ferry from the Region Bretagne and benefited from the financial help of the GDR d'écologie chimique CNRS no. G2827 for the chemical analysis.

Introduction

Mutualisms are widespread, ranging from plant pollinators to microbes hosted by plant roots or animal guts. Their long-term persistence is striking given that selection should favor individuals that increase their fitness at the expense of the mutualist partner. To counter this evolutionary instability, each partner must be able to prevent overexploitation by the other. Identifying the mechanisms that prevent overexploitation of one species by its partner is fundamental to understanding the evolutionary stability of mutualisms.

Some plants are highly specialized in pollination and use insects whose larvae feed on the developing seeds of the host plant. An increase in insect fitness (i.e., more eggs laid and more seeds eaten) is costly for plant seed production, creating a conflict of interest between the interacting species. The strategies evolved by plants to prevent overexploitation by seed predators include morphological traits, such as long styles preventing oviposition in figs, or yucca fruit morphology preventing seed access to yucca moth larvae, and fruit abortion in yucca and senita cactus (Pellmyr and Huth 1994; Holland and DeAngelis 2006). Surprisingly, although the chemical response of plants to damage from phytophagous insects through constitutive (Wittstock and Gershenzon 2002) and induced (Bennett and Wallsgrove 1994; Roda and Baldwin 2003) secondary compounds is an acknowledged phenomenon, the role of plant chemical defenses in regulating plant-seed eating pollinator mutualisms has so far been underexplored.

The European globeflower *Trollius europaeus* is exclusively pollinated by six species of flies (genus *Chiastocheta*), whose larvae feed only on globeflower seeds. The female deposits one to several eggs, on or between the carpels at various flower stages, depending on the species (Pellmyr 1989; Després and Jaeger 1999). The larva from each species has a specific location in the globeflower complex fruit, which is composed of several follicles (hereafter referred to as carpels). After hatching, the larvae develop on seeds throughout fruit maturation. Previous experiments have shown that the number of seeds eaten by each larva sharply decreases when the number of larvae per fruit increases, despite the fact that seeds are still available (Jaeger et al. 2001; Després and Cherif 2004). Moreover, larval mass is negatively correlated with the number of larvae co-developing in an infrutescence. Such density-dependent larval growth inhibition might result from the induction of a chemical defense by the attacked plant.

Among the secondary metabolites, phenolic compounds have traditionally been considered to play an important role in plant–insect interactions (Harborne 1999; Simmonds 2003) and can act as attractors, feeding deterrents, or toxic compounds (Summers and Felton 1994; Takemura et al. 2002). They have been identified as active inhibitors of larval growth for the larvae of corn earworm (*Heliothis zea*) (Elliger et al. 1980), autumnal moth (*Epirrita autumnata*) (Ossipov et al. 2001), and fall armyworm (*Spodoptera frugiperd*a) (Johnson et al. 2002; Urrea-Bulla et al. 2004). To determine whether plant phenolics could be involved in the control of seed predation in the *Trollius europaeus–Chiastocheta* system, we compared the phenolic profiles of unparasitized fruits vs. fruits naturally parasitized by an increasing number of larvae in two alpine sites at different altitudes. We found that a flavonoid is overproduced in the carpel walls of parasitized fruits. We quantified the variation of this compound in several *Trollius* species, in various plant organs, and at different developmental stages. Mechanical damages were performed on unparasitized plants to test for the specificity of the plant response. We discuss the potential implication of this tissue-specific, density-dependent induced chemical compound in the evolutionary stability of this obligate plant-seed eating mutualism.

Material and Methods

Study Species The European globeflower *Trollius europaeus L.* (Ranunculaceae) is a hermaphroditic arctic-alpine perennial species growing in moist meadows (Després and Jaeger 1999; Jaeger et al. 2000). Two study sites were chosen in two mountain massifs in the French Alps (Chartreuse and Galibier), 100 km apart. These two sites (Cherlieu, 950 m a.s.l. 5°46′E 45°18′N and Galibier 2,300 m a.s.l. 6°24′E 45°04′N) below and above the tree line, respectively, were previously extensively studied (Jaeger and Després 1998; Hemborg and Després 1999; Jaeger et al. 2000, 2001; Després et al. 2007).

Phenolic Profiles of Parasitized vs. Unparasitized Fruits To obtain unparasitized fruits, flower buds were bagged with a nylon mash bag and hand pollinated with pollen from several donors. Parasitized and unparasitized fruits were sampled 3 wk after flowering in 2003, June 18th in Cherlieu (N=15 and N=30, respectively) and July 8th in Galibier (N=11 and N=36, respectively). Back in the laboratory, the fruits were dissected immediately, and the developing larvae were counted and discarded. From each fruit, three parts (the carpel walls, seeds, and floral receptacle) were carefully separated and individually stored at −18°C until they were analyzed. A first subset of 22 fruits from Cherlieu (eight without larva, seven with one larva, and seven with several larvae) was submitted for an analysis of total phenolic compounds, which was carried out on each of the three fruit components. Based on preliminary results (see below), the entire set of carpel walls was submitted for complementary analysis (phenolic acids and flavonoids). This individual procedure and the tiny size of some of the samples meant that dry weight could not be measured. Therefore, all results were expressed in fresh weight (FW). Five of the larvae were pooled, stored at − 18°C, and analyzed for phenolic content.

Each sample was weighed and separately extracted twice with 50 ml of an ethanol–water (50:50) mixture under reflux. After evaporation under vacuum, the residue was redissolved in a precise volume of distilled water, filtered (0.45 μm), and used for Folin-Ciocalteu colorimetric determination of total amounts of phenolic compounds (Marigo 1973).

Aliquots (20 μl) of the ethanolic solution were used for high performance liquid chromatography (HPLC) analysis on a RP C18 μBondapak column, 4.6×250 mm, and gradients were monitored by a Waters 600 Controller. Solvent A was acetic acid 0.5% in distilled water and solvent B acetic acid 0.5% in acetonitrile. Phenolic acids were determined by using a linear gradient from 0 to 20% of B in A in 45 min, with a 1.5 ml min^{-1} flow. The spectra were recorded with a Waters 996 PDA in the 200- to 400-nm range. Chromatographic peak areas were determined at 280 nm. Areas were compared after multiplying the area by the volume of extraction corresponding to each carpel. Standards of common phenolic acids and aldehydes were obtained from Sigma. Flavonoids (including adonivernith) were separated with an isocratic flow (1.5 ml min^{-1}) of 20% of B in A. The peak areas were recorded at 354 nm. Standards (luteolin, orientin, homorientin) were obtained from Extrasynthese (Lyon, France). The standards were prepared in methanol as stock solutions at 1 mg ml^{-1}.

Structural Elucidation of Flavonoid Liquid chromatography-mass spectrum (LC-MS) analysis: ten ethanolic extractions were pooled, concentrated, and used for mass determination with electrospray ionization MS (ESI-MS) on the positive mode [M+H]. Mass spectra were recorded from a ZQ Waters Mass detector (electrospray voltage 4.2 kV) coupled to a μBondapak RP C18.

Nuclear magnetic resonance (NMR) analysis: To obtain sufficient amounts of flavonoid, 75 g FW of frozen flowers were extracted with methanol (70:30) under reflux for 30 min. The methanolic extract was filtered and evaporated. The aqueous residue was successively extracted with petroleum ether and ethyl acetate. The ethyl acetate fraction was evaporated

to dryness, redissolved in MeOH, and fractionated by gel filtration using Sephadex LH-20 (Amersham, 3.5×50 cm, MeOH, 2 ml min^{-1}) to obtain 40 fractions. The fractions were monitored by HPLC, and fractions containing adonivernith were combined and dried.

The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker DPX-400 and a Varian Unity+ 500, respectively, in MeOH-d_4 as solvent at 303 K. Standard pulse sequences and parameters were used for the experiments (COSY, DEPT, HMQC, HMBC, TOCSY, and NOESY). Chemical shift references were given from the solvent resonances at 3.30 ppm for ^{1}H and 49 ppm for ^{13}C.

Adonivernith Occurrence in T. europaeus and in Other Trollius Species To assess the distribution of adonivernith within the whole *T. europaeus* plant, six flowering plants (without larvae) were collected in Cherlieu in 2004 and dissected into seeds, floral receptacle, leaves, staminodias, sepals, carpels, and stamens. The six samples were pooled and extracted by ethanolic mixture as described above.

The kinetics of the synthesis of adonivernith by the whole flower was followed over five developmental stages (N=3), from green bud to old fruits (21 d after flowering). The entire organ (flower or fruit) was analyzed for flavonoid content as previously described. Fruits of three other species of *Trollius of Asian Origins Trollius chinensis*, *T. ledebouri*, and *T. pumilus* were collected during summer 2005 in the Alpine Garden of the Joseph Fourier station (Col du Lautaret, 2,100 m a.s.l.) and stored frozen (−18°C) until analysis.

Mechanical Damage Mechanical damage was inflicted in two ways: first, low-intensity wounds were inflicted in Cherlieu by piercing the carpel walls or the stem (to measure a systemic response) with a needle; and second, high-intensity wounds were inflicted in Galibier by incising the carpel wall with a scalpel (five incisions). In Cherlieu, 59 young floral buds were bagged and hand-pollinated 1 wk later. Ten holes were pierced on the stems of 19 flowers and on the carpel walls of 21 other flowers; this treatment was repeated 1 wk later. Three-week-old fruits were collected, and stored at −18°C until they were analyzed. In Galibier, incisions were made on 25 flowers. The wounded flowers and 21 control flowers (at the same developmental stage) were bagged to prevent infestation. Fruits were collected 11 d later and kept frozen (−18°C) until they were analyzed.

Statistical Analysis Data were checked for normality of distribution and homogeneity of variances (Kolmogorov–Smirnov and Levene tests). Where the data did not satisfy these criteria, nonparametric tests were performed (e.g., Spearman's rank correlations R_s, Mann–Whitney tests). Otherwise, t tests were used to compare parameter of parasitized and intact fruits. To examine whether globeflowers from the two sites differed in their chemical response to increasing larval numbers, the slopes of the correlations between the number of larvae and the flavonoid amounts were compared in Cherlieu and Galibier by performing an analysis of covariance (ANCOVA), testing for the effect of population, larvae number, and interaction on the amount of flavonoid. A significant interaction indicates that the slopes are different within each population.

Results

Phenolic Composition of Parasitized versus Unparasitized Fruits Concentrations of total phenolic compounds did not differ significantly in seeds from unparasitized vs parasitized fruits collected in Cherlieu (8.6±0.7 vs. 9.1±1.0 mg g^{-1} FW) (Mann–Whitney test, U=54,

$P>0.05$), or in the floral receptacle (7.3±1.0 vs. 8.5±0.6 mg g^{-1} FW) ($U=39$, $P>0.05$). In contrast, the carpel walls of fruits infested by one or several larvae exhibited higher concentrations of total phenolic compounds (7.8±0.4 mg g^{-1} FW) than intact, uninfested fruits (5.7±0.5 mg g^{-1} FW) ($U=28$, $P<0.01$). As a single larva contained only 0.024 mg of total phenolic compounds, this increase is not caused by larvae excretion (the larvae were discarded during dissection).

Further analyses were, therefore, carried out on the carpel walls only. Because the number of larvae developing in a globeflower increased with carpel number and with the mass of the carpels (Fig. 1) ($R_s=0.477$, $P<0.01$, $N=29$ at Cherlieu; $R_s=0.603$, $P<0.01$, $N=26$ at Galibier), we preferentially assessed phenolic synthesis by measuring the absolute amount per fruit rather than the concentration.

The two populations did not differ in terms of total amounts of phenolics in unparasitized carpels (Mann–Whitney test, $U=63$, $P>0.05$), but the concentration was higher in Galibier (7.8±0.6 mg g^{-1} FW) than in Cherlieu (5.4±0.3 mg g^{-1} FW) ($U=30$, $P<0.01$). This was because of the higher carpel mass in Cherlieu ($m=0.31\pm0.04$ g) compared to Galibier ($m=0.18\pm0.03$ g). The total amount of phenolics per fruit (Fig. 2) was correlated to larval number per fruit in each of the two study populations ($R_s=0.562$, $P<0.05$, $N=45$ at Cherlieu; $R_s=0.705$, $P<0.01$, $N=47$ at Galibier). The highest amount per fruit (6.0 mg) was recorded in Galibier in a fruit parasitized by six larvae and was four times higher than the mean amount observed in unparasitized fruits from the same site (1.3±0.2 mg). To determine which fraction was responsible for the increase of total phenolics with the increasing number of larvae, we carried out a chromatographic analysis adapted to detection of phenolic acids and flavonoids.

Seven compounds were recorded when using the chromatographic conditions for phenolic acid determination (Table 1). These compounds could not be identified as any of the most common phenolic aglycones used as standards, probably because they occur as glycosides. Because unparasitized and parasitized fruits did not differ in the relative area of each compound (Mann–Witney tests, $P>0.05$), no further attempt was made to identify them.

Five flavonoids had areas high enough to be recorded on the chromatogram (Table 2). Concentrations of the five compounds significantly increased with larval number per fruit in Galibier, whereas the concentration of only one flavonoid (F3) significantly increased in Cherlieu. This compound, characterized by a retention time of 5.4 min, also exhibited the

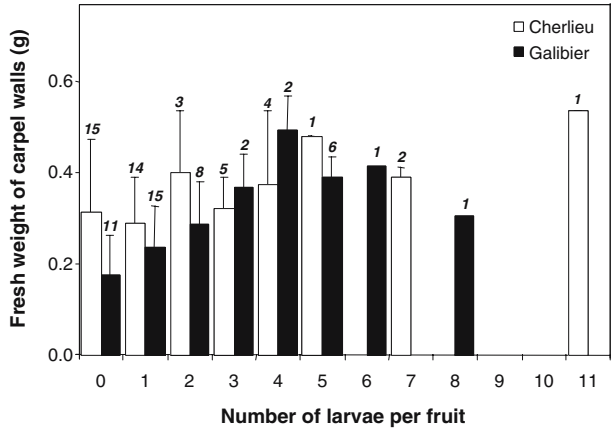

Fig. 1 Fresh weight (mean + SE) of carpel walls according to the number of larvae per fruit for the two populations: Cherlieu ($N=45$) and Galibier ($N=47$). Sample numbers (italics) are indicated above the bars

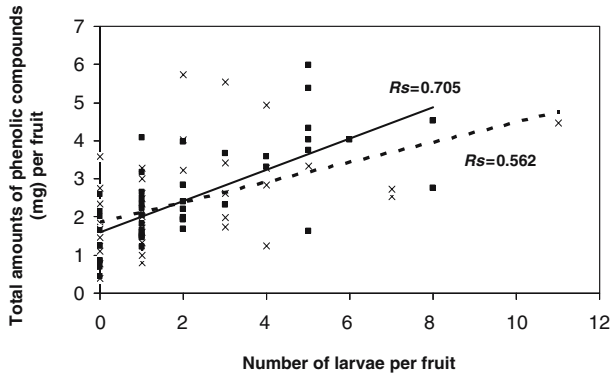

Fig. 2 Spearman correlation (*Rs*) between total amounts of phenolic compounds and the number of larvae in fruits of *T. europaeus* from low altitude (Cherlieu, x, dashed line) (N=45) and high altitude (Galibier, ■, solid line) (N=47) sites. Total amounts of phenolic compounds (Folin-Ciocalteu) were expressed in milligrams of gallic acid equivalent per fruit

highest area (68–79% of the total area). It was selected for structural identification and further identified as adonivernith (see below). Moreover, total amounts of phenolics and amounts of adonivernith were highly correlated (R_s=0.786 and 0.691, P<0.001, in Cherlieu and Galibier, respectively). F2 and F4 have the same UV spectra as F3, indicating the same flavone basis.

In unparasitized fruits, the amount of adonivernith per fruit was slightly higher in the population at low altitude (Mann–Whitney test, U=45, P=0.051) because of larger fruits, but no differences were detected when concentrations were compared between the two populations (U=68, P>0.05). In contrast, in parasitized fruits, the amounts of adonivernith (and the concentrations) were higher at the high altitude site: 117±13 μg in Galibier vs. 62± 6 μg in Cherlieu (U=245, P<0.005). The highest amount of adonivernith (331 μg) was observed in Galibier in a fruit parasitized by five larvae, and represented 17 times the mean amount (19 μg) in unparasitized fruits. In Cherlieu, the highest increase was only by a factor of 4 (from 38 μg for the mean amount in unparasitized fruits to 151 μg for the highest amount). The stronger chemical response to larval infection of plants at the high-altitude site was confirmed by significantly different slopes for the correlation between the number of larvae and the amounts of adonivernith induced in Galibier and in Cherlieu: R_s 0.851 vs. R_s

Table 1 Peak areas (mean ± SE) of phenolic acid like compounds obtained by chromatographic analysis (HPLC-DAD) of intact (N=5) and parasitized (N=5) carpel wall extracts

Phenolic Compounds	Peak Areas[a]	
	Without Larvae	With N>1 Larvae

0.479, respectively (Fig. 3) (ANCOVA, larval number: $F_{1,\ 85}$=39.01 P<0.001; population $F_{1,\ 85}$=4.32, P=0.04; larval number by population interaction: $F_{1,\ 85}$=11.77, P<0.001).

Structural Elucidation of Adonivernith The UV spectra recorded from HPLC-DAD analysis gave λ_{max} 256(sh), 270, 350 nm, characteristic of the flavone luteolin. The positive ion mode MS spectra gave an $[M+H]^+$ ion at *m/z* 581, indicating a possible derivative of luteolin containing one hexose and one pentose substitute. ^{13}C and ^{1}H NMR were required to allow characterization of the linkage and configuration of the sugar moieties. The compound was identified as luteolin 8-β-D-glucopyranosyl-2″-*O*-D-xylopyranoside (or orientin 2″-*O*-D-xylopyranoside), and the spectral data are in good agreement with respective literature data (Wagner et al. 1975; Markham et al. 1987). This compound was previously named adonivernith from its first identification in *Adonis vernalis* (Hörhammer et al. 1960).

Mechanical Induction of Phenolic Metabolism To measure the specificity of the phenolic response as previously demonstrated, we carried out two experiments with mechanical damage of different intensities on flowering globeflowers and analyzed the production of adonivernith in the carpel walls (Fig. 4). Compared to the control plants, no differences were observed between the amount of adonivernith in the carpel walls pierced by a needle (*t* test, t=0.766, P>0.05), nor in those more seriously injured by using a scalpel (t=1.714, P>0.05), nor when the floral stem was pierced (t=0.563, P>0.05). None of these wounds influenced carpel mass.

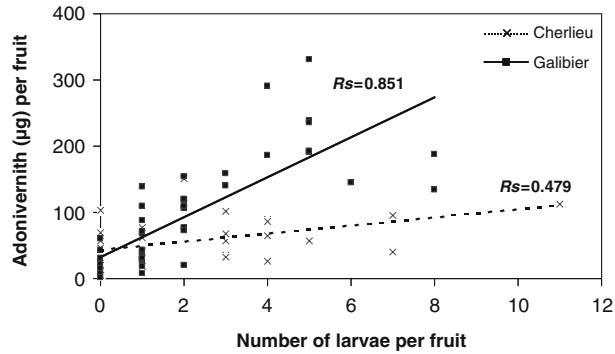

Fig. 3 Spearman correlation (*Rs*) between adonivernith amounts and the number of larvae in fruits of *T. europaeus* from low altitude (Cherlieu, x, dashed line) (*N*=44) and high altitude (Galibier, ■, solid line) (*N*=47) sites. Adonivernith amounts were expressed in micrograms of luteolin equivalent per fruit

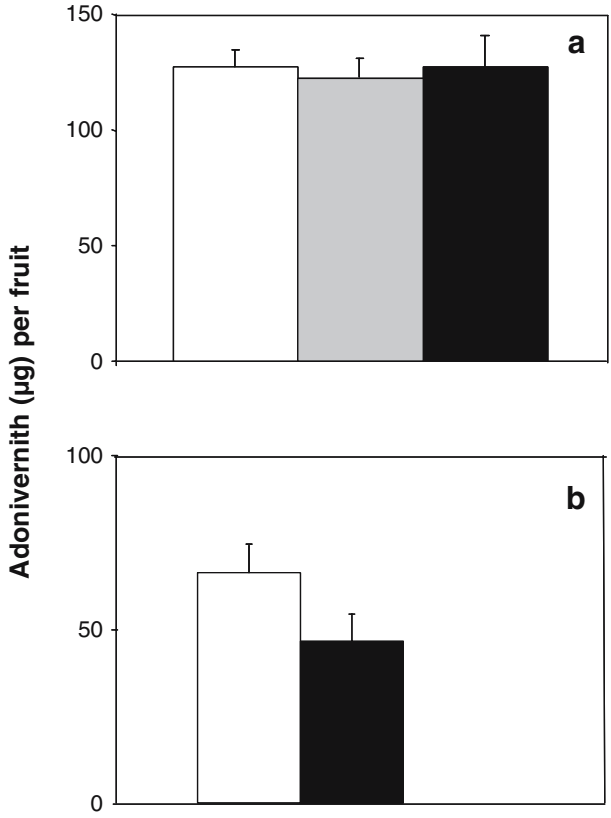

Fig. 4 Amounts (mean + SE) of adonivernith in carpel walls of *T. europaeus* mechanically damaged. (**a**) In Cherlieu, wounds (10 holes) were inflicted with a needle (= low wound) on the carpel (■ black, *N*=19) or on the stem (▒ gray, *N*=21) and compared to control plants (□ white, *N*=19). (**b**) In Galibier, wounds (five incisions) were inflicted with a scalpel (= severe wound) on the carpel (■ black, *N*=21) and compared to control plants (□ white, *N*=25). Adonivernith amounts were expressed in micrograms of luteolin equivalent. No statistically significant differences were observed

Adonivernith Occurrence in T. europaeus and Other Species The fruits of three other *Trollius* species (*T. chinensis*, *T. ledebouri*, and *T. pumilus*) did not contain adonivernith in detectable amounts. However, *T. chinensis* extracts contained two compounds characterized by close retention time (4.6 and 6.1 min, respectively) and similar UV spectra when compared to adonivernith, indicating the likely occurrence of the luteolin flavone.

In *T. europaeus*, adonivernith was not present in the seeds and the floral receptacle, but was found in all the other floral parts and in the leaves (Table 3). Its concentration in the yellow sepals (3.9 mg g^{-1}) was especially high. Except for staminodias, adonivernith was generally more concentrated in all the flowering parts than in unparasitized mature carpels previously analyzed (0.11 mg g^{-1}). The decrease in adonivernith concentrations during the maturation process (Table 4) was also observed when the complete flowers at different developmental stages (from buds to mature fruits) were analyzed.

Discussion

This study is the first to show that larvae of a specific mutualist can induce a chemical plant response, suggesting a means of partner control to prevent overexploitation. This is also one of a few studies on induced plant defenses that have been conducted in field conditions,

Table 3 Concentration of adonivernith in the different organs of *T. europaeus* plants (N=6, pooled) collected at 1-day flower stage

Plant Organs	Adonivernith (mg of luteolin eq./g)
Leaf	0.83
Floral receptacle	_[a]
Sepal	3.88
Staminodia	0.09
Carpel wall	0.24
Stamen	0.20
Seed	_[a]

[a] Below the detection limit

rather than in controlled environment. Therefore, it was not possible to set up a control for the abiotic environmental conditions (e.g., UV intensity) nor for the biotic stresses other than *Chiastocheta* parasitism (e.g., pathogens) that might influence plant phenolic metabolism (Koricheva et al. 1998; Reifenrath and Muller 2007). For instance, adonivernith concentrations in intact carpel walls ranged from 52 to 394 μg g^{-1} in Cherlieu, and from 7 to 355 μg g^{-1} in Galibier. Large variability in plant secondary metabolite production, presumably under both genetic and environmental determinism, is a well-documented phenomenon, and is consistent with previous findings that the chemical profiles of the roots of *Caltha leptosepala* and *Trollius laxus* are highly influenced by habitat characteristics (Kuhajek et al. 2004). Despite these field constraints, individual fruit analyses showed that *Chiastocheta* larval development enhances phenolic metabolism in the carpel walls of the globeflower, and that this increase in content of phenolics is mostly caused by a C-glycosyl flavone that we identified as the rare adonivernith.

The occurrence of luteolin and of C-glycosylflavones in *T. europaeus* leaves has previously been reported (Gonnet 1981; Lebreton 1986), but this is the first report of its presence in several organs of this plant. In the *Trollius* genus and in the closely related genus *Adonis* (Després et al. 2002), the classical flavonols and *O*-glycosyl flavonols are largely replaced by the less widespread flavones and C-glycosyl flavones (Jensen 1995). Adonivernith was first isolated from *Adonis vernalis* (Hörhammer et al. 1960) and more recently from *Trollius macropetalus* (Liu et al. 1992), but was also reported in the Poaceae *Setaria italica* (Harborne and Baxter 1999). *T. chinensis* and *T. ledebouri* have been more extensively studied than *T. europaeus*, and C-glycosyl flavones structurally related to adonivernith (like vitexin and orientin) have been found in their flowers (Liu et al. 2004;

Table 4 Adonivernith concentration (mean ± SE) (N=3) of *T. europaeus* flowers at different developmental stages

Developmental Stage of the Flower	Adonivernith (mg of luteolin eq./g)
Green floral bud	2.38 ± 0.76^{a}
1-day flower	1.09 ± 0.49^{ab}
7-day flower (nonpollinated)	0.71 ± 0.24^{b}
7-day flower	0.64 ± 0.11^{b}
14-day fruit	0.08 ± 0.02^{c}
21-day fruit	0.04 ± 0.04^{c}

[a] Different superscript letters indicate significant differences (Mann–Whiney test, P<0.05) between the developmental stages

Zou et al. 2005; Li et al. 2006). However, we found no adonivernith in these two species, nor in *T. pumilus*, indicating species specificity.

Adonivernith has been found in significant amounts in most organs of *T. europaeus* plants, especially in the sepals where it probably contributes to the bright yellow coloration. Phenolic compounds found in flowers play both attractive and defensive functions (Gronquist et al. 2001) leading to the question of the significance of the correlation between mutualism-linked traits (attractive colors) and antagonism-linked traits (defensive compounds) (Herrera et al. 2002). However, adonivernith induction by larval infestation seems restricted to the carpel walls. Other minor flavonoids also participate in the globeflower-induced response, but their contribution to the total flavonoid production is low. At least two of them are structurally close to adonivernith, i.e., luteolin-based C-glycosyl flavones, indicating possible metabolism intermediates.

Another argument to support the specificity of this chemical plant response to larval infestation is the lack of induced response to mechanical damage, whatever the intensity and the location of the wounding. *Chiastocheta* larval regurgitant might be required to trigger plant-induced response as found in other plants (Alborn et al. 1997). The increase in adonivernith production observed in parasitized fruits might be an efficient defense mechanism if it affects the survival or growth of the larvae. Another luteolin-based C-glycosyl flavone, maysin, induced after infestation of corn by caterpillars of corn earworms (*Helicoverpa zea*) reduces larval growth (Elliger et al. 1980; Wiseman et al. 1993). Such a growth inhibitor effect by adonivernith on *Chiastocheta* larvae has not been demonstrated. So far, experimental bioassays have been limited by the difficulty of breeding *Chiastocheta* larvae in the laboratory. Preliminary experiments have nevertheless been conducted during short time periods: *Chiastocheta* larvae exposed on paper imbibed with carpel extracts for 4 hr did not exhibit increased mortality, compared to larvae on watered paper. In the same manner, choice experiments showed no deterrence of those extracts. The observations in the field that larval survival is independent from the number of larvae developing in a fruit (Jaeger et al. 2001), and that individual larval fresh mass at the end of development decreases according to that number, although seeds are not limited (Després and Cherif 2004), supports the hypothesis that the induced compound inhibits larval growth rather than kills the larvae.

The present study also shows that the increase in adonivernith production is proportional to the number of larvae developing within the infrutescence. Recent empirical and theoretical studies suggest that density-dependent processes control mutualistic interactions (Holland and DeAngelis 2006). For example, yucca moth density was shown to be regulated by selective abortion of highly parasitized fruits (Pellmyr and Huth 1994). These results were later challenged by several studies that showed that fruit abortion was random in yucca (Addicott 1998; Shapiro and Addicott 2004); however, although random, fruit abortion might limit and regulate yucca moth population growth through density-dependent recruitment. Similar density-dependent population level processes are believed to occur in the senita cactus–senita moth mutualism (Holland and DeAngelis 2006). The density-dependent chemical response of globeflowers might limit fly population growth at densities where the interaction is still mutualistic, which could contribute to the interaction stability.

We also found that adonivernith overproduction is tissue specific: only the carpel walls of parasitized fruits show an increase in the chemical defense, whereas the seeds and the floral receptacle remain unchanged. Such carpel-specific accumulation of phenolic compounds has been observed in *Hypericum calycinum*, raising the question of the development of specific chemical defensive profiles by plant carpels (Gronquist et al. 2001). Although larvae of all *Chiastocheta* species feed on *T. europaeus* seeds, the larvae

from each species are spatially partitioned within a single infrutescence, either in the floral receptacle (the first ovipositing species), or mining their way through the inner or outer carpels (the five remaining species) (Després and Jaeger 1999; Pompanon et al. 2006). The first species infesting the fruit occupies the only undefended part of the fruit (adonivernith-free refuge), whereas all the other species appear to be more exposed to adonivernith. The tissue-specific differential induction of adonivernith after larval infestation creates a heterogeneous chemical environment within a single fruit ("chemical niches") that might have selected for different fly resistance strategies, such as escape to a phenolic-free refuge for the first visitor, and evolution of metabolic resistance for later visitors. This hypothesis remains to be tested by evaluating the differential resistance of early vs. late *Chiastocheta* species to adonivernith exposure. If verified, this mechanism might explain the unusually large number of congeneric flies coexisting on *T. europaeus* fruits.

Acknowledgments This work was partly supported by the CNRS (GDR 2877). We thank Charlotte Tollenaere for assistance in the field and the UMS 2925 Joseph Fourier Alpine Station for logistics support provided and for giving us access to the exotic *Trollius* species. We thank C. Bosso from CERMAV for LC/mass analysis and Kim Barrett for correcting our English.

may be impaired by direct anthropogenic disturbances. For example, Wolf and Moore (2002) found that exposure to the pesticide metolachlor rendered crayfish unable to detect food sources and also elicited inappropriate behavior to other chemicals that could jeopardize their survival. Human impact can also alter the concentration of naturally occurring substances, which may additionally impair chemical recognition. This study examines the potential effect of the naturally occurring substance humic acid (HA). HA is a by-product of degrading organic matter and is increased by processes such as eutrophication (Thomas 1997).

Dissolved organic matter and humic substances constitute the majority of dead organic matter (Steinberg and Münster 1985; Thomas and Eaton 1996; Thomas 1997; Wetzel 2001). HA is a ubiquitous, naturally occurring organic component in aquatic environments associated with agricultural manure and other organic wastes (Atiyeh et al. 2002; Kappler and Haderlein 2003). Elevated levels of HA in aquatic habitats are of particular interest because of their apparent effect in impairing the recognition of conspecific sexual pheromones (Hubbard et al. 2002; Fisher et al. 2006). Mesquita et al. (2003) found that humic acids adsorb relatively water-insoluble organic substances such as steroidal pheromones, reducing their biological availability to organisms that normally detect these chemicals as part of their communication. Hubbard et al. (2002) proposed that the steroids adsorb onto the surface of humic acid microvesicles that form in water, rendering the pheromone effectively unavailable for olfactory detection by *Carassius auratus* and other teleosts in natural environments.

Female swordtail fish (*Xiphophorus birchmanni*) lose their preference for conspecific males over heterospecific males in water with elevated levels of HA (Fisher et al. 2006). This impairment of chemical communication may have implications for the evolutionary fate of many species because of the potential for interspecific hybridization.

The zebrafish, *Danio rerio* (family Cyprinidae), is an important vertebrate model system in many areas of biological research. Zebrafish are native to freshwater streams and rice paddies in the Ganges River of eastern India, Bangladesh, and Burma, where they are likely exposed to many naturally occurring organic substances (Mcclure et al. 2006; Spence et al. 2006). Environmental effects reported from many of the rice-producing countries include soil degradation, water contamination with nitrogen, eutrophication, and increased ammonia and other nitrogen trace gas emissions (Li 1995; Robertson et al. 2000). Additionally, from 1980 to 2000, use of synthetic nitrogen fertilizers in East Asian rice-producing nations has increased from approximately 4 to 10 Tg [Food and Agricultural Organization (FAO) 2002] as part of a transition from more traditional to industrialized, broad-scale rice production. As zebrafish use chemical communication in the context of reproductive suppression and stimulation (Van den Hurk et al. 1987; Delaney et al. 2002; Gerlach 2006) and kin recognition (Mann et al. 2003; Gerlach and Lysiak 2006), the chemical environment is likely to affect transmission and reception of chemical stimuli. In this study, we investigated the ability of adult *D. rerio* to discriminate between conspecific and heterospecific chemical cues in the presence and absence of HA, as well as their habitat preferences for water with and without HA.

Methods and Materials

Animal Care and Housing We tested wild-type adult zebrafish that were raised together in the zebrafish facility at the Marine Biological Laboratory, Woods Hole, MA, USA. Fish were housed in an Aquatic Habitats tank system with a 14 L:10 D cycle and were fed twice daily with dry fish pellets and live *Artemia salina* nauplii. We used adult zebrafish from the

F_1 generation of wild-type individuals that originated from several pet shops and breeding centers in the USA, with the objective of obtaining out-crossed strains with higher genetic variability than fish from the same source.

Choice Tests Trials were performed in a choice flume (Fig. 1) powered by a peristaltic pump. The flume allows a laminar flow separation of two water stimuli (Atema et al. 2002; Mann et al. 2003; Gerlach and Lysiak 2006). The water height was maintained at approximately 1.5 cm, and uniform unidirectional flow was maintained at a constant rate of 106 ml/min or 6.2 cm/s). Dye tests were conducted to confirm proper separation of the two different water flows.

During odor choice tests, a single test fish was placed into the flume to acclimatize for 5 min before measurements began. The test consisted of two 5-min periods where odor stimuli were presented on alternate sides of the flume to control for possible side bias of the fish. After the first 5-min, another 1-min acclimation time was allowed when stimuli were alternated in the flume, and the test continued for another 5 min. From position records taken every 10 s, we calculated how often each fish selected a given stimulus. Water association time is widely used as a measure of preference in studies of kin recognition, shoaling preferences, and mate choice in laboratory studies on zebrafish (Rosenthal and Ryan 2005; Gerlach and Lysiak 2006; Gerlach et al. 2007) and poeciliids, including swordtails (see Wong and Rosenthal 2005 and references therein). We calculated the difference between the total number of observations in which a test fish was in the lane of the flume associated stimulus A or B, and tested whether that difference was significant from zero by using the Wilcoxon matched-pairs signed-ranks (WSR) test. If the fish did not have a preference for one of the odor stimuli or was unable to detect a difference between them, we would expect a random distribution on either side of the flume, which would result in no (zero) difference in distribution frequency between treatments. A nonparametric Van der Waerden chi-squared test was used to analyze differences between experiments (discussed below). Analyses were performed with SAS 3.1 software (SAS Institute).

We performed three sets of tests. First, we tested the response of male and female zebrafish to untreated water (dechlorinated tap water, pH 7.0) vs water containing 200 mg/l supplemental HA. Second, we presented female zebrafish with water containing conspecific cues vs water containing heterospecific cues (goldfish, *Carassius auratus*). Heterospecific water was created by isolating one goldfish with a body mass of approximately 35 g to a standing tank

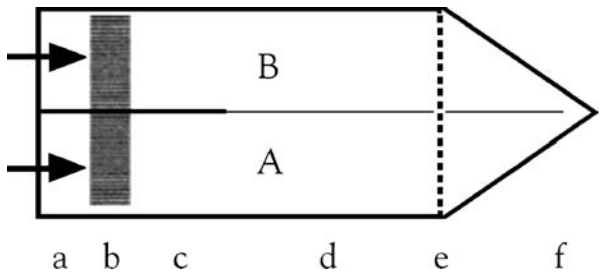

Fig. 1 Diagram of the choice flume. **a** Water inflow area, **b** collimator to homogenize turbulent flow, **c** barrier-separated channels, **d** area of flume where water columns remain separated (*fine dotted center line*), **e** screen to contain test subjects, and **f** outflow channel. *A* The left side of the flume and *B* the right side of the flume, when oriented toward the start of the flow. The dimensions of the flume are 33.6×7.1×6.5 cm (after Mann et al. 2003)

of untreated water. Conspecific water was made by isolating a single male zebrafish with a body mass of approximately 1 g to a separate standing tank. Tanks were filled with the same volume of untreated water (7 l) with airstone aeration 24 h before being used in the flume experiments. The heterospecific water was then diluted 35 times in untreated water to correct for body mass difference between the goldfish and the zebrafish. Third, we repeated the second set of experiments, this time treating both conspecific and heterospecific water stimuli with HA (Fluka cat. #53680) for a final concentration of 200 mg/l HA (Fisher et al. 2006). Several workers, including Malcolm and Mccarthy (1986) have pointed out differences between commercial humic acids, like the ones used in the present study, and HA derived from natural sources. Specifically, commercial HA have considerably higher carbon-to-nitrogen ratios and high ash contents (Malcolm and Mccarthy 1986). These factors are unlikely to fundamentally affect the behavior of HA with respect to chelating chemical signals or acting as antagonists to chemoreceptors.

To prepare HA-treated water, we measured 200 mg of HA and placed the amount in a 1,000-ml volumetric flask. The flask was filled with 500 ml of untreated water, magnetically stirred for about 15 min, and the final volume was brought up to 1,000 ml. The mixture was transferred to a bottle that was capped and shaken vigorously for 5 min, then set aside for 1–2 h before being used. The solution was shaken thoroughly once more before being used in flume trials.

Results

In odor choice tests that assayed habitat preference, zebrafish associated more with untreated water over HA-treated water (WSR test, $z=59$, $N=19$, $P=0.015$; Fig. 2).

Female zebrafish tested in water without supplemental HA preferentially associated with conspecific cues over heterospecific cues (WSR test, $z=162.5$, $N=25$, $P<0.001$; Fig. 3).

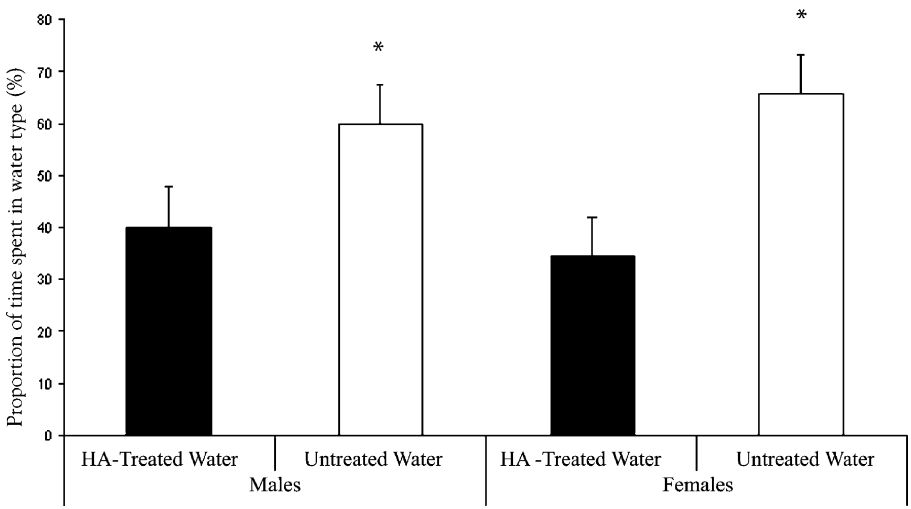

Fig. 2 Response (mean±SE) of zebrafish to untreated water vs water containing supplemental HA. *Error bars* indicate the standard error of means, and an *asterisk above a column* indicates a significant difference between untreated water and HA-treated water (*$P<0.02$)

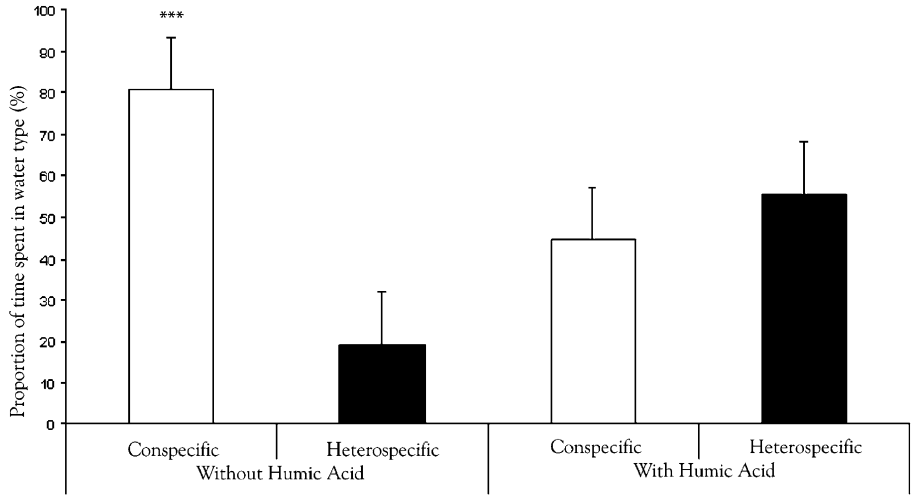

Fig. 3 Preference of female zebrafish (mean±SE) for conspecific (*black*) vs heterospecific (*white*) stimuli in water with and without 200 mg/l HA. *Error bars* indicate standard error of means, and an *asterisk above a column* indicates a significant difference between association with conspecific and heterospecific cues in untreated water (***$P<0.001$)

When 200 mg/l HA were added to stimuli containing conspecific and heterospecific odor cues, zebrafish failed to show a preference ($z=63$, $N=25$, $P=0.09$; Fig. 3). The observed association for conspecific cues was significantly reduced in water containing supplemental HA. Zebrafish spent 82±3% of the observation time in proximity to conspecific odor stimulus in water without supplemental HA, but when tested in HA-treated water, they associated 44±3% of the trial with the conspecific odor cue (van der Waerden test, $\chi^2=26.3$, $df=1$, $P<0.001$; Fig. 3).

Discussion

Our results suggest that humic acid can interfere with recognition of conspecific chemical cues in zebrafish. While zebrafish showed a strong association with olfactory cues of conspecifics vs heterospecifics, they did not differentiate between these odor cues when tested in conditions with elevated levels of HA. These findings suggest that humic acid either reduces zebrafish preference for conspecific cues or reduces their avoidance from heterospecific cues. Our experimental design, however, does not allow us to discriminate between these two hypotheses; nevertheless, the biological significance is the same in either case: Humic acid alters zebrafish behavior toward chemical cues.

Elevated levels of HA in the environment as a byproduct of anthropogenic disturbance could potentially lead to misidentification of shoalmates and hybridization (Fisher et al. 2006). Zebrafish are sympatric with other danionin fishes over part of their range (Mcclure et al. 2006) and shoal assortatively with respect to species-typical visual cues (Engeszer et al. 2004; Rosenthal and Ryan 2005). The olfactory channel may be critical in social communication, particularly, when transmission of visual information is poor (Rosenthal and Lobel 2006).

Chemical cues may also influence habitat choice. Zebrafish strongly avoided water containing HA in favor of clean water. The chemical environment may be an important

determinant of habitat choice. Given the physiological (Yang et al. 2002; Steinberg et al. 2004) and sensory (Fisher et al. 2006) costs of HA exposure, selection may favor individuals who actively avoid high HA concentrations. These findings have important implications for species living in aquatic habitats with high levels of pollutants and agricultural runoff. In response to such environmental disturbances, many organisms may avoid areas important for survival, such as foraging areas and mating grounds (Sprague 1962; Geckler et al. 1976). High HA concentrations may drive organisms into suboptimal but less polluted habitats.

Several studies have demonstrated the deleterious effect of HA on a variety of organisms. High levels of HA in a natural habitat may have effects on multiple physiological and behavioral functions. HA can decrease olfactory response to pheromones in goldfish (*Carassius auratus*) and prevent pheromones from binding properly to chemoreceptors (Hubbard et al. 2002; Mesquita et al. 2003). Most known fish sexual pheromones are either steroids or prostaglandins (Stacey et al. 2003; Yambe et al. 2006), and their hydrophobic properties may make them more susceptible to HA binding. It remains to be seen how olfactory communication is maintained in fish that live in areas with naturally high concentrations of HA (Rosenthal and Lobel 2006).

of a ripe fruit odor—either in combination with visual cues or when presented alone. Fruit bats also used fruit odors to distinguish between ripe and unripe fruits. By using gas chromatography (GC) and GC/mass spectrometry (MS), a total of 16 main compounds were identified in the ripe fruit odor of *Ficus hispida* and 13 in the ripe fruit odor of *Ficus scortechinii*—including alcohols, ketones, esters, and two terpenes. Additional compounds were also recorded in *F. hispida*, but not identified—four of which also occurred in *F. scortechinii*. Total scent production increased in both species when fruits ripened. Both natural and synthetic fruit odors resulted in feeding attempts by bats, with no feeding attempts elicited by unscented controls. Reaction rates to natural fruit odors were higher than those to synthetic blends.

Introduction

Observations in tropical rain forests have revealed a broad dietary overlap between birds and mainly diurnal mammals when feeding on figs (Breitwisch 1983; Leighton and Leighton 1983; Shanahan et al. 2001a). This has led to the widespread belief that interactions between figs and their vertebrate seed dispersers are relatively generalized, as characterized by large crops of low-quality fruits consumed and dispersed by diverse and taxonomically disparate groups of frugivores. However, more recent studies on the feeding ecology of fruit bats, in both Neo- and Paleotropical rain forests, have revealed a distinct subset of fig species that are consumed and dispersed almost exclusively by nocturnal mammals—especially bats (Kalko et al. 1996; Korine et al. 2000; Shanahan and Compton 2001; Shanahan et al. 2001a; Hodgkison et al. 2003).

In contrast to diurnally dispersed figs, which are often characterized by visually conspicuous fruit displays, particularly bright colors that stand out against surrounding vegetation (e.g., orange and red), nocturnally dispersed species are often characterized by distinctive odors (Lambert 1987, 1989; Lambert and Marshall 1991; Kalko et al. 1996; Korine et al. 2000; Shanahan and Compton 2001; Shanahan et al. 2001a; Hodgkison et al. 2003). These adaptations in fruit display and fruit chemistry correspond closely with the sensory capabilities and foraging behavior of both groups of disperser—as birds and diurnal mammals have well-developed color vision, and locate fruits primarily by sight (Dominy et al. 2003; Smith et al. 2006; Schaefer et al. 2007), whereas fruit bats and other nocturnal mammals have an acute sense of smell, and locate fruits primarily by olfaction (Rieger and Jakob 1988; Laska 1990a, b; Acharya et al. 1998; Thies et al. 1998; von Helversen et al. 2000; Luft et al. 2003; Sanchez et al. 2004, 2006; Korine and Kalko 2005). Thus, many fig species are likely to be more specialized in their interactions with frugivores than previously thought (Kalko et al. 1996; Shanahan et al. 2001b; Hodgkison et al. 2003). The chemical compounds that mediate the interactions between figs and their vertebrate seed dispersers are currently unknown, although high levels of ethanol, which are often associated with overripe fruits, may act as a feeding deterrent to fruit bats (Sanchez et al. 2004).

The goals of this study were to investigate the fruit odors of two bat-dispersed fig species (*Ficus)* in the Paleotropics, in relation to the foraging behavior of fruit bats (Pteropodidae). We tested the following hypotheses: 1) fruit odor plays a critical role for the detection and selection of ripe figs by fruit bats; 2) bat-dispersed figs are characterized by

the same, or similar, chemical compounds; and 3) total scent production, in bat-dispersed figs, increases significantly when fruits ripen. We performed bioassays to test the effect of both natural and synthetic fruit odors on the foraging behavior of the short-nosed fruit bat, *Cynopterus brachyotis* (Müller), an important disperser of fig species within the study area (Hodgkison et al. 2003).

Methods and Materials

Study Site The field work was conducted at Kuala Lompat (3°43′N, 102°17′E), within the Krau Wildlife Reserve, Pahang, Peninsular Malaysia between March 2005 and August 2006. The Krau Wildlife Reserve consists of a large area of old-growth forest, which rises from 50 m (asl) at Kuala Lompat, to over 2000 m at the summit of Gunung Benom. The vegetation at Kuala Lompat can be described as lowland evergreen mixed dipterocarp forest (Raemaekers et al. 1980). However, compared to many other lowland dipterocarp forest sites in Malaysia, most of which have now been cleared for agriculture, this site is unusually rich in large Leguminosae. The site is also extremely rich in strangler and free-standing figs (*Ficus* spp.), with 41 species reported to date, at least 25 of which are consumed by birds and 10 by bats, with little overlap (Lambert 1987, 1989; Lambert and Marshall 1991; Hodgkison et al. 2003). The majority of fig species consumed and dispersed by birds at Kuala Lompat are characterized by visually conspicuous fruit displays that are produced as a result of distinct color changes upon ripening, often following the transition from green or yellow-green to bright orange or scarlet red (Lambert 1987, 1989). Figs consumed and dispersed by bats, by contrast, tend to be visually less conspicuous to humans, typically yellow-green, or dark red-brown, but are often characterized by the production of faint or strong odors when ripe. Several bat-dispersed fig species at Kuala Lompat are also caulicarpic, producing fruits on woody knobs or long runners that grow directly from the main trunk (Hodgkison et al. 2003).

The bat-dispersed species selected for sampling in the present study contrast in both color and odor production when ripe. *Ficus hispida* Linn. F. has a distinct color change upon ripening, from green to yellow, and emits a strong fruity odor as an attractant. *Ficus scortechinii* King, by contrast, exhibits only a slight color change upon ripening, from dark red-brown to slightly paler red-brown, and produces an odor, which, to a human nose, is almost completely imperceptible.

Fruit Odor Sampling Fruit odors of bat-dispersed figs were sampled in the field by using dynamic headspace adsorption techniques (Dobson et al. 2005; Kalko and Ayasse in press). Both ripe and unripe fruits were removed from plants and placed inside glass sample chambers, all of which were connected by equal lengths of silicon tubing to a single battery-operated pump (SKC, type 224). Air drawn into each glass sample chamber through a single inlet was filtered and cleaned of atmospheric pollutants by a cylindrical borosilicate glass cartridge packed with activated charcoal (Orbo-32, Supelco), and plugged with silanized glass wool (Raguso and Pellmyr 1998). Air drawn out of each chamber, through a single outlet, was sampled for volatile fruit odor compounds, by a sorbent tube containing a thin layer of activated charcoal (CLSA-Filter 1.5 mg). Both the sorbent tubes and charcoal filters were connected to the glass sample chambers by short lengths of Teflon tubing.

In total, four glass sample chambers were used to collect fruit odors during each sampling session. This allowed up to three fruits to be sampled simultaneously, along with a blank control. Each sampling session was conducted at night (between 1930 and 0500 hours)

with a flow rate of 100 ml min^{-1} per chamber and a total sampling time of 4 hr for *F. hispida* and 5 hr for *F. scortechinii*.

After sampling, all sorbent tubes were wrapped in aluminum foil, labeled, and sealed in airtight glass jars, with Teflon-coated lids, and then stored at −18°C. The samples were eluted the following day with 0.040 ml of 10:1 pentane/acetone. Eluted samples were sealed in small airtight borosilicate glass specimen tubes and returned for storage at −18°C.

After each sampling session, all glassware was thoroughly cleaned three times with ethanol (Absolute Alcohol, Hayman Ltd., Essex, UK), acetone (LiChrosolv, Merck, Darmstadt, Germany), and pentane (SupraSolv, Merck), and placed in a sterilizing oven set at 150°C for 1 hr. Sorbent tubes were cleaned three times with ethanol, dichloromethane (LiChrosolv, Merck), and pentane, and then wrapped in aluminum foil and stored for future use in airtight glass jars with Teflon-coated lids.

Chemical Analysis of Compounds For quantitative analyses, 0.1 μg of *n*-octadecane was added as an internal standard to each of the eluted fruit odor samples collected by dynamic headspace adsorption (see above). All samples were analyzed with an HP5890 Series II gas-chromatograph (Hewlett-Packard, Palo Alto, CA, USA), equipped with a DB5 capillary column (30 m×0.25 mm i.d.) that used hydrogen as the carrier gas (2 ml min^{-1} constant flow). One microliter of each sample was injected splitless at 40°C. After 1 min, the split valve was opened and the temperature increased by 4°C min^{-1} until reaching a temperature of 300°C.

GC/MS analyses were carried out on an HP 6890 Series GC connected to an HP 5973 mass selective detector (Hewlett-Packard) fitted with a BPX5 fused-silica column (25 m, 0.22 mm i.d., 0.25 μm film thick, SGE). Mass spectra (70 eV) were recorded in full scan mode. Retention indices were calculated from a homolog series of *n*-alkanes. Esters and alcohols were purchased (Sigma-Aldrich, Schnelldorf, Germany) when commercially available. If not, target compounds were synthesized by conventional esterification by using an acid chloride and the respective alcohol under Schotten–Baumann conditions (Autorenkollektiv 1999). α-Bergamotene was identified by comparing the mass spectrum and retention index with the data of a critically evaluated database (Joulain and König 1998).

Behavioral Experiments Six behavioral experiments were conducted. The first set consisted of simple fruit detection tests, designed to assess the relative effect of three cues (color, shape, and odor) on the foraging behavior of captive bats. This involved four separate feeding trials, in which each bat was exposed to the following sequence of treatments: 1) ripe fruits, without modification; 2) unripe fruits, without modification; 3) ripe fruits, wrapped in a triple layer of 15 denier black nylon stocking; and 4) ripe fruit pulp smeared on an adhesive polyester patch and covered with a double layer of black stocking. The second set of experiments were two-choice feeding trials, designed to test the hypothesis that bats use fruit odors to distinguish between ripe and unripe fruits. This involved two separate feeding trials in which each bat was offered the following options: 1) an unripe fruit and a ripe fruit; and 2) two unripe fruits, one of which had been artificially scented with ripe fruit pulp. Bioassays were performed to test the effect of both natural and synthetic fruit odors on the foraging behavior of captive bats.

For bioassays, each bat was presented with a single unripe fig (control) or an unripe fruit that had been artificially scented with either a natural ripe fruit odor sample of *F. hispida* (collected by dynamic headspace adsorption techniques—see above) or a synthetic blend of the available compounds present and identified in the ripe fruit odor of the same species. The composition of the synthetic blend was mixed according to the relative proportions identified by gas chromatography. As the enatiomeric compositions of the chiral compounds were unknown, the synthetic blend used racemic (50:50) mixtures of both

enantiomers. The synthetic blend was diluted and applied to the figs at the same concentration as the dynamic headspace samples, using the solvent pentane. This concentration was equivalent to two fruits sampled for 4 hr. Compounds included in the synthetic blend are listed in Table 1. Control bioassays were also performed with pure pentane with no added ripe fruit odors (Nolte and Mason 1998).

All behavioral experiments and bioassays were conducted in a large flight cage (3×3×2.5 m-width × length × height), with newly captured and, hence, naïve bats. Bats were

[b] Compounds included in the synthetic mixture of *F. hispida*

obtained by using ground and canopy mist nets within the study area at Kuala Lompat (Hodgkison et al. 2002; Kunz et al. in press). To facilitate the capture of specific fruit bat species that consume figs, mist nets were positioned adjacent to fruiting fig trees, opened at dusk (c. 1900 hours), and checked every 15 min for captured bats—with one individual bat retained for behavioral experiments or bioassays during each night of sampling. All newly captured bats were introduced to the flight cage on the night of capture, and then left undisturbed, with an abundant supply of food, until the following day. Immediately before dusk the following evening, any uneaten fruits were removed from the flight cage to prevent bats from becoming distracted during experiments.

Behavioral reactions of bats were recorded on videotape with the "nightshot" facility of a Sony digital video camera (Handycam DCR-PC350E). The effect of each treatment was quantified by the presence or absence of four types of behavioral response: circling, approaching, landing, and feeding. An "approach" was differentiated from circling, both by its greater precision in relation to the position of the fruit, and by a perceptible reduction in flight speed. A "feeding" attempt was scored when a bat attempted to bite and remove a fruit. Landing always occurred before feeding, and no fruit bat was observed to remove a fruit while in flight. To motivate the bats throughout the experiments, each bioassay was preceded by a feeding trial with a reward of one ripe fruit (*F. hispida*). Each experiment lasted for 20 min, with each individual bat exposed to up to six behavioral experiments or four bioassays per night. All fruits were presented to the bats in a natural way, by using wires to fix them to the trunks of small trees incorporated into the sides of the cage. To prevent bats from learning the spatial arrangements within the cage, all fruits were presented in different locations during each successive trial (Nolte and Mason 1998). The only artificial light source was an infrared beam emitted from the camera.

When experiments were completed, all bats were recaptured in the flight cage with a hand net, marked with an individually numbered stainless steel ball chain necklace (Ball-Chain Manufacturing Company, NJ, USA), and then released at the site of capture (Kunz and Weise in press). This ensured that no individual bat was exposed to a single experiment or bioassay on more than one occasion.

Data Analysis Total scent production and the relative amounts of each compound produced by the ripe and unripe fruits of *F. hispida* and *F. scortechinii* were compared by using the Mann–Whitney *U* test. The relative amounts of all compounds commonly found in both species of *Ficus* were compared with a discriminant function analysis (DFA). The standardized discriminant function coefficients and the factor loadings of each compound were used to assess the differences between the ripe and unripe fruits of both species. All statistical analyses of fruit odors were performed by using SPSS version 11.0.

The results of the behavioral experiments and bioassays were arranged on 2×2 contingency tables to express the observed frequencies of the four behavioral reactions in response to *n* treatments (i.e., approach vs. no approach × *n* treatments, and feeding vs. no feeding × *n* treatments). These results were analyzed with Fisher's Exact Test of independence (Sokal and Rohlf 1995).

Results

Chemical Composition of Fruit Odors Several odor compounds were identified by GC/MS by comparing their mass spectra and retention times with those of authentic reference

samples. This revealed a series of odd numbered 2-alkanones, 2-alkanols, and their respective acetates, butanoates, and hexanoates (Table 1). Compound 3 (Table 1) showed a mass spectrum similar to that of pent-3-en-2-ol. However, a higher molecular mass, by 42 Da, and a more intense ion *m/z* 43 suggested an acetate. Comparisons with synthetic samples of all possible pentenol acetates revealed this compound to be (*E*)-pent-3-en-2-yl acetate (Fig. 1). The corresponding hexanoate was identified by using the same method. Compound 9 (Table 1) proved to be an ester of 2-pentanol with a C_5-acid. Comparisons with authentic reference samples of 2-pentyl pentanoate, 3-methylbutyrate, and 2-methylbutyrate revealed the natural compound to be the latter. The only terpenes found were the furanoid form of linalooloxide and α-bergamotene. Structures of the identified compounds are shown in Fig. 2.

A total of 16 compounds were identified in the ripe fruit odor of *Ficus hispida*, whereas six additional compounds remained unidentified. Twelve of the identified, and four of the unidentified, compounds also occurred in the ripe fruit of *Ficus scortechinii* (Table 1), producing a reduced but similar bouquet (Fig. 3). 2-Heptyl acetate was particularly prominent in the ripe fruit odors of both species, and accounted for ca. 30% of total scent production in *F. scortechinii*, and 21% in *F. hispida* (Table 1). Other prominent compounds included 2-hepanol and 2-heptanone (Table 1).

Total scent production of ripe fruits was significantly greater than that of unripe fruits (Fig. 4), and included a greater number of compounds (Fig. 3). On average, total scent production per fruit of *F. scortechinii* increased from 0.008±0.017 μg hr^{-1} (mean ± SD) to 0.148±0.162 μg hr^{-1} upon ripening (N=12 in both cases); whereas total scent production per

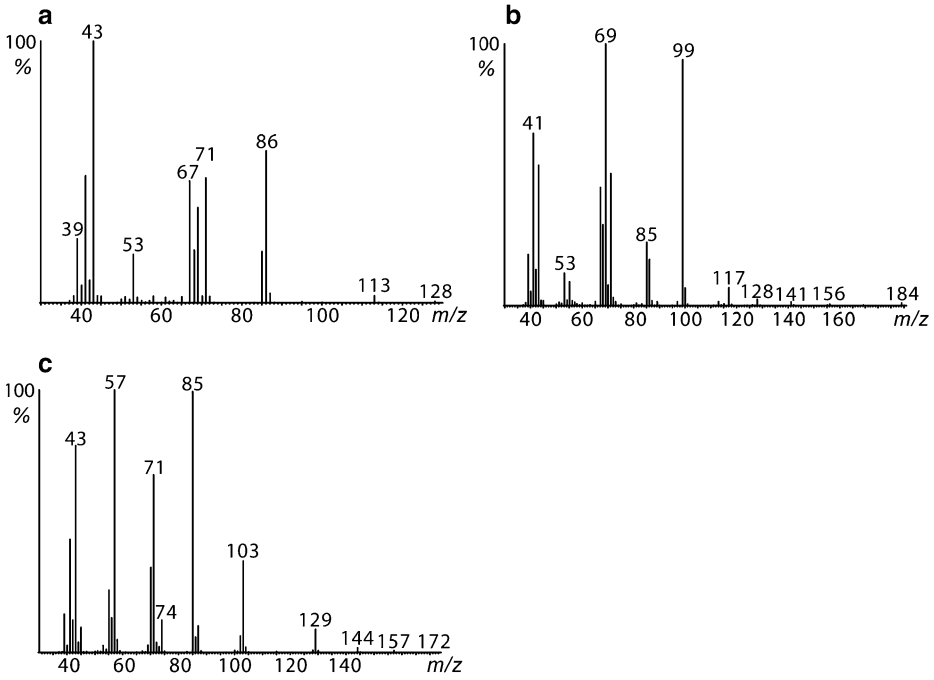

Fig. 1 Mass spectra of (*E*)-pent-2-en-3-yl acetate (**a**), (*E*)-pent-2-en-3-yl hexanoate (**b**), and 2-pentyl 2-methylbutyrate (**c**)

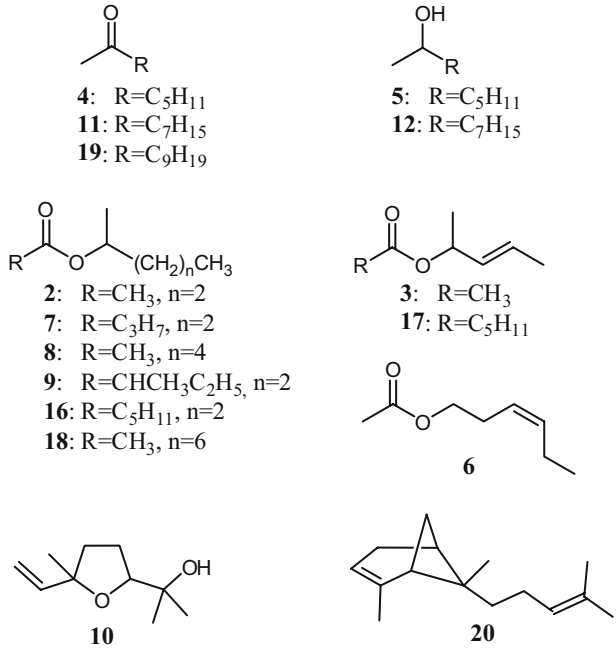

Fig. 2 Structures of compounds identified in the ripe fruit odors of *Ficus scortechinii* and *Ficus hispida*. Numbers refer to entries in Table 1

fruit of *F. hispida* increased from 0.017±0.020 μg hr^{-1} to 0.507±0.546 μg hr^{-1} (N=10 and 20, respectively). Relative amounts of several compounds also increased (e.g., 2-heptanol and 2-heptyl acetate) or decreased significantly (e.g., 2-nonanol and α-bergamotene) when fruits ripened (Table 1). No compounds were associated exclusively with unripe fruits of either fig species.

The discriminant function analysis (DFA) of fruit scents produced four chemically distinct clusters, which corresponded with the ripe and unripe fruits of both fig species (Fig. 5). The first discriminant function, which accounted for 66.5% of the total variance, was mainly important for discriminating between the unripe fruits of *F. scortechinii* and the ripe fruits of *F. hispida* (DF1: Chi-square=267, df=45, P<0.001). The second function, which accounted for 31.6% of the total variance, was mainly important for discriminating between the ripe fruits of *F. scortechinii* and the unripe fruits of *F. hispida* (DF2: Chi-square=129, df=28, P< 0.001). The third function was not statistically significant. Compounds with the highest standardized canonical discriminant function coefficients were pentyl acetate, compound 15, and (*E*)-pent-3-en-2-yl hexanoate (in DF1), and 2-undecanone and compound 22 (in DF2). Of the 54 samples used in the DFA, 53 (98.1%) were correctly assigned to groups—with a cross-validated accuracy rate of 83.3%.

Fruit Bat Foraging Behavior Fruit bats responded to both visual and chemical (olfactory) cues when foraging for fruits. However, in the absence of a ripe fruit scent, the proportion of individuals that approached, or attempted to land or feed on unripe fruits, was significantly lower than on the ripe fruit control (P>0.01, in each case). Of the 20 individual bats tested, only 70% of individuals approached unripe fruits, 15% attempted to land, and only 5% attempted to feed (N=20). By contrast, approach rates of 100% were recorded for all scented treatments, with landing and feeding rates ranging from 95 to 100% (Table 2). In two-choice feeding trials, bats showed a strong preference for ripe fruits over

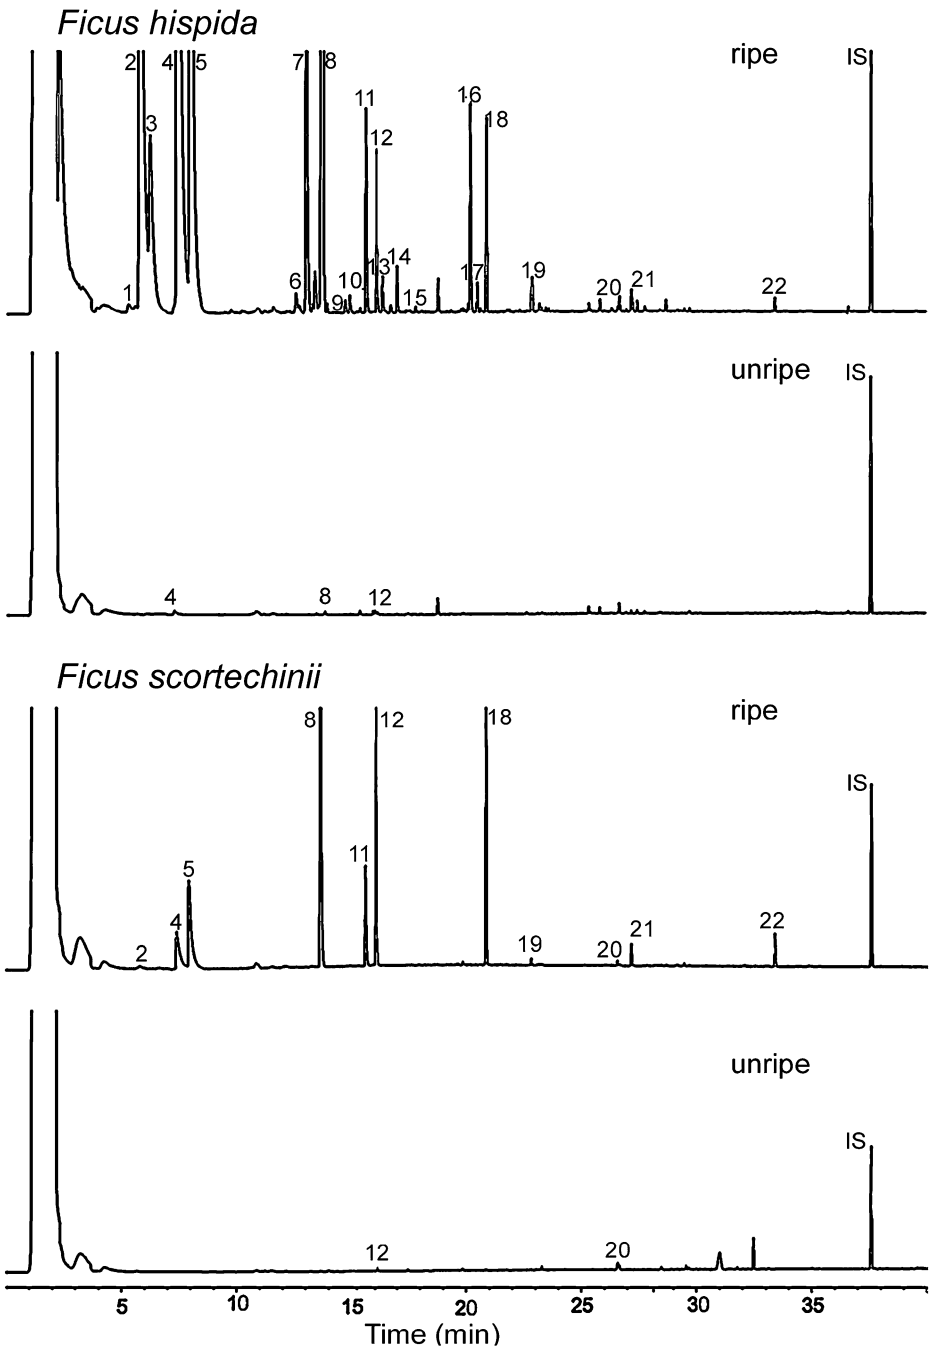

Fig. 3 Gas chromatograms of the ripe and unripe fruit odors of *Ficus hispida* and *Ficus scortechinii*. All labels correspond with the numbers in Table 1. IS = internal standard (octadecane). N.B. compounds 10, 15, 16, and 17 occurred only in trace amounts in *F. scortechinii*

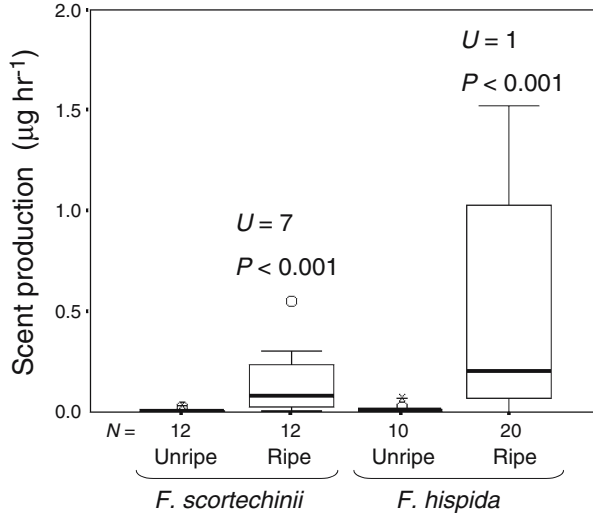

Fig. 4 Total scent production in ripe vs. unripe fruits of *Ficus scortechinii* and *Ficus hispida*. Included are medians, mid-quartiles, 90th and 10th percentiles and outliers. There was a significant increase in total scent production in both species when fruits ripened (Mann–Whitney *U* test)

unripe fruits, and scented (i.e., manipulated) unripe fruits over unscented (i.e., unmanipulated) unripe fruits (Table 3). Responses to ripe and manipulated unripe fruits, smeared with ripe fruit pulp, were not significantly different (P=0.43), with feeding attempts by 100 and 93% of the individuals tested, respectively (Table 3).

Feeding attempts by fruit bats were elicited by both natural fruit odors and synthetic blends. However, a greater proportion of bats reacted to natural headspace samples of *F. hispida* than to synthetic blends of the same species (55 and 15% respectively, N=20, P=0.019). Compared to the two unscented controls, the synthetic blend of *F. hispida* had no significant affect on the proportion of bats attempting to feed (P=0.23). Of the 20 bats tested, only 15% attempted to feed on fruits treated with the synthetic blend, whereas no bats attempted to feed on untreated unripe fruits or on unripe fruits treated with pure pentane.

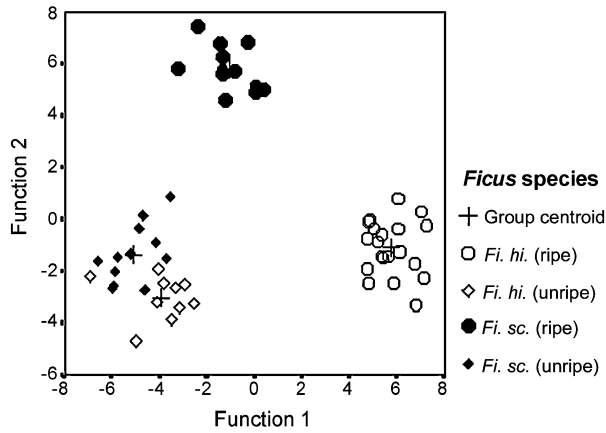

Fig. 5 Discriminant Function Analysis of the ripe and unripe fruit odors of *Ficus hispida* (*Fi. hi.*) and *Ficus scortechinii* (*Fi. sc.*). This analysis was based on the relative proportions of 15 compounds that commonly occurred in the headspace samples of both species (see Fig. 3 and Table 1). Both discriminant functions accounted for 98.1% of the total variance

Table 2 The relative effect of three cues (color, shape, and odor) on the foraging behavior of four species of pteropodid bat—*Balionycteris maculata* (*N*=1), *Chironax melanocephalus* (*N*=1), *Cynopterus brachyotis* (*N*=18), and *Cynopterus horsfieldi* (*N* =2)

Treatment	Sensory Cue	*N*	Frequency of Behavioral Response (%)			
			Circling	Approaching	Landing	Feeding
1) Ripe fruit	Color, shape, odor	22	100	100	100	100
2) Unripe fruit	Color, shape	20	85	70	15	5
3) Ripe fruit in black stocking	Shape, odor	20	100	100	95	95
4) Smeared fruit pulp	Odor	12	100	100	100	100

Discussion

Fruit bats responded to both visual and chemical (olfactory) cues when foraging for figs. However, the strongest foraging reaction, resulting in a landing or feeding attempt, was almost exclusively associated with the presence of a ripe fruit odor, either in combination with visual cues, or when presented on its own. Thus, no visual cues were required for a fruit bat to locate the source of an odor. Fruit bats also used fruit odors to distinguish between ripe and unripe fruits. These results support the conclusions of previous studies (Acharya et al. 1998; Luft et al. 2003), that Old World fruit bats use mainly chemical, rather than visual, cues for the location and acquisition of food.

