revealed a mixture of 12 volatile ketones and alcohols, with the most abundant compounds being 2-methyl-3-buten-2-ol, (2*S*)-pentanol, (3*E*)-2-methyl-3-penten-2-ol, and the enantiomers of 4-methyl-3-penten-2-ol. None of these compounds had previously been reported in a triatomine species. However, 2-methyl-3-buten-2-ol has been reported as part of the aggregation pheromones of several species of bark beetles (Giesen et al. 1984; Klimetzek et al. 1989; Schlyter et al. 1992) and also as part of the alarm pheromone of the hornet wasp, *Vespa crabro* (Veith et al. 1984). 2-Pentanol has been found in the alarm pheromone of hornet wasps (Ono et al. 2003; Ono 2005), as an attractant to fruits for the coleopterans, *Carpophilus hemipterus* and *Conotrachelus nenuphar* (Phelan and Lin 1991; Prokopy et al. 2001), and as part of the defensive secretions of *Polyzosteria* and related cockroaches (Wallbank and Waterhouse 1970). To our knowledge, 2-methyl-3-penten-2-ol and 4-methyl-3-penten-2-ol have not been reported as semiochemicals for any insect species. Minor components of the secretions, 2-butanone, 2-methyl-1-butanol, and 3-hexanol have been found previously in MG secretions of *T. infestans* by Manrique et al. (2006).

Interestingly, the saturated alcohols we identified in *R. prolixus* all had an (*S*)-configuration, suggesting a common enzymatic system in their biosynthesis. In accord with what is known about the biosynthesis of 2-methyl-3-buten-2-ol in bark beetles (Lanne et al. 1989; Martin et al. 2003; Seybold et al. 2006), it is conceivable that a common allylic carbocation in the biosynthetic pathway gives rise to both (3*E*)-2-methyl-3-penten-2-ol and 4-methyl-3-penten-2-ol. Hydration at the allylic positions of the carbocation would form 2-methyl-3-penten-2-ol and 4-methyl-3-penten-2-ol. The latter addition appears not to be stereoselective as both enantiomers of 4-methyl-3-penten-2-ol are formed.

We demonstrated that the volatile compounds found in the MGs of *R. prolixus* are emitted by virgin adult bugs of both sexes. Emission of these compounds was detected more frequently from females than males. Females also released these chemicals more frequently during the early hours of the scotophase, the period when sexual activity in this species is at its peak (Manrique, personal communication). That these compounds may be involved in sexual communication is suggested by their detection, albeit in low amounts (e.g., 10–100 pg for 2-pentanol) over copulating pairs of *R. prolixus*. That only three of the MG compounds were detected over copulating pairs could have been due to the very low concentration of compounds emitted by bugs. It is worth noting that the SPME collections for analysis of MG content were of headspace above 12 glands heated to 50°C, whereas, at most, the headspace above a pair of bugs emitting volatiles consisted of the contents of four glands at 26°C. For most of the compounds identified in the glands (i.e., from two MGs), the amount was close to the detection limit of our instrument. Manrique et al. (2006) detected 3-pentanone, the main component of the MG secretions of *T. infestans*, over copulating pairs, and suggested that this species may use MG odors for communication during mating. A role for the MG odors in the sexual behavior of *R. prolixus* was further suggested by our occlusion experiments in which occlusion of the MG orifices of either males or females resulted in a significant decrease in copulation, relative to the various controls. A similar result was obtained for *T. infestans* (Crespo and Manrique 2007).

It is worth noting that we did not detect any Brindley's gland secretions during our sampling of copulating pairs. These secretions have previously been detected (Ríos Candelaria 1999; Guerenstein and Guerin 2004) over *R. prolixus* mating pairs, and it has been suggested that they may be involved in sexual communication. However, it cannot be excluded that the detection of Brindley's gland compounds in those studies may have been the result of an alarm response (Manrique et al. 2006) rather than a sexual signal. Further work is needed to clarify the role of Brindley's glands secretions in the sexual behavior of *R. prolixus*.

Overall, our data show that the release of compounds found in the MGs of adult *R. prolixus* corresponds with sexual activity of this species, and that furthermore, females

appear to release greater quantities of these compounds than males. However, whether these chemicals actually mediate sexual behavior in this species is unknown. Further work is required to determine whether the compounds are directly involved in mediating sexual behavior of adults and, if so, what is their precise role. If these chemicals are attractive to adult *R. prolixus*, they could prove useful as chemical baits in traps for monitoring or controlling *R. prolixus* populations, thereby limiting the transmission of Chagas disease to humans. The development of new methods for controlling *R. prolixus* is critical as certain populations have already developed resistance to the pyrethroid insecticides used in control programs (Zerba 1999).

Acknowledgements We thank Dr. C. Lazzari and Dr. G. Manrique for reviewing the manuscript and the reviewers for their valuable comments. We also thank Dr. C. Zani for kindly allowing access to the GC-MS set-up. Age-Dependent Changes in the Chemistry of Exocrine Glands of *Bombus terrestris* Queens

Klára Urbanová · Lucie Cahlíková · Oldřich Hovorka · Vladimír Ptáček · Irena Valterová

Received: 1 October 2007 / Revised: 8 January 2008 / Accepted: 21 February 2008 / Published online: 28 March 2008

Abstract Extracts of three different glands (mandibular, labial, and Dufour's) of virgin *Bombus terrestris* queens at ten different ages (1–8, 12, and 18 days) were analyzed for chemical composition. One hundred and twenty-seven compounds were identified in the extracts. The mandibular and labial glands contained previously reported electroantennogram-active compounds (3-hydroxydecanoic acid, fatty acids of different chain lengths, their esters, and heptacosene). These compounds reached a maximum concentration in 3- to 7-d-old queens. Geranylcitronellol was found in both labial and Dufour's glands. Its amount was inversely correlated to age of queens.

Introduction

Chemical communication in bumblebees has been studied since the late 1960s when male-marking pheromones were first described (Calam 1969; Kullenberg et al. 1970). Since then, male pheromones of a great number of species have been examined, particularly in Scandinavia (reviews Bergström et al. 1981; Morse 1982; Valterová and Urbanová 1997). These pheromones are always complex mixtures, with a species-specific composition and, as such, are useful for chemotaxonomy (Bergström and Svensson 1973; Terzo et al. 2003; Rasmont et al. 2005).

Less information is available on the chemistry of bumblebee queen sex pheromones. The experiments of Free (1971) demonstrated that the head of a bumblebee queen is important in releasing male mating behavior, suggesting that the head is a source of a pheromone. Van Honk et al. (1978) reported that the mandibular gland secretion of young virgin queens contained a sex pheromone that released mating behavior of conspecific males. Cahlíková et al. (2004) described the compositions of several exocrine gland secretions of five bumblebee species. These included secretions from mandibular, labial, and Dufour's glands of *Bombus terrestris* queens. Krieger et al. (2006) recorded electrophysiological responses of antennae of *B. terrestris* males to the queen's head and body extracts and found 21 electroantennogram (EAG)-active components, including fatty acids, their methyl and ethyl esters, ketones, hydrocarbons, and diterpenes, potentially related to sexual communication. Male mating behavior (approach, touch, and mounting) was stimulated by components of cephalic extracts, although no copulations were observed. The failure to stimulate copulation by chemicals alone suggests that a combination of different stimuli such as visual, physical (e.g., cuticular surface, hairs,

special physico-chemical or physico-mechanical properties of the surface), and chemicals may be needed (Krieger et al. 2006).

In the search for the source of the sex pheromone, we present here results on changes in quantities of the EAG-active components reported by Krieger et al. (2006) during the ontogenic development of the mandibular, labial, and Dufour's gland composition of *B. terrestris* queens. Furthermore, we correlate the quantities of some of these compounds with the mating behavior of queens as published earlier by Přidal and Hofbauer (1996) and Tasei et al. (1998).

Methods and Materials

Insects A colony of *B. terrestris* was established by the known two-queen cascade method (Ptáček et al. 2000) to stimulate queen egg laying in the laboratory. All mother queens were taken from their natural habitats during the search period to minimize the possible negative influence of artificial conditions on progeny. When the colonies turned to queen production, the queen cocoons were removed from the parental hives and allowed to mature separately. These cocoons were cared for by several bumblebee workers (Ptáček 1999). Freshly emerged queens were removed and kept separate according to age.

Virgin queens, 1 ($N=9$), 2 ($N=8$), 3 ($N=8$), 4 ($N=10$), 5 ($N=11$), 6 ($N=9$), 7 ($N=11$), 8 ($N=11$), 12 ($N=5$), and 18 ($N=5$) -d-old, were killed by freezing (−18°C) and kept frozen before dissection. Mandibular, labial, and Dufour's glands were dissected and extracted with hexane containing 1-bromodecane as internal standard (2.2 mg/ml, 30 µl per gland; purity 97%, Fluka). After 15 min of shaking and 1 hr of standing at ambient temperature, the extracts were removed and kept at −18 °C before analysis.

Chromatography Extracts were analyzed by using a gas chromatograph with a splitless injector (200°C) and a mass detector (200 °C, Fisons MD 800). A ZB-5ms column (30 m×0.25 mm, film thickness 0.25 µm, Zebron, Phenomenex, U.S.A.) and helium gas, at a constant flow of 1 ml min^{-1}, were used for analyses. The temperature program started at 70°C and, after a 2-min delay, increased at 10°C min^{-1} to 320°C.