A total of 16 compounds were identified in the ripe fruit odor of *F. hispida*, and 13 in the ripe fruit odor of *F. scortechinii*—including alcohols, ketones, and esters. All 13 compounds that were identified in the ripe fruit odor of *F. scortechinii* were also present in the ripe fruit odor of *F. hispida*. This large overlap in fruit odor chemistry suggests that both species use the same compounds for bat attraction. However, none of the compounds identified in the fruit odors of either species is known to be associated with the attraction of bats (Bestmann et al. 1997; von Helversen et al. 2000; Knudsen and Tollsten 1995; Knudsen et al. 1993; Pettersson and Knudsen 2001; Pettersson et al. 2004). Indeed, many compounds that are commonly associated with Neotropical bat-pollinated flowers (e.g., sulfur-containing compounds) were completely absent (Bestmann et al. 1997; von Helversen et al. 2000).

Of the 16 compounds identified in the ripe fruit odors of figs, the methyl ketones and the secondary alcohols and their acetates are common fruit odor components within a wide

Table 3 Discrimination between ripe and unripe fruits (*Ficus hispida* and *Ficus scortechinii*) by four species of fruit bat (*Balionycteris maculata*, *Chironax melanocephalus*, *Cynopterus brachyotis*, and *Cynopterus horsfieldi*) in relation to fruit odor

Treatment	*N*[a]	Food Choice	Frequency of Feeding Attempts (%)
1) Unripe fruit vs. ripe fruit	20	Unripe fruit	0
		Ripe fruit	100
2) Unripe fruit vs. unripe fruit smeared with ripe fruit odor (from fruit pulp)	15	Unripe fruit	0
		Unripe fruit-smeared with ripe fruit odor (from fruit pulp)	93

range of plant taxa (e.g., Laska 1990b; Jordan et al. 2001). In contrast, butyrates and hexanoates are much rarer. Interestingly, (*E*)-2-penten-3-yl esters, which were present in both species, have not, to the best of our knowledge, been reported from nature before. This suggests that a single, unique, bat-attracting compound could be present within the two fig species analyzed in this study. Alternatively, a combination of other compounds, particularly those that increase in production when fruits ripen (e.g., 2-heptanol and its acetate), could also function as attractants or markers, allowing the bats to differentiate between different fig species.

Both natural and synthetic fruit odors of *F. hispida* resulted in feeding attempts by fruit bats during bioassays. However, reaction rates to natural fruit odors were significantly higher than those displayed toward synthetic blends. Thus, the fruit bats could either detect subtle differences in chirality between the two treatments, or some additional compounds that are attractive to bats were missing from the synthetic blend. In the case of the former hypothesis, the use of racemic mixtures of 12 chiral compounds could at least partially explain the lower reaction rates of bats toward the synthetic blend used. Given the chiral nature of the receiving proteins, it seems likely that bats, and many other mammals, can distinguish between enantiomers of many different compounds (e.g., compounds 2, 3, 5, 7, 8, 9, 10, 12, 16, 17, 18, and 20, Table 1). Hence, the enantiomeric composition that occurs in nature could be of great importance to bat foraging behavior. However, the effect of enantiomeric composition on the foraging behavior of Old World fruit bats is currently unknown.

Spatial information on the precise location of fruits could also depend to some extent on the presence of low volatility compounds, such as sesquiterpenes (e.g., α-bergamotene), which were omitted from the synthetic blend used here. Compared to relatively high-volatility compounds, such as ketones and alcohols, sesquiterpenes are likely to produce a more localized plume of scent, which could allow bats to discriminate between ripe and unripe fruits situated in close proximity.

Further studies on the composition of fruit odors and the foraging behavior of fruit bats are needed to identify the key attractive compounds, and also to assess the occurrence of these compounds, more generally, within the genus *Ficus*. However, the results of this study have demonstrated the key importance of fruit odors for the mediation of interactions between bats and figs in the Paleotropics, and have also revealed many compounds of interest for future studies.

Acknowledgments We thank the Department of Wildlife and National Parks, Malaysia and the Economic Planning Unit of the Prime Minister's Department, for granting us permission to work in Malaysia. We also gratefully acknowledge Mr. Ahmad Bin Dagu, for assistance in the field, and two anonymous referees for comments on the manuscript. This project was funded by a grant from the Lubee Bat Conservancy to THK and RH and by funds from the German Science foundation (DFG) to EKVK and MA (KA 124 8-1).

Introduction

Many herbivores are exposed to a diverse array of plant secondary compounds (PSC) naturally present in their diet. Many of these are recognized for their toxicity and generate physiological damage when consumed. The detoxification limitations hypothesis (Freeland and Janzen 1974) proposed that xenobiotic metabolism is the principal physiological mechanism responsible for neutralizing the harmful effects of PSC. This hypothesis suggested also that the paucity of mammalian dietary specialists is the result of constraints on the evolution of a xenobiotic metabolizing system capable of eliminating the large concentrations of similar toxins present in a specialist diet (Freeland and Janzen 1974; Marsh et al. 2006).

Previous studies on biotransformation mechanisms suggest that specialists differ intrinsically from generalists in enzymatic metabolism of PSC. Specialist herbivores appear to rely more on enzymes that add a functional group (Phase 1) and less on those that add an endogenous conjugate (Phase II) compared to generalist herbivores (McLean et al. 1993, 2001; McLean and Foley 1997; Boyle et al. 2001). In these studies, several species of marsupials that specialize on *Eucalyptus* had higher Phase I activity and lower Phase II, when exposed to *Eucalyptus* PSC compared to generalists (McLean and Foley 1997; Boyle et al. 1999, 2001). Additionally, *Eucalyptus* specialists expressed different levels of specific classes of Phase I enzymes (i.e., cytochrome P450s) than generalists exposed to the same compounds (Bolton and Ahokas 1997; Stupans et al. 1999).

We evaluated the prediction that a eutharian specialist woodrat (*Neotoma macrotis*) had higher levels of Phase I and lower levels of Phase II enzyme activities than a sympatric generalist woodrat (*N. lepida*). Both woodrats include oak (*Quercus* spp.) leaves in their diet. *Neotoma macrotis* is an oak specialist with up to 85% of its diet being *Quercus agrifolia* (Atsatt and Ingram 1983; Matocq 2002). In lab studies, populations of *N. macrotis* selected *Q. agrifolia* leaves over foliage from other dominant species (Atsatt and Ingram 1983). *Neotoma lepida* includes oak as a portion of their diet but is considered a generalist. In areas where *N. lepida* is sympatric with *N. macrotis*, the diet is primarily *Opuntia occidentalis*, cactus, and *Salvia apiana* (Cameron 1971; Atsatt and Ingram 1983). Oak is high in phenolics that are considered toxic to most other mammals (Atsatt and Ingram 1983; Lindroth and Batzli 1984; Thomas et al. 1988; Iason and Murray 1996). The differential consumption of oak by the specialist and generalist is predicted to be a result of xenobiotic metabolizing capabilities (Atsatt and Ingram 1983).

We took a comparative pharmacological approach to determine the xenobiotic metabolizing mechanisms used by the specialist and generalist when consuming oak foliage. We investigated the biotransformation activities of five major enzymes and three specific isozymes that include members from the two classes of xenobiotic metabolizing enzymes: Phase I and Phase II. The Phase I enzymes assayed were oxidation (cytochrome P450s; CYP) and reduction (NAD(P)H: quinone oxidoreductase; QOR). In addition to overall CYP concentration, catalyzed oxidations characteristic of three isozymes (CYP1A, CYP2B, and CYP3A) were included either for their role in biotransformation of PSC in a variety of animal systems and/or because they are common enzymes in pharmacological studies (Gregus et al. 1983; Hiroi et al. 1995; Parkinson 1996; Pass et al. 1999, 2001; Danielson 2002; Liukkonen-Anttila et al. 2003; Sivapathasundaram et al. 2003a). The Phase II enzymes assayed were UDP-glucuronosyltransferase (UGT), glutathione S-transferase (GST), and sulfotransferase (SULT), each chosen for their common role in the biotransformation of a variety of compounds (Gregus et al. 1983; Sivapathasundaram et al. 2003b). UGT and GST represent the major Phase II enzymes in mammals (Dutton 1980; Daniel 1993). SULT is an important alternative to glucuronidation for phenolics (Parkinson 1996).

Materials and Methods

Study System *Neotoma macrotis* and *N. lepida* were trapped at Caspers Wilderness Park in Orange County, CA, USA. The animals were transported to the University of Utah Animal Facility, housed in individual cages (48×27×20 cm) with bedding and cotton batting and put on a 12–12 hr L/D cycle for at least 3 months before experiments to allow for Sin Nombre hantavirus screening. All the animals were maintained on standard rabbit chow (Harland Teklad formula 2031) and water ad libitum before experimentation. All procedures were approved by the University of Utah IACUC.

Dietary Treatments The animals were fed one of two diets (control or 70% oak). Control diet consisted of the same rabbit chow used for the maintenance diet with the exception that it was in powdered form. *Quercus agrifolia* used in diet treatments was stripped from several trees (>10) at sites where animals were trapped in California and stored at −20°C until use. Foliage was homogenized by grinding in a Waring blender (model CB-5) with dry ice until it passed through a 1-mm screen. Homogenization of the oak was necessary to control for oak diet intake but may have caused some chemical oxidation of the PSC present in the foliage. Oak diets were prepared by adding ground oak to ground rabbit chow on a percent dry weight basis of each component. The diets that contained oak were prepared daily to minimize the potential for chemical degradation. Total food intake (g dry matter) was measured each day. For the control treatment, the specialist, *N. macrotis* (N=7), and generalist, *N. lepida* (N=7), were fed the control diet of rabbit chow for 5 days to determine constitutive levels of xenobiotic metabolizing enzymes. Animals in another group of specialists (N=9) and generalists (N=7) that were given the 70% oak treatment diet were first acclimated to a 25% oak diet for 3 days, followed by 50% oak diet for 1 days, and then fed 70% oak diet for 3 days. Before treatment, all the animals were given a control diet that consisted of standard rabbit chow (Harland Teklad) for several weeks.

Microsomal Preparation and Enzyme Assays Enzyme activity assays were used to measure activity of hepatic enzymes among species and treatment groups. Enzyme activities were determined in subcellular fractions isolated from whole liver tissue. On the last day of each dietary treatment, the animals were killed with CO_2. The liver was immediately perfused in situ by injecting cold isotonic saline into the hepatic portal vein, and the gall bladder was removed. The liver was then removed and weighed. Microsomal and cytosolic fractions were prepared by differential ultracentrifugation as described by Franklin and Estabrook (1971) and stored at −80°C until assayed for activity. Protein concentrations were determined colorimetrically by the method of Lowry (1951) to standardize enzyme activity to protein concentration.

Cytosolic NAD(P)H/quinone oxidoreductase (QOR) activities were determined by the dicoumarol-inhibited rate of reduction of 2, 6-dichlorophenolindophenol (Aldrich Chemical Co., Milwaukee, WI, USA) by NADH at pH 7.4 detected with spectrophotometry (Benson et al. 1980). Overall CYP concentration was determined from microsomes by using the carbon monoxide difference spectrum on a spectrophotometer by the method of Omura and Sato (1964) that measures the reduced P450/CO complex characteristic of all CYP isozymes cumulatively. CYP1A activities were determined by the method of Klotz et al. (1984) that measures the rate of resorufin production during the metabolism (*O*-deethylation) of 7-ethoxyresorufin (EROD; Sigma Chemical Co., St. Louis, MO, USA). CYP2B activities were determined according to Lubet et al. (1985) by measuring the rate of

resorufin production during the metabolism (de-alkylation) of pentoxyresorufin (PROD; Sigma). CYP3A activities were determined by testosterone 6$\tilde{\beta}$ hydroxylation (Sigma) where the testosterone metabolite (6$\tilde{\beta}$ hydroxytestosterone) was separated by high-performance liquid chromatography and quantified from its absorbance at 236 nm (Guengerich et al. 1986).

Hepatic microsomal UGT activities were determined by spectrophotometry (Bock et al. 1983) in reactions containing detergent (0.05% Triton X-100; Sigma). We measured the UDPGA-dependent disappearance rate of *p*-nitrophenol (Sigma). Cytosolic GST activities were determined by spectrophotometry (Habig and Jakoby 1981) detecting change in absorbance at 340 nm upon conjugation of glutathione to 1-chloro-2,4-dinitrobenzene (CDNB, a general reference substrate; Aldrich Chemical Co., Milwaukee, WI, USA). SULT cytosolic activities were determined by detecting the PAPS-dependent disappearance rate of *p*-nitrophenol (Sigma) with spectrophotometry (Sekura et al. 1981).

The probe substrates used in the assays are considered isozyme specific. For example, isozyme CYP 1A catalyzes the metabolism of 7-ethoxyresorufin; SULT enzymes catalyze the metabolism of *p*-nitrophenol. Although these protocols were designed and validated in laboratory rats, they are often used in disparate species. Given that laboratory rats are in the same suborder (Myomorpha) as woodrats, the use of these assays is likely to provide a valid estimate of enzyme specific activities. The probe substrates, CDNB and *p*-nitrophenol, are relatively nonspecific substrates for GST and UGT isozymes, respectively. However, CDNB generally targets the alpha class of GST in liver assays and *p*-nitrophenol targets UGT1A's. The SULT substrate targets SULT1 that is used for phenol metabolism.

Statistical Analysis Body mass and the activities of each detoxification enzyme analyzed were compared by using a two-way analysis of variance (ANOVA) with species and diet as the independent variables. When significant ($P<0.05$), a post hoc Fisher's LSD for pair-wise comparisons was conducted. Because there were differences in body mass, an ANCOVA was used to compare dry matter intake and liver mass by using body mass as a covariate, and diet and species as the independent factors. Systat 10 (SPSS, Chicago, IL, USA) was used for analysis.

Results

Body Mass, Dry Matter Intake, and Liver Mass The body mass of the specialist was approximately 20% greater than the generalist (Table 1). As a result of the difference, food intake was analyzed with body mass as a covariate. Dry matter intake did not differ between

Table 1 Mean body mass, dry matter intake (DMI) and liver mass from the specialist, *N. macrotis* and the generalist, *N. lepida* fed control diets or diets containing 70% oak (*Quercus agrifolia*; data represented as means±1 SE)

Variable	*N. macrotis* (specialist)		*N. lepida* (generalist)	
	Control diet	Oak diet	Control diet	Oak diet
Body mass (g)	208±15.4^{a}	204±13.6^{a}	161±15.4^{b}	162±15.4^{b}
Dry matter intake (g)	10.5±1.5^{a}	24.7±1.3^{b}	11.5±1.5^{a}	22.5±1.5^{b}
Liver mass (g)	5.05±0.36^{a}	4.15±0.32^{b}	5.59±0.36^{a}	4.94±0.36^{b}

^{a,b} Denote means that are significantly different ($P<0.05$) as determined by Fisher's LSD

the specialist and generalist (Table 2). However, both species had twofold higher intake when consuming oak diet compared to control diet (Table 1). Liver mass was not different between the specialist and generalist, but liver mass was significantly smaller in animals on the oak treatment compared to control groups in both species irrespective of body size (Table 2).

Cytochrome P450 Concentration Overall, there were no significant cytochrome P450 concentration differences among the treatment groups (Fig. 1). However, there was a trend for the generalist, *N. lepida*, to have higher activity than the oak specialist (Table 3).

Quinone Oxidoreductase The specialist had higher QOR activity than the generalist, *N. lepida* (Fig. 1). Specifically, the levels of constitutive QOR activity were more than two times higher in the specialist compared to the generalist and did not change on oak diet (Table 3).

Cytochrome P450 Isozymes Activity levels for the specific isozymes CYP1A, CYP2B, and CYP3A varied among the groups (Fig. 2). CYP1A activities in the generalist were constitutively 30% higher than that of the specialist (Fig. 2). Neither the specialist nor generalist significantly increased CYP1A activity between control and oak diet (Table 3). CYP2B activities in the control treatment groups were similar (Fig. 2). However, there was a significant effect of diet on CYP2B activities (Table 3). Both the specialist and generalist increased activity by more than 20% on the oak treatment. Finally, CYP3A activity levels were not different between the specialist and generalist fed control or oak diets (Table 3).

UDP-Glucuronosyltransferases Levels of UGT activity were constitutively different between the specialist and generalist (Fig. 3). UGT activity in the specialist was nearly two times higher compared to the generalist. Levels of UGT did not change with diet treatment groups and remained higher in the oak specialist compared to the generalist (Table 3).

Sulfotransferase Levels of SULT activity were constitutively different between the specialist and generalist (Fig. 3). SULT activity in the generalist was more than two times higher than the specialist in both treatments (Table 3). There was no change in SULT activity by either the specialist or the generalist from control to oak diets.

Table 2 Summary of *F*-values, degrees of freedom (*df*) and *P* values for ANOVA analysis of body mass and ANCOVA analyses of food intake and liver mass among *N. macrotis* and *N. lepida* in two treatment groups: control diet and 70% oak diets

Glutathione Transferase Levels of constitutive GST activity were significantly higher in the specialist compared to the generalist (Table 3). There was a change in GST activity in the generalist when consuming the oak diet treatment (Fig. 3). The generalist significantly decreased GST activity by approximately 25% from the control diet compared to the oak diet treatment group (Table 3).

Discussion

Previous research suggests that mammalian xenobiotic metabolism is the primary physiological mechanism that permits specialist feeders to consume high levels of a limited class of plant secondary compounds (PSC). We predicted that the mammalian oak specialist would have higher activities of Phase I xenobiotic metabolizing enzymes and

lower activities of Phase II enzymes than the generalist. However, both the specialist and generalist had high levels of different Phase I enzyme activities. Furthermore, the specialist had higher overall levels of Phase II enzyme activities than the generalist in two of the three Phase II enzymes assayed. There were few differences in enzyme activity levels from control diet to an oak diet. There was only one enzyme induced by oak diet, CYP2B, and it by little more than 20% in both specialist and generalist. In addition, the generalist appeared to suppress GST activities by approximately 30% on an oak diet, although there was not a significant interaction effect. There were major differences in constitutive enzyme activity between the species. The specialist, *N. macrotis*, had higher activity of QOR, UGT, and GST. QOR and UGT activities were both twofold higher, and GST activities were 37% higher than the generalist when both were consuming control diet. When both species were consuming an oak diet, GST activities were twofold higher in the specialist than the generalist. The generalist, *N. lepida*, had higher constitutive activity levels of CYP1A and SULT. CYP1A activities were approximately 30% higher, and SULT activities nearly threefold higher than the specialist.

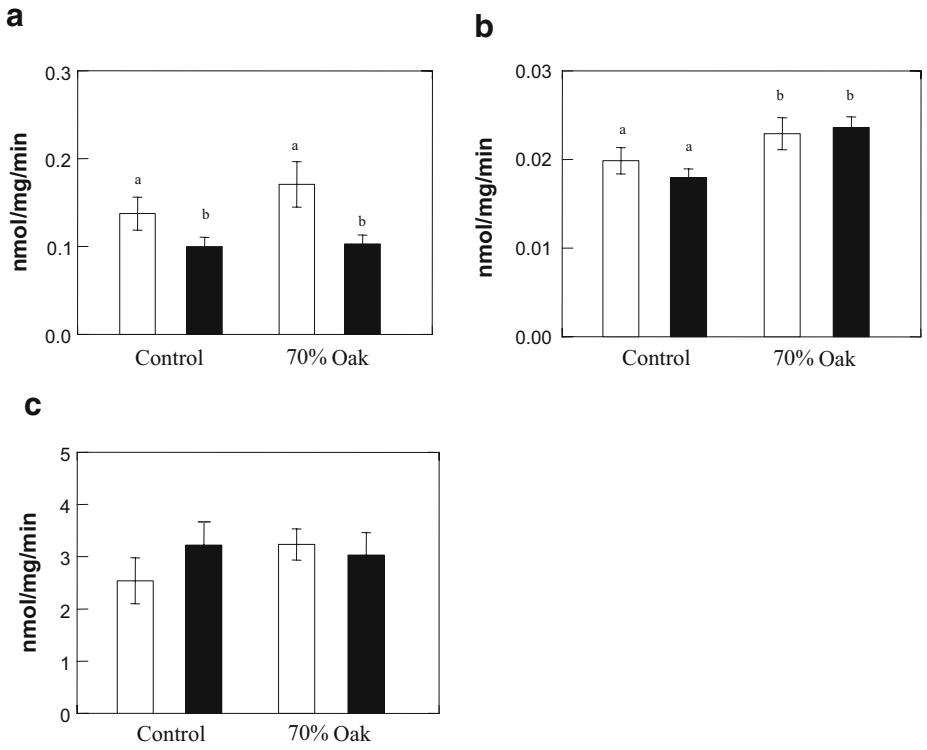

Fig. 2 Hepatic cytochrome P450 isozyme activities (mean±SE) in the specialist, *N. macrotis* (*filled bar*), and the generalist, *N. lepida* (*open bar*), fed control diets and diets containing 70% oak (*Quercus agrifolia)*: **a** Isozyme CYP1A; **b** Isozyme CYP2B; **c** Isozyme CYP3A. Data are represented as the mean+SE. Bars with different letters (*A* and *B*) denote means that are significantly different ($P<0.05$) as determined by Fisher's LSD

Oak expresses high levels of phenolic PSC (Atsatt and Ingram 1983). Phenolics, including tannins, are known to be deterrent or toxic to herbivores. Their toxic effects have been demonstrated in a number of plant–herbivore interactions, and protective mechanisms are required to allow for their consumption (Feeny 1970; Haukioja et al. 1985; Rhoades 1985; Rossiter et al. 1988). Tannins may act as digestability reducers and bind dietary protein during digestion, resulting in elevated levels of fecal nitrogen. Since both species have similar nitrogen retention efficiencies, the digestability reducing effect of tannins and the level of protection provided by proline-rich salivary proteins is also likely similar (Atsatt and Ingram 1983). Tannins are only a portion of the total polyphenols that have toxic potential in oak. Furthermore, their effect is not limited to digestability reduction because they can be degraded and absorbed into circulation resulting in toxicity. In either case, xenobiotic metabolizing enzymes may either enhance or reduce the harmful effects of oak phenolics (Foley and McArthur 1994).

The fate of most absorbed phenolics involves biotransformation by Phase I oxidation (most notably carried out by cytochrome P450s). CYP1A was 30% higher in the generalist compared to the oak specialist, but activity was not induced with oak diet. A number of plant compounds including caffeine, indole-3-carbinol, and warfarin are metabolized by CYP1A (Ayalogu et al. 1995; Vang et al. 1999; Kuo et al. 2006). CYP2B was induced by around 20% in both the specialist and the generalist. Elevation of this enzyme on an oak

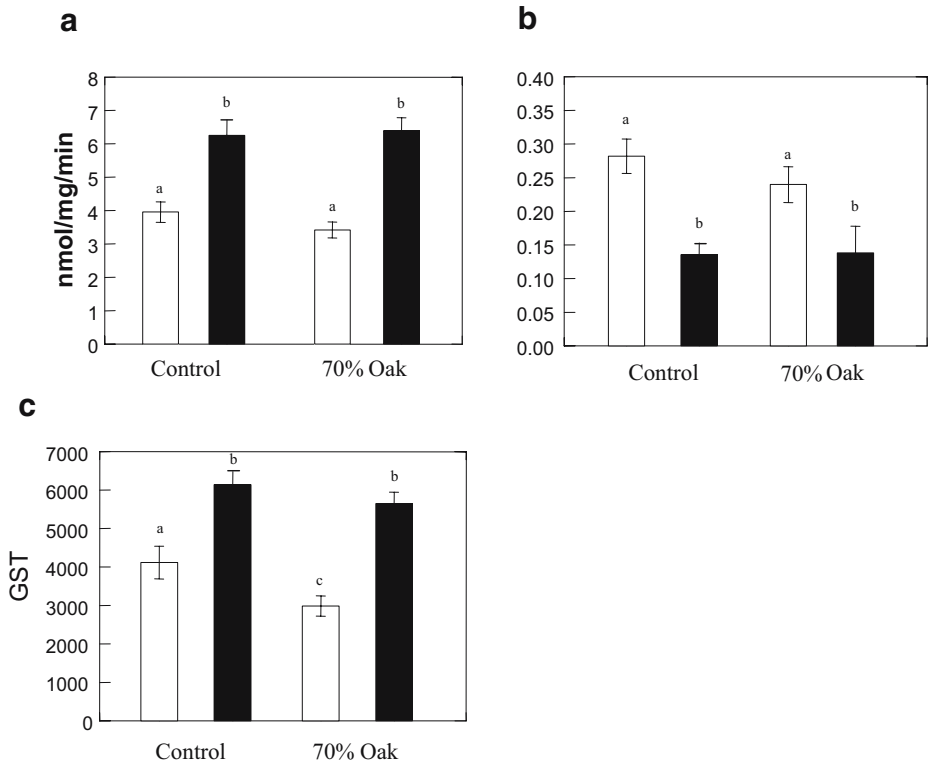

Fig. 3 Hepatic conjugation enzyme activities (mean±SE) in the specialist, *N. macrotis* (*filled bar*), and the generalist, *N. lepida* (*open bar*), fed control diets and diets containing 70% oak (*Quercus agrifolia*): **a** UDP-glucuronosyltransferase (UGT); **b** Sulfotransferase (SULT); **c** Glutathione transferase (GST). Data are represented as the mean+SE. Bars with different letters (*A*, *B* and *C*) denote means that are significantly different ($P<0.05$) as determined by Fisher's LSD

diet rich in polyphenolics is somewhat surprising because a number of plant phenolics (e.g., tannic, ellagic, and protocatechuic acids) are known to inhibit the activity of CYP2B (Szaefer et al. 2003).

The induction of CYP2B by both the specialist and generalist indicates that both have similar capacities to induce this enzyme when consuming an oak diet. In a field study, the specialist had a higher rate of CYP2B activity, as measured by in vivo hexobarbital clearance rates, than the generalist (Dearing et al. 2006). The enhanced ability of the specialist to metabolize hexobarbital under field conditions is not surprising due to the greater consumption of oak in the wild. Therefore, while the generalist consumes mostly *Opuntia occidentalis*, cactus, and *Salvia apiana* in its natural habitat, it would have lower levels of CYP2B activity. However, the activities observed here indicate that the generalist has the capacity, when consuming oak, to increase CYP2B activity to an extent similar to the oak specialist.

The differences in the pattern of conjugation enzymes used by the two species could explain their natural diet preferences. The oak specialist had higher constitutive activity levels of UGT, whereas the generalist had higher levels of SULT. Species variation in the rates of glucuronidation (UGT) and sulfation (SULT) can lead to differences in tolerance for phenolic compounds because there are differences in capacity for conjugation between these two Phase II enzymes (Parkinson 1996). SULT requires PAPS (3′-phosphoadenosine-

5′-phosphosulfate) as a sulfate donor to conjugate xenobiotics, and PAPS is in limited supply. Thus, SULT activity in vivo has a relatively low capacity. UGT's cofactor, UDP-glucuronic acid, is not as limited as PAPS, and UGT has a higher capacity as a result (Klaassen and Boles 1997). This difference may be more profound when oak is a constant diet component. The cost or toxic effect of chronic intake of a particular compound can be different from that produced by short-term exposure, particularly with regard to cofactor abundance. In a diet containing high levels of phenolics that are consumed chronically, the difference may alter a species' ability to specialize.

While the constitutive activity differences may explain oak tolerance, any inference regarding these differences should be viewed cautiously, as they were not altered by a change from control to oak diet. Many of the differences measured between the specialist and generalist were constitutive. These may be due to species phylogenetic distance and not necessarily short-term dietary behavior. The fact that few of the enzymes analyzed were affected by the change from control diet to oak diet constricts inference concerning which enzymes metabolize the PSC in oak. Many xenobiotic metabolizing enzymes are also important in the metabolism of endogenous compounds (e.g., hormones, bilirubin, and bile acids; Parkinson 1996). Therefore, while differences in xenobiotic enzymes likely influence oak consumption, assays to look specifically at oak phenolic metabolism as influenced by these specific enzymes will be necessary. The reduced size of the liver in both the specialist and generalist may indicate that mechanisms other than hepatic xenobiotic metabolizing enzymes are involved. For example, some intestinal proteins (multi-drug resistant proteins) prevent the absorption of compounds into circulation (Bodo et al. 2003).

Although a theory has emerged may postulate that specialists rely more heavily on Phase I than Phase II xenobiotic metabolizing enzymes in comparison to generalists, this research indicates that it is not a widespread pattern broadly applied to all specialist/generalist comparisons. Although this study included many of the major xenobiotic metabolizing enzymes used by mammals, and although we found differences between the specialist and generalist species, future work with inhibitors and cloning of specific genes may be necessary to tease apart the role these enzymes play.

Acknowledgement We thank committee members Dr. G. Yost, Dr. F. Goller, Dr. D. Feener for their invaluable input. We also thank Dr. J. Sorensen, Dr. M. Skopec and Ann-Marie Torregrossa for critical reading of the manuscript and the undergraduates in Dr. Dearing's lab, especially Katie Young and John Matthews, for assistance with feeding, tissue collection as well as collection and maintenance of woodrats. Research was supported by National Science Foundation (NSF IBN 023402).

Introduction

It is well-known that secondary metabolites (SMs) are synthesized uniquely in specific plant species. Various viewpoints have served as a basis for the investigation of their function in nature: attraction of pollinators (Pellmyr and Thien 1986), host plant selection of phytophagous insects (Hsiao 1985; Endo et al. 2004), and interference effects between plants (Harper 1977; Rice 1984). The antimicrobial activities of SM have also been investigated (Osbourn 1996), and the active compounds behind the activities of some have been identified and used as pesticides either in their natural or synthetic forms.

Many studies have also reported about the antiphytopathogenic fungal activities of essential oils in aromatic plants, including spices and herbs (Muller-Riebau et al. 1995; Letessier et al. 2001; Oxenham et al. 2005). While the antifungal effects of volatile compounds of plants, for example the 2-hexenal "wound volatile" compound, have been investigated extensively (Hamilton-Kemp et al. 1992; Archbold et al. 1997), antimicrobial investigation of aromatic plants has been limited, despite the high degree of activity shown by these plants against phytopathogens (Shimoni et al. 1993; Soylu et al. 2006).

The use of volatiles from plants as bio-fumigation materials to reduce soil-borne diseases also has been reported. Indian mustard and hairy vetch, which releases antifungal compounds, allyl isothiocyanate and cyanamide, respectively, are possible controls against *Fusarium* wilt of spinach (Takehara et al. 2004).

Many SMs are phytotoxic. Several methods are known for studying phytotoxic effects of volatile compounds (Reuveni et al. 1984; Hamilton-Kemp et al. 1992; Kong et al. 1999). Fujii et al. (2005) developed the "dish pack method" to study effects on seed germination by using six-well multidishes. The speed of diffusion and intensity of activity are estimated based on the relationship of the distance of the seeds from the test plants or chemicals and the growth inhibition of the seed. We applied the method to check the anti-phytopathogenic fungal activities of volatile compounds from 52 samples of spices and herbs against the soil-borne phytopathogen, *Fusarium oxysporum*. Our objective was to determine the component of the species with the strongest anti-fungal effect.

Materials and Methods

Screening of Spices and Herbs

Dried samples of 52 spices and herbs were tested (Table 1): 37 (gifts from YASUMA, Tokyo, Japan) and 15 others (cultivated in the fields of Miyagi Prefectural Agriculture and Horticulture Research Center, National Institute for Agro-Environment Science, or Ferdowsi University, Iran). Samples were dried in a hot air circulation oven at 60°C for 1–2 days and then ground finely with a Japanese traditional grinder "Yagen" just before the experiment.

The antifungal bioassay was conducted following the principles of the dish pack method (Fujii et al., 2005), using six-well multidishes (Nunc, external dimensions: 128×86 mm, 35 mm-diameter wells; Fig. 1). Ground sample (500 mg) was placed at the lower left, 0-mm-distance well (source well) of the multidish, while 2.5 ml of potato dextrose agar (PDA) with streptomycin (200 ppm) was poured into each of the other five wells and then allowed to harden. A 4-mm plug of a mycelial disk of *F. oxysporum*, cultured on PDA for 5 days at 25°C, was placed on top of the agar, with the side of mycelial growth facing down. *F. oxysporum* was obtained originally from the crown of a diseased strawberry, and the cultures were established and maintained on PDA. The multidish was covered, and the

[a] For spices and herbs without specified part(s) the edible parts were used.
[b] These spices and herbs were gifts from YASUMA, and the rest were cultivated at our research sites.
[c] Mycelial growth inhibitions shown are the average of the two 41-mm wells. Black zira, cumin, and cardamon had three replicates each, while other values were derived from a single experiment. Negative values indicate stimulated mycelial growth.

sides were sealed with adhesive tape to prevent compound losses because of volatilization. A 1-mm headspace between the multidish cover and the wells allowed volatiles from the samples to spread throughout the multidish. The degrees of vapor diffusion and antifungal activity were estimated by the relationship of the degree of fungal inhibition of the mycelial disk and its distance from the source well. The multidish was incubated in a dark growth chamber for 3 days at 25°C, and then the growth of the mycelial colony in each well was determined by measuring its increase in diameter from that of its original 4 mm diameter. A

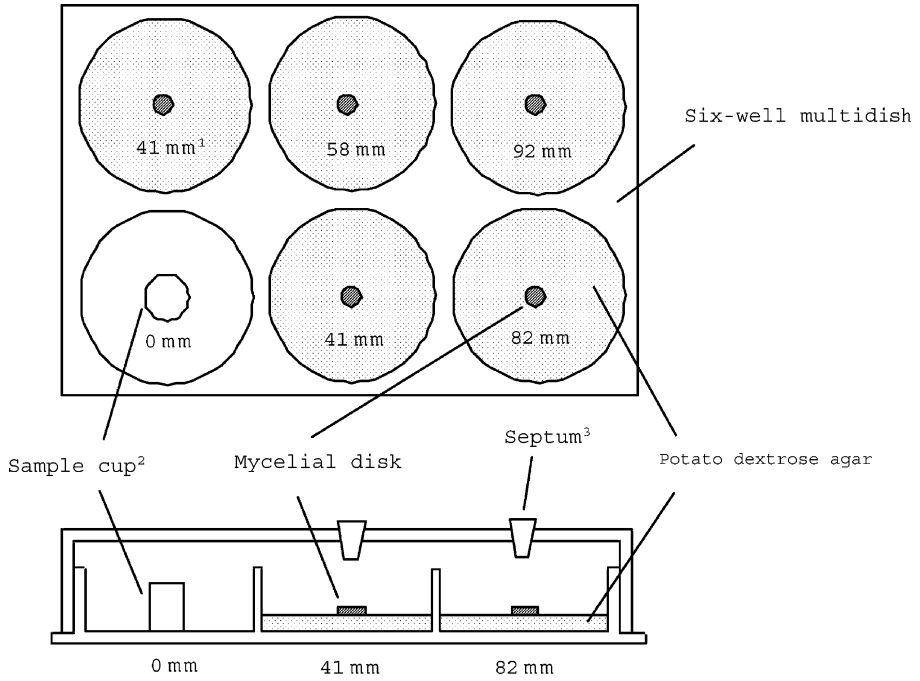

Fig. 1 Top and side views of the dish pack method used for testing the antifungal activities of volatile compounds. *1*, The distance from the sample or compound. *2*, Source well or cup (in the case of authentic compounds). *3*, Septa were attached for headspace vapor sampling done through the use of a Hamilton gas-tight syringe and analyzed by GC-MS analysis

control dish was set up in the same manner, except that the source well contained no sample. Finally, the mycelial growth inhibition was calculated as follows:

$$\textit{Mycelial growth inhibition}(\%) = \begin{pmatrix} \textit{growth of the control mycelial colony} \\ -\textit{growth of the treatment mycelial colony} \end{pmatrix} \Big/ (\textit{growth of the control mycelial}) \times 100$$

No replications were made during the first bioassay, but two additional replicates were done for black zira, cumin, and cardamom after initial results showed their high antimycelial activities.

Isolation of Antifungal Volatiles from Black Zira and Their Antifungal Activities

The presence of volatiles from black zira was analyzed with the headspace method. A finely ground sample of black zira (200 mg) was put into a glass vial equipped with an aluminum crimp seal cap with a polytetrafluoroethylene/silicone septum and was kept for 30 min under laboratory conditions. A headspace vapor sample (1 ml) was withdrawn from the bottle through the septum with a Hamilton gas-tight syringe and then immediately injected into the gas chromatography–mass spectrometry (GC-MS). Spectra were recorded with a QP-5050A instrument (SHIMAZU, Kyoto, Japan) using an EQUITY-5 column (Supelco, 30 m×0.25 mm, inside diameter 0.25 μm). Each compound was identified by comparing its mass spectrum in the National Institute of Standards and Technology library and with the retention time of an authentic sample on the GC. The quantity of each compound was determined by comparing the peak area of the compound with that of its authentic sample. The operating conditions of GC-MS were as follows: inlet, 200°C; column oven, 40°C for 30 s, then programmed to rise at 8°C/min to 160°C, which was maintained for 5 min. Splitless injection into the GC-MS with 1.0 ml of vapor phase sample or 2.0 μl of the liquid sample was applied. The concentrations of volatile compounds from black zira were calculated from their peaks. These headspace samplings and analyses were not replicated.

The corresponding authentic samples of the seven detected compounds were also tested for their activities against *F. oxysporum* by applying the same procedure used in testing the dried samples, except that a cup containing 50 μl of the authentic compound was placed into the source well instead of the dried samples (Fig. 1). Based on previous tests (Fujii, unpublished report), this amount was found as the most appropriate level for tested compounds to show signs of activity. Authentic samples of α-pinene, β-pinene, limonene, cuminaldehyde, and γ-terpinene were purchased from Wako Pure Chemicals, *p*-cymene from Sigma Chemical, and myrcene from Tokyo Chemical Industry. Four replications were made for the bioassay. To measure the vapor concentration of the authentic compound in each well, another five multidishes were set out in the same manner as above, but without mycelial disks. The five multidishes represented each of the five well distances, 0, 41, 58, 82, and 92 mm, and the collection of vapor from the assigned dish for each well was done just once to prevent unusual diffusion of vapor during the withdrawal process. The vapor was collected 24 h after the test compound was placed into the multidish by using a Hamilton gas-tight syringe (1.0 ml) through a septum located on top of each well. Headspace sampling and analysis of each well were not replicated. The same procedures, as described previously, were followed for the GC-MS analysis and the calculation of mycelial growth inhibitions of the authentic compounds. Cuminaldehyde and *p*-cymene showed the highest antifungal activities and were further

investigated against another soil-borne phytopathogenic fungus, *Varticillium dahliae*, and foliar phytopathogenic fungi, *Botrytis cinerea* and *Alternaria mali*, which were obtained from diseased chrysanthemum, strawberry fruit, and apple leaf, respectively. The fungi were precultured on PDA as for *F. oxysporum*, except that their preculture periods were different: 10 days for *V. dahliae*, 3 days for *B. cinerea*, and 5 days for *A. mali*. The testing periods were 2 days for *B. cinerea* and 3 days for *V. dahliae* and *A. mali*.

The biological activities of cuminaldehyde and *p*-cymene were also evaluated based on their specific activity, expressed as (EC_{50}), which is the effective concentration of the compound to induce half-maximum inhibition. In our study, the EC_{50} values of *p*-cymene and cuminaldehyde against *F.oxysporum* were calculated with probit analysis (Finney 1971), and then the total activities were calculated as follows: Total activity = $(1/EC_{50}) \times$ concentration in Black zira (μg/g plant).

Results

Mycelial growth inhibitions of 52 spices and herbs against *F. oxysporum*, based on the average result of the two 41-mm wells, are shown in Table 1. Forty-two samples showed varying degrees of mycelial growth inhibition, with black zira the strongest, followed by cumin and cardamom. Mycelial growth inhibition of these three samples at each well was evaluated (Fig. 2). Black zira showed a significantly strong mycelial growth inhibition over cumin and cardamom at the 41-mm wells. Thus, further investigation to determine the main component(s) responsible for the antifungal activity was done.

Seven volatile compounds, γ-terpinene, limonene, *p*-cymene, β-pinene, α-pinene, cuminaldehyde, and myrcene, were detected from black zira from headspace sampling and GC-MS analysis (Table 2). All these are terpenes, except for cuminaldehyde. To confirm which compounds were antifungal, authentic samples of the seven identified compounds were investigated for mycelial growth inhibition against *F. oxysporum.* Cuminaldehyde showed the highest inhibition at 92% in the 41-mm wells (Table 3), declining sharply to 18% in the farthest well (92 mm). *p*-Cymene followed at 56% (41-mm wells) with a gradual decline that reached 48% in the farthest well.

Vapor phase concentrations of the six terpenes in the 41-mm wells were each more than 100 ppm, while that of cuminaldehyde was 0.147 ppm, indicating the higher inhibitory

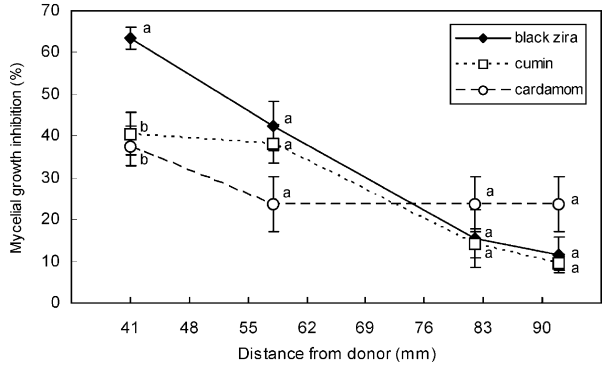

Fig. 2 Relationship between well distances from samples (black zira, cumin, and cardamom) and mycelial growth inhibition of *Fusarium oxysporum*. Each value represents the mean of three replicates. *Bars* represent standard error of the mean. The same letters at each distance indicate that the values are not significantly different ($P<0.05$) according to Tukey's test

Table 2 Volatile compounds from black zira by headspace sampling and GC-MS analysis

Compound	Concentration (μg/g plant)[a]
γ-Terpinene	14.4
Limonene	4.42
p-Cymene	4.31
β-Pinene	2.94
α-Pinene	2.37
Cuminaldehyde	2.23
Myrcene	1.01

[a] Amount of volatile compound evolved from finely ground black zira during 30 min of incubation.

strength of cuminaldehyde. The strong antifungal activities of cuminaldehyde and *p*-cymene were further confirmed by testing them against three other phytopathogenic fungi, *B. cinerea*, *V. dahliae*, and *A. mali*.

The inhibition effect of *p*-cymene and cuminaldehyde vapor phase concentration on the mycelial growth of four phytopathogenic fungi was determined (Fig. 3). Cuminaldehyde had significantly stronger mycelial growth inhibition (more than 85%) than *p*-cymene against *F. oxysporum*, *V. dahliae*, and *A. mali* in the 41-mm wells, but this decreased at the 92-mm well. Mycelial growth inhibition of *p*-cymene against all four fungi was more than 40% in each well.

The activities of cuminaldehyde and *p*-cymene against *F. oxysporum* were evaluated based on their $EC_{50,}$ and total activity. The EC_{50} against *F. oxysporum* was 99.7 ppm for *p*-cymene and 0.0312 ppm for cuminaldehyde, respectively. Total activity was 0.0432 for *p*-cymene and 71.5 for cuminaldehyde, which is 1,700 times larger than that of *p*-cymene.

Discussion

The dish pack method, which was originally designed to evaluate the effects of volatile compounds on seed germination, was applied in this study to evaluate antifungal activity.

Table 3 Mycelial growth inhibition against *Fusarium oxysporum* and vapor phase concentrations of authentic compounds detected from black zira

Compound	Vapor phase		Mycelial growth inhibition (%)[b]		
	concentration (ppm v/v)[a]	41 mm[c]	58 mm	82 mm	92 mm
γ-Terpinene	101	18.3±1.5a	9.8±1.6a	7.5±1.4a	2.5±0.8a
p-Cymene	122	56.2±4.8b	51.3±3.8bc	48.0±4.5b	48.0±4.5b
Limonene	183	38.7±5.1c	35.8±4.2bd	26.1±8.0ac	31.8±6.5bc
β-Pinene	896	41.8±3.1bc	37.9±2.6bd	37.3±2.4bc	33.8±2.8bc

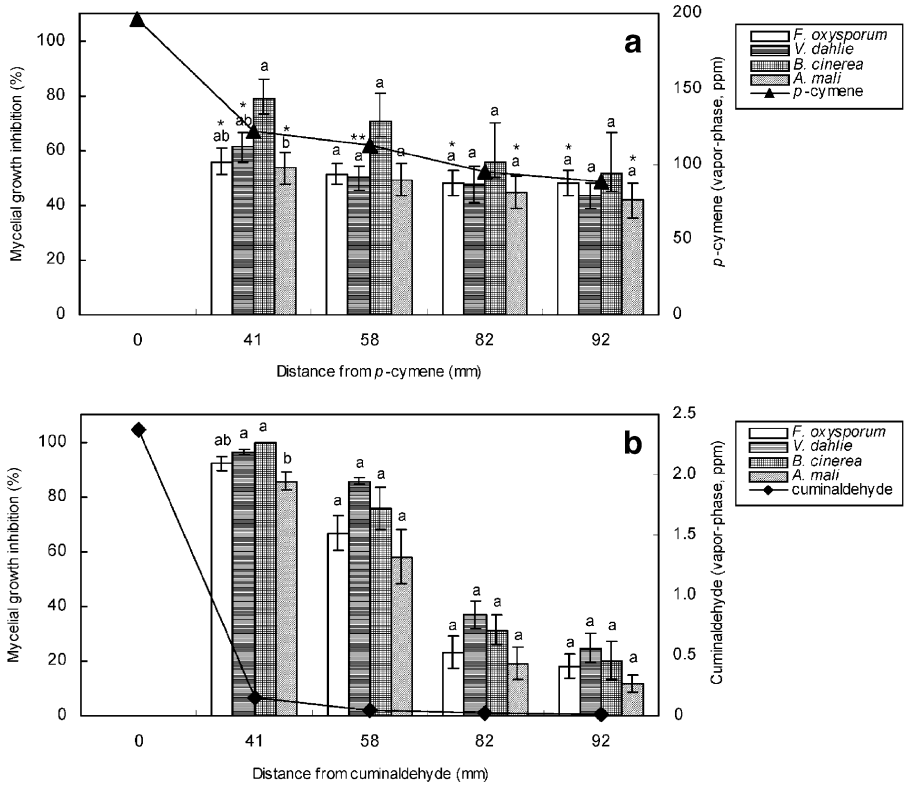

Fig. 3 Effect of *p*-cymene (**a**) and cuminaldehyde (**b**) vapor phase concentrations on the mycelial growth inhibition of four phytopathogenic fungi. Each value represents the mean of four replicates. *Bars* represent standard error of the mean. For each compound, the same letters at each distance indicate that the values are not significantly different ($P<0.05$) according to Tukey's test. *Asterisks* in **a** indicate significant differences between *p*-cymene and cuminaldehyde on the same fungus and in the same well according to Mann–Whitney's *U* test (*asterisk*, $0.01 \leq P < 0.05$, *double asterisk*, $P<0.01$)

The speed of diffusion and intensity of activity of the volatile compounds were estimated based on the relationship of the growth inhibition of the mycelial disk and its distance from the source well. Although black zira showed significant strong mycelial growth inhibition at the 41-mm wells over the two other samples, its inhibition activity sharply decreased as the wells were further distant from the source well. This indicated the low volatility of the volatile(s) in black zira. Beyond the 41-mm-distance wells, the differences in inhibition among the three samples were not significant.

Black zira, which had the strongest activity in the 41-mm wells against *F. oxysporum*, contained seven volatile compounds, γ-terpinene, limonene, *p*-cymene, β-pinene, α-pinene, cuminaldehyde, and myrcene. Baser et al. (1997) analyzed the essential oils of a black zira originating from Tajikistan, and they detected 22 compounds, including *p*-mentha-1,4-dien-7-al, γ-terpinene, β-pinene, and cuminaldehyde, although *p*-mentha-1,4-dien-7-al was not detected in our analysis. This may indicate that our black zira (of Iranian origin) does not contain *p*-mentha-1,4-dien-7-al or that the volatile quantity of this compound was too low to be detected by our analysis procedures.

The mycelial growth inhibition rate of authentic cuminaldehyde declined sharply in the wells farther away from the source well, a characteristic similar to that exhibited by black

zira. On the other hand, the effect of authentic *p*-cymene declined gradually, suggesting that *p*-cymene spread through the multidish faster than cuminaldehyde, resulting in a smaller concentration gradient across the wells.

Evaluation of allelochemicals based on their specific activities (biological activity per unit weight of the compound) expressed as $EC_{50,}$ which is the effective concentration of the compound to induce half-maximum action, is important for the purposes of developing pesticides. If a compound exhibits a small EC_{50} value, it means it has a high specific activity. On the other hand, evaluation by total activity (biological activity per unit weight of the sample containing the bioactive compound) is important for biological uses (Fujii and Hiradate 2005; Hiradate, 2006). By using the concept of total activity, for example, Hiradate et al. (2004) isolated novel plant-growth inhibitory compounds from *Spiraea thunbergii*. In our study, the comparison of the EC_{50} values of both compounds indicated that cuminaldehyde showed higher specific activity, i.e., higher antifungal activity at lower concentration, than *p*-cymene. Furthermore, evaluation by total activity indicated that the activity of cuminaldehyde contained in black zira was more than 1,700 times stronger than *p*-cymene. Therefore, this suggests that the main antifungal compound of black zira is cuminaldehyde.

The strong mycelial growth inhibition by cuminaldehyde against the four phytopathogenic fungi is a good indication of its potential use in disease control. Soylu et al. (2006) also reported that volatiles of essential oils obtained from oregano and thyme inhibited fungal growth of *Phytophthora infestans*, the phytopathogen of tomato late blight disease. The possibility of controlling diseases by using natural volatile compounds from plants is not limited to aromatic species (Wilson et al. 1987; Hamilton-Kemp et al. 1992; Archbold et al. 1997). If the use of natural volatiles with antifungal activities as pest control materials could be established through further screening and research, it could lead to a large reduction in the use of chemical pesticides and labor.

With its high total activity, cuminaldehyde may have a strong influence on the microflora in the neighborhood of black zira in nature. So far, only a few reports regarding plant–microbe interactions through SMs at the community level are available. Karamanoli et al. (2000, 2005) reported the influence of SMs on bacterial colonization on the phyllosphere. Vokou and Liotiri (1999) reported interactions between soil microbes and essential oils. The amount of volatiles from plants generally ranges approximately from 5 to 40 ppt but could reach 50–1,200 ppt in the case of areas surrounded with flowers or in plant communities (Shibuya, 1990). It is likely that under these conditions, volatile compounds influence the growth of nearby microorganisms.

In summary, the antifungal activities of volatile compounds from 52 species of spices and herbs were evaluated by applying the dish pack method. Black zira showed the strongest activity against all four phytopathogenic fungi tested and contained seven volatiles compounds, detected through headspace sampling and GC-MS analysis. Bioassays with authentic compounds showed cuminaldehyde as the main antifungal component of black zira. Natural antifungal volatiles like cuminaldehyde may be used in developing new alternative fungicides that are safe for humans, animals, and the environment. Additionally, our study has demonstrated the effectiveness of the dish pack method in evaluating the antifungal activities of volatiles from spices and herbs, and it could be useful for future investigations of other plant volatiles.

Acknowledgments This work was supported by a Research Fellowship of the Ministry of Agriculture, Forestry, and Fisheries of Japan. We thank Ms. Pariasca for her critical reading of the manuscript.

Introduction

The heartwood of trees has long been known to produce and accumulate biologically active compounds from a variety of chemical classes (Rennerfelt and Nacht 1955; Rudman 1962, 1963; Scheffer and Cowling 1966) that protect them from microbial decay. Alaska yellow-cedar (*Callitropsis nootkatensis*; previously *Chamaecyparis nootkatensis*; Little et al. 2004; Little 2007) heartwood is an excellent example. Even after these trees die, defensive heartwood chemicals continue to protect standing snags for up to a century in the coastal forests of southeast Alaska and western Canada (Hennon et al. 1990, 2005, 2007a). Changes in snag heartwood chemistry are minimal until after the protective bark sloughs off, and the sapwood is lost from decay and weathering, about 26 years after death (Kelsey et al. 2005). Direct exposure of the snag heartwood to abiotic environmental conditions results in a continuous decline in the concentration of protective chemicals (Kelsey et al. 2005) and eventually a reduction in decay resistance, about 80 years after death (Degroot et al. 2000; Hennon et al. 2007b).

The presence of these strong antimicrobial compounds in yellow-cedar heartwood and its greater resistance than Port-Orford-cedar (*Chamaecyparis lawsoniana*) to the root disease, *Phytophthora lateralis* (McWilliams 2000), were the basis for our previous testing of its heartwood and select components against *P. ramorum* (Manter et al. 2006). *P. ramorum* is an exotic pathogen (Ivors et al. 2006) that causes the stem canker disease known as sudden oak death, which has killed thousands of tanoak (*Lithocarpus densiflorus*), coast live oak (*Quercus agrifolia*), California black oak (*Q. kelloggii*), and Shreve's oak (*Quercus parvula* var. *shrevei*) in coastal counties of California and one county in southwest Oregon since 1995 (Rizzo et al. 2002a, b; Garbelotto and Rizzo 2005; Goheen et al. 2006a). In Europe and the UK, this pathogen is primarily in nurseries or seminatural managed gardens (Werres and De Merlier 2003). It can also cause nonlethal shoot blight or leaf blight in various hosts (Goheen et al. 2006a). The list of proven and suspected hosts has grown to over 50 genera of predominately trees and shrubs (updated list at http://www.aphis.usda.gov/ppq/pramorum). The potential ecological and economic impacts from *P. ramorum* could be extensive depending on its level of direct or indirect influence on nurseries or the composition, structure, diversity, and function of native forests (Rizzo et al. 2005; Goheen et al. 2006a). Management of this pathogen focuses on slowing its spread by preventing introductions and establishment into new areas (Garbelotto and Rizzo 2005; Rizzo et al. 2005). As spores are the key dispersal mechanism (Davidson et al. 2005), control measures that target spore survival may contribute to successful management actions.

Previously, we demonstrated that wood chips, essential oil, and four individual compounds (nootkatin, carvacrol, nootkatone, and valencene) in yellow-cedar heartwood were fungitoxic to *P. ramorum* zoospores and sporangia and fungistatic against hyphae in culture assays (Manter et al. 2006). Microscopic observations detected rupturing of the zoospore outer membrane, and disruption, or release of the cellular contents from developing sporangia before zoospore formation. In addition, heartwood essential oils from incense cedar (*Calocedrus decurrens*), western redcedar (*Thuja plicata*), Port-Orford-cedar (*Chamaecyparis lawsoniana*), and western juniper (*Juniperus occidentalis*) were tested. All four essential oils killed zoospores and inhibited hyphal growth just as strongly as the oil from yellow-cedar, but their heartwood constituents were not further investigated until now. The main objectives of this study were to test the procedure described by Kuhajek et al. (2003) as a potential bioassay technique for antimicrobial activity against *P. ramorum* and to test the antimicrobial activity of individual compounds (most of them commercially available) present in the heartwood of the other conifer

species with antimicrobial activity against *P. ramorum*. In addition, we conducted a field experiment to determine if heartwood chips can limit the proliferation of *P. ramorum in situ*.

Methods and Materials

Heartwood Extracts Tested An initial study was conducted to identify heartwood extracts with antimicrobial activity against *P. ramorum*. We obtained bulk samples of heartwood from single trees of seven conifer species at the locations listed in Table 1. After air drying, each sample was mechanically chipped and then ground in a Wiley mill to pass a screen with 4 or 6 mm openings and finally through a 20 mesh screen. Extracts were prepared in triplicate by weighing 1.0 g of ground heartwood into a glass vial followed by 10.0 ml of ethyl acetate (99.9%, Fisher Scientific). Sealed extracts were kept at room temperature for 24 h with periodic swirling and then filtered through paper (Whatman No. 1 qualitative) into a storage vial.

Compound Identification and Quantification in Heartwood Extracts Volatile constituents in the extracts from incense cedar, western redcedar, Port-Orford-cedar, and western juniper were identified by gas chromatography–mass spectrometry (GC–MS) using a Hewlett Packard 5890 Series II gas chromatograph, with a 5970 mass selective detector and J&W Scientific DB-5 column (30 m×0.25 mm×0.25 μm film thickness). Helium was the carrier gas, with a 1.0 ml min^{-1} flow through the column at 100°C and a 1:10 split. Injector and detector temperatures were 250°C. The oven program started a 100°C for 1.0 min, then increased at 5°C min^{-1} to 150°C, followed by an increase of 3°C min^{-1} to 220°C, with no final hold. Instrument conditions for the analysis of western redcedar extracts were modified to those used by Taylor (2004). The injector and detector were set at 275°C, with an initial column temperature of 100°C and no hold, then increased at 5°C min^{-1} to 130°C, followed by an increase of 30°C min^{-1} to 250°C with a 7.0 min hold. Helium flow through the column was 2.0 ml min^{-1} at 100°C with a 1:10 split. Extracts of western redcedar, western juniper, and Port-Orford-cedar were concentrated by gently evaporating 50–75% of the solvent with a steam of compressed air. Two microliters of these concentrates, or the original incense cedar extract, was injected. Compounds were tentatively identified by comparison of their spectra and relative retention times with those in the Wiley and Adams

Table 1 The antimicrobial activity of ethyl acetate extracts from the heartwood of seven western conifer trees toward *Phytophthora ramorum*

Species	Log_{10} EC_{50} (ppm)[a]	Tree\heartwood Source
Strong inhibitors		
Incense cedar	2.74 (0.08)a	Warm Springs, OR
Western red cedar	2.78 (0.06)a	Alsea, OR
Moderate inhibitors		
Yellow-cedar	3.18 (0.08)b	Prince of Wales Island, AK
Western juniper	3.27 (0.11)b	Warm Springs, OR
Port-Orford-cedar	3.29 (0.09)b	East of Orick, CA
Weak or no activity		
Douglas-fir	>4.00	Warm Springs, OR
Redwood	>4.00	Fortuna, CA

(2007) libraries and authentic samples of the compounds tested for antimicrobial activity (Table 2). Constituents in yellow-cedar heartwood extracts were recently identified by GC–MS (Kelsey et al. 2005) and were recognized by their relative retention times.

Compound concentrations in the extracts were determined on the same GC with an flame ionization detector (FID) detector and Phenomenex ZB-5 column (30 m×0.25 mm× 0.25 μm film thickness), which is equivalent to the DB-5. The instrument operating conditions were the same as above including the modified settings for western redcedar. Before injection, an internal standard solution containing known quantities of limonene or fenchone in ethyl acetate (Fisher Scientific 99.9%) was added to each extract (1:4, standard/extract measured with analytical syringes). Limonene was the standard for yellow-cedar and fenchone the standard for western juniper, Port-Orford, incense, and western redcedar. Two microliters of each extract/standard mixture was injected. Mean compound concentrations are reported from the three technical replicates of each heartwood extract, except western juniper that had just two replicates.

Individual Compounds Bioassayed Thirteen different volatile compounds were identified from the GC–MS analysis of the conifer heartwood extracts and were selected for further testing. Selected compounds were limited to those that were soluble in ethyl acetate and commercially available or previously isolated in our laboratory (Table 2). Compound purity was determined by transferring 1–2 mg to 1.0 ml of ethyl acetate and analyzing 2μl by GC–FID as described above for compound quantitation. Preliminary studies showed that ethyl

Table 2 The antimicrobial activity, purity as tested, and source for individual compounds tested in *Phytophthora ramorum* bioassays and found in the heartwood extracts of one or more western conifer species

[b] Compound class: *T* tropolone; *M* monoterpene; *S* sesquiterpene

[c] For details of isolation and identification of yellow-cedar compounds, see Xioung (2000) and Khasawneh (2003). Nootkatol synthesized from sodium borohydride reduction of nootkatone

acetate exhibited no antimicrobial activity against *P. ramorum* at concentrations less than or equal to 1% (data not shown).

Bioassays Antimicrobial activity of heartwood extracts or individual compounds was measured with the photometric assay developed by Kuhajek et al. (2003) for bioassays with *Phytophthora* spp., but not tested with *P. ramorum*. Zoospores from one isolate of *P. ramorum* (A1 mating type, obtained from an infected rhododendron plant at a commercial nursery in Clackamas, Oregon) were obtained by flooding 2-week-old cultures grown on clarified V8 agar plates (66.7 ml of V8 juice and 2 g $CaCO_3$, filtered through cheesecloth, plus 15 g of agar [Bacto-agar, Difco Laboratories, Detroit, MI, USA] per liter of distilled water) with 10 ml H_2O and incubating at 4°C for 4 h. Zoospore solutions were quantified by direct counting with a hemocytometer (×40 magnification) and diluted to appropriate concentrations with dH_2O. One isolate was considered adequate as six *P. ramorum* isolates (A1 and A2 mating types) responded similarly in previous bioassays (Manter et al. 2006). Growth of *P. ramorum* was evaluated in a 96-well microtiter format by measuring optical density at 650 nm (OD_{650}) at 0, 16, 24, 48, and 72 h with a microplate reader (Vmax Kinetic Microplate Reader, Molecular Devices, Menlo Park, CA, USA). Between measurements, plates were covered and incubated at room temperature with gentle shaking at 80 rpm. All OD_{650} values were corrected for background absorbance at time zero. The effect of starting zoospore concentrations on growth curves was analyzed by adding 50µl of a zoospore solution (0, 10, 100, 1,000, 2,500, 5,000, 7,500, or 10,000 zoospores ml^{-1}) and 100µl of clarified V8 broth to each of six replicate wells. Antimicrobial activity of all test compounds was analyzed by adding 50µl of a zoospore solution (10^4 zoospores ml^{-1}) and 100µl of V8 broth amended with an individual test compound to each of six replicate wells. All heartwood extracts were tested at 0, 10, 50, 100, 500, 1,000, 5,000, and 10,000 ppm (*v*/*v*), and all individual compounds were tested at 0, 1, 5, 10, 50, 100, 500, and 1,000 ppm (*v*/*v*). Additional concentrations at 25 ppm were included for hinokitiol, nootkatin, nootkatol, carvacrol, and valencene-11,12-diol and at 250 ppm for α-terpineol and valencene-13-ol. Each experimental plate also included six replicate sterility control wells (100µl of V8 broth and 50µl dH_2O). Plates with growth in the sterility control wells were discarded from the analysis. Each compound and concentration combination was replicated ×3, and a Log_{10} EC_{50} was determined for each trial as described below.

Heartwood Field Trial To determine whether chips of redcedar heartwood can limit *P. ramorum* buildup in soil and litter under natural conditions, we conducted a field test on the Rush Creek Open Space Preserve, at Novato, California (38°7.22′N, 122°33.70′W), in the spring and early summer of 2006. A fresh bulk sample of redcedar heartwood was collected in January 2006 from the same tree sampled for the laboratory bioassays reported in Table 1. The wood was cut into pieces, air dried in the laboratory, and chipped (1–3 cm long, 0.5–3 cm wide, 0.1–0.5 cm thick). Redwood was selected as a control because it was inactive in the laboratory bioassays. Kiln-dried and planed redcedar boards were obtained from a commercial source in Eugene, Oregon in January 2006 and chipped in our laboratory. Water content was measured on six subsamples of each species by oven drying them for 16 h at 102°C and cooling to room temperature in a desiccator box before reweighing. The dry weight equivalent of 140 g of fresh chips was enclosed in a nylon mesh bag (approx. 20×20 cm, 2.5×3.5 mm hole) sealed on the edges with cloth tape and staples.

On March 1, 2006, ten *Umbellularia californica*, California bay laurel, trees with leaves symptomatic of *P. ramorum* infection (Goheen et al. 2006a) were selected to serve as

blocks on the northwest side of Pinheiro ridge in the Rush Creek Preserve. Two plots (1× 1 m) were located beneath each tree where the canopy had the most symptomatic leaves. Six bags of redcedar chips were randomly positioned on one plot (selected from a 5×5 grid of 20×20 cm subplots) and six bags of redwood on the other plot. The bags were placed on top of the litter and secured with long wire pins on each corner penetrating into the soil to minimize movement by passing animals. On two sample dates (2 months posttreatment: May 2, 2006; 4 months posttreatment: June 29, 2006), three randomly chosen subplots were sampled from each plot. Bags were lifted carefully, and the litter beneath the center of the bag was gathered. We wore plastic gloves that were changed after each sample to minimize cross contamination. The litter depth varied tremendously; in some instances, it was only one or two leaves deep, and on other sites, it was 1–2 cm or greater. Although leaves of *U. californica* were usually present, leaves from other tree species nearby or grass blades were also common and were included in the sample that was sealed in a glass scintillation vial. Bits and pieces of surface soil may have adhered to leaves in direct contact with the soil. A plug of soil beneath the litter was taken to a depth of 3.0 cm with a #8 cork borer (1.4-cm diameter) and sealed in a glass scintillation vial. The borer was cleaned between samples with a 70% isopropyl alcohol swab and dried with a fresh tissue to reduce cross contamination.

Analysis of Phytophthora ramorum Proliferation by Quantitative Polymerase Chain Reaction Soil and litter samples from the Rush Creek Preserve were shipped back to the laboratory on ice and stored at −20°C until DNA extraction. Total genomic DNA was extracted from each sample by using Ultraclean Soil or Plant DNA kits (MoBio, Carlsbad, CA) per the manufacturer's protocol. DNA from the litter samples was further purified by phenol/chloroform/isoamyl alcohol (25:24:1) extraction and ethanol precipitation. Amplification of *P. ramorum* DNA was performed by using the species-specific nested protocol developed by Hayden et al. (2006). The amount of *P. ramorum* DNA present in each sample was calculated from measured cycle threshold values (BioRad, iCycle, Hercules, CA, USA) and an external standard curve generated from serially diluted *P. ramorum* genomic DNA isolated from pure cultures. All reported values of *P. ramorum* DNA are per unit dry weight of soil or litter extracted. The three subsamples (bags) from each plot were averaged, and treatment differences were analyzed by analysis of variance (ANOVA) as described below.

Data Analysis Kuhajek et al. (2003) suggested that bioactivity can be determined from the ratio of treatment and control OD values at a particular time point. However, unless a linear relationship between OD and initial zoospore concentration exists at the chosen time point, this technique will lead to an inaccurate estimate of activity. In our study, we did not observe a linear relationship at any of the selected time points (data not shown); furthermore, activity estimates will vary depending upon the chosen time point, if the slope of the OD vs. initial zoospore concentration regression line changes. To minimize these problems, the following analysis procedures were used. For each concentration of extract or compound bioassayed, a sigmoidal curve was fitted to the corrected OD_{650} growth curves (e.g., Fig. 1a) to obtain an estimate of $time_{1/2}$ or time (h) it takes to reach the midpoint between minimum and maximum OD_{650} values. This calculated parameter ($time_{1/2}$) was linearly related to initial zoospore concentration (Fig. 1b) and has the advantage that it is independent of the specific time points included in the analysis. Antimicrobial activity of each compound was then determined by fitting a sigmoidal curve to the $time_{1/2}$ vs. Log_{10} concentration (ppm) of each test compound and calculating the Log_{10} EC_{50} from this curve.

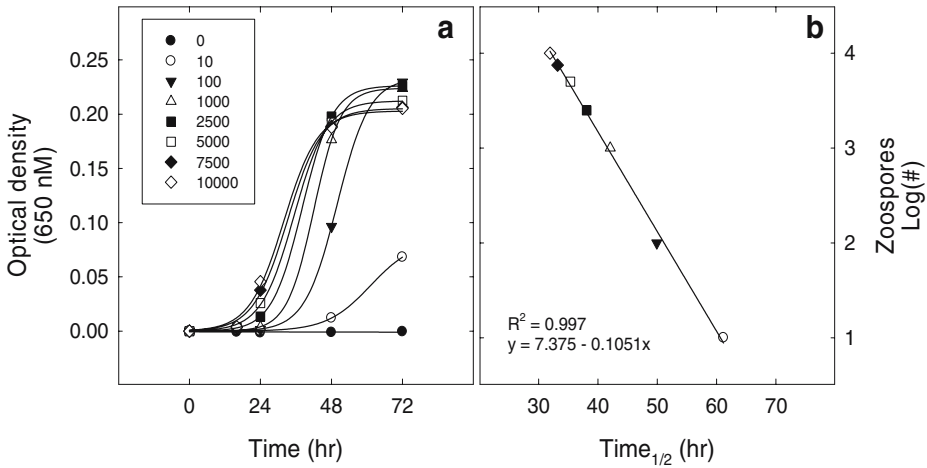

Fig. 1 Changes in optical density (OD_{650}) over time for microplate well cultures of *P. ramorum* initiated with different zoospore concentrations (number ml^{-1}; **a**) and the relationship between starting zoospore concentrations on a log_{10} scale and the well culture OD_{650} midpoints, or $time_{1/2}$ (**b**)

All regressions were performed by using SigmaPlot 9.0 (Systat Software Inc., Point Richmond, CA, USA). Significant differences between treatments (compounds) were tested by ANOVA and Fisher's least significant difference post hoc comparison ($P<0.5$) using SAS Vers 9.1 (Cary, NC).

P. ramorum DNA concentrations in the litter beneath the redcedar and redwood chips after 0, 2, or 4 months of treatment were analyzed as a randomized complete block design with ten replications by ANOVA using SAS Ver. 9.1. Data were natural log transformed to meet the assumption of homogeneous variance, and back-transformed least squares means and pooled standard errors are presented. Differences among means were determined by Fisher's protected least significant difference ($P<0.05$). The DNA concentrations in soil samples were analyzed separately using the same analysis procedure.

Results

Heartwood extracts from the trees sampled were grouped into three levels of antimicrobial activity: (1) strong—incense cedar and western redcedar; (2) moderate—yellow-cedar, western juniper, and Port-Orford-cedar, and (3) weak or no activity—Douglas-fir (*Pseudotsuga menziesii*) and redwood (*Sequoia sempervirens*) (Table 1). Individual compounds were separated into four activity categories: (1) strong (Log_{10} $EC_{50}<1.0$ ppm)—hinokitiol, thymoquinone, nootkatin; (2) moderate—(Log_{10} EC_{50} 1.0–2.0 ppm) nootkatol, carvacrol, valencene-11,12-diol; (3) weak (Log_{10} EC_{50} 2.0–3.0 ppm)—α-terpineol, valencene-13-ol, β-cedrene, and thujopsene; and (4) no activity (Log_{10} $EC_{50}>3.0$ ppm)—cedrol, δ-cadinene, methylcarvacrol (Table 2).

The volatile compounds identified in each extract are shown in Table 3 and were distinct for each tree (species), except for a few compounds. Carvacrol was detected in three trees—incense cedar, western redcedar, and yellow-cedar. α-Terpineol and δ-cadinene were both present in western redcedar and Port-Orford-cedar. Constituents in the Douglas-fir and

[a] Compounds (μg ml^{-1}) listed alphabetically within species, except those in multiple species. All compounds were identified by comparison of their spectra and retention times with those in the Wiley and Adams (2007) libraries. Those in *italicized font* were also compared with the authentic samples tested individually for antimicrobial activity (Table 2).

[b] Identities of *p*-methoxythymol and *p*-methoxycarvacrol were assigned based on molecular weights (Zavarin and Anderson 1955) and molecular ions in their mass spectra and relative retention times for thymol and carvacrol provided by Adams (2007).

[c] Number of unknown peaks in parentheses.

redwood extracts were not analyzed because they exhibited no antimicrobial activity. Two or more of the individual compounds tested for antimicrobial activity were present in the extracts that exhibited bioactivity (Table 3).

P. ramorum DNA was present at detectable levels in all soil and litter samples on both sample dates. For both heartwood chip treatments, *P. ramorum* DNA increased over time with the greatest increases in the litter layer. On May 1, 2 months after placing the chips on the forest floor, there was no difference between treatments in the amount of *P. ramorum* DNA in the litter (Fig. 2a). Between May 1 and June 29, *P. ramorum* DNA on the redwood control plots increased 11.1 times, compared with only 2.6 times on the redcedar plots, resulting in the redwood plots having 4.3 times more *P. ramorum* DNA than the redcedar (Fig. 2a). Soils from redwood and redcedar plots had the same quantities of DNA in May and June (Fig. 2b).