Compound Identification and Quantification Compounds were identified by comparison of their mass spectra to spectra in the NIST library, as well as by co-chromatography with synthetic (Valterová et al. 1996) or commercially available standards.

Double bond positions of compounds were determined from the mass spectra of dimethyl disulfide (DMDS) adducts (Francis 1981; Vincenti et al. 1987). The proportions of isomeric alkenes were calculated from the relative intensities of characteristic fragments in the spectra of DMDS adducts. Acids and hydroxy acids in the mandibular gland extract were methylated with diazomethane (50 µl per gland extract; Klimetzek et al. 1989) before analysis.

Amounts of compounds of interest were expressed as proportions of the peak area of the compound to the peak area of the internal standard.

Results and Discussion

One hundred and twenty-seven compounds were identified in the extracts of three different glands (mandibular, labial, and Dufour's) of virgin *B. terrestris* queens. These compounds included hydrocarbons (saturated and unsaturated, straight-chain and methyl-branched), fatty acids and their esters, and isoprenoids. Many of the compounds were present in minor or trace quantities only. Tables 1, 2, 3 summarize the more abundant (>1%, or >0.5% for mandibular gland) components present in the extracts. Although the variability among specimens in a given age category was great, the mean and median values were almost identical, indicating a normal distribution of data.

Recently, Krieger et al. (2006) published EAG-active components from both head extracts and surface washes of *B. terrestris* queens. Although most of these compounds were present in our samples (see below), there were some differences, possibly due to the different extraction procedures (diethyl ether vs. hexane, 24 hr vs. 75 min extraction time). Components of queen *B. terrestris* head extract can originate from both mandibular and labial gland (or the hypopharyngeal gland, which was not included in our study because it does not appear to be involved in communication; Pereboom 2000). On the other hand, all exocrine glands present in the body may be present in the surface washes studied by Krieger et al. (2006). We did not detect three of the EAG-active compounds reported by Krieger et al. (2006): 2-nonanone, dodecyl hexanoate, and geranylgeraniol. In addition, we found several compounds with unknown activity. In particular, the labial gland contained substantial amounts of geranylcitronellol and its derivatives.

Mandibular Gland Mandibular gland extracts contained lower amounts of all detected compounds compared to the labial or Dufour's glands (Cahlíková et al. 2004). The extract was characterized by the prevalence (72–93%) of fatty acids. A substantial proportion (6–24%) of unbranched hydrocarbons (both unsaturated and saturated) was also identified. These extracts were methylated before analysis because of the large amounts of acids (Table 1).

Table 1 Relative abundances of compounds (>0.5% in one or more age groups) present in the mandibular gland extract of *B. terrestris* queens of different age

[a] Double bond not determined (DMDS adducts not found)

The majority of aliphatic compounds found in the mandibular gland extracts have been previously reported by Krieger et al. (2006) as EAG-active, indicating potential pheromonal activity. However, we found that certain compounds, hexadecenoic acids (Δ^9 and Δ^{11}, while Krieger et al. 2006 reported Δ^7 and Δ^{11}) and heptacos-9-ene (Krieger et al. 2006 reported Δ^{12} and Δ^{13}), had different double bond positions compared to those reported by Krieger et al. (2006).

The composition of mandibular gland extracts of our virgin queens was similar to that reported by Hefetz et al. (1996) for egg laying queens, although a major difference was the absence of higher esters in our samples. These esters may be formed in glands of older or fertilized queens when the mandibular gland plays a potentially different role—that of producing queen pheromone (Van Honk et al. 1980; Röseler et al. 1981). Recently, Ayasse et al. (2007) reported preliminary results on the chemical basis of queen dominance. In cuticular washes, they found a fraction of esters that suppressed ovarian development in workers. Thus, the mandibular gland may not be the source of queen pheromone as reported in older literature.

The profile of the reported EAG-active components in mandibular glands of virgin queens appeared to be related to queen age. 3-Hydroxydecanoic acid and 3-hydroxyoctanoic acid showed a peak (35%) in 5-d-old queens (Fig. 1a), followed by a decline and then a second increase in queens 8 days and older. The abundances of these two compounds were strongly correlated ($R=0.97$; $P<10^{-6}$; $N=77$) with each other. Octadec-9-enoic (oleic) acid was the main component in mandibular gland extracts of females of all ages (22–52%), with the greatest amounts observed in older queens (12 and 18 d, Fig. 1b). Other fatty acids showed no clear maxima with respect to age of queens.

The amount of heptacos-9-ene was maximal in mandibular glands of 7-d-old queens (Fig. 2). This age-related maximum was also observed in labial gland extracts, but not in the Dufour's gland extracts, for which the amount of this compound was greatest in the oldest queens (18 d). The absolute amounts of this compound differed among the glands, with the labial and Dufour's gland extracts containing 10 times and 250 times, respectively, more heptacosene than the mandibular gland extracts.

A relatively high abundance of tetradecane was observed in queens of all ages (2–12%) in all three glands. Even-

Table 2 Relative abundances of compounds (>1% in one or more age groups) present in the labial gland extract of *B. terrestris* queens of different age

numbered chain hydrocarbons are generally uncommon in bumblebees. The relatively high amounts of this compound suggest that its biological significance may be worth studying.

According to Tasei et al. (1998), the majority of *B. terrestris* queens mate at age 6.1±0.4 days, although this varied between colonies (7.8±0.6 days in one, and 3.0± 0.3 days in another). Přidal and Hofbauer (1996) observed that the greatest percentage (30%) of mating took place in 6- to 7-d-old queens, although a relatively high percentage of queens (15%) also mated at 5-d-old. Thus, the EAG-active compounds in the mandibular glands that peak in 5-d-old queens may be important in sexual communication in *B. terrestris*.

Labial Gland Several compounds reported by Krieger et al. (2006) as EAG-active were found in the labial gland extracts (Table 2). The extracts consisted mostly of esters (30–70%, increasing with age), acids (0–7%, decreasing with age), isoprenoids (2–22%, decreasing with age), and hydrocarbons (10–25%, no pattern with age).

Table 3 Relative abundances of compounds (>1% in one or more age groups) present in the Dufour's gland extract of *Bombus terrestris* queens of different age

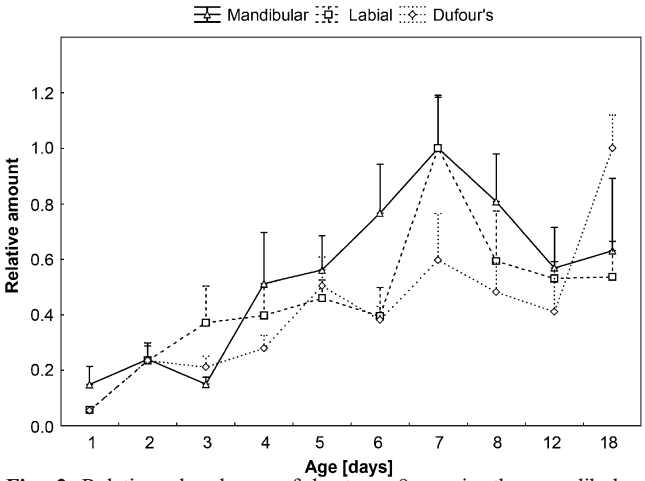

Fig. 2 Relative abundance of heptacos-9-ene in the mandibular, labial, and Dufour's glands of different aged *B. terrestris* queens. Data are mean±SE

The amounts of methyl and ethyl esters of fatty acids reached a maximum in 3- to 7-d-old queens (Fig. 3). Hexadec-9-enoic (palmitoleic) and hexadecanoic (palmitic) acids were maximal in the labial glands of 6-d-old queens (Fig. 4a). The amount of fatty acids was about ten times lower in the labial gland than in the mandibular gland. The amounts of higher esters increased with age as shown in the example of dodecyl octadecenoate (Fig. 4b).

As found for mandibular gland compounds, some compounds in the labial glands had different double bond positions than those reported by Krieger et al. (2006). Hexadec-9-enoic acid and its methyl ester were found in our samples, while Krieger et al. 2006 reported Δ^7 and Δ^{11}. Seven heptacosene isomers (Δ^7 to Δ^{13}) were detected in our samples, whereas Krieger et al. 2006 reported only Δ^{12} and Δ^{13} isomers as EAG-active compounds.

Hydroxy acids were not found in the labial gland extracts. Although Krieger et al. (2006) detected geranylgeraniol in head extracts, geranylcitronellol was the most abundant (2–11%) isoprenoid detected in our labial gland extracts. We found geranylcitronellol in both labial and Dufour's gland extracts, but not in the extracts of the mandibular gland. In the labial gland, its amount peaked in 3-d-old queens (Fig. 5). The difference in the presence of geranylgeraniol (Krieger et al. 2006) and geranylcitronellol (our work) is interesting. Krieger et al. (2006) failed to obtain good separation of geranylgeraniol from linoleic

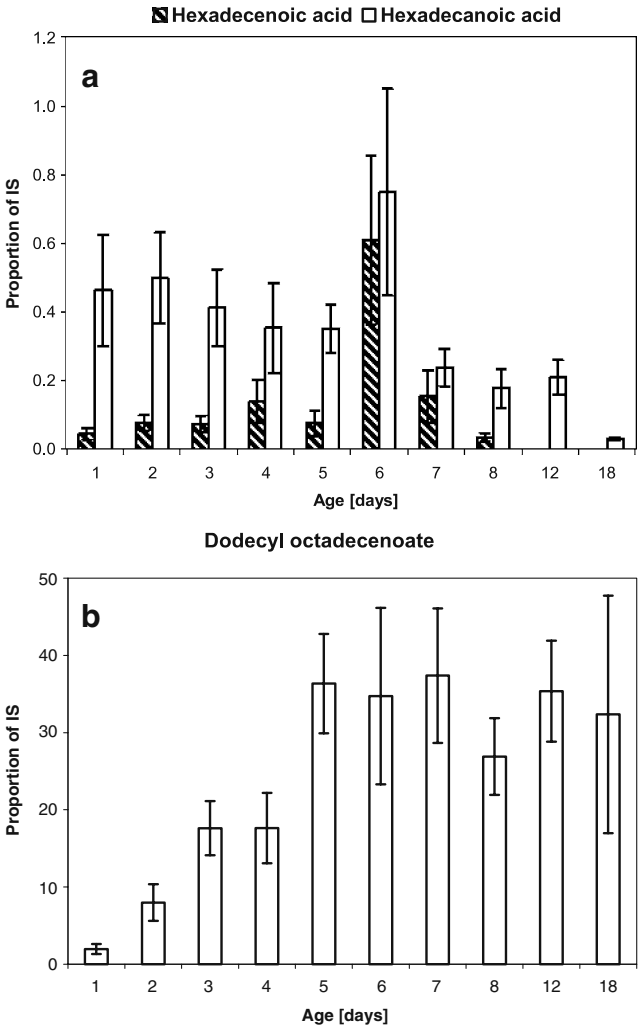

Fig. 4 Content (percentage of area of a gas chromatograph peak to the internal standard, IS) of selected fatty acids (**a**) and dodecyl octadec-11-enoate (**b**) in the labial glands of different aged *B. terrestris* queens. *Bars* represent mean±SE

acid, thereby precluding them from determining which component actually elicited an EAG response. In preliminary EAG tests, we found geranylcitronellol elicited responses from both males' and workers' antennae (Kalinová, unpublished results), suggesting this compound may play a role in communication.

Reports on the chemical composition of the labial gland in bumblebee queens are scarce. Preliminary analyses of *Bombus hypnorum* were reported by Genin et al. (1984). Hefetz et al. (1996) studied the chemistry of several glands of egg laying *B. terrestris* queens. Our data on labial gland composition of young virgin queens is similar to theirs (Hefetz et al. 1996) for egg laying queens, except we found large amounts of geranylcitronellol, whereas they detected esters of this alcohol with fatty acids of different chain lengths. As the relative proportion, as well as the quantity, of geranylcitronellol in the labial gland decreases with queen age (Table 2, Fig. 5), it seems likely that increasing esterification in older females consumes this alcohol.

Dufour's Gland The majority of compounds present in the Dufour's gland extracts were hydrocarbons (65–80%), with alkanes (10–32%) and alkenes (32–56%) being the major constituents. Tricosane and nonacos-9-ene were the most abundant hydrocarbons, with alkadienes of medium abundance (5–20%) and branched alkanes present in trace amounts only (<0.5%). Beside hydrocarbons, acids (0.1–5%), methyl esters (4–17%), and isoprenoids (5–9%) were detected in the Dufour's gland extracts. Among all the compounds we identified in the Dufour's gland, only five (heptacos-12-ene, heptacos-13-ene, oleic acid, linoleic acid, and linolenic acid) were reported by Krieger et al. (2006) as EAG active. All five of these compounds were present in only minor or trace amounts (< 5%) in our Dufour's gland extracts and did not show any specific pattern in amount with respect to queen age.

Geranylcitronellol was produced in low quantities in Dufour's glands of young queens, and its amount increased with age (7 d and older, Fig. 5). Geranylcitronellol was detected previously in the Dufour's gland of *B. terrestris* workers (Tengo et al. 1991), but its function was not determined. However, it has been described in several bumblebee species as a component of the male marking pheromone (see review by Valterová and Urbanová 1997). Geranylcitronellol appears to be a common compound in different bumblebee species, and it may play different roles in different contexts.

The Dufour's gland is one of the best studied glands, with regard to chemistry, in bees. Its primary function is the

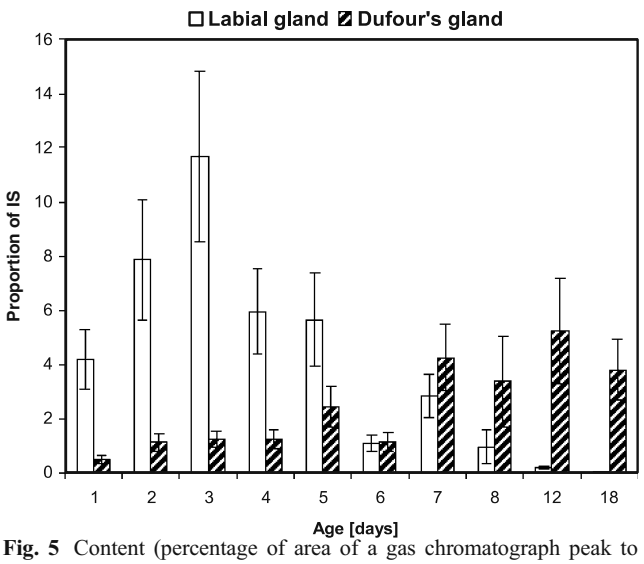

Fig. 5 Content (percentage of area of a gas chromatograph peak to the internal standard, IS) of geranylcitronellol in the labial and Dufour's glands of different age *B. terrestris* queens. *Bars* represent mean±SE

production of a hydrophobic secretion for the isolation of brood cells (Hefetz 1987). In bumblebees, the Dufour's gland has several functions, not all of which are fully understood. Three main functions have been determined: (1) marking of the nest entrance or construction of an odor trail from the nest entrance to the core of the nest in underground nesting species (Cederberg 1977; Pouvreau 1996), (2) nest-mate (kin) recognition (Tengo et al. 1991; Hefetz et al. 1993), and (3) egg marking (Ayasse et al. 1999). Social nest parasites (*Psithyrus*) are known to recognize and prefer the nest odor of host bumblebee species (Cederberg 1979; Fisher 1984; Foster and Gamboa 1989).

With regard to the findings of Krieger et al. (2006), the sex pheromone of queens is likely to be produced in some of the cephalic glands. Thus, a role for the Dufour's gland secretion in sexual communication seems unlikely. Furthermore, most of the compounds found in this gland were not reported as EAG-active by Krieger et al. (2006). Our results suggest that the sexual pheromone of *B. terrestris* will likely be present in either the mandibular or the labial glands, possibly in the mandibular gland where the amounts of active compounds correlate with the receptivity of queens. We suggest that hydroxy acids, with their high abundance and timing of maximum quantities, are the most likely candidates for constituents of the sex pheromone of *B. terrestris* queens and should be studied further in behavioral tests.

Homofarnesals: Female Sex Attractant Pheromone Components of the Southern Cowpea Weevil, *Callosobruchus chinensis*

Kenji Shimomura · Satoshi Nojima · Shunsuke Yajima · Kanju Ohsawa

Received: 12 November 2007 / Revised: 06 February 2008 / Accepted: 11 February 2008 / Published online: 20 March 2008

Abstract The southern cowpea weevil, *Callosobruchus chinensis* (Coleoptera: Bruchidae), is a major pest of stored legumes in warm temperate and tropical climates. The female sex attractant pheromone was extracted from filter-paper shelters taken from containers that housed virgin females. The extracts were purified by various chromatographic techniques, and the biologically active components in the fractions were screened by gas chromatographic–electroantennographic detection analysis with male antennae. Two compounds that elicited electrophysiological responses were isolated, and gas chromatography–mass spectrometry, nuclear magnetic resonance, and micro-chemical analyses suggested that the active compounds were homofarnesals, (2*Z*,6*E*)- and (2*E*,6*E*)-7-ethyl-3,11-dimethyl-2,6,10-dodecatrienals. Males of *C. chinensis* were significantly attracted to filter paper discs loaded with the synthetic compounds at 0.01–0.1 ng compared to solvent control in a Y-tube olfactometer assay. These pheromone components represent unique chemical structures within the genus *Callosobruchus*.

Introduction

Seed beetles of the genus *Callosobruchus* (Coleoptera: Bruchidae), especially *Callosobruchus chinensis* and *Callosobruchus maculatus*, are economically important pests of stored legumes (Labeyrie 1981; Fujii et al. 1990). Females of these species lay their eggs on seeds, and newly emerged larvae immediately bore into the seeds. They spend their entire larval stage in the seeds, excavating the inside to feed, and before they pupate, larvae mine escape routes for adult emergence. Each larva consumes a considerable amount of the seed content (Hariri 1981; Rees 1995). These species are polyvoltine and can reproduce continuously under suitable conditions (Watanabe 1990; Rees 1995), resulting in rapid population increases when compared to other stored products pests (Imura 1990; Rees 1995). Thus, seed damage by these beetles can be devastating.