Discussion

The new protocol tested here and developed initially by Kuhajek et al. (2003) is easier to use, allows more samples to be quickly analyzed, and requires much smaller amounts of media and test materials than the bioassay procedure used previously for testing the activity of yellow-cedar compounds toward *P. ramorum* (Manter et al. 2006). Disadvantages include the inability to directly test heartwood activity because of interference with light transmittance. Furthermore, it does not distinguish inhibition or disruption of zoospore or sporangia germination from inhibition of hyphal growth. Our previous results suggest that the key mode of action for many of the toxic yellow-cedar compounds is lysis of zoospore and sporangia cell membranes (Manter et al. 2006). The antibacterial activity of essential oils and individual oil constituents, including carvacrol, has been attributed to their hydrophobicity, which allows them to enter the cell or mitochondrial membranes (reviewed by Burt 2004). This disruption increases membrane permeability and leakage of the cellular contents. Hinokitiol, a redcedar component, also causes cell lysis for some Gram-negative bacteria (Trust and Coombs 1973) and can rupture cercariae of *Schistosoma mansoni* (Chisty et al. 2004). However, regardless of the mechanism for reducing growth (i.e.,

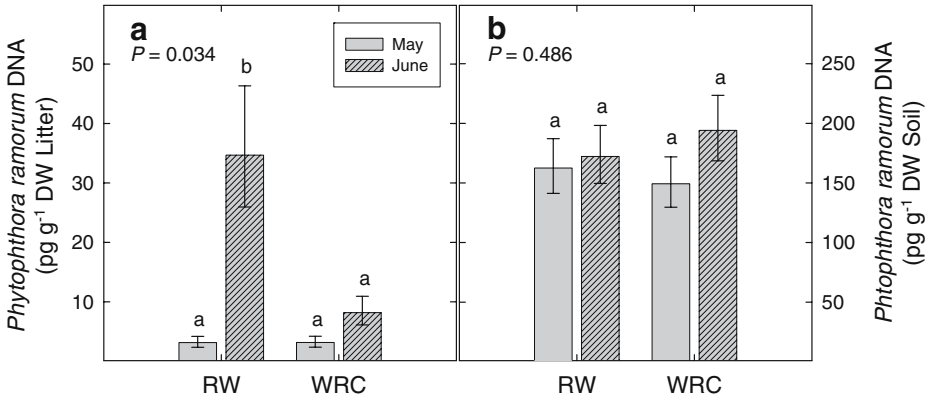

Fig. 2 Concentrations of *P. ramorum* DNA in the litter (**a**) and soil (**b**) after 2 and 4 months treatment with western redcedar (*WRC*) or redwood (*RW*) chips beneath the canopy of *U. californica* trees with leaves showing symptoms of *P. ramorum* leaf blight. *Bars* represent the median and pooled standard errors resulting from back-transformations. *Bars with different letters* are statistically significant at $P<0.05$

disruption of zoospore or sporangia membranes and/or limiting hyphal growth rates), compounds with antimicrobial activity will be detected by the photometric methodology used in this study. Nootkatin and carvacrol were tested here and with our earlier procedure (Manter et al. 2006). In both instances, nootkatin was more active than carvacrol. Previously, nootkatin had a Log_{10} EC_{50} of 0.18 and 0.84 ppm for inhibition of zoospore and sporangia germination, respectively, compared with 1.03 and 1.85 ppm for carvacrol (Manter et al. 2006). In the current assay, the Log_{10} EC_{50} for nootkatin was 1.00± 0.09 ppm, and carvacrol was 1.81±0.08 ppm.

Of the seven different conifer heartwood extracts bioassayed in the initial experiment, those from western redcedar and incense cedar were more than twice as active (less than half of the EC_{50}) toward *P. ramorum* than extracts from the group including yellow-cedar, western juniper, and Port-Orford-cedar (Table 2). Douglas-fir and redwood extracts were inactive. Previously, the steam distilled essential oils from yellow-cedar, western juniper, Port-Orford-cedar, and incense cedar were shown to have nearly identical levels of activity toward *P. ramorum* zoospore germination and hyphal growth when tested at 140 ppm (Manter et al. 2006). As the chemical composition of conifer heartwood can be extremely variable among trees (DeBell et al. 1999; Kelsey et al. 2005), our ranking of species activities in Table 2 applies only to the trees used in this study. Confirmation of these species differences will require testing of a larger random sample.

All individually tested compounds with strong or moderate antimicrobial activity contained a free hydroxy group, except for thymoquinone. The importance of this functionality is demonstrated by the tremendous difference in activity between carvacrol (Log_{10} EC_{50} 1.81±0.08 ppm) and methyl carvacrol (>3.0 ppm) with a methyl group blocking the hydroxyl. The antibacterial action of carvacrol against the food pathogen, *Bacillus cereus*, is also dependant on the free hydroxyl (Ultee et al. 2002). In contrast, the cytotoxicity of thymoquinone decreases 1.7-fold when the two ketones are reduced to alcohols (Johnson et al. 1998). Hydroxylated compounds with the lowest antimicrobial activity in our bioassays included two sesquiterpenes (cedrol and valencene-13-ol) and one monoterpene (α-terpineol). Valencene-13-ol and nootkatol expressed weak activity as tested at 55 and 66.6% purity, respectively. Had they been at 95% purity, the valencene-13-ol would probably have increased to the moderate level of activity, and nootkatol might have reach the strong category. Of the three sesquiterpene hydrocarbons tested, β-cedrene and thujopsene were weakly active, and δ-cadinene had no activity toward *P. ramorum*.

All compounds in the strong and moderate categories here have been shown to be active against a range of other organisms. Hinokitiol is probably the most rigorously investigated with activity against human tumor cells and a variety of microorganisms that cause plant disease or decay, and diseases of humans (Trust and Coombs 1973; Fallik and Grinberg 1992; Inamori et al. 1993, 1999; Baya et al. 2001; Arima et al. 2003; Voda et al. 2003; Chisty et al. 2004; Yamano et al. 2005). Studies of carvacrol have demonstrated bactericidal, fungicidal, insecticidal, nematicidal, and acaricidal activities (Rennerfelt and Nacht 1955; Ahn et al. 1998; Oka et al. 2000; Voda et al. 2003; Burt 2004). Nootkatin has antimicrobial properties against wood decay fungi (Rennerfelt and Nacht 1955) and *Candida albicans*, a yeast that causes infections in animals (Johnston et al. 2001). Thymoquinone is cytotoxic for certain human tumor cells and is insecticidal toward yellow fever mosquito larvae (Johnson et al. 1998).

Conifer heartwood typically contains a complex mixture of compounds from various chemical classes and in varying concentrations (Renerfelt and Nacht 1955; Rudman 1962, 1963; Scheffer and Cowling 1966). This study focused on volatile compounds soluble in ethyl acetate and detectable by GC. Not all of the active compounds in these extracts would

be detected by this method, and there could be other active compounds remaining in the wood because of their low solubility in this solvent. This is especially relevant for redcedar because its heartwood contains many nonvolatile phenolics, such as plicatic acid, plicatin, or thujaplicatin (Barton and MacDonald 1971) with weak antimicrobial properties (Roff and Atkinson 1954). Some proportion of these compounds would be removed with ethyl acetate, as they are soluble in acetone (Barton and MacDonald 1971), but they are not detectable by GC. Thus, woody tissues of the conifers tested here could have stronger *in vivo* bioactivities than their extracts demonstrated *in vitro*. Despite our limited search of the chosen conifer metabolomes, we successfully identified a number of highly active, commercially available compounds that provide strong activity against *P. ramorum* in culture.

Results from the field trial with chips of western redcedar and redwood were consistent with *in vitro* bioassays of their heartwood extracts. After just 2 months of treatment, there was no difference in the *P. ramorum* DNA or biomass in the litter beneath the redwood or western redcedar chips. In the subsequent 2 months, however, *P. ramorum* DNA on the redwood plots increased 4.3 times the amount on the redcedar plots. A combination of rainfall, spore production, and bioactivity of the wood chips may explain these results. Warm winter or spring rains stimulate *P. ramorum* to grow and sporulate on wet leaf surfaces of suitable hosts, especially bay laurel. Once zoospores or chlamydospores are produced on the leaves, subsequent rainfall washes them to new leaves or the forest floor. Upon installation of the field plots at the beginning of March, there were relatively few leaves on the bay laurel with visible symptoms. During March and April, the site experienced heavy rainfall, 205 and 127 mm, respectively (California Climate Data Archive [http://www.calclim.dri.edu/ccda/ncacoop.html], weather station 046826 located 16 km North of the field site). At the first sampling date in early May, the number of visibly infected bay laurel leaves had increased substantially in the lower canopy. In May and June, rainfall decreased to 8 and 0 mm, but the level of bay laurel canopy infection had expanded further by the last collection date on 29 June.

In the absence of woodchips covering the forest floor, Davidson et al. (2005) observed a 2- to 4-month lag between peak rainfall and detection of *P. ramorum* in the litter and soil. The low levels of *P. ramorum* DNA in the two chip treatments of the May sample are thus not unexpected because of the time lag between rainfall and spore deposition. Additionally, the presence of a layer of woodchips, with or without antimicrobial activity, could physically trap and reduce spore movement to the litter layer below. Furthermore, spores directly contacting the western redcedar wood, or its leachate, would be exposed to antimicrobial compounds that can damage spore membranes and stop their further movement to the litter layer. It is also possible that chlamydospores present in the litter before treatment germinated and formed new sporangia and zoospores in response to the heavy March and April rainfall. Here again, those exposed to the antimicrobial compounds of western red cedar would experience lower germination and growth rates compared to those in the redwood treatment, which had no antimicrobial activity. An alternative interpretation of the field data is that western redcedar had no impact on *P. ramorum*, and the redwood treatment stimulated its growth in the litter. This seem unlikely given the strong activity of western redcedar extracts *in vitro* and the observation that direct inoculations of logs and stems of both redwood and western redcedar showed no differences in the growth of *P. ramorum* (Hansen et al. 2005).

We chose to quantify *P. ramorum* biomass in the field trial by quantitative polymerase chain reaction because of its high reproducibility and sensitivity to detect changes in *P. ramorum* biomass (Hayden et al. 2006; Schena et al. 2006). However, this technique cannot

distinguish between viable and nonviable biomass present in a sample. Although other techniques, such as leaf baiting or direct plating, will detect only viable *P. ramorum* biomass, they are at best semi-quantitative or not species specific. Furthermore, even if some nonviable *P. ramorum* was detected in our samples, it is clear that viable *P. ramorum* is present and is increasing significantly over time under the redwood, but not the redcedar chips. Finally, we suggest that the presence of any nonviable *P. ramorum* in the redcedar plots may be masking our ability to detect the full bioactivity of redcedar chips *in situ*—not only does it limit the proliferation and development of new biomass, but it also kills any *P. ramorum* already present in the system.

Management of this pathogen focuses on slowing its spread by preventing introductions and establishment into new areas (Garbelotto and Rizzo 2005; Rizzo et al. 2005). With spores being the key dispersal mechanism (Davidson et al. 2005), control measures that target spore survival may contribute to successful management actions. An integrated management program may be able to utilize bioactive conifer heartwoods in some instances to help limit the number of *P. ramorum* spores in soils and the potential for new infections via splash dispersal (Davidson et al. 2005) or long-distance transport to new areas. For example, people living, working, and recreating in areas infested with *P. ramorum* can vector spores on their shoes, bicycle tires, or other items that contact spore contaminated soils or plant tissues (Cushman and Meentemeyer 2005; Davidson et al. 2005). Previously, we proposed that chips of yellow-cedar might be spread over trails, bike paths, or parking lots used by recreationists to reduce spore movement and redistribution from these areas (Manter et al. 2006). However, this will not affect movement of viable hyphal fragments.

Alternatively, some of the most active individual heartwood compounds might be developed into useful products. There are several fungicides that can protect against *P. ramorum* infection when applied in advance of inoculation (Heungens et al. 2006; Linderman and Davis 2006; Tjosvold et al. 2006; Turner et al. 2006), but their protection against foliar infection varies with host species, age of leaves, and source of the fungal isolate (Goheen et al. 2006b). Post inoculation applications tend to be less effective, and none of the fungicides is capable of eradicating the pathogen from infected plants (Heungens et al. 2006; Linderman and Davies 2006; Tjosvold et al. 2006). In addition, there are concerns for rapid development of fungicide resistance (Turner et al. 2006). Thus, it may be worthwhile to test additional hydroxylated compounds from conifer species that have not yet been bioassayed and to examine the efficacy of foliar spray applications of the most active compounds such as hinokitiol and thymoquinone.

Acknowledgements We thank the US Department of Agriculture, Forest Service, Pacific Southwest Research Station for funding and the Marin County Open Space District for a permit to work on the Rush Creek Preserve. We thank John Bannister, Ketchikan Wood Technology Center for samples of Alaska yellow-cedar, Gene Braber, USDA, Orleans Ranger District for the sample of Port-Orford-cedar, and Greg Jennings, Bureau of Land Management, Arcata, California Field Office for the sample of redwood. We are especially thankful to Dr. Everett Hansen at Oregon State University for providing the *P. ramorum* isolate and use of his laboratory facilities and to Lyndsay Frady for her assistance conducting the bioassays.

spot to overwinter. Aggregation pheromones, as well as sex pheromones, are essential components of integrated pest management methods that are used in push–pull strategies to repel the target pests from a protected host, while luring them toward an attractive trap (Cook et al. 2007). Although the multicolored Asian lady beetle, *Harmonia axyridis* Pallas (Coleoptera: Coccinellidae), was introduced in Europe and North America as an effective natural enemy of various pests that include aphids and mites, adverse effects of *H. axyridis* on nontarget insects, humans, and crops have been identified. Furthermore, *H. axyridis* negatively impacts native coccinellids, as *H. axyridis* is the top predator in the aphidophagous guild. It occupies the ecological niches of endemic lady beetles and other aphid-specific predators such as the two-spotted lady beetle, *Adalia bipunctata* L., or the seven-spotted lady beetle, *Coccinella septempunctata* L. (Koch 2003; Sato et al. 2005). *Harmonia axyridis* is also considered a nuisance pest because it migrates from the field into houses and other structures when temperatures decline, and forms mass overwintering aggregations in elevated, dark, and concealed portions of structures (Huelsman et al. 2002). In addition to its invasive behavior, *H. axyridis*, when disturbed, secretes hemolymph that imparts an unpleasant odor to any surfaces (walls, furnishings, etc.) where beetles aggregate (Huelsman et al. 2002; Magnan et al. 2002). The secretions and the unpleasant odor can lead to allergic reactions in human occupants.

To develop efficient push–pull strategies, better knowledge is required of the potential semiochemicals involved in the establishment and persistence of overwintering aggregations of *H. axyridis*. While observing *H. axyridis* aggregation sites, Nalepa et al. (2000) concluded that there was little evidence for volatile aggregation pheromones and that contact chemoreception with conspecifics probably mediates the aggregation behavior. However, Brown et al. (2006) reported the identification of (−)-β-caryophyllene from the headspace of *H. axyridis* females under conditions that simulated natural overwintering conditions. (−)-β-Caryophyllene is also commonly released from various plant families, including the Brassicaceae (Rohloff and Bones 2005), Solanaceae (Farag and Paré 2002), and Poaceae (Dean and De Moraes 2006).

To demonstrate the potential role of (−)-β-caryophyllene in the aggregation behavior of *H. axyridis*, and the impact of (*E*)-β-farnesene (major component of the aphid alarm pheromone) on the foraging behavior of this aphid predator, we conducted both electrophysiological and behavioral experiments. These two methodological approaches have been used widely in the identification of lady beetle-related semiochemicals (Zhu et al. 1999; Al Abassi et al. 2000; Acar et al. 2001; Francis et al. 2001, 2004; Ninkovic et al. 2001).

Methods and Materials

Insects Larvae of *H. axyridis* were collected in May 2007 on the edges of a bean field and placed in aerated plastic boxes (up to 25 individuals per container). The larvae and the resulting adults were provisioned daily *ad libitum* with aphids, *Acyrthosiphon pisum* Harris, reared on beans. Sugar, water-impregnated cotton, and multiflower pollen were also provided. Boxes were placed in controlled environment incubators (16-hr-light photoperiod; 25±2°C; 70% RH). Males and females were separated at least 1 wk prior to electrophysiological and behavioral bioassays.

Electrophysiology (EAG) The *H. axyridis* antenna was carefully excised from the head so that all segments and the basal nerve were still attached. The antenna was mounted between two glass Ag–AgCl electrodes (Harvard Apparatus, Holliston, MA, USA; 1.5 mm o.d.×

1.17 mm i.d.) filled with saline solution (NaCl, 7.5 g/l; $CaCl_2$, 0.21 g/l; KCl, 0.35 g/l; $NaHCO_3$, 0.2 g/l) and in contact with a silver wire. The base of the antenna was first inserted into the ground glass electrode. The tip of the recording electrode was bowl-shaped, and half of the last distal antennal segment was immersed into the saline solution. This setup was previously shown to produce elegant results in the study of the olfactory responses of the confused flour beetle, *Tribolium confusum* Du Val (Coleoptera: Tenebrionidae), to its aggregation pheromone (Verheggen et al. 2007). The DC potential was recorded on a computer (Auto Spike v. 3.0) by using an amplifier (IDAC-4, Syntech®, Hilversum, The Netherlands) with 100-fold amplification. A 0.5-cm^2 piece of filter paper that was impregnated with 10 μl of the chemical under examination was placed in a Pasteur pipette and used to puff an air sample in a constant 1.5 l/min airstream. As a negative control, the antennae were first stimulated with semiochemical-free filter paper (=mechanical stimulus). Later, the antennae were stimulated with (−)-β-caryophyllene or (*E*)-β-farnesene (EβF). (−)-β-Caryophyllene was purchased from Sigma-Aldrich (Chemie Gmbh, Steinheim, Germany) and had a chemical purity of >97% (determined by GC). EβF was synthesized from farnesol (Tanaka et al. 1975) and had a chemical purity of 98% (also determined by GC). Ten antennae were tested for each sex.

Four-arm Olfactometer Assays The four-arm olfactometer was similar to that previously described by Vet et al. (1983). It was constructed entirely of Teflon® and was closed with a removable glass roof, both previously cleaned with *n*-hexane. The walking arena was 40 cm wide (from center to odor source) and 1.5 cm high (from Teflon® walking arena to glass ceiling). Charcoal-filtered air was pushed in each of the four olfactometer arms through Teflon® tubing and adjusted to 100 ml/min with a digital flowmeter. A pump ventilated the walking arena by removing air from the center at 400 ml/min. A 0.5-l glass chamber was connected to one of the four olfactometer arms and was used to dispose of the odor source. Three stimuli were tested on both *H. axyridis* males and females: (1) the four arms of the olfactometer were connected to pure air sources, the glass chamber remained empty; (2) 20 unwinged adult aphids, *Myzus persicae* Sultzer, were rapidly crushed inside of the glass chamber by using a small glass pestle left inside the chamber [as a natural source of EβF: according to previous studies, the volatiles released by crushed *M. persicae* consist exclusively of EβF (Edwards et al. 1973; Francis et al. 2005)]; (3) a 0.5-cm^2 piece of filter paper was impregnated with 10 μl of (−)-β-caryophyllene and placed inside the glass chamber. The glass chamber was randomly connected to one of the four arms of the olfactometer. Both the walking arena and the glass ceiling were washed with *n*-hexane after each lady beetle was tested. The olfactometer was divided into one central 10-cm squared area and four other areas related to the four odor sources. The choice of the lady beetle was determined by (a) the first area it entered, (b) the first area where it stood for 30 consecutive seconds, and (c) the area where it stood at the end of the 3 min of observation (=last entered area). The behavioral observations were conducted in a laboratory at 22±1°C and under uniform lighting to avoid interference with behavior of the test insects.

Aggregation Assays Three 5-cm-diameter holes were cut into a 30×15×15-cm plastic box, and the holes were covered with metal screening. One hole was located on each lateral side (30 cm apart) and a third hole was located on the top. A 4-cm^2 piece of filter paper impregnated with 10 μl of (−)-β-caryophyllene was attached to the screen cover of one of the lateral holes by using a rubber band. Ten males and 10 females *H. axyridis* were introduced into the box for 1 hr, and the side where they stood was recorded after 30 and 60 min. Behavioral observations were conducted under the same conditions as mentioned above.

Statistical Analyses A Student's *t* test was performed to compare the mean EAG responses to the semiochemical stimuli with the EAG responses to the mechanical stimulant, as well as to compare EAG responses between the sexes. Observed frequencies related to the choice of *H. axyridis* in olfactometer assays (four-arm and aggregation bioassays) were compared to corresponding theoretical frequencies by using a χ^2 goodness-of-fit test. All statistical tests were conducted using Minitab® release 14.2.

Results

Electroantennography To the best of our knowledge, this is the first report of successful EAG recordings from *H. axyridis* antennae. Both pure EβF and (−)-β-caryophyllene elicited good activity from antennae of both sexes. Female and male antennal responses to the latter semiochemical were higher than those produced mechanically (Student's *t* test, t_{obs}=4.89, P<0.001, and t_{obs}=5.49, P<0.001, for females and males, respectively). Male antennae were more sensitive to (−)-β-caryophyllene (338±31 μV, N=10) than female antennae (178±19 μV, N=10) (t_{obs}=4.41, P=0.001).

The mean EAG responses to EβF were significantly higher than those to mechanical stimuli (t_{obs}=2.43, P=0.027, and t_{obs}=2.53, P=0.022, for females and males, respectively). The mean EAG responses to EβF was higher in males (202±17 μV) than in females (120± 18 μV) (t_{obs}=3.30, P=0.004). (−)-β-Caryophyllene induced higher EAG responses than EβF (t_{obs}=2.22, P=0.040, and t_{obs}=3.84, P=0.002, for females and males, respectively).

Four-arm Olfactometer Assays In the four-arm olfactometer, EβF (crushed *M. persicae* as a natural source) and (−)-β-caryophyllene elicited significant behavioral activity from both *H. axyridis* males and females (Table 1). According to the three behavioral criteria that we observed and recorded, males were attracted to (−)-β-caryophyllene. Females were less attracted than males to (−)-β-caryophyllene, as significant results were obtained only while observing the last area entered (χ^2=7.92, P=0.048). EβF attracted both male and female *H. axyridis* (Table 1).

Aggregation Assays After 30 min, both sexes of *H. axyridis* aggregated on the (−)-β-caryophyllene side of the box (χ^2=20.48, P<0.001, and χ^2=18.00, P<0.001, for males and females, respectively) (Fig. 1). Similar results were observed after 1 hr, as both males and females were still aggregated in the side of the box where (−)-β-caryophyllene was released (χ^2=11.52, P=0.001, and χ^2=13.52, P<0.001, respectively).

Discussion

Comprehension of the chemical ecology of *H. axyridis* is essential before developing push–pull strategies for the efficient use of this lady beetle in aphid control or for the control of this new urban pest in structures. (−)-β-Caryophyllene and EβF are ubiquitous plant volatiles, and previous studies have demonstrated the role of plant semiochemicals in the searching behavior of aphid natural enemies (Tumlinson et al. 1992). In our experiments, (−)-β-caryophyllene and EβF elicited antennal activity in both sexes and significant attraction in a four-arm olfactometer. It has been suggested that lady beetles orient

Table 1 Behavioral responses [observed frequencies (N=50) were compared to expected frequencies assuming random distribution (one odor source and three controls) by using a χ^2 test] of *H. axyridis* to two sesquiterpenes

Odor Source	*H. axyridis* Gender	Behavioral Observations	Observed Frequencies	χ^2	P
(−)-β-Caryophyllene	Female	First entered area	0.38	4.56	0.207
		First area entered for 30 sec	0.38	4.56	0.207
		Last entered area	0.42	7.92	0.048
	Male	First entered area	0.44	9.68	0.021
		First area entered for 30 sec	0.46	11.92	0.008
		Last entered area	0.44	9.84	0.020
(*E*)-β-Farnesene[a]	Female	First entered area	0.50	16.72	0.001
		First area entered for 30 sec	0.52	16.60	<0.001
		Last entered area	0.54	22.80	<0.001
	Male	First entered area	0.52	19.60	<0.001

		Last entered area	0.58	29.20	<0.001

[a] Natural source of EβF was 20 unwinged adult aphids, *M. persicae* Sultzer (crushed in the olfactometer release chamber)

themselves toward aphid prey by discriminating aphid punctual and EβF emission from the continuous plant release of EβF, usually joined with (−)-β-caryophyllene emission (Dawson et al. 1984). The latter has also been shown previously to counteract the attraction of lady beetles to EβF, acting thus as a natural alarm pheromone inhibitor, allowing the beetles to differentiate between EβF of plant and aphid origin. As *H. axyridis* releases its aggregation pheromone at the end of autumn, when the temperatures get lower and aphids are present in lower densities, no inhibition happens.

Our results demonstrated that (−)-β-caryophyllene and EβF act as semiochemicals for *H. axyridis*. Indeed, (1) there are some specific neuronal receptors that allow their perception and (2) a behavioral attraction/aggregation was noted in the two behavioral assays. Al Abassi et al. (2000) obtained similar electrophysiological results while studying *C. septempunctata* olfactory cell responses toward the same two sesquiterpenes: Cells having high specificity for (−)-β-caryophyllene and EβF were identified. In the 12-spotted lady beetle, *Coleomegilla maculata* (Coleoptera: Coccinellidae), the highest EAG responses were obtained while testing EβF, (−)-β-caryophyllene, and two other terpenoid alcohols (Zhu et al. 1999). Therefore, it is not surprising that *H. axyridis*, which also belongs to the Coccinellidae, possesses similar specific receptors.

(−)-β-Caryophyllene is specifically released by *H. axyridis* females in overwintering aggregation conditions (Brown et al. 2006). The production of (−)-β-caryophyllene by females of *H. axyridis* was confirmed in the present study by volatile collection and subsequent GC-MS analysis (data not shown). Whereas cases of aggregation pheromone release by one sex only are common in the Coleoptera (e.g., Verheggen et al. 2007), the use of a chemical commonly found in the headspace of various plants as an aggregation pheromone might be inappropriate. One might put forth the assumption that lady beetles have different antennal sensitivity to (−)-β-caryophyllene according to the season, being more sensitive during winter conditions. (−)-β-Caryophyllene has an attractive effect on *H.*

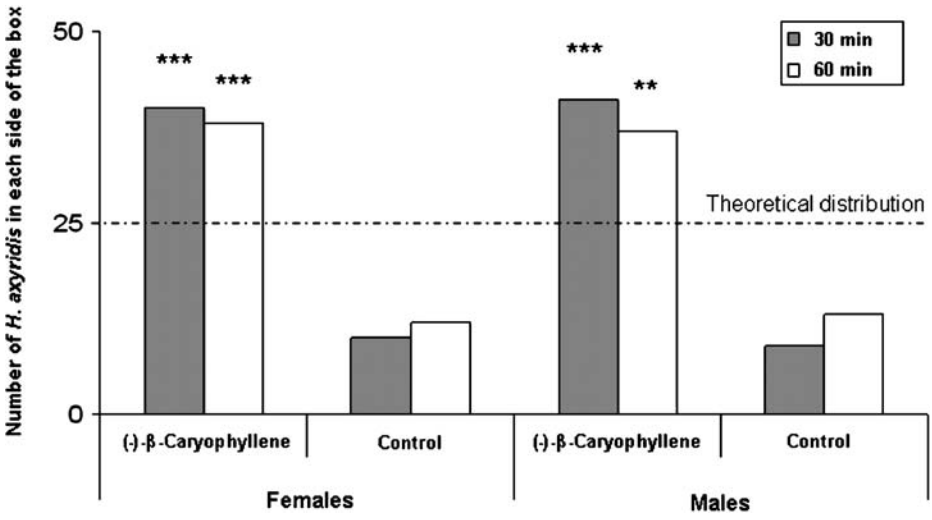

Fig. 1 Observed distribution of female and male *H. axyridis* (N=50 for each sex) relative to the release site of (−)-β-caryophyllene in an aggregation bioassay. *Double* and *triple asterisks* indicate significant differences between observed and expected distributions at $P<0.01$ and $P<0.001$, respectively (χ^2 goodness-of-fit test)

axyridis, although the responses of the females in the four-arm olfactometer were significant in only one of the three behavioral observations. However, in the second set of behavioral assays, the distribution of both males and females in the (−)-β-caryophyllene-treated side of the box was significant. These behavioral data, the antennal perception of (−)-β-caryophyllene, and its specific period of release (i.e., in the early winter) support the hypothesis that it acts as a component of an aggregation pheromone rather than a sex pheromone.

Like other lady beetle species, including *A. bipunctata* (Hemptinne et al. 2000; Francis et al. 2004), *H. convergens* (Acar et al. 2001), and *C. septempunctata* (Nakamuta 1991; Al Abassi et al. 2000), *H. axyridis* is able to perceive and orient itself toward EβF, the main component of the aphid alarm pheromone. Our electrophysiological and behavioral results support previous research that demonstrated that *H. axyridis* has a high ability to track aphid populations in space and time (Osawa 2000). Indeed, this aphid predator showed fast and pronounced orientation behavior toward the EβF source in the four-arm olfactometer. Having the ability to localize aphids under predation represents an undeniable advantage for a mobile and voracious predator like *H. axyridis*. Although previous studies demonstrated that *H. axyridis* responded to volatiles from aphids and aphid-damaged plants (Han and Chen 2002), our results do not support previous work that demonstrated that *H. axyridis* was attracted toward a colony of *A. pisum*, but not toward cornicle secretions (Mondor and Roitberg 2000), which are known to contain EβF (Francis et al. 2005).

In summary, push–pull strategies that target the use of *H. axyridis* as a biological control agent in aphid-infested sites, or that are designed to control this new urban pest in human dwellings, should take into account the potential attractive effect that (−)-β-caryophyllene could have in outdoor conditions. Our data also suggest that, in aphid biological control strategies, one should incorporate EβF as an attractant for various aphid natural enemies, including *H. axyridis*.

Acknowledgments The authors are grateful to Dr. Bartram, from Max Planck Institute for Chemical Ecology, for the synthesis of (*E*)-β-farnesene. We also thank Dr. Yves Brostaux and Adeline Gillet, from Gembloux Agricultural University, for advice on statistical analysis. This work was supported by the *Fonds National pour la Recherche Scientifique* (grant M 2.4.586.04.F).

visibly attractive click beetles of Central Europe is a rare species throughout its entire distribution, which ranges from Spain to the Caucasus, and from Italy in the south to Sweden in the north (Horion 1953).

Elater ferrugineus develops in hollows of various old living deciduous trees that are filled with a special kind of wood mold, which is usually generated by the larvae of scarab beetle species such as *Osmoderma eremita* (Scopoli), *Gnorimus variabilis* (L.), *Protaetia aeruginosa* (Drury), or *Protaetia lugubris* (Herbst). The larvae of *E. ferrugineus* are facultatively carnivorous and occasionally prey on eggs and larvae of these scarab beetles. However, they can also develop on wood mold alone. The life cycle of *E. ferrugineus* can last up to 6 years, depending on the abundance of prey organisms in the breeding substrate. Unless an inhabited tree is dying or felled, it can sustain a population of *E. ferrugineus* for several decades.

In Central Europe, adults of *E. ferrugineus* occur in midsummer from late June to August. However, the adults live cryptically and are rarely encountered in the field. This, and occasional reports on single specimens attracted by artificial light sources, have led several authors to conclude that *E. ferrugineus* might be nocturnally active (e.g., Horion 1953; Lohse 1979). Larvae of *E. ferrugineus* have been recorded more frequently, as they are present throughout the year much more abundantly than the adults and strictly located in their breeding substrate. As a result, adult *E. ferrugineus* preserved in collections have mostly been bred from late instars. Nevertheless, larvae are normally only collected when an inhabited old tree is occasionally felled or otherwise opened, which usually accompanies the destruction of the habitat.

As a result of massive habitat loss in Europe caused by decades of intense and profit-orientated forestry, *E. ferrugineus* appears in the Red Data Books throughout its distribution, classified as endangered (e.g., Germany: Geiser 1998; Sweden: Gärdenfors 2005) or critically endangered (e.g., Czech Republic: Vavrá 2005). In Central Europe, *E. ferrugineus* is regarded as an "Urwald relict species," i.e., a species associated with primeval forest ("Urwald") structures and features (Müller et al. 2005), and is used as indicator species for old and species-rich deciduous forests in landscape ecology (Schmidl and Bussler 2004). However, a large degree of experience is needed for recognizing trees suitable for *E. ferrugineus* and for distinguishing larvae from even many similar more abundant species. Therefore, especially in official ecological surveys, the species is frequently overlooked.

In this paper, we report the identification and synthesis of the sex pheromone of *E. ferrugineus*. In addition to chemotaxonomical aspects, we were interested in developing a specific and effective monitoring tool, and we found the synthetic pheromone blend to be highly attractive to swarming *E. ferrugineus* males.

Methods and Materials

Laboratory Studies

Insects Late instars of *E. ferrugineus* (>4 cm) were collected from three different field sites in Germany: 1) Forst Göhrde/Niedersachsen, seven larvae from an old hollow oak, *Quercus petraea* (Matt.) Liebl. (Jan. 2002, March 2003); 2) Kühkopf/Hessen, three larvae from a wind-broken hollow ash, *Fraxinus excelsior* L. (Feb. 2005); and 3) Tübingen/Baden-Württemberg, eight larvae from an old linden, *Tilia* sp. (March 2005).

Larvae were kept isolated at room temperature in single plastic screw-capped glass jars (500 ml) with the wood mold that they were collected in. They were fed with pieces of

yellow mealworm, *Tenebrio molitor* L., during the following months. Pupation took place in early May of the collection year, and adult beetles emerged about 3 wk later. In total, seven females were reared and examined. Sexes of the beetles were distinguished by examining the shape of their antennae, which are considerably longer and more serrate in the males. They were sometimes verified by examination of the genitalia.

Extracts Beetles were deep-frozen (20 min at −20°C), the abdomen was broken off by bending it over to the ventral side, and the tergites were removed to excise the paired pheromone glands that are similar to those described by Merivee and Erm (1993) for the click beetle *Agriotes obscurus*. Separate extracts were prepared for each beetle by transferring the glands to 300 µl CH_2Cl_2.

Chemical Analyses Analyses of extracts were carried out by coupled gas chromatography–mass spectrometry (GC–MS). A 6890 GC/5973N MSD quadrupole instrument (Agilent Technologies, Santa Clara, CA, USA) was employed in electron impact mode at 70 eV, 230°C. Compounds were separated with a 30 m×0.25 mm i.d., 0.25 µm film thickness HP5-MS fused silica capillary column (Agilent), starting at 60°C for 3 min, then programmed to 300°C at a rate of 3°C/min. Carrier gas was helium with a flow rate of 1.2 ml/min. In addition, a 50 m×0.25 mm i.d., 0.27-µm film thickness FS-FFAP column (Macherey & Nagel, Düren, Germany) was used (60°C for 3 min, then 3°C/min to 220°C, and held for 20 min).

For separation of vicinal dimethyl thioderivatives of extract compounds, produced for the determination of double bond positions, the HP5-MS capillary column was used as described, but the final temperature of 300°C was held for 60 min. Reaction of double bonds was carried out with dimethyl disulfide (DMDS) (Buser et al. 1983). Nuclear magnetic resonance (NMR) spectra of synthetic compounds were recorded with a Varian INOVA 300 instrument (Varian, Palo Alto, CA, USA).

Chemical Syntheses Chemicals and solvents were purchased from Sigma-Aldrich (Munich, Germany) or Merck (Darmstadt, Germany) and were of highest purity available. Purification of synthetic products was carried out by flash chromatography on silica gel (silica 32-63, 60 Å ICN-Biomedicals, Eschwege, Germany) at 1.3 bar with mixtures of ethyl acetate and hexane.

Monobenzylation of commercially available 1,5-pentanediol (Sigma-Aldrich) employing sodium hydride and benzyl bromide gave alcohol **1**, which was oxidized to the corresponding aldehyde **2** by Swern oxidation (Fig. 1). Wittig reaction of **2** with isobutyltriphenylphosphonium bromide produced the benzyl ether of 7-methyl-5-octen-1-ol (**3**), which was hydrogenated over 10% Pd/C catalyst to yield 7-methyloctan-1-ol (**4**), the alcohol moiety of all subsequently synthesized esters. An aliquot of **4** was oxidized to 7-methyl octanoic acid (**5**) by using CrO_3/H_2SO_4 in acetone (Jones chromic acid). 7-Methyloctyl octanoate (**6**) was synthesized from **4** and octanoyl chloride (Sigma-Aldrich) in ether. Oxalyl chloride was used to transform acid **5** into its chloride, which was treated *in situ* with **4** to yield 7-methyloctyl 7-methyloctanoate (**7**). With the same procedure, commercially available 5-methylhexanol (**8**) was converted to the acid **9** and esterified with **4** to yield 7-methyloctyl 5-methylhexanoate (**10**). Similarly, (*Z*)-4-decenoic acid was synthesized from (*Z*)-4-decenol (**11**), and converted to 7-methyloctyl (*Z*)-4-decenoate (**12**) with alcohol **4**.

The synthesis provided alcohol **4** in 34 % from **1**, the esters **6**, **7**, **10**, and **12** in 80–85% from alcohol **4** (Fig. 1). Chemical purity of the four esters after chromatographic purification was >98%.

In the NMR data of the esters **6**, **7**, **10**, and **12**, carbon atom numbers of the acid moieties are indicated by an apostrophe.

Field Studies

Bait Dispensers and Traps A synthetic blend of 7-methyloctyl 5-methylhexanoate (**10**), 7-methyloctyl octanoate (**6**), 7-methyloctyl 7-methyloctanoate (**7**), and 7-methyloctyl (*Z*)-4-

decenoate (**12**) was mixed in a ratio of **10**:**6**:**7**:**12** = 1:1:3:3, which resembled the natural ratio found in the glands. Dispensers were prepared from 0.2-ml PCR tubes (Thermo-Tube™, Peqlab, Erlangen, Germany) by piercing each tube with an insect pin (diameter 0.5 mm) on the front side 2 mm below the lid (Fig. 2), and then adding 2 mg of the four-compound blend into each tube. Under laboratory conditions (ca. 24°C), the odor dispensers had a stable mean release rate of approximately 10 μg per day, regardless of the amount in the tubes (unpublished data).

Funnel traps (Fig. 2) were modified from those described by Ruther et al. (2000). Two transparent plexiglass sheets (17 cm height × 20 cm width) were arranged crosswise over a 185-mm powder funnel with its outlet (diam. 40 mm) connected to a 1-l polyethylene collection bottle. Dispensers were mounted on a thread in a gap at the top between the plastic sheets (Fig. 2). Each collecting bottle was filled with brine (200 ml) to preserve the beetles and minimize the possible attraction of beetles to the already captured individuals.

Flight Bioassays Bioassays were performed from 14 July to 5 August, 2005 in three urban parks in Tübingen, Stuttgart, and Hohenheim (Baden-Württemberg, Southwest Germany). Predominant old deciduous trees at the study sites were *Tilia* sp. (Tübingen), *Fagus sylvatica* L., *Platanus* × *hybrida* Br. (Stuttgart), and *Populus nigra* L. (Hohenheim), with some individuals up to 300 years old. A total of 28 traps were grouped into 14 sets, each set containing a baited trap and an unbaited control. Four of these sets were used in Tübingen, five in Stuttgart, and five in Hohenheim. Traps were suspended approximately 5–10 m above the ground from the lower crown branches of solitary old trees. The distance between traps within one set was about 10 m, whereas the distances between the sets at a site were at least 50 m. Traps were checked weekly, captured beetles were removed, and the brine was replaced. After sex determination, numbers of beetles trapped were analyzed by the Wilcoxon matched-pairs test using Statistica 6.1 (Statsoft 2003).

An additional trap was placed 15 m above the ground in front of the lab window (Hohenheim Institute, fourth floor) to monitor the daily flight activity. This trap was observed continuously during the day, arriving beetles were removed immediately, and time and sex were noted. As this trap was without an empty control, catches were not analyzed statistically.

Results

Laboratory Studies

Gas chromatography–mass spectrometry (GC–MS) analysis of the gland extracts revealed four main compounds (**A**–**D**, Fig. 3) with only small quantitative variation among samples of different females. Compounds **A**–**C** showed typical mass spectra of long-chained saturated esters with 16, 17, and 18 carbon atoms, respectively, nine of these belonging to the alcohol moiety. The difference in retention time between **A** and **B** was more than twice the difference between **B** and **C** (Fig. 3), suggesting a methyl-branched chain for compound **A**.

A micro-transesterification performed with half of a crude extract by substituting the dichloromethane with an equal amount of methanol and storing the extract at 60°C for 48 hr yielded only one alcohol. It showed a shorter retention time than *n*-nonanol and was identified as 7-methyloctanol (**4**) by comparison with an authentic sample. Compound **B** was subsequently identified as 7-methyloctyl octanoate (**6**) by converting synthetic **4** to its heptanoate, octanoate, and nonanoate by employing the corresponding *n*-acyl chlorides and comparing retention times and spectra. Compound **A**, showing a shorter retention time than the *n*-heptanoate of **4** and indicating another methyl branch, turned out to be 7-methyloctyl 5-methylhexanoate (**10**). Accordingly, compound **C** was identified as 7-methyloctyl 7-methyloctanoate (**7**).

The mass spectrum of extract compound **D** resembled those of **A**, **B**, and **C**, but a molecular mass of 296 g/mol indicated a double bond. Given that transesterification only produced **4**, the double bond could be located only in the acid moiety of **D**, which pointed to a 7-methyloctyl decenoate. DMDS-derivatization yielded a product with a molecular ion of *m*/*z* 390 and a pair of diagnostic ions of *m*/*z* 131 and 259, indicating that the unsaturation was between C-4 and C-5 of the acid moiety (Fig. 4).

For determination of the double bond geometry, 7-methyloctyl (*Z*)-4-decenoate (**12**) was synthesized from commercially available (*Z*)-4-decenol (**11**). The mass spectrum of **12** and the retention times on the HP5-MS and FS-FFAP capillary columns were identical to those of extract compound **D** (data not shown). Thus, we concluded that the natural product has

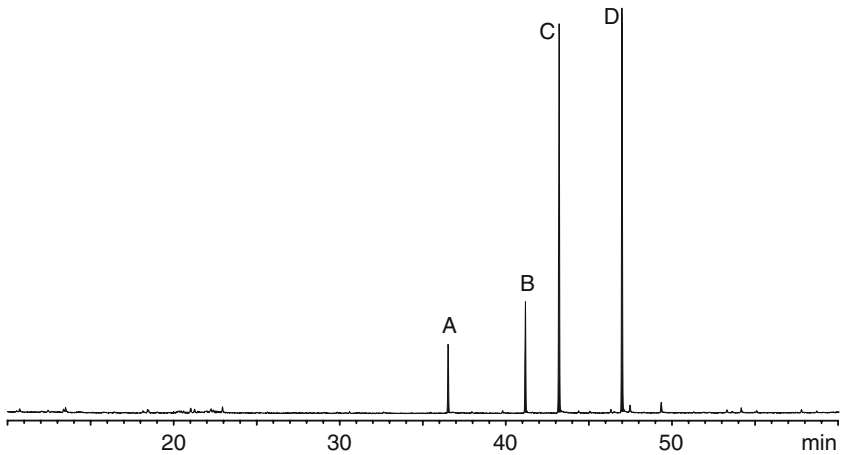

Fig. 3 Representative gas chromatogram (total ion current) from an analysis of a female *Elater ferrugineus* gland extract (30 m HP5-MS capillary column, 3 min at 60°C, then 3°C/min to 300°C)

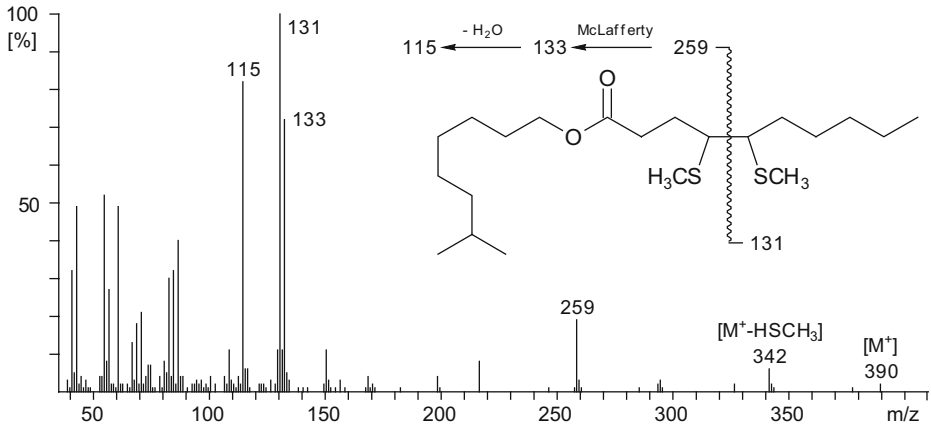

Fig. 4 Determination of double bond position in compound **D**: mass spectrum of the DMDS derivative and assignment of prominent ions to the resulting structure

the (*Z*)-configuration. In two samples, the amount of the major pheromone component **D** was estimated to be 6.9 and 5.9 μg/female, respectively.

Field Studies

Unexpectedly, the first proof for the attractiveness of the identified compounds was the response of several male *E. ferrugineus* that appeared at the open lab window (fourth floor) while the substances were purified over SiO_2 (12 July, 2005). In the field bioassay, a total of 57 male *E. ferrugineus* were caught with the pheromone blend, and one beetle was caught in an unbaited control trap, showing a highly significant difference (Fig. 5). As a result of single traps that vanished during the test, the number of replicates were reduced from 42 to 39.

An additional 33 males were caught at the lab window, including the catches in the funnel trap. Most responses were observed directly, or at least recorded within an hour of the response. Catches occurred exclusively during the day. The earliest recorded response was at 7:25 (CET) and the latest was at 19:30. Within this range, no preferred time of the day was found, but warm and sultry weather conditions, without intense sunlight and wind, seemed to be essential. In 2005, the flight season ended during the first week of August.

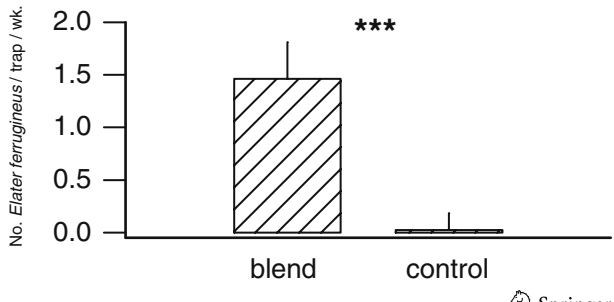

Fig. 5 Mean (+ SE) weekly trap catches of *Elater ferrugineus* from 14 July to 5 August 2005 in response to the synthetic blend of compounds 6,7,10, and 12 (Fig. 1) (***$P<0.001$, $N=39$, Wilcoxon matched pairs test)

Discussion

Our results show that the identified gland compounds comprise the female sex pheromone of *E. ferrugineus*. Nevertheless, it remains unknown whether all four compounds are necessary to attract the males, or if only one or a few of them are biologically active. The benefits of further field testing of all combinations of these four compounds, however, must be weighed against the potential damage that trapping would do to populations of this rare beetle.

Although the attractive effect of our four-compound-blend was highly significant, the total number of captured males in the traps was relatively low. However, *E. ferrugineus* is a rare species that likely occurs at a much lower population density than the average pest insect. In addition, field tests in 2005 were conducted during the second half of the flight period because it took longer than expected to complete the syntheses to bait the experimental traps. In 2006, when we set out nonkilling traps to survey and estimate population sizes, we recorded daily trap catches of up to 20 males/trap during the first half of the flight season (unpublished data).

Although their structures are comparatively simple, all compounds represent new natural products. The *iso*-methyl branches in the acid or alcohol moieties likely result from a biosynthesis that employs leucine as the chain initiating unit, which is then, after conversion to an isovaleryl derivative, elongated with acetyl units. A similar biosynthetic pathway has been found by Charlton and Roelofs (1991) in an arctiid moth.

Before our study, female-produced click beetle pheromones could be divided into three groups based on their structural properties. Interestingly, this division fits the taxonomical classification as well. The first group comprises the members of the genus *Agriotes* (Elaterinae: Agriotini), from which, as a result of their economical importance, comparatively many species have been investigated (e.g., Tóth et al. 2003). In females of this genus, several esters of acyclic isoprenoid alcohols with equal chain acids (two to eight carbon atoms) have been identified as pheromone components. A typical example is (*E*,*E*)-farnesyl butyrate, which, together with geranyl butyrate, is the major component of the sex pheromone of *A. brevis* Candeze (Tóth et al. 2002). In a second group, which contains the genus *Melanotus* (Melanotinae), compounds resembling moth pheromones have been reported, i.e., unbranched esters of alcohols with 12 and 14 carbon atoms. The eastern Palearctic *Melanotus okinawensis* Ohira uses dodecyl acetate, whereas in *M. sakishimensis* Ohira, a mixture of (*E*9,11)-dodecadienyl butyrate and -hexanoate is present (Iwanaga and Kawamura 2000). The central European species, *M. punctolineatus* (Pelerin), uses a tetradecenyl butyrate, whereas *M. rufipes* (Herbst) uses a tetradecadienyl butyrate (Tolasch, unpublished). A third group contains the first biologically active and most simple compounds identified from click beetles. These are hexanoic acid and pentanoic acid from *Limonius canus* LeConte and *L. californicus* (Mannerheim), respectively (Jacobson et al. 1968), both members of the subfamily Dendrometrinae.

The four 7-methyloctyl esters reported in this paper do not fit well into any of these three groups. However, *E. ferrugineus* (Elaterinae: Elaterini) does not belong to any of the subfamilies or tribes noted in the taxonomic discussion above. Further investigations of other members of the Elaterini (e.g., *Sericus* spp.) would be instructive to elucidate whether this tribe represents a fourth group with respect to the structural properties of their sex pheromones.

In our study, males of *E. ferrugineus* were caught only during the day. This is remarkable, as *E. ferrugineus* has generally been considered to be a nocturnal species. One of us (T. T.) questioned this hypothesis because he observed an impressive midday swarming flight of

E. ferrugineus (28 July 1985), when several beetles were hovering in the canopy of some old willow trees, *Salix* spp., near the Elb River in Niedersachsen at 13.00 (CET). No such swarming behavior has been reported in the literature to date, and discussions with several coleopterists suggested that this observation was quite unique. However, single beetles attracted occasionally by artificial light sources during the night may have been dispersing females.

The hermit beetle, *Osmoderma eremita* (Scopoli), is one of the scarab beetles that inhabit and extend hollows in old living deciduous trees, thus making them suitable for *E. ferrugineus*. The peach-like scent of *O. eremita* was recently identified as (*R*)-γ-decalactone (Larsson et al. 2003), which is emitted in large quantities by the males as a pheromone that indicates suitable tree cavities to conspecifics. Interestingly, Svensson et al. (2004) found (*R*)-γ-decalactone to be slightly attractive to *E. ferrugineus* as well. While trapping *O. eremita* with lactone-baited funnel traps suspended near inhabited tree hollows, a few male and female *E. ferrugineus* were obtained as by-catches. The authors suggested a kairomonal role of the substance that leads *E. ferrugineus* to suitable tree hollows, and they discussed a possible function for *E. ferrugineus* males as an "indirect cue to find females of their own species." However, because our study reveals the existence of a highly attractive sex pheromone, the rationale for the use of (*R*)-γ-decalactone as a sexual kairomone appears moot, particularly as *E. ferrugineus* frequently develops in the absence of *O. eremita*.

With respect to conservation biology, the present study highlights the large potential of sex pheromones for monitoring populations of scarce and cryptic species. Insects that inhabit old hollow trees are usually collected by direct sampling of the wood mold, by placing pitfall traps into the cavities, or by suspending window traps outside the hollows (e.g., Ranius and Jansson 2002). Adults of *Elater ferrugineus*, however, are rarely caught with these methods, especially as, in the majority of cases, the openings of the inhabited cavities are narrow and located in the treetop, and inaccessible for mold sampling or pitfall traps.

In contrast, our four-ester blend provides a monitoring tool for *E. ferrugineus*. The serendipitous responses at our laboratory window suggest that traps do not have to be placed in the direct vicinity of inhabited trees, and one or two traps would be sufficient to cover a large area. Males are trapped exclusively; ovipositing females are preserved; and no other species (e.g., the highly protected *O. eremita*) are harmed. For entomofaunistic studies, pheromone traps will be particularly useful in regions where *E. ferrugineus* is considered extinct, but perhaps still exists below the limit of detection offered by conventional collecting methods. For example, the population that we identified that inhabits the old park area around the University of Hohenheim was unknown before our pheromone study. Generations of biology students had conducted their field studies at this site that included substantial insect collecting. Apart from our recent catches, only eight specimens of *E. ferrugineus* had been recorded during the last 60 years in the entire federal district of Baden-Württemberg/Germany (Frank and Konzelmann 2002), consisting of seven larval records and a single adult record.

Acknowledgments Financial support of this work by the Geschwister-Stauder-Stiftung, Hohenheim, is gratefully acknowledged. We thank Bernd Schmid for drawing the field trap illustration.

the larvae of the coccinellid *Adalia bipunctata* (L.) that showed ODP activity. They identified the constituents to be a complex mixture of typical insect cuticular hydrocarbons but did not test for the presence of compounds not detectable by gas chromatography (GC)/mass spectrometry (MS). Furthermore, no bioassays were performed with individual compounds. We report here the identification of an ODP present in extracts of first instars of *C. sexmaculata*, from bioassay-guided fractionation of the extract.

Materials and Methods

Analysis The procedures in GC/MS are as follows: HP 5890 GC coupled with HP 5973 mass selective detector, splitless injection, BPX-5 column (SGE), 60–320°C, 5°C/min. In electrospray ionization (ESI)-MS, analyses were performed on a Finnigan MAT 95 XLT with direct injection by using a microspray interface in positive and negative ionization mode. Samples were dissolved in a 1:1 CH_2Cl_2/CH_3OH mixture. Dimethyldisulfide (DMDS) derivatives were prepared according to Schulz et al. (2000). In nuclear magnetic resonance (NMR) experiments, a DRX-400 (400 MHz, Bruker) was used. Precocinelline and hippocasine were identified by comparison with respective mass spectra in the National Institute of Standards and Technology database. Injection of coccinelline into the injection port of a gas chromatograph at 250°C furnished a chromatogram that contained these two compounds as the only major peaks.

Separation Unfed first instars (5,000, laboratory culture, generations 5–20 originating from the Arab Emirates, 2004) were extracted with 20 ml chloroform for 10 min. The extract was concentrated under a gentle stream of N_2, separated on Sephadex LH-20 (12×1.4 cm) with dichloromethane/methanol (1:1) as eluent into 35 fractions. Fractions that showed an almost identical compound profile by GC/MS were combined, resulting in six fractions, which were analyzed by GC/MS and ESI-MS. After concentration, residues were redissolved in 5 ml of dichloromethane/chloroform (1:4) for bioassays. The final concentration was 135 larval equivalents/ml, assuming that no dilution by the separation process occurred.

Bioassays Oviposition-deterring effects were studied in dual-choice tests as described (Růžička 1997). The test solution (three different concentrations, see Table 1) or chloroform as control was applied to filter papers in dual-choice tests. Ten females of *C. sexmaculata* were placed in the test chamber for 24 h. Water and surfeit of *Aphis fabae* Scopoli were provided as food. Each test had ten replicates. The numbers of eggs laid on treated and

Table 1 Number of eggs laid by *Cheilomenes sexmaculata* females on filter papers treated with a chloroform extract of conspecific first-instar larvae (*) and with different amounts of (*Z*)-pentacos-12-ene[a] vs solvent controls

Concentration μg/cm^2 or larval equivalent/cm^2 (*)	Treatment	Control	Wilcoxon test
0.25*	46±6.7	81.5±4.7	P=0.002
1.25	121.5±12.4	207.5±10.9	P=0.004
0.125	105.0±16.3	166.7±11.0	P=0.006
0.0125	148.7±10.4	135.9±10.4	P=0.625

control papers were counted and analyzed statistically by using the Wilcoxon paired sample test.

Chemicals (*Z*)-Pentacos-12-ene was synthesized by alkylation of 1-tridecyne with dodecyl triflate, modifying a procedure of Matsuda et al. (2002). After purification by column chromatography, unreacted 1-tridecyne was removed by washing with $AgNO_3$ solution, yielding pure 12-pentacosyne. Hydrogenation with Lindlar's catalyst and H_2 in pentane provided pure (*Z*)-pentacos-12-ene in 18% overall yield, containing less than 2% of the (*E*)-isomer.

Results and Discussion

Chloroform extracts of first-instar larvae showed strong oviposition deterrent activity in bioassays (Table 1). Analysis of the extract by GC/MS (Fig. 1) showed that the major compounds in the chromatogram, constituting up to 95% of the extract, were the alkaloids precocinelline and hippocasine, accompanied by mostly unbranched C_{23}–C_{35} hydrocarbons. However, NMR analysis revealed that the sample actually contained almost pure coccinelline (LeBrun et al. 1999), but this alkaloid proved to be inactive in our bioassay. The free amine alkaloids observed were formed in the injection port of the gas chromatograph from the alkaloid-*N*-oxide coccinelline. It might be possible that compounds not detectable by GC/MS may play a role as ODP. Therefore, we decided to fractionate the extract by chromatography on Sephadex LH-20. Six fractions were obtained, of which one showed a pronounced oviposition-deterrent activity. The investigation of this fraction by

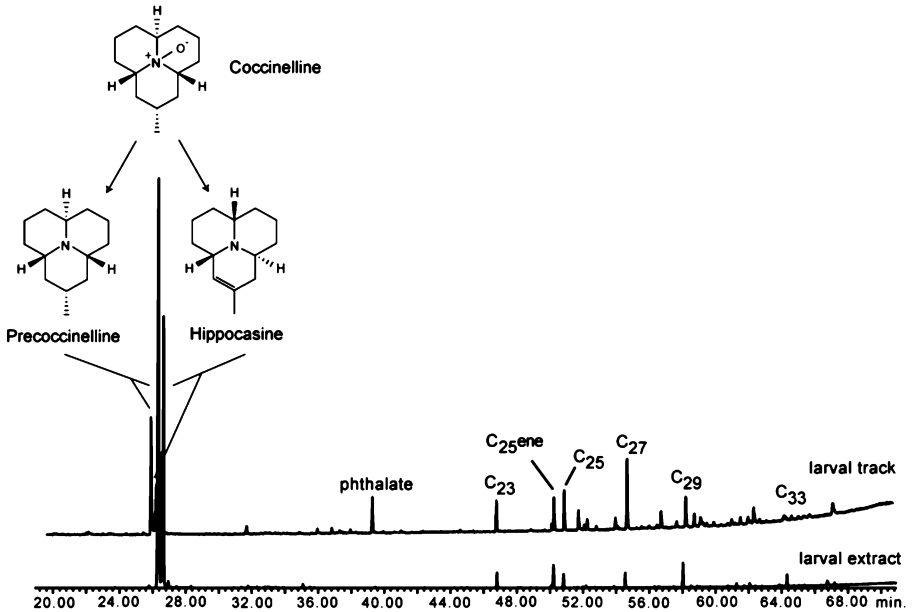

Fig. 1 Gas chromatogram of extracts of *Cheilomenes sexmaculata* first instars and a first-instar larval track

nanospray ESI-MS should reveal the presence of nonvolatile and/or polar compounds not analyzable by GC/MS, but no such compounds were found. Instead, we observed by GC/MS that this fraction contained a complex mixture of cuticular hydrocarbons. Major components in the fraction were pentacosane, heptacosane, and nonacosane, which were bioassayed individually and as a mixture in natural proportions but which were not active. An additional compound present in this fraction was a pentacosene, the only alkene occurring in the mixture in significant amounts. The position of the double bond was determined by using DMDS derivatization (Schulz et al. 2000). The formation of the DMDS adduct showed that the double bond was located at C-12, as evidenced by the strong α-cleavage ions at *m/z* 215 $(C_{12}H_{24}SCH_3)^+$ and *m/z* 229 $(C_{13}H_{26}SCH_3)^+$. Therefore, (*Z*)-pentacos-12-ene was synthesized by alkylation of 1-tridecyne with dodecyl triflate (Matsuda et al. 2002), followed by Lindlar-catalyzed hydrogenation. Gas chromatographic comparison showed that the natural compound did indeed have the (*Z*)-configuration because the two geometric isomers had different retention times on the BPX-5 phase used. In addition, (*Z*)-pentacos-12-ene was also found in extracts of tracks of first-instar larvae, proving the actual presence on the substrate (Fig. 1). This pentacosene showed considerable oviposition-deterrent activity in our bioassay. At high concentrations (1.25 μg/cm^2), the activity was strong, equivalent to the chloroform extract of 20 larvae per substrate. With lower concentrations (0.125 and 0.0125 μg/cm^2), the activity decreased as expected (Table 1). Nevertheless, because the activity of the extract was higher than that of the pentacosene, it is likely that other extract constituents are also active or might act synergistically with (*Z*)-pentacos-12-ene.

Our results prove that (*Z*)-pentacos-12-ene, most likely present on the cuticle and also found in tracks of the larvae, is an ODP of *C. sexmaculata*, the first such pheromone identified from coccinellids.

Introduction

Understanding of plant defense via major resistance (*R*) genes and parasite adaptation via avirulence (*Avr*) genes has advanced considerably in the past decade. Numerous *R* genes from host plants and *Avr* genes from parasites have been cloned and characterized (Martin et al. 2003). In some cases, plant defense responses are triggered when an *R* protein recognizes a specific *Avr* elicitor (Dodds et al. 2006) in what is historically referred to as a gene-for-gene interaction (Flor 1955; Cook 1998). Plant defense can also be triggered by the action of general elicitors produced by the parasite or by the damaged plant (Nimchuk et al. 2003; Garcia-Brugger et al. 2006; Schmelz et al. 2006). Current understanding of *R*/*Avr* interactions is based almost entirely on studies of plant–pathogen systems.

In contrast, progress in plant–insect systems has been relatively slow. Only one insect *R* gene, *Mi-1.2*, has been cloned (Dogimont et al. 2003; Kaloshian and Walling 2005). The *Mi-1.2* gene, initially cloned because of its resistance to root-knot nematodes (Milligan et al. 1998), was found to confer resistance to both potato aphids and whiteflies (Rossi et al. 1998; Goggin et al. 2001; Nombela et al. 2003). Another putative insect *R* gene, the melon *Vat* gene for virus aphid (*Aphis gossypii*) transmission resistance, encodes a cytoplasmic protein with a nucleotide binding site and leucine-rich repeat (NBS-LRR) structure, but its effectiveness against insects has not yet been proven (Dogimont et al. 2003). Other genomic and molecular studies of plant responses to insect attack have revealed additional features, some of which are similar to those seen in plant–pathogen interactions (reviewed by Kalashian 2004; Kaloshian and Walling 2005; Thompson and Goggin 2006).

Among plant–insect systems, the wheat–Hessian fly (HF) [*Mayetiola destructor* (Say)] interaction is relatively well-characterized (reviewed in Harris et al. 2003). There are 32 *R* genes (designated *H1-H32*) that were originally found in wheat or its relatives. Both *R* genes and *Avr* genes confer dramatic differences in plant and parasite phenotypes. When attacked by virulent larvae, wheat seedlings without an effective *R* gene stop growing and often die without producing seed (Byers and Gallun 1972; Anderson and Harris 2006). It is likely that plant growth is suppressed because virulent larvae induce a nutritive tissue (i.e., a sink for photoassimilates) at the attack site (Harris et al. 2006). In contrast, *R* gene plants attacked by avirulent larvae can recover from an attack (Anderson and Harris 2006). Avirulent larvae invariably die 3 to 5 days after initiating attack of *R* gene plants. The wheat–HF interaction shows common features of the gene-for-gene model (Keen 1990; Harris et al. 2003). Thus, studies that use the traditional tools of Mendelian genetics have shown that each HF *Avr* gene corresponds with a plant *R* gene (Hatchett and Gallun 1970; Lobo et al. 2006). Analyses indicate that alleles at these *Avr* loci determine whether the insects will succeed in manipulating cell development and plant growth (the compatible interaction) or die without harming the plant (the incompatible interaction).

Molecular analyses of compatible and incompatible wheat–HF interactions are now proceeding. Several genes in wheat that encode lectin-like proteins including *Hfr-1* (Williams et al. 2002), *Hfr-2* (Puthoff et al. 2005), *Hfr-3* (Giovanini et al. 2007), and *Wci-1* (Subramanyam et al. 2006) are regulated differentially. *Hfr-1* and *Hfr-3* are up-regulated dramatically during incompatible interactions but only slightly during compatible interactions. *Hfr-2*, on the other hand, is only up-regulated during compatible interactions. *Hfr-1* and *Wci-1* are also up-regulated in response to other biotic and abiotic stresses (Subramanyam et al. 2006). In addition to these lectin-like genes, several other genes are

expressed differentially in wheat nearly isogenic lines with and without the *H21* gene (Jang et al. 2003). Given the dramatic physiological and phenotypic differences exhibited during compatible and incompatible wheat–HF interactions, it seems likely that these plant genes are not the only ones that respond to HF attack. In this paper, we report the global pattern of transcription during compatible and incompatible interactions, as revealed using the Affymetrix GeneChip® Wheat Genome Arrays.

Methods and Materials

Plant and Insect Materials Experimental design is shown in Table 1. Wheat near-isogenic lines "Iris" and "Molly" were provided by Dr. H. Ohm from Purdue University. Iris contains *R* gene *H9*, whereas Molly contains *R* gene *H13*. Both Iris and Molly were obtained via backcrossing for seven generations to the susceptible recipient "Newton" (Patterson et al. 1994). Because *H9* and *H13* are located on two different chromosomes that originated from different genomes (Liu et al. 2005a, b) but exhibit essentially the same phenotypic symptoms during compatible and incompatible interactions (Anderson and Harris 2006), their commonly up-regulated or down-regulated genes are likely to play a role in host-plant resistance or susceptibility.

The HF genotypes that include biotypes L, v*H9*, and v*H13* were maintained on Karl 92 (susceptible to all biotypes), Iris (*H9*), and Molly (*H13*), respectively, in the greenhouse. Biotype L is avirulent to both *H9* and *H13*. Biotype v*H9* is virulent to *H9* but avirulent to *H13*. Biotype v*H13* is virulent to *H13* but avirulent to *H9*. All three biotypes are virulent to Newton, the susceptible recipient parent.

Experimental Treatments and RNA Extraction Wheat seedlings were grown and infested with different biotypes in a growth chamber set at 20±1°C in daytime and 18±1°C at night with a 14:10 h (L/D) photoperiod. Seedlings were infested at two-leaf stage with eggs from 10 mated females per 20 plants. Larval hatching time was monitored with additional infested plants under the same growth chamber. Tissue samples from 20 plants in each replicate were collected and pooled 3 days after larval hatching. Only those plants with 10 to 15 larvae per plant were chosen for tissue collection. The time chosen for sample

Table 1 Experimental design

Wheat Lines	HF Biotypes	Phenotypes
Iris (*H9*)	L	Incompatible
	vH9	Compatible
	Uninfected	Control
Molly (*H13*)	L	Incompatible
	vH13	Compatible
	Uninfected	Control
Newton (S)	L	Compatible
	Uninfected	Control

Iris (*H9*) and Molly (*H13*) were infested with two biotypes: *L* (avirulent) and *vH9* or *vH13* (virulent). Newton was infested with biotype *L* (virulent). Three independent biological replicates were included for each treatment. The data obtained from each treatment were compared with the corresponding uninfested control within each wheat line under identical conditions.

collection was based on the biology that the third day is critical to determine whether a larva can live or will die on a specific plant (Byers and Gallun 1972). Only the tissue at the feeding site (about 1.5 to 2 cm) of the second leaf sheath was collected for RNA extraction. The *H9* seedlings infested with v*H9* or L were defined as *H9*-compatible (*H9*-C) or *H9*-incompatible (*H9*-I), respectively; the *H13* seedlings infested with biotypes v*H13* or L were defined as *H13*-compatible (*H13*-C) or *H13*-incompatible (*H13*-I), respectively. Seedlings of each wheat genotype under the same conditions but without infestation were used as uninfected control. Each experiment contained three independent sets of seedlings that were treated in the same way at different times in different chambers as biological replicates. A portion of the seedlings in each experiment was kept for phenotypic confirmation later.

Total RNA was extracted from wheat tissues by using TRI reagent™ according to the procedure provided by the manufacturer (Molecular Research Center, Inc., Cincinnati, OH, USA). The RNA samples were further purified through an RNease kit according to the manufacturer's instruction (Qiagen Inc., Valencia, CA, USA). The RNA concentrations were measured with a NanoDrop-1000 Spectrophotometer (NanoDrop Technologies, Wilmington, DE, USA). RNA was quantified using Agilent 2100 Bioanalyzer (Agilent, Foster City, CA, USA).

Microarray Hybridization and Data Analysis GeneChip® wheat genome arrays containing 61,127 probe sets were purchased from Affymetrix (Santa Clara, CA, USA). Labeling and hybridization on the wheat microarrays were performed according to the standard protocol provided by Affymetrix. (http://www.affymetrix.com/support/technical/manual/expression_manual.affx). After hybridization and washing, the arrays were scanned with an Affymetrix GeneChip Scanner 3000. Hybridization quality was verified by scaling factor, overall hybridization rate, and signal strength of several bacterial spike controls. The spike controls were hybridized with labeled targets in different concentrations resulting in particular ratios between different spikes.

Image acquisition, image setting, and raw data generation were done with Affymetrix GeneChip® Operating Software (GCOS). After alignment of the image settings for each chip, raw data were extracted and marked as "present" (well above the background), "marginal," or "absent" (similar to or below the background) under default settings. The overall target signal intensity of each chip was scaled to 500 and then loaded into GeneSpring GX 7.3.1 software (Agilent Technologies, Palo Alto, CA, USA) for further analysis. The data were prenormalized to the 50th percentile per chip and then normalized based on per-gene normalization with the median method, from which the signal of each gene in a particular sample was divided by the median signal of the same gene in all samples. In the subsequent paired comparison between the experimental treatment and the corresponding uninfected control, only those transcripts (genes) that were declared "present" for at least three out of six chips within a given triplicate comparison were retained for further analysis. The genes that showed significant changes in their expression in treated and control plants were selected by applying a *t* test (one-way analysis of variance with "Benjamini and Hochberg False Discovery Rate" for multiple comparisons, $P=0.05$). The fold-change values were calculated between the treatment and control samples on the basis of the normalized average measurement of the signal intensity. A cutoff value of twofold change, which is commonly used for microarray analysis (Eisen et al. 1998), was adopted to discriminate expression of genes that were differentially altered in response to HF infestation. Annotation of the genes represented on the microarray to genomic open reading frames was done with programs of HarvEST: Wheat v1.13 (http://www.harvest.ucr.edu/), Affymetrix NetAffx, and GeneSpring. The functions of the genes listed in Tables 3

to 8 were further manually updated by searching the GenBank with BLASTX. Cluster analysis was carried out according to Eisen et al. (1998) using the current version of Cluster/TreeView programs at http://www.rana.stanford.edu/clustering.

Northern Blot Validation and Correlation Analysis Five micrograms of total RNA of each sample were separated on 1.5% agarose gels that contained formaldehyde and were blotted onto GeneScreen membrane (Perkin Elmer, Boston, MA, USA). Membranes were baked at 80°C for 2 h to fix the RNA to the membrane, and then were hybridized with complementary DNA (cDNA) probes labeled with ^{32}P-dCTP using the random labeling kit from Stratagene (La Jolla, CA, USA), separately. Specific cDNAs used for generating probes were isolated through PCR amplification of reverse-transcripts derived from a messenger RNA (mRNA) sample purified from wheat sheath by using a pair of primers synthesized according to the corresponding expressed sequence tag sequences. Hybridization was carried out overnight at 42°C in a plastic bag containing 15 ml hybridization solution (10% dextran sulfate/1% sodium dodecyl sulfate (SDS)/1 M NaCl, pH 8.0) as described by Chen et al. (2004). After hybridization, the membranes were washed twice with 2× saline-sodium citrate (SSC) at room temperature for 30 min, twice with 2× SSC plus 1% SDS at 65°C for 30 min, and twice with 0.1× SSC plus 0.1% SDS at room temperature for 30 min. The membranes were then exposed to Kodak SR-5 X-ray film for 1 to 3 days, depending on signal intensity. Both autoradiographs and the 18S ribosomal RNA (rRNA) band on the negatives of the photographs of agarose gels used for Northern blot analysis were quantified by scanning laser densitometry with an Ultroscan XL laser densitometer and the GSXL2 software package (Pharmacia). Densitometry signals from exposed X-ray films were the average of the three readings.

Results

Overview Among a total of 61,127 probe sets contained in the microarrays, 25,246 (41%) produced detectable hybridization signals under our experimental conditions. To identify genes expressed differentially under various conditions, we use the twofold cut-off criterion, which is used in most studies. Among the 25,246 probe sets that produced detectable signals, 4,112 (16%) and 3,516 (14%) detected at least twofold changes (either up or down) between non-attacked and attacked *H9* plants and between non-attacked and attacked *H13* plants, respectively. The distribution of these differentially expressed genes during compatible or incompatible interactions is shown in Table 2. In general, the number of genes that were up-regulated was about three times greater than the number of genes that were down-regulated during both compatible and incompatible interactions. The number of genes that were either up- or down-regulated during compatible interactions was ~1.5 times greater than during incompatible interactions.

Comparative analysis of the differentially expressed genes identified 1,227 genes that were commonly affected in both *H9* and *H13* plants: 629 genes with altered expression during compatible interactions, 584 genes with altered expression during incompatible interactions, and 14 genes with altered expression during both compatible and incompatible interactions. Joint analyses of these commonly up- or down-regulated genes revealed six expression clusters (Fig. 1). Cluster I contained genes down-regulated during compatible interactions (Dc) and cluster II contained genes up-regulated during incompatible interactions (Ui). The altered expression of the genes in clusters I and II resulted in higher

Table 2 Distribution of genes expressed differentially in response to HF infestations

Fold Change	*H9-C*	*H13-C*	*H9-I*	*H13-I*
Up-regulated				
2~4	1,343	1,423	811	903
4~8	542	336	388	251
>8	404	136	273	147
Total	2,289	1,895	1,472	1,301
Down-regulated				
<1/8	56	28	10	51
1/8~1/4	139	74	36	59
1/4~1/2	557	394	322	251
Total	752	496	368	361

H9-C, *H13*-C, *H9*-I, and *H13*-I represent *H9*-compatible, *H13*-compatible, *H9*-incompatible, and *H13*-incompatible, respectively.

levels of expression during incompatible interactions than those during compatible interactions. The genes with known functions in clusters I and II mainly belong to six functional categories: antibiotic defense-related including protease inhibitors and defensins; phenylpropanoid metabolism-related including various *O*-methyltransferases, isoflavone

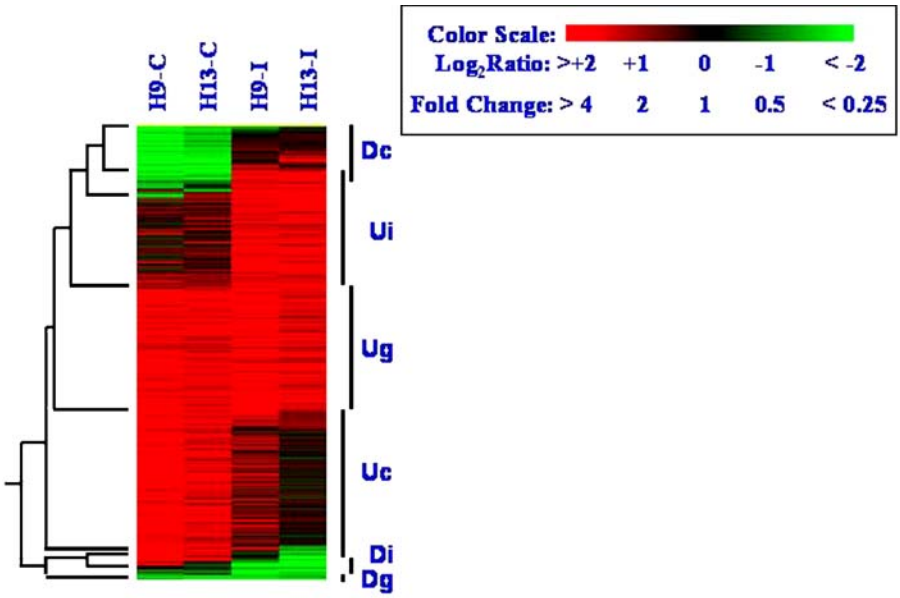

Fig. 1 Cluster display of genes expressed differentially during compatible and incompatible interactions. *H9-C, H13-C, H9-I*, and *H13-I* represent *H9*-compatible, *H13*-compatible, *H9*-incompatible, and *H13*-incompatible interactions, respectively. Six clusters were defined as *Dc* down-regulated during compatible interactions, *Ui* up-regulated during incompatible interactions, *Ug* up-regulated generally during both compatible and incompatible interactions, *Uc* up-regulated during compatible interactions, *Di* down-regulated during incompatible interactions, *Dg* down-regulated generally during both compatible and incompatible interactions. The cut-off for up- or down-regulation is ±2-fold

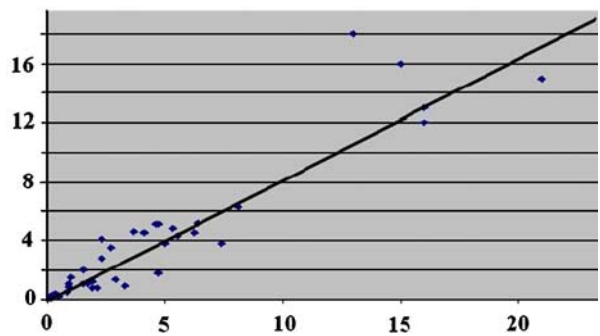
reductases, chalcone synthases, betanidin-*O*-glucosyltransferases, and flavanone 3-hydroxylases; lipid metabolism-related including lipid transfer proteins, lipases, and other enzymes; oxidation-related including glutathione transferases, peroxidases, and cytochrome P450; cell wall metabolism-related including cellulose synthases, xyloglucan endotransglycosylases (XET), glucanases, expansins, pectinesterases, and chitinases; and genes that encode various histones. Cluster III contained genes up-regulated during both compatible and incompatible interactions (Ug). Genes in this cluster are involved in various cellular processes including metabolism, transport, and regulation of gene expression and/or signal transduction. Cluster IV contained genes up-regulated during compatible interactions (Uc), and cluster V contained genes down-regulated during incompatible interactions (Di). The altered expression of the genes in clusters IV and V resulted in higher expression levels during compatible interaction than those during incompatible interactions. The genes with known functions in clusters IV and V mainly belong to three functional categories: genes involved in stress response, including various heat-shock proteins; genes involved in nutrient metabolism and transport; and genes involved in regulation and/or signal transduction. Cluster VI contained genes that were down-regulated during both compatible and incompatible interactions (Dg). There are only a few genes in this cluster.

Data Validation The microarray results were validated via Northern blots with two types of samples: the same RNA samples that were used for microarray analysis and newly prepared RNA samples from independent infestations. Fifty-two comparable pairs of microarray and Northern blot data sets were obtained from the same RNA preparations. The 52 data sets produced a 0.98 correlation ($P<0.001$) between microarray results and Northern blot data (Fig. 2). The high correlation suggests that the microarray data were reliable. Northern blots were also conducted with RNA samples prepared from independent infestations with multiple time points (Fig. 3). Again, the Northern blot results are generally in agreement with microarray data.

Analysis of Genes Responded Differentially to HF Attack We analyzed the genes that appeared to be major targets for differential regulation during compatible and incompatible interactions. These genes could be sorted into seven groups: genes involved in antibiotic defense, genes involved in the phenylpropanoid pathway, genes involved in cell wall metabolism, genes involved in lipid metabolism, genes involved in nutrient metabolism and transport, genes that encode histones and cellular structural proteins, and genes that encode heat-shock proteins and ubiquitins.



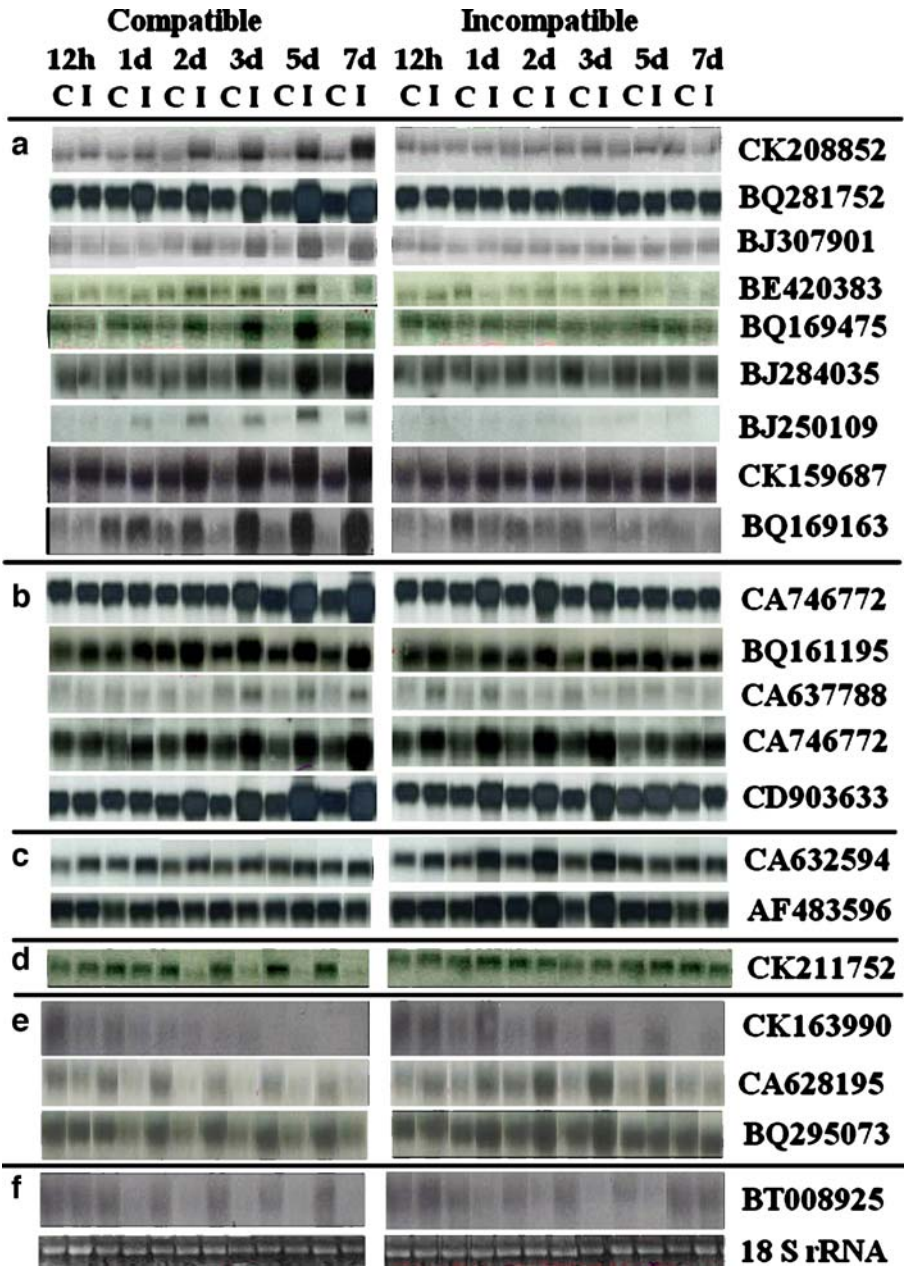


Fig. 2 Correlation analysis of microarray and Northern blot data sets. The same RNA samples were used in both microarray and Northern blot experiments

Genes Involved in Antibiotic Defense Table 3 lists genes that either encode proteins that are toxic to insects directly or encode an enzyme that participates in producing toxic molecules. The genes can be classified into three groups: genes that encode protease inhibitors (some of them also sharing sequence similarity with defensins or thionin), the genes that encode jacalin-like lectins or horcolins that have a jacalin-like lectin domain, and a gene that

◀ **Fig. 3** Northern blot analyses with RNA samples obtained from independent infestations. RNA samples were prepared from susceptible (compatible) and resistant (incompatible) plants at 12 h (*12h*), 1 day (*1d*), 2 days (*2d*), 3 days (*3d*), 5 days (*5d*), and 7 days (7d) after initial HF attack, respectively. *C* represents control plants whereas *I* presents infested plants. The accession numbers of cDNA probes were given on the *right side* of the figure. The image of 18 S rRNA was given to demonstrate relatively equal loadings. The blots were sorted into different groups: **a** genes up-regulated during compatible interactions, **b** genes up-regulated during both compatible and incompatible interactions, **c** genes up-regulated during incompatible interactions, **d** a gene down-regulated during compatible interactions, **e** genes down-regulated during compatible interactions but up-regulated during incompatible interactions, and **f** a gene down-regulated during both compatible and incompatible interactions. **b** Correlation analysis of Northern blot results and microarray data with 20 randomly selected cDNA probes

encodes a mandelonitrile lyase (an enzyme participating in hydrogen cyanide production). All these genes were expressed at least twofold higher levels during incompatible interactions than during compatible interactions.

Genes Involved in the Phenylpropanoid Pathway The first committed step in the biosynthesis of phenylpropanoids and other phenolic compounds is the conversion of L-phenylalanine to *trans*-cinnamic acid by phenylalanine ammonia-lyase (PAL; Rasmussen and Dixon 1999). Seven out of eight related cDNAs (with 65 to 96% sequence identity) that encode PALs were strongly up-regulated (4- to 46-fold) during both compatible and incompatible interactions (Table 4). The eighth one (BJ318940) was also up-regulated slightly during both types of interactions. The up-regulation patterns among the genes were different between compatible and incompatible interactions: Three of the cDNA probes detected lower levels of up-regulation during incompatible interactions (an I/C ratio 0.5 to 0.72), whereas the rest of the cDNA probes detected higher levels of up-regulation during incompatible interactions (an I/C ratio 1.35 to 2.7).

Table 3 Expression levels of genes that encode putative defense molecules

Gene ID	I/C Ratio	H9-C	H13-C	H9-I	H13-I	Putative Identification

Gene IDs are the accession numbers from GenBank. I/C ratio represents the ratio of average fold change between incompatible and compatible interactions. *H9-C*, *H13-C*, *H9-I*, and *H13-I* represent fold changes in *H9* compatible, *H13* compatible, *H9* incompatible, and *H13* incompatible interactions, respectively, in comparison with the corresponding controls.

Table legends are as defined in Table 3.

A group of enzymes called *O*-methyltransferases (OMT) participate in various steps in the phenylpropanoid metabolism pathway, including the step that converts caffeic acid into ferulic acid (Dixon et al. 2002). Ferulic acid is a substrate for the biosynthesis of lignin, an important component of cell-wall polymers. In contrast to PAL-encoding genes that were up-regulated during both compatible and incompatible interactions, all OMT cDNAs except two (BJ283780 and CA626582) detected strong down-regulation of the corresponding genes during compatible interactions. These OMT genes were either not affected or up-regulated during incompatible interactions. A combination of down-regulation during compatible interactions and up-regulation during incompatible interactions resulted in significant higher expression of these genes during incompatible interactions (I/C ratio 4 to 372) than that during compatible interactions. The two exceptions also exhibited different expression patterns: CA626582 exhibited a slight up-regulation during compatible interactions and a strong up-regulation during incompatible interaction, whereas

BJ283780 exhibited strong up-regulation during both compatible and incompatible interactions. Several other genes that encode enzymes involved in the metabolism of chalcone, flavonoids, isoflavonoids, and other secondary metabolites exhibited expression similar to those of patterns as the OMT genes during compatible and incompatible interactions.

Genes Involved in Cell-Wall Metabolism In general, enzymes involved in cell-wall loosening or in basic component synthesis exhibited higher expression levels during incompatible interactions than those during compatible interactions (IC ratio 1.5 to 151, Table 5). Enzymes involved in cell-wall loosening during growth include XET, β-expansin, pectinesterase, polygalacturonase, and endo-1,4-β glucanases (Cosgrove 2003). Enzymes involved in basic cell-wall component synthesis include cellulose synthase, eceriferum (CER1; involved in the conversion of long-chain aldehydes to alkanes, a key step in wax biosynthesis, Aarts et al. 1995), and dirigent, which participates in lignan and lignin biosynthesis (Davin and Lewis 2005).

On the other hand, several genes exhibited lower expression during incompatible interaction than that during compatible interactions (I/C ratio, 0.12 to 0.72, Table 4). These genes encode, respectively, pectin-glucuronyltransferase, which participates in synthesis of pectin (Iwai et al. 2002); pectinacetylesterase, which catalyzes the deacetylation of pectins (Vercauteren et al. 2002); xyloglucan fucosyltransferases involved in hemicellulose xyloglucan branching (Perrin et al. 1999); and arabinofuranohydrolase, which hydrolyzes arabinoxylan (Ferre et al. 2000).

Table legends are as defined in Table 3.

In addition to the genes listed in Table 5, several other genes are involved in cell-wall metabolism including chitinases, β-1,3-glucanases, glucan 1,3-β-glucosidases, and a xylanase inhibitor. These enzymes and enzyme inhibitors are typically associated with fungal cell-wall metabolism and may be used as defensive weapons by the plant against secondary fungal invasion.

Genes Involved in Lipid Metabolism Genes involved in lipid metabolism can be classified into five groups based on their encoding proteins: lipid transfer proteins; lipases; enzymes involved in the biosynthesis of fatty acids, wax, or phytohormones; enzymes involved in fatty acid degradation or energy metabolism; and enzymes involved in phospholipid metabolism (Table 6).

All lipid transfer protein genes exhibited higher expression during incompatible interactions than during compatible interaction (I/C ratio, 1.71 to 24.2). Similarly, all lipase genes except two (BG605132 and BJ272793) exhibited higher expression levels during incompatible interactions (I/C ratio, 1.77 to 8.92). The two exceptions, BG605132 and BJ272793, which encode a lipase-like protein and a triacylglerol lipase, respectively, exhibited lower levels of expression during incompatible interaction (I/C ratio, 0.315 and 0.806, Table 6). In addition, all the genes that encode enzymes involved in the biosynthesis of fatty acids, wax, or other substances also exhibited higher expression levels during incompatible interactions (I/C ratio, 1.46 to 24.166). In contrast, all genes with one exception involved in fatty acid degradation and phospholipid metabolism exhibited lower expression during incompatible interactions than during compatible interaction (I/C ratio, 0.105 to 0.887). The exception, CK213159, which encodes a lipoxygenase, was strongly up-regulated during both compatible and incompatible interactions with an I/C ratio of 1.2.

Genes Involved in Nutrient Metabolism and Transport Genes involved in nutrient metabolism and transport were expressed at much higher levels during compatible interactions than during incompatible interactions (I/C ratio from 0.04 to 0.75, Table 7). Most of the genes that encode metabolic enzymes and nutrient transporter were strongly up-regulated during compatible interactions but were not affected or even down-regulated during incompatible interactions.

Genes that Encode Histones and Cellular Structural Proteins Sixteen different histone genes, together with a histone acetyltransferase B gene, were consistently down-regulated during compatible interactions (Table 8). These histone genes either were not affected or were slightly up-regulated during incompatible interactions. The combination of down-regulation during compatible interactions and up-regulation during incompatible interactions resulted in significantly higher expression of these genes during incompatible interactions (I/C ratio, 2.28 and 7.78).

Although the genes that encode histones, the chromatin structural proteins, were down-regulated during compatible interactions, the genes that encode cellular structural proteins including actins and α-tubulin, were highly (2- to 22-fold) up-regulated during compatible interactions. The actin and tubulin encoding genes either were not affected or were only slightly up-regulated during incompatible interactions.

Genes that Encode Heat-Shock Proteins and Ubiquitins There were 12 differentially expressed genes that encode various heat-shock proteins (*HSP*; Table 8). During compatible interactions, all these *HSP* genes were expressed at higher levels than those during incompatible interactions (I/C ratio, 0.004 to 0.494). With one exception (AJ603283), all

these genes were up-regulated during compatible interactions, and some of them were dramatically up-regulated (up to 200-fold).

Another group of stress-related cDNAs, which encode ubiquitins or ubiquitin-pathway proteins, exhibited expression patterns similar to those of the heat-shock protein genes. These ubiquitin pathway genes exhibited higher expression levels during compatible interactions (I/C ratio, 0.048 to 0.861).

Discussion

Although resistance to insects has been identified in various plant species and is used extensively for the management of insect pests (Panda and Khush 1995; Quisenberry and Clement 2002), understanding of molecular events that contribute to this resistance is limited. Among plant–insect interactions, the molecular aspects of tomato resistance to aphids mediated by the *Mi-1.2* gene are the most extensively studied (Milligan et al. 1998; Rossi et al. 1998; Nombela et al. 2003). *Mi-1.2* confers resistance to both insects (aphids and white flies) and nematodes, and it contains the NBS-LRR structural motif common to many *R* genes that confer resistance to various pathogens. The fact that *Mi-1.2* confers resistance to taxonomically different parasites and that its product shares structural similarity with disease *R* genes suggests that recognition and activation of plant defense in response to attacks from insects, nematodes, and pathogens has been conserved throughout evolution.

However, because of differences in how parasites attack plants and obtain their nutrition, plant strategies for defense must, to some degree, be tailored to the specific parasite. Although *Mi-1.2* confers resistance to both nematodes and aphids, resistance to nematodes is effective in all growth stages of the plant and is associated with induction of hypersensitive response (HR), whereas resistance to aphids exists only in mature plants and is not associated with HR (Goggin et al. 2004; Bhattarai et al. 2007). Moreover, in crops other than tomato, *Mi-1.2* transgenic plants exhibit resistance to nematodes but not to aphids (Goggin et al. 2006). Clearly, the downstream events that lead to aphid resistance are different from those leading to nematode resistance. This makes sense, as nematodes and aphids have very different ways of obtaining nutrients from the plant.

The wheat–HF interaction is similar to a number of plant–pathogen interactions in that it shows features of gene-for-gene interactions between plant *R* genes and insect *Avr* genes (Ratcliffe and Hatchett 1997; Lobo et al. 2006). HF larvae are also similar to many pathogens in that they appear to secrete various effector proteins into plant cells (Hatchett et al. 1990; Chen et al. 2004, 2006; Harris et al. 2006). These common features indicate that the defense response of wheat to HF attack follows a similar molecular process in signal perception and transduction. Thus, the *R* product is part of the plant's surveillance system (Nimchuk et al. 2003; Chisholm et al. 2006; Dodds et al. 2006; Garcia–Brugger et al. 2006) and confers resistance by allowing the plant to mount early and effective defense. Early defense is especially necessary when the parasite creates a feeding tissue within the plant and also actively suppresses defense responses. The former has been shown to be the case with the virulent HF larva, which induces a feeding tissue (Harris et al. 2006) that is associated with the suppression of growth in the seedling (Anderson and Harris 2006).

Induced Susceptibility Vs Induced Resistance Based on the extensive published literature on the wheat–HF interaction (reviewed in Berzonsky et al. 2003; Harris et al. 2003) and the results of this study, a model for wheat–HF interaction is proposed (Fig. 4). By using a specialized pattern of attack (Rohfritsch 1992), HF larvae inject various substances into plant cells (Chen et al. 2004, 2006) and, thereby, elicit a range of physiological changes in the plant. During compatible interactions, these changes lead to the activation of susceptibility-related transcription regulators, which up-regulate the expression of genes involved in the metabolism and transport of nutrients, and down-regulate genes involved in cell-wall metabolism and in the synthesis of phenylpropanoids and other defense molecules. The larva, therefore, induces the plant to provide enhanced nutrition and to

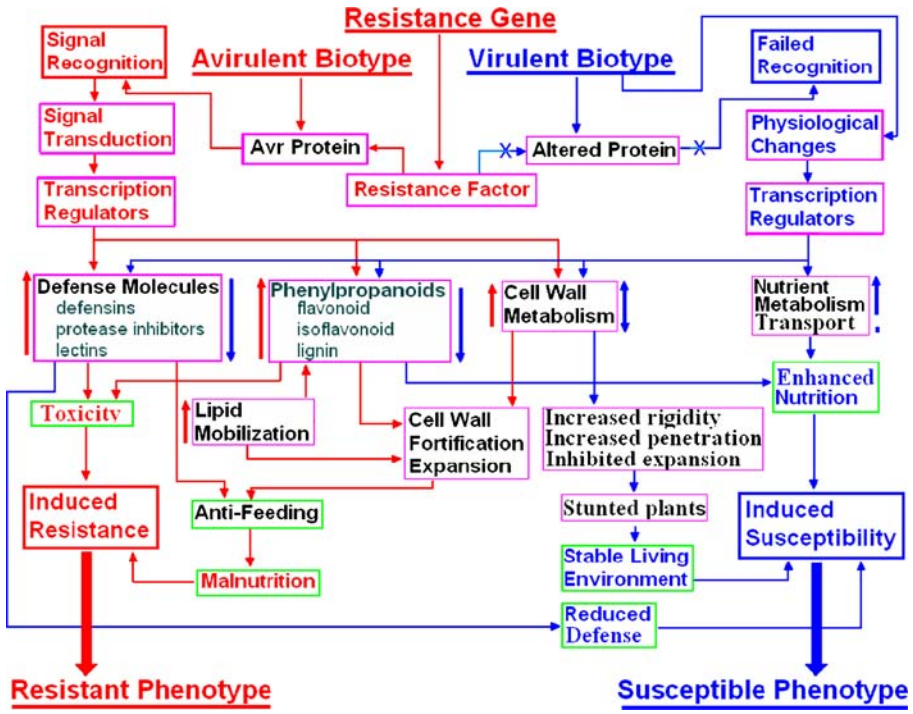

Fig. 4 A model for induced resistance vs induced susceptibility. During incompatible interactions, the recognition of an *avr* protein (produced by avirulent insects) by the resistance factor (encoded by an *R* gene) induces signal transduction and activates transcription, resulting in up-regulation (*arrow up*) of the pathways involved in antibiotic defense, phenylpropanoid synthesis, cell-wall expansion, and lipid mobilization. The up-regulation of these pathways results in increased toxicity and malnutrition, which constitute to host resistance. During compatible interactions, the resistance factor fails to recognize the (altered) protein produced by virulent insects. Instead, the invasion of the insect causes physiological changes in host plants, activating a different set of transcription regulators. These regulators up-regulate (*arrow up*) the pathways involved in nutrient metabolism, nutrient transport, and cell wall rigidity; and down-regulate (*arrow down*) the pathways involved in defense, phenylpropanoid synthesis, and cell-wall expansion. The combination of up- and down-regulation of these genes results in enhanced nutrition, stable living environment, and reduced defense, which contribute to host susceptibility

reduce exposure to plant defenses, i.e., the compatible interaction is actually a state of "induced susceptibility."

During incompatible interactions, the process begins when the wheat *R* protein detects HF attack by recognizing one or more of the secreted HF elicitors (*Avr* protein). This initiates a rapid defense response through a cascade of signal transduction, leading to the activation of defense-related transcription regulators. This, in turn, induces changes in gene expression in various pathways. As a result, the resistant plant prevents "induced susceptibility" by (1) not allowing the elevated production and transport of nutrients to the larval attack site, (2) producing plant defense chemicals, (3) fortifying the cell wall at the larval attack site, and (4) restoring normal plant growth. Taken together, these plant defense responses prevent the larva from obtaining nutrients from the plant, and the larva dies without changing in size. The prevention of susceptibility manipulation and enhanced defense constitute "induced resistance" during incompatible interactions.

Molecular Basis for Induced Susceptibility

Enhanced Nutrition During compatible interactions, enhanced larval nutrition results from better food quality and increased nutrient flow. Evidence for improved food quality came from the strong up-regulation of genes involved in nutrient metabolism, including genes involved in carbohydrate degradation such as α-glucosidase (BQ169475) and neutral invertase (BQ170874); genes in glycolysis and the citric acid cycle such as enolase (CK208852), pyruvate dehydrogenase (CD903633), and oxidoreductases (BE446498, BQ161195, CA657311); and genes in amino acid synthesis such as aspartate aminotransferase (CA653416) and methionine synthase (BJ250109) (Table 6). The up-regulation of the carbohydrate degradation enzymes indicated that more carbohydrates were degraded. The up-regulation of enzymes in glycolysis and the citric acid cycle, and in the pathways for amino acid synthesis indicated that some of the degraded carbohydrates were converted into intermediates for amino acid synthesis. This observation is consistent with the finding that HF attack causes dramatic shift from carbon-containing compounds to nitrogen-containing compounds during compatible interactions (Zhu et al. 2007). The increase in amino acids should result in better food quality for HF larvae.

Evidence for increased nutrient flow came from the strong up-regulation of genes that encode various transporters, including genes encoding general sugar transporters (CD931721, BJ320954, BJ275570), glucose transporters (CD892342, BJ231104), a myo-inositol transporter (BQ171988), ammonium transporters (BT009318, CA601803), and amino acid transporters (BJ275567, CA737017, CA638660, CK205233, BJ286275, BT009250; Table 6). The up-regulation of these transporters should facilitate nutrient flow from other parts of the plant to the HF feeding site.

Reduced Defense In contrast to the up-regulation of genes involved in nutrient metabolism and transport, genes involved in plant defense were down-regulated during compatible interactions (Tables 3 and 4). For example, five out of the seven protease inhibitor genes were significantly down-regulated during compatible interactions. Two of them (BJ316836 and BJ314399) were completely suppressed. Plant protease inhibitors are toxic to insect digestive systems (Murdock et al. 1988). HF larvae use various proteases including trypsins, chymotrypsins, and carboxypeptidases for food digestion (Zhu et al. 2005; Liu et al. 2006). The lower expression of protease inhibitor genes indicated weaker antibiotic defense.

Altered Phenylpropanoid Metabolism The strong down-regulation of many genes involved in the phenylpropanoid pathway during compatible interactions indicated that the phenylpropanoid pathway was crucial for induced susceptibility. However, the exact mechanism of phenylpropanoid-related susceptibility remains unknown. All of the PAL genes were highly up-regulated in both compatible and incompatible interactions (Table 3), indicating that more L-phenylalanine was converted to *trans*-cinnamic acid in both cases. But most of the downstream genes that convert cinnamates into other phenylpropanoids, including caffeic acid *O*-methyltransferases (COMT), a dirigent (DT), a chalcone synthase (CHS), a flavanone 3-hydroxylase (F3H), betanidin-5-*O*-glucosyltransferases (BOGT), flavonoid 7-*O*-methyltransferases (Fl-OMT), an isoflavone *O*-methyltransferase (IOMT), and an isoflavone reductase (IRT), responded differently to HF attack during compatible and incompatible interactions. These genes were down-regulated during compatible interactions, but they either were not affected or were up-regulated during incompatible interactions.

The combination of up-regulation of PAL and down-regulation of the downstream genes during compatible interactions indicated that there was more accumulation of cinnamic acid. If that was the case, it would be interesting to know the biological impact of cinnamic acid on HF larvae. One possibility for the accumulated cinnamic acid is to be converted into cinnamic acid derivatives via alternative pathways (Dixon et al. 2002). High concentration of cinnamic acid derivatives might benefit HF larvae because of their antioxidant activity (Natella et al. 1999). The down-regulation of the downstream genes also indicated lower concentration of other phenylpropanoids such as chalcone, flavonoids, isoflanoids, and lignin. Many of these phenylpropanoids may be toxic to insects. For example, isoorientin, an abundant flavonoid in wheat, is toxic to corn earworm larvae (Widstrom and Snook 1998). The lower concentration of toxic phenylpropanoids again indicated weaker antibiosis during compatible interactions.

Cell-Wall Weakening and Growth Inhibition Lower concentrations of some phenylpropanoids such as lignin could also have a negative impact on cell-wall fortification and expansion because they are also cell-wall components. By coincidence, genes that encode enzymes that are in the pathways for the biosynthesis of other cell wall components, such as cellulose (cellulose synthase) and wax (CER1), were also down-regulated during compatible interactions (Table 5). In addition, genes that encode enzymes involved in cell-wall loosening (a necessary process for cell-wall expansion, Cosgrove 2003), such as XET, β-expansin, endo-1,4-β glucanases, pectinesterase, and polygalacturase, were also down-regulated during compatible interactions. Lower expression of the genes in the biosynthetic pathways for cell-wall components and loosening were consistent with the inhibition of cell-wall fortification and expansion during compatible interactions. Weaker cell wall could facilitate insect feeding.

While lower expression of genes in the biosynthetic pathways for cell-wall components and loosening were consistent with the inhibition of cell wall fortification and expansion, there were, however, several genes that exhibited up-regulation during compatible interactions. The up-regulated genes included the genes that encode a pectin-glucuronyltransferase (pectin synthesis), a pectinacetylesterase (pectin deacetylation), two xyloglucan fucosyltransferases (hemicellulose xyloglucan branching), and an arabinofuranohydrolase (hemicellulose hydrolysis). The relevance of the up-regulation of these genes to the inhibition of cell-wall fortification and expansion remains to be elucidated. It is possible that an increase in pectin and hemicellulose content and in xyloglucan branching can increase the rigidity of the cell wall, thus, inhibiting cell-wall expansion. Phenotypically, the growth of host plants is irreversibly inhibited during compatible interactions, whereas the overall growth of host plants is not significantly affected during incompatible interactions (Byers and Gallun 1972; Anderson and Harris 2006).

Molecular Basis for Induced Resistance

Prevention of Elevated Production and Transport of Nutrients The mechanism for induced resistance mediated by *R* genes appears to be the prevention or reversal of events leading to susceptibility. The prevention of elevated production and transport of nutrients might be an important mechanism for *R* gene-mediated resistance. This could be seen from the fact that the genes involved in nutrient metabolism and transport exhibited much lower expression during incompatible interactions than that during compatible interactions (Table 7). The I/C ratio for the 12 nutrient metabolic genes ranged from 0.105 to 0.751, and the I/C ratio for the 14 transporter genes ranged from 0.04 to 0.704. Many

other nutrient metabolic genes that were not included in the microarray were also up-regulated strongly during compatible interactions, but were either not affected or down-regulated during incompatible interactions according to Northern blots that use probes derived from wheat-related species such as rice or corn (Zhu et al. 2007). The lower expression of genes involved in nutrient metabolism and transport could effectively limit nutrients available to HF larvae at the attacking site, thus, inhibiting larval growth and development.

Enhanced Antibiosis Evidence for increased defense in resistant plants came from the elevated expression of the genes that encode molecules toxic to insects. For example, several genes that encode protease inhibitors exhibited significant higher expression during incompatible interactions (Table 3).

In addition to protease inhibitors, a group of genes that encode lectins or lectin-like proteins, including *Hfr-1*, *Wci-1*, and *Hfr-3*, had been previously reported as up-regulated strongly during incompatible interactions, and, therefore, were proposed to be involved in wheat defense against HF (Williams et al. 2002; Subramanyam et al. 2006; Giovanini et al. 2007). Lectins have been also reported to have antifeedant effects on other insects (Moreno et al. 1990; Peumans and Van Damme 1995). In this research, five lectin or lectin-like genes, including the previously idenfied *Hfr-1*, were up-regulated strongly during incompatible interactions (Table 3). The strong up-regulation of these lectin genes indicated that they were likely to have played a role in wheat antibiotic defense.

Phenylpropanoids and other phytochemicals are also defense molecules produced by plants when under attack (Dixon et al. 2002). As mentioned earlier, the up-regulation of the PAL genes during both compatible and incompatible interactions indicated more conversion of L-phenylalanine to *trans*-cinnamate. During incompatible interactions, cinnamate might have been converted into chalcones, flavonoids, isoflavonoids, lignin, and other phenylpropanoids because many genes that encode downstream enzymes that convert cinnamates into these phenylpropanoids were up-regulated, including COMT, CHS, F3H, BOGT, Fl-OMT, and IOMT. Higher concentration of toxic phenylpropanoids during incompatible interactions should also enhance antibiosis.

Cell-Wall Fortification and Plant-Growth Restoration Cell-wall fortification plays a major role in plant resistance to pathogens (Hammond-Kosack and Jones 1996). Cell-wall fortification may also play a critical role in wheat resistance to HF larvae. Most of the genes involved in biosynthesis of cellulose (cellulose synthase), wax (CER1), and lignin (dirigent), and the genes involved in cell-wall loosening and expansion, including xyloglucan endotransglycosylases, β-expansins, pectinesterases, and glucanases, were up-regulated strongly during incompatible interactions (Table 5). The up-regulation of these genes is favorable for cell-wall fortification and expansion. The fortification of the cell wall could play a role in anti-feeding by inhibiting HF larvae to establish feeding sites. The continuous expansion of cell wall might accelerate the restoration of plant growth after some initial growth inhibition during incompatible interactions (Anderson and Harris 2006).

Other Changes during Compatible and Incompatible Interactions

Histones and Other Cellular Structural Proteins The genes that encode various histones and a histone acetyltransferase were consistently down-regulated during compatible

interactions. The down-regulation of the histone genes could be a result of reduced cell division because the levels of histone mRNAs are believed to be regulated through rapid degradation in non-dividing cells (Kaygun and Marzluff 2005). Alternatively, the lower expression levels of histone genes could be caused by the differentiation of nutritive cells (Harris et al. 2006). Whether the down-regulation of the histone genes is the cause or the result of wheat growth inhibition during the compatible interactions will have to be determined in future experiments. Although the genes that encode histones (the chromosomal structural proteins) were down-regulated during compatible interactions, the genes that encode cellular structural proteins including actins and α-tubulin (usually up-regulated in growing tissues) were significantly up-regulated during compatible interactions. The growth of susceptible plants was completely inhibited during compatible interactions. While evidence suggested that actins and tubulins may be involved in plant defense against pathogens (Kobayashi et al. 1997; Kobayashi and Hakuno 2003), the biological significance of up-regulation of actin- and tubulin-encoding genes during compatible interactions in our experiments remains to be resolved. One possibility is that more actins and tubulins are needed to fortify the cells mechanically in non-dividing tissues to withstand mechanical damages caused by HF larvae.

Greater Stress Response During Compatible Interactions In terms of gene regulation, there was much greater stress response to HF infestation during compatible interactions than during incompatible interactions. Many genes that encode various heat-shock proteins were dramatically up-regulated during compatible interactions, whereas these genes were not affected or even down-regulated during incompatible interactions (Table 8). A similar phenomenon was also observed with several genes that encode ubiquitins or ubiquitin-pathway enzymes. In addition, many other genes that encode other stress proteins, such as dehydrins, wound-inducible proteins, and cold-responsive proteins, were also dramatically up-regulated during compatible interactions. Again, these stress genes, with only a few exceptions, were not significantly affected during incompatible interactions. The greater stress response during compatible interactions may simply be a reflection of greater stresses upon susceptible plants, which were completely taken over by the HF larvae with plant metabolism totally redirected to feed the larvae (Anderson and Harris 2006; Harris et al. 2006). Some of the stress genes might also be linked with host susceptibility. Many of the known host plant *R* genes in wheat are temperature-sensitive. Resistant wheat plants that carry a temperature-sensitive *R* gene become susceptible at higher temperature. Whether there is a relationship between these stress proteins and temperature sensitivity of host-plant resistance will need further investigation.

Acknowledgment This work was supported by two grants from the National Research Initiative Competitive Grant program, the US Department of Agriculture (USDA 04-35607-14861 and USDA2005-35302-16254). This paper is contribution no. 07-81-J from the Kansas Agricultural Experiment Station. Hessian fly voucher specimens (no. 150) are located in the KSU Museum of Entomological and Prairie Arthropod Research, Kansas State University, Manhattan, Kansas. The microarray chips were processed with the Affymetrix GCS 3000 system in the Gene Expression Facility, Kansas State University. The system was purchased through the NSF Major Research Instrumentation grant DBI-0421427. The authors thank Dr. Subbaratnam Muthukrishnan, Dr. Guihua Bai, and Dr. Scot Hulbert for reviewing an earlier version of the manuscript. considering more than one generation. Thus, cyanide-containing precursors can have negative effects even on herbivores adapted to feed on cyanogenic plants.

Keywords Herbivory · Chemical defense · Plant–herbivore interaction · Generalist · Specialist · Lima bean · *Phaseolus lunatus* · Cyanogenic glycosides · Mexican bean beetle · *Epilachna varivestis*

Introduction

Plant cyanogenesis is considered a direct plant defense against herbivores and means the release of hydrogen cyanide (HCN) from damaged plant tissues (Poulton 1990). More than 2,500 species of vascular plant taxa belonging to over 130 families are cyanogenic (Møller and Seigler 1999). As HCN is toxic to the plant itself, nontoxic cyanide-containing precursors are synthesized and stored in compartments, spatially separated from specific enzymes (β-glucosidases and α-hydroxynitrile lyases) required for their degradation and the following release of HCN (Selmar et al. 1989). In lima bean, the glycosidic precursors linamarin and lotaustralin accumulate in the vacuoles (Frehner and Conn 1987). Specific β-glucosidases are located in the apoplast, whereas α-hydroxynitrile lyases are membrane-associated (Conn 1981; Selmar et al. 1987, 1989).

The release of HCN occurs only in disintegrated tissue. Although cyanogenesis is generally regarded as a constitutive mechanism, recent studies on lima bean have demonstrated an induced component: β-glucosidases involved in the release of HCN from cyanide-containing compounds were activated in response to herbivore damage (Ballhorn et al. 2006).

There is increasing evidence that plant cyanogenesis or cyanogenic glucosides deter generalist, but not specialist, herbivores (Jones 1988; Patton et al. 1997; Ballhorn et al. 2005). Strongly cyanogenic plants are protected from generalists (Viette et al. 2000; Ballhorn et al. 2005) but nevertheless can be attacked by specialists (Benson et al. 1976; Davis and Nahrstedt 1987). Generally, specialist or oligophagous herbivores with restricted host ranges are able to tolerate or to detoxify defensive compounds of their respective host plants because of physiological or behavioral adaptations (Rausher 1996; Agrawal and Kurashige 2003; Agrawal and Van Zandt 2003). In some cases, they even use the toxic plant compounds for their own defense (Bowers and Stamp 1997; Dobler et al. 1998), and other cases are known, in which cyanogenic glycosides act as phagostimulants for herbivores adapted to cyanogenic plants (Lapidus et al. 1963).

Studies conducted so far on specialists that live on cyanogenic plants have shown that, in principle, they can develop on such plants (Beesley et al. 1985; Engler et al. 2000; Urbańska et al. 2002). Nevertheless, whether or not specialists are quantitatively affected by cyanogenic features of their hosts remains elusive (Miguel and Alberto 2005). Long-term studies are lacking on the quantitative dependence of parameters relevant to fitness, such as growth rates, developmental period, and success of reproduction itself, as quantitatively depending on cyanogenic features of host plants.

The present study was conducted to fill this gap in functional understanding of distinct cyanogenic components. We studied quantitative effects of cyanogenic precursor concentration (HCNp, cyanogenic potential) and cyanogenic capacity (HCNc; release of gaseous HCN per unit time) on Mexican bean beetle (Coleoptera: Coccinellidae: *Epilachna varivestis* Mulsant).

We analyzed several fitness-relevant parameters over four consecutive generations of beetles (the performance of all four larval stages, the duration of pre-pupation and pupal

stages, and the body mass at emergence, and total reproduction) in different experimental settings by using selected plants with well-defined cyanogenic properties (Ballhorn et al. 2005, 2006, Ballhorn and Lieberei 2006). Based on significant differences in their HCNp, we grouped lima bean accessions into high cyanogenic (HC) and low cyanogenic (LC) plants. This set of experimental plants allowed us to quantify effects of plant cyanogenic features on the performance of beetles.

Materials and Methods

Plants and Insects The lima bean (Fabaceae: *Phaseolus lunatus* L.) is an obligate cyanogenic plant of Mesoamerican and Andean origin (Baudoin et al. 1991). We used lima beans of 12 accessions (11 domesticated lines and 1 wild-type native to Cuba) characterized by different cyanogenic features. Seeds were provided by the Institute of Plant Genetics and Crop Plant Research (IPK) in Gatersleben, Germany. For further description of plant material, see Ballhorn et al. (2006). In addition, snap bean *Phaseolus vulgaris* cv. Saxa (Carl Sperling, Lüneburg, Germany, stock number 40.176), hereafter referred to as "Saxa," was used as a non-cyanogenic control.

The Mexican bean beetle (Coccinellidae: *E. varivestis* Muls.) is an oligophagous insect that feeds on a range of legumes (Barrigossi et al. 2001) but with distinct preference for *Phaseolus* species (Dover et al. 1988) and especially lima bean (Flanders 1984; Baudoin et al. 1991). As feeding of the beetle is stimulated by cyanogenic glycosides even in artificial diets, an adaptation to diets containing these compounds can be assumed (Lapidus et al. 1963). Mexican bean beetle is native to southern Mexico as are lima beans of the Mesoamerican gene pool. The life cycle of the beetles encompasses four larval stages followed by a short pupal stage of 5–10 days. Females deposit eggs in clutches of 40–75 on the lower surface of host plant leaves, and both larvae and adults feed on foliage.

Rearing of Plants and Insects Plants were cultivated under greenhouse conditions (16:8 L/D with a photon flux density of 350–450 μmol s^{-1} m^{-2} at the plant container and 850–950 μmol s^{-1} m^{-2} on top of the plants depending on natural radiation). Additional light was provided by 400 W high-pressure sodium lamps (Son-Targo 400, Philips®). To avoid effects by hot spots under the lamps, position of plants was changed every 3 days. Temperature (25/20°C) and ambient relative air humidity (60–70%) were controlled by Intergro® software. Plants were fertilized with a nitrogen–phosphate fertilizer (Blaukorn®-Nitrophoska®-Perfekt, Compo GmbH) twice a week (3 mg per pot) and were cultivated in plant containers 18 cm diameter in a 1:1 ratio of standard substrate (TKS®-1-Instant, Floragard®) and sand (grain size 0.5 – 2.0 mm). Plants (N=12 per accession) were grown from seeds obtained by self-fertilization of a single mother plant.

Beetles were maintained on "Saxa" to prevent them from developing preferences for any particular *P. lunatus* accession. In addition, large numbers of beetles (>250 per accession) were maintained on plants of all 12 lima bean accessions used in the feeding trials. Ambient conditions adjusted for both maintenance cultures of insects and feeding experiments were identical.

Analysis of Leaf Quality Individual leaves of all accessions were used for analysis of cyanogenic features (HCNp, β-glucosidase activity, and HCNc) and nutritive traits (soluble

protein and total phenolics). Young trifoliate leaves (N=12 leaves per accession, N=1 leaf per plant) fully unfolded for 5–7 days were selected for the experiments as described in Ballhorn et al. (2006). One randomly selected leaflet of each trifoliate leaf was cut along the midrib. One half was used for HCNp analysis, the other half for the determination of soluble protein concentration and β-glucosidase activity. The remaining two leaflets were used for quantification of HCNc and total phenolics.

Cyanogenic potential (HCNp) was analyzed by complete enzymatic degradation of cyanogenic glycosides, and HCN released from cyanogenic precursors was spectrophotometrically quantified (585 nm) by using the Spectroquant® cyanide test (Merck, Darmstadt, Germany) following Ballhorn et al. (2005). External β-glucosidase isolated from rubber tree (Euphorbiaceae: *Hevea brasiliensis*) was added to ensure complete degradation of cyanogenic precursors. This enzyme showed high affinity to cyanogenic glycosides in lima bean and was isolated following Ballhorn et al. (2006).

Cyanogenic capacity (HCNc) was measured as gaseous HCN released into the atmosphere per unit time after leaves were treated with chloroform. We used an air-flow system (7 l air min^{-1}) for detection of the HCNc as described in Ballhorn et al. (2005).

Soluble protein concentration was quantified according to Bradford (1976). Leaf material was homogenized in ice-cold sodium acetate buffer (pH 5.0). Leaf extracts were centrifuged (Heraeus®Biofuge Fresco, 13,000 rpm, 4°C), and the supernatant was filtered over NAP™ columns containing Sephadex™ G-25 DNA-Grade (GE Healthcare Bio-Sciences AB). Subsequently, 5 µl of the eluate were pipetted on microplates (96-well Microplates, PS, F-bottom, Greiner Bio-One GmbH, Maybachstr. 2, 72638 Frickenhausen, Germany), and 250 µl Bradford reagent (diluted with aqua dest. in the ratio 1:4) were added. Protein concentration of samples was spectrophotometrically quantified at 595 nm (Spectra MAX 190 PC, Molecular Devices). BSA solutions (Merck, Darmstadt, Germany) in the range between 10 and 300 µg ml^{-1} served as standard.

Activity of β-glucosidase was measured according to Ballhorn et al. (2006). We used *p*-NP-glucoside (Merck) as chromogenic artificial substrate. The released *p*-nitrophenol was quantified spectrophotometrically at 400 nm (Pharmacia Biotech, Ultraspec 3000).

Total phenolics were analyzed following Tikkanen and Julkunen-Tiitto (2003). Homogenates of leaves were extracted three times for 15 min while stirring in 50-ml acetone diluted with aqua dest. (60:40). After each extraction, samples were incubated in an ultra sonic bath (3 min) and were finally centrifuged for 10 min at 5,000×g. The supernatant was transferred in 2-ml concentrated acetic acid (Merck), acetone was removed in vacuum (60 mbar) at 40°C, and the residue was quantitatively transferred by using aqua dest. Samples were diluted with 2.5% acetic acid, and 1 ml of this solution was mixed with 0.5 ml Folin–Ciocalteus phenol reagent (Merck). After adding 2 ml 20% Na_2CO_3, the solution was made up to 10 ml with aqua dest. Samples were incubated at 70°C and, after cooling, spectrophotometrically quantified at 730 nm against a blank containing water instead of sample. Epicatechine (Sigma, Deisenhofen, Germany) served as standard.

Feeding Trials Beetles' performance on leaves of *P. lunatus* accessions was analyzed in no-choice long-term feeding experiments. Males and females were considered separately due to inter-sex variability in weight gain. These experiments included four consecutive generations. Freshly hatched larvae (N=11 per generation) were individually placed on single detached leaves supplied with water (perforated Eppendorf tubes). Feeding trials were carried out in petri dishes (9.5 cm) lined with slightly moist filter paper to avoid wilting of leaf material under controlled conditions (25/20°C, photon flux density of

200 μmol s^{-1} m^{-2} in a 16:8 L/D period). Leaf material was renewed daily, and larvae were weighed daily until pupation. At the end of the assays, body weight and sex of the freshly emerged beetles were documented.

In these long-term experiments, trans-generational effects were also considered. The reproduction of beetles on different bean accessions was analyzed by pooling freshly emerged female beetles in a cage that contained four intact plants of the respective accession. Male beetles that emerged in the same experiment were immediately exchanged against freshly emerged males from large maintenance populations of Mexican bean beetles (>250 beetles per accession). These populations were kept for the same time period on the same lima bean accessions that were used in the feeding trials. These "external" males were added to the females in a 1:1 sex ratio. Number of males added depended on number of females that emerged in the experiment. By this procedure, we avoided creating a family bias on the different accessions, which otherwise might have led to artificial effects of development of different beetle genotypes. Eggs produced by the beetles were removed from plants by cutting leaf discs around the attached egg clutches. Eggs were incubated until hatching under identical ambient conditions that were adjusted for long-term feeding trials. The number of eggs and of hatched larvae was documented for all egg clutches. Because females started oviposition simultaneously and there were constant intervals of 8–9 days between productions of egg clutches per female, these clutches were assigned as consecutive clutches (1, 2, and 3) in this pooled experimental setup. A part of the progeny (N=11 randomly selected larvae per accession) was used for the next generation again, which was studied under the same experimental conditions as mentioned above.

In these long-term experiments, detached leaves were used. Detached leaves are sensitive to changes in leaf biochemistry depending on degradation processes of cell components. These processes can lead to a spontaneous release of gaseous HCN from leaf material, which complicates quantitative analysis of cyanogenesis and its impact on herbivore performance. Therefore, to test for losses of HCN during the experimental period, water-supplied leaves were placed in an air-flow system according to Ballhorn et al. (2005) under ambient conditions identical to those used for feeding experiments, and released HCN from leaf material was measured quantitatively. No loss of HCN from leaves was detected.

Larval Efficiency of Food Utilization We calculated three parameters of food utilization efficiency (Farrar et al. 1989; Anaya et al. 2003; Jallow et al. 2003). Relative growth rate (RGR) was calculated as: biomass gained (mg fresh weight)/[duration of feeding period (days) × mean fresh weight (mg) of larvae during feeding period]. The relative consumption rate (RCR) estimates the weight of food consumed relative to time and mean weight of the insect during the feeding period and was calculated as: food ingested (mg dry weight)/[duration of feeding period (days) × mean fresh weight (mg) of larvae during feeding period]. The efficiency of conversion of ingested food (ECI) estimates the percentage of ingested food that is converted to biomass. It was calculated as: [biomass gained (mg fresh weight)/food ingested (mg dry weight)] × 100.

The experiments were carried out in Petri dishes (9.5 cm). We used larvae of the third instars between days 6 and nine from hatching and leaf discs (2.73 mm diameter), which were exchanged daily. Two discs per setup were cut from two randomly selected leaflets of one trifoliate leaf, each from one leaflet. Positions on the lamina at which the discs were removed were the same for both leaflets. One disc was used for the feeding trial; the other was dried at 45°C to constant weight for determination of dry matter and leaf mass per unit

leaf area (LMA). Leaf discs cut for the feeding trials were put on moist filter paper and then were placed in the air-flow system according to Ballhorn et al. (2005) before the experiment. Leaf discs were used for feeding trials when no more gaseous HCN was released from the cutting edge (5–10 min after cutting). Release of gaseous HCN from leaf discs by wilting during the feeding trial was avoided by placing leaf discs on moist filter paper in the Petri dishes. We tested for spontaneous loss of HCN over the experimental period from leaf discs in the same way as described for long-term feeding trials with intact detached leaves.

After the feeding trial, remaining leaf material was dried at 45°C and weighed to the nearest 0.001 mg. Dry weight equivalents of food consumed by individual larvae were obtained by multiplying the daily wet weight of food consumed by percentage dry matter in each diet (Waldbauer 1968). The remaining third leaflet of the leaf was used for analysis of cyanogenic precursor concentration (HCNp) to check for constancy in precursor concentrations of leaves actually used in feeding trials, as compared to leaves that were used for analysis of leaf quality of the respective accessions before.

Statistical Analysis Differences in HCNp, HCNc, and nutritive components, i.e., soluble protein concentration and total phenolics among lima bean accessions and differences in beetles' performance on different accessions, were analyzed by one-way analysis of variance (ANOVA) and *post hoc* comparisons (HSD). The effects that different accessions of lima bean, i.e., plants with different HCNp, had on egg production were consequently analyzed with a repeated measures ANOVA design on a balanced subset of data created by randomly selecting four females per generation/accession/clutch number-combination after testing the assumption of sphericity with Mauchly's test. Data comprised four consecutive generations of beetles and three consecutively laid egg clutches per generation. Statistical analyses were carried out by use of Statistical Package for the Social Sciences (SPSS) 13.0 (SPSS for Windows, SPSS, Chicago, IL, USA).

Results

Leaf Quality Lima bean accessions showed distinct differences in leaf HCNp (Table 1). The three accessions with the highest (high cyanogenic, HC) and the lowest concentration of cyanogenic precursors (low cyanogenic, LC) were used (Table 1).

The difference in HCNp between HC- and LC-plants was significant (one-way ANOVA; $F_{173}=500.57$, $P<0.001$). In addition to HCNp, HCNc was highly variable among the accessions that were used for feeding experiments, depending on cyanogenic precursor concentration and activity of specific endogenous β-glucosidases. For instance, accession 2116 was characterized by the highest concentration of cyanogenic precursors, yet showed low HCNc due to a low activity of β-glucosidase (Table 1).

In contrast to cyanogenic features, total phenolics and concentration of soluble protein in leaves and LMA did not differ significantly among the accessions (Table 1).

Body Mass of Beetles Substantial inter-sex variability in beetles' body mass was observed among HC- and LC-plants. Females showed higher body mass compared to males independent of plant cyanogenic features (HC: $F_{1,12}=102.56$, $P<0.001$; LC: $F_{1,13}=82.18$, $P<0.001$; "Saxa": $F_{1,44}=69.31$, $P<0.001$). Thus, male and female beetles were considered

[a] Values shown for leaf characteristics are means (±SD; N=12 individual plants per accessions). Significant differences between accessions were calculated by a *post hoc* test (Tukey's HSD; $P<0.001$) after one-way ANOVA and are indicated by different letters in parentheses.

[b] Accessions used for feeding trials (data for HCNp presented also in Fig. 1)

[c] Accession WT represents lima bean, *P. lunatus*, wild type (Cuba) with small seeds and leaves.

[d] Saxa represents *P. vulgaris* cv. Saxa

separately (Fig. 1). Male and female adults had significantly lower body mass at emergence when larvae had developed on HC-plants as compared to LC-plants and "Saxa", whereas beetles that had developed on LC-plants showed no significant differences in body mass compared to beetles whose larvae had fed on "Saxa" (Fig. 1). Body mass of male and female beetles on plants of the same accessions did not vary significantly among four consecutive generations. In contrast to clear effects of high HCNp on beetles' body mass, variation of HCNc in the group of high HCNp plants had no significant effect on adult weight. Beetles feeding on the accession 2116 (high HCNp, low HCNc) showed no differences in body mass compared to the other two HC-plants, accession 2357, and to lima bean wildtype (WT), which were characterized by high HCNp and HCNc (males: $F_{2.611}=2.23$, $P=0.117$; females: $F_{2.512}=0.734$, $P=0.485$).

Development of Beetles The developmental period of individual beetles was affected quantitatively by HCNp concentrations. Among HC-plants, larval feeding period, pre-pupation phase (larvae attached to leaves but not yet pupated), and pupal dormancy were significantly prolonged on HC-plants as compared to LC-plants and non-cyanogenic "Saxa" (Table 2). We found no significant differences in phase length between LC-plants and "Saxa" in any of the beetles' life cycle phases. In contrast to strong quantitative effects of HCNp, no difference in performance and reproduction of beetles among HC-plants depending on quantitative variation of HCNc were observed. Females produced at least three egg clutches in intervals of 8–9 days. Females kept laying eggs after 27 days, but these eggs were often deformed and were not positioned in distinct clutches. Thus, only the first three egg clutches were included in analyses of reproduction.

Egg clutch sizes, i.e., the numbers of eggs per clutch, significantly depended on generation and clutch number and on plant accession (Table 3). Interactions between all these factors indicate that the intergenerational effect depended on the accession on which beetles developed and that the strength of the intergenerational effect was different among the consecutively produced egg clusters (Table 3). In fact, the differences between HC- and LC-plants were already visible in the first generation but became more prominent in the following generations (Fig. 2). In particular, the third clutches became consecutively smaller in beetles reared on HC-plants, whereas no such effect was visible in beetles reared on LC-plants, or "Saxa". Consequently, *post hoc* analysis (LSD) grouped the three HC-accessions in one group that was significantly different from the three LC-accessions and

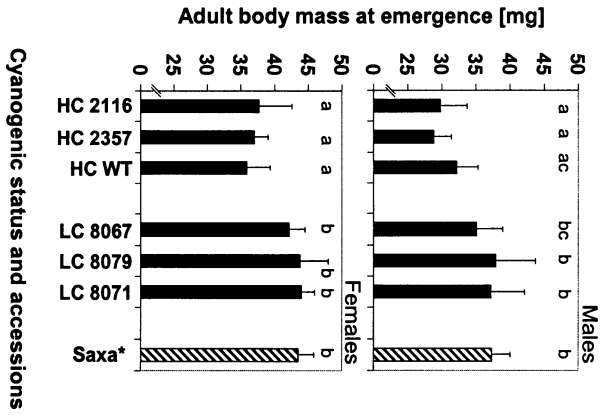

Fig. 1 Adult body mass at emergence. Body mass of male and female beetles, which had developed on lima beans with different HCNp (*HC* high cyanogenic, *LC* low cyanogenic, see Table 1) was measured. Values are means (±SD) among beetles of four consecutive generations (for number of replications see Table 2). Significant differences between groups were calculated by a *post hoc* test (Tukey's HSD; $P<0.001$) following one-way ANOVA and are indicated by different letters. Saxa* (= *P. vulgaris*), no HCN detected

Table 2 Effects of host plant cyanogenic status on developmental phases in beetles' life cycle

Accessions	Cyanogenic Status	Sex	*N*	Larval Feeding Period (day)	Pre-pupation Period (d)	Pupal Dormancy (d)
2116	HC	♂	23	18.1 ± 1.0^{ab}	3.0 ± 1.0^{a}	8.3 ± 0.8^{b}
2357	HC	♂	27	19.0 ± 0.4^{a}	3.1 ± 0.3^{a}	7.4 ± 0.8^{ab}
WT	HC	♂	25	19.0 ± 1.1^{a}	2.8 ± 0.7^{ab}	7.5 ± 1.1^{ab}
8067	LC	♂	22	17.5 ± 1.0^{bc}	1.8 ± 0.6^{c}	6.3 ± 0.6^{de}
8079	LC	♂	20	16.9 ± 0.9^{bc}	2.0 ± 0.4^{bc}	5.6 ± 0.8^{cd}
8071	LC	♂	22	16.6 ± 1.0^{c}	2.2 ± 0.6^{bc}	5.3 ± 0.5^{c}
Saxa	Non-cyanogenic	♂	21	16.8 ± 1.0^{c}	2.0 ± 0.6^{c}	6.7 ± 0.7^{ae}
2116	HC	♀	21	18.1 ± 0.6^{a}	3.0 ± 0.4^{a}	8.1 ± 0.6^{a}
2357	HC	♀	15	18.6 ± 0.5^{a}	3.1 ± 0.4^{a}	6.7 ± 0.5^{b}
WT	HC	♀	18	18.8 ± 1.1^{a}	2.5 ± 0.6^{ab}	7.8 ± 0.9^{a}
8067	LC	♀	21	17.9 ± 1.1^{ac}	2.0 ± 0.7^{b}	6.1 ± 0.8^{bc}
8079	LC	♀	24	17.0 ± 0.6^{bc}	1.9 ± 0.5^{b}	5.6 ± 0.6^{c}
8071	LC	♀	20	16.4 ± 0.9^{b}	2.0 ± 0.6^{b}	5.3 ± 0.7^{c}
Saxa	Non-cyanogenic	♀	22	17.1 ± 0.5^{bc}	2.2 ± 0.4^{b}	6.5 ± 0.6^{b}

Differences in performance of beetles depending on host plant accessions characterized by different HCNp (*HC* high cyanogenic, *LC* low cyanogenic) were tested using a *post hoc* test (Tukey's HSD) following one-way ANOVA. Different letters indicate significant differences in developmental period among beetles of four consecutive generations ($P<0.001$). Values shown for developmental periods are means (±SD).

"Saxa". Over four generations, larval hatching was also negatively affected by high host plant HCNp (Fig. 3).

Efficiency of Larval Food Utilization Indices of food utilization differed significantly among beetles on beans with different HCNp (Table 4). Larvae reared on HC-plants ($N=33$ larvae) showed an increased consumption rate and a reduced ECI into insect biomass compared to larvae reared on LC-plants (RCR: $F_{1,63}=19.126$, $P<0.001$; ECI: $F_{1,63}=83.820$, $P<0.001$; $N=55$). The RGR was reduced on HC-plants compared to LC-plants ($F_{1,63}=117.67$, $P<0.001$). We found no significant differences in all three parameters between the LC-plants and "Saxa" ($N=11$ larvae). The variation of HCNc in the group of HC-plants had no effect on beetles' food utilization.

Table 3 Intergenerational effects on clutch size

	Sum of Squares	*df*	*F*	*P* value
Within-subject effects				
gen	2,513.390	3	9.557	<0.001
gen × acc	7,205.881	18	4.567	<0.001
clu	39,629.720	2	160.523	<0.001
clu × acc	3,381.113	12	2.368	0.020
gen × clu × acc	3,829.994	6	5.760	0.000
	8,924.173	36	2.240	0.001
Between-subject effects				
Acc	15,087.619	6	9.262	<0.001

Effects of generation (*gen*) and clutch number (*clu*) as well as accession (*acc*) on clutch size (i.e., number of eggs per clutch) were tested by using a repeated measures ANOVA after confirming that there was no significant deviation from sphericity (tested with Mauchly's test). Four consecutive generations and three clutches per female were considered and generation and clutch were therefore included as within-subject variables, whereas lima bean accession served as between-subject variable.

Fig. 2 Eggs per clutch. Female beetles produced three egg clutches in each of the reproductive cycles between the feeding trials [total number of clutches per generation (gen): *gen 1* N=120; *gen 2* N=99; *gen 3* N=96; *gen 4* N=108]. Missing clutches were considered as 0. Values shown for number of eggs per clutch are means. For statistical analyses of effects on clutch size (i.e., number of eggs per clutch) such as beetle generation, clutch number, and accession of host plants see Table 3. Plants with different cyanogenic status were used for the experiments (*HC* high cyanogenic, *LC* low cyanogenic). Saxa* (= *P. vulgaris*), no HCN detected

Discussion

Defenses mediated by secondary plant compounds are generally believed not to affect specialist herbivores due to their capacity to tolerate or to detoxify defensive compounds of their host plants by behavioral or physiological adaptations (Rausher 1996; Zagrobelny et al. 2004). The specialist herbivore paradigm predicts that adapted herbivores—including oligophagous herbivores with restricted host range—are less affected by a given chemical defense as compared to generalists (Van Der Meijden 1996; Van Dam et al. 2000). However, the observation that a herbivore can develop successfully on a given host plant—or even that it prefers this particular host plant under artificial or natural conditions—does not necessarily mean that it is not affected negatively by some of its host plant's chemical defenses at higher thresholds, which actually occur in nature (Agrawal and Kurashige 2003).

To study such effects, quantitatively, we used an oligophagous herbivore, the Mexican bean beetle (*E. varivestis*), and reared it on different accessions of cyanogenic lima bean (*P. lunatus*), its preferred natural host plant species. The plants significantly differed in their cyanogenetic traits: Three accessions were characterized by concentrations of 64.7 to 76.5 μmol HCN g^{-1} fw (high-cyanogenic, HC) bound in cyanogenic precursors, whereas the "low cyanogenic" (LC) accessions had 7.3 to 18.5 μmol HCN g^{-1} fw.

In spite of its specialization on lima bean, concentration of cyanide-containing compounds significantly affected several fitness-relevant traits of the beetles. Larvae feeding on HC-leaves showed prolonged developmental times (Table 2) and gained less weight per time, although food intake rates were even higher on HC- than on LC-leaves (Table 4). Consequently, the conversion efficiency was lower on HC- than on LC-leaves (Table 4). As longer developmental times were not sufficient to compensate for lower growth rates, the average weight of adult beetles was lower on HC- than on LC-leaves (Fig. 1). Although male and female beetles differed in weight gain, both a reduced total body weight and a lowered larval and pupal performance were significant for both sexes.

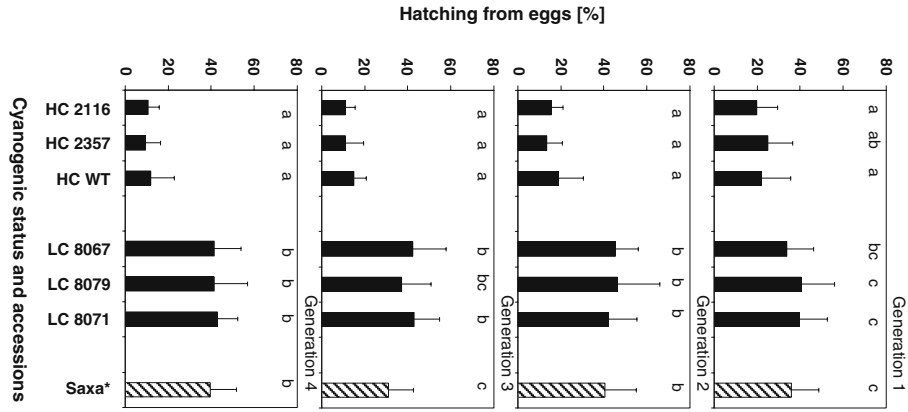

Fig. 3 Number of larvae per female beetle and generation. Hatching of larvae on different lima bean accession was observed over four consecutive generations of beetles. Values are means (±SD) of percentage hatching of larvae including eggs from all three clutches laid per female (N=141 female beetles). Significant differences between groups were calculated by a *post hoc* test (Fishers LSD; P<0.001) following one-way ANOVA and are indicated by different letters. Plants with different cyanogenic status were used for the experiments (*HC* high cyanogenic, *LC* low cyanogenic). Saxa* (= *P. vulgaris*), no HCN detected

The effects of defensive compounds and/or products released from these compounds on insect growth depend strongly on the background variation in nutritive leaf traits (Slansky and Wheeler 1992). For example, compensatory feeding on low nutritive diets increases the intake of defensive compounds, and the availability of growth-limiting nutritive compounds may thus modify the effects of chemical defense (Simpson and Raubenheimer 2001; Haukioja 2003). In the present study, we compared HC- and LC-accessions of the same species and can exclude other factors that may vary strongly among different plant species. Yet, we also quantified the most important nutritive and defensive traits of the food plants, i.e., soluble protein concentration and total phenolics, as well as leaf mass per area, which means an approximate measure for crude fiber content. None of these traits differed significantly among young leaves of the accessions (Table 1). Additional analyses indicate that there was no variation of the digestible sugar concentration in leaf developmental stages among the accessions studied (unpublished data). Differences observed among beetles reared on HC- and LC-accessions resulted from differences in plants cyanogenic features.

The quality of resources encountered during development can have effects on individual performance and on reproductive success (Janzen 1977; Fox et al. 1995; Ojeda-Avila et al. 2003). Reproductive success is even more relevant than growth rates, as it directly determines fitness. Females that had been reared as larvae and that were feeding as adults on HC-leaves produced significantly fewer eggs than females on LC-leaves (Fig. 2; Table 3). This effect intensified with every consecutive generation. It was also observed in different episodes of oviposition within a single generation. Females of the fourth generation that had developed consecutively on HC-plants produced smaller second clutches than comparable females that had developed on LC-plants or “Saxa” plants. Fourth generation females from HC-plants rarely produced a third egg clutch (Fig. 2). The size of the first clutches, in contrast, was affected.

The quality of eggs was affected by the type of food utilized by females. Eggs laid by females that fed on HC-leaves hatched at lower rates than those laid by females that fed on

Table 4 Indices of consumption, growth, and food utilization

Accession	Cyanogenic Status	Relative Growth rate (mg)	Relative Consumption Rate (mg)	Efficiency of Conversion of Ingested Food (mg)
2116	HC	0.26 ± 0.09^{b}	0.42 ± 0.07^{a}	63.20 ± 16.98^{b}
2357	HC	0.28 ± 0.07^{ab}	0.37 ± 0.09^{ab}	78.19 ± 26.30^{ab}
WT	HC	0.25 ± 0.04^{b}	0.34 ± 0.07^{ab}	76.24 ± 22.25^{ab}
8067	LC	0.42 ± 0.05^{c}	0.31 ± 0.05^{b}	142.33 ± 35.11^{c}
8079	LC	0.38 ± 0.13^{ac}	0.29 ± 0.07^{b}	136.04 ± 26.19^{c}
8071	LC	0.43 ± 0.06^{c}	0.29 ± 0.08^{b}	160.86 ± 53.76^{c}
Saxa	Non-Cyanogenic	0.39 ± 0.06^{c}	0.33 ± 0.08^{b}	123.14 ± 23.39^{ac}

Larvae were reared on leaves of different *P. lunatus* accessions. Values shown for different performance efficiency are means (±SD). Letters indicate significant differences calculated by a *post hoc* test (Tukey's HSD; $P<0.001$) after one-way ANOVA.

LC-leaves or "Saxa" leaves (Fig. 3). This effect appeared to be cumulative and became stronger with each successive generation. So far, such long-term effects of cyanogenesis have been underestimated in analyses of herbivore–plant interactions. However, our study suggests that the long-term effects of cyanogenic features on herbivores must be considered. Future studies should reassess the potential costs arising from host plant defensive traits even on specialist herbivores.

We did not carry out a comparative study between a specialist and a generalist. Thus, we cannot exclude in this study that a generalist herbivore would be affected more severely by cyanogenic features of lima beans. However, negative long-term effects of host plant cyanogenic features on the specialized Mexican bean beetle were definitive. Although negative long-term effects of host plant cyanogenesis were established, the exact physiological mechanism by which this effect is mediated is unclear. Cyanide may interfere with P450 cytochromes involved in final steps of cell respiratory pathways or it may affect nutrient availability for the insects by inhibition of digestive enzymatic activities (Solomonson 1988). As we did not create a balance between cyanide incorporated in bound form as cyanogenic precursors and cyanide released during the feeding process of beetles, we cannot tell in what way the insects came into contact with inhibitory concentrations of cyanide. However, previous studies with the generalist herbivore *Schistocerca gregaria* (Ballhorn et al. 2005) showed that even lima beans with high concentrations of cyanide-containing precursors and highly active β-glucosidase—and therefore rapid and substantial release of gaseous HCN as a reaction to insect feeding—released only about 5–20% of the HCN present as precursors in the consumed leaf material. Thus, as observed in this study, feeding on all high HCNp plants should result in substantial incorporation of cyanide in bound form. The incorporation of intact precursors and the subsequent release of HCN within the gastrointestinal tract by herbivore-internal β-glucosidases appear to be the most harmful way to contact plant cyanide (Ballhorn et al. 2005; Amelot et al. 2006).

In summary, our results demonstrate that the Mexican bean beetle, although being an oligophagous species, is still quantitatively affected by its host plant cyanogenic features. As variation of HCNc among plants that contain high amounts of cyanogenic precursors did not result in differences in food utilization, development, or reproduction, the HCNp is the crucial cyanogenic parameter that affects performance of Mexican bean beetles.

Keywords Toxic nectar · Secondary compounds · Terpenoids · Honeybees · Deterrence · Toxicity

Introduction

Apart from sugars and amino acids, secondary compounds such as phenolics, alkaloids, and terpenoids are of widespread occurrence in nectar (Baker and Baker 1982; Nicolson and Thornburg 2007). Thus far, studies of toxic nectars have focused on the possible fitness benefits to the plants that produce them (Adler 2000) rather than on the sensitivity of natural floral visitors to the nectars. Rhoades and Bergdahl (1981) argued that the ability of specific pollinators to tolerate toxic or repellent compounds would serve as a coevolutionary mechanism to exclude nectar thieves and encourage legitimate pollinators. Adler's (2000) review of toxic nectar emphasized that there have been, first, many studies on the chemistry of secondary compounds in nectar and, second, many demonstrations of nectar toxicity to honeybees (in which the responsible compounds are usually not identified). Less common, however, are studies in a third category: those that make the link between chemistry and toxicity by presenting nectar toxins in sucrose solutions to pollinators in the field (Stephenson 1982; Masters 1991; Hagler and Buchmann 1993; Singaravelan et al. 2005; Liu et al. 2007).

The efficient recruitment behavior of honeybees ensures that good nectar sources are exploited rapidly: colonies focus on the best nectar sources in a large area by working relatively few patches at any one time and making frequent adjustments to the number of foragers at those patches (Visscher and Seeley 1982). The response of bees to a particular nectar depends on the ecological context, especially other available nectar sources (Gegear et al. 2007). This is an important consideration for experiments that involve feeder choices in a natural environment. In a classic study, Lindauer (1948) showed that the threshold sucrose concentration for eliciting recruitment behavior in honeybees declined from ~55% w/w during the main nectar flow in spring to around 3.5% in mid-summer when bee forage became scarce and competition was intense.