The host ranges and distributions of *C. chinensis* and *C. maculatus* are relatively wide when compared with congeneric pest species (reviewed in Tuda et al. 2005), and they are expanding their habitats *via* international trade in legumes (Yoneda et al. 1990). However, the life histories of these two species are different. While *C. maculatus* has been reported only in cultivated and stored legumes (reviewed in Tuda et al. 2005), *C. chinensis* has the capability to infest not only cultivated host plants in the field and stored legumes but also a few wild legumes (Shinoda and Yoshida 1985, 1990; Shinoda et al. 1991, 1992; Tuda et al. 2005). Shinoda and Yoshida (1990) suggested that populations that complete their life cycle on wild hosts could serve as reservoirs and a source of both field and storage infestation, making *C. chinensis* a potentially more threatening and persistent pest than *C. maculatus*.

Synthetic pesticides and fumigants have been employed to control seed beetles and other stored product pests (White and Leesch 1996; Heaps 2006). However, because these chemicals are not environmentally safe and pose human health concerns, they need to be replaced with alternative tools (Subramanyam and Hagstrum 2000).

Chemical signals are indispensable for almost all insects for communication between conspecific individuals (e.g., mate finding, social organization, and defense) and for the recognition of specific features of the environment (e.g., for finding food sources, preferred hosts, and suitable oviposition habitats) (Cardé and Bell 1995). These chemical cues, i.e., semiochemicals, can be an alternative tool for pest control. In fact, some semiochemicals, e.g., female sex attractant pheromones of moths, have been used directly to suppress pest populations (Minks and Cardé 1997). These agents generally act on only the target pest species and are harmless to natural enemies and other beneficial insects and humans (Minks and Cardé 1997).

Several classes of semiochemicals have been studied in *C. chinensis*, including oviposition stimulants from host seeds (Ueno et al. 1990; Matsumoto et al. 1994; Tebayashi et al. 1995; Ignacimuthu et al. 2000), an oviposition-marking pheromone (Oshima et al. 1973; Sakai et al. 1986; Honda and Ohsawa 1990), and a female sex pheromone (Tanaka et al. 1981). The process of mate location and mating in *C. chinensis* is mediated by two distinct pheromonal signals: a sex attractant pheromone that attracts males from a distance and a contact sex pheromone that elicits copulation behavior from males (Tanaka et al. 1981). The contact sex pheromone has been characterized as a mixture of (*E*)-3,7-dimethyl-2-octene-1,8-dioic acid and C_{25}–C_{35} straight chain and methyl branched hydrocarbons (Tanaka et al. 1981, 1982), but the sex attractant pheromone has not been identified despite its high potential for pest control applications (Burkholder and Ma 1985; Phillips 1997).

In this paper, we report the isolation and identification of the female sex attractant pheromone of *C. chinensis* and discuss the unique structural properties of its components relative to previously identified pheromones of congeneric species.

Methods and Materials

Insects A laboratory colony was used in the experiment. Insects were reared on *Vigna angularis* in a dark incubator at 27°C and 50% relative humidity. Newly emerged adults were sexed and held apart until they were used.

Pheromone Collection: 1. Volatile Trapping A glass chamber (500 ml) with a charcoal filter tube in the inlet was used for the collection of airborne female sex attractant pheromone. The pheromone in the headspace was drawn (approximately 1.0 l/min) by a vacuum pump through a Tenax TA tube (1.5 g, 80/100 mesh, 12 mm i.d., 90 mm length; GL Science, Inc., Tokyo, Japan). The airborne collections were made for 7 d from 1,000 virgin females, and then, the pheromone was eluted from the adsorbent with 10 ml pentane (Sigma-Aldrich Inc., St. Louis, USA). The extracts were combined and concentrated in a nitrogen stream in an ice bath and kept in a freezer (−30°C) until they were used.

Pheromone Collection: 2. Filter Paper Extraction Preliminary gas chromatographic–mass spectrometric (GC-MS) analysis of volatile pheromones obtained by air-borne collections suggested that the pheromone components are novel compounds and that they occur in small amounts in the volatile collection. Therefore, pheromone collection was scaled up by using the filter paper collection method (Tanaka et al. 1981) to facilitate the isolation of sufficient amounts of the pheromone components for nuclear magnetic resonance (NMR) analysis. Virgin females were kept in a group in glass containers (90 mm i.d., 100 mm height) with corrugated filter paper shelters (90 mm i.d., Advantec No.2, Toyo Roshi Kaisha, Ltd., Tokyo, Japan) for 14–20 d. Filter paper shelters were collected from the containers and Soxhlet-extracted with pentane for 24 hr. The solvent was evaporated under reduced pressure, and the extracts were kept at −30°C until they were used. Extracts were collected from approximately 32,000 virgin females.

Column Chromatography Crude pheromone extracts were fractionated by column chromatography with 1 g of silica gel (Wakogel C-200, Wako Pure Chemical Industries Ltd., Osaka, Japan). The column was eluted sequentially with 10 ml each of pentane–diethyl ether in ratios of 10:0 (*v*/*v*), 9.5:0.5, 9:1, 8:2, 5:5, and 0:10.

High Performance Liquid Chromatography Active fractions were further purified by high performance liquid chromatography (HPLC) with LC-5A (Shimadzu, Kyoto, Japan) and a silica gel column (Shim-pack HRC-SIL, 5 µm, 4.6×250 mm, Shimadzu). The solvent system comprised of a pentane–diethyl ether gradient, programmed as follows: 0% ether in pentane for 1 min, then increased linearly to 50% diethyl ether at 1%/min. Flow rate was set at 1 ml/min, and the effluent was monitored with a SPD-2A (Shimadzu) variable wavelength detector at 254 nm, a wavelength providing high sensitivity for conjugated chemicals, and collected every 1 min.

Preparative Gas Chromatography Electroantennographic detection (EAD) active compounds were isolated by a

micro-preparative GC integrated with an NMR sample preparation technique (Nojima et al. 2004). An HP 5890 series II GC (Palo Alto, CA, USA) equipped with a ZB-1 wide bore capillary column (30 m×0.53 mm i.d., 1.50 μm film thickness; Phenomenex, Torrance, CA, USA) was operated in splitless mode. Nitrogen was used as a carrier gas at a head pressure of 21 kPa and a flow rate of 4 ml/min. Oven temperature was set initially at 60°C for 3 min, then increased at 10°C/min to 280°C, and held for 10 min. The injector and preparative collection port temperatures were set at 250°C and 150°C, respectively. A pre-cleaned collection trap, consisting of a 40-cm long deactivated wide bore capillary tube (Agilent, Palo Alto, CA, USA), was connected to the end of the separation column with a press fit connecter (Alltech Associates, Inc., Deerfield, IL, USA). The other end of the trap was set into the preparative GC outlet port so its end protruded a few centimeters above the port.

To collect an active component, the trap was drawn out of the port just before the retention time of a target component, and a preconditioned cooling sheath (Nojima et al. 2004) was set on the exposed collection trap. Retention times of active components were established before preparative GC work by flame ionization detector (FID) under the same analytical conditions. After the sample collection window was over, the sheath was removed and the collection trap pulled out to detach it from the press fit connector. The collection trap was immediately set up for NMR sample preparation and eluted with $CDCl_3$ (99.996%, Isotec, Miamisburg, OH, USA) directly into a 5 mm i.d. NMR micro tube (Shigemi, Tokyo, Japan).

Coupled Gas Chromatographic–Electroantennographic Detection Analysis GC-EAD technique was used for a high throughput screening tool to check male antennal active compounds in fractions to facilitate purification processes. An HP 5890 series II GC was modified for GC-EAD analyses (Nojima et al. 2003). A DB-5 or DB-WAX capillary column (30 m×0.25 mm i.d., 0.25 μm film thickness; J&W scientific, Folsom, CA, USA) was used for the analyses. Nitrogen was used as the carrier gas at a head pressure of 135 kPa and a flow rate of 2 ml/min. Samples were injected in the GC in splitless mode, and the purge valve was off for 1 min. Oven temperature was set initially at 60°C for 3 min, then increased at 10°C/min to 220°C for DB-WAX or 280°C for DB-5, and held for 10 min. Injector temperature was set at 250°C for DB-5 and 230°C for DB-WAX, and FID and EAD outlet temperatures were set at 280°C. The column effluent was combined with nitrogen make-up gas (30 ml/min) and then split 1:1 to the FID and EAD. The EAD outlet was secured in a charcoal-filtered and humidified air stream flowing at approximately 300 ml/min over the antennal preparation in a sample delivery glass tube (12 mm i.d., 100 mm length).

A male antenna was plucked from the head of the beetle, and the tip of the antenna was cut with scissors on moistened filter paper. Then, the antenna was bridged between Ag–AgCl electrodes bathed in 0.5% NaCl solution. The antennal preparation was placed inside of the sample delivery tube. The output signal from the antenna was amplified 10-fold by a customized high-input impedance DC amplifier (Nojima et al. 2003). The outlet signal was filtered by a resistance/capacitor high-pass filter with the cut-off frequency of about 0.5 Hz. A dual tracking constant voltage power supply (SK Electronics CO. LTD., Fukuoka, Japan) was used for the amplifier at ±15 V. The EAD signals were recorded on a D-2500 Chromatography integrator (Hitachi, Tokyo, Japan) synchronized with the GC integrator.