During periods of dearth, colonies of honeybees have a considerably more restricted range of plant choices, and in the course of the seasons, they are inevitably forced by floral circumstances to readjust their threshold of nectar acceptability. It is in this context of natural dearth in southern China that honeybees, *Apis cerana*, forage on the toxic nectar of a perennial vine, *Tripterygium hypoglaucum* (Level.) Hutch (Celastraceae). Powdered roots of this plant, also known as Lei Gong Teng ('Thunder God Vine'), have been used in traditional Chinese medicine for 2,000 years, and the main active ingredient is a potent diterpenoid, triptolide (Zhen et al. 1995; Qiu and Kao 2003; Brinker and Raskin 2005; Brinker et al. 2007). In this paper, we report the results of experiments on the foraging sensitivity of honeybees to the honey of this plant and its toxicological effects, and assess whether the bees alter their nectar acceptability threshold under conditions of dearth.

Methods and Materials

The toxic honey of *T. hypoglaucum* was collected from five *A. cerana* colonies in Yaoan county, Yunnan Province, China in June 2006, when *T. hypoglaucum* was one of only very few plants providing nectar for foraging insects. Pollen grains from both *T. hypoglaucum* flowers and the honey derived from this plant species were examined microscopically to confirm their common origin.

Determination of Triptolide The concentration of triptolide in honey derived from *T. hypoglaucum* was measured by using high-performance liquid chromatography (HPLC), preceded by a solid-phase extraction step. A 25-g sample of toxic honey was placed in a centrifuge tube with 40 ml water, and when it was completely dissolved, 40 ml ethyl acetate and 30 ml petroleum ether were added to the honey solution. The sample was treated ultrasonically to accelerate dissolution and then centrifuged for 10 min at 3,000 rpm. Finally, the supernatant was transferred to another centrifuge tube and was re-extracted with 30 ml ethyl acetate and 20 ml petroleum ether. The supernatant was concentrated in a rotary evaporator, and the residue was redissolved in ethyl acetate and filtered with 20 ml ethyl acetate through a neutral aluminum column, which was immersed in ethyl acetate. The eluant was collected and concentrated to dryness, then dissolved in 1 ml methanol and filtered through a 0.45-μm millipore membrane.

For standard solutions, 2.5 mg of triptolide (Medical Research Institute, Fujian Province, China, Fig. 1) were dissolved in 5 ml methanol to obtain a 0.5 mg/ml solution and kept at 4°C. Chromatographic conditions were as follows: Symmetry® C18 column (4.6×150 mm, 5 μm), acetonitrile–water (30:70) as the mobile phase, flow rate of 1 ml/min, detection at a wavelength of 218 nm, and sample size of 20 μl. The same method was used to test for triptolide in the honey of *Vicia sativa* L. (Fabaceae) and *Elsholtzia ciliata* (Thunb.) Hyl. (Lamiaceae): three samples were tested for each species.

Cage Tests To establish toxicity of the *T. hypoglaucum* honey samples, six groups of 40 young adult worker bees were collected randomly from one beehive and placed into each of six cages. A test group of three cages were given toxic honey as food and a control group of three cages received normal honey as food. Honey and powdered sugar were mixed (1:1) to make the cake to feed the bees. Cages were kept in an incubator at 25°C and 70% relative humidity. The number of dead bees in each cage was counted three times a day for 6 d.

Feeder Experiments Honeybee foraging preferences for normal and triptolide honey were tested in a series of experiments. A feeder containing 30% w/w sucrose solution was placed on a small square of blue board, 15×15 cm, at the entrance of an *A. cerana* observation hive. When a few foraging workers had been lured to it and had begun to imbibe the solution, the feeder and bees were moved to a site 5 m away. After having consumed

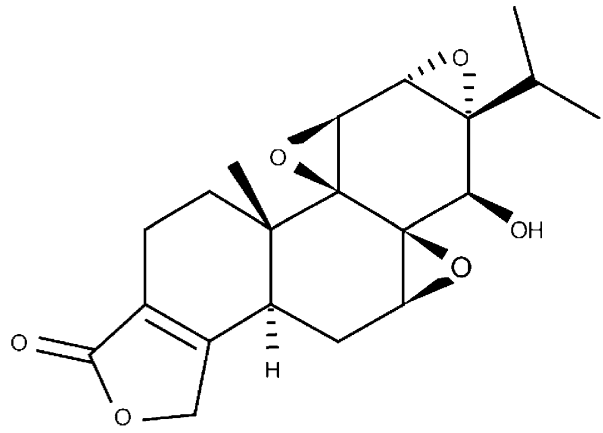

Fig. 1 Structure of triptolide

sufficient sucrose solution, these bees returned to their hive, and about 15 min later, additional, newly recruited foragers arrived at the feeder. At this point, we began to use paired feeders (A and B), which were placed at the same site. Visiting frequencies (the number of bees visiting in 10 min) and imbibition times of individual bees (sec) were recorded at both feeders. The ambient temperature was around 25°C during these tests.

Initially, both feeders (A and B) contained the same 30% sucrose solution. Then, the position of the feeders was reversed, and recordings continued for three more exchanges of position to assess whether there might be a position bias in the bees' responses. We then compared honeybee responses to the toxic honey of *T. hypoglaucum* and the nontoxic normal honeys of *V. sativa* and *E. ciliata* (all diluted 1:3 with water). We also compared the responses to 30% sucrose solution, with and without added triptolide at a concentration of 0.6 μg/g. This triptolide concentration is higher than in the diluted honey of *T. hypoglaucum*, but additional toxic compounds are likely to be present in the honey. All test solutions were of a similar sugar concentration, thus excluding effects of viscosity on imbibition time. Finally, we simulated the dearth conditions under which the bees actually forage on *T. hypoglaucum* by removing the normal honey and measuring responses to *T. hypoglaucum* honey alone.

Statistical Analysis Data are presented as mean±SD. Pearson χ^2 tests were used to test for significant differences in the percentage mortality of worker bees between the control and test groups. Log-linear *G* test analysis was used to test for homogeneity of mortality rates within the groups (Sokal and Rohlf 1995).

Analysis of variance (ANOVA) procedures with dependent samples (feeders A and B) were used to test for significant group effects in the visiting frequencies and imbibition times of foragers. Levene's test was used to test for homogeneity of the variances, and heterogeneity of the variances was stabilized after a square–root transformation of the visiting frequencies. Scheffé post-hoc multiple comparison tests were used for significant group effects. In one comparison, small sample size necessitated the use of a Mann–Whitney *U* test. All tests were performed by using Statistica© (StatSoft 2006).

Results

Determination of Triptolide Pollen grains from both *T. hypoglaucum* flowers and the honey derived from these flowers were examined, and it was confirmed microscopically that the honey had the same pollen grains as the flowers.

In the HPLC tests, 20, 10, 5, 2, and 1 μl of the authentic triptolide solution (0.5 mg/ml) were run to obtain the standard chromatogram for the pure compound. Using the peak area as the ordinate and concentration as the abscissa, a regression equation (y=2,511,038x+ 165,934, r=0.999) was obtained demonstrating linearity over the range of 1–20 μg/g. Repeated HPLC analyses of the authentic toxin established that the relative standard deviation (RSD) of the peak area was 2.63%. Samples (20 μl) of the toxic *T. hypoglaucum* honey were injected three times, with a 30-min run. The results showed that the retention time and the peak area were both stable; the RSD of the peak area was 0.61%. Triptolide was present in honey at a concentration of 0.61±0.11 μg/g (n=5) but was absent from the honeys of *V. sativa* and *E. ciliata*.

Cage Tests The toxicity of *T. hypoglaucum* honey was reflected in the numbers of dead bees in each cage. The results showed that significantly more worker bees in the test group (toxic honey) died within 6 d (68.3±25.0%) compared to the control group with nontoxic *E. ciliata* honey, where only 15.8±12.3% died (χ^2=67.9, *df*=1, *P*<0.001). The mortality rates were homogeneous among the cages in the control group (*G* test: G^2=4.5, *df*=2, *P*=0.107), while in the test group (*G* test: G^2=15.3, *df*=2, *P*<0.001), two cages were homogeneous, but in one cage a large number of bees (22) died on the sixth day.

Feeder Experiments When both feeders A and B contained 30% sucrose, Scheffé post-hoc results showed no significant differences in the visiting frequencies and imbibition times of foragers visiting the feeders (number of visits in 10 min: A=145.1±41.9, B=143.7±42.1, *N*=9 replicates; imbibition times: A=26.2±10.2 sec, B=27.8±13.6 sec, *N*=20 bees; Scheffé: *P*>0.05). This establishes that there was no position bias in the worker bees.

Subsequent tests measured selectivity in the foraging behavior of worker honeybees for the test groups (*T. hypoglaucum*, sucrose solution with triptolide) and control groups (*V. sativa* and *E. ciliata* honeys, sucrose solution only). ANOVA showed significant differences in the visiting frequencies and imbibition times of foragers between the control and test groups (number of visits: $F_{1,\ 24}$=72.3, *P*<0.001, Fig. 2; imbibition times: $F_{1,\ 115}$=43.0, *P*<0.001, Fig. 3) and significant group and food type interaction effects (number of visits: $F_{4,\ 24}$=13.1, *P*<0.001, Fig. 2; imbibition times: $F_{4,\ 115}$=6.6, *P*<0.001, Fig. 3).

Post-hoc test results showed that visiting frequencies to the feeders with normal honey were significantly higher than to those with toxic honey (*V. sativa*=275.3±75.6 bees per 10-min period, *T. hypoglaucum*=54.2±29.4, and *E. ciliata*=304.0±179.3, *T. hypoglaucum*=118.8±75.8, all *N*=6; Scheffé: *P*<0.001, Fig. 2). Likewise, the imbibition times of foragers at the feeders with normal honey were longer than at those with toxic honey (*V. sativa*=24.6±

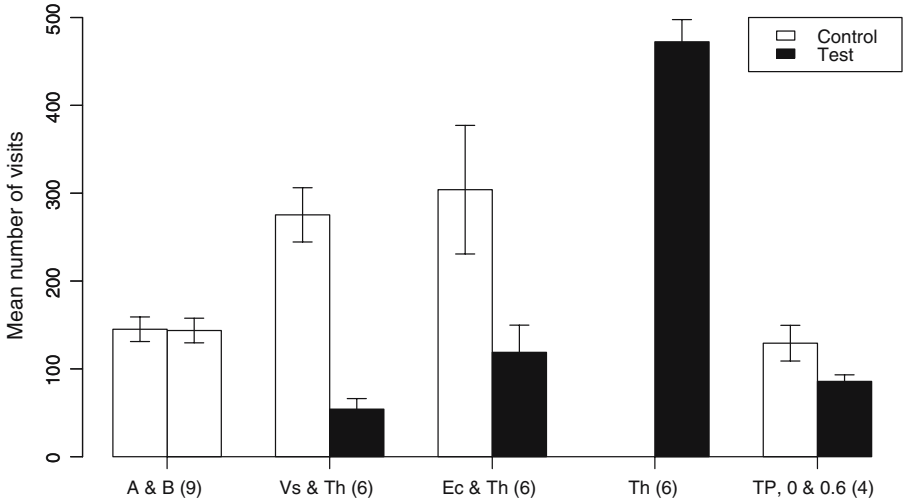

Fig. 2 Bee visits to feeders (10-min counts, means±SE, number of replicates in *parentheses*). In all cases, the control food is shown by *clear bars* and the toxic food by *black bars*. *A & B* Identical feeders containing 30% w/w sucrose solution, *Vs & Th* honeys of *Vicia sativa* and *Tripterygium hypoglaucum*, *Ec & Th* honeys of *Elsholtzia ciliata* and *Tripterygium hypoglaucum*, *Th* honey of *Tripterygium hypoglaucum.* All honeys were diluted 1:3 with water. *TP, 0 & 0.6* 30% sucrose solution and the same solution containing 0.6 μg/g triptolide

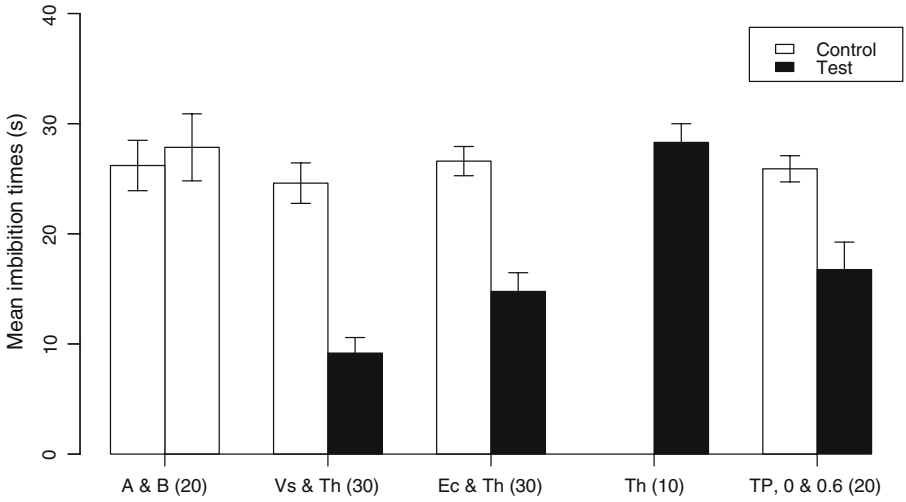

Fig. 3 Imbibition times (sec, means±SE, number of bees in *parentheses*). In all cases, the control food is shown by *clear bars* and the toxic food by *black bars*. *A & B* Identical feeders containing 30% w/w sucrose solution, *Vs & Th* honeys of *Vicia sativa* and *Tripterygium hypoglaucum*, *Ec & Th* honeys of *Elsholtzia ciliata* and *Tripterygium hypoglaucum*, *Th* honey of *Tripterygium hypoglaucum.* All honeys were diluted 1:3 with water. *TP, 0 & 0.6* 30% sucrose solution and the same solution containing 0.6 μg/g triptolide

10.1 sec, *T. hypoglaucum*=9.2±7.7 sec, and *E. ciliata*: 26.6±7.3 sec, *T. hypoglaucum*=14.8±9.3 sec, all N=30; Scheffé: P<0.001, Fig. 3).

There were significant differences in the visiting frequencies of foragers to feeders that contained sucrose solution with and without triptolide (normal=129.2±40.6, triptolide=85.7±14.9, N=4; Mann–Whitney: U=1.0, P=0.043). There was likewise a significant difference in imbibition times (normal=25.9±5.3 sec, triptolide=16.7±11.1 sec, N=20; Scheffé: P=0.050).

When the feeder of normal honey of *E. ciliata* was removed from the feeding site, leaving only the feeder of toxic *T. hypoglaucum* honey, within a few seconds, all of the foraging bees landed and began to imbibe the toxic honey. The visiting frequency and imbibition period increased significantly, reaching and even exceeding levels previously recorded at the feeder of normal honey (ANOVA: visits [N=6]=472.3±61.9, $F_{2,\ 15}$=13.5, P<0.001; imbibition times [N=10]=28.3±5.3 sec, $F_{2,\ 47}$=16.3, P<0.001). Post-hoc test results showed a significant increase in mean visiting frequencies and imbibition times of foragers at the feeders with toxic honey after *E. ciliata* honey was removed (visits, Scheffé: P<0.001; imbibition times, Scheffé: P<0.001) but no significant difference in mean visiting frequencies and imbibition times between toxic honey after *E. ciliata* was removed and normal honey when toxic honey was also present (visits, Scheffé: P=0.077; imbibition times, Scheffé: P=0.923).

Discussion

Terpenoids, especially monoterpenoids such as linalool, are common constituents of floral scent (Raguso and Pichersky 1999), and it is usually assumed that their presence in nectar is due to passive acquisition from scented corollas (Raguso 2004). Kessler and Baldwin (2006) recently reported a large number of secondary compounds in the headspace, nectar,

and floral parts of *Nicotiana attenuata* (Solanaceae), including many terpenoids. When defensive compounds are produced in other plant tissues and appear in phloem, it is likely that they will also occur in nectar (Adler 2000). Triptolide is presumably present in nectar as a consequence of its occurrence in the leaves and roots of *T. hypoglaucum*: the roots are used for commercial extraction of this compound (Brinker and Raskin 2005). It was suggested by Detzel and Wink (1993) that terpenoids may be less toxic or repellent to bees than other secondary compounds because of the role they play in the attraction of pollinators by floral volatiles. The olfactory responses of bees to terpenoids in floral volatiles are well known (Pham-Delegue et al. 1997; Laska et al. 1999). However, to our knowledge, the study by Detzel and Wink (1993) is the only previous test of the responses of bees to terpenoids in artificial nectar.

Although the triptolide concentration in nectar of *T. hypoglaucum* is unknown, we cannot assume that it is much lower than in honey because of the concentrating process. Phenolics in the nectar of *Aloe littoralis* appear to be deactivated during the manufacture of honey (Liu et al. 2005), and nicotine concentrations in fresh honey have been recorded as 90% lower than the concentrations in experimental diets from which that honey was manufactured (Singaravelan et al. 2006). Almond honey also contains lower amygdalin concentrations than the nectar (London-Shafir et al., 2003). Naef et al. (2004) compared the biochemistry of nectar, honeybee crop contents, and ripe honey and attributed changes in the chemistry of terpenoids and other compounds to the highly oxidative atmosphere in the hive.

Visiting frequencies measured at feeders demonstrated a strong preference of the worker bees for normal sucrose solution or diluted honey as opposed to the toxic equivalent. Similarly, in all comparisons, the imbibition rates were significantly shorter on the toxic honey and sucrose solution when the bees had a choice between toxic and nontoxic diets. Because any honey is a complex mixture of many compounds, it was necessary to demonstrate that pure triptolide had the same effects as did the toxic honey. This suggests that the bees perceive differences between the diets and reduce the risks associated with a toxic honey by reducing the amount of uptake. This is supported by the fact that when there was no alternative to a toxic honey, the visiting frequencies and imbibition times increased to the same levels as for normal honey. Indeed, this is precisely what happens under dearth conditions when there is little flower choice, and people in southern China avoid collecting honey during the flowering of *Tripterygium*. Although our cage and feeder experiments showed that toxic nectar of *T. hypoglaucum* has a significant toxicological effect on honeybees and acts as a deterrent, the seasonal context is important.

Similar results to ours were reported by London-Shafir et al. (2003) for almond flowers, whose nectar contains amygdalin, a cyanogenic glycoside. Preference tests with sugar solutions containing various concentrations of amygdalin showed avoidance of amygdalin in early summer. However, bees did not differentiate among the different amygdalin concentrations in mid-summer, when floral resources are scarce and the bees are less discriminating. This also meant that the authors had to use a lower sugar concentration for their experiments in mid-summer (15 compared to 25%) to avoid overcrowding at the feeders.

Secondary compounds that are repellent to bees at some concentrations can sometimes stimulate them to feed. Recently, Singaravelan et al. (2005) tested the responses of honeybees to four compounds found naturally in floral nectar: nicotine, anabasine, caffeine, and amygdalin. Except for anabasine, naturally occurring concentrations had no deterrent effect, and low concentrations of nicotine and caffeine elicited a significant feeding preference. These compounds were presented to the bees in 20% sucrose solutions. In

addition, feeding experiments with caged bees showed no deleterious effect of natural concentrations of nicotine (Singaravelan et al. 2006).

Most studies (including the present one) use a single sugar concentration for feeding experiments with bees. However, an important recent finding is that the response of *A. cerana* to phenolics in artificial nectar depends on the sugar concentration of the nectar (Liu et al. 2007). Phenolics had an inhibitory effect at low and high sugar concentrations but an attractant effect in the mid-range of 15–35% w/w. Therefore, the attractive or deterrent effect of a secondary compound in nectar depends not only on the concentration of that particular compound but also on the sugar concentration.

In a recent study of the complex nectar chemistry of *N. attenuata* and its effect on pollinators, Kessler and Baldwin (2006) found that visit frequency and visit time were inversely correlated for hawkmoths and hummingbirds presented with choices involving various secondary metabolites. These authors suggest that if nectar repellents decrease visit time and thus the amount of nectar removed, while at the same time increasing visit frequency, pollination can be achieved with smaller nectar rewards. This does not, however, apply to *T. hypoglaucum*, where the presence of triptolide decreases both visit time and visit frequency of honeybees. The ecological consequences for reproduction in this plant with toxic nectar are not clear. However, our feeder experiments show that the bees are only partially deterred by nectar of *T. hypoglaucum* when given the option of good-quality nectar, and in the absence of alternative food sources, the threshold for acceptability of toxic honey is rapidly reduced. The responses of honeybees to differences in nectar concentration and to the variety of chemicals present in nectar are complex and depend on the ecological context.

over constitutive defense mechanisms that have higher metabolic costs (Agrawal and Karban 1999). Inducible defense includes the emission of volatile organic compounds (VOCs) after herbivore attack. Herbivore-induced VOCs may defend the plant directly by repelling other herbivore species (Landolt 1993; Bernasconi et al. 1998; Kessler and Baldwin 2001) or indirectly by attracting natural enemies of the herbivore (predators and parasitoids) that exert control over the feeding herbivore. The latter phenomenon, referred to as "indirect defense" has been observed in many tritrophic systems (Dicke 1999; Turlings and Wäckers 2004).

Herbivore-induced VOCs include an array of terpenes (mono-, sesqui-, and homoterpenes) that are the result of an increased release of constitutively emitted terpenes (Vuorinen et al. 2004) as well as terpene synthesis *de novo*. Among the most commonly induced are the oxygenated monoterpene linalool, the sesquiterpenes β-caryophyllene and α-farnesene, and the homoterpenes (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene (Holopainen 2004). In addition, many alcohols, esters, and aldehydes referred to as green leaf volatiles (GLVs) are also emitted (Paré and Tumlinson 1999). The activation of genes behind the synthesis of inducible terpenes (Van Poecke et al. 2001; Arimura et al. 2000, 2004) and their systemic emission (Paré and Tumlison 1999) support the view that they are not passively released. In contrast, GLVs are thought to be released from damaged plant organelles, 1 or 2 sec after mechanical damage (Fall et al. 1999). However, there is evidence that some can also be emitted by undamaged tissue (Holopainen 2004). The differences found in ratios among GLVs by the feeding of two different insect species on the same plant species (Turlings and Wäckers 2004) and their ability to induce the emission of VOCs (Ruther and Kleier 2005; Yan and Wang 2006) as well as to activate defense genes (Arimura et al. 2001) in neighboring plants suggest that they have an active role in ecological interactions. Individual terpenes and GLVs are enough to attract natural enemies (Kessler and Baldwin 2001; Reddy et al. 2002; Ibrahim et al. 2005). However, under natural conditions where many plant species coexist, natural enemies may rely on ratios between different compounds (Bruce et al. 2005) that are the result of qualitative or quantitative changes from the constitutively emitted VOC profile (Dicke and Van Loon 2000).

Biogenic VOCs, including terpenes and oxygenated compounds, are also involved in chemical processes that occur in the low atmosphere (Fuentes et al. 2000; Atkinson and Arey 2003; Holzinger et al. 2005). In particular, terpenes are not only a source of ozone (O_3), but also a source of secondary organic aerosols when oxidized with common oxidants from the troposphere (e.g., OH, O_3, and NO_3). Terpenes and some oxygenated compounds have short atmospheric life times that can range from seconds to hours when they react with O_3 (Atkinson and Arey 2003). O_3 concentrations are expected to increase in future environments (IPCC 2007). Although the exposure of herbivore-induced VOCs to O_3 results in the degradation of many terpenes and GLVs and consequently in altered ratios among the compounds, the orientation of two selected natural enemies is not disrupted (Pinto et al. 2007a). In the tritrophic system *Brassica oleracea–Plutella xylostella–Cotesia plutellae*, atmospherically stable herbivore-induced compounds such as benzyl cyanide (Scascighini et al. 2005) seem to be sufficient synomones for the parasitoids in O_3-enriched environments. They might act as long-distance cues under natural conditions, in which the presence of O_3 and other oxidants is unavoidable (Pinto et al. 2007a). However, the role of terpenes and GLVs as synomones for wasps that parasitize *Brassica* spp. herbivores is unclear.

Terpenes have been acknowledged as important synomones for predators and parasitoids (Dicke 1994), but they might not contribute to the attraction of parasitoids of *Brassica* spp. herbivores. The quantitative emission of terpenes released by herbivore-damaged plants does not differ greatly from those released by mechanically damaged or intact cabbage plants. Therefore, the relative proportion of terpenes in the herbivore-induced blend is low,

as other compounds are also induced (Mattiaci et al. 1994). Similarly, in the related species *B. oleracea* var. *gemmifera*, the amounts of terpenes induced by herbivory do not increase significantly over time suggesting that they do not correlate with preference of the parasitoid *Cotesia glomerata* (Scascighini et al. 2005). This observation suggests that herbivore-induced terpenoids might not play a crucial role in the orientation of parasitoids of *Brassica* spp. herbivores. GLVs are enhanced in *Brassica* spp. by herbivory (Mattiacci et al. 1994; Geervliet et al. 1997; Scascighini et al. 2005), but *C. plutellae* prefers herbivore-damaged over mechanically damaged plants (Shiojiri et al. 2000, 2006), which also emit large amounts of GLVs (Van Poecke et al. 2001 and references therein). This suggests that GLVs are not sufficient cues for this specialist parasitoid. GLVs emitted by cabbage plants can be also recognized by other predators (Reddy et al. 2002), and thus, other compounds may be more reliable cues for specialist parasitoids.

The oxidation of VOCs results in a series of more atmospherically stable compounds (Calogirou et al. 1999; Yu et al. 1999), and there is a likelihood that natural enemies may have learned to use these oxidation products as synomones. In the present study, we investigated the role of terpenes and GLVs and their oxidation products on the orientation of *C. plutellae* toward *P. xylostella*-damaged plants. By degrading herbivore-induced terpenes and GLVs with O_3, we tested whether the wasps show preference toward unoxidized herbivore-induced volatiles (herbivore-damaged plants at 0 nl l^{-1} O_3) or oxidized herbivore-induced volatiles (herbivore-damaged plants at 120 nl l^{-1} O_3).

Materials and Methods

Living Material and Induction of VOCs White cabbage (*B. oleracea* L. ssp. *capitata* L. cv. Lennox) was grown individually in polypropylene plastic pots filled with *Sphagnum* peat and sand (3:1 v/v) under greenhouse conditions. They were used for trials when they had developed four leaves (approximately 3 to 4 weeks). *P. xylostella* L. (Lepidoptera: Yponomeutidae) and its parasitoid *Cotesia plutellae* (Hymenoptera: Braconidae) were reared on broccoli plants (*B. oleracea* L. ssp. *italica* Plenck) as described by Vuorinen et al. (2004). For inducing damage, ten second-instar *P. xylostella* were transferred onto the leaves of each plant, 48 hr before the bioassays, and removed just before the bioassays.

Setup for Oxidation of VOCs The setup is shown in Fig. 1. It is a modification of that previously described by Pinto et al. (2007a). The modification was aimed to compare the responses of the parasitoid between odor sources in either 0 or 120 nl l^{-1} O_3. A main 1.6 l min^{-1} airflow, previously passed through a charcoal filter, was equally divided in two (0.8 l min^{-1}). For the odor source exposed to 0 nl l^{-1} O_3, 0.8 l min^{-1} was directed into the vessel (22.3-l glass desiccators, Schott Duran, Schott AG, Mainz, Germany) that contained the odor source. The outgoing airflow from the vessel was divided in two, and 0.4 l min^{-1} was used for collecting VOCs or conducting behavioral tests. The remaining 0.4 l min^{-1} was removed via a vacuum pump. For the odor source destined for O_3 exposure, the remaining 0.8 l min^{-1} was directed through an O_3 generator (Model 1008-RS, Dasibi Environmental, California, USA) before contact with the plants. In addition to using the outgoing airflow from the vessel for VOC collections or behavioral tests in the conditions previously described, 0.4 l min^{-1} was diluted in an airflow and directed to an O_3 analyzer (Model O342M, Environment S.A., Poissy, France) to monitor the O_3 concentration targeted to 0 and 120 nl l^{-1}. O_3 scrubbers (potassium iodide—KI) were placed before the end of the line that was used for behavioral tests and VOC collections. The purpose of the scrubber was to remove O_3 before the Tenax TA and to avoid any O_3

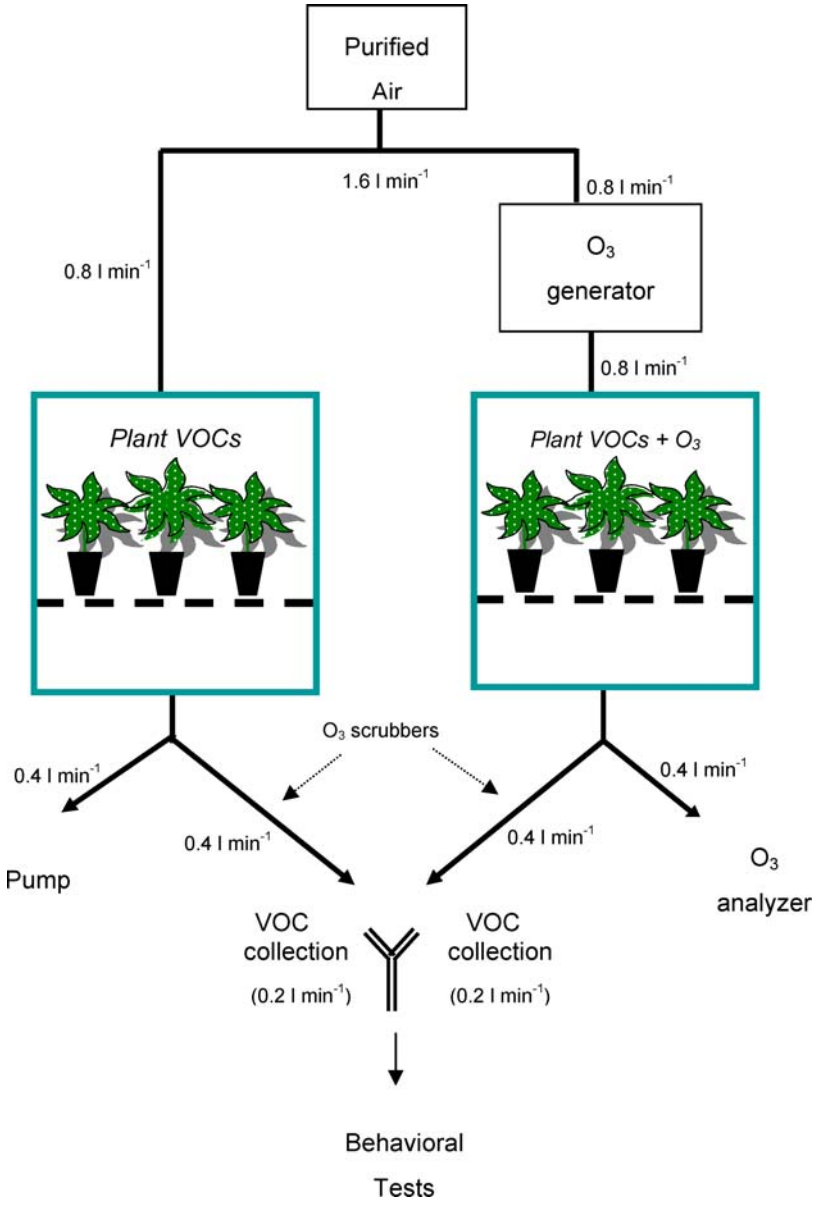

Fig. 1 Experimental setup for the VOC collection and behavioral tests. A main charcoal-filtered 1.6-l min^{-1} airflow was equally divided. 0.8 l min^{-1} were directed into one of the odor sources, whereas the remaining 0.8 l min^{-1} was previously passed through an O_3 generator targeted to 0 and 120 nl l^{-1} O_3 before being directed into one odor source. Out-flowing air from the odor sources was used for behavioral tests at 0.4 l min^{-1} or VOC collection at 0.2 l min^{-1}. The O_3 concentration was constantly measured

effect on the behavior of the parasitoid. To avoid any effect of the O_3 scrubber itself, a similar one was placed in both sides. The whole system was connected by Teflon tubing, and each odor source (experimental unit) consisted of a set of four intact or *P. xylostella*-damaged cabbage plants.

VOC Collection and Analyses VOC collection and analysis were previously described by Pinto et al. (2007a, b). In brief, VOCs were collected from each odor source (intact or damaged plants) onto approximately 150 mg Tenax TA adsorbent (mesh 60/80, Supelco, Pennsylvania, USA) by suction with a vacuum pump at a rate of 0.2 ml min^{-1}. Four replicates were collected for each herbivore treatment. VOCs were analyzed by gas chromatography–mass spectrometry (GC-MS, Hewlett Packard GC type 6890, MSD 5973). Trapped compounds were thermodesorbed (ATD400 Automatic Thermal Desorption System) at 250°C for 10 min, cryofocused at −30°C and injected onto an HP-5MS capillary column (50 m long, 0.20 mm inner diameter, 0.33 mm film thickness, Hewlett Packard). Compounds were identified with pure standards and by comparing their mass spectra to those in the Wiley Library. Only α-thujene, (*E,E*)-α-farnesene, and benzyl cyanide, which were not present in the pure standard, were quantified on the basis of α-pinene, (*E,E*)-β-farnesene, and the internal standard 1-chlor-octane, respectively, also present in the pure standard. Emissions in filtered air were calculated as ng g^{-1} dry weight hr^{-1}, and concentrations at the different O_3 treatments were expressed in ng l^{-1}.

Behavioral Tests For the experiment, 3–4-d-old female *Cotesia* wasps were used. Before the experiment, wasps were offered a *P. xylostella*-infested plant (infested as previously described) for 20 min to increase responsiveness (Potting et al. 1999). The behavioral tests were previously described by Pinto et al. (2007a). In brief, wasps were introduced individually to the end of a Y-tube (diameter=1.6 cm, main arm, 10.5 cm, other arms 10 cm, and angle between them 90°). They were left to choose between the two odor sources for a maximum of 5 min. A "choice" was recorded when they walked further than two thirds of one arm and remained in that area for at least 5 sec. Otherwise, a "no choice" was registered. We assessed the preference of *C. plutellae* between the VOCs emitted by intact (control) plants at 0 nl l^{-1} O_3 and *P. xylostella*-damaged plants 120 nl l^{-1} O_3 and between VOCs emitted by *P. xylostella*-damaged plants at 0 and 120 nl l^{-1} O_3. As a control, we conducted the same bioassays with both odor sources in the absence of O_3. Six and five pairs of odor sources were used for the intact vs. *P. xylostella*-damaged plants bioassays and the *P. xylostella*-damaged vs. *P. xylostella*-damaged plants bioassays, respectively, and no more than 15 insects were tested per each pair of odor sources.

Statistical Analyses Statistical analyses were performed by using the SPSS 14.0 for Windows Statistical Package. Before the analysis, normality was tested, and some compounds were transformed by calculating the inverse ($1/x$). Differences between the emission rates from intact and herbivore-damaged plants in the absence of O_3 were analyzed by using the independent-samples *t* test. The effect of the O_3 treatment on each individual compound from the herbivore-induced VOC blend was analyzed with the paired-samples *t* test. Only (*Z*)-3-hexen-1-ol was not normally distributed and was analyzed using the nonparametric Wilcoxon Signed Rank test. Additionally, the concentration of the oxidized herbivore-induced VOCs was compared with that of VOCs from intact plants with the independent-samples *t* test, with the exception of (*Z*)-3-hexen-1-ol that was analyzed with the nonparametric Mann–Whitney *U* test. The behavioral responses of the natural enemies were analyzed with the nonparametric Binomial test.

Results

VOCs in the Headspace of Cabbage Plants The monoterpenes α-thujene, α-pinene, sabinene, β-myrcene, D-limonene, and 1,8-cineole were emitted by intact plants. *P. xylostella* induced an increase in their emissions but only D-limonene (P=0.023) was significantly increased. In addition, *P. xylostella* induced the emission of the homoterpene DMNT, the GLVs (*Z*)-3-hexen-1-ol and (*Z*)-3-hexenyl acetate, and the nitrile, benzyl cyanide (Table 1). The sesquiterpene (*E,E*)-α-farnesene was detected only in two samples (Table 1).

At 120 nl l^{-1} O_3, with exception of 1,8-cineole that increased (P=0.005), the concentration of all the compounds decreased. A statistically significant decrease was found for α-thujene (P=0.010), α-pinene (P=0.011), β-myrcene (P=0.008), D-limonene (P=0.007), and DMNT (P=0.007). (*E,E*)-α-Farnesene was not detected in any of the samples at 120 nl l^{-1} O_3 (Fig. 2). The concentration of (*Z*)-3-hexenyl-acetate was unable to be quantified at 120 nl l^{-1} O_3 because this compound was not separated from octanal by the column, and the latter is not affected by O_3.

When the concentration of the oxidized herbivore-induced VOCs was compared with that of VOCs from intact plants, the concentration of the constitutively emitted terpenes sabinene (P=0.048), D-limonene (P=0.529), and 1,8-cineole (P=0.001) were still higher after oxidation of herbivore-induced VOCs. Because herbivore-induced compounds were not emitted by intact plants, DMNT (P=0.009) and benzyl cyanide (P=0.007) were higher.

Behavioral Responses of C. plutellae *C. plutellae* clearly preferred the VOCs emitted by *P. xylostella*-damaged plants at 0 (P<0.001) and at 120 nl l^{-1} of O_3 (P=0.006) to intact plants at 0 nl l^{-1}. When *C. plutellae* was challenged to choose between two similar VOC blends of *P. xylostella*-damaged plants at 0 nl l^{-1} O_3, no preferences were observed. However, they preferred the induced VOC blend at 0 nl l^{-1} to that at 120 nl l^{-1} (P=0.001; Fig. 3).

Table 1 VOC emissions (ng g^{-1} DW hr^{-1}) from intact and *P. xylostella* (Px)-damaged cabbage in the ozone-free environment

	Intact	Px-damaged	*P* Value
α-Thujene[a]	1.6±0.2	2.0±0.3	0.304
α-Pinene	1.1±0.2	1.2±0.1	0.536
Sabinene	4.3±0.5	6.4±1.5	0.257
β-Myrcene	1.1±0.3	1.7±0.1	0.070
D-Limonene	7.5±1.1	11.7±0.8	*0.023*
1,8-Cineole	2.9±0.5	3.4±0.3	0.242
DMNT	0	10.5±1.2	*0.000*
(*E,E*)-α-Farnesene[a]	0	0.7±0.4	0.197
(*Z*)-3-Hexen-1-ol	0	2.5±0.9	0.060
(*Z*)-3-Hexenyl acetate	0	8.4±3.8	0.072
Benzyl cyanide[a]	0	1.2±0.2	*0.008*

Data are expressed as means±SE (N=4). *P* values from the independent-samples *t* test. Significant *P* values are shown in italics.

[a] Compound tentatively identified with the Wiley Library.

Discussion

In future environments, where O_3 is forecasted to prevail (IPCC 2007), parasitoids will not be able to choose spatially between two different O_3 environments, although in nature, the range of 1 hr mean daily maximum concentration may change from approximately 30 to approximately 90 nl l^{-1} within 2 d (Holopainen et al. 1994). However, we used this unrealistic situation to study the role of herbivore-induced terpenes and GLVs and their products after reacting with O_3 in the orientation of the parasitoid *C. plutellae* during host search. The identification of products resulting from the oxidation of terpenes is not easily achieved from direct GC-MS (Yu et al. 1998), and this approach may help to assess whether these products play an ecological role in interactions between plants and higher trophic levels. The results of a classical dual-choice bioassay under filtered air conditions support previous observations that *C. plutellae* prefers the VOCs emitted by *P. xylostella*-damaged plants over intact plants (Potting et al. 1999; Vuorinen et al. 2004). Elevated O_3 results in the degradation of induced terpenes and GLVs and does not affect orientation (Pinto et al. 2007a). This supports the view that *C. plutellae* is able to rely on compounds other than reactive terpenes and GLVs, such as benzyl cyanide (Scascighini et al. 2005) that are not significantly affected by O_3 exposure (Pinto et al. 2007a). However, it is possible that in the present study terpenes and GLVs, which were not totally degraded, also contributed to the attractiveness of the VOC blend. When the concentration of the oxidized herbivore-induced VOCs was compared with that of VOCs from intact plants, sabinene, 1,8-cineole, and DMNT, in addition to benzyl cyanide, which was not significantly degraded, were still present in significantly higher concentrations. Moreover, other inducible compounds that were not detected by the GC-MS after ozone exposure might have played a role in orientation of the wasps because the antennal receptors of the wasps are able to detect very

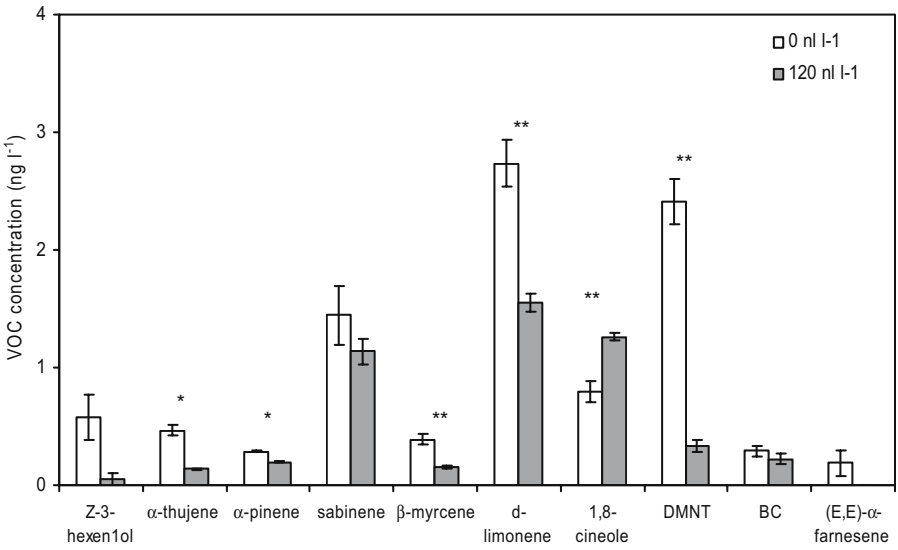

Fig. 2 VOCs (ng l^{-1}) in the headspace of four cabbage plants damaged by *P. xylostella* at 0 (*white bars*) and 120 nl l^{-1} (*gray bars*) of O_3. Data are expressed as means±SE (N=4). The *asterisks* show significance by the paired-samples *t* test (*asterisk*, $P<0.05$, *double asterisk*, $P<0.01$). *BC* Benzyl cyanide

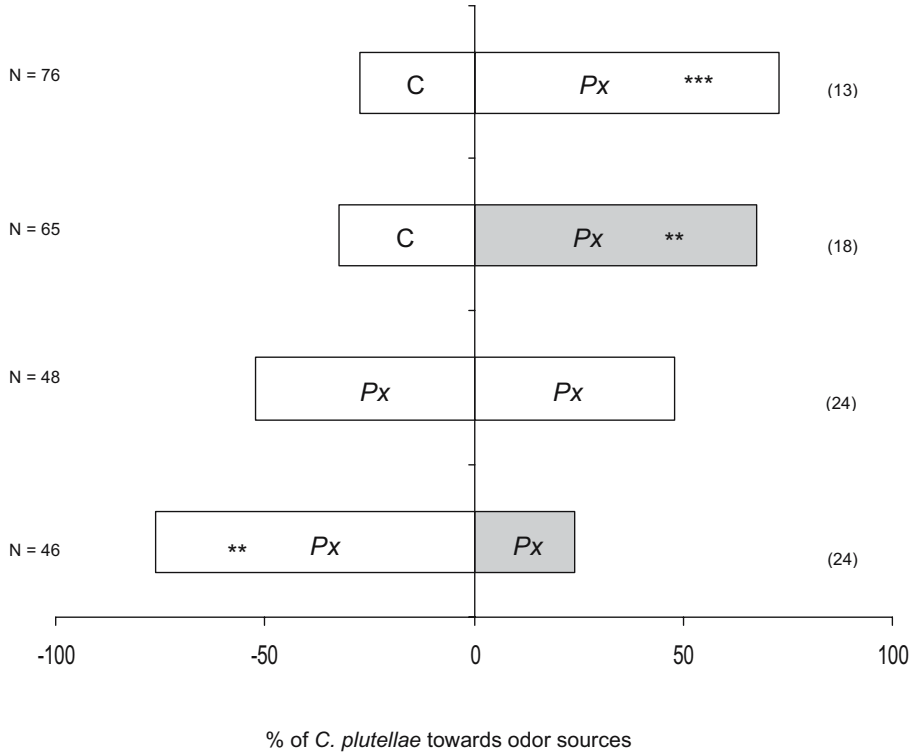

Fig. 3 The behavioral responses of the solitary endoparasitoid *C. plutellae*. The figure shows the percentage of female wasps choosing between control (*C*) and *P. xylostella*-damaged (*Px*) plants or between *P. xylostella*-damaged plants at 0 (*white bars*) or 120 nl l^{-1} (*gray bars*) of O_3-enriched airflows. The significances of the Binomial tests are shown with *asterisks* (*double asterisk*, $P<0.01$, *triple asterisk*, $P<0.001$). The total number of individuals making a choice is shown as *N*, and the number of wasps that did not choose between the two odor sources is in *parentheses* for each series

small volatile concentrations (Schoonhoven et al. 2006). On the other hand, if wasps relied on small concentrations of terpenes and GLVs, our observations would indicate that changes in the ratio among these compounds does not play a crucial role in the orientation of this species of wasp. At longer O_3 exposures, α-thujene, β-myrcene, and DMNT and (*Z*)-3-hexen-1-ol were not detected by the GC-MS at 120 nl l^{-1} (Pinto et al. 2007a). It is known that the extension of the reaction time can increase the amount of terpenes that react (Pommer et al. 2004).

When *C. plutellae* was challenged to choose between the unoxidized herbivore-induced VOCs and the oxidized herbivore-induced VOCs, a preference toward the unoxidized blend was seen. These results indicate that ozone might reduce their preference to cabbage plants. In addition, the results suggest that terpenes and GLVs increase the attractiveness of the herbivore-induced VOC blend. It is more likely that herbivore-induced compounds evoke a response from wasps, as constitutively emitted VOCs may not offer information on the presence of the host. DMNT is a terpene that is induced by the feeding of *P. xylostella*. This compound is emitted by many plant species exclusively after herbivore feeding, and its role as a synomone has been acknowledged (Karban and Baldwin 1997, for a review). In our

study, DMNT was emitted in great quantities but also degraded by O_3. It has been shown that plants infested with *P. xylostella*+*Pieris rapae* together emit lower amounts of DMNT than plants infested by *P. xylostella* alone that were more attractive to *C. plutellae* (Shiojiri et al. 2001). The authors of that study suggested that the behavioral response of *C. plutellae* was partly due to differences in the emission of DMNT, and this may have also occurred in our experiment. GLVs are known to attract *C. plutellae* (Reddy et al. 2002), and greater concentrations of the unoxidized VOC blend might also have contributed to the decision making of the wasps. *C. plutellae* has also been shown to be attracted to D-limonene itself, and this may be a behaviorally active compound in the VOC blend of cabbage plants (Ibrahim et al. 2005). Indeed, D-limonene is detected by the olfactory receptors of related *Cotesia* species (Smid et al. 2002). In this study, D-limonene was the only compound that showed a significant increase as a result of herbivore feeding. Therefore, it is possible that differences in its concentrations in the odor sources may contribute to wasp orientation. Herbivore-damaged *Brassica* species emit nitriles, isothiocyanates, and sulfides (Agelopoulos and Keller 1994; Mattiacci et al. 1994; Geervliet et al. 1997) that may be also reliable synomones for foraging parasitoids of *Brassica* herbivores (Agelopoulos and Keller 1994). We detected another nitrile, allyl nitrile (3-butene nitrile), and methyl thiocyanate in the herbivore-induced VOC blend. However, in contrast to benzyl cyanide, traces of these compounds were also detected in the emissions of intact plants. To our knowledge, the lifetimes of allyl nitrile and methyl thiocyanate when reacting with O_3 have not been reported. Although pure compounds should be used to assess accurately their lifespan in the atmosphere, we estimated their concentrations (data not shown) and assessed whether they significantly decreased after reacting with O_3. No differences were found for allyl nitrile (P=0.167, t test for paired samples) or methyl thiocyanate (P=0.198, t test for paired samples), which suggests that they did not readily react with O_3. We expected them to be emitted by both the unoxidized and the oxidized herbivore-induced VOC blend. Thus, we can assume that the preference of *C. plutellae* for damaged plants in the absence of O_3 is due to greater concentrations of terpenes and GLVs.

Before bioassays, wasps were offered a *Plutella*-infested plant for oviposition experience and to increase their response (Potting et al. 1999). Because parasitoids are able to learn to recognize individual compounds in mixture, as well as complex blends themselves (Meiners et al. 2003), it is possible that the wasps learned the odors from the cabbage plants that were not exposed to high O_3 concentrations. Therefore, they might have preferred the odor of damaged plants in filtered air over that one of damaged plants in elevated O_3.

In this study, we have shown that terpenes and GLVs play a role in the herbivore-induced VOC blend emitted by cabbage plants because *C. plutellae* are more attracted to cabbage plants where these compounds have not been oxidized by O_3. However, decreases and changes in ratio among these compounds do not affect the orientation of *C. plutellae*, suggesting that they can rely on other more O_3-stable-induced compounds. In nature, not only O_3 but other oxidizing agents such as OH radicals present in the atmosphere (Atkinson and Arey 2003) might degrade terpenes and GLVs that are in proximity to the odor source. It is possible that terpenes and GLVs provide information to *C. plutellae* on the presence of its host *P. xylostella* in the short range, but long-range orientation may rely on more stable compounds such as breakdown products of glucosinolates, including benzyl cyanide.

which often results in the attraction of natural enemies of the herbivores (Dicke et al. 1990; Turlings et al. 1990; Vet and Dicke 1992; Takabayashi and Dicke 1996; Powell et al. 1998; Dicke 1999; Vet 1999). The vast majority of studies have considered simple tritrophic systems that involve plant defense responses to attack by a single herbivore species. However, plants in both natural and cultivated ecosystems are frequently subjected to simultaneous infestation by more than one species (Futuyma and Gould 1979; Thompson 1998; Rodriguez-Saona et al. 2003). Detailed analyses of plant volatile emissions have shown that different herbivore species often induce different volatile profiles in the same host plant species, even when the herbivores are of the same type, e.g., different lepidopteran caterpillars or different aphid species (Du et al. 1996, 1998; De Moraes et al. 1998; Turlings et al. 1998; Dicke 1999; Yan and Wang 2006). This specificity is often reflected in the responses of parasitoids and predators to herbivore-induced volatiles: specialist species in particular responding to specific plant volatile blends, while generalist species appear to be less selective (Du et al. 1996; Powell et al. 1998; De Moraes et al. 1998; Geervliet et al. 1998; Shiojiri et al. 2000; De Boer et al. 2005; Takabayashi et al. 2006; Yan and Wang 2006). Potentially, responses by parasitoids to specific, host-induced volatile blends could be compromised when two or more different herbivores are feeding on the same plant (Takabayashi et al. 2006).

Recent studies have investigated parasitoid responses to herbivore-induced plant volatiles when Brussels sprouts or cabbage plants (*Brassica oleracea* L.) were simultaneously infested with two lepidopteran caterpillars (Shiojiri et al. 2000, 2001; Vos et al. 2001). The presence of *Pieris rapae* L. caterpillars hindered the response of *Cotesia vestalis* (Haliday) to cabbages infested with its host *Plutella xylostella* L, whereas the presence of *P. xylostella* caterpillars appeared to enhance the response of *Cotesia glomerata* (L.) to plants infested with its host *P. rapae* (Shiojiri et al. 2000). It is interesting to note that in a different study, *C. glomerata* did not make a significant choice between Brussels sprout plants infested with the nonhost *P. xylostella* and plants infested with both *P. xylostella* and *P. rapae* (Vos et al. 2001). However, in these studies both herbivores were leaf-chewers, which probably both induce the same metabolic pathway. The presence of phloem-feeding whiteflies, *Bemisia argentifolii* Bellows and Perring, reduced by 60% the volatile emissions, from cotton plants infested with *Spodoptera exigua* Hübner caterpillars (Rodriguez-Saona et al. 2003). Fungal plant pathogens also induce changes in volatile emissions, and infection of maize plants by the fungus *Setosphaeria turcica* (Leonard and Suggs) reduced by 48% the total amount of volatiles released by maize plants infested with caterpillars of *Spodoptera littoralis* (Boid.) (Rostás et al. 2006). However, the presence of the fungus did not interfere with the responses of two hymenopteran parasitoids of *S. littoralis* to host-infested plants (Rostás et al. 2006).

In the present study, we investigated the responses of an aphid parasitoid, *Diaeretiella rapae* (McIntosh), to odors from cabbage plants infested with the peach-potato aphid *Myzus persicae* (Sulzer), in the presence and absence of a lepidopteran caterpillar, *P. xylostella*, to see whether presence of a chewing herbivore hindered the responses of a parasitoid to a phloem-feeding host. Brassicaceous plants are frequently infested by more than one herbivore species, including aphids and lepidopteran caterpillars, which often co-occur on the same leaf (Vos et al. 2001).

Materials and Methods

D. rapae was reared on *M. persicae* feeding on Chinese Cabbage plants, *Brassica chinensis* variety *pekinensis* (Rubr.) Sun., maintained in a Perspex cage in a controlled environment

room at 18±1°C, 75±5% relative humidity (RH), and at 18:6-hr light/dark photoperiod. The original laboratory culture had been set up in 1990 from mummies collected in the field from an oilseed rape, *Brassica napus* L., crop at Rothamsted Research farm in Hertfordshire, UK. *M. persicae* aphids were obtained from a laboratory culture maintained under the same conditions but in a separate room. Larvae of the diamondback moth *P. xylostella* were obtained from a laboratory culture maintained on oilseed rape plants in another controlled environment room at 22±1°C, 75±5% RH and at 18:6-hr light/dark photoperiod.

All experiments were done by using a Y-tube olfactometer made from 1-cm-internal diameter glass tubing with 5-cm-long arms, set at an angle of 45°, and with a 7-cm-long basal stem. The airflow through each of the olfactometer arms was created by a small electric pump and was maintained at 900 ml/min by means of a flow meter attached to each arm. The air flow to each arm was passed through activated charcoal to remove any contaminating odors, through a water trap to humidify the air, and then through a 5-l glass vessel containing the odor source before entering each olfactometer arm. The apparatus was lit by an overhead fluorescent light that emitted daylight wavelengths and was fitted with a plane-polarizing prismatic refractive cover to provide even illumination.

Female *D. rapae*, 24–48-hr-old, were tested in the following olfactometer bioassays:

1. Uninfested cabbage plant vs clean air
2. Cabbage plant infested with *M. persicae* vs clean air
3. Cabbage plant infested with *M. persicae* vs uninfested cabbage plant
4. Cabbage plant infested with *P. xylostella* vs uninfested cabbage plant
5. Cabbage plant infested with *M. persicae* vs cabbage plant infested with *P. xylostella*
6. Cabbage plant infested with *M. persicae* vs cabbage plant infested with both *M. persicae* and *P. xylostella*

For each of the six bioassays, 40 inexperienced followed by 40 experienced female parasitoids were tested. Inexperienced females had had no contact with either plant material or aphid hosts before testing, whereas experienced females had been allowed to oviposit in *M. persicae*. During the bioassays, a response was recorded if the parasitoid spent more than 15 sec beyond a line marked midway along an olfactometer arm, without crossing back out again. Each individual parasitoid was tested only once, and the positions of the two treatment arms of the olfactometer were reversed after each ten individuals to allow for any directional bias within the bioassay room. Young, potted cabbage plants (*B. oleracea* L.) with four to five leaves were used in all bioassays. To produce infested plants, either 100 *M. persicae* (mixed ages) or 50 first instars of *P. xylostella* were placed on the plants 2–3 d before use in the bioassays. For both inexperienced and experienced females, a χ^2 test was used to determine differences between numbers of parasitoids choosing different odor treatments within each bioassay.

Results

There were no significant differences between naïve and experienced *D. rapae* in their responses to plant volatiles in any of the bioassays. Therefore, the data were combined for further analyses and presentation (Fig. 1). Parasitoids showed a strong response ($P<0.001$) to odors from both uninfested and host aphid-infested plants when presented alongside clean air in the olfactometer (Fig. 1). However, when they were given a direct choice between odors from uninfested and aphid-infested plants, they made a significant ($P< 0.001$) choice

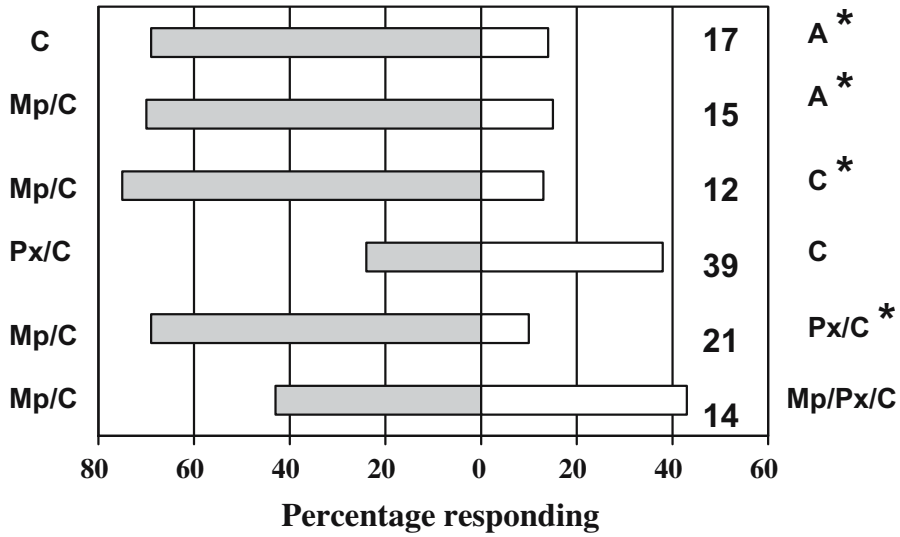

Fig. 1 Responses of female *Diaeretiella rapae* in a Y-tube olfactometer to odors from clean cabbage plants and plants infested with its aphid host, *Myzus persicae* and/or larvae of *Plutella xylostella*. N=80 for each test. *Numbers to the right of the bars* indicate percent nonresponders. *Asterisk*, $P<0.001$. (*A* clean air, *C* uninfested cabbage, *Mp/C* cabbage infested with *Myzus persicae*, *Px/C* cabbage infested with *Plutella xylostella*, *Mp/Px/C* cabbage infested with both *M. persicae* and *P. xylostella*)

of those from infested plants (Fig. 1). In contrast, they did not make a choice (P=0.058) between the odors of an uninfested plant and a plant infested with diamondback moth larvae (Fig. 1). When given a choice between odors from an aphid-infested plant and those from a plant infested with diamondback moth larvae, they significantly ($P<0.001$) chose the former (Fig. 1). Finally, the parasitoids responded equally to odors from a plant infested with aphids only and those from a plant infested with both aphids and moth larvae (Fig. 1).

Discussion

D. rapae females showed strong responses to volatiles from both uninfested and aphid-infested cabbage plants when compared with clean air, but when given a choice between these two odor sources, they strongly preferred that from aphid-infested plants. This indicates that the parasitoids respond to both noninduced brassicaceous plant volatiles and volatiles induced by host aphid feeding and that they can distinguish between the two. Girling et al. (2006) also recorded responses by *D. rapae* to *Arabidopsis thaliana* plants infested with *M. persicae* in Y-tube olfactometer bioassays, but in that study, only experienced parasitoids made a statistically significant choice between uninfested and aphid-infested plants. Similarly, experienced *D. rapae* females made a significant choice of *M. persicae*-infested turnip plants (*Brassica rapa* L.) over uninfested plants, whereas naïve females did not (Blande et al. 2007). Oviposition experience allows parasitoids to learn new olfactory foraging cues, but there is also evidence that it increases the level of existing responses (Turlings et al. 1993; Du et al. 1997; Guerrieri et al. 1997; Grasswitz 1998). It is possible that the host-induced volatile signals emitted by the *M. persicae*-infested cabbage plants used in our study were sufficiently strong to elicit a significant response from naïve parasitoid females, without a pretesting oviposition experience.

Previous studies have shown that feeding damage by *P. xylostella* larvae induces the release of volatiles from brassicaceous plants, including cabbage, and that parasitoids of the moth distinguish between uninfested and host-infested plants (Potting et al. 1999; Shiojiri et al. 2000, 2001; Bukovinsky et al. 2005; Ibrahim et al. 2005). Some parasitoids of other lepidopteran caterpillars that feed on Brassicaceae are also attracted to *P. xylostella*-damaged plants, although they do not use this species as a host (Agelopoulos and Keller 1994a; van Roosjen et al. 2003). However, the aphid parasitoid *D. rapae* did not distinguish between uninfested and *P. xylostella*-infested cabbage plants but did make a significant choice of *M. persicae*-infested plants over *P. xylostella*-infested plants. This supports the hypothesis that the aphid and the caterpillar induce different changes in the volatile profile of cabbage plants and that *D. rapae* females readily distinguish between the two. However, the aphid parasitoids did not distinguish between plants infested with aphids and plants infested with both the aphid and the caterpillar, indicating that the changes to the plant volatile profile induced by the caterpillar did not hinder the detection of aphid induced signals by *D. rapae*.

Brassicaceous plants release isothiocyanates, which are known to be used as foraging cues by both phytophagous and predatory insects, including *D. rapae* (Bartlet et al. 1997; Blight and Smart 1999; Bradburne and Mithen 2000; Cook et al. 2006; Blande et al. 2007). Feeding damage by *P. xylostella* larvae is known to induce the release of isothiocyanates from cabbage (Agelopoulos and Keller 1994b), so it might be expected that *D. rapae* would be attracted to *P. xylostella*-damaged plants. However, *P. xylostella* induces the release of allyl isothiocyanates (Agelopoulos and Keller 1994b), whereas *D. rapae* females are particularly attracted to 3-butenyl isothiocyanate (Bradburne and Mithen 2000; Blande et al. 2007).

The presence of a chewing insect that is known to induce changes in the volatile profile of cabbage plants did not disrupt the responses of a parasitoid to volatile cues induced by a sucking insect. This implies that the production of volatiles by cabbage plants in response to aphid feeding and that attract *D. rapae* is not hindered by concurrent caterpillar feeding damage. This makes sense because aphid-infested plants are frequently attacked simultaneously by chewing insects such as caterpillars, and the indirect defense strategy of plants is likely to have evolved in the context of multiple-herbivore attacks.

implicated in CM host finding, attraction of the moth to host chemicals under field conditions is limited to a male-only response to *E*-β-farnesene (Coracini et al. 2004) and attraction of both sexes to ethyl-(*E*,*Z*)-2,4-decadienoate, the pear ester (Light et al. 2001).

Although a moth host kairomone might be expected to be used for the finding and selection of oviposition sites, it is unclear what role pear ester plays in codling moth location of oviposition sites. Pear ester is emitted from fully ripe pears (Jennings et al. 1964; Shiota 1990) late in the season after most CM oviposition has occurred. Females are attracted to this compound, even when unmated (Knight et al. 2002), before they would be ovipositing. Pear ester is more attractive to males than females (Thwaite et al. 2004), sometimes exclusively so (Kutinkova et al. 2005). In summary, our knowledge of CM attraction to pear ester is not always consistent with moth attraction to host odor to locate oviposition sites. Landolt and Guédot (2008) suggested an additional hypothesis that CM moth attraction to ripe fruit odor, and to pear ester specifically, may also be a food-finding behavior.

Many species of moths feed at sugar sources, such as floral and extrafloral plant nectars, fruit and fruit juices, saps and honeydews (Norris 1936). However, information on codling moth adult feeding is limited. They are attracted to sweet baits (Eyer 1931), they live longer and may lay more eggs when provided sugar (Howell 1981), and they can be trapped with acetic acid (Yothers 1927; Dethier 1947), which is a microbial fermentation product in sweet baits (Utrio and Eriksson 1977). Codling moths may also be attracted to ripe fruit odor as a food-finding behavior (Landolt and Guédot 2008). However, there are no published accounts of CM feeding on ripe or damaged ripe fruit in nature and no reports of acetic acid being emitted from ripe fruit (but see Chen et al. 2006 for acetic acid in extracts of ripe pear fruit).

We hypothesize that CM attraction to ripe fruit odorants such as pear ester (as a food-finding behavior) might be enhanced by the presence of acetic acid (as a sugar cue). Acetic acid has been found to be coattractive and synergistic with other compounds found in sweet baits for vespid wasps (Landolt 1998) and noctuid and pyralid moths (Landolt 2000). In this paper, we report laboratory and field experiments that test the hypothesis that acetic acid with pear ester acts synergistically to attract CM.

Methods and Materials

Laboratory Experiments

Insects All CM used in the laboratory experiments were reared by the Okanagan–Kootenay sterile insect-rearing facility in Osoyoos, British Columbia, Canada (Judd and Gardiner 2006). Larvae were reared on artificial diet (Brinton et al. 1969) at the Pacific Agri-Food Research Centre, Summerland, British Columbia where they were held at 24°C under a 16:8 h L/D photoperiod. Pupae were removed from the diet, sexed, and placed in separate and sealed 10-l plastic buckets. Newly emerged unmated adults were collected daily at the end of the scotophase and held under the same conditions for 48 h until tested. Mated female moths were obtained by placing both sexes together in a 2:1 male/female ratio into a single bucket on the first day of adult emergence. Responding females were dissected, and mated status was confirmed by the presence of spermatophores.

Flight tunnel Two flight tunnels described by Judd et al. (2005) were used to assess behavioral responses of naïve codling moths to attractants in clean air. Both tunnels were

used at the same time to expedite the timely completion of assays with moths provided from the colony. Unmated males were tested in the push-type tunnel, and females were tested in the pull-type tunnel (Judd et al. 2005). Mated females were tested in the pull-type tunnel because it has a removable cover that facilitated the removal of eggs laid on the tunnel walls. Testing of each sex in a different tunnel provided prevention of possible male responses to contamination from female pheromone. Details of moth handling and trapping procedures are reported by Judd et al. (2005). For each experiment, 48-h-old moths were placed in a lighted, 2°C chamber 60 min before scotophase and cooled for approximately 10 min. Immobilized moths were transferred to release cages (2 cm high by 9 cm diameter mesh cylinders attached to an 11-cm^2 base). Thirty minutes before the onset of the scotophase, caged moths were transferred to their respective flight tunnel and placed on a platform in the center of the tunnel within the overlapping plumes (visualized by prior smoke tests) of two lures when two were used. Lures were hung inside cylindrical polyester traps (13 cm long × 11 cm diameter) coated internally with Stickem Special™ (PheroTech, Delta, BC, Canada) to trap alighting moths. In all assays, the two traps were hung from a metal ring stand at the upwind end of each tunnel's flight section. Traps were hung in the same horizontal plane and separated by 20 cm from center to center. In the pull-type tunnel, moths were released 37 cm above the tunnel floor and 118 cm downwind from odor sources. In the push-type tunnel, moths were released 44 cm above the tunnel floor and 150 cm downwind from odor sources. At 1000 hours P.S.T. each day, flight-tunnel room lights were turned off, and both tunnels were lit by uniform, overhead white light provided by four 25 W incandescent bulbs (Philips 120 V Inside Frost, Philips Electronics, Scarborough, ON, Canada) housed in a light box constructed from white Coroplast® (Boyds, Kelowna, BC, Canada) positioned 13 cm above the tunnel. The mean light intensity at the point of moth release and odor plume height was 1.8 lx (Minolta Auto Meter IVF). Room lights remained off for 22 h at which time the assay was concluded, trapped moths were counted, and nonresponders were vacuumed from the tunnel in time to prepare for the next assay protocol at 1000 hours. Air moved through each tunnel at 30–40 cm s^{-1} and was exhausted directly to the roof of the building. All experiments were conducted at 22–24°C.

Assay protocol On each of the five assay days (replicates), 34–75 moths, depending upon moth availability, were placed in a flight tunnel. The numbers of moths caught in each of two traps during the next 22-h assay period were recorded, and the percentages of moths in each trap and the number recaptured out of the total released during each replicate were calculated.

Lures Acetic acid was dispensed from 15 ml polypropylene bottles (Nalg-Nunc International, Rochester, NY, USA). Each bottle contained 10 ml of glacial acetic acid (Aldrich Chemical, Milwaukee, WI, USA) applied to cotton balls in the bottom of the bottle. Volatilized acetic acid was emitted through a 1-mm diameter hole in the bottle lid (Landolt and Alfaro 2001). Pear ester (Aldrich Chemical, Milwaukee, WI, USA) was dispensed from gray halobutyl rubber septa (West, Lyonville, PA, USA) with a lure load of 100 μg pear ester and 10 mg butylated hydroxytoluene (BHT; Aldrich Chemical, Milwaukee, WI, USA; as an antioxidant) per septum. Septa were preextracted with methylene chloride and were then aired for 24 h at 24°C in a fume hood before use. Loaded septa were stored in a freezer at 0°C between experiments. Upright bottles and septa were attached to either end of a 10-cm long wire bent to the shape of a horseshoe, such that they were separated by 1 cm in the same horizontal plane. Lures were hung by this wire in the geometric center of each trap with the septum always located directly downwind of the bottle's opening such that volatilized acetic acid could drift over the septum.

Experimental design Five dual-choice laboratory experiments (experiments 1–5) were conducted and repeated separately with virgin males, virgin females, and mated females. All insects used in these experiments had no prior exposure to test chemicals. In experiment 1, we quantified the catches of moths in two paired, blank traps placed upwind, thus revealing any upwind flight tendencies of the different moths and potential positional trap biases. Experiments 2–4 quantified the attraction of moths to acetic acid and pear ester alone and in combination, respectively, relative to a blank trap in paired comparison tests. In these experiments, blank traps were provided with empty bottles, clean septa, or both, respectively. In experiment 5, we compared the relative attractiveness of the combination of acetic acid plus pear ester vs. pear ester alone.

Moth catches were expressed as proportions (p) and transformed by using an arcsine-$\sqrt{p}$. Mean proportions caught (N=5) were compared by using a paired t test. The mean total proportions of virgin male, virgin female, and mated female moths caught during each dual-choice experiment were compared by using an analysis of variance (ANOVA) followed by Tukey's multiple comparisons test with the experiment-wise error rate set at α=0.05 (Zar 1984). All statistical analyses were performed with SigmaStat® version 3.0.1 (SYSTAT Software, San Jose, CA, USA).

Field Experiments

Three trapping experiments evaluated CM responses to four treatments: no chemical lure as a control, acetic acid, pear ester, and the combination of acetic acid with pear ester. Acetic acid was dispensed from a 15-ml polypropylene bottle with a 3-mm diameter hole in the lid. Each bottle was loaded with 10 ml of glacial acetic acid on cotton balls. Pear ester was dispensed from gray rubber septa, preextracted, and handled as described above. Each septum was loaded with 200 μl of a solution of 1 mg of pear ester and 10 mg of BHT in methylene chloride.

The first experiment, conducted near Zillah, Yakima County, Washington, USA, used Universal Moth Traps (AgriSense, Norwich, UK). A 6-cm^2 piece of Vaportape (Hercon Environmental, Emigsville, PA, USA) was stapled to the inside of the trap bucket to kill captured moths. Acetic acid lures were suspended upright within the buckets of the traps, and pear ester lures were placed within the lure baskets of the traps at the center of the underside of the trap lid. A randomized complete block design was used with 10 block replicates set up in a commercial apple orchard on August 24, 2006. Traps were checked weekly for 2 wk. The orchard had been treated with codling moth pheromone for mating disruption.

The second experiment was conducted also near Zillah and used the Pherocon 1C trap (Trece, Adair, OK, USA). These traps have a white plastic roof and floor separated by an open space for entry of moths with a sticky liner as the trap floor. Acetic acid dispensers were placed upright in the adhesive at the center of the traps' sticky liners. Each pear ester septum was pinned to a 6-cm^2 piece of cardboard placed in the trap liner adhesive. A randomized complete block design was used with 10 replicates. This was set up in a commercial apple orchard that had been treated with CM pheromone on September 12, 2006. Traps were checked weekly for 2 wk.

The third experiment was conducted near Lincoln, the South Island of New Zealand. Red Delta traps (HortResearch, Aukland, NZ) were baited with the same lures used in the previous two field experiments. The Delta trap is a tent-shaped trap open at two ends allowing entry of moths with a sticky liner in the bottom of the trap (Clare et al. 2000). Lures were placed upright at the center of the trap liner. Ten blocks were set up in an experimental apple orchard on November 28, 2006, and traps were maintained for 4 wk.

Mean numbers of moths captured were compared between treatments by using ANOVA, and following a significant F value, means were separated using Tukey's test at $\alpha<0.05$.

Results and Discussion

Laboratory Experiments

In experiment 1, blank (unbaited) traps surprisingly caught large and similar numbers of virgin males and mated females. However, fewer virgin females than virgin males or mated females were in blank traps (Table 1). Most virgin females appeared to be stationary and engaged in "calling" behavior immediately after the lights went out, whereas many mated females and virgin males repeatedly made upwind excursions and eventually landed in the traps.

In experiment 2, acetic acid was not attractive (Table 1), although the response by mated females was nearly significant ($P=0.051$). Pear ester lures in experiment 3 were attractive to both males and mated females (Table 1), consistent with field reports (Light et al. 2001), but not to virgin females. The combination of acetic acid and pear ester in experiment 4 was attractive to all three categories of moths with the greatest percentage response by mated females (Table 1).

The percentages of males caught per test were similar across laboratory tests, irrespective of the treatment comparison. However, captures of mated and virgin females were greater in experiments where acetic acid plus pear ester was evaluated. This suggests that more of the females engaged in upwind flight when this lure was in the flight tunnel. We speculate that virgin males may engage in anemotactic flights even in the absence of relevant odor cues, but will then likely follow the plume of a relevant attractant to its source, depending on their "motivational" state. Collectively, these results support the hypothesis that this lure elicits a food-finding response by males and mated females. Virgin females are perhaps "motivated" to find a mate before feeding.

In experiment 5, males, mated females, and virgin females were all more attracted to the combination lure than to pear ester alone. A positive interaction, possibly synergy, of acetic acid and pear ester was most clearly demonstrated in the responses of virgin females to this lure, because neither lure was more attractive than a blank when tested alone, but a significant response was shown to the combination lure (Table 1).

Field Experiments

In all three field experiments, both female and male CM were more strongly attracted to (trapped with) the combined lure than to either individual component (Table 2), consistent with the results of laboratory tests. This enhanced response to the combined lure was more than 200% higher compared with either compound alone. Acetic acid alone attracted no more CM than unbaited traps, and only in the New Zealand test were numbers of CM trapped with pear ester higher than the controls (Table 2). There are no prior reports of codling moth attraction to acetic acid with pear ester, combinations of other nonpheromonal chemicals with pear ester, or other chemicals with acetic acid.

Codling moth has been trapped with acetic acid (Yothers 1927; Eyer 1931; Dethier 1947) and with pear ester (Light et al. 2001). However, in this study, there was no attraction to acetic acid. Perhaps, a significant response would have been observed with a different acetic acid release rate, higher moth densities, or with more replications. Knight and Light (2004) in Washington captured both sexes with pear ester; but in other studies, mostly

Tests were conducted in Washington (WA) and in New Zealand (NZ). Means within a column followed by the same letter are not significantly different by Tukey's test at $\alpha<0.05$.

males (Il'ichev 2004; Thwaite et al. 2004) or only males were trapped (Kutinkova et al. 2005). Our results from Washington did not find a response by either sex to pear ester, but those from New Zealand showed responses by both sexes, as did our laboratory tests with virgin males and mated females. Codling moth attraction to pear ester varies with season, pheromone treatments for mating disruption, orchard type, and other parameters (Knight et al. 2002; Il'ichev 2004; Knight and Light 2005c; Kutinkova et al. 2005; Trimble and El-Sayed 2005). A significant response to pear ester may have been observed in our field tests in Washington under different conditions, such as higher moth populations.

Codling moths may respond to pear ester with acetic acid to locate adult food. The possibility that CM orient to ripe fruit and to acetic acid plus pear ester as food finding behavior does not exclude the additional possibility that their attraction to fruit odorants, such as pear ester, is also a means to locate oviposition sites or potential mates. Indeed, females are stimulated to lay eggs in the presence of the ripe fruit odorants *E*,*E*-α farnesene (Sutherland et al. 1974) and pear ester (Knight and Light 2004).

It remains to be determined if acetic acid enhances attraction of CM to other fruit odorants, such as those emitted from ripe apples. Several compounds emitted by mature or ripe apple fruit have been identified, are antennally and behaviorally active, but have not been demonstrated to be attractive in the field (Hern and Dorn 1999, 2001, 2004; Yan et al. 1999; Backmann et al. 2001; Bengtsson et al. 2001; Vallat and Dorn 2005). Tests should be conducted to determine if any of these or a blend of apple odorants are coattractive with acetic acid. Codling moths are attracted to ripe 'Braeburn' apples, although less so than to ripe 'Bartlett' pears (Landolt and Guédot 2008), and the attractive chemicals from those apples have not yet been isolated.

Our results hold promise for improving the power of attraction of nonpheromonal lures for CM with a greater than twofold increase in both sexes trapped with acetic acid with pear ester. Where pear ester has shown promise as a management tool for CM, on apple, walnut, and pear crops (Knight and Light 2004, 2005a, b), this lure might improve the efficacy of monitoring, attract-and-kill, or mass trapping. Where the response of females to pear ester has been weak or nonexistent (Kutinkova et al. 2005), perhaps an improved response would be obtained with acetic acid with pear ester, as was shown for both Washington and New Zealand.

Acknowledgments Technical assistance was provided by Daryl Green in Washington, USA; Vanessa Mitchell in New Zealand; and Mark Gardiner and Sarah Cockburn in British Columbia, Canada. valuable levels of resistance. A screening of seven sunflower genotypes in a field experiment showed a correlation between these compounds and resistance to *Sclerotinia*.

Keywords Acetophenones · Ayapin · Demethoxyencecalin · Scopoletin · Phenolics · Coumarins · Sunflower · Bracts · *Sclerotinia sclerotiorum* · Allelochemicals

Introduction

Sunflower (*Helianthus annuus* L.) represents an important crop that is a source of oils, high-protein meal, birdseed, and ornamental flowers. *Sclerotinia sclerotiorum* (Lib.) de Bary is a worldwide distributed sunflower pathogen that attacks most parts of the plant, including the root, stem, capitulum, leaf, and terminal bud, at any developmental stage. This disease is of special virulence in Argentina, France, and Japan (Acimovic 1985). Under favorable climatic conditions, high humidity and mild temperature, the fungus causes yield losses, especially in the case of capitulum infection (head rot disease) (Purdy 1979). Losses caused by *Sclerotinia* vary according to the maturation stage of the capitula at the onset of infection. The period of maximum susceptibility is at the onset of flowering (when the outermost and next inner radii of florets reach anthesis), causing losses of up to 100% at this stage (Purdy 1979).

Head rot starts when spores, transported by the wind, reach a healthy sunflower capitulum. Under high humidity, spores germinate and penetrate into the flowers, thus spreading to the bracts and receptaculum (Pereyra et al. 1991), and degrading the capitulum. As the fungus degrades tissues, mycelia accumulate and form sclerotia that fall into the soil where they can survive up to the following crop season when sclerotia germinate and the apotecia liberate the new spores, thus starting a new disease cycle. The isolation and structural characterization of defense compounds in resistant varieties is an important goal of plant breeders who are pursuing crop improvement. Moreover, the development of easy analytical methods for chemical detection would provide a powerful tool for observing the transfer of resistance traits during the breeding process. As chemical control is not practical, genetic control through the development of resistant lines appears to be the best crop protection strategy. Accordingly, a major goal of research is to identify compounds that are involved in resistance, to use them as biochemical markers in plant breeding programs, or to design appropriate control strategies.

Sunflower constitutes a rich source of biologically active secondary metabolites with a wide spectrum of activities (Macías et al. 1999). Many are specifically located in the trichome glands (Spring et al. 1992, 2003), and it has been hypothesized that many play a role in chemical defense. Some have proved their effectiveness as insecticidal, e.g., against the sunflower fly *Homoesoma ellectellu*m (Waiss et al. 1981) or *Diabotrica virgifera* (Mullin et al. 1991), fungicidal (Picman and Schneider 1993), or allelopathic (Macías et al. 1998) agents.

In a previous study, we assessed the resistance of a large number of sunflower genotypes to *Sclerotinina* head rot (Prats et al. 2003). Based on differences in susceptibility, four of these were selected for detailed analysis. The resistant genotype not only contained the highest constitutive phenylalanine ammonia-lyase (PAL) activity and total soluble phenolic content, but *S. sclerotiorum* infection also induced PAL activity, and consequently, the synthesis of phenolics (Prats et al. 2003). By contrast, the most susceptible genotype showed a relatively low constitutive PAL activity level and phenolic content, and there was no disease-induced response. We further observed high correlations between coumarins (especially scopolin and ayapin) and *Sclerotinia* resistance (Prats et al. 2006). From thin

layer chromatography (TLC) analyses, it appeared that other phenolics were also more abundant in the resistant genotype. The present study extended the previous work by isolation of the compounds that may be involved in *Sclerotinia* head rot resistance.

Methods and Materials

General methods Solvents were glass-distilled or commercial HPLC grade. Column chromatography was performed on silica gel (35–75 mesh), and TLC analysis was carried out by using aluminum-packed precoated silica gel and Silicagel 60 F_{254} plates (Merck). For HPLC, LiChrosorb silica 60 was used in the normal-phase mode with a differential refractometer (RI) on a Hitachi L-6020 HPLC instrument. ^{1}H NMR and ^{13}C NMR were recorded on a Varian Unity 400 spectrometer with $CDCl_3$ as solvent. The resonances of residual chloroform at δ_H 7.25 and δ_c 77.0 were used as internal reference for ^{1}H NMR and ^{13}C NMR spectra. Mass spectra were obtained with a VG 1250 AUTOSPEC instrument at 70 eV. The IR spectra were recorded on a BioRad FTS-7. UV spectra were recorded on an HP 8453 UV/Vis spectrophotometer.

Plant material Sunflower genotypes were provided by Advanta Seeds S.A.I.C. (Balcarce, Argentina). For the isolation and characterization of new compounds, a 2,500-m^2 experimental field in Balcarce, Argentina was sowed with genotype 1V8410. Sunflower inner bracts from each plant were collected 14 d after flowering when the outermost and next inner radii of florets reached anthesis (maximum susceptibility stage).

To test the relation between the new compounds and resistance to *S. sclerotiorum in vivo*, a set of seven sunflower experimental genotypes, different from the genotype used for isolation and purification of phenolics, was sowed in an experimental field. Each plot consisted of two rows, which are 6 m long and 0.7 m apart (20 plants per row). For each genotype, five plants were randomly chosen to assess constitutive phenolic content. Bracts were harvested 14 d after the beginning of flowering, frozen in liquid nitrogen, and maintained at −80°C before analysis. At beginning of flowering, between 7 and 16 plants of similar flowering date were inoculated artificially by spraying with 1.5 ml of a water suspension of ascospores (20,000 ascospores ml^{-1}). To ensure high humidity conditions with no thermal stress, plants were covered with a paper bag (Prats et al. 2003). Thirty days after inoculation, the percentage of necrosed capitulum was determined. Necrotic lesions in the receptacle were quantified using a discontinuous scale from 0% (no necrotic lesions observed) to 100% (tissue totally necrosed) with intermediate values of 10, 25, 50, and 75, indicating the percentage of the total receptacle affected. For each genotype, bracts of five randomly chosen plants were harvested 14 d after inoculation to assess phenolic content.

Isolation of compounds Fresh plant material was lyophilized (438 g) and ground in a mortar with a mixture of acetone/methanol 5:1 (*v*/*v*) at room temperature. After filtration, the extract was evaporated under vacuum (40°C) to yield 24 g of crude extract. The extract was fractionated by column chromatography on silica gel by using mixtures of hexane/diethyl ether of increasing polarity, yielding 164×50 ml fractions. TLC analysis of the crude extract with different hexane/diethyl ether mixtures as mobile phases allowed us to group the crude extract into six fractions (I–VI). The coumarins ayapin (**1**), scopoletin (**2**), and scopolin (**3**) were detected as fluorescent spots under the 254-nm wavelength by comparison of their Rf values with pure samples. Further HPLC purification of fractions I,

IV, and VI with a UV detector monitored at 254 nm wavelength afforded compounds **4** (19 mg), **5** (12.2 mg), and **6** (1.7 mg), respectively.

In vitro bioassay To check the inhibitory effect of the different isolated compounds, a quantitative test for *Sclerotinia* growth inhibition was performed in flat-bottomed microtiter plates. Different concentrations (0.025, 0.05, 0.075, and 0.1 μg equivalent of chlorogenic acid) of 3-acetyl-4-hydroxyacetophenone (**6**), demethoxyencecalin (**4**), 3-acetyl-4-acetoxyacetophenone (**5**), and ayapin (**1**) in methanol were vacuum-dried. The residue was redissolved by repeated aspiration with a pipette in 100 μl of Czapek–Dox broth (Sigma) containing *Sclerotinia* ascospores (2×10^4 ml^{-1}). Plates were incubated for 18 h at 21°C with continuous illumination (4 μEm^2 s^{-1}). The lengths of 15 ascospore germ tubes were measured in each of the 3 replicates of each treatment using an inverted white light microscope (CK2 Olympus, ×100).

TLC assay TLC plates were used to visualize and semiquantify the phenolic content of the seven experimental genotypes. Bracts were extracted as reported in Prats et al. (2003). Frozen tissue was homogenized with prechilled (−20°C) 1:10 (*w*/*v*) acetone in a mortar. After filtering the solvent, the residue was further sequentially extracted with a similar volume of acetone and acetone/methanol (1:1 *v*/*v*). The combined organic extracts were concentrated under vacuum, redissolved in a minimum volume of methanol, and applied to a TLC plate. Ethylacetate was used as the mobile phase. Plates were visualized under UV light (254 nm), and compounds were identified according to Rf values. The content of each compound was estimated visually according to a 0–5 scale from the lowest to the highest intensity and transformed to a 0–100 scale for easy comparison with disease levels.

Results

Previous analysis from *Sclerotinia* resistant sunflower genotype (1V8410) demonstrated that bract and corolla extracts contained high amounts of the known coumarins ayapin (**1**), scopoletin (**2**) and its glucoside derivate, scopolin (**3**) (Prats et al. 2006), and three other unknown compounds **4**, **5**, and **6** with Rf values of 0.7, 0.6, and 0.4, respectively. These showed violet fluorescence under the 254-nm UV light in the TLC analysis (Prats et al. 2003). TLC showed low concentrations of these compounds in the susceptible genotype (cv.30302) and moderate concentrations in the moderately resistant genotypes (FRTS and 30145) (Prats et al. 2003). Two were identified by means of their spectroscopical data (^{1}H NMR and ^{13}C NMR, UV, IR, and MS) as the already known compounds demethoxyencecalin (**4**) and 3-acetyl-4-hydroxyacetophenone (**6**). Compound **5** was identified as 3-acetyl-4-acetoxyacetophenone (Fig. 1). This compound presented a molecular ion in the HRMS at *m*/*z* 220.22213 corresponding to a molecular formula $C_{12}O_4H_{12}$. The ^{1}H NMR spectra was similar to that of compound (**6**), being characterized with the presence of an ABX system in the aromatic zone (δ 8.31, δ 8.27, and δ 7.25); two aromatic methyl groups at δ 2.61 and δ 2.39 (3H, s, H-10), and one acetoxyl group at δ 2.14.

*3-Acetyl-4-acetoxyacetophenone (***5***)* IR: ν_{max} (KBr) cm^{-1}: 1740 (ester group), 1650 (carbonyl group), 1614 (carbonyl group); HRMS $[M]^+$ 220.22213, $C_{12}O_4H_{12}$ requires

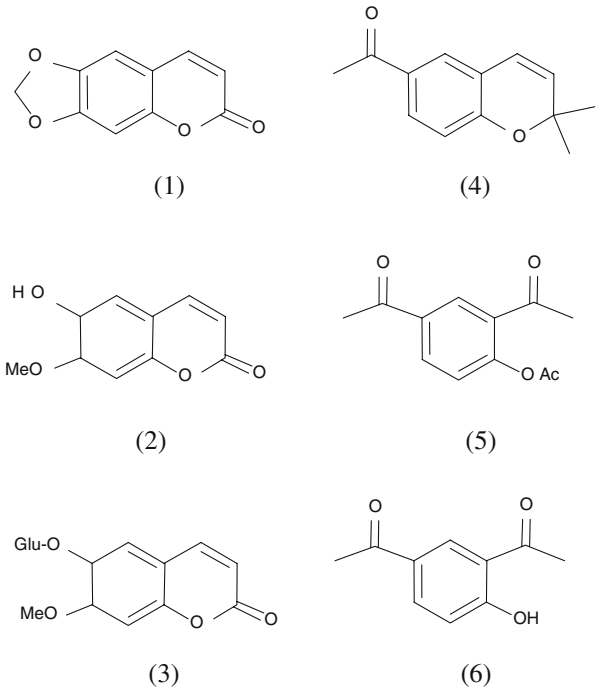

Fig. 1 Fungicidal compounds isolated from *Sclerotinia* resistant sunflower bracts. Ayapin (**1**), scopoletin (**2**), scopolin (**3**), demethoxyencecalin (**4**), 3-acetyl-4-acetoxyacetophenone (**5**), 3-acetyl-4-hydroxyacetophenone (**6**)

220.07356; UV $\lambda_{max}^{CHCl_3}$nm: 235.3, 290.0; ^{1}H NMR (400 Mz, $CDCl_3$): δ 2.14 (3H, s, –OCO–*CH*$_3$); δ 2.39 (3H, s, H-10); δ 2.61 (3H, s, H-8); δ 7.25 (1H, *d*, *J*=8.7 Hz, H-5); δ 8.27 (1H, *dd*, *J*=8.7 Hz, *J*=2.0 Hz, H-6); δ 8.31 (1H, *d*, *J*=1.9 Hz, H-2). Fluorescence: 290 (λEx); 412 (λEm).

An *in vitro* bioassay carried out with **4**, **5**, **6**, and ayapin as a known potent *Sclerotinia* inhibitor showed that 3-acetyl-4-hydroxyacetophenone (**6**) had the highest inhibitory effect against *Sclerotinia*, followed by demethoxyencecalin (**4**). The new compound, 3-acetyl-4-acetoxyacetophenone (**5**), was also a potent *Sclerotinia* inhibitor with its activity being in the same range as that observed for ayapin (**1**) (Fig. 2).

Data from the field experiment showed a significant (P=0.022) correlation between the total amount of these three compounds and disease resistance, thus supporting the hypothesis of an *in vivo* inhibitory effect. Genotype CP03-1790, which had the lower percentage of necrosed capitulum, showed the highest amounts of **4**, **5**, and scopoletin, and was the only genotype with **6** (Table 1). This was true for both noninoculated and inoculated plants. An overall analysis of all genotypes showed that these compounds did not significantly increase after inoculation. Ayapin tended to increase after inoculation in most genotypes, however, the increase was not significant. Genotypes CP03-1791, CP03-1792, and CP03-1793 showed intermediate resistance with necrosed values ranging from 4.2% to 43%, and also had intermediate values of the compounds. Genotypes CP03-1794, CP03-1795, and CP03-1796 showed the highest disease values with more than 60% necrosed capitulum. This was associated with the lowest amount of phenolic compounds (Table 1). When analyzed individually, only **4** and **5** showed significant correlations with disease resistance (P=0.03).

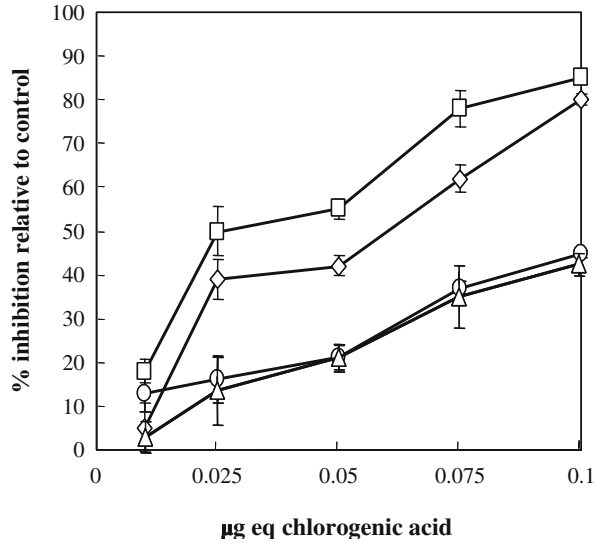

Fig. 2 Effect of 3-acetyl-4-acetoxyacetophenone (**5**), 3-acetyl-4-hydroxyacetophenone (**4**), demethoxyencecalin (**3**), and ayapin (**2**) on *Sclerotinia* development. *Lines* represent the percentage of inhibition of different compounds respect control (spores incubated only in Czapek–Dox broth medium). *Bars* indicate 95% confidence intervals. *Open squares* 3-acetyl-4-hydroxyacetophenone, *open diamonds* demethoxyencecalin, *open triangles* 3-acetyl-4-acetoxyacetophenone, *open circles* ayapin

Discussion

Sunflower produces phenolic compounds from the phenylpropanoid biosynthetic pathway (reviewed by Dixon et al. 2002), which is regulated by the conversion of phenylalanine to *trans*-cinnamic acid by the enzyme PAL (Bate et al. 1994). Among phenolics, sunflower coumarins have attracted attention because of evidence that their biosynthesis is induced by abiotic stress (Cabello-Hurtado et al. 1998) and by the attack of the parasitic plant *Orobanche* (Serghini 2000) and pathogenic fungi (Ding et al. 2000; Prats et al. 2002). In particular, ayapin and scopoletin inhibit *S. sclerotiorum* growth (Urdangarin et al. 1999), and scopolin has antifungal activity similar to scopoletin (Prats et al. 2006).

To our knowledge, this is the first report of phenolic compounds, other than the known coumarins, with high inhibitory effects against *S. sclerotiorum*. Demethoxyencecalin (**4**) is a chromene that was previously isolated from other species (Becerra et al. 1983; Kulkarni et al. 1987) and *Helianthus annuus* (Varga et al. 1984; Satoh et al. 1996). It was isolated from the stem and receptaculum. Demethoxyencecalin, along with other chromenes, has been described as an insect feeding deterrent against *Phythorimaea operculella* and *Spodoptera litoralis* (Kulkarni et al. 1987; Srivastava and Proksch 1993). This compound is also fungicidal, bactericidal, and possesses antioxidant activity (Okunade et al. 1997; Tsuda et al. 1997). Isolation from resistant sunflower varieties, thus, is in agreement with a proposed protective role. 3-Acetyl-4-hydroxyacetophenone (**6**) has been isolated previously from *Artemisa campestris* subsp. *glutinosa* (De Pascual et al. 1981), but there are no previous references to biological activity. In this study, we showed that this compound has fungicidal activity. Indeed, the *in vitro* assay showed that **6** had the highest inhibitory effect on *Sclerotinia* growth. Furthermore, *in vivo* experiments showed that the only genotype containing this compound, CP03-1790, had the lowest disease level. It is interesting to note that the genotype 1V8410, which was used for the isolations and characterizations, showed high levels of 3-acetyl-4-hydroxyacetophenone (**6**) and less than 1% of necrosed capitulum. The new compound 3-acetyl-4-acetoxyacetophenone (**5**) also showed a high *in vitro*

Content of each compound was estimated visually from a TLC plate according to a 0–5 scale from the lowest to the highest intensity and transformed to a 0–100 scale for easy comparison with disease level. Values of demethoxyencecalin and 3-acetyl-4-acetoxyacetophenone with close Rf values were identical in all cases and are expressed as Dem/Ac. Data are the mean of at least five plants and are expressed as mean±standard error.

inhibitory effect on *Sclerotinia*, similar to that of ayapin, and was also significantly correlated with reduced disease levels *in vivo*.

It is important to point out that the compounds are localized on the bracts and corollas where the most virulent attack of the pathogen is confined, and also their constitutive nature. Previous results have shown low coumarins and total phenolic accumulation in vegetative organs compared to those observed in bracts and corollas (Prats et al. 2003, 2006). Head rot infection usually starts in bracts and corollas; therefore, these compounds there represent a first defense barrier against infection. We did not observe an increase after inoculation. However, in previous work, we observed a slight significant increase of coumarins after inoculation in resistant genotypes, which is supported by the increase in PAL activity (Prats et al. 2003, 2006). Although visual evaluation of TLC plates allowed us to discriminate susceptible and resistant genotypes, this method may not be accurate enough to detect slight changes after inoculation. In general, *Sclerotinia* infection proceeds rapidly, so that in susceptible genotypes, the capitula are highly colonized within 14 d. In such cases, high constitutive coumarin/phenolic concentrations coupled with *de novo* synthesis in response to attack might lead to a sufficient accumulation to inhibit the fungus. This might not be possible only with *de novo* production. Previous work also has demonstrated that sunflower coumarins, produced constitutively or after treatment with a systemic inducer of resistance, inhibit rust appressorium formation (Prats et al. 2002, 2007).

Coumarins and other phenolic compounds can be detected and semiquantified rapidly with TLC preparations under UV light (254 nm). HPLC/diode array detection and quantification methods are also easy to develop. Thus, the compounds may be useful markers for head rot resistance in operational sunflower plant breeding programs. The speed and simplicity of the detection approaches make them suitable as screening procedures for identifying resistant genotypes.

frequency on root surfaces and fungal sensitivity to totarol. We conclude that totarol is one factor that selects for fungi on root surfaces of *T. dolabrata* var. *hondai* in the early growth stage.

Keywords *Thujopsis dolabrata* var. *hondai* · Seed fungi · Soil fungi · Rhizosphere · Antifungal compound · Totarol

Introduction

Hinoki-asunaro (*Thujopsis dolabrata* Sieb. et Zucc. var. *hondai* Makino; also called hiba or ate) is an endemic tree in Japan. It is distributed from the Oshima Peninsula (42°10′N) on Hokkaido to Tochigi Prefecture (36°47′N) on Honshu (Kobayashi and Asakawa 1981). The seeds (Hasegawa and Hirose 1980), leaves (Takahashi et al. 1981; Nagahama et al. 1996), trunk, and branches contain characteristic secondary metabolites. In particular, essential oil extracted from *T. dolabrata* var. *hondai* wood, which contains sesquiterpenes and hinokitiol-related compounds, has antimicrobial activity against bacteria (Okabe et al. 1994; Saito et al. 1997; Morita et al. 2001), wood-rotting fungi (Inamori et al. 2000), and plant pathogens (Morita et al. 2004), and is insecticidal against termites (Miyazaki 1996; Lee et al. 1997; Ahn et al. 1998). Houses made of the timber are free of decay and infestation for a long period, thus making *T. dolabrata* var. *hondai* a commercially important tree in Japan.

Seedlings show physiologically and ecologically characteristic germination. Because of slow growth, several nursing systems for *T. dolabrata* var. *hondai* have been developed (Aoki 1936; Fujimori 1958; Sakurai and Mori 1985a, b; Itoya and Shimoda 1995, 1999; Nakano 2000; Mori et al. 2003; Aomori Forestry Research Institute 2004). In naturally regenerated forests, seedlings grow in mineral soil without humus (Mori et al. 2003). Tohoku Research Center of the Forestry and Forest Products Research Institute (FFPRI) in Japan has developed a nursing system that imitates conditions in natural forests. The seedlings require 6–30% relative light intensity to germinate and grow, although *T. dolabrata* var. *hondai* is a shade-tolerant tree (Sakurai and Mori 1985a, b; Itoya and Shimoda 1995). Therefore, the nursery bed is set 20 cm lower than the surrounding ground and is covered with plastic shading nets (Itoya and Shimoda 1999). Instead of the humic nursery soil generally used for the seedbed (Aomori Forestry Research Institute 2004), Kanuma pumice is used as a model mineral soil of the naturally regenerated forest (Mori et al. 2003).

Plant roots interact with symbiotic, pathogenic, or epiphytic microorganisms in the rhizosphere, and root exudates (amino acids, nucleotides, sugars, and secondary metabolites) influence microbial populations in the rhizosphere (Brimecombe et al. 2001). Flavonoids and isoflavonoids exuded from roots act as organic signals in legume–rhizobia symbiosis (Werner 2001). For instance, species of *Rhizopus* and *Fusarium* in the rhizosphere of Brassicaceae plants are selected by secondary metabolites (isothiocyanates) exuded from the roots (Ishimoto et al. 2000). Seeds of *T. dolabrata* var. *hondai* have resin cavities on the seed surface and contain several diterpenes and lignans (C_6C_3 dimers; Hasegawa and Hirose 1980), and terpenoids and phenolics that are generally antifungal (Waterman and Mole 1994). Nursery beds of *T. dolabrata* var. *hondai* smell like terpenoids after germination, and germination gradually continues for 5 mo after sowing (Sakurai and Mori 1985a; Itoya and Shimoda 1995; K. Yamaji, unpublished data).

Based on these previous findings, we hypothesized that antifungal compounds of seeds might select for fungi on root surfaces of *T. dolabrata* var. *hondai* seedlings in the early growth stage, i.e., antifungal compounds of seeds might influence seed and soil fungi, and

those seed and soil fungi tolerant of antifungal compounds might grow on seedling root surfaces. In this study, we examined seedlings growing in Kanuma pumice and nursery soil because different soil fungi and nutrient conditions may influence which fungi will grow on the root surfaces. We identified seed and soil fungi and examined the sensitivity of these to methanol extracts of the seeds. In addition, we identified fungi on the seedling root surfaces and calculated the fungal detection frequency (FDF, %). We then examined the relationship between FDF on root surfaces and the fungal sensitivity to the seed extract. Finally, we isolated from the seeds the antifungal compound totarol, and tested it for antifungal sensitivity.

Methods and Materials

Seeds, Soil, and Seedlings *Thujopsis dolabrata* var. *hondai* seeds were randomly collected from approximately 20 felled trees in natural forests in Nakasato, Aomori Prefecture, northern Honshu, Japan (40°58′N, 140°28′E) in October 2002. *T. dolabrata* var. *hondai* trees have good, normal, and poor harvest years, and the harvest (3.23 g fresh weight [FW], 1000 seeds) was poor in 2002. Seeds were kept at 4°C in a paper bag until use.

Kanuma pumice, a volcanic andesitic rock and highly weathered, was purchased (Kyodo-Jirushi, Kanuma, Japan). Fifteen 18-l bags of Kanuma pumice were mixed uniformly and used for the experiments. Humic nursery soil that has andic and allophanic properties was collected in a *T. dolabrata* var. *hondai* nursery in Hiranai (50×100 m), Aomori Prefecture, Japan (40°53′N, 141°00′E) on 16 April 2003. Approximately 18 l of soil was collected from 15 sites (0–10 cm depth) at the nursery and was uniformly mixed. Table 1 shows the general characteristics of the Kanuma pumice and the nursery soil.

Fifty nonsterilized seeds were sown per plastic pot (90-mm height×100-mm diameter) that contained Kanuma pumice or nursery soil on 25 April 2003. Seeds were not covered with soil (Itoya and Shimoda 1995). Pots were kept in a greenhouse at the Tohoku Research Center, FFPRI, Morioka, Japan (39°46′N, 141°08′E). Twenty pots per soil were placed in a block, and 10 blocks were prepared for replications of each soil. After 1 mo, pots were transferred from the greenhouse to a nursery covered with plastic shading nets that allowed 32% of photosynthetically active radiation, as evaluated by using an LI-1400 datalogger

Table 1 General characteristics of Kanuma pumice and nursery soil (0–10 cm depth)

Characteristic	Kanuma Pumice	Nursery Soil
pH (KCl)	4.79±0.01	4.25±0.02***
Exchangeable Na (cg/kg)	22.9±0.90	22.3±1.09

Exchangeable Mg (cg/kg)	11.7±0.97	16.5±0.09**
Exchangeable Ca (cg/kg)	120.9±4.47	126.6±1.58
Available P (mg/kg)	Trace	22.2±2.21***
Total C (%)	0.13±0.01	9.34±0.07***
Total N (%)	0.01±0.00	0.56±0.00***
C/N	28.0±7.83	16.6±0.16

Results are expressed as value ±S.E. Differences between values for Kanuma pumice and nursery soil were evaluated by using Student's *t*–test.

***$P<0.001$, **$P<0.01$.

with a quantum sensor (Li-Cor, Lincoln, NE, USA). Seeds were watered every 2 or 3 d, and the position of the blocks was randomized every month. On 1 July 2003, five seedlings were randomly selected from pots of each soil type. Heights and basal diameters of the seedlings were measured before the collection. Seedling roots were rinsed with water and dried on filter paper. Fresh weights of the aboveground parts and roots of each seedling were measured separately (Table 2). Roots of these seedlings were used to isolate fungi on the root surfaces.

Fungal Isolation from Seeds Forty-five seeds were randomly selected and used to isolate fungi. Two seeds were placed separately per plate (90-mm diam) of potato dextrose broth (10 ml; Wako, Osaka, Japan) that contained 2% agar (PDA). They were incubated for 10 d in the dark at 25°C. Fungal colonies were detected with a microscope (×40 and ×100, Nikon Eclipse E400, Tokyo, Japan) and were inoculated onto acidic PDA (pH 3) that contained 0.025% citric acid to separate fungi from bacteria. The fungi were transferred again onto acidic PDA, cultivated for 7 d in the dark and then transferred and cultivated on normal PDA. Fungal genera were identified based on Watanabe (2002) and Barnett and Hunter (1998). Fungal detection frequency on the seeds was calculated as: FDF on seeds (%) = $(N_d/N_t) \times 100$, where N_d is the number of seeds from which the fungus was detected, and N_t is the total number of seeds (= 45).

Fungal Isolation from Soil Soil fungi were isolated by using the method of Warcup (1950). Four boxes (240×120×100 mm high) each were prepared to hold Kanuma pumice and nursery soil. Soil in each box was fully mixed, and water was added to the boxes until it poured from the bottom. The soil was incubated for 2 d at room temperature. The water contents of the Kanuma pumice and nursery soil after the incubation were 43.3% and 48.6%, respectively. Ten milligrams of Kanuma pumice were collected and crushed in sterile demineralized water (1 ml) by using sterile tweezers on a plastic plate (90-mm diam). Liquid PDA (10 ml, approximately 40°C) was poured into the plate and mixed fully with the crushed soil. The plate was incubated for 10 d in the dark at 25°C. Ten milligrams of nursery soil were collected and shaken with 10 ml of sterile water in a screw-topped test tube (120-mm height×25-mm diam) for 5 min under reciprocal rotation at 250 rpm. A 1-ml sample was then placed in a plastic plate (90-mm diam), and melted PDA (10 ml, approximately 40°C) was poured into the plate. The plate was incubated for 10 d in the dark at 25°C. Eight replications were prepared for each soil type. Fungal isolation methods and identification of genera were the same as for fungal isolation from seeds. The FDF in the soil was calculated as: FDF in soil (%) = $(N_d/N_t) \times 100$, where N_d is the number of plates from which the fungus was detected and N_t is the total number of plates (= 8).

Table 2 Fresh weight, height, and basal diameter of seedlings used for fungal isolation on the root surface

Seedlings	Total FW (mg ± SE)	FW of Leaves and Stem (mg ± SE)	FW of Roots (mg ± SE)	Height (mm ± SE)	Basal Diameter (mm ± SE)
Kanuma pumice	28.3±1.83	20.2±1.55	8.04±0.73	17.9±0.63	0.78±0.04
Nursery soil	34.4±3.10	25.6±1.75	8.76±1.61	19.6±1.06	0.88±0.07

No significant difference was detected between the soils for any variable (Student's *t*-test, $P>0.05$).

Fungal Isolation from Seedling Roots Mycelia were isolated from root surfaces of seedling growing in soils by using the method described by Harley and Waid (1955). Roots were rinsed twice with demineralized water and transferred to a screw-topped test tube (120-mm height×25-mm diam) that contained sterile demineralized water (7 ml). The test tube was reciprocally shaken at 250 rpm for 3 min, and then all the water was discarded, and sterile demineralized water (7 ml) was aseptically added to the test tube. The test tube was shaken again at 250 rpm for 3 min; this procedure was repeated nine times. Roots were then placed on a sterile filter paper (no. 1, Advantec, Tokyo, Japan) to remove extra water and were cut into 5-mm pieces on a glass plate. The pieces were separately placed onto PDA plates and incubated for 10 d in the dark at 25°C. Fungal isolation methods and identification of genera were the same as for fungal isolation from seeds. The FDF on roots was calculated as: FDF on roots (%) = $(N_d/N_t) \times 10$, where N_d is the number of root pieces from which the fungus was detected and N_t is the total number of root pieces. The FDF values for roots of five seedlings were averaged and used for correlation analyses.

Fungal Sensitivity to Seed Extract The following strains were isolated from seeds and soils and were used for the fungal sensitivity test: the seed fungi *Alternaria* (isolate nos. 1a, 26c), *Cladosporium* (isolate nos. 5a, 10e), *Pestalotiopsis* (isolate nos. 8b, 17b2, 35b), and *Phomopsis* (isolate nos. 3a, 6c); the Kanuma pumice fungi *Mortierella* (isolate nos. C, D) and *Mucor* (isolate nos. A, F); and the nursery soil fungi *Trichoderma* (isolate nos. 4-5, 3-10) and *Umbelopsis* (isolate nos. 9-3a, 10-3). These were the most frequently isolated genera. *Mucor* and the other fungal genera were identified to species level by rDNA sequence analysis by using primer pairs NL1/NL4 (O'Donnell 1993) and ITS1/ITS4 (White et al. 1990), respectively.

Soils (800 g) in 800 ml of demineralized water were autoclaved at 121°C for 20 min. The liquid was stored overnight at 4°C and filtered *in vacuo*. The filtrate was adjusted to 800 ml, 0.16 g of K_2HPO_4 and 1.6 g agar were added, and the mixture was autoclaved at 121°C for 20 min to produce Kanuma pumice extract agar (KPA) or nursery soil extract agar (NSA).

To produce seed extract, seeds (N=150, totaling 490 mg FW) were soaked in methanol (10 ml) and cut into pieces with a scalpel. The mixture was left for extraction overnight in the dark at room temperature. The extract was evaporated and stored at −20°C for later use.

The sensitivities of seed fungi and Kanuma pumice fungi were examined on KPA, and those of seed fungi and nursery soil fungi were examined on NSA. Methanol (50 μl) containing seed extract equivalent to 0.2, 0.4, or 0.8 seeds was added to a plastic plate (60-mm diam) and was mixed with melted KPA or NSA (5 ml, approximately 40°C). As a control, only methanol (50 μl) was used. A piece (2×2 mm) cut from the edge of freshly grown mycelia on PDA was inoculated at the center of a soil extract agar plate (60-mm diam). The plate was incubated in the dark at 25°C until the mycelial diameter on the control plate was approximately 30 mm for slow-growing fungi (*Alternaria*, *Cladosporium*) or approximately 40 mm for fast-growing fungi (*Pestalotiopsis*, *Phomopsis*, *Mortierella*, *Mucor*, *Umbelopsis*, *Trichoderma*); two mycelial diameters at right angles to each other were measured with a digital caliper square (Shinwa Rules Co., Ltd., Nigata, Japan). Four replications were prepared for each seed extract concentration, and the eight mycelial diameters were averaged.

The average mycelial growth on control plates was defined as 100%, and the relative growth rates on plates that contained seed extract were calculated. Regression analysis was performed to examine the relationship between the percentage of mycelial growth and seed extract concentration. All regression coefficients (P<0.05) were negative, so the absolute

value was used as an index of fungal sensitivity (Fig. 1). High fungal sensitivity values indicate that fungal growth was strongly inhibited by the seed extract. The fungal sensitivity values for the same species were averaged and used to calculate correlations with the FDF on root surfaces of the seedlings.

Antifungal Compounds of Seeds A thin-layer chromatography (TLC) bioautography assay was used to test the compounds in the seed extract against *Mucor* (strain A), which showed the highest sensitivity to the extract. Seed extract equivalent to 1.6 seeds was charged on a TLC plate (0.25 mm, Kieselgel 60 F_{254}, Merck, Darmstadt, Germany) and was developed in chloroform–methanol (9:1 *v*/*v*). A spore suspension in nutrient solution was sprayed over the developed TLC plate, which was then incubated at 25°C for 3 d (Homans and Fuchs 1970). Inhibitory zones were detected under UV light by binding with the fluorescent brightener Calcofluor White M2R (Woodward and Pearce 1985).

To isolate the compounds, 370 seeds (total=1.2 g FW) were soaked in methanol (20 ml) and cut into pieces with a scalpel, and the mixture was left for extraction overnight in the dark at room temperature. The extract (16.5 ml) was evaporated to produce an oily residue (246.5 mg), which was dissolved in ethyl acetate. The precipitate (45.8 mg) was removed on a filter paper, and the filtrate was evaporated to give an oily residue (220.6 mg). This residue (183.8 mg) was applied to a silica gel column (Wakogel C-60, 13 g, Wako, Tokyo, Japan) and eluted with chloroform–methanol (9:1). Fractions 13–17 (2 ml each) were concentrated together (90.6 mg). This residue (72.4 mg) was applied to a silica gel column (Wakogel C-60, 10 g) eluted with chloroform, and fractions 29–42 (1 ml each) were concentrated to 10.5 mg.

For identification, we used ^{1}H and ^{13}C NMR spectra and 2D NMR (H-H COSY, HMQC, HMBC, NOESY, and HOHAHA) with a JEOL Alpha-500 spectrometer (JEOL Ltd., Tokyo, Japan) to clarify the carbon sequences of the compound. The solvent was $CDCl_3$ and chemical shifts were recorded relative to the TMS (^{1}H) and solvent peaks (δ77.0°, ^{13}C). An EI–MS spectrum was obtained with a JMS-DX303HF mass spectrometer (JEOL Ltd., Tokyo, Japan) to clarify the fragmentation.

Quantification of Totarol Gas chromatography analysis was performed with an Auto System XL Gas Chromatograph (Perkin Elmer, Inc., Waltham, MA, USA) with a split-

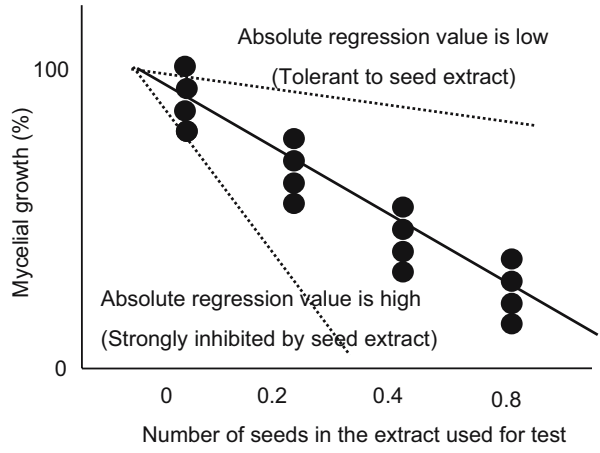

Fig. 1 Fungal sensitivity value. Regression analysis was performed between the percentage of mycelial growth and the concentration of the seed extract. All regression coefficients were negative ($P<0.05$), so the absolute value was used as an index of fungal sensitivity. High fungal sensitivity values indicate that fungal growth was strongly inhibited by the seed extract

splitless injector (1:10 ratio, 230°C) and FID detector (230°C). Nitrogen gas was used as a carrier gas at 1 ml min^{-1}. Hicap series CBP1 25 m×0.25 mm column (Shimadzu, Kyoto, Japan) was used for the analysis. The temperature program was 100–200°C at 10°C min^{-1}. The analysis was repeated three times, and the values were averaged. Standard curves were prepared as follows: totarol (0.138, 0.275, 0.55, 1.1 μg in 2 ml acetone; Sigma-Aldrich, St. Louis, MO, USA) was analyzed three times and values were averaged. The amount of totarol in the seed extract was read from the standard curve.

Examination of Fungal Sensitivity to Totarol Methanol (50 μl) that contained totarol equivalent to 0.2, 0.4, or 0.8 seeds (5.75, 11.5, and 23 μg, respectively) was added to a plastic plate (60-mm diam) and was mixed with KPA or NSA (5 ml, approximately 40°C). As a control, only methanol (50 μl) was used. Fungal inoculation and calculation of fungal sensitivity were the same as described for the fungal sensitivity to seed extract.

Statistical Analyses The StatView 5.0 (Macintosh) computer package (SAS Institute, Inc., Cary, NC, USA) was used for statistical analyses. Fungal sensitivity was obtained by regression analysis. The relationship between FDF (%) on root surfaces and fungal sensitivity to seed extract or totarol were examined with Pearson's correlation test. Differences were considered significant at $P<0.05$.

Results

Seed Fungi Penicillium (several species; FDF 46.7%), *Alternaria* (40.0%), *Cladosporium* (35.6%), *Pestalotiopsis* (17.8%), and *Phomopsis* (8.9%) were the main isolates. *Alternaria* (isolate nos. 1a, 26c), *Cladosporium* (isolate nos. 5a, 10e), *Pestalotiopsis* (isolate nos. 8b, 17b2, 35b), and *Phomopsis* (isolate nos. 3a, 6c) were selected to examine fungal sensitivities to the seed extract and the antifungal compound totarol. *Papulospora* (FDF 6.7%), *Aspergillus* (2.2%), *Mortierella* (2.2%), *Phoma* (2.2%), *Sclerotium* (2.2%), and *Trichoderma* (2.2%) were also isolated.

Soil Fungi (Kanuma Pumice) Penicillium (several species; FDF 100.0%), *Mucor* (75.0%), *Cladosporium* (62.5%), *Mortierella* (50.0%), *Alternaria* (12.5%), *Aspergillus* (12.5%), *Aureobasidium* (12.5%), *Gliocladium* (12.5%), and *Ulocladium* (12.5%) were isolated. These *Cladosporium* and *Alternaria* species were different species from the seed fungi found in these genera. *Mortierella* (isolate nos. C, D) and *Mucor* (isolate nos. A, F) were selected to examine fungal sensitivities to the seed extract and totarol.

Soil Fungi (Nursery Soil) Penicillium (several species; FDF 100.0%), *Umbelopsis* (87.5%), *Trichoderma* (62.5%), *Truncatella* (50.0%), *Pestalotiopsis* (25.0%), *Mucor* (12.5%), and *Stagonospora* (12.5%) were isolated. The *Pestalotiopsis* species was different from the seed fungus in this genus. *Trichoderma* (isolate nos. 4-5, 3-10) and *Umbelopsis* (isolate nos. 9-3a, 10-3) were selected to examine fungal sensitivities to the seed extract and totarol.

Fungi on Roots (Kanuma Pumice) Penicillium (several species; FDF 38.4%), *Phomopsis* (24.4%), *Cladosporium* (21.8%), *Pestalotiopsis* (16.7%), *Alternaria* (15.6%), *Gliocladium* (11.3%), *Coniothyrium* (10.9%), *Staphylotrichum* (5.4%), and *Mortierella* (4.4%) were isolated. The *Mortierella* and *Gliocladium* species were the same as the Kanuma pumice

fungi in these genera. Several different *Penicillium* species originated from the seeds and soil.

Fungi on Roots (Nursery Soil) *Cladosporium* (FDF 26.0%), *Penicillium* (several species; 22.4%), *Trichoderma* (13.7%), *Phomopsis* (10.1%), *Pestalotiopsis* (9.0%), *Humicola* (6.2%), *Fusarium* (4.7%), *Alternaria* (4.2%), *Aspergillus* (4.2%), *Torula* (2.9%), *Papulaspora* (1.8%), *Geotrichum* (1.3%), and *Paecilomyces* (1.3%) were isolated. The *Alternaria*, *Cladosporium*, *Pestalotiopsis*, and *Phomopsis* species were the same as the seed fungi in these genera, and *Trichoderma* was the same species as the nursery soil fungus. Several different *Penicillium* originated from the seeds and soil.

Fungal Sensitivity to Seed Extract Fungal sensitivities to the seed extract on KPA were 45.6 for *Alternaria* (seed fungi), 25.0 for *Cladosporium* (seed fungi), 46.4 for *Phomopsis* (seed fungi), 45.6 for *Pestalotiopsis* (seed fungi), 80.0 for *Mortierella* (Kanuma pumice fungi), and 84.0 for *Mucor* (Kanuma pumice fungi). Fungal sensitivities to the seed extract on NSA were 57.5 for *Alternaria* (seed fungi), 22.1 for *Cladosporium* (seed fungi), 44.4 for *Pestalotiopsis* (seed fungi), 58.1 for *Phomopsis* (seed fungi), 41.4 for *Umbelopsis* (nursery soil fungi), and 38.2 for *Trichoderma* (nursery soil fungi).

Correlation Results Significant and negative correlations were found between the FDF on seedling root surfaces and fungal sensitivity to the seed extract in both soils ($P<0.05$; Fig. 2a,b). Correlation coefficients (r^2) for Kanuma pumice and nursery soil were −0.915 ($P=0.007$) and −0.834 ($P=0.038$), respectively.

Relationship between FDF on Root Surfaces and Fungal Sensitivity to Totarol Based on analyses of ^{1}H and ^{13}C NMR data and EI-MS data, we identified the antifungal compound in the seeds of *T. dolabrata* var. *hondai* as totarol (Fig. 3), which agreed with the NMR findings of Ying and Kubo (1991).

Fungal sensitivities to totarol on KPA were 68.6 for *Alternaria* (seed fungi), 55.1 for *Cladosporium* (seed fungi), 64.4 for *Phomopsis* (seed fungi), 62.2 for *Pestalotiopsis* (seed fungi), 75.2 for *Mortierella* (Kanuma pumice fungi), and 90.6 for *Mucor* (Kanuma pumice

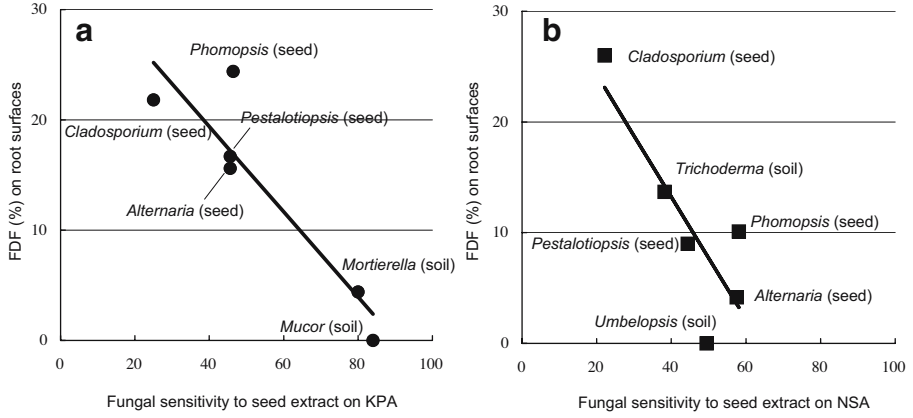

Fig. 2 Relationship between the fungal detection frequency (FDF) on the root surfaces and fungal sensitivity to seed extract: (**a**) Kanuma pumice ($r^2=-0.915$, $P=0.007$); (**b**) nursery soil ($r^2=-0.834$, $P=0.038$). The origin of each fungus is shown in parentheses

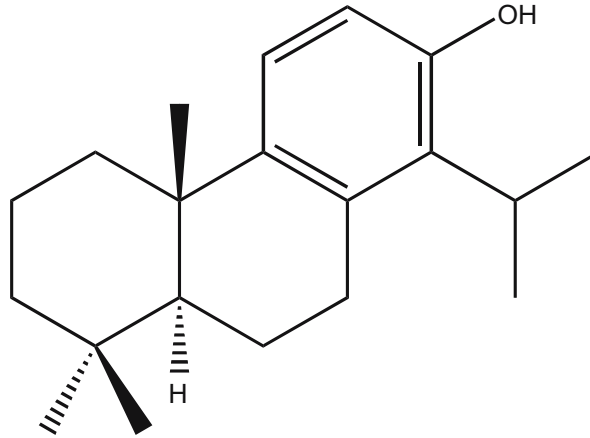

Fig. 3 Chemical structure of totarol

fungi); those on NSA were 70.2 for *Alternaria* (seed fungi), 40.5 for *Cladosporium* (seed fungi), 57.5 for *Pestalotiopsis* (seed fungi), 55.9 for *Phomopsis* (seed fungi), 56.7 for *Umbelopsis* (nursery soil fungi), and 54.1 for *Trichoderma* (nursery soil fungi).

Significant and negative correlations were found between the FDF on seedling root surfaces and fungal sensitivity to totarol in both soils ($P<0.05$; Fig. 4a,b). Correlation coefficients for Kanuma pumice and nursery soil were −0.898 ($P=0.01$) and −0.814 ($P=0.049$), respectively.

Discussion

The FDF values on root surfaces in both soils were significantly correlated with the fungal sensitivity to the seed extract and totarol, an antifungal compound of seeds. Our results indicate that seed and soil fungi tolerant of totarol can grow on the root surfaces of *T.*

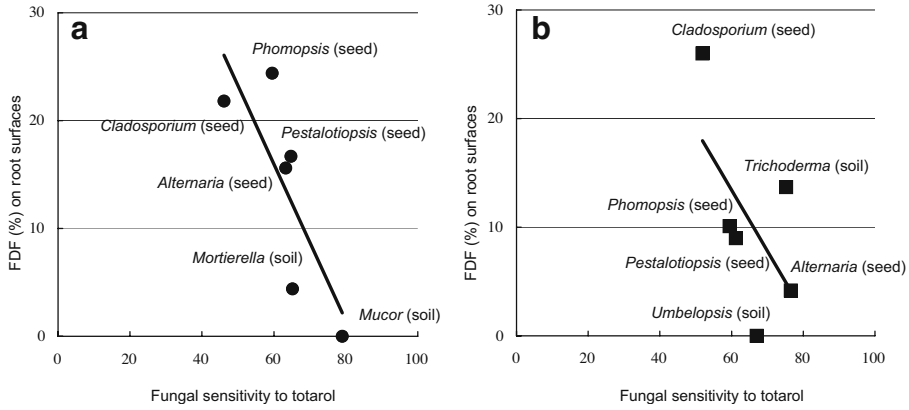

Fig. 4 Relationship between the fungal detection frequency (FDF) on the root surfaces and fungal sensitivity to totarol. (**a**) Kanuma pumice ($r^2=-0.898$, $P=0.01$). (**b**) Nursery soil ($r^2=-0.814$, $P=0.049$). The origin of each fungus is shown in parentheses

dolabrata var. *hondai* seedlings. Totarol has been isolated from *T. dolabrata* var. *hondai* seeds (this study; Hasegawa and Hirose 1982) as well as from *Pilgerodendron uviferum* (D. Don) Florin bark extracts, from which it was shown to be antifungal against *Rhizoctonia solani* and *Phragmidium violaceum* (Solís et al. 2004). In our study, totarol was also detected in Kanuma pumice and nursery soil (0.38±0.08 μg g^{-1} soil FW and 0.61±0.16 μg g^{-1} soil FW, respectively) in which 2-mo-old *T. dolabrata* var. *hondai* seedlings were growing. The seedling roots also contained totarol (0.45±0.06 μg g^{-1} root FW grown in Kanuma pumice and 0.84±0.16 μg g^{-1} root FW grown in nursery soil, respectively), and thus, totarol would select fungi on root surfaces of the seedlings in the early growth stage. α- and β-Eudesmol have been isolated from *T. dolabrata* var. *dolabrata* seeds (Hasegawa and Hirose 1982). β-Eudesmol has been extracted from amboyna wood and is antifungal against the wood-rotting fungus *Pleurotus pulmonarius* (Kusuma et al. 2004). In our study, mixtures of α-, β-, and γ-eudesmol (2:2:1) were isolated from *T. dolabrata* var. *hondai* seeds; these compounds were identified by analyses of ^{1}H and ^{13}C NMR data, which agreed fully with those of Raharivelomanana and Bianchini (1995). However, the amount of eudesmols in the seeds was too low to be antifungal against the tested fungi, except for *Mucor* (4.95 μg per seed). Therefore, we conclude that totarol is the main antifungal compound in the *T. dolabrata* var. *hondai* seeds.

Soil nutrient conditions influence mycelial growth, and the rate of mycelial growth seems to be one factor that selects fungi in the rhizosphere. We also examined the rates of mycelial growth of seed and soil fungi on both KPA and NSA. However, the mycelial growth rates were not related to the FDF on the roots (r^2=−0.11, P=0.85 for Kanuma pumice; r^2=0.05, P=0.93 for nursery soil). This result indicates that the nutrient differences between Kanuma pumice and nursery soil did not affect which fungi grew on the seedling root surfaces.

The seed extract would include amino acids and vitamins that stimulate fungal growth. Therefore, the correlation between FDF and fungal sensitivity to the seed extract was different from that between FDF and fungal sensitivity to totarol (Figs. 2, 4). Complicated interactions between chemical compounds (including antifungal compounds and nutrients) and fungal growth would be expected.

Our method (Fig. 1) did not allow us to compare fungal sensitivity values with the minimum inhibitory concentration (MIC). To examine the interaction between an antifungal compound and fungal growth in a natural environment, fungal sensitivity values need to be better than MIC, which is calculated by using an impractically high amount of antifungal compounds against tolerant fungi. Because our fungal sensitivity values reflect the actual amount of antifungal compounds in plant tissues, these values should more accurately estimate the influence of antifungal compound on fungi.

Seeds were collected directly from felled *T. dolabrata* var. *hondai* trees, and thus, seed fungi would be epiphytic on trees. *Alternaria*, *Cladosporium*, *Penicillium*, and *Trichoderma* have been isolated from various conifer seeds (Watanabe 2002), and thus are not specific to *T. dolabrata* var. *hondai* seeds. *Pestalotiopsis* has weak pathogenicity to conifer seedlings, and *Phomopsis* causes cankers of conifer trees and seedlings (Ito 1974). Future work should examine the influences of these fungi on *T. dolabrata* var. *hondai* seedlings.

Based on the findings of this study, we conclude that the antifungal compound totarol that is produced by *T. dolabrata* var. *hondai* seeds is one factor in the selection of fungi on root surfaces in the early growth stage.

Acknowledgments We thank the Hiranai Hiba Forestry Research Group for providing us with nursery soil; the Forestry Technology Center, Tohoku Regional Forest Office, for helping with the seed collection; and Mr.

N. Shimoda for technical help with our work in the nursery. Financial support was provided in part by Research Fellowships of Japan Society for the Promotion of Science for Young Scientists and by a research grant of the Forestry and Forest Products Research Institute, Japan.

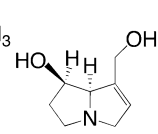
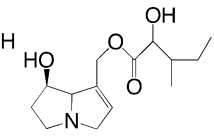
1999; Hartmann and Ober 2000; Eisner et al. 2002; Pasteels et al. 2003; Conner and Weller 2004). Many aspects remain to be explored and can be expected to reveal rich and rewarding examples of evolutionary biology.

PAs taken up from host plants are often converted into insect-PAs in which the acid moiety of plant origin is replaced by small, branched, aliphatic 2-hydroxy acids of insect origin. Commonly found insect-PAs include callimorphine (**1**), the 2-acetoxy-2-methylbutanoic O^9 ester of retronecine (**2**), creatonotine A, 9-(2-hydroxy-3-methylbutanoyl) retronecine, and creatonotine B (**3**), 9-(2-hydroxy-3-methylpentanoyl) retronecine (Fig. 1; Aplin et al. 1968; Edgar et al. 1980; Hartmann et al. 1990, 2004a; Schulz et al. 1993). Insect-PAs are predominantly esters of **2**. Insects that ingest PAs with a heliotridine (**4**) moiety commonly invert the C^7 (*S*) hydroxyl to C^7 (*R*); for example, 7*S*-heliotrine (**5**) is converted to 7*R*-*epi*-heliotrine (**6**) by several species before formation of insect-PAs (Wink et al. 1988; Schulz et al. 1993). Insect-PAs with a retronecine (**2**) moiety also occur as O^7 esters including isocallimorphine (**7**) and isocreatonotine B (**8**) (Hartmann et al. 1990, 2004a).



Hartmann et al. (2003b, 2004a, b, 2005a) have presented evidence that insect-PAs, specifically creatonotines, are converted into the pheromone hydroxydanaidal (**9**) in males of the arctiid moth *Estigmene acrea*, but no biosynthetic reason has been given for why insect-PAs are involved, and it is not immediately clear why this would be the case from consideration of the currently accepted biosynthetic pathway for hydroxydanaidal (**9**) proposed by Schulz et al. (1993) (Scheme 1, dotted arrows). It also is not known if insect-PAs are the precursors of **9** in other species. We have, therefore, looked for evidence that insect-PAs are also involved in the biosynthesis of hydroxydanaidal (**9**) in the arctiid moth *Creatonotos transiens* and have considered possible mechanisms of biosynthesis of hydroxydanaidal (**9**) that specifically require insect-PAs as precursors. In a preliminary investigation, we established that when final male instars of *C. transiens* are fed with pure supinine (**10**) (an alkaloid lacking a C^7 hydroxyl), they produce the insect-PAs 7-desoxycallimorphine (**11**) and estigmine B (=7-desoxycreatonotine B) (**12**), which do not proceed to hydroxydanaidal (**9**) or produce its 7-desoxy analogue danaidal in the adult moths. Thus, **10** can be used as an indicator of insect-PA biosynthesis activity. We have, thus, used **10** to indicate insect-PA biosynthetic activity in *C. transiens*, while simultaneously feeding increasing amounts of **5**, a PA known to produce **9,** to look for evidence that insect-PAs derived from **5** are intermediates in the biosynthesis of **9** in *C. transiens*.

Methods and Materials



GC-MS and LC-MS Analysis Electron impact mass spectra (70 eV) were obtained with a Hewlett-Packard 5972 mass spectrometer coupled to a Hewlett-Packard 5890 series II gas chromatograph equipped with splitless on-column injection and an SGE BPX5 column: 30 m×0.25 mm 0.5 μm film thickness. The injector and transfer line were set at 250°C, ion source temperature was 150°C, and gas chromatograph oven temperature was 80°C for 2 min then programmed to 300°C at 20°C/min. The carrier gas was helium at 1.6 ml/min and spectra were recorded at 70 eV. Liquid chromatography/mass spectrometry (LC-ESI-MS) was performed by using a ThermoFinnigan Surveyor autosampler and liquid chromatography system coupled to a ThermoFinnigan LCQ ion-trap mass spectrometer as described previously by Boppré et al. (2005).

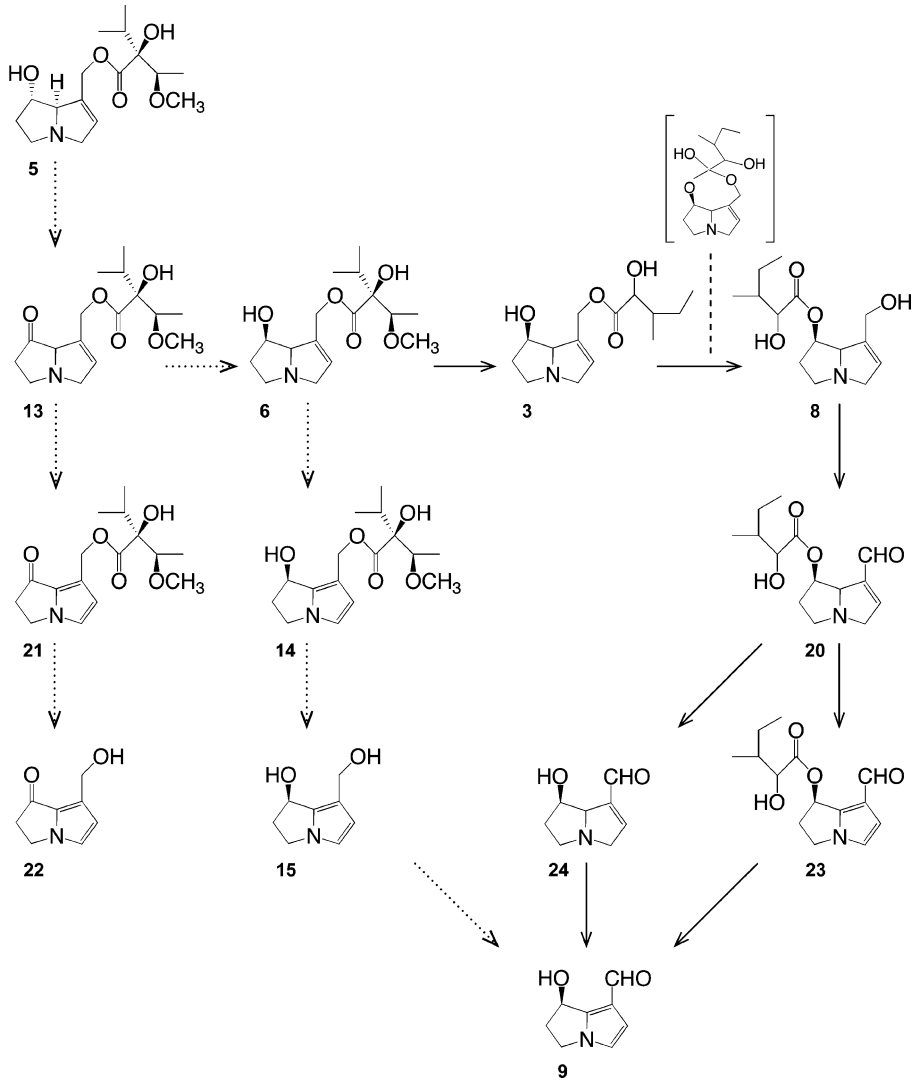

Fig. 1 Structures of some 1,2-dehydro-pyrrolizidine ester alkaloids (PAs), insect-PAs, and dihydropyrrolizines, including insect pheromones, derived from these. For simplicity, the PAs shown are depicted as free bases, although they usually occur and are strictly maintained in plants and insects as *N*-oxides (see review by Hartmann and Ober 2000). It should be noted, however, that the dihydropyrrolizine ("pyrrole") oxidation products shown, viz. **9**, **14**, **15**, **21**, **22**, and **23**, do not occur as *N*-oxides because the nitrogen lone pair electrons required for *N*-oxidation are delocalized in the aromatic "pyrrole" ring system. Callimorphine (**1**), retronecine (**2**), creatonotine B (**3**), heliotridine (**4**), heliotrine (**5**), 7*R*-*epi*-heliotrine (**6**), isocallimorphine (**7**), isocreatonotine B (**8**), 7*R*-hydroxydanaidal (**9**), supinine (**10**), desoxycallimorphine (**11**), estigmine B (=7-desoxycreatonotine B) (**12**), 7-ketoheliotrine (**13**), dehydro-7*R*-*epi*-heliotrine (**14**), dehydro-retronecine (**15**), anhydro-retronecine (**16**), 9-angeloylretronecine (**17**), 7-angeloylretronecine (**18**), lycopsamine (**19**), isocreatonotine B aldehyde (**20**), dehydro-7-ketoheliotrine (**21**), loroquin (**22**), dehydro-isocreatonotine B aldehyde (**23**), retronecine aldehyde (**24**), viridiflorine β-lactone (**25**), ithomiolide A (**26**), and hydroxy-lycopsamine (**27**)

Thin Layer Chromatography Thin layer chromatography (TLC) was performed on Polygram® SIL G/UV254 precoated plastic sheets (Merck) with chloroform/methanol/conc. ammonia (85:14.5:0.5) as solvent. PAs were made visible by iodine vapor or by spraying with chloranil and subsequently Ehrlich reagent (Molyneux and Roitman 1980).

Chemicals Pure hydroxydanaidal (**9**), supinine (**10**), and heliotrine (**5**) were obtained from a collection of PAs, and their metabolites held at CSIRO Australian Animal Health Laboratory, Geelong, Australia, where they were isolated from various plant sources or synthesized and characterized by nuclear magnetic resonance, mass spectra, microanalysis, melting point, and comparison with authentic samples.

Identification of PAs and Their Metabolites PAs **10** and **5**, extracted from *C. transiens*, were identified by comparison of their TLC R_f values, GC retention times (13.42 and 14.25, respectively), mass spectra molecular weights (*m*/*z* 283 and 313, respectively), and MS fragmentation patterns with those of the authentic standards given to the larvae. Hydroxydanaidal (**9**) was identified also by comparison of TLC R_f and GC retention time (10.01 min) and mass spectrum (M^+, *m*/*z* 151) with that of an authentic standard. The insect-PAs callimorphine (**1**) (GC retention time 13.35 min; M^+, *m*/*z* 297), creatonotine B (**3**) (13.65 min; M^+, *m*/*z* 269), isocreatonotine B (**8**) (13.46 min; M^+, *m*/*z* 269), 7-desoxycallimorphine (**11**) (12.44 min; M^+, *m*/*z* 281), estigmine B (=7-desoxycreatonotine B) (**12**) (12.56 min; M^+, *m*/*z* 253), and 7*R*-*epi*-heliotrine (**6**) (14.15 min; M^+, *m*/*z* 313) were tentatively identified by comparison of their electron impact spectra with published spectra (Edgar et al. 1980; Wink et al. 1988; Ehmke et al. 1990; Hartmann et al. 2004a). Molecular weights were confirmed by LC-ESI-MS.

Feeding Experiments Larvae of *C. transiens* (Walker), from an established laboratory culture that originated from females collected in Indonesia and maintained on an artificial diet (Bergomaz and Boppré 1986), were used. Four groups of three to five male and four groups of three to five female larvae were each given either 500 μg supinine (**10**) alone (group A); or 500 μg **10** plus 200 μg **5**, (group B); 500 μg **10** plus 500 μg **5**, (group C); or 500 μg **10** plus 1,000 μg **5** (group D). The alkaloid stock solutions were made up in reagent grade methanol, and the appropriate volumes were applied to glass microfiber filter discs (Whatman® GF/B, 2.1 cm), which were offered to final instars as their first meal after molting. After the larvae had consumed the entire sample, they were fed with PA-free artificial diet until pupation [larvae of *Creatonotos* are pharmacophagous with respect to PAs—thus, pure PAs act as feeding stimulants, and larvae consume PAs offered on glass

Scheme 1 Showing the previous (*dotted arrows*; Schulz et al. 1993) and proposed (*solid arrows*) mechanisms for conversion of **5** to **9**. For simplicity, PAs are shown as free bases, although in the insects, they are strictly maintained as *N*-oxides (Hartmann and Ober 2000). It should be noted, however, that, as indicated in the legend of Fig. 1, the non-alkaloidal dihydropyrrolizine oxidation products, viz. **9**, **14**, **15**, **21**, **22**, and **23** cannot form *N*-oxides. Creatonotine B (**3**), heliotrine (**5**), 7*R*-*epi*-heliotrine (**6**), isocreatonotine B (**8**), 7*R*-hydroxydanaidal (**9**), 7-ketoheliotrine (**13**), dehydro-7*R*-*epi*-heliotrine (**14**), dehydro-retronecine (**15**), isocreatonotine B aldehyde (**20**), dehydro-7-ketoheliotrine (**21**), loroquin (**22**), dehydro-isocreatonotine B aldehyde (**23**), retronecine aldehyde (**24**)

microfiber (or other materials), thus allowing for quantiative feeding with PAs; cf. Boppré and Schneider 1985].

Quantification of PAs Newly emerged adults were held for 24 hr before the male coremata were artificially protruded and excised. The moths from each group were combined and macerated in methanol, filtered, and the methanol evaporated. The residue was dissolved in 2 N H_2SO_4, treated with Zn dust, and stirred at room temperature for 3 hr before being filtered. The filtrate was extracted three times with ether. The acid solution was then basified to above pH 10 with conc. ammonium hydroxide and extracted three times with an equal volume of dichloromethane. The dichloromethane was dried with anhydrous sodium sulphate, filtered, evaporated, and the residue transferred into a vial and dissolved in methanol ready for gas chromatography–mass spectrometry (GC-MS), LC-ESI-MS, and TLC analysis.

Adult moths reared on PA-free diet were injected with each of the stock solutions of the various mixtures of **10** and **5** used in the feeding experiments, and then extracted by the standard procedure to provide recovery data for GC-MS comparison with levels found in moths fed with these solutions as larvae.

Coremata from males were extracted with dichloromethane. Aliquots were immediately analyzed by GC-MS and TLC. The amount of **9** was estimated by GC-MS comparison with an authentic standard.

Results

Female *C. transiens* moths given only 500 μg of supinine (**10**) as final instars stored 260 μg (52%) in their bodies (Fig. 2a, ♀; Table 1). Only a trace of the insect-PA **11** was detected (Fig. 2a, ♀; Table 1). A similar level of storage of **10**, accompanied by traces of **11**, persisted as the amount of heliotrine (**5**) increased in the larval diet, and no insect-PAs derived from **5** were detected (Fig. 2b–d, ♀; Table 1). The virtual absence of insect-PAs in all groups indicates that female *C. transiens* have a limited capability for producing insect-PAs. A significant quantity of **5** fed to the female larvae was stored in the adult bodies as approximately equal amounts of **5** and 7*R-epi*-heliotrine (**6**) (Fig. 2b–d, ♀; Table 1), indicating that the females also have a limited ability to epimerise the C^7 hydroxyl group of **5**.

In marked contrast to females, male *C. transiens* given only 500 μg of pure **10** converted 318 μg to insect-PAs **11** and **12** (Table 2; Fig. 2a, ♂). Only a small amount (60 μg) was stored as unchanged **10** (Fig. 2a, ♂). No hydroxydanaidal (**9**) (Table 2) or danaidal, the C^7 desoxy analogue of **9**, was detected on the enlarged coremata. When 200 μg of **5** was fed along with 500 μg of **10** (Fig. 2b, ♂), a high proportion of the former (approximately 50%), allowing for molecular weight differences, 151 (**9**) vs 313 (**5**), was converted to **9**, also on enlarged coremata (Table 2). There was no evidence of **5** in the body extracts (Fig. 3b, ♂), and only a small amount (7 μg) of 7*R-epi*-heliotrine (**6**) (Table 2, Fig. 2b, ♂). No insect-PAs from **5** or **6** were detected, but the 7-desoxy analogues **11** and **12** from **10** were, as before (Fig. 2a, ♂), present in high amounts (Table 2, Fig. 2b, ♂). The insect-PAs **11** and **12** were, respectively, 39 and 36% by weight of the PAs detected in the extract of the bodies, excluding the pheromone **9** (Fig. 2b, ♂). Compounds **10** (23%) and **6** (2%) made up the remainder of the PAs in the body extract. The absence of insect-PAs derived from **5** and **6**

Fig. 2 GC-MS total ion chromatograms of alkaloid extracts of female and male *C. transiens* moths given in final larval stage 500 μg **10** (**a**), 500 μg **10** plus 200 μg **5** (**b**), 500 μg **10** plus 500 μg **5** (**c**), and 500 μg **10** plus 1,000 μg **5** (**d**). *x*=contaminant. For structures, see Fig. 1

but high levels of **11** and **12** that arise from **10** supports the hypothesis that insect-PAs originating from **5** and **6** were being used to produce **9**.

When the male *C. transiens* larvae were given a mixture of 500 μg of supinine (**10**) and 500 μg of heliotrine (**5**), a small amount of **5** (9 μg, 2% of total PAs in the bodies) was seen in the adults, along with an increased amount (50 μg, 12%) of 7*R-epi*-heliotrine (**6**) (Fig. 2c, ♂, Table 2). Only traces of insect-PAs from **6** were present, in agreement with the idea that they are intermediates in the formation of **9**, and were being rapidly used for that purpose. About 75 μg of **9**, equivalent to 30% of the amount of **5** fed, were detected on the enlarged coremata (Table 2). Evidence of significant insect-PA formation activity was again indicated by the presence of high levels of the 7-desoxy insect-PAs, **11** (33%) and **12** (26%), derived from supinine (**10**). Unchanged **10** represented 27% of the total PAs in the bodies (Fig. 2c, ♂, Table 2).