Gas Chromatographic–Mass Spectrometric Analyses Gas chromatography–electron impact mass spectrometry (GC-EI-MS) was carried out with a Shimadzu GC 17A equipped with a DB-5 capillary column (30 m×0.25 mm i.d., 0.25 μm film thickness) in splitless mode, coupled to a Shimadzu QP-5000 quadrupole MS in EI mode. Helium was used as the carrier gas at a head pressure of 100 kPa and a flow rate of 1.6 ml/min. Oven temperature was set initially at 60°C for 3 min, increased at 10°C/min to 280°C, and held for 10 min. The injector and interface temperatures were set at 250°C and 280°C, respectively. Gas chromatography–chemical ionization mass spectrometry (GC-CI-MS) was performed on a Shimadzu GCMS-QP2010. Iso-butane was used as the reagent gas at 50 kPa, and other analytical conditions were the same as those of GC-EI-MS analysis.

Nuclear Magnetic Resonance Analysis ^{1}H-NMR analysis of an isolated EAD active compound was performed on a JNM-ECA 400 MHz (JEOL, Tokyo, Japan), while all NMR spectra of synthetic compounds were recorded on a JNM-A400 (JEOL; 400 MHz for ^{1}H and 100 MHz for ^{13}C) in $CDCl_3$. Chemical shifts were expressed in parts per million relative to TMS.

Microchemical Analysis: 1. N,N-Dimethylhydrazone Derivatization An aliquot of the isolated EAD active compounds in hexane (approximately 300 female equivalents) was mixed with a solution of *N*,*N*-dimethylhydrazine in hexane (0.1%, 50 μl) in a 600 μl glass vial. The solution was vigorously mixed, and then the reaction mixture was subjected to GC-EI-MS.

Microchemical Analysis: 2. Ozonolysis A microgenerator of ozone was prepared (Beroza and Bierl 1966, 1967) with oxygen (3 ml/min) passing through a high-voltage spark generated by Tesla lamp checker HF-20 (Shinko Electric &

Instrumentation Co. Ltd., Osaka, Japan). A slow stream of ozone was bubbled in a vial containing an aliquot of the isolated EAD active compound in hexane. To prevent the sample from evaporating, the vial was cooled in a dry ice/acetone bath. After bubbling for 20 sec, a few microliters of a solution of triphenylphosphine in dichloromethane were added to the reaction mixture to reduce the ozonides to carbonyl compounds, and the reactants were analyzed by GC-MS.

Synthesis: 1. Nonstereospecific Preparation of 7-Ethyl-3,11-Dimethyl-2,6,10-Dodecatrienal Isomers A mixture of (2*Z*,6*Z*)-, (2*Z*,6*E*)-, (2*E*,6*Z*)-, and (2*E*,6*E*)-methyl 7-ethyl-3,11-dimethyl-2,6,10-dodecatrienoates was prepared (Mori et al. 1971) and converted to the corresponding aldehydes via alcohols as follows. One molar diisobutylaluminium hydride in hexane solution (16 ml, 16 mmol) was added dropwise to a solution of the mixture of methyl dodecatrienoates (1.6 g, 6.1 mmol) in dry hexane (20 ml) at −78°C under argon. After 10 min stirring, methanol and dilute HCl solution were added, and the reaction mixture was allowed to warm to room temperature. Then, the mixture was extracted with ether, washed with H_2O, saturated $NaHCO_3$ solution and saturated NaCl solution, dried with $MgSO_4$, and evaporated. The residue was purified by column chromatography on silica gel eluted with hexane–EtOAc (3:1) to give a mixture of 7-ethyl-3,11-dimethyl-2,6,10-dodecatrienols (1.4 g, 5.9 mmol, 97%). An activated MnO_2 (16.5 g) was added to the mixture of the dodecatrienols (1.4 g, 5.9 mmol) in hexane solution (100 ml) at 0°C and stirred for 8 hr. After removing the MnO_2, the residue was concentrated and purified by column chromatography on silica gel eluted with hexane–EtOAc (3:1) to give an isomeric mixture of 7-ethyl-3,11-dimethyl-2,6,10-dodecatrienals (1.2 g, 5.1 mmol, 86%). MS: (2*Z*,6*Z*)-isomer: 234 (M^+, 0.6), 205 (2), 150 (6), 137 (5), 109 (12), 107 (12), 95 (39), 84 (36), 81 (32), 69 (71), 55 (32), 41 (100). MS: (2*Z*,6*E*)-isomer: 234 (M^+, 0.4), 205 (2), 150 (7), 137 (6), 109 (16), 107 (12), 95 (52), 84 (38), 81 (49), 69 (69), 55 (44), 41 (100). MS: (2*E*,6*Z*)-isomer: 234 (M^+, 2), 205 (5), 151 (11), 137 (7), 109 (19), 107 (18), 95 (55), 84 (72), 81 (29), 69 (84), 55 (42), 41 (100). MS: (2*E*,6*E*)-isomer: 234 (M^+, 1), 205 (2), 150 (10), 137 (12), 109 (17), 107 (17), 95 (50), 84 (80), 81 (33), 69 (86), 55 (47), 41 (100).

Synthesis: 2. (2Z/E,6E)-7-Ethyl-3,11-Dimethyl-2,6,10-Dodecatrienals A mixture of (2*Z*,6*E*)- and (2*E*,6*E*)-methyl 7-ethyl-3,11-dimethyl-2,6,10-dodecatrienoate was prepared (Mori 1972) and converted to the corresponding aldehydes in the same way as described in nonstereospecific preparation of the isomers to give a mixture of (2*Z*,6*E*/*Z*)-7-ethyl-3,11-dimethyl-2,6,10-dodecanals (585 mg, 2.5 mmol, 83% from methyl ester). The geometrical isomers were separated and purified by preparative silica HPLC (isocratic solvent system at 3% EtOAc in hexane) resulting in (2*Z*,6*E*)-7-ethyl-3,11-dimethyl-2,6,10-dodecatrienal (>95% chemical purity, and >99% isomeric purity by GC and HPLC analyses, respectively) and (2*E*,6*E*)-7-ethyl-3,11-dimethyl-2,6,10-dodecatrienal (>95% chemical purity and >97% isomeric purity by GC and HPLC analyses, respectively). (2*Z*,6*E*)-7-Ethyl-3,11-dimethyl-2,6,10-dodecatrienal; δH (ppm) 9.93 (1H, d), 5.88 (1H, d), 5.06 (2H, m), 2.60 (2H, t), 2.26 (2H, q, *J*=7.3 Hz), 1.94–2.05 (6H, br), 1.68 (3H, s), 1.60 (3H, s), 1.56 (3H, s), 0.96(3H, t, *J*=7.3 Hz), δC (ppm) 191.18, 164.32, 143.36, 131.84, 128.91, 124.49, 121.94, 36.70, 31.90, 27.06, 25.99, 25.45, 23.49, 22.96, 18.01, 13.54.

(2*E*,6*E*)-7-Ethyl-3,11-dimethyl-2,6,10-dodecatrienal; δH (ppm) 10.00 (1H, d), 5.89 (1H, d), 5.06 (2H, m), 2.24 (2H, m), 2.18 (2H), 1.97–2.06 (6H, br), 1.68 (3H, s), 1.60 (3H, s), 1.56 (3H, s), 0.96(3H, t), δC (ppm) 191.95, 164.33, 142.91, 131.81, 127.77, 124.58, 122.30, 40.85, 36.30, 26.66, 25.47, 25.19, 23.00, 17.44, 17.39, 12.88.

Behavioral Assays A Y-tube olfactometer (15 mm i.d. glass Y-tube, 70 mm long arms connected to a 100-mm long stem at 120° angle) was used for behavioral assays. The assay was carried out at 27°C and 55% relative humidity. Newly emerged males were kept singly in a glass tube (8 mm i.d. × 30 mm long) both ends of which were covered with nylon mesh. Males were conditioned in an assay room in the dark overnight. The lights in the assay room were turned on 3 hr before assays to acclimatize the test insects to the light conditions. A test sample in hexane was applied to a filter paper disc (6 mm i.d.). The disc was inserted in the end of one arm of the olfactometer after the solvent had evaporated, while a control disc treated with hexane alone was inserted in the end of the other arm. Then, the nylon mesh cover of the glass tube containing the male was removed, and the tube was introduced into the end of the Y-tube olfactometer. Immediately, a vacuum pump was connected to the stem, and air filtered through an activated-charcoal cartridge was drawn through the Y-tube from the stem at approximately 1 l/min.

The number of males that reached the discs within 10 min was recorded. Attraction to the individual synthetic pheromone components was tested against the solvent-only control at various doses, whereas attraction to mixtures of synthetic pheromone components at various ratios was tested against a pure synthetic pheromone component [either the (2*Z*,6*E*)- or the (2*E*,6*E*)-isomer] at one dose (10 ng). Thirty males were tested in for each comparison. The distribution of males between the two stimuli in the comparison was subjected to a binomial test (two-tailed test with test proportion set at 0.5) (Siegel 1956). Males that did not reach either stimulus during the test were not included in the data analysis.