In the last male group, in which larvae received 1,000 μg of **5** and 500 μg of **10**, we believe that the requirement for **9** is largely satisfied, and the profile of alkaloids in the bodies (Fig. 2d, ♂) was similar to that seen in the equivalent female group (Fig. 2d, ♀) except that females were less efficient in converting **5** to **6**. Compound **6** represented 32% by weight of PAs present in the body extract of the males, and **10** was 62% of the stored PAs (Fig. 2d, ♂), the reverse of that seen in group D females. A small amount of the insect-PA **11** was present, and a trace of **1** was detected (Fig. 2d, ♂). As in the females, there were barely detectable levels of insect-PAs from either **10** or **5** present in males. The total ion chromatogram shown in Fig. 2d, ♂ was also, in respect to **5** and its metabolites, similar to that seen when 1,000 μg of **5** alone were fed to final instar males (Edgar et al., unpublished data). The virtual absence of insect-PAs, even those arising from **10** when 1,000 μg of heliotrine (**5**) are given to final instar male *C. transiens* larvae, is noteworthy. It suggests that **5**, or more specifically its epimer **6**, became the primary substrate for insect-PA production so that no insect-PAs from **10** were generated in males, and all of the insect-PAs from **6** were converted to **9**. An estimated 287 μg per moth of hydroxydanaidal (**9**) were

Insect-PAs formed from **10** were 7-desoxycallimorphine (**11**) and 7-desoxycreatonotine B (**12**). **5** was completely or partially epimerized to 7*R-epi*-heliotrine (**6**) then partially converted, via insect-PAs, e.g., creatonotine B (**3**) (only trace amounts of which were seen, Fig. 3, ♂), into hydroxydanaidal (**9**), which was secreted on coremata as a pheromone

[a] Percentage of recovered compounds

[b] Values for **9** are doubled to compensate for molecular weight differences between **9** and **5** (151 vs 313)

detected on enlarged coremata (Table 2), and this represented 57% of the heliotrine (**5**) fed to the larvae.

Discussion

*Insect-PAs as Precursors of Hydroxydanaidal (**9**) in C. transiens* The data obtained from feeding mixtures of **10** and **5** to final instars of *C. transiens* strongly support the hypothesis that insect-PAs that arise from **5** are intermediates in the biosynthesis of the pheromone hydroxydanaidal (**9**) in male *C. transiens*, in agreement with a similar conclusion drawn by Hartmann et al. (2003b, 2004a, b) in regard to formation of **9** in male *E. acrea*. By using supinine (**10**) as an indicator of insect-PA biosynthetic activity and heliotrine (**5**) as a precursor of hydroxydanaidal (**9**), it was apparent that insect-PAs formed from **5** were being rapidly and almost completely converted into hydroxydanaidal (**9**) in male *C. transiens*. The fact that female *C. transiens* were significantly less efficient in epimerizing the 7*S*-hydroxyl and in producing insect-PAs also points to the insect-PAs in *C. transiens* being primarily required to produce the male pheromone hydroxydanaidal (**9**).

*Mechanism for Formation of Hydroxydanaidal (**9**) from Insect-PAs* Heliotrine (**5**) is a well-established precursor of 7*R*-hydroxydanaidal (**9**) in *C. transiens* (Bell et al. 1984; Wink et al. 1988; Schulz et al. 1993). Schulz et al. (1993) proposed the currently accepted biosynthetic pathway from **5** to **9** (Scheme 1, dotted arrows). They demonstrated that *C. transiens* first oxidizes the 7*S*-hydroxyl of **5** to give 7-ketoheliotrine (**13**), which is then stereo-selectively reduced to 7*R-epi*-heliotrine (**6**), the epimer with the correct stereochemistry for **9**. They proposed that **6** is then aromatized to dehydro-7*R-epi*-heliotrine (**14**), hydrolyzed to dehydro-retronecine (**15**), and finally the primary hydroxyl is oxidized to give **9**. This proposal has been widely accepted as a model for the biosynthesis of **9** from PAs by insects, but it was put forward before it was found that insect-PAs, e.g., creatonotine B (**3**), may be required as intermediates in formation of **9** (Hartmann et al. 2003b, 2005b). The pathway proposed by Schulz et al. (1993) also involves formation of chemically reactive, hazardous dihydropyrrolizine ("pyrrole") intermediates such as **14** and **15**. These

are the very PA metabolites responsible for PA toxicity that PA-adapted insects, such as *C. transiens*, have evolved a specific mechanism to avoid, by maintaining PAs as non-toxic *N*-oxides that cannot be oxidized by cytochrome P450 isozymes to pyrrole esters such as **14** (Hartmann 1999). The mechanism of toxicity of 1,2-dehydropyrrolizidine ester alkaloid free bases, e.g., **6**, requires their metabolic conversion, *in vivo*, by cytochrome P450 enyzmes into dihydropyrrolizines, e.g., **14**, that are highly reactive biological alkylating agents. The relatively inert C^9 ester and C^7 alcohol or ester groups of alkaloids, such as **6,** become activated benzylic esters and alcohols once converted to dihydropyrrolizines, such as **14**. Compound **14** and its hydrolysis product **15** spontaneously generate carbonium ions at C^7 and C^9, and these immediately react with, and cross link, DNA and proteins at the site of their formation *in vivo*. This results in damage to biological systems in the organism unfortunate enough to consume PAs of this type. P450 enzymes are widespread, and they play important general and specific roles in virtually all organisms, including insects (Werck-Reichhart and Feyereisen 2000), so that 1,2-dehydro ester PAs can be expected to have broad-ranging toxicity against a wide spectrum of organisms, including insects. Abundant generalist insect herbivores avoid PA plants, indicating the anti-feeding and/or toxicity of PAs. Those insects that have adapted to PAs must actively maintain them as *N*-oxides that, unlike the free bases, are not oxidized to dihydropyrrolizines such as **14** by P450 enzymes. Thus, doubts are raised about the biosynthetic pathway suggested by Schulz et al. (1993), both by the recently demonstrated involvement of insect-PAs in the biosynthesis of **9** (Hartmann et al. 2003b) and the hazardous nature of the proposed chemically reactive dihydropyrrolizine ester intermediates (e.g., **14**).

The question arises: What are the structural features or chemical properties that make insect-PAs, such as **3**, more suitable for conversion into **9** than superficially similar alkaloids of plant origin such as **6**? We propose a biosynthetic pathway (Scheme 1, solid arrows) that specifically requires the structural attributes of insect-PAs, i.e., 7*R* stereochemistry and low molecular weight esterifying acids. This pathway, illustrated with creatonotine B (**3**), is equally applicable to other known retronecine ester insect-PAs, e.g., callimorphine (**1**), although Hartmann et al. (2005b) have concluded that the creatonotines, e.g., **3**, rather than callimorphines, e.g., **1**, are the specific precursors of **9** in *E. acrea*. Our proposal avoids the intermediacy of hazardous dihydropyrrolizine esters such as **14** or their hydrolysis product **15**. A key step is the intramolecular transesterification of O^9 ester insect-PAs, e.g., **3**, formed from 7*R*-*epi*-heliotrine (**6**), to the O^7 ester insect-PAs, e.g., **8**. This is only possible in the case of retronecine (**2**) esters with low molecular weight esterifying acids.

In retronecine (**2**), unlike heliotridine (**4**), the hydroxyl groups at C^9 and C^7 are close together, thus enabling, for example, the formation of the ether anhydro-retronecine (**16**) (Bull et al. 1968). Formation of such an ether structure is not physically possible with **4** where the hydroxyls are widely separated (Giordan et al., 1996). More importantly in the current context is the ability we have observed of retronecine O^9 monoesters such as 9-angeloylretronecine (**17**) to undergo intramolecular transesterification to 7-angeloylretronecine (**18**) in conc. aqueous NH_4OH at room temperature (unpublished data). The insect-PAs occur as both O^9 and O^7 esters, e.g., **1** and **7** and **3** and **8**, indicating that intramolecular O^9–O^7 transesterification is occurring with these molecules *in vivo*. Further evidence for this comes from the observation that rare insect-PAs with a heliotridine (**4**) moiety, which are unable to undergo O^9–O^7 intramolecular transesterification, have so far only been reported as O^9 esters (Hartmann et al. 2005b).

We propose (Scheme 1, solid arrows) that retronecine-based O^9 ester insect-PAs, e.g., **3**, are converted to O^7 ester insect-PAs, e.g., **8**, by internal, intramolecular transesterification.

If the insect-PAs were formed directly as O^7 esters, no intramolecular transesterification would be required. Intramolecular transesterification does not occur with any retronecine (**2**)-based PA monoesters. Bulky acids, for example, heliotric or viridifloric acids found in 7*R-epi*-heliotrine (**6**) and lycopsamine (**19**), appear not to be capable of intramolecular transesterification, and the O^7 ester isomers of **6** and **19** have never been found in nature. We note, however, that (Hartmann et al.2003a) have found the O^7 ester, 5′-demethylisolycopsamine (=isoideamine A), in extracts of the chrysomelid beetle *Platyphora boucardi*. They attribute this to intramolecular transesterification of the corresponding O^9 ester (ideamine A), suggesting that the acid involved, 2,3-dihydroxy-2-ethylbutanoic acid, may be near the upper size limit of acids able to undergo intramolecular O^9–O^7 transesterification and that the extra methyl group(s) present in heliotric and viridifloric acid, the esterifying acids of **6** and **19**, may be sufficient to prevent intramolecular O^9–O^7 transesterification. Brehm et al. (2007) have also found ideamine A and isoideamine A in *Prestonia amabilis* (Apocynaceae). Most PAs present in arctiine larval host plants have much bulkier O^9 esterifying acids than those found in insect-PAs and are unlikely to undergo O^9–O^7 intramolecular transesterification and, thus, according to our proposed pathway, cannot be used by *C. transiens* to make hydroxydanaidal (**9**). We, therefore, propose that *C. transiens* must convert some of the more complex plant PAs they ingest with their larval host plants into insect-PAs for intramolecular O^9–O^7 transesterification to occur. Our proposed biosynthetic pathway is premised on the ability of retronecine O^9 ester PAs, with small esterifying acids such as found in the insect-PAs, to transfer the esterifying acid to the O^7 position to allow the C^9 hydroxyl to be oxidized to an aldehyde. In this context, it is interesting to note that we found that the desoxy insect-PAs, **11** and **12,** do not give rise to danaidal in *C. transiens*, possibly because there is no C^7 hydroxyl group to facilitate exposure of the C^9 hydroxyl to oxidation. Esterase hydrolysis of the O^9 ester to gain access to the C^9 hydroxyl is apparently not an option, and this is not unexpected because plant-PAs, and to a lesser extent insect-PAs, have sterically hindered ester linkages that increase both their resistance to detoxication by esterases and their toxicity (Edgar et al., unpublished data).

Our biosynthetic pathway (Scheme 1, solid arrows) finds support in studies on the mechanism of epimerization of heliotrine (**5**) to 7*R-epi*-heliotrine (**6**) in *C. transiens* (Scheme 1; Schulz et al.1993). The epimerization was found to proceed via 7-ketoheliotrine (**13**), a structural analogue to **20**. Schulz et al.1993 also reported finding **21** and **22** in all *C. transiens* feeding experiments. These structures are analogues of **23** and **9**, respectively, in our pathway. Thus, we surmise that without O^9–O^7 intramolecular transesterification, *C. transiens* would only be able to produce **22** and not **9**. By generating insect-PAs, able to undergo intramolecular transesterification from O^9 to O^7, *C. transiens* is able to expose the primary alcohol to oxidation and to produce **9**.

Hartmann et al. (2005a) reported formation of O^7, O^9 diester insect-PAs, the platyphorines, in the arctiine *E. acrea*, but only in females. The same diesters have been found previously in leaf beetles of the genus *Platyphora* feeding as specialists on plants that contain PAs (Hartmann et al. 2001; Pasteels et al. 2001). Neither female *E. acrea* nor leaf beetles make **9**, and we envisage that platyphorines arise because, in female moths and in leaf beetles, the free C^9 primary hydroxyl in the intermediate O^7 ester insect iso-alkaloids, e.g., equivalent to **8**, is not oxidized to the aldehyde **20** as in male *E. acrea* but is available to be re-esterified by a second insect-derived acid. The C^9–C^7 diester platyphorines are expected to be more toxic than monoester insect-PAs, so there is an evolutionary advantage in producing them.

The reactions proposed in our pathway are occurring in the PA *N*-oxides and not in the free bases depicted in Scheme 1. PAs are rigorously maintained by arctiines as *N*-oxides (Hartmann 1999; Naumann et al. 2002) because the *N*-oxides are not amenable to cytochrome P450 oxidation that is normally associated with aromatization of PAs *in vivo* to chemically reactive, biologically hazardous dihydropyrrolizine ("pyrrole") esters such as **14**. This is why the previously proposed conversion of **6** to **14** (Scheme 1) is unlikely. The point at which the *N*-oxide oxygen is lost in our proposed pathway and whether cytochrome P450 isozymes are involved in aromatization are issues for future determination. However, because the *N*-oxides of **20** and **24** are already at the same level of oxidation as the dihydropyrrolizines **23** and **9**, an alternative and more likely mechanism is "dehydration" of the *N*-oxides of **20** and/or **24** directly to **23** and **9**, respectively, as shown in Fig. 3. The electron withdrawing influence of the aldehyde group would facilitate this, and the conversion of the *N*-oxides of **20** to **23** and/or **24** to **9** (Fig. 3) may occur spontaneously. A bio-mimetic demonstration of the conversion of **24** *N*-oxide to **9** by dehydration is the conversion of retronecine (**2**) *N*-oxide to **9** in high yield by manganese dioxide oxidation that proceeds via **24** *N*-oxide (Culvenor et al. 1970b). Loss of the *N*-oxide oxygen, under the conditions of the MnO_2 reaction, can only be explained by spontaneous dehydration of the intermediate **24** *N*-oxide to give **9**. *In vitro*, the aromatization of PA *N*-oxides is facilitated by acetylation of the *N*-oxide group and subsequent facile elimination of acetic acid (Bull et al. 1968; Mattocks 1986). This application of the Polonovsky reaction has traditionally been used to convert PA *N*-oxides to dihydropyrrolizines (Culvenor et al. 1970a) and is used to detect PA *N*-oxides on TLC plates and paper chromatograms (Molyneux and Roitman 1980; Mattocks 1986).

A key aspect of our proposal is that the aldehyde **20** is generated before aromatization, thus avoiding the intermediacy of hazardous "pyrrole" esters such as **14** proposed by Schulz et al. (1993). The presence of an electron withdrawing carbonyl on the aromatic "pyrrole" ring greatly reduces the alkylating potential of the O^7 ester of **23**. Compound **23** is expected, from knowledge of analogous structures, e.g., 7-angeloyldanaidal (Culvenor et al. 1970b), to be considerably more stable and relatively biologically inert in contrast to intermediates such as **14**. 7-Angeloyldanaidal is, however, readily hydrolyzed by warm water to **9** (Culvenor et al. 1970b), mimicking the proposed conversion of **23** to **9**.

An important aspect that must be addressed in considering the pathway we are proposing for the conversion of **5** to **9** (Scheme 1, solid arrows) is the requirement for retention of stereochemistry at C^7 during hydrolysis of the C^7 ester linkages of either **20** and/or **23**. Retention of stereochemistry is expected in the hydrolysis of **20** to **24.** There is, however, a risk of racemization in the hydrolysis of **23**, where the electron withdrawing aldehyde group may participate. Indeed the *in vitro* hydrolysis of 7*S*-angeloyldanaidal by warm water

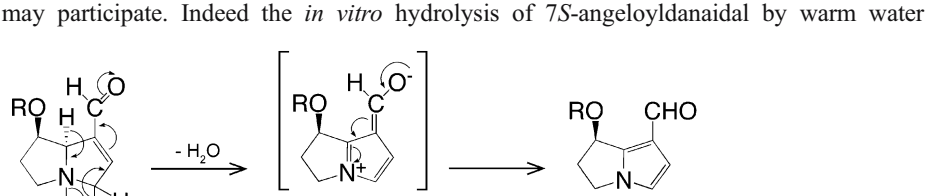

Fig. 3 Proposed mechanism for conversion of *N*-oxides of aldehydes **20** and **24** into dihydropyrrolizines **23** and **9**, respectively

resulted in racemization of the C^7 position (Culvenor et al. 1970b). Whether similar racemization occurs *in vivo* to the 7*R* analogue **23** needs to be determined by feeding synthetic **23** to *C. transiens* larvae.

It is clear from the results described above and the previous work of Hartmann et al. (2003b, 2005a) that one important role of insect-PAs, especially the creatonotines, e.g., **3**, is as mandatory intermediates in the production of hydroxydanaidal (**9**) by males of some arctiine species.

Broader Implications for PA-adapted Species Many Lepidoptera use hydroxydanaidal (**9**) as a male pheromone. In addition to the species of Danainae, Ithomiinae, and Arctiinae listed by Schulz (1998) and Schulz et al. (2004), **9** is also used by arctiines of *Haploa* (Davidson et al. 1997), *Pericallia*, *Amsacta*, and *Argina* (Boppré, unpublished) and probably others. The biosynthetic pathway to **9** proposed in this study for *C. transiens* may be employed by some of these. However, many species have not yet been investigated for insect-PAs let alone been the subject of biosynthetic studies on conversion of PAs to **9**. Very different biologies are involved, which are clearly the result of quite different origins, evolutionary pathways, and selection pressures, so that there are likely to be several biosynthetic mechanisms for producing **9** in PA-adapted species. Trigo et al. (1996) have, however, reported insect-PA-like substances in some ithomiine butterflies, raising the possibility that some of these species may also produce hydroxydanaidal (**9**) via insect-PA intermediates as shown in Scheme 1.

Another biosynthetic pathway for producing **9**, which avoids hazardous "pyrrolic" ester intermediates such as **14**, can be deduced from the use of viridifloric acid derived lactones **25** and **26** as pheromones by certain ithomiine and danaine butterflies (Edgar et al. 1976; Nishida et al. 1996; Schulz et al. 2004). These species may gain access to the C^9 hydroxyl by intramolecular transesterification reactions from lycopsamine (**19**), either directly in the case of lactone **25** or via an intermediate **27** in the case of lactone **26**. The retronecine (**2**) *N*-oxide released in each case could then be oxidized to **24**-*N*-oxide, and as previously proposed, this would yield **9** by spontaneous dehydration (Fig. 3).

Coremata Morphogenesis As a by-product of our experiments, we have shown that supinine (**10**) and/or insect-PAs **11** and **12**, although not precursors of the male pheromone **9**, may act as morphogens for development of the coremata. This shows that the size of the coremata does not indicate the amount of **9** a male possesses. In this new light, coupling vs non-coupling of coremata morphogenesis and pheromone biosynthesis and the specificity of inducing corematal growth require detailed quantitative studies (Boppré et al., unpublished data).

extracted and identified compounds from the cuticle of workers, the postpharyngeal gland of workers, ant pupae and larvae, and the fungal symbiont of three species of higher attine ants: *Atta colombica*, *Acromyrmex echinatior*, and *Sericomyrmex amabilis*. The relative proportions of identified compounds were compared and represented 11 classes: *n*-alkanes, alkenes, branched methylalkanes, branched dimethylalkanes, trimethylalkanes, branched alkenes, aldehydes, alcohols, acetates, acids, and esters. The chemical profiles in all three species are likely to be sufficiently different to allow discrimination at the species and colony level and sufficiently similar within colonies to generate a relatively constant colony-specific chemical gestalt. The relative likelihood of individual compounds being derived from the ants, the ant brood, or the fungal symbiont are discussed. We hypothesize that hydrocarbons are particularly important as recognition cues because they appear to simultaneously allow the assessment of developmental stages and the identification of symbiont, colony, and species.

Keywords Cuticular hydrocarbons · Colony odor · Recognition · Symbiosis

Introduction

Cuticular hydrocarbons profiles are thought to provide the main nestmate recognition templates in social insects (Singer 1998; Lahav et al. 1999), and many studies have shown that these compounds are involved in recognition processes between individuals, castes, and colonies (Vander Meer and Morel 1998). A colony's "odor profile" is typically determined by specific proportions of a series of hydrocarbons that function as a blurred barcode and prompts colony members to expel non-nestmate individuals with a different odor profile (Wilson 1971; Breed 1983). The origin of the chemical compounds involved in recognition and discrimination processes may differ across species, both for idiosyncratic reasons and because of variation in the genetic (Hölldobler and Wilson 1990; Beye et al. 1997, 1998; Boomsma et al. 2003) and environmental components (Obin 1986; Crosland 1989) of odor profiles. Environmental factors that contribute to colony odor include ambient temperature, humidity, soil characteristics, food, and nest material (Jutsum et al. 1979; Obin 1986; Crosland 1989; Heinze et al. 1996; Singer and Espelie 1996; Nielsen et al. 1999; Liang and Silverman 2000; Silverman and Liang 2001; Richard et al. 2004; Howard and Blomquist 2005).

The fungus-growing ants are exclusively a New World tribe of myrmicine ants (Attini) and are restricted largely to the tropics and subtropics of Central and South America. The attine tribe contains 13 genera and more than 210 species (Brandão and Mayhé-Nunes 2001; Mueller et al. 2001). The tribe is subdivided into a derived monophyletic group called the "higher attines," which includes the genera *Atta*, *Acromyrmex* (including *Pseudoatta*), *Trachymyrmex*, and *Sericomyrmex*, and a largely paraphyletic group called the "lower attines" that contain the remaining genera (*Apterostigma*, *Cyphomyrmex*, *Mycetarotes*, *Mycetophylax*, *Mycetosoritis*, *Mycetoagroicus*, *Mycocepurus*, and *Myrmicocrypta*; Chapela et al. 1994; Schultz and Meier 1995). While leaf-cutting ants collect fresh leaves for fungiculture, lower attines use feces or dead plant or arthropod material as substrate for their fungus gardens. Colony size is relatively small (around 10–100 workers) in the lower attines compare to the thousands of workers in a *Sericomyrmex* colony, the tens of thousands in an *Acromyrmex* colony, and the millions of workers in an *Atta* colony (Weber 1972; Hölldobler and Wilson 1990). All attine ants cultivate fungi that belong to the tribe

Leucocoprineae; the association is believed to have originated in the Amazon Basin more than 50 million years ago (Chapela et al. 1994; Mueller et al. 1998). The symbiosis is obligate and has at least diffusely coevolved with respect to several nutritional, physiological, and antibiotic characteristics (Mueller 2002; Currie et al. 2003, 2006; Richard et al. 2005; Mikheyev et al. 2007).

Previous work on *Acromyrmex* species has shown that the workers and fungus gardens of the same colony have partly similar and partly different chemical profiles (Viana et al. 2001; Richard et al. 2004, 2007) and that nestmate recognition within and across closely related species is related to differences in surface chemistry (Lambardi et al. 2007; Richard et al. 2007). The purpose of the present study was to further investigate the magnitude and variability of these differences by: (1) comparing the qualitative and quantitative differences among three different sympatric species that belong to different genera of higher attine ants (*Atta*, *Acromyrmex*, and *Sericomyrmex*) and (2) comparing the chemical profiles of different colony members and developmental stages (workers, worker PPGs, brood, and the fungus garden) within and between these ant genera.

Methods and Materials

Biological Material We used five colonies of *Atta colombica* (one without larvae), nine colonies of *Acromyrmex echinatior* (one without larvae; colony number Ae48, Ae109, Ae124, Ae132, Ae168, Ae210, Ae219, Ae221, Ae223), and four colonies of *Sericomyrmex amabilis* (two without larvae and pupae; colony numbers Sal220402-1, Sal210402, Sal110601-18, Sal030603-1). All colonies were collected in Gamboa, Panama, between 1994 and 2002, and had been maintained in the laboratory for a minimum of 2 years on a similar diet. At the time of sampling (July 2004), nest boxes were maintained at the University of Copenhagen under standardized conditions of approximately 70% relative humidity and 25°C. Colonies were provided with a diet of bramble leaves and rice grains, except for *Sericomyrmex* colonies that were provided with dried flower petals and small pieces of cut bramble leaves.

Chemical Analyses of Colonies Extracts were obtained from 200 mg of larvae or pupae or ten workers immersed in 1 ml of pentane for 10 min. Another ten workers from each colony were frozen for later dissection of their postpharyngeal glands (PPGs). Fragments of fungus garden were taken from all colonies of *Sericomyrmex* with two replicates per colony and from all colonies of *Atta* and *Acromyrmex* with four replicates per colony. To minimize any effects of leaf material on the chemical profiles, the fungus garden samples were taken from the mature middle section of fungus gardens where all leaf material was degraded (cf. Richard et al. 2007). All brood and workers were removed from the fungus fragments before chemical extraction, which was performed on 200 mg of fungus material immersed in 3 ml pentane for 10 min.

Extracts were stored at −20°C until analyzed. Before analysis, any remaining pentane was allowed to evaporate, and dried extracts were redissolved in 50 μl pentane containing 10 ng/μl eicosane (n-C_{20}) as an internal size standard. Two microliters of these mixtures were injected into a gas chromatograph coupled with a mass spectrometer, and compound quantification and identification were performed on an HP6890 gas chromatograph with an HP5973 mass-selective detector, equipped with an HP-5 column (30 m×0.32 mm inner diameter, film thickness=0.25 μm). The initial temperature was 80°C for 1 min with a

subsequent gradual increase of 10°C/min until 200°C was reached and finally a gradual temperature increase of 3°C/min until the maximum temperature of 340°C was reached and maintained for 10 min. The mass spectrometer was operated at 70 eV, and scanning was done from 40 to 550 amu at 1.5 scans/sec.

Identification of Compound Classes The objective of this study was to compare the chemical profiles of different species of ants, their larvae, pupae, and the fungus—not to provide absolute identifications of all of the different compounds that were found. Cuticular hydrocarbons (alkanes and mono-, di-, and trimethyl alkanes) were characterized to class level by using diagnostic ions, comparisons with standard mass spectrometry (MS) databases, and by determination of Kovats indices (see Carlson et al. 1998; Lommelen et al. 2006). The position of the double bond in the alkenes was not determined because our purpose was not to identify specific compounds. The identification of other compounds was based on comparison of retention times and diagnostic ions with NIST/EPA/NIH 172 mass spectral libraries. Our chemical profiles were also compared with previous studies where we did identify the chemicals associated with leaf-cutting ant fungus gardens (Richard et al. 2007).

Statistical Analyses The chemical profiles of the different colonies were obtained by gas chromatography (GC)–MS analysis and were compared within and among species. Quantification and chemical profile characterization were done by GC-MS peak integration using the relative abundance of the various peaks. To test for differences in chemical profiles among different groups, we used factorial analyses and nested two-way analyses of variance (ANOVAs) having ant species, ant colony nested within species, and development stage as main factors (using arcsine square root [X] transformed individual peak areas of all identified compounds; Statistica 6.0, StatSoft®). To evaluate the relative contribution of ant species origin, ant colony, and developmental stage or symbiont origin to the profiles, we performed type II ANOVAs on each of these factors individually, both for all compounds present in the profiles and for the class of hydrocarbons alone. Data are presented as median±semi-interquartile ranges of the relative areas. To compare the relative quantities of the different compound categories between the different species, we used nonparametric Kruskal–Wallis tests on ranks.

Results

A total of 179 compounds, of which 139 hydrocarbons (16 *n*-alkanes, 22 alkenes, 49 Me-alkanes, 44 Dime-alkanes, and 8 Trime-alkanes), were identified (see Supplementary material: Appendix Table 1) and present in sufficient quantities to be analyzed for their contribution to the overall chemical profiles of the three focal species *A. colombica*, *A. echinatior*, and *S. amabilis* (Appendix Tables 2, 3 and 4). The cuticular profiles of worker ants contained a mixture of alkanes, alkenes, and mono- and dimethylalkanes with chain lengths ranging from C16 to C39 in *A. colombica*, C18 to C37 in *A. echinatior*, and C27 to C37 in *S. amabilis* (Appendix Tables 1, 2, 3, and 4). Considerable amounts of 5, 9+5, 11 Dime C35, and trimethylalkanes were present in *A. colombica* and four other compounds were specific for workers of *A. echinatior*: C20:2; C23:2, 11MeC21, and xMeC21. *S. amabilis* was characterized by the presence of 3MeC29 in all samples and 7MeC33 and 12,16+14,18 Dime C32 in all samples except larvae.

When evaluating compounds in the five major classes of hydrocarbons only, there were significant differences among the three species, with *A. colombica* having more alkenes and trimethylalkanes, *A. echinatior* having more alkanes, and *S. amabilis* having more methylalkanes and dimethylalkanes (Tables 1 and 3). No chemical compounds other than hydrocarbons were identified on *S. amabilis* worker cuticles, but *A. echinatior* cuticles contained an appreciable fraction of aldehydes, whereas *A. colombica* workers expressed small quantities of aldehydes, alcohols, and formates (Tables 2 and 3). Larval and pupal profiles consisted almost exclusively of hydrocarbons in all three species (Table 2). In general, brood profiles were less variable in chain length than worker profiles in *A. colombica* (C18 to C37) and *A. echinatior* (C18 to C33) and shorter than worker profiles in *S. amabilis* (C21 to C33). Finally, there was a striking difference between the very small total amounts of hydrocarbons on the bodies of larvae and pupae, relative to the much larger amounts on worker cuticles (Table 3). Thus, developmental stages and symbionts had a highly significant impact on all compound groups, while only some compound groups appeared affected by colony-of-origin (alkanes and alkenes) and ant species (hydrocarbons and branched alkanes). Because of the difficulty of standardizing tissue samples among groups, such absolute quantity estimates need to be interpreted with caution. However, the fact that the amount of compounds on larvae and pupae was an order of magnitude less than on worker cuticles and fungus garden material makes it reasonable to infer that these quantitative differences are real.

The fungus chemical profiles contained alkanes, alkenes, and methyl alkanes with chain lengths ranging from C18 to C36 for *A. colombica*, C18 to C33 for *A. echinatior,* and C25 to C35 for *Sericomyrmex* (Appendix Tables 1, 2, 3 and 4). The fungus garden methylalkanes were MeC23 and MeC26 for *A. colombica* and *A. echinatior*, and MeC27 to MeC35 for *S. amabilis*. Dimethylalkanes with chains ranging from DimeC33 to DimeC35 were found in *A. colombica* and DimeC31 to DimeC33 in *S. amabilis*, whereas trimethyl alkanes were only found in *A. colombica* fungus gardens. The diversity of chemical compounds in the fungus garden was higher than the diversity in brood, workers, and PPGs (see Supplemantary material: Appendix Tables 1, 2, 3, 4). However, hydrocarbons were more abundant than all other chemical classes in the fungi cultivated by *A. colombica* and *A. echinatior*, whereas the *S. amabilis* symbionts also had relative large amounts of acetates (Table 2).

Table 1 Relative proportions (median±semi-interquartile ranges) of alkanes, alkenes, methylalkanes, dimethylalkanes, and trimethyl alkanes based on the total cuticular hydrocarbon quantities in three species of higher attine ants

Species	Number of Colonies	Alkanes	Alkenes	Methylalkanes	Dimethylalkanes	Trimethylalkanes	Hydrocarbons (%)
Atta colombica	5	21.41± 2.99	29.13± 0.56	0.29±0.02	8.10±0.35	41.11±1.59	100
Acromyrmex echinatior	9	77.78± 5.48	19.72± 4.97	2.5±1.96	0		100
Sericomyrmex amabilis	4	31.98± 6.59	1.35± 0.68	38.75±4.31	26.39±2.67		100
H (*P*) (Kruskal–Wallis)		13.9 (<0.001)	12.6 (0.01)	9.5 (0.008)	16.4 (<0.001)		

Table 2 Relative proportions (median±semi-interquartile ranges) of 8 different classes of compounds for three species of higher attine ants

	Sample size replicate (number of colonies)	Hydrocarbons	Aldehydes	Acetates	Alcohols	Esters	Formates	ANOVA

Factorial analyses showed that the chemical profiles of larvae and pupae lie between the profiles obtained from worker cuticles and the fungal symbionts (Fig. 1) and that PPG profiles are most different from those of the fungal profiles. Moreover, each of these developmental stage or symbiont components of the colony had its own specific chemical profile nested within the overall characteristic profile for the colony and species (Fig. 2). Type II ANOVAs were performed to evaluate how much of the variation in the complete chemical profiles and in the profiles including only hydrocarbons could be attributed to ant species, ant colony, and developmental stage or symbiont origin. While the species component only explained 0.34% (R^2) of the variation in the complete chemical profiles, colony-of-origin explained 21%, and developmental stage or symbiont origin explained 35% of the variance in profiles. When only hydrocarbon compounds were included in the analysis, 11.4, 23.7, and 23.0% of the variation could be attributed to species, colony, and developmental stage/symbiont origin, respectively. The low amount of variation explained by ant species in the former analyses indicates that the presence of abundant nonhydrocarbon

F values given with degrees of freedom as subscripts and *P* values in parentheses

compounds, particularly in the fungal samples of all three species (Table 2), tend to swamp the species differences that emerge when hydrocarbons are analyzed alone.

Discussion

We have shown that: (1) a large variety of potential recognition compounds is present in the colonies of fungus-growing ants; (2) workers express mostly hydrocarbons, whereas fungus gardens have a number of additional compounds; (3) ants and fungal symbionts of the three species (genera) can be statistically distinguished based on their chemical profiles; and (4)

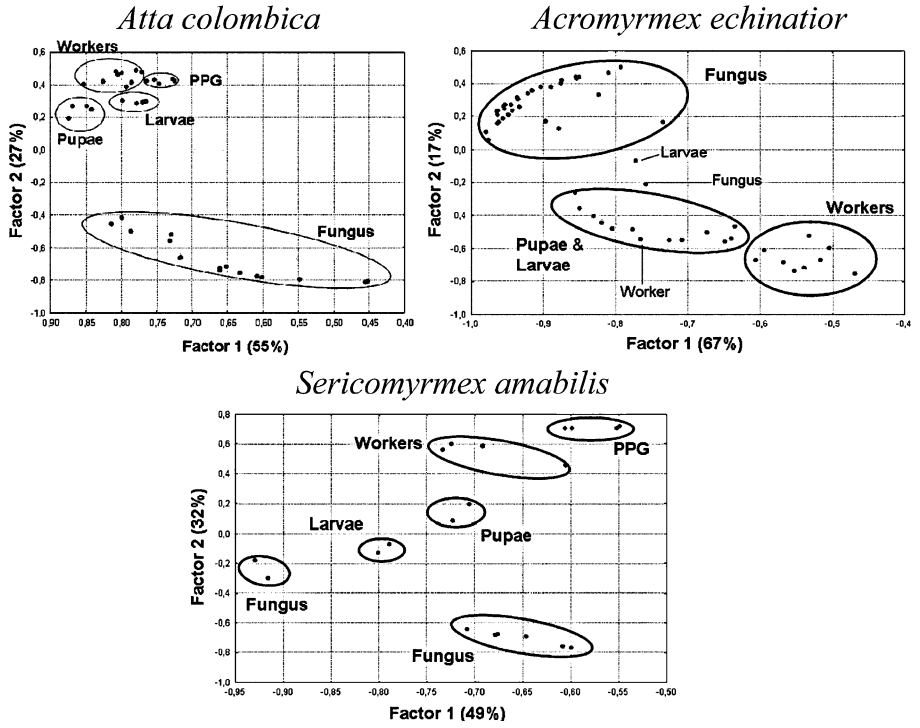

Fig. 1 Factorial analyses showing the differences in chemical profiles between worker cuticles, workers PPGs, pupal cuticles, larval cuticles, and fungus garden mycelium in *Atta colombica*, *Acromyrmex echinatior*, and *Sericomyrmex amabilis*. All analyses were based on the relative proportions of all chemical compounds identified by GC/MS. *Ellipses* have been drawn to emphasize the categories but have no specific statistical meaning

larvae and pupae have much smaller absolute quantities of cuticular hydrocarbons than workers. In the following sections, we discuss some of the implications of these results.

The Spectrum of Surface Chemicals in Fungus-growing Ants Both intra- and interspecific variation in the chemical profiles expressed by *A. colombica*, *A. echinatior*, and *S. amabilis* were found, but the intraspecific differences were much less than the interspecific differences both when complete and partial (hydrocarbons only) chemical profiles were considered. Moreover, species are characterized by some specific chemical compounds. Provisional data on *Atta cephalotes* (one colony: workers, larvae, and fungus) and *Acromyrmex octospinosus* (two colonies: workers, PPG, larvae, and fungus) from the same site in Gamboa, Panama, showed that differences between congeneric species are intermediate (Appendix Table 1). The species-specific chemical profiles are qualitatively similar among colonies (i.e., all colonies have the same compound composition), so that the differences obtained from multivariate statistics (Fig. 1) are mostly based on quantitative differences of the same compounds, except for the fungus gardens that harbor a number of unique nonhydrocarbon compounds. Differences in profiles were especially prominent among the hydrocarbons, which is consistent with these compounds having an important role in intra- and intercolony recognition (Lahav et al. 1999; Singer 1998; Wagner et al. 2000). Workers of all three species tended to have more (and more complex) hydrocarbons than the brood and the fungus gardens, which

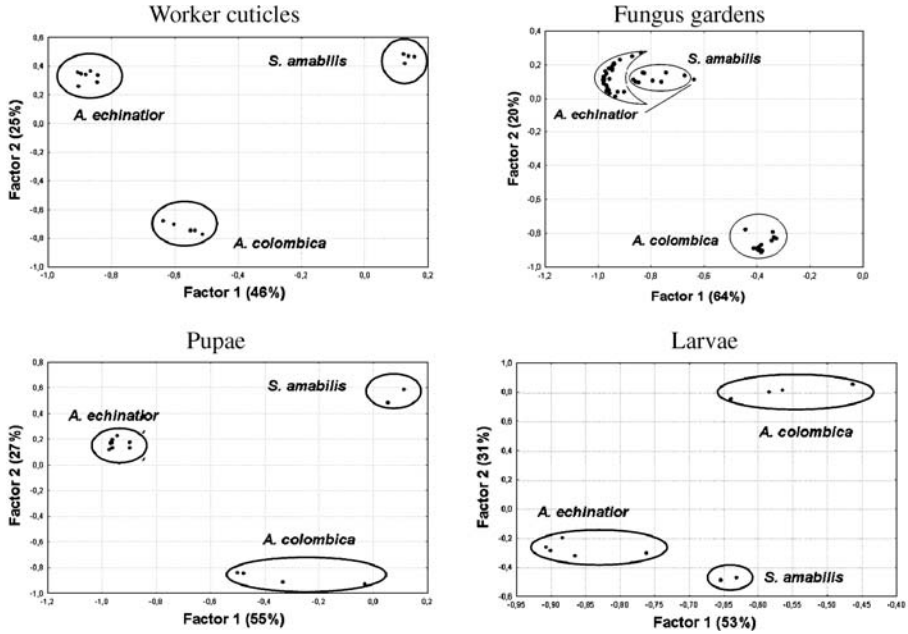

Fig. 2 Factorial analyses showing the differences in chemical profiles between the three species of fungus-growing ants *Atta colombica*, *Acromyrmex echinatior*, and *Sericomyrmex amabilis* for worker cuticles (*top left*), fungus gardens (*top right*), pupae (*bottom left*), and larvae (*bottom right*). All analyses were based on the relative proportions of all chemical compounds identified by GC/MS. *Ellipses* have been drawn to emphasize the categories but have no specific statistical meaning

generally have simpler profiles consisting mostly of *n*-alkanes and *n*-alkenes. Similar differences in worker and brood chemical composition have been observed in other ant species (*Myrmica* [Elmes et al. 2002], *Camponotus vagus* [Bonavita-Cougourdan et al. 1989], and *Lasius sakagamii* [Akino and Yamaoka 1998]). However, it is remarkable that the larvae and pupae of fungus-growing ants have so few cuticular compounds and such low quantities of them. This finding is unlikely to be an artifact as it matches an earlier result on leaf-cutting ants by Viana et al. (2001). Whether this adult-brood difference is typical only for fungus-growing ants or for ants in general remains to be determined.

Fungus Garden Chemistry The fungus produces several classes of compounds that ants do not synthesize, which confirms previous findings that workers only have alkanes, alkenes, and branched alkanes (Viana et al. 2001; Lambardi et al. 2007), whereas fungus gardens of *Acromyrmex* contain both aldehydes, alcohols, acetates, acids, and esters (Richard et al. 2007). The latter study that compared the fungus garden chemistry of Panamanian *A. octospinosus* and *A. echinatior* leaf-cutting ants showed that these fungi express the same chemical compounds but in different relative quantities among ant species and colonies (Richard et al. 2007). The same profiles, with the same chemical classes, were found in two colonies of *A. octospinosus* (Appendix Table 1), and the single colony of *A. cephalotes* likewise had a fungal profile that was similar to that of *A. colombica* both characterized by the presence of trimethylalkanes (Appendix Table 1). Richard et al. (2007) also showed that the fungus-derived compounds in *A. echinatior* and *A. octospinosus* have a, albeit weak, genetic component and that they are shared between the two species (see also Bot et al. 2001). As

Mikheyev et al. (2007) recently showed that the symbiont fungi of Panamanian *Atta* and *Acromyrmex* in Gamboa, Panama, are similar genetically, it appears that the *Atta* and *Acromyrmex* fungus gardens each express at least some compounds that are ant species specific but not shared by the ants. Given that all colonies were reared on the same laboratory diet, this suggests that the same fungi express different chemical (and thus possibly metabolic) traits depending on the ant genus that they are associated with. The degree to which symbionts of *Sericomyrmex* are related to those reared by *Atta* and *Acromyrmex* leaf-cutting ants is not clear (Chapela et al. 1994; Hinkle et al. 1994), but it seems unlikely that they belong to the same pool. Thus, the differences in chemistry between *Sericomyrmex* symbionts and symbionts of *Atta* and *Acromyrmex* leaf-cutting ants may, in part, be genetic.

Recognition in Fungus-growing Ants Differences in the proportion of hydrocarbons in workers (cuticle and PPG), brood, and fungus garden material are consistent with these compounds playing a central role in caste recognition, nestmate recognition, and discrimination between resident and alien strains of the fungal symbiont (Bot et al. 2001; Viana et al. 2001; Poulsen and Boomsma 2005; Richard et al. 2007). The patterns observed (Figs. 1 and 2) and the partitioning of variance in chemical profiles suggest that chemistry differences may allow efficient within-colony distinction between brood and symbionts without jeopardizing efficient nestmate recognition as hypothesized by Vander Meer and Morel (1998). This agrees with findings in other social insects; for example, cuticular hydrocarbons in the ant *Pachycondyla inversa* vary within and among colonies but also with an individual's social and reproductive status (Heinze et al. 2002). Similarly, cuticular hydrocarbons in the ant *Formica truncorum* vary among colonies, to some extent between patrilines within colonies, and among samples taken from the same colony in different seasons (Nielsen et al. 1999; Boomsma et al. 2003). In addition, in the termite *Reticulitermes virginicus* and the ant *C. vagus*, all castes carry the same hydrocarbons, but the caste-specific proportions differ (Howard et al. 1978, 1982; Blomquist et al. 1979; Bonavita-Cougourdan et al. 1989).

Specificity of the chemical profiles of workers, brood, and fungi is intriguing because these different components of the same insect society interact constantly. For example, workers could transmit colony odor to the fungal substrate when they chew the harvested leaves before integrating them into the garden. Other workers may regurgitate the content of their PPG (which is known to be a reservoir of colony gestalt odor profiles) to nestmates by a process called trophallaxis (Soroker et al. 1994, 1995). Grooming and other social interactions may further promote the circulation of hydrocarbons through the colony. Given these close interactions, it is interesting that the hydrocarbon compounds present in fungus material were always present on workers and brood but that the opposite is not true (Viana et al. 2001; Lambardi et al. 2007; Richard et al. 2007). Previous studies combined with our present data, therefore, indicate that hydrocarbons are transferred by workers when moving around in the garden while grooming fungus fragments and other workers, but whether the ants or the fungus are the ultimate producers of these compounds is not yet clear.

Acknowledgements We thank the Smithsonian Tropical Research Institute (STRI) for providing logistic help and facilities to work in Gamboa and the Autoridad Nacional del Ambiente y el Mar (ANAM) for permission to sample ant colonies in Panama and export them to Denmark. Fieldwork was supported by grants from the Carlsberg Foundation and the Danish Natural Science Research Council to JJB. All experiments performed in this manuscript comply with current Danish and USA law.

Introduction

Moths are one of the most speciose insect groups with an estimated 185,000 species (Holloway et al. 1987). Cardé and Haynes (2004) speculated that one factor promoting this diversity is the ability to persist at low densities because of pair formation mediated by volatile female-produced sex pheromones. This hypothesis will be difficult to test; however, it is clear that the dominant paradigm among moths is that of long-distance attraction of males by female-produced sex pheromones. For example, Byers (2002) surveyed the published literature and estimated that attractant sex pheromones (or attractants known from empirical screening) have been identified in 1,572 moth species from 619 genera (not all major lineages are represented).

In their seminal discussion of chemical communication among animals, Wilson and Bossert (1963) suggested that volatile pheromones would have between 5–20 carbon atoms, minimal chemical complexity (e.g., few points of unsaturation, terminal acetate, alcohol, or aldehyde functional moieties), and a molecular weight between 80 and 300. Extrapolation from this model generated the predictions that: (1) in evolutionary time, the number of odorant molecules and thus species was unlimited, and (2) the number of sympatric moth species that could coexist would be defined by the number of unique pheromones used. Early models of reproductive isolation in moths were predicated on the latter prediction and emphasized the role of single compound, species-specific sex pheromones (e.g., Shorey 1970). As more moth sex pheromones were identified, it became clear that neither prediction was supported. The majority of moth pheromones are multi-component blends [the mean (±SE) number of components per species in 702 moth species was 1.86±0.05 (Byers 2002)], and sympatric species with similar phenologies and calling periodicities often share pheromone components (Arn 2001; Byers 2002, 2005, 2006).

The single species, single-pheromone component model of reproductive isolation was replaced by a model that predicts reproductive isolation as a result of the existence of species-specific blends of pheromone components (e.g., Löfstedt et al. 1991; Cardé and Haynes 2004). The principal prediction of this model is that individuals with pheromone blend ratios that deviate from the population mean will be less likely to attract mates (see Butlin and Ritchie 1989; Groot et al. 2006). The associated variation in mating success would impose stabilizing selection on the signal and constrain phenotypic evolution (Endler 1992). Yet, comparative studies of the sex pheromones of related species and populations show that moth sex pheromone signals vary (e.g., geographically) and are apparently less rigid than the stabilizing selection model predicts (e.g., Roelofs and Comeau 1969; Tumlinson et al. 1974; Cardé et al. 1977; Klun et al. 1979; Roelofs and Brown 1982; Löfstedt et al. 1991; Löfstedt and Kozlov 1996; McElfresh and Millar 2001).

Reconciliation of the observed patterns of moth sex pheromone variation and the species-specific pheromone component blends model requires a mechanism for directional selection capable of periodically overcoming the stabilizing effects of variation in mating success. Communication interference with sympatric moths that use similar blends of the same pheromone components is one putative mechanism. Groot et al. (2006) hybridized and backcrossed two moth species and measured the effects of communication interference between parental and backcross pheromone strains. Their data suggested that the resulting directional selection would be strong enough to overcome stasis in the pheromone blend. Evolutionary change in the pheromone blend as a result of communication interference requires the existence of heritable genetic variation in the pheromone blend.

The female-produced sex pheromone of the almond moth, *Cadra cautella*, is a two-component blend of (*Z,E*)-9,12-tetradecadienyl acetate (*Z*9,*E*12–14:Ac, the major compo-

nent capable of inducing attraction alone) and (*Z*)-9-tetradecenyl acetate (*Z*9–14:Ac, the minor component, which is unattractive alone but augments attraction of the major component; Brady et al. 1971; Read and Haines 1979). Previous study of the pheromone biology of this species has documented high levels of phenotypic variation in the sex pheromone, narrow-sense heritabilities of 1.2±0.32, 0.75±0.24, and 0.46±0.17 for the titer of *Z*9,*E*12–14:Ac, *Z*9–14:Ac and pheromone blend ratio, and stabilizing male preference functions in wind-tunnel choice assays (Allison and Cardé 2006, 2007). These observations suggest that, whereas the pheromone blend ratio in *C. cautella* may experience stabilizing selection, it should respond to directional selection, a hypothesis tested in this study. The selected lines were maintained for five generations after the discontinuation of selection and sampled the last three to estimate the stability of the selected change in the ratio of the two sex pheromone components.

Methods and Materials

Insect Rearing and Pheromone Extraction and Analysis Selection lines were reared by using the same protocol and conditions as the general laboratory colony in a controlled environment rearing room. The laboratory colony used to initiate the selection lines and the rearing protocol and conditions has been previously described (Allison and Cardé, 2006). Temperature, humidity, and the light–dark regime were verified periodically with a Hobo® sensor (Onset Computer, Bourne, MA, USA). The ratio and titer of pheromone components was measured by gas chromatographic (GC) analysis of solvent extracts of pheromone glands excised from 1-d-old virgin female *C. cautella* during the second hour of the scotophase with procedures described in Allison and Cardé (2006). The mean phenotype (ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac) of each family was estimated from a pooled extract of the pheromone glands of five full-sibling females. Although this procedure greatly reduces GC analysis time, the contribution of each individual to the family mean is weighted by the amount of pheromone produced. The validity of this procedure for determining family pheromone characteristics was verified by Collins and Cardé (1989).

Selection Lines and Regime The aim of our selection protocol was to establish lines with high and low ratios of *Z*9,*E*12–14:Ac to *Z*9–14:Ac. Analysis of female pheromone gland content post-mating and oviposition is not practical because post-mating pheromone gland titers are low and unlikely to be representative of pre-mating titers and ratios (Raulston et al. 1975; Webster and Cardé 1984; Raina et al. 1986; Tang et al. 1992; but see Svensson et al. 2002). Excision and extraction of the female pheromone gland is a destructive process, and as female almond moths mate only once (J.D.A., personal observation), it was not possible to analyze the contents of the pheromone gland from a female and collect her progeny. Therefore, individual selection was not possible, and we used sib selection, a form of family selection in which the selected individuals have not contributed to the estimate of their family mean but are siblings of the individuals that were measured (Falconer and Mackay, 1996).

The parental generation of each selection line was initiated with 24 families formed of a single male–female pair (1–3 d old) chosen randomly from the base laboratory colony. The progeny of each pair was reared on 50 g of artificial diet (see Allison and Cardé, 2006). Last instars were collected, sexed (male testes are easily seen through the dorsal larval cuticle), and transferred to 180-ml plastic cups for pupation (larvae were kept together but separated by sex). The ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac produced by female

progeny of each family was measured by GC analysis of a pooled extract of five full-sib female progeny. High, low, and control lines were each started simultaneously by using this protocol and cumulatively were considered a replicate. There were three replicates started on consecutive weeks. The high, low, and control lines from all replicates were housed in the controlled rearing room described in Allison and Cardé (2006). Approximately 20 female and 10 male last instars were collected from each family each generation for the determination of the family phenotype and (if selected) propagation of the line. The collected larvae were kept on artificial diet as described above in a light box kept in the controlled environment rearing room. There was a separate light box for each selection regime, each of which was offset so that the second hour of the scotophase occurred first in the high regime light box and 3 and 6 h later in the low and control regime light boxes. The light boxes were identical, and Hobo® sensors (Onset Computer) were used periodically to verify rearing conditions. Determination of which families would contribute to the next generation had to be done while the remaining siblings were still reproductively viable (about 3–4 d). Once the lines were established, subsequent generations of the selected lines were propagated by crossing males and unsampled females from the six families with the highest (or lowest) ratios of *Z*9,*E*12–14:Ac to *Z*9–14:Ac. Subsequent generations of the control lines were propagated similarly except that the families were chosen randomly. To minimize inbreeding, siblings were never crossed, and six families were chosen independent of the number of families sampled each generation (Table 1).

Post-selection Selection in the high and low lines was discontinued after the F5. All of the selection lines (including the control lines) were reared following the same protocol described above without selection (i.e., pairs contributing to the next generation were randomly chosen without any knowledge of pheromone blend). The absolute and relative

pheromone titers of each selection line were sampled as described above in generations F8, F9, and F10 and compared to titers in the last selected generation.

Statistics The effects of selection regime on the ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac in female *C. cautella* were analyzed by analysis of covariance (ANCOVA) by using generation as the primary covariate. Initial analyses used the complete model (i.e., all three selection regimes: high, low, and control). A significant generation by selection regime interaction would indicate divergence among lines in the pheromone blend ratio. Subsequent ANCOVA analyses tested for a generation by selection regime interaction within each replicate by comparing each selected line to the control line from the same replicate with a Bonferroni corrected *P* value (0.05/6). Analysis of variance was used to test for significant differences in the component ratios and titers among generations within selection lines. Differences between specific generations were evaluated with the Students–Newman–Keuls' multiple range test (Steel and Torrie 1980). The narrow-sense heritability observed in each selection line (realized heritability) was estimated if a significant response to selection was observed. This estimate was based on the slope of the regression line of the cumulative selection differential on generation mean.

Results

Effect of Selection Regime on Pheromone Blend Ratio Initial ANCOVA analyses showed a highly significant generation by selection regime interaction for each replicate (replicate 1, $F_{2,352}=41.7$, $P<0.001$; replicate 2, $F_{2,349}=48.6$, $P<0.001$; replicate 3, $F_{2,336}=25.7$, $P<0.001$).

Selection for Higher Blends Artificial selection resulted in a significant increase in the ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac in two of the three lines selected for high ratios (replicate 1, $F_{1,232}=31.0$, $P<0.001$; replicate 2, $F_{1,232}=30.9$, $P<0.001$; replicate 3, $F_{1,229}=2.5$, $P=0.11$; Fig. 1; Table 2). In high lines 1 and 2, the mean ratio (±SE) went from 13.72±1.02:1 to 20.13±0.68:1 and 9.87±0.54:1 to 15.89±0.85:1; a significant increase in the ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac had occurred by the F2 in high line 1 and the F3 in high line 2. A significant response to selection did not occur in high line 3.

The observed increases in ratio reflect an increase in the titer of *Z*9,*E*12–14:Ac relative to *Z*9–14:Ac and could be as a result of an increase in the absolute titer of *Z*9,*E*12–14:Ac, a decrease in the absolute titer of *Z*9–14:Ac, or some combination thereof. It is clear that, in high lines 1 and 2, it was the titer of the major pheromone component (*Z*9,*E*12–14:Ac) that increased (Table 2; Fig. 2), whereas the minor component remained stable (Table 2; Fig. 3). The increase in the ratio of *Z*9,*E*12–14:Ac: *Z*9–14:Ac therefore was caused by an increase in the absolute titer of *Z*9,*E*12–14:Ac.

Randomly Selected Control Lines There was no significant change in the ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac between the unselected parental generation and the last selected generation in any of the control lines (Table 3). There was a significant effect of generation on pheromone blend ratio in control line 3 (Table 3), although the parental and F5 generation did not differ. In control line 1, the titer of the major pheromone component *Z*9,*E*12–14:Ac increased 45% from 21.41±1.44 ng to 31.27±2.17 ng, whereas concurrently, the titer of the minor pheromone component also increased 45% from 2.23±0.15 to 3.21±

Means within rows not followed by the same letter are significantly different, Student–Newman–Keuls' multiple range test.

Selection for Lower Blends Artificial selection lowered the ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac in all three of the low selected lines (replicate 1, $F_{1,232}=12.5$, $P<0.001$; replicate 2, $F_{1,233}=16.7$, $P<0.001$; replicate 3, $F_{1,223}=55.6$, $P<0.001$; Table 4). In low lines 1, 2, and 3, the mean ratio (±SE) changed from 10.74±0.78:1 to 7.35±0.41:1, 10.11±0.66:1 to 5.65±0.55:1 and 13.63±0.82:1 to 6.47±0.26:1 (Table 4; Fig. 1). It was not until the last, F4 and F1 generation that a significant decrease in ratio occurred in low lines 1, 2, and 3, respectively.

The titers of the individual pheromone components in all three of the low lines selected for decreased ratios of *Z*9,*E*12–14:Ac to *Z*9–14:Ac changed. The titer of the major pheromone component *Z*9,*E*12–14:Ac was significantly higher in the last selected generation than the unselected parental generation in low lines 1, 2, and 3 (Table 4; Fig. 2). At the same time, the titer of the minor pheromone component *Z*9–14:Ac also increased significantly in low lines 1, 2, and 3 (Table 4; Fig. 3). The decrease in the ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac was caused by a greater relative increase in the titer of *Z*9–14:Ac than in the titer of *Z*9,*E*12–14:Ac.

Post-selection The mean pheromone blend ratio (±SE) decreased from the last selected generation (the F5) of high lines 1 and 2; five generations after selection was discontinued (the F10; there was no change in the pheromone blend ratio of high line 3; Table 5). Thus, in both high lines 1 and 2, the ratio of components had drifted (or been selected by unknown forces) down. In all three high selected lines, there was a significant decrease in the titer of *Z*9,*E*12–14:Ac within five generations of the termination of selection (Table 5). In high line 3, the titer of *Z*9–14:Ac was significantly lower in the F10, five generations after the termination of selection (Table 5). The titers of *Z*9–14:Ac in the F10 of high lines 1 and 2 did not differ from titers in the F5, the last selected generation.

14:Ac did not differ between F10 or the last selected generation in either of low line 1 or 3. The titer of *Z*9–14:Ac did not differ between the F10 and the last selected generation in any of the low selected lines (although differences among generations were observed in all three lines).

Selection Differential The mean (±SE) selection differentials during the six generations of selection in high lines 1, 2, and 3 were 4.18±0.4, 3.40±0.32, and 3.59±0.39, respectively. Among the high selection lines, on average, the ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac was 3.72±0.23 parts *Z*9,*E*12–14:Ac higher in the selected families than in the average high line family. The transient declines in ratio observed in the F1 of high line 1, F2 and F5 of high line 2, and F1, F2, and F3 in high line 3 cannot be attributed to low selection pressure. The mean (±SE) selection differentials for low lines 1, 2, and 3 during the six generations of selection were 2.64±0.39, 2.81±0.24, and 1.94±0.51, respectively. Among the low selection lines, the ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac was on average 2.46±0.27 parts *Z*9, *E*12–14:Ac lower in the selected families than in the average low line family. The transient increases in ratio observed in the F2 of low line 1, F2 of low line 2, and F4 of low line 3 do not appear to be caused by low selection pressures. The mean selection differentials for the low and high lines differed significantly (t=3.54; P<0.05).

Realized Heritability The mean realized heritability of the lines that responded to selection was 0.74±0.03 and 0.80±0.26 for the high and low lines, respectively. The overall realized heritability for all five lines that responded to selection was 0.77±0.14. These estimates indicate that a large proportion of the phenotypic variance is caused by additive genetic factors and are higher than the narrow-sense heritability previously reported to the ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac (0.46±0.17; Allison and Cardé, 2006).

Discussion

Few studies have examined the effect of artificial directional selection on moth sex pheromone production traits. Sreng et al. (1989) selected for high and low ratios of (*E*)-9-dodecenyl acetate to (*E*)-9-dodecenyl acetate plus (*E*)-11-tetradecenyl acetate in the redbanded leafroller, *Argyrotaenia velutinana* (Lepidoptera: Tortricidae) sex pheromone. In three generations of selection, the percent (*E*)-9-dodecenyl acetate went from approximately 24 to 14% and 28 to 42% in the low- and high-selected lines, respectively. As Sreng et al. (1989) point out, (*E*)-9-dodecenyl acetate is a minor pheromone component, and thus, the behavioral significance of this result is unclear. In the pink bollworm, *Pectinophora gossypiella* (Lepidoptera: Gelechiidae), 12 generations of selection increased the mean (±SD) percentage of (*Z*,*E*)-7,11-hexadecadienyl acetate from 42.9±1.0 to 48.2± 1.2 (Collins and Cardé 1989), whereas six generations of selection increased the titer of both pheromone components from 24.0±8.1 to 45.8±7.9 ng per female (Collins et al. 1990). As Collins and Cardé (1989) point out, the observed change in blend ratio is likely transparent to male pink bollworm moths because of their broad response spectrum.

In this study, selection for a novel ratio of *Z*9,*E*12–14:Ac to *Z*9–14:Ac was successful in all three of the low lines and two of the three high selected lines. Change in the ratio of pheromone components occurred via a different mechanism between selection regimes and the same mechanism within selection regimes. In the two high lines that responded to artificial selection, selection for high ratios resulted in a significant increase in the titer of *Z*9,*E*12–14:Ac with no concomitant change in the titer of *Z*9–14:Ac. In all three of the low

selected lines, the titers of both pheromone components increased as a result of selection; however, the proportional increase in the titer of *Z*9–14:Ac was greater. The observed change in pheromone blend ratio is consistent with selection as a result of mate choice driving the evolution of sexual signals (Darwin 1871; Andersson 1994).

The preference function of male *C. cautella* is dependent on bioassay design. In no-choice trials, the probability that a male will initiate upwind flight and subsequently contact the pheromone point source is independent of the ratio of pheromone components tested. Independence of male orientation behavior and the pheromone blend ratio suggests the absence of discrimination in male *C. cautella*. Conversely, choice trials documented the predicted unimodal preference function, as male *C. cautella* preferred the median pheromone blend of 13 parts *Z*9,*E*12–14:Ac to 1 part *Z*9–14:Ac over lures baited with 0, 2, 6.6, and 20 parts *Z*9,*E*12–14:Ac to 1 part *Z*9–14:Ac and lures baited with just *Z*9,*E*12–14:Ac (Allison and Cardé 2007). In two of the low selected lines and one of the high selected lines, the mean female pheromone blend ratio moved beyond the point where males discriminate (i.e., 6.6 parts *Z*9,*E*12–14:Ac to 1 part *Z*9–14:Ac and 20 parts *Z*9,*E*12–14:Ac to 1 part *Z*9–14:Ac). These results demonstrate that not only can significant changes in mean pheromone blend occur in only a few generations, but that they could have significant fitness consequences on mate attraction.

Assuming the absence of genetic constraints, the response of a phenotypic trait to selection is defined by the equation ($R=h^2S$), where the response, R, is the product of the narrow-sense heritability of the trait (h^2) and the selection differential (S) (Roff, 1997). The realized heritability describes how the response to selection (R) is related to the selection differential (S) and ultimately how the trait responded to selection. Published estimates of realized heritabilities from selection experiments on moth sex pheromone production traits range between 0.50 and 1 (Collins and Cardé 1989; Sreng et al. 1989; Collins et al. 1990). Like the realized heritabilities observed in this study (0.74±0.03 and 0.8±0.26 for the high and low selected lines), these estimates suggest the existence of abundant heritable variation in the ratio of sex pheromone components in moths.

The shape of the mating preference of the responding sex (males in most moths) defines the relationship between a signal phenotype and the probability of the signal phenotype being accepted (see Ritchie 1996). Although few studies have examined mating preferences, both directional and stabilizing preference shapes have been observed (see Basolo 1996, 1998; Ritchie 1996; Ritchie et al. 2005; Allison and Cardé 2007). Both types of mating preference should deplete the amount of additive genetic variation available to selection (see Roff 1997). Male moths are expected to possess stabilizing mating preferences (see Butlin and Ritchie 1989; Groot et al. 2006), and choice assays in *C. cautella* document their existence (Allison and Cardé 2007). However, the results of this selection experiment demonstrate the existence of abundant additive genetic variance in the ratio of pheromone components.

It remains a major challenge to explain the maintenance of additive genetic variance in characters that experience strong stabilizing or directional selection (Barton and Turelli 1989; Roff 1997). Several mechanisms have been proposed (see Roff 1997), but to date it, has not been possible to determine which, if any, of these explain the abundant additive genetic variation in moth pheromone blends (see Allison and Cardé 2006). Alternatively, the assumption that moth sex pheromone blends experience strong stabilizing selection may be incorrect. Data in *C. cautella* are inconsistent with the existence of strong stabilizing selection [e.g., abundant additive genetic variance and male response data in no-choice trials that suggests male discrimination among naturally occurring pheromone blend ratios may not occur (see Allison and Cardé 2006, 2007)]. The possibility exists that the

importance of the pheromone blend in the maintenance of reproductive isolation in moths has been overstated, at least in *C. cautella*.

Pheromone evolution has relevance for both our understanding of the speciation process in moths (e.g., Linn and Roelofs 1995; White et al. 1995; Löfstedt and Kozlov 1996) and pest management (e.g., Cardé and Minks 1995; Cardé 2007). In part, interest in the identification of moth sex pheromones has been generated by the expectation that they could be used operationally in pest management programs. Direct (e.g., mass trapping, attract-and-kill formulations, and mating disruption) and indirect (e.g., monitoring of emergence and population levels) pheromone-based pest management tactics exist. Like chemical pesticides, the broad-scale implementation of direct pheromone-based pest management tactics will result in strong selection pressure. Because of the necessity of coordination between signaler and receiver, there is debate over the probability of the evolution of resistance to direct pheromone-based pest management tactics. Despite being used operationally for over 20 yrs against a variety of moth pests (see Cardé and Minks 1995; Cardé 2007), there has been only one published report suggestive of the evolution of resistance to a direct pheromone-based pest management tactic (Mochizuki et al. 2002). The results of the present study demonstrate that significant change in the pheromone blend ratio can occur in only a few generations of selection in *C. cautella*. Evaluation of selection favoring novel pheromone blend ratios as a potential mechanism for the evolution of resistance to direct pheromone-based pest management tactics will require further empirical study; however, these results suggest that it is a possibility.

Acknowledgments We acknowledge T. Berhane, K. Buhrmeister, and S. Roufian for reliable and invaluable technical assistance rearing insect colonies; Drs J. D. Hare, K. A. Justus, J. G. Millar, R. A. Redak, and D. A. Roff for helpful the comments and discussions, and NSERC Canada and the University of California, Riverside for financial support.

Introduction

Phytochemicals influence the mating behavior of phytophagous insects in two main ways. Specific compounds that occur in host plants may signal the presence of food or oviposition resources to females; males, responding to the same signals, high female traffic, or both, may aggregate at the same sites because they offer high probability of encountering potential mates (Thornhill and Alcock 1983; Bernays and Chapman 1994). Males of many phytophagous insects aggregate at the primary feeding and oviposition sites of females, and chemical stimuli may guide males, not only to the appropriate plant species (Quiroz et al. 2005) but also to plants or structures of a given host species that is preferred by females. For example, males and females of an oligophagous, desert-dwelling grasshopper tend to settle preferentially on those creosote bushes (the primary food resource) whose leaves contain relatively low amounts of the potent antioxidant nordihydroguaiaretic acid (Greenfield et al. 1987). Males of a longhorn beetle species respond to the odor of eucalyptus logs, where females aggregate for egg-laying (Hanks et al. 1996; see also Ginzel and Hanks 2005). Male attraction to host plant volatiles, leading to increased encounter rates with receptive, pre-ovipositing females, has also been reported in moths (Coracini et al. 2004) and bark beetles (Hovorka et al. 2005).

In addition to affecting male and female spatial distributions, plant chemicals may have a more subtle effect on insect mating systems through mediation of the production and release of sex pheromones (Landolt and Phillips 1997). For example, particular plant chemicals ingested by larvae (Connor et al. 1981; Lofstedt et al. 1989) or adults (Pliske 1975; Krasnoff and Dussourd 1989) may serve as precursors for pheromone synthesis. Feeding on the host plant may also stimulate production of male sex pheromone (Hughes and Renwick 1977), and exposure to host plant volatiles may trigger pheromone release (Jaffe et al. 1993). In addition, plant odors may affect female responsiveness to male sex pheromones. In various taxa, including flies (Bartelt et al. 1988), beetles (Dowd and Bartelt 1991), and moths (Landolt et al. 1994), female attraction to male pheromone is enhanced in the presence of host plant odors.

These main effects of plant chemicals—influencing mate location and intersexual communication—appear to be important in shaping the lek mating system (Prokopy and Hendrichs 1979) of the Mediterranean fruit fly (medfly), *Ceratitis capitata* (Wiedemann) (Tephritidae). Males aggregate in the canopy of host and nonhost trees and defend individual leaves as mating territories. Whereas perching on the leaf undersurfaces, males engage in 'calling behavior' in which the abdomen is curled upward, a bubble-like structure (the rectal epithelial sac) is everted, and a sex pheromone is emitted (Arita and Kaneshiro 1986). The pheromone is a complex blend that contains three to five major components known to be attractive to females (Heath et al. 1991; Jang et al. 1994) plus at least 50 minor components whose function has not yet been elucidated (Jang et al. 1989). After female arrival at a male perch, the male initiates vigorous wing movements coupled with side-to-side head rocking (Féron 1962). If the female remains stationary, the male mounts and attempts to copulate. Copulation generally lasts 2–3 hr (Whittier et al. 1992). Females are highly selective and reject courting males in more than 90% of laboratory observations by moving away during male signaling or dropping from the substrate after male mounting (Whittier et al. 1994).

Regarding intersexual encounter sites, field data (Hendrichs and Hendrichs 1990) showed that mating aggregations (leks) were non-randomly distributed among available host trees, with most matings (49%) occurring on orange trees (*Citrus sinensis* L.) although this host represented only a small fraction (12%) of all available host trees in the habitat. Furthermore, within the canopy of individual trees, both sexes settled in greater numbers in the vicinity of oranges than in locations having comparable physical characteristics (e.g., light level, temperature, and leaf density) but no fruits (Shelly and Kennelly 2007). Although visual stimuli are probably involved as well, strong attraction to citrus volatiles has been demonstrated for both sexes of *C. capitata* under field conditions (Katsoyannos et al. 1997).

Recent work has shown that plant-derived chemicals may also influence the mating success of male medflies. Papadopoulos et al. (2001) and Shelly et al. (2004a) found that *C. capitata* males exposed to oranges obtained significantly more copulations than non-exposed males. In one case, the exposed males obtained 66% of the total matings (Shelly et al. 2004a). Similarly, male medflies exposed to the bark and fruits of guava trees (*Psidium guajava* L.) had a mating advantage over males deprived access to these substrates (Shelly and Villalobos 2004). Using commercially available oils, Shelly et al. (2004a, b) and Papadopoulos et al. (2006) further demonstrated that the aroma of ginger root oil (*Zingiber officinale* Roscoe) and orange oil conferred a mating advantage to male medflies. Encouraged by these latter results, Shelly et al. (2007a) have promoted the implementation of 'aromatherapy' (large-scale exposure of flies to ginger root oil) to increase the mating competitiveness of medfly males used in sterile release programs.

It is not known why exposure to certain fruits or oils enhances the mating competitiveness of male medflies. Most of the work conducted thus far has involved male exposure to the aroma of ginger root oil (GRO hereafter), and several conclusions can be drawn. Males exposed to GRO spend a greater proportion of their time pheromone-calling than non-exposed males (Shelly 2001; Papadopoulos et al. 2006). However, the relative increase in calling activity appears insufficient to explain the magnitude of the observed mating increase. For example, Shelly (2001) found that GRO-exposed males obtained approximately twice as many matings as non-exposed males, but that the level of pheromone-calling displayed by GRO-exposed males was only about 30% higher than that observed for non-exposed males. Subsequent trials with a wind tunnel confirmed that females were equally attracted to the pheromone of GRO-exposed and non-exposed males (Papadopoulos et al. 2006). Thus, whereas GRO exposure results in a slight increase in male signaling activity, it does not appear to affect the attractiveness of the pheromone signal to females.

The present study further investigates the mechanism that underlies the increased mating success of GRO-exposed males of *C. capitata*. In particular, we present the results of two sets of behavioral experiments that examined the possibility that female preference for GRO-exposed males was mediated by a 'perfume effect', whereby the aroma of GRO affected the male cuticle in some manner that enabled females to distinguish between exposed and non-exposed individuals. In the first set of experiments, we presented females with freshly killed flies or hexane extracts from flies and monitored female presence near the different treatments. By offering such stimuli, we eliminated the possibility that active displays, behavioral or pheromonal, influenced female response. In the second set, we compared mate choice between intact females and females from which one or both antennae were surgically removed. By removing the primary olfactory receptors, we directly examined the role of male odor in affecting female choice. We also conducted the converse experiment, i.e., we compared mating success between non-

exposed males and GRO-exposed males that were intact or in which one or both antennae were surgically removed before the exposure. By performing this surgery, we directly examined the importance of male perception of the GRO odor in influencing mating success.

Methods and Materials

Study Insects Medflies used in this study were derived from a laboratory colony started with >500 adults reared from coffee (*Coffea arabica* L.) berries collected on the island of Kauai, Hawaii. The colony was four to five generations removed from the wild when this study was conducted. Adults of *C. capitata* were held in screen cages and provided a mixture of sucrose and yeast hydrolysate (3:1, *v*/*v*) in a Petri dish, water, and oviposition substrate (perforated plastic vials containing small sponges soaked in lemon juice). Eggs were placed on standard larval medium (Tanaka et al. 1969), and mature larvae 'popped' onto a layer of vermiculite for pupation. Adult medflies used in the experiments were separated by sex within 48 hr of eclosion, well before reaching sexual maturity at 6–8 d of age. When used in the experiments, males were 9–13 d old and females were 10–15 d old. Flies were held in screen-covered, plastic containers (5 l; 125–150 flies per container) at 23–26°C and 60–90% RH and received both natural and fluorescent light on a 12 L/12 D photoperiod. Experimental flies were maintained on the same sugar-yeast hydrolysate mixture used for the colony.