Results

In a preliminary experiment, GC-EAD analyses of headspace volatiles collected from virgin female *C. chinensis* consistently revealed three EAD active compounds A, B, and C (Fig. 1). Since GC-MS analysis of headspace collection suggested that pheromone components are novel compounds and occur small amounts in the collection, pheromone collection was scaled up by using the filter paper collection method (Tanaka et al. 1981). Crude pheromone extracts were accumulated from approximately 32,000 virgin females and fractionated by silica gel column chromatography, and active compounds were monitored by GC-EAD analysis. All EAD active compounds were found in the 5% ether fraction, and the fraction was further purified by normal-phase HPLC. The EAD active compounds were found in the 20–21 min (compound A) and 22–23 min (compounds B and C) fractions, respectively. Compounds A and B were further purified by preparative GC, and a relatively concentrated sample of compound A (approximately 27,000 female equivalent, approximately 20 μg/$CDCl_3$ 0.4 ml) was subjected to NMR analysis. We did not pursue the purification and chemical identification of compound C, which gave relatively weak EAD responses and was present in relatively small amounts in the extracts, less than 10% of compounds A and B, in this study.

GC-EI-mass spectra of compounds A (Fig. 2a) and B (Fig. 2b) showed a base peak at *m/z* 41 and almost identical characteristic fragments at *m/z* (percent intensity relative to the base peak) 81 (46), 84 (35), and 150 (9) for compound A, and *m/z* 81 (31), 84 (66), and 150 (9) for compound B, suggesting that these are closely related compounds. In GC-CI-MS, compounds A and B showed an identical set of characteristic fragments at *m/z* 217 $[M + 1\text{-}H_2O]^+$ (100), 235 $[M + 1]^+$ (40), 277 $[M + 43]^+$ (3) and 291 $[M + 57]^+$ (5), indicating a molecular weight of 234.

The ^{1}H-NMR spectrum of compound A was difficult to interpret due to signals that likely originated from contaminants, especially in the high-field region. However, verifiable and clearly distinguishable signals were observed at δ 9.90 (d, 1H, *J*=8.2 Hz), 5.88 (d, 1H, *J*=8.2 Hz), 5.06 (m, 2H) 2.59 (t, 2H), 2.26 (q, 2H, *J*=7.4 Hz), and 0.95 (t, 3H, *J*=7.4 Hz). Obscured signals that overlapped with contaminant signals were observed around δ 1.56–2.08. The presence of an aldehyde group is evident from one proton doublet at δ 9.90, which is coupled to an olefinic proton at δ 5.88, indicating α,β-unsaturated aldehyde moiety. The presence of an ethyl group is also evident in the spectrum from the three-proton triplet at δ 0.95 and two-proton quartet at δ 2.26 with an appropriate coupling constant, *J*=7.4 Hz.

The mass spectra of compounds A and B gave little useful information to elucidate the chemical structures. The compounds were converted into *N*,*N*-dimethylhydrazones, which often give important fragments for structural elucidation of aldehyde compounds (Attygalle 1998). The mass spectra of the *N*,*N*-dimethylhydrazone of both compounds A and B showed a molecular ion peak at *m/z* 276 M^+ and an intense peak at *m/z* 125 in the higher mass region. *N*,*N*-dimethylhydrazone derivatives of α,β-unsaturated straight chain aldehydes give an intense ion fragment at *m/z* 111 from an allylic fission of the molecular ion (Attygalle 1998). Thus, it was suggested that compounds A and B could be α,β-unsaturated aldehydes with a methyl branch either in the β or γ positions.

To obtain more structural information, compounds A and B were subjected to ozonolysis. The resultant products were characterized as 4-oxo-pentanal and 4-oxo-hexanal by GC-MS analysis. Compound A gave 4-oxo-hexanal as the

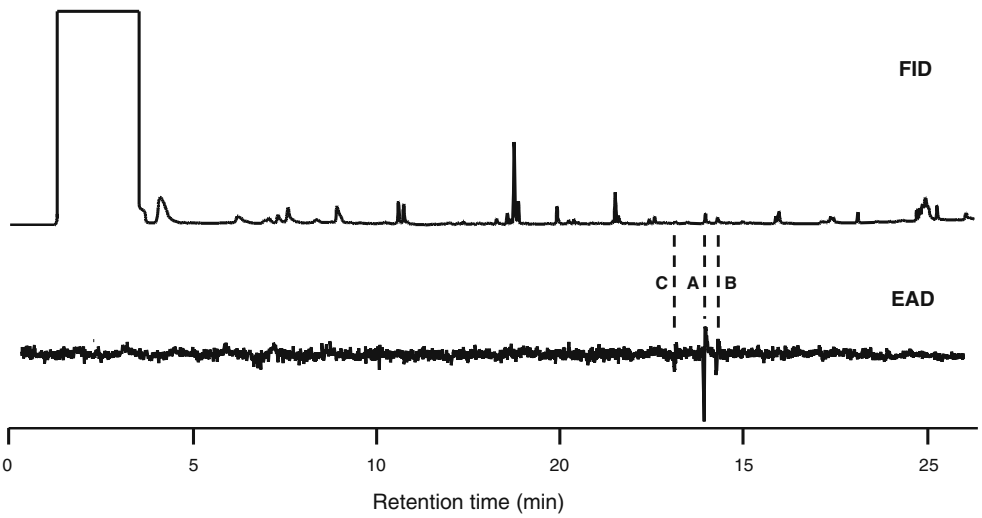

Fig. 1 Coupled gas chromatographic–electroantennographic detection analysis of antenna of male *Callosobruchus chinensis* to headspace volatile collections from virgin female *C. chinensis* (DB-5 column)

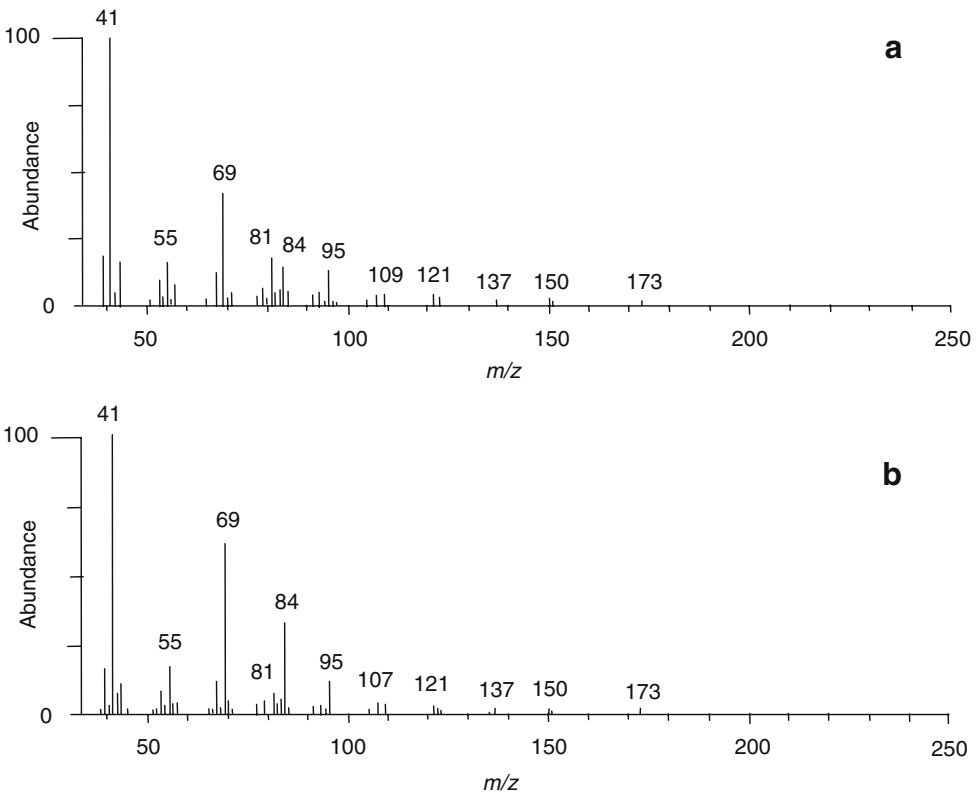

Fig. 2 EI-mass spectra of EAD-active compounds A (**a**) and B (**b**) from female *Callosobruchus chinensis*

only detectable product. However, we deduced the chemical structure of compound A by referring to the ozonolysis results of compound B because compound A was likely an isomer of compound B.

The pieces of the structure for 4-oxo-pentanal, 4-oxo-hexanal, and α,β-unsaturated aldehyde use C_5H_8, C_6H_{10}, and C_2H_2O, respectively (Fig. 3b–d), and these pieces make $C_{13}H_{20}O$. A molecular weight of 234 can take a number of likely molecular formulas, which contain at least one oxygen atom for the aldehyde moiety, including $C_{12}H_{26}O_4$, $C_{13}H_{14}O_4$, $C_{14}H_{18}O_3$, $C_{15}H_{22}O_2$, and $C_{16}H_{26}O$. Of these molecular formulas, only $C_{15}H_{22}O_2$ or $C_{16}H_{26}O$

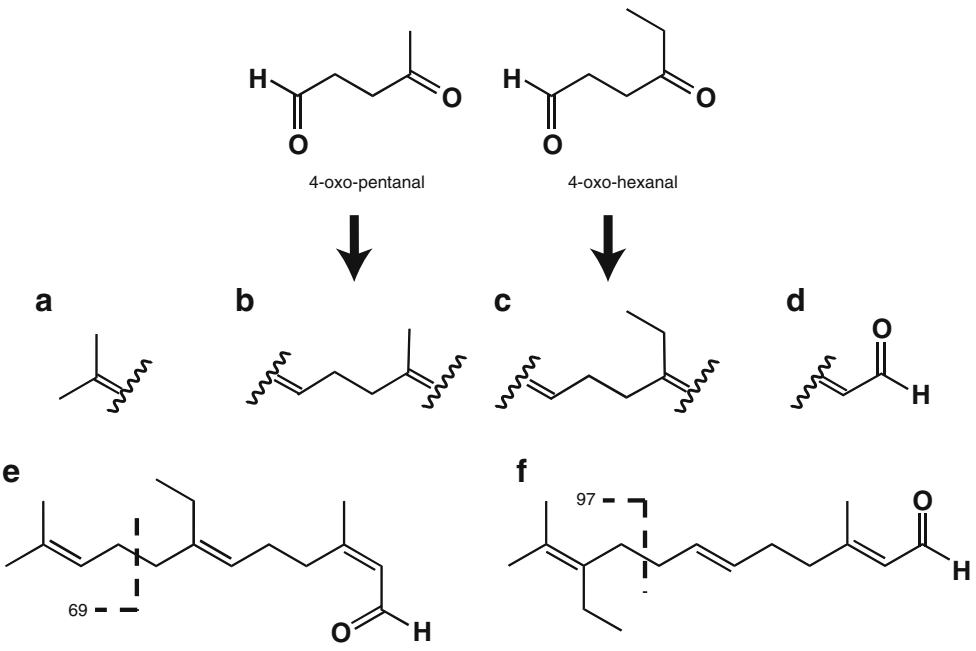

Fig. 3 Structural elucidation of EAD active compound A from female *Callosobruchus chinensis*. Partial structures of compound A, *a*, *b*, *c*, and *d*, were elucidated based on the results of GC-MS, microchemical, and ^{1}H-NMR analyses. Structures *e* and *f* are candidate structures of compound A, showing expected fragments at a diallylic fission in GC-MS analysis

satisfy the partial formula $C_{13}H_{20}O$. Then, the remaining pieces of the structure are calculated as C_2H_2O or C_3H_6. The first piece can be either of an α,β-unsaturated aldehyde, CHO–CH=, or a distorted epoxyside, O<CH_2–C=, while the second piece can be either of $(CH_3)_2C$= or an ethyl group, CH_3–CH_2–CH=. Taking account of the ^{1}H-NMR spectrum of compound A, in which one aldehydic proton and three olefinic protons were observed, together with ozonolysis results in which three olefinic protons were already assigned (Fig. 3b–d), the most likely partial structure accounting for the remaining piece was $(CH_3)_2C$= (Fig. 3a). Thus, the molecular formula of compound A was elucidated as $C_{16}H_{26}O$.

Considering compound A has a methyl branch at either the β or γ positions of the aldehyde group, the structure of compound A was deduced to be either 7-ethyl-3,11-dimethyl-2,6,10-dodecatrienal or 10-ethyl-3,11-dimethyl-2,6,10-dodecatrienal (Fig. 3e,f). However, the mass spectra of compound A showed a fragment at *m/z* 69 (Fig. 2a), suggesting a diallylic fission between C-8 and C-9 of structure e, not between C-8 and C-9 of structure f, which would give a fragment at *m/z* 97 (Fig. 3f). Therefore, the structure of compound A was elucidated as a homofarnesal, 7-ethyl-3,11-dimethyl-2,6,10-dodecatrienal, and compound B was deduced as a stereoisomer of compound A.

There are four possible geometrical isomers for 7-ethyl-3,11-dimethyl-2,6,10-dodecatrienal. To verify the structural elucidations, the four isomers were synthesized as a mixture. The GC-EAD analysis of the mixture showed that two of the four isomers elicited responses in male antennae (Fig. 4), and the retention times and the fragment patterns of these two isomers matched those of the natural compounds A and B.

7-Ethyl-3,11-dimethyl-2,6,10-dodecatrienal is a homolog of farnesal, 3,7,11-trimethyl-2,6,10-dodecatrienal, in which a C-7 ethyl group is substituted to methyl group. Farnesal also has four geometrical isomers, and those isomers can be easily resolved and determined by GC retention times and MS fragmentation patterns (Zagatti et al. 1987; Leal et al. 1989). By referring to the retention orders on GC columns and MS patterns of farnesals, compounds A and B were elucidated to be (2*Z*,6*E*)- and (2*E*,6*E*)-7-ethyl-3,11-dimethyl-2,6,10-dodecatrienals, respectively.

To confirm the geometrical configurations of compounds A and B, (2*Z*,6*E*)- and (2*E*,6*E*)-7-ethyl-3,11-dimethyl-2,6,10-dodecatrienal were synthesized as a mixture. Then, each isomer was purified and isolated by HPLC, and the geometrical configurations of the isomers were unambiguously determined by GC and spectroscopic analyses. Consequently, compounds A and B were identified as (2*Z*,6*E*)- and (2*E*,6*E*)-7-ethyl-3,11-dimethyl-2,6,10-dodecatrienals, respectively. The ratio of the 2*Z*,6*E*- and 2*E*,6*E*-isomers in the pheromone extracts was estimated at 1:1 by GC analysis.

Y-tube olfactometer assays with synthetic pheromones showed that males responded dose-dependently to both synthetic pheromone components (Fig. 5). The attractive threshold of the (2*Z*,6*E*)-isomer was lower, and the number of males attracted to the (2*Z*,6*E*)-isomer (Fig. 5a) was higher than to the (2*E*,6*E*)-isomer (Fig. 5b) at the same doses. The activities of mixtures of the isomers in various ratios were compared with either the (2*Z*,6*E*)- or (2*E*,6*E*)-isomer alone. The attraction of the (2*Z*,6*E*)-isomer (Fig. 6a) was not significantly different from the mixtures in various ratios except for a 1:9 ratio of (2*Z*,6*E*):(2*E*,6*E*), which was less attractive. The attraction of the (2*E*,6*E*)-isomer (Fig. 6b) was significantly lower than the mixtures of (2*Z*,6*E*) and (2*E*,6*E*) in the ratios 9:1, 7.5:2.5, and 5:5. More than 87% of males reached either discs in all comparative trials between the mixtures and pure isomers,

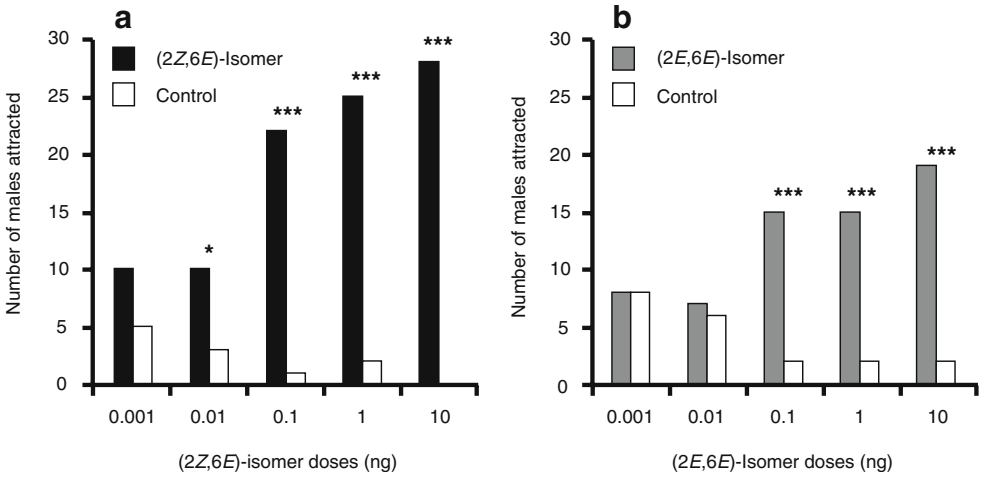

Fig. 5 Responses of male *Callosobruchus chinensis* to **a** (2*Z*,6*E*)- and **b** (*2E,6E*)-isomers in a Y-tube olfactometer. Thirty males were tested at each dose. The distribution of males between a sample and control in each treatment was subjected to a binomial test (two-tailed test with the test proportion set at 0.5). *Asterisks above bars* indicate significant differences from the test proportion (*$P<0.1$, **$P<0.05$, ***$P<0.01$). Males that did not reach either stimulus in each comparison were not included in the data analysis

which was similar to or more than those of (2*Z*,6*E*)-isomer alone vs. control trials at the dose–response study.