In several experiments, we also used males of the oriental fruit fly, *Bactrocera dorsalis* (Hendel), derived from a laboratory colony started with >200 adults reared from guava (*Psidium guajava* L.) fruits collected on the island of Oahu, Hawaii. The colony was two generations removed from the wild when this study was conducted. The oriental fruit fly colony was maintained in much the same manner as the medfly colony, except that eggs were deposited and larvae developed in fruit (papayas, *Carica papaya* L.). When used in the experiments, *B. dorsalis* males were 22–30 d old (sexual maturation in this species occurs between 15–21 d of age).

Female Response to Dead Flies: Basic Protocol Experiments in which we monitored the response of *C. capitata* females to various treatments of freshly killed flies followed the same basic protocol (with the single exception of experiment 11, see below). On a given test day, 30 females were transferred (with an aspirator) from the holding containers to screen cages (30 cm cubes) between 0830–0900 hours and held (in a different room from the test room) until tested between 1000–1130 hours. Groups of ten 'stimulus' flies from the treatments being compared were transferred from holding containers to a freezer for 15–20 min; flies from the different treatments were placed in separate freezers. Upon removal from the freezer, dead flies were held at room temperature for 10 min, transferred to plastic Petri dishes (5.4 cm diameter) and introduced into the test cages containing the females. Thus, for all trials, a given screen cage contained 30 females and two Petri dishes (10 cm apart), each holding ten freshly killed flies from the two treatments being compared.

Starting 1 min after placement of the stimulus flies, we recorded the number of females resting on each of the dishes at 1-min intervals over a 30-min period. Because females were not marked, the number of sightings recorded represented a composite index that encompassed both female arrival to and retention on a particular dish. An observer

monitored two cages simultaneously (containing the same two treatments of stimulus flies) and one pair of cages per day (with different, randomly selected treatments of stimulus flies in the first and second pairs). During observations, the cages were resting on a table (0.5 m apart) adjacent to a window. For a given experiment, the locations (right or left from the observer's vantage) of the two treatments within the test cages were alternated among the replicates to control for a possible position effect. Females and stimulus flies were used for a single trial only, and the test cages and Petri dishes were rinsed with water at the end of daily observations.

For several experiments, we compared a given pair of treatments first by using uncovered dishes, and then we conducted a second set of replicates by using covered dishes (i.e., a 5 cm square of white cotton cloth over the stimulus flies). By preventing females from seeing or touching the stimulus flies, the cloth cover was used to isolate more completely the role of olfactory cues in influencing female settlement.

Female Response to Dead Flies: Species- and Sex-Specific Attraction We first investigated species- and sex-specific attraction of *C. capitata* females. In experiment 1, females were offered conspecific males and *B. dorsalis* males, and in experiment 2, females were offered conspecific males and females.

Because females showed strongest attraction to conspecific males, we conducted three additional experiments to determine whether conspecific males (not exposed to GRO) had hexane-extractable compounds that were attractive to females. In experiment 3, we monitored female response to paper discs (8 mm diameter) treated with hexane extract from male medflies *vs* discs treated with hexane only. We placed ten chilled males in 0.25 ml of hexane for 1 min, removed them, and then placed a paper disc in the extract until the extract was entirely absorbed. The disc was then dried for 1 hr before testing. The 'control' discs absorbed the same volume of hexane and were dried for 1 hr before use. During the trials, discs were presented in Petri dishes following the standard procedure.

In experiment 4, we compared female sightings between hexane-washed and non-washed males (neither group was exposed to GRO). In this case, washed males were chilled, placed individually in glass beakers that contained 2 ml of hexane, shaken gently for 30 sec, and dried for 1 hr before testing. Because this treatment appeared to remove the volatile attractants, given that hexane-washed males were less attractive to females than non-washed males, we performed experiment 5 to examine the possibility that females were simply avoiding the hexane-washed males. We compared female attraction to two dishes of (non-exposed, uncovered) conspecific males, one of which also contained ten hexane-washed males (obtained following the protocol of the preceding experiment) beneath a cloth cover and the other had only a cloth with no flies beneath (the cloth covers used in this experiment were 2 cm squares, and thus covered only a portion of the dish).

Female Response to Dead Flies: GRO-Exposure to Conspecific Males We next investigated the influence of GRO exposure on the attraction of *C. capitata* females. In experiment 6, we offered females either GRO-exposed or non-exposed conspecific males. To obtain exposed males, we applied 0.25 ml of GRO to a cotton wick, placed the wick in a container (5 l) that held 30 males, and then removed it 2 hr later. Adjusted for container volume, this dose was equivalent to one previously demonstrated to increase male mating performance (Shelly 2001). GRO exposure was conducted in an isolated room between 1000–1200 hours; flies were exposed 1 d before testing (i.e., flies were freeze-killed and bioassayed the following morning).

Because females were more frequently observed near the GRO-exposed than the non-exposed males and given the results of experiment 4, we considered the hexane-wash procedure to be an effective means of extracting compounds responsible for attraction. Therefore, in experiment 7, we repeated the protocol of experiment 6 but (after chilling) extracted the GRO-exposed males with hexane following the procedure described above for experiment 4.

Additional Tests on the Impact of GRO Exposure on Female Response Four experiments were conducted to investigate additional aspects of how GRO exposure affects female attraction.

In experiment 8, we monitored the response of females to paper discs treated with hexane extract from GRO-exposed males *vs* non-exposed males. The GRO exposure and hexane washing procedures followed those described for experiments 6 and 3, respectively.

In experiment 9, we compared female response to conspecific males that had no direct GRO exposure but were confined with GRO-exposed males immediately before testing. This experiment investigated the possibility that the attractant could be transferred among crowded individuals, a phenomenon demonstrated in several *Drosophila* species (Coyne et al. 1994; Marcillac and Ferveur 2004). We placed ten GRO-exposed males (exposure followed the same procedure described for experiment 6, except that in this instance the males were chilled just before GRO exposure and the distal tip of the right wing was clipped for identification) and ten non-exposed males in a vial (*h*/*w*, 5.4 cm, 2.3 cm) for 1 hr. During this interval, there was considerable physical contact among males, presumably allowing for the transfer of scent from the GRO-exposed males to the non-exposed males. The vial was chilled, and the males that were not exposed directly to GRO (those with intact wings) were used in the trials. Males in the other treatment, i.e., those not exposed to GRO-exposed males, were subject to the same confinement protocol, but in this case the 'other' (non-test) males placed in the vial had not been exposed to GRO.

In experiment 10, we assessed whether GRO exposure per se (i.e., independent of the object exposed) resulted in higher female attraction by comparing female attraction between GRO-exposed *vs* non-exposed males of *B. dorsalis*. Protocol followed that described for experiment 6.

In experiment 11, we monitored female response to GRO-exposed *vs* non-exposed males in a more complex environment, i.e., in the canopy of live, potted plants of *Ficus benjamina* L. Observations were made in a glass aquarium (*l*/*w*/*d*, 50×27×30 cm) that contained two plants; the aquarium was oriented 90° from normal (i.e., with a short side resting on the table top) with the open side covered with a screen mesh. For a given trial, we suspended two screen cages (cylinders, *h*/*w*, 5.0 cm, 3.0 cm) in the canopy that contained four GRO-exposed (after the exposure protocol used in experiment 6) or four non-exposed males (males from both groups were freshly killed through chilling), introduced 40 females, and then recorded the number of females resting directly on, or within 3 cm of, each cage at 1-min intervals over 30 min. The cages were placed at the same locations over all replicates, but the type of male (GRO-exposed or non-exposed) placed at a given location was alternated between successive trials. The aquarium, plants, and cages were rinsed with water after each trial.

Mating Trials: Female and Male Antennal Removal Two sets of mating trials were performed. In the first, we manipulated female ability to perceive olfactory stimuli emitted by males, and in the second, we manipulated male ability to perceive the odor of GRO.

In the first set, we presented GRO-exposed and non-exposed males to intact females or females from which either one or both antennae were removed. Although olfactory sensilla may also occur on the mouthparts (as in *Drosophila*, Shanbhag et al. 1999), the antennae are believed to be the primary olfactory structures in *C. capitata* females (Levinson et al. 1987), and removal of both antennae completely eliminates female response to male pheromone (Nakagawa et al. 1973). For surgery, flies were chilled at 4°C, and the entire antenna(e) was cut off with a finger nail clipper under a dissecting microscope. Intact females were chilled only. Treated males were exposed to GRO (following the method described above) 1 d before testing; both GRO-exposed and non-exposed males were chilled and marked 1 d before testing by placing a small dot of enamel paint on the thorax (the chilling procedure had no apparent adverse effects on subsequent male behavior).

In the second set, we presented intact females with non-exposed and GRO-exposed males from which either one or both antennae were removed, i.e., the two male groups differed in the presence or absence of GRO exposure only and were identical with respect to possible effects of 'surgical trauma' associated with antennal removal. In trials conducted in large screen cages (75×90×120 cm), males lacking both antennae were rarely captured in GRO-baited sticky traps (Shelly, unpublished data), and we presume that removal of both antennae effectively prevented olfactory perception in males. Surgery was performed on males 2 d before testing, and GRO exposure and marking were completed 1 d before testing. All handling procedures were identical to those described above.

Mating Trials: Test Procedure Mating trials were conducted in the laboratory by using screen cages (30 cm cubes) under the same ambient conditions noted above. By using an aspirator, we placed 25 males from each treatment category, GRO-exposed or non-exposed, and 25 females into a cage (females were introduced 15 min after the males). Trials commenced between 0730–0800 hr, and mating pairs were collected at 0.5 hr intervals over a 4-hr period. We established three cages on each of 8 days for trials that involved manipulation of female antennal number (corresponding to intact females and females missing one or two antennae) and two cages on each of 10 d for trials that involved manipulation of male antennal number (corresponding to males missing one or two antennae). Because removal of both female antennae inhibited mating dramatically (a result also noted by Nakagawa et al. 1973 and Levinson et al. 1987), we conducted an additional 17 replicates with these females to gain an adequate sample of mated pairs.

Statistical Analyses In analyzing female attraction, two-way analysis of variance (ANOVA) was used to compare samples in experiments that included covered and uncovered stimulus flies (experiments 1, 2, 6, and 7), and a one-way ANOVA (Student's *t* test for two sample comparisons) was used in experiments using uncovered stimulus flies exclusively (experiments 4, 5, 9, 10, and 11) or paper discs (experiments 3 and 8). In all cases, the Tukey test to identify significant pair-wise differences. In analyzing mating frequency, samples were compared with the Student's *t* test. The data met parametric assumptions in most cases; when they did not, a log transformation was performed to normalize the data. Analyses were performed using SigmaStat Statistical Software (version 2.0). Means + 1 SE are given.

Results

Female Response to Dead Flies: Species- and Sex-Specific Attraction In experiment 1, uncovered or covered males of *C. capitata* and *B. dorsalis* were offered to *C. capitata*

females, and both factors—species identity and presentation method (covered or uncovered)—had effects on female visitation (species, $F_{1,44}$=90.0, P<0.001; presentation, $F_{1,44}$=11.1, P<0.01; Fig. 1a). In addition, the interaction term was significant ($F_{1,44}$=7.0, P<0.05). For both uncovered and covered stimulus flies, females were sighted significantly more often near the *C. capitata* males than near the *B. dorsalis* males. Fewer female sightings were made for covered than uncovered medfly males, whereas no effect of the cloth cover was observed for the oriental fruit fly males.

In experiment 2, uncovered or covered conspecific males and females were offered to *C. capitata* females, and both factors—sex and presentation method—had effects on female visitation (sex, $F_{1,\ 44}$=29.8, P<0.001; presentation, $F_{1,44}$=35.8, P<0.001; Fig. 1b). The interaction term was significant as well ($F_{1,\ 44}$=8.4, P<0.01). For both uncovered and covered stimulus flies, there were more female sightings made near the conspecific males than near conspecific females. For both sexes of stimulus flies, there were fewer female sightings near the covered than the uncovered individuals.

Conspecific males appeared to possess hexane-extractable compounds attractive to females. In experiment 3, there were more female sightings made near paper discs soaked in hexane-wash from male medflies (21.3+3.1) than near discs soaked in hexane only

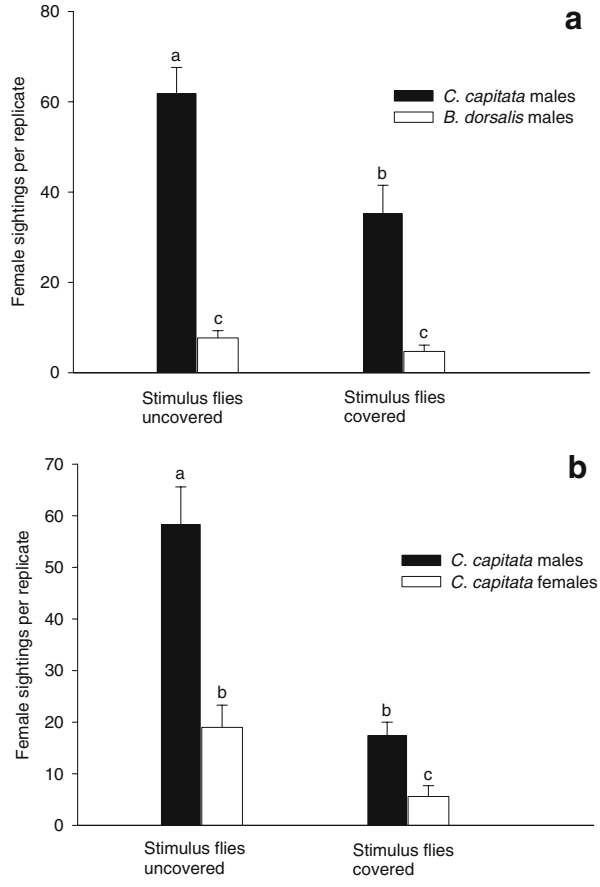

Fig. 1 Sightings of *Ceratitis capitata* females in choice tests near freshly killed **a** males of *C. capitata* and *B. dorsalis* (experiment 1) and **b** males and females of *C. capitata* (experiment 2). *Bar heights* represent mean number (+1 SE) of sightings per replicate (N=12). Means *labeled with same letter* are not significantly different (Tukey test, P=0.05). Note that whereas ANOVA was performed using all sample means, covered and uncovered treatments were presented in separate trials

(10.3+1.8, t=2.4, df=22; P<0.05). In addition, in experiment 4, the number of female sightings recorded for non-hexane-washed males was greater than that recorded for hexane-washed males (85.3+7.5 *vs* 42.1+8.5, respectively, t=2.7, df=22, P<0.05; only trials that used uncovered males were conducted). This difference did not appear to result from female avoidance of the hexane treatment itself. The presence of (covered) hexane-washed males close to non-washed males did not reduce female sightings below that observed for non-washed males presented alone. Female sightings were, in fact, slightly higher for the former group than the latter group, although this difference was not statistically significant (52.8+5.6 *vs* 47.2+4.9 sightings/replicate, t=0.51, df=22, P>0.05, experiment 5).

Female Response to Dead Flies: GRO Exposure to Conspecific Males In experiment 6, uncovered or covered conspecific males that were GRO-exposed or non-exposed were offered to *C. capitata* females, and both factors—GRO treatment and presentation method—had effects on female visitation (GRO exposure, $F_{1,44}$=13.2, P<0.001; presentation, $F_{1,44}$=69.4, P<0.001; Fig. 2a). The interaction term was significant as well ($F_{1,44}$=5.4, P<0.05). For both uncovered and covered stimulus flies, there were more female sightings made near the GRO-exposed males than near the non-exposed males. For both the GRO-exposed and non-exposed stimulus flies, there were fewer female sightings near the covered than the uncovered individuals.

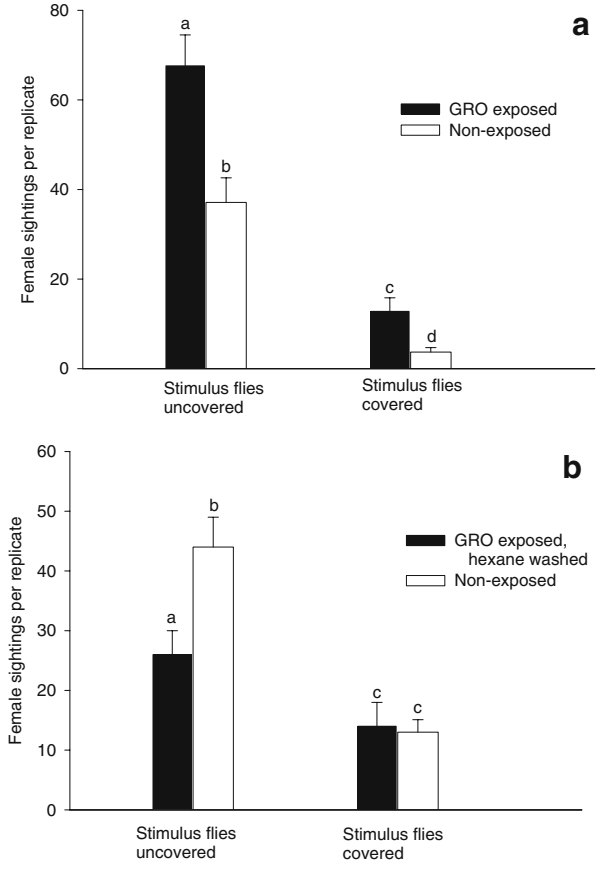

Fig. 2 Sightings of *Ceratitis capitata* females in choice tests near freshly killed males of *C. capitata* that were **a** exposed to GRO or non-exposed (experiment 6) and **b** exposed to GRO and then washed in hexane or non-exposed (experiment 7). *Bar heights* represent mean number of sightings per replicate (N=12); *error bars* represent +1 SE. Means *labeled with same letter* are not significantly different (Tukey test, P=0.05). Note that, whereas ANOVA was performed using all sample means, covered and uncovered treatments were presented in separate trials

Extraction with hexane reduced the attractiveness of GRO-exposed males. In experiment 7, uncovered and covered conspecific males that were GRO-exposed and then hexane-washed or non-exposed were offered to *C. capitata* females, and both factors had effects on female attraction (GRO/hexane treatment, $F_{1,44}=14.4$, $P<0.001$; presentation, $F_{1,\ 44}=6.1$, $P<0.05$; Fig. 2b). The interaction term was significant as well ($F_{1,44}=7.2$, $P<0.05$). For uncovered stimulus flies, there were more female sightings near the non-exposed males than near the hexane-washed, GRO-exposed males. For covered stimulus flies, there was no difference in the number of female sightings for the two male types.

Additional Tests Regarding the Effect of GRO Exposure on Female Response Table 1 presents the results from experiments 8–11. When presented with paper discs that contained extract from hexane-washed males, females were sighted more frequently near discs treated with extracts of GRO-exposed males than non-exposed males (experiment 8). There was also evidence that GRO-induced scent was transferable between males: Females were sighted more frequently near non-exposed males that had been confined with GRO-exposed males than non-exposed males that had been confined with other non-exposed males (experiment 9). Although these tests, along with the previous ones, indicate that GRO has an effect on female response, it does not appear that *C. capitata* females are attracted indiscriminately to GRO-exposed objects independent of their identity. When presented with males of *B. dorsalis*, medfly females were sighted equally near GRO-exposed or non-exposed individuals (experiment 10). When monitored in the larger and more physically complex environment established in the aquaria (experiment 11), females were sighted more frequently near GRO-exposed males than non-exposed males, although this difference was only marginally significant ($P=0.09$).

Mating Trials The first set of mating trials involved manipulation of female antennal number. Both intact females and those lacking one antenna mated preferentially with GRO-exposed males (Table 2). As noted above, females that lacked both antennae showed low mating propensity, and only three matings (one GRO-exposed and two non-exposed males) were recorded for such females over eight cages. Consequently, we set up additional 17 cages with these females, and over all 25 cages, we observed 8 matings with GRO-exposed males and 11 matings with non-exposed males, indicating random choice of mates ($P=0.64$, binomial test).

Table 1 Response of *Ceratitis capitata* females to GRO under varying modes of presentation

Experiment	Mode GRO presentation	GRO treatment	Female sightings per replicate
8	Disc with hexane from medfly males	Exposed	21.2 (4.1)
		Non-exposed	10.3 (1.8)*
9	Medfly males from crowded vials	Exposed	97.3 (7.7)
		Non-exposed	71.4 (4.5)*
10	Oriental fruit fly males	Exposed	6.7 (1.9)
		Non-exposed	7.2 (2.0)**
11	Medfly males in aquarium	Exposed	11.1 (2.5)
		Non-exposed	5.2 (1.4)**

Values represent means (+1 SE) of 12 replicates for experiments 8 and 10 and of 18 and 16 replicates for experiments 9 and 11, respectively. See text for methods used in the individual experiments. Significance level is given for between-treatment comparisons within each experiment, where *$P< 0.05$, **$P>0.05$.

Table 2 Mating trials for *Ceratitis capitata*

	Male treatment		Significance
	GRO-exposed	Non-exposed	
Set 1—Female antennal manipulation (female treatment antennae removed)			
0	12.6 (0.9)	8.6 (0.7)	$P<0.01$
1	12.3 (1.0)	7.8 (0.7)	$P<0.001$
2	8	11	$P>0.05$
Set 2—Male antennal manipulation (male treatment antennae removed)			
1	14.6 (1.1)	8.8 (1.3)	$P<0.01$
2	12.4 (1.0)	8.3 (0.9)	P<0.01

Mean number (SE) of matings per replicate (N=8 for set 1 and N=10 for set 2) are presented with significance level based on the t test, with the exception of the experiment involving removal of both antennae from females where the total numbers of matings are presented over 25 cages, and significance was assessed using the binomial test. In all trials, 25 females and 25 males of each GRO exposure category were placed in screen cages.

In the second set, we manipulated antennal number in males. In these trials, GRO-exposed males achieved significantly more matings than non-exposed males independently of the number of antennae removed from the test males. Among GRO-exposed males, there was no difference in the number of matings obtained by individuals lacking one *vs* two antennae ($P<0.05$). Furthermore, GRO-exposed males accounted for a similar proportion of the total matings in their respective trials (-1 or -2 antennae: 62.8 and 59.9%, respectively, $P>0.05$, test performed using arc sine transformed values).

Discussion

Species- and Sex-Recognition Within the Diptera, profiles of cuticular hydrocarbons, which are primarily contact pheromones with low volatility (Amrein 2004; Vogt 2005), differ among closely related species (e.g., *Drosophila*, Etges and Jackson 2001; *Tabanus*, Hoppe et al. 1990; and *Anopheles*, Carlson et al. 1997) and have an important role in species recognition and reproductive isolation. In contrast, the present study indicates that females of *C. capitata* distinguished conspecific from heterospecific males based on chemical cues associated with volatile compounds. Females displayed species-specific discrimination even when the test males were covered and could not be seen or touched directly. Female medflies were only weakly attracted to *B. dorsalis* males, and their response was independent of the manner in which the heterospecific males were presented (i.e., covered or uncovered). In contrast, females showed a significantly higher attraction to uncovered than covered conspecific males, indicating that visual and/or contact cues influenced female response. Species-specific differences in cuticular hydrocarbon profiles have been reported for larvae of several tephritid species (Carlson and Yocom 1986; Sutton and Steck 1994), and, along with the volatile attractants suggested by the present findings, contact pheromones may also function in species recognition in the Tephritidae.

Our tests also revealed that female medflies use volatile olfactory cues to distinguish sex among conspecific individuals. As with species recognition, *C. capitata* females distinguished conspecific individuals by sex even when these individuals were covered and could not be seen or touched. For both sexes, female attraction was greater for

uncovered individuals, indicating that visual and/or contact chemical cues also influenced female response. Sexual differences in cuticular hydrocarbons have been reported for other Diptera (e.g., *Drosophila*, Suvanto et al. 2000; *Fannia*, Uebel et al. 1977) but, to our knowledge, have not been documented for any tephritid species.

Discrimination Among Conspecific Males Trials that tested female response to freshly killed flies or paper discs indicated that females distinguished GRO-exposed and non-exposed males on the basis of olfactory cues. Even when the males were covered, females were sighted more often near GRO-exposed than non-exposed males, and females preferred to settle near paper discs treated with extract from GRO-exposed than non-exposed males. Washing GRO-exposed males in hexane eliminated female preference for these males, whereas confining non-exposed males with GRO-exposed males increased the attractiveness of non-exposed males, suggesting transfer of substances from the GRO-exposed flies.

Surgical removal of the antennae of females allowed a direct test of the role of olfaction on mate choice. Unfortunately, as noted previously (Nakagawa et al. 1973; Levinson et al. 1987), females lacking both antennae do not mate readily, and we obtained a total of only 19 matings that involved such females. These matings showed no deviation from random choice, with GRO-exposed and non-exposed males, accounting for 42 and 58% of the matings, respectively. Costanzo and Monteiro (2007) reported a similar finding in a nymphalid butterfly, where females with 'blocked' antennae (covered with nail varnish) mated indiscriminately with control males emitting normal odors and treated males whose scent producing glands were blocked and rendered non-functional (see also Pivnick et al. 1992). Based on our results, it appears that the previously noted GRO-mediated increase in male mating success (Shelly 2001; Shelly et al. 2004b) depends on female perception of male-derived olfactory cues. The converse approach—antennal removal from males—showed that male ability to perceive the odor of GRO was not necessary for enhanced mating performance. Males exposed to GRO after removal of both antennae achieved significantly more matings than non-exposed (but antenna-less) males. It thus appears that GRO treatment confers a mating advantage through an external phenomenon, i.e., an alteration in body scent, rather than internal processing, e.g., utilization in pheromone synthesis after absorption of airborne molecules.

Two studies on female attraction to pheromone-calling males further support this interpretation. As noted previously, Shelly (2001), working in a field cage, established leks comprised of GRO-exposed or non-exposed males, respectively, and monitored male calling and female visitation. These observations showed that female visitation was directly related to the calling activity associated with given leks (independent of male type) and, as such, was apparently influenced by signaling level per se independent of signal composition (quality). Additionally, Papadopoulos et al. (2006), working in a laboratory wind tunnel, reported that similar numbers of females arrived to spheres emitting the pheromone odor of GRO-exposed or non-exposed males, respectively. The absence of female preference in this experiment suggests that the increased mating success of GRO-exposed males does not reflect the production of a more attractive, long-range pheromonal signal by GRO-treated males. Instead, it appears that GRO's impact is greatest during close-range courtship.

Briceño et al. (2007) found that GRO-exposed and non-exposed males displayed the same behavioral elements of courtship and that wild (but not mass-reared) females accepted GRO-exposed males, not only more frequently but also more rapidly than non-exposed males. The absence of major behavioral differences between males in the two treatments suggests that other sensory modalities, i.e., auditory or olfactory, may be responsible for the

GRO-mediated increase in courtship success. During courtship, males produce sounds via rapid vibration and rhythmic forward-and-backward movements of the wings (Sivinski et al. 1989), but the significance of such acoustic signals has not been investigated experimentally. Whereas auditory cues cannot be dismissed, the present study supports the hypothesis that females may discriminate among courting males, in part at least, on the basis of GRO-related body scent.

Implications for Understanding Female Mate Selection in Natural Populations

The mating success of male medflies is enhanced through exposure, not only to GRO (Shelly 2001) but also to certain fruits (oranges and guavas; Papadopoulos et al. 2001; Shelly et al. 2004a; Shelly and Villalobos 2004), tree bark (guava, Shelly and Villalobos 2004), and other commercially available oils (e.g., orange oil, Shelly et al. 2004a; manuka oil, Shelly et al. 2007b). Although the active compound is not known with certainty, all these substances (GRO, Takeoka et al. 1990; oranges, MacLeod et al. 1988; Nishida et al. 2000; orange oil, Takeoka et al. 1990; guava bark and fruits, MacLeod and De Troconis 1982; Shelly and Villalobos 2004; manuka oil, Douglas et al. 2004) contain the hydrocarbon sesquiterpene α-copaene, which is known to be a powerful attractant to male medflies (Warthen and McInnis 1989; Flath et al. 1994a,b). Importantly, exposure to α-copaene alone was found to increase the mating success of *C. capitata* males (Shelly 2001). As α-copaene is widely distributed among plants, it appears reasonable to assume that this compound (and possibly other related compounds) influences the mating success of *C. capitata* males in the wild.

One pattern that has emerged from studies of α-copaene-containing substances is that, for the commercially available oils, exposure to the aroma alone is sufficient to boost male performance in *C. capitata*, whereas, for the fruits and bark, physical contact is required for mating enhancement. For example, males exposed to the odor of orange oil enjoy increased mating success, whereas males provided oranges in screened containers (thus preventing contact) gain no mating advantage (Shelly et al. 2004a). This trend may reflect the higher concentration of α-copaene (and related compounds) in the oils than in the plants. The concentration of α-copaene in orange oil is 0.2% (S. Young, personal communication) compared to only 0.7 μg/g for the peel of the fruit (Nishida et al. 2000). Based on these observations, it appears likely that, in the wild, male medflies must touch α-copaene-containing plant structures to gain a mating advantage. We are planning future studies to address whether contact of these structures alone (i.e., without feeding) enhances male mating success.

Adaptive Benefit of Female Preference for Scented Males The adaptive benefit of female preference for scented males remains unknown. In a laboratory study (Shelly 2005), females mated with GRO-exposed males did not lay significantly more eggs or live significantly longer than females mated with non-exposed males. Likewise, whether or not a male was exposed to GRO before mating had no significant effect on the proportion of eggs that hatched or the proportion of eggs that yielded pupae (Shelly 2005). Thus, it does not appear that GRO-exposed males transfer some material resource that directly increases female fecundity or vigor. Alternatively, the emission of particular phytochemically derived scents by males may indicate a superior ability to locate the appropriate plants in the habitat; that is, by selecting males with, presumably, an α-copaene-derived scent over others, female medflies may increase the odds that their sons will have high ability to locate sources of α-copaene and hence enjoy high mating success. This scenario constitutes a case

of runaway selection, whereby female choice provides indirect benefits via a trait that confers an advantage to her sons in sexual competition but is arbitrary with respect to offspring viability (Andersson 1994).

If this runaway selection hypothesis is valid, the honesty inherent in a scent-based signal would appear to vary inversely with the ease with which sources of α-copaene were locatable. In cases where such sources are relatively common, a larger proportion of males might find them by chance alone, and female selection of scented males may be less likely to yield sons with high searching capacity. This situation raises the interesting, more general, possibility that female choice based on exogenously derived, olfactory signals (body scent) may be less reliable than choice based on endogenously produced pheromonal signals, e.g., where mate selection is based on the chemical composition of male pheromone, which may serve as an honest indicator of, for example, developmental stability (Thornhill 1991), immunocompetence (Rantala et al. 2002), or dominance status (Moore 1988).

Acknowledgments We thank Eric Jang, Jocelyn Millar, David Robacker, and Keng-Hong Tan for technical advice. Sylvia Young of Citrus and Allied Essences Ltd. supplied information regarding the chemical composition of ginger root oil. Eric Jang, Jocelyn Millar, and Boaz Yuval provided comments on an earlier draft.

Introduction

Sponge-feeding nudibranchs of the family Chromodorididae sequester selected chemicals from their prey and reuse them for defense (Karuso 1987; Faulkner 1992; Cimino et al. 1999). Several studies on chromodorid species have suggested a genus-specific distribution of terpenoid secondary metabolites, which are generally furanosesquiterpenes for *Hypselodoris*, diterpenes for *Chromodoris*, and sesterterpenes for *Glossodoris* (Karuso 1987; Faulkner 1992; Cimino et al. 1999). However, this specialization is only a tendency, and it would appear that the various species are not equally specialized (Wahidullah et al. 2006). When specialization evolves, there would likely be intermediate stages from more generalized to more specialized forms. In addition, which metabolites will be found in a given specimen is contingent upon environmental circumstances. Additionally, some confusion in the chemotaxonomy of Chromodorididae has been generated by changes in species names and synonymies. For example, *Chromodoris youngbleuthi*, which has been reported to contain scalarane sesterterpenes (Terem and Scheuer 1986), is currently called *Glossodoris rufomarginata*.

Well-described associations link *Glossodoris* nudibranchs to sponges that contain scalarane compounds (Rogers and Paul 1991; Avila and Paul 1997; Fontana et al. 1999, 2000; Gavagnin et al. 2004). However, sesterterpenoid scalarane metabolites have also been reported from species belonging to the genus *Hypselodoris* (Cimino et al. 1993) and *Chromodoris* (Kernan et al. 1988; Miyamoto et al. 1992, 1999), whereas some *Glossodoris* nudibranchs contain diterpenoid metabolites that exhibit a spongiane skeleton (de Silva and Scheuer 1982; Fontana et al. 1997; Somerville et al. 2006).

The typical sponge metabolite scalaradial (**1**) (Cimino et al. 1974) that contains the biologically significant bis-aldehyde functionality has been described only for *Glossodoris pallida* from Guam (Rogers and Paul 1991). An unidentified epimer of scalaradial has also been reported for *Glossodoris hikeurensis* and *Glossodoris cincta* (Rogers and Paul 1991), whereas metabolites with the scalarane framework but showing different functionalities have been isolated from the other *Glossodoris* nudibranchs.

In particular, it is interesting to note that scalarane sesterterpenes that exhibit the keto function at C-12 have been found in *Glossodoris* nudibranchs (Terem and Scheuer 1986; Fontana et al. 1999; Gavagnin et al. 2004). The 12-keto structural feature is unusual in the scalarane series, and it has been encountered exclusively in *Glossodoris* metabolites, leading to the suspicion that some selected species are able to oxidize the hydroxyl function at the C-12 position of dietary derived scalaranes.

Studies on a population of *G. pallida* from Guam showed that the mollusk is able to sequester scalarane compounds (Fig. 1) from its diet (Rogers and Paul 1991) and to store

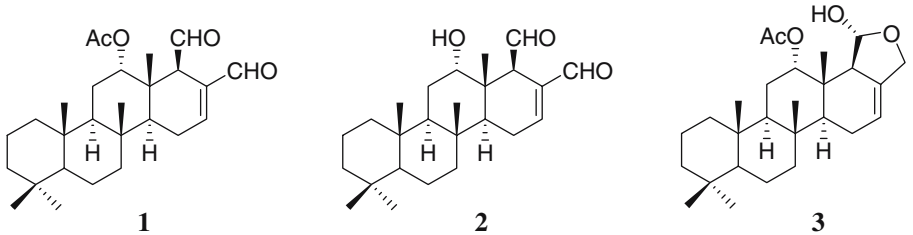

Fig. 1 Scalarane metabolites of *G. pallida* from Guam. Scalaradial (**1**), deacetylscalaradial (**2**), deoxoscalarin (**3**)

them strategically in some selected parts of the body (Avila and Paul 1997). In that work, scalaradial (**1**) (Cimino et al. 1974) and the corresponding deacetyl derivative (**2**) (Yasuda and Tada 1981) were predominant in the mantle dermal formations (MDFs) along the border of the mantle, whereas deoxoscalarin (**3**) was present mainly in the reproductive system/hermaphroditic gland. Ecological experiments demonstrated that the compounds that are localized in the mantle border function as defense compounds against crabs and predatory reef fishes (Avila and Paul 1997). The presence of deoxoscalarin, which was absent in the analyzed sponge prey, was ascribed to the ability of the mollusk to modify dietary scalaradial into a less toxic metabolite by a detoxification process.

In this study, we investigated the chemistry of three *Glossodoris* species from Indo-Pacific areas, *G. pallida* (Ruppell and Leuckart 1828) from China, of *Glossodoris vespa* Rudman, 1990, and *Glossodoris averni* Rudman, 1985 from Eastern Australia. In addition, we re-analyzed the secondary metabolism of a population of *G. pallida* from Guam. Our main purpose was to check the presence of scalaranes in the previously unstudied *G. vespa* and *G. averni* and to verify whether the oxidation of the tricyclic carbon skeleton of scalaradial (**1**) is a peculiarity of *Glossodoris* mollusks.

Methods and Materials

General Procedures Thin layer chromatography (TLC) plates (Merck Silica Gel 60 F254) were used for analytical TLC and Merck Kieselgel 60 for preparative column chromatography. High resolution electron-spray ionization mass spectra (HRESIMS) were carried out on a Micromass Q-TOF micro. HPLC Waters 501 pumps with a refractometer detector were used and equipped with direct-phase column Kromasil Silica, 5 μ (250×4.60 mm, Phenomenex). Nuclear magnetic resonance (NMR) spectra, recorded at the NMR Service of Istituto di Chimica Biomolecolare of CNR (Pozzuoli, Italy), were acquired on a Bruker Avance-400 operating at 400 MHz, in $CDCl_3$ and in C_6D_6 (δ values reported referenced to $CHCl_3$ at 7.26 ppm and to C_6H_6 at 7.15 ppm, respectively) with an inverse probe fitted with a gradient along the *Z*-axis. ^{13}C NMR were recorded on a Bruker DPX-300 operating at 300 MHz (δ values are reported relative to $CDCl_3$, 77.0 ppm and to C_6D_6, 128.0 ppm with a dual probe). Optical rotations were measured on a Jasco DIP 370 digital polarimeter, whereas CD spectra were measured on a Jasco J 710 spectropolarimeter.

Biological Material A single individual of *G. pallida* (size, 5 cm) was collected by scuba diving at a depth of 18 m along the coast of Hainan, in the South China Sea, during September 2004. Animals from the Pacific were collected at a depth of 24 m in Apra Harbor, Guam, at a small patch reef called Sponge Mount, during January 2007. Four individuals (average of 1 cm length) were found on the sponge *Cacospongia* sp., and corresponding sponge pieces were collected with each nudibranch.

Six individuals of *G. averni* (size, 2–7 cm) and seven individuals of *G. vespa* (size, 4 cm) were collected by scuba diving at a depth of 10–16 m along the Queensland coast (Australia) at the Gneerings Reef and at Mudjimba Island offshore from Mooloolaba, during December 2004.

Nudibranchs and sponges from Guam were identified by one of us (P. Schupp, University of Guam), immediately frozen and extracted within a week after collection. The nudibranchs from China and Australia were identified by one of us (E. Mollo, ICB-CNR Italy), immediately frozen and then transferred to ICB in Naples, where they were kept at −80°C until extraction.

Extraction and Isolation Procedures

Glossodoris pallida The single *G. pallida* specimen from Hainan was carefully dissected into the mantle border, rest of the mantle, and internal organs, and these different tissue types were separately extracted with acetone by using ultrasound. The acetone extracts were concentrated in vacuo, and the residual waters were partitioned with diethyl ether. The organic phases were concentrated under reduced pressure giving crude ether extracts for the three anatomical sections: 32, 20, and 111 mg were obtained for mantle border, rest of the mantle, and internal organs, respectively.

The ether extract of the mantle border (32 mg) was subjected to a silica gel column that was eluted with a light petroleum ether/diethyl ether gradient to give the main compound, 12-deacetoxy-12-oxo-scalaradial **4** [12 mg, R_f 0.52 (light petroleum ether/diethyl ether 2:8)] along with a lipid fraction (15 mg). The ether extract of the rest of the mantle (20 mg) gave 1.1 mg of **4** along with a fatty acid fraction (12 mg). The ether extract of the internal organs (111 mg) was purified by silica-gel under the same conditions as above yielding, in order of increasing polarity (TLC with light petroleum ether/diethyl ether 2:8): 12,16-deacetoxy-12-oxo-scalarafuran (**5**, 0.6 mg, R_f 0.96), 19-acetyl-12-deacetoxy-12-oxo-deoxoscalarin (**6**, 25.0 mg, $_f$ 0.71), deoxoscalarin (**3**, 20.0 mg, $_f$ 0.52), 12α,16β-diacetoxy-scalarolbutenolide (**7**, 0.9 mg, R_f 0.50), 12-deacetoxy-12-oxo-deoxoscalarin (**8**, 1.1 mg, R_f 0.47), and 12-deacetyl-12−*epi*-deoxoscalarin (**9**, 1.0 mg, R_f 0.40).

The four *G. pallida* individuals from Guam were not dissected due to their small size (0.236–0.066 g wet weight). Each specimen was extracted three times by soaking in acetone (60 min) and by using ultrasound (1 min each). Acetone extracts were dried under flowing N_2 to give four crude residues A–D (17, 14, 13, and 7 mg, respectively). Four specimens of *Cacospongia* sp. (18–10 g wet weight) were each extracted three with acetone on stirring (60 min each). The acetone extracts were first concentrated in vacuo, and final concentration of the four crude extracts I–IV (441, 400, 304, and 160 mg, respectively) was achieved under flowing N_2.

The nudibranch acetone extract A (17 mg) was purified by silica-gel chromatography (petroleum ether/diethyl ether gradient) to give, in order of increasing polarity, deacetyl scalaradial **2** [2.0 mg, R_f 0.58 (light petroleum ether/diethyl ether 2:8)], scalaradial **1** (3.0 mg, R_f 0.52), and deoxoscalarin (**3**, 1.0 mg), along with a lipid fraction (7.0 mg).

Analogously with the procedure above described, the sponge acetone extract I (441 mg) was purified by silica-gel chromatography (petroleum ether/diethyl ether gradient) to afford, in order of increasing polarity, deacetyl scalaradial (**2**, 13 mg) and scalaradial (**1**, 71 mg), along with a lipid fraction (220 mg).

Glossodoris averni Six specimens of *G. averni* were treated with acetone by using ultrasonic vibration for 2 min. This procedure allows the selective extraction of the metabolites present only in the external part of the mollusk. Subsequently, the animals were extracted again with acetone by using a pestle (internal part extract). Both acetone extracts were concentrated in vacuo, and the residual waters were partitioned with diethyl ether. The organic phases were concentrated under reduced pressure giving crude ether extracts, 40 mg from the external part and 82 mg from the internal part. Careful comparative TLC chromatography in different eluent systems of both extracts showed a similar secondary metabolite composition, so they were combined and processed together. The total ether extract (122 mg) was purified on a silica gel column eluted with a light petroleum ether/diethyl ether gradient to give, in order of elution, 12,16-deacetoxy-12-oxo-scalarafuran (**5**, 1.5 mg), 12-deacetoxy-12-oxo-scalaradial

(**4**, 4.0 mg), 16-deacetoxy-12-*epi*-scalarafuran acetate (**10**, 2.5 mg) [R_f 0.40 (light petroleum ether/diethyl ether 2:8)], and deoxoscalarin **3** (2.5 mg) [R_f 0.38 (light petroleum ether/diethyl ether 2:8)] along with a lipid fraction (80 mg).

Glossodoris vespa Seven *G. vespa* individuals were extracted as described for *G. averni*. The acetone extracts of external and internal parts were concentrated in vacuo, and the residual waters were partitioned with diethyl ether. The organic phases, which were concentrated under reduced pressure, were compared by TLC chromatography showing identical secondary metabolite distribution. Thus, they were combined to give 70 mg of crude extract. This extract was subjected to a silica gel column and eluted with a light petroleum ether/diethyl ether gradient to give 16-deacetoxyscalarafuran **11** [5 mg, R_f 0.62 (light petroleum ether/diethyl ether 2:8)] and 12-deacetoxy-12-oxo-scalaradial **4** (10 mg) along with a lipid fraction (40 mg).

Results and Discussion

The TLC chromatographic analysis of the three anatomical sections of the single specimen of *G. pallida* from Hainan showed a unique secondary metabolite composition. The mantle border extract contained a spot by TLC (R_f 0.52, light petroleum ether/diethyl ether 2:8), which was selectively present in this section, along with the common fatty acid fraction. A preliminary ^{1}H-NMR analysis revealed that the extract contained a single terpenoid component that exhibits signals typical of a scalarane dialdehyde. A TLC comparison with a standard sample of scalaradial (**1**) showed similar chromatographic behavior (R_f scalaradial 0.52, light petroleum ether/diethyl ether 2:8), but NMR analysis of the purified sample (about 38% of ether extract) indicated that it was 12-deacetoxy-12-oxo-scalaradial (**4**), the scalarane dialdehyde previously reported from *G. rufomarginata* (Gavagnin et al. 2004). The extract of the rest of the mantle contained fatty acids and traces of compound **4**, probably due to a contamination from the border, whereas the extract derived from the internal organs was a complex mixture of metabolites at R_f 0.96–0.40 (light petroleum ether/diethyl ether 2:8). Purification of the internal organs extract led to the isolation of an additional six scalarane compounds, which included deoxoscalarin (**3**) (Cimino et al. 1973) and 19-acetyl-12-deacetoxy-12-oxo-deoxoscalarin (**6**) (Gavagnin et al. 2004) as major components. Among the minor compounds, the new scalarane 12,16-deacetoxy-12-oxo-scalarafuran (**5**) and three known components, 12α,16β-diacetoxy-scalarolbutenolide (**7**) (Lu and Faulkner 1997), 12-deacetoxy-12-oxo-deoxoscalarin (**8**) (Fontana et al. 1999; Gavagnin et al. 2004), and 12-deacetyl-12-*epi*-deoxoscalarin (**9**) (Fontana et al. 1999; Fig. 2) were also isolated.

Acetone extracts of *G. pallida* and *Cacospongia* sp. from Guam were analyzed by ^{1}H-NMR spectroscopy and showed similar metabolite patterns for each of the nudibranch individuals and for each of sponge specimens. The chemical profile of the nudibranch extracts was different from that obtained for the Hainan individual, being characterized by three scalarane compounds, whereas the sponge extracts all contained only two of these metabolites. A representative nudibranch extract (17 mg) was subjected to silica gel chromatography and provided scalaradial (**1**) (Cimino et al. 1974), deacetyl scalaradial (**2**) (Yasuda and Tada 1981), and deoxoscalarin (**3**) (Cimino et al. 1973). Compounds **1** and **2** were also isolated from a representative sponge extract (441 mg) by silica gel chromatography, thus indicating their dietary origin in the mollusk. However, the ratio

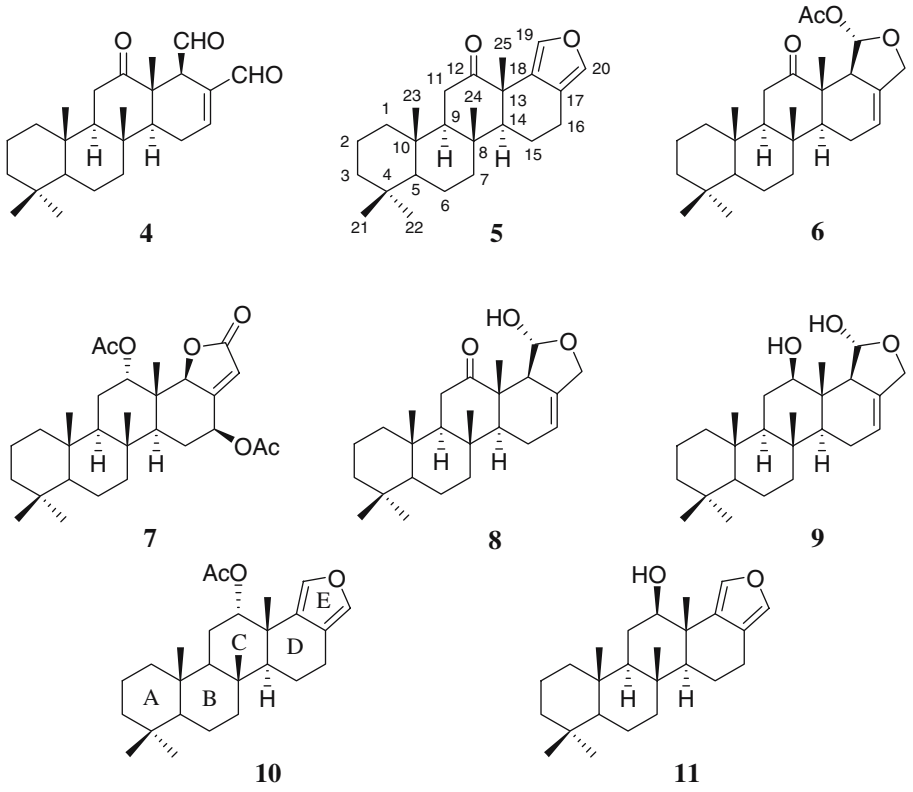

Fig. 2 Scalarane metabolites of *G. pallida* from Hainan and *G. vespa* and *G. averni* from Mooloolaba (compound **3** is not included). 12-Deacetoxy-12-oxo-scalaradial (**4**),12,16-deacetoxy-12-oxo-scalarafuran (**5**), 19-acetyl-12-deacetoxy-12-oxo-deoxosalarin (**6**), 12α,16β-diacetoxy-scalarolbutenolide (**7**), 12-deacetoxy-12-oxo-deoxoscalarin (**8**), 12-deacetyl-12-*epi*-deoxoscalarin (**9**), 16-deacetoxy-12-*epi*-scalarafuran-acetate (**10**), 16-deacetoxyscalarafuran (**11**)

between scalaradial (**1**) and deacetyl scalaradial (**2**) in the nudibranch (**1**:**2**, 3:2) was different from that observed in the sponge (**1**:**2**, 11:2), thus suggesting either distinct accumulation mechanisms or, more likely, that the majority of scalaradial (**1**) is transformed by the mollusk into deoxoscalarin (**3**).

The TLC analysis of the extracts obtained from external and internal parts of *G. averni* revealed similar secondary metabolite patterns. In particular, both extracts contained a mixture of metabolites at R_f values between 0.96 and 0.38 (light petroleum ether/diethyl ether 2:8). After chromatographic purification of the combined extracts, a series of scalaranes (Fig. 2), including the new 12,16-deacetoxy-12-oxo-scalarafuran (**5**), the main compound 12-deacetoxy-12-oxo-scalaradial (**4**) (Gavagnin et al. 2004), 16-deacetoxy-12-*epi*-scalarafuran-acetate (**10**) (De Giulio et al. 1989), and deoxoscalarin (**3**) (Cimino et al. 1973) were isolated along with a lipid fraction.

Analogously with *G. averni*, the TLC chromatographic analysis of the ether extracts of the external and internal parts of *G. vespa* showed a similar composition and distribution of scalarane metabolites. Both extracts were characterized by two main spots on TLC R_f 0.62–0.52 (light petroleum ether/diethyl ether 2:8). Silica-gel purification of the combined extract afforded 16-deacetoxy-scalarafuran **11** (Walker et al. 1980; Tsukamoto et al. 2003) and 12-deacetoxy-12-oxo-scalaradial (**4**) (Gavagnin et al. 2004) along with a lipid fraction (Fig. 2).

The known compounds **1**–**4** and **6**–**11** were identified by comparison of their spectral data (^{1}H-NMR, ^{13}C-NMR, MS, $[\alpha]_D$) with those reported in the literature, whereas the unprecedented 12,16-deacetoxy-12-oxo-scalarafuran (**5**) was characterized as follows.

The molecular formula $C_{25}H_{36}O_2$ was deduced by HRESIMS on the sodiated molecular ion at 391.2618 ($C_{25}H_{36}NaO_2$ requires 391.2613). Analysis of both ^{1}H- and ^{13}C-NMR spectra revealed the presence of a functionalized scalarane skeleton that exhibited a ketone group and a furan moiety. In particular, the ^{1}H-NMR spectrum displayed signals at δ 7.69 (1H, s, H-19) and δ 7.09 (1H, bs, H-20), due to the α-protons of a furan moiety, and at δ 2.78 (1H, dd, J=6 and 16 Hz, H-16a) and δ 2.47 (1H, m, H-16b), attributable to an allylic methylene, which was coupled with another methylene group (H_2-15, δ 1.76, and δ 1.88), in turn linked to an angular methine resonating at δ 1.57 (1H, m, H-14). These data suggested a partial structure (rings D and E), the same as 16-deacetoxy-12-*epi*-scalarafuran-acetate (**10**) and 16-deacetoxy-scalarafuran (**11**), isolated here from *G. averni* and *G. vespa*, respectively. An ABX system at δ 2.68 (1H, t, J=14 Hz), δ 2.41 (1H, dd, J=2.5 and 14 Hz), and δ 1.29 (1H, m) was attributed to the α-keto methylene H_2-11 coupled with the angular methine H-9, thus supporting the location of the keto function at C-12. Finally, as expected for a scalarane skeleton, typical signals for five singlet methyls at δ 1.40 (3H, s, H_3-25), δ 1.10 (3H, s, H_3–24), δ 0.89 (3H, s, H_3–23), δ 0.86 (3H, s, H_3–21), and δ 0.84 (3H, s, H_3–22) completed the proton spectrum. These data indicated the presence of the same partial structure (rings A–C) as compounds **4**, **6,** and **8**. All ^{1}H and ^{13}C NMR resonances of compound **5** (Table 1) were assigned by mono- and bi-dimensional NMR experiments (COSY, HSQC, and HMBC) and were in agreement with the proposed structure. The absolute stereochemistry of compound **5**, which was expected to be the same as that of the natural scalarane series, was further confirmed by comparing the CD profile of compound **5** with that of 12-deacetoxy-12-oxo-scalaradial (**4**), the absolute stereochemistry of which has been determined by synthesis (Gavagnin et al. 2004).

This study has confirmed the typical presence of scalarane metabolites in *Glossodoris* nudibranchs and reinforces the chemical trends reported in the literature for several species belonging to this genus (see Table 2). In addition, the occurrence of scalaranes that exhibit the unusual 12-keto functionality, which has been already reported for other *Glossodoris* nudibranchs, has been observed in the three different mollusks that were investigated. Interestingly, the scalarane content of *G. pallida* from Guam, which was lacking in 12-keto derivatives, displayed significant differences from that of the same species from Hainan.

It is generally assumed that mollusk scalarane metabolites have a dietary origin from sponges belonging to the order Dictyoceratida. The ability of *Glossodoris* nudibranchs to transform selected dietary scalaranes into related compounds as a possible enzymatic detoxification process has been suggested (Rogers and Paul 1991; Avila and Paul 1997; Fontana et al. 2000; Gavagnin et al. 2004). The results obtained in this work on *G. pallida*, *G. averni*, and *G. vespa* seem to confirm this strategy. In fact, 12-keto derivatives, which have never been encountered in sponges, should be obtained by the mollusks by oxidizing the hydroxyl/acetoxyl group located at C-12 in the ring C of dietary scalaranes. Interestingly, similar oxidative modifications that involve rings A or B of the scalarane framework occur in other chromodorid species, such as *Chromodoris funerea* (Kernan et al. 1988) and *Hypselodoris orsini* (Cimino et al. 1993). These mollusks contain a keto-deoxoscalarin with the keto moiety tentatively placed at C-1 or C-3 (**12**) and 6-keto-deoxoscalarin (**13**), respectively (Fig. 3).

A plausible chemical correlation of selected *Glossodoris* scalarane metabolites is depicted in Fig. 4. Deoxoscalarin (**3**) or 12-deacetoxy-12-oxo-scalaradial (**4**) could both be

obtained from scalaradial (**1**) either by C-20 reduction then formation of the intramolecular acetal linkage, or by hydrolysis then C-12 oxidation, respectively. 12-Deacetoxy-12-oxo-deoxoscalarin (**8**) is formed either by hydrolysis of **3** and subsequent C-12 oxidation of the intermediate compound 12-deacetyl-12α-deoxoscalarin (**14**) or by C-20 reduction of **4**. Finally, the new 12-deacetoxy-12-oxo-scalarafuran (**5**) could be obtained by dehydration and double bond shift of 12-deacetoxy-12-oxo-deoxoscalarin (**8**).

In conclusion, although biosynthetic experiments are necessary to investigate the pathway leading to 12-keto-scalarane derivatives, it seems reasonable to hypothesize that some mollusk species belonging to genus *Glossodoris* have the extraordinary and unique ability to obtain such compounds by enzymatic oxidation of dietary scalaranes. Accordingly, the absence of 12-keto-scalaranes in *G. pallida* from Guam could be explained by the occurrence of geographic variation in the biosynthetic gene expression within the same species, with remarkable evolutionary implications.

different year from most previous studies. Also, large quantities of catechin were detected in blanks for two sampling periods in the present study, leading us to discard those data. This contamination suggests that previous reports of high catechin concentrations that did not include blanks should be viewed with caution. Our results suggest that pure catechin is only rarely present in *C. maculosa* bulk soils. Thus, although catechin may play a role in *C. maculosa* invasion, the infrequency of soil catechin that we determined in this study suggests that we cannot be as certain of its role as previous reports of high soil catechin concentrations suggested.

Introduction

Centaurea maculosa Lam. (spotted knapweed, recently suggested to be *C. stoebe* L. [USDA, NRCS 2007]) is a Eurasian species in the Asteraceae that invades North American grasslands. It reduces native biodiversity and rangeland forage quality (Watson and Renney 1974; Tyser and Key 1988). A possible role of allelopathy in *C. maculosa* invasion has received considerable attention. Allelopathy has been proposed to mediate some plant invasions because allelopathic exotic plants may produce chemicals to which native species have not yet evolved resistance (i.e., the novel weapons hypothesis) (Callaway and Aschehoug 2000; Callaway and Ridenour 2004). Initial studies of *C. maculosa* allelopathy indicated phytotoxins in *C. maculosa* shoot tissue (Fletcher and Renney 1963; Kelsey and Locken 1987). More recently, an experiment that used activated carbon, which adsorbs organic compounds, suggested that phytotoxins in *C. maculosa* root exudates may inhibit native species (Ridenour and Callaway 2001).

Efforts to identify phytotoxins in *C. maculosa* root exudates revealed a racemic mixture of (±)-catechin (hereafter catechin) (Bais et al. 2002). Since then, several studies have reported high catechin concentrations in *C. maculosa* soils (Bais et al. 2002, 2003; Perry et al. 2005b; Thelen et al. 2005; Weir et al. 2006). Catechin also has been reported to inhibit growth and/or reduce survival of susceptible North American plants *in vitro* (Bais et al. 2002, 2003; Weir et al. 2003; Perry et al. 2005a), in soil in controlled environments (Bais et al. 2003), and in soil in the field (Thorpe 2006). (+)-Catechin alone also has been reported to inhibit growth of several plant species *in vitro* (Buta and Lusby 1986; Iqbal et al. 2003; Furubayashi et al. 2007; K. Simoes, unpublished data), but not in one experiment in soil (Furubayashi et al. 2007). (−)-Catechin alone has been reported to inhibit green algae (D'Abrosca et al. 2006). However, catechin effects vary considerably among experimental conditions and species within and among studies (Bais et al. 2003; Weir et al. 2003; Blair et al. 2005; Perry et al. 2005a; Thorpe 2006). Minimum concentrations reported for catechin phytotoxicity range from 0.0016–0.0032 mg g^{-1} (Thorpe 2006) to 0.04 mg g^{-1} (J. Pollock, unpublished data), 0.05 mg ml^{-1} (Weir et al. 2003), 0.25 mg ml^{-1} (Perry et al. 2005a), and >1.0 mg ml^{-1} (Blair et al. 2005). Catechin at high concentrations has been reported to inhibit *C. maculosa* growth and germination, acting as an autoinhibitor (Perry et al. 2005a, b). Finally, catechin has been reported to inhibit the North American species displaced by *C. maculosa* more than European species that coexist with *C. maculosa*, thus providing support for the novel weapons hypothesis (Bais et al. 2003; Thorpe 2006; W. He and Y. Feng, unpublished data).

Other recent studies have reported much lower soil catechin concentrations or have failed to find catechin in *C. maculosa* soil (Blair et al. 2005, 2006). Furthermore, some

studies have reported weak or no effects of high catechin concentrations on the same species for which other studies have reported strong effects (Bais et al. 2003; Weir et al. 2003; Blair et al. 2005; Perry et al. 2005a; Thorpe 2006; W. He and Y. Feng unpublished data; S. Duke personal communication). These results have raised doubts about the role of catechin in *C. maculosa* invasion, and suggested a need for additional research to resolve differences among studies. Therefore, we conducted extensive measurements of soil catechin concentrations. Most previous studies have sampled *C. maculosa* soil at only one time point and at only one or a few sites (Bais et al. 2002, 2003; Blair et al. 2005; Perry et al. 2005b; Thelen et al. 2005; Weir et al. 2006), with the exception of Blair et al. (2006), who sampled *C. maculosa* soil from July to October. Here, we examined soil catechin in many sites and over a 1-yr time course at one site to better assess spatial and temporal variation in catechin concentrations in *C. maculosa* soils.

Methods and Materials

Sites Soil catechin concentrations were examined at 11 North American sites where *C. maculosa* was abundant (>20% cover; G. Thelen, pers. obs.). Samples were collected during the 2005 and 2006 growing seasons (Table 1). Most sites were sampled only once, but one site (Nelson Gulch 1) was sampled twice and another (Mt. Sentinel) was sampled seven times.

Collection of Soils At each site, 10 1.5-cm diameter×5-cm deep cores were collected from within 5 cm of each of 7–20 randomly selected *C. maculosa* plants with root crown diameters greater than 5 mm. Some sampled plants at the Nelson Gulch site were smaller because *C. maculosa* plants there were generally smaller than at other sites. The cores from around each plant were pooled immediately after collection, sieved through a 2-mm screen, and homogenized by stirring. Two 3-cm^3 subsamples from each homogenized sample were mixed thoroughly with 10 ml of methanol in 15-ml centrifuge tubes. Most samples were placed in methanol immediately in the field. However, samples from Mt. Sentinel on June 14 and July 2, 2005 were placed in methanol 1–2 hr after collection, and samples from Big Creek were placed in methanol 3–4 hr after collection. All samples were stored in methanol at 4°C until processed.

Sample Extraction In preparation for analysis, samples were centrifuged for 5 min at 7,000 rpm (Sorvall SL 50T; relative centrifugal force=5,867×*g*). Supernatants were transferred to new 15-ml tubes, concentrated under blown N_2, resuspended in two rinses of 0.75 ml methanol, transferred to 2.0-ml centrifuge tubes, and centrifuged for 5 min at 14,000 rpm (VWR Galaxy 16; relative centrifugal force=15,996×*g*). The resulting supernatants were transferred to new 2.0-ml tubes, concentrated under blown N_2, resuspended in 0.4 ml methanol, and stored at 0°C until analysis. Extracted soil samples were dried to a constant weight in a 65°C forced-air drying oven and weighed. Soil weights were corrected for 0.06% hydrostatic water determined from weights of a subset of samples dried in a 105°C forced-air drying oven. Catechin concentrations were calculated on a per gram dry soil basis.

Determination of Catechin Concentrations We used methanol to extract soil catechin because we wanted to use methods similar to those with which we had previously measured high catechin concentrations (Bais et al. 2003; Perry et al. 2005b; Thelen et al. 2005; Weir

[a] Soil information was obtained from the USDA-NRCS web soil survey (http://websoilsurvey.nrcs.usda.gov/app/). Soil information was unavailable for some sites.

[b] The Nelson Gulch 1 site was sampled twice and the Mt. Sentinel site was sampled seven times. All other sites were sampled once.

[c] Number of samples in which catechin was detected.

[d] One subsample, rather than two, was collected from the pooled cores from each plant for this site and date.

et al. 2006). However, methanol extraction results in poor recovery efficiency (<17%) for pure catechin added to soil at known concentrations (Blair et al. 2005; L. Perry, unpublished data). Poor catechin recovery with our method may have caused us to underestimate catechin concentrations, or fail to detect catechin at concentrations lower than our detection limit (0.025 mg g^{-1}).

Catechin concentrations were determined by HPLC in comparison to 1 mg ml^{-1} (±)-catechin standards (Shivambu International, Himachal Pradesh, India). HPLC separations used mobile phase solutions of (A) 1% acetic acid in distilled water and (B) absolute methanol, with a multistep gradient of 0–5 min, 5% B; 5–15 min, increase to 20% B; 15–20 min, 20% B; 20–

40 min, increase to 100% B; 40–50 min, 100% B; 50–55 min, 5% B. The column was a reverse phase, 5 μm C_{18} (4.6×150 mm) (Dionex Corp., Sunnyvale, CA, USA), the flow rate was 1 ml min^{-1}, the sample injection volume was 20 μl, and absorbance was measured at 280 nm. For samples in which catechin was detected by HPLC, the presence of catechin was confirmed by LCMS. LCMS analyses that used mobile phase solutions of (A) 0.1% acetic acid in distilled water and (B) 0.1% acetic acid in absolute methanol, with a multistep gradient of 0–3 min, 10% B; 3–43 min, increase to 90% B; 43–51 min, 90% B. The column was a reverse phase, 5 μm C_{18} (4.6×150 mm) (Dionex Corp., Sunnyvale, CA, USA), the flow rate was 0.7 ml min^{-1}, and absorbance was measured at 280 nm. Ionization for MS analysis was performed in both positive and negative ion modes by using elecrospray ionization with a nitrogen flow of 80 psi, cone voltage of 70 V, needle voltage of 3 kV, and cone temperature of 600°C. Mass data were collected over the range of the gradient program at a rate of one scan per 1.5 sec.

Results and Discussion

In the most extensive study of soil catechin to date, we examined catechin in 402 samples from 11 *Centaurea maculosa* sites. We detected catechin in 20 samples, all collected on one date (May 16, 2006) at one site (Mt. Sentinel, Missoula, MT) (Table 1). No other sites were sampled on that date. The infrequency with which we detected catechin differs from many previous studies of catechin in *C. maculosa* soils in which catechin was detected in most samples regardless of site or date (Bais et al. 2002, 2003; Perry et al. 2005b; Thelen et al. 2005; Weir et al. 2006) but is similar to results from Blair et al. (2005, 2006), who reported no catechin or only trace amounts (<0.0001 mg g^{-1}) on eight of 10 dates. The catechin concentrations on May 16, 2006 at Mt. Sentinel (Table 1), however, are comparable to previous reports of high catechin concentrations, which include means of ~2.2±0.2 (Bais et al., 2003), 1.6±0.1 (Perry et al. 2005b), 0.7±0.02 (Weir et al. 2006), and 0.3±0.02 to 3.6±0.1 (± SE) mg g^{-1} (Thelen et al. 2005), and are much higher than those Blair et al. (2006) reported (0.001±0.0004 mg g^{-1}).

There are several potential explanations for the infrequency with which we detected catechin compared to previous studies. Variation in results could be caused by temporal or spatial variation in soil catechin. We detected catechin in every sample from one date at one site, suggesting that specific environmental conditions may be necessary for catechin production, stability, or detection. Conditions could have been poor for catechin in 2005, when little or none was found (Table 1; Blair et al. 2006), compared to 2004 and 2006 when results were mixed (Table 1; Blair et al. 2005; Perry et al. 2005b; Weir et al. 2006), and 2001 when high concentrations were found (Bais et al. 2002, 2003). In the one site studied in multiple years (Mt. Sentinel), high concentrations were reported in 2004 (Perry et al. 2005b), no catechin was detected in 2005, and results were mixed in 2006 (Table 1). Temperature and precipitation did not differ substantially among these years at Mt. Sentinel (Fig. 1), but other factors were not measured. The data from Mt. Sentinel seem to suggest that catechin is present in soil mainly in spring, but other reports from summer and autumn (Bais et al. 2003—June, August; Blair et al. 2006—August; Thelen et al. 2005—November; Weir et al. 2006—July) suggest that it is not predictable with seasons. Thus, temporal variation in conditions such as climate, soil chemistry, microbes, insects, or vegetation might be responsible for variation in soil catechin, but the particular factors that might be important are uncertain. The infrequency with which we detected catechin also

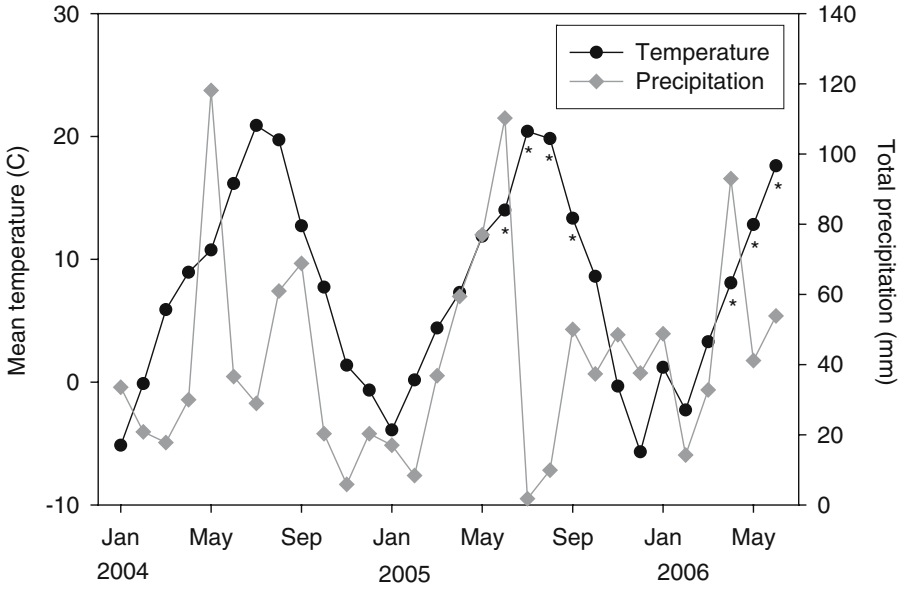

Fig. 1 Climate data for Missoula, Montana from January 2004 to May 2006. Data were obtained from the Western Regional Climate Center (http://www.wrcc.dri.edu). Asterisk indicates months in which samples were collected from Mt. Sentinel, Missoula, MT for the present study (Table 1)

could be explained by spatial variation, with unfavorable conditions in the sites we sampled this time; however, it seems unlikely that 10 of our 11 sites contained unfavorable conditions for catechin, whereas most previous studies sampled favorable sites.

The high catechin concentrations reported previously also could have been caused by undetected catechin contamination. Throughout the present study, we included blanks that contained only methanol as negative controls with our samples during extraction. In one set of samples, we found relatively high catechin concentrations (0.35±0.41 [SD] mg g^{-1}), but also found large quantities of catechin (1.4±0.6 [SD] mg) in all six blanks. In another set of samples, we found catechin in only one sample (0.03 mg g^{-1}), but again found it (0.3 mg) in one of three blanks. Several tests failed to identify the source of the contamination but indicated that it was not an artifact of the HPLC protocol. Because catechin was present in the blanks, we discarded the data for these dates; they are not included in Table 1. In subsequent tests, no quantifiable catechin was found in blanks. However, blanks were not included during sample extraction for most previous reports of high catechin concentrations (Bais et al. 2002, 2003; Weir et al. 2003, 2006; Perry et al. 2005b; Thelen et al. 2005). An exception is Fig. 1C of Thelen et al. (2005), which had one blank. Given the potential for catechin contamination demonstrated by the current study, previous results not including blanks should be regarded with caution.

Differences in our methods between this and previous studies are unlikely to account for our infrequent detection of catechin here. In previous studies, we stored intact soil cores for weeks or months before extracting 0.5-cm^3 subsamples with 1 ml of methanol (Bais et al. 2002, 2003; Perry et al. 2005b; Thelen et al. 2005; Weir et al. 2006). In the current study, we sieved and homogenized the soil and extracted 3-cm^3 subsamples with 10 ml of methanol immediately upon collection. Such changes in protocol seem unlikely to have reduced recovery efficiency, particularly to such an extent that we could no longer detect

catechin in most samples. Furthermore, a preliminary experiment in which we compared the two methods suggested that the changes in methods improved catechin detection (data not shown).

The absence of catechin on most dates in the present study and studies by Blair et al. (2005, 2006) suggests that pure catechin (i.e., not complexed with other compounds) may occur only rarely at sufficient concentrations in *C. maculosa* bulk soils to inhibit other plants. Catechin concentrations required to inhibit other plants are uncertain, as minimum concentrations for inhibition vary among studies from 0.0016–0.0032 mg g^{-1} (Thorpe 2006) to 0.04 mg g^{-1} (J. Pollock, unpublished data), 0.05 mg ml^{-1} (Weir et al. 2003), 0.25 mg ml^{-1} (Perry et al. 2005a), 0.27 mg g^{-1} (Inderjit, unpublished data), and weak effects of 1.0 mg ml^{-1} (Blair et al. 2005). Here, our detection limit was 0.025 mg g^{-1}. The detection limits of Blair et al. (2005, 2006) were even lower, 0.00002 mg g^{-1} or trace amounts (<0.0001 mg g^{-1}), much lower even than those Thorpe (2006) reported to be inhibitory. Thus, if pure, stable catechin in bulk soil is an important driver of competitive effects, these results suggest that those effects would have to occur sporadically.

Nevertheless, our results do not disprove a role of catechin or other allelochemicals in *C. maculosa* competitive effects. Studies that have used activated carbon soil amendments, which adsorb organic compounds, indicated that *C. maculosa* root exudates may inhibit growth of neighboring plants (Ridenour and Callaway 2001; Callaway et al. 2005; Perry et al. 2005b). Although catechin does not appear to influence *C. maculosa* ecology via continuously high concentrations of pure catechin in bulk soil, it could play a role through episodic effects on competitors, by producing phytotoxic soil concentrations more frequently, either of phytotoxic catechin-metal complexes (J. Pollock and B. Holben, unpublished data) or phytotoxic degradation products, by occurring more frequently in the rhizosphere or near competing roots than in bulk soil, or by producing frequent but transient catechin pulses (Appel 1993). *C. maculosa* also may produce other phytotoxins with ecological effects. However, none of these hypotheses has been tested.

Although previous consistent reports of high soil catechin concentrations provided circumstantial evidence for a role of catechin in *C. maculosa* invasion (Bais et al. 2002, 2003; Perry et al. 2005b; Thelen et al. 2005; Weir et al. 2006), this more extensive study, together with those of Blair et al. (2005, 2006), suggests that high catechin concentrations rarely occur in *C. maculosa* soil. More confidence can be placed in the current results. Thus, the infrequency of soil catechin weakens the hypothesis that it plays a role in *C. maculosa* invasions.

Acknowledgments This research was supported by the U.S. Department of Defense SERDP (SI-1388 to J.M.V., M.W.P. and R.M.C.). Corey Broekling performed mass spectrometry analyses to confirm the presence of catechin in samples with catechin. Tiffany Weir provided helpful discussions and HPLC troubleshooting. Tom Bassett, Kyle Evans, Courtney Hall, and Nick Wegman assisted with soil sample collection. We thank John Romeo and four anonymous reviewers for comments on previous versions of the manuscript.