Discussion

Two homofarnesals, (2*Z*,6*E*)- and (2*E*,6*E*)-7-ethyl-3,11-dimethyl-2,6,10-dodecatrienal, were identified from the solvent extracts of filter paper-shelters taken from virgin female containers of *C. chinensis*. Both compounds elicited consistent EAD responses from the antennae of conspecific males. Males were attracted to 0.01–10 ng of the synthetic homofarnesals in Y-tube olfactometer assays. The (2*Z*,6*E*)-isomer showed equal or better activity than various mixtures of the (2*Z*,6*E*)- and (2*E*,6*E*)-isomers, and the responses to either mixtures or pure isomers in each trial were similar to those to the pure (2*Z*,6*E*)-isomer, which suggests that there is neither synergism nor antagonism between the two isomers.

Some bioactive natural products have been mischaracterized due to unexpected factors, such as thermal and chemical lability of the compounds during purification and/or analytical procedures (Mori 2005). The controversy over the periplanone-A, a component of the female sex attractant pheromone of the American cockroach, *Periplaneta americana*, is a case in point. Thermal lability of the genuine pheromone at the GC purification step misled the structural identification (Mori 2005). The pheromone components of *C. chinensis* have three double bonds: two isolated and one conjugating to the aldehyde group. These double bonds can be isomerized to other forms by physical or chemical factors. In fact, farnesal, which has almost the same chemical and geometrical structure as the pheromone components, was reported to isomerize spontaneously to other forms, i.e.,

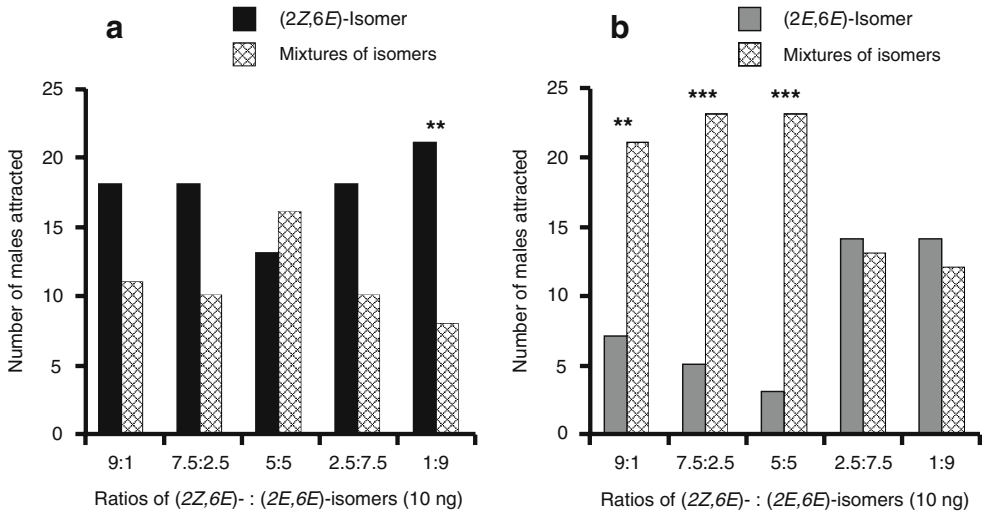

Fig. 6 A comparison of responses of male *Callosobruchus chinensis* to mixtures of (*2Z,6E*)- and (2*E*,6*E*)-isomers at various ratios and either a the (2*Z*,6*E*)-isomer or **b** the (2*E*,6*E*)-isomer at 10 ng. Thirty males were tested in each treatment. The distribution of males between samples in each treatment was subjected to a binomial test (two-tailed test with the test proportion set at 0.5). *Asterisks above bars* indicate significant differences from the test proportion (*$P<0.1$, **$P<0.05$, ***$P<0.01$). Males that did not reach either stimulus in each comparison were not included in the data analysis

(*E*,*E*)-farnesal isomerizes to (*Z*,*E*)-farnesal (Zagatti et al. 1987). Indeed, we found that the conjugated double bond of the synthetic pheromones was thermally isomerized to other configurations under our GC conditions. The percentages of isomerization of (2*Z*,6*E*) to (2*E*,6*E*)-isomers and (2*E*,6*E*) to (2*Z*,6*E*)-isomers were approximately 60% and 30%, respectively. Thus, although the ratio of the isomers in the pheromone extracts was estimated at 1:1 by GC analysis, the naturally occurring ratio probably tends to the (2*Z*,6*E*)-isomer. Therefore, together with the results of behavioral assays, (2*Z*,6*E*)-isomer appears to be more biologically significant than the (2*E*,6*E*)-isomer in the pheromonal communication system of *C. chinensis*. However, this needs to be clarified, and a field evaluation using synthetic compounds is under way.

The genus *Callosobruchus* is comprised of about 20 species (Borowiec 1987), and the distributions and habitats of some overlap considerably (Tuda et al. 2005). To date, female sex attractant pheromones have been identified from three species, *Callosobruchus analis*, *Callosobruchus subinnotatus*, and *C. maculatus*, as homologs of short chain fatty acids, including (*Z*)-3-methyl-2-heptenoic acid for *C. analis* (Cork et al. 1991), a mixture of (*Z*)-3-methyl-2-heptenoic acid and (*E*)-3-methyl-2-heptenoic acid for *C. subinnotatus* (Shu et al. 1998, 1999), and a mixture of (*Z*)-3-methyl-2-heptenoic acid, (*E*)-3-methyl-2-heptenoic acid, (*Z*)-3-methyl-3-heptenoic acid, (*E*)-3-methyl-3-heptenoic acid, and 3-methyleneheptanoic acid for *C. maculatus* (Phillips et al. 1996). The pheromone composition and the ratio of the mixture seem to play important roles in conspecific discrimination among these species (Phillips et al. 1996; Shu et al. 1999; Mbata et al. 2000). Interestingly, the chemical structure of the female sex attractant pheromone of *C. chinensis* is quite different from those of other species in the genus.

Recently, a molecular-based phylogenic study of the genus *Callosobruchus* separated this genus group into two distinct clades; one contains *C. chinensis*, which was designated the *chinensis* group, whereas the other contains *C. analis*, *C. subinnotatus*, and *C. maculatus*, which was designated the *maculatus* group (Tuda et al. 2006). This topology is also congruent with morphological character states of male genitalia and primary locality (Tuda et al. 2006). The divergence of pheromone compounds between the two clades is another corroboration of the results of the molecular phylogenic analysis.

Besides the female sex attractant pheromone, females of *C. chinensis* employ a contact sex pheromone that elicits copulation behavior from males (Tanaka et al. 1981). The contact sex pheromone of *C. chinensis* was characterized as a mixture of a monoterpene dicarboxylic acid, (*E*)-3,7-dimethyl-2-octene-1,8-dioic acid, and C_{25}–C_{35} straight chain and methyl-branched hydrocarbons (Tanaka et al. 1981, 1982). *C. maculatus* has a similar contact sex pheromone system, whose composition has recently been characterized as a mixture of dicarboxylic acids and hydrocarbons, 2,6-dimethyloctane-1,8-dioic acid and nonanedioic acid, and a mixture of C_{27}–C_{35} straight chain and methyl-branched hydrocarbons (Nojima et al. 2007). Interestingly, they reported that both *C. chinensis* and *C. maculatus* could elicit copulation behavior from heterospecific males in laboratory observations, suggesting that the contact sex pheromones lack species specificity.

Males of *C. chinensis* and *C. maculatus* are attracted to females by species-specific sex attractant pheromones. In this behavioral context, the contact sex pheromone need not be species-specific. A systematic study of the sex pheromones of *Callosobruchus* spp. could provide a key to understanding the evolution of the attractant and contact sex pheromone communication systems of this genus.

The female sex attractant pheromone of *C. chinensis*, (2*Z*,6*E*)- and (2*E*,6*E*)-7-ethyl-3,11-dimethyl-2,6,10-dodecatrienals, are homosesquiterpenoid, in which one extra carbon unit is added to the C-7 methyl group of a sesquiterpenoid, farnesal. Some homosesquiterpenes have been reported from insects, and those are synthesized *via* the mevalonate pathway from mevalonate and homomevalonate (Morgan 1999). The pheromone components of *C. chinensis* are likely to be biosynthesized *via* a similar pathway to that of other homosesquiterpenoids, but this remains to be clarified.

Acknowledgments The authors are grateful to Dr. Kaoru Tanaka for his early efforts in this project in our laboratory and valuable comments on the study. We thank Drs. Izuru Yamamoto and Hiroshi Honda for helpful advice. We also thank Drs. Goro Yabuta and Arata Yajima for help with the chemical synthesis. We also express our gratitude to Dr. Coby Schal for reviewing the manuscript. Finally, we are also thankful to two anonymous reviewers and an associate editor (Dr. Steven J. Seybold) for their help on the previous draft of this manuscript.

Received: 5 October 2007 / Revised: 25 January 2008 / Accepted: 6 February 2008 / Published online: 2 April 2008

Abstract The behavioral and electroantennographic responses of *Prorhinotermes canalifrons* to its soldier frontal gland secretion, and two separated major components of the secretion, (*E*)-1-nitropentadec-1-ene and (*E*,*E*)-α-farnesene, were studied in laboratory experiments. Behavioral experiments showed that both the frontal gland secretion and (*E*,*E*)-α-farnesene triggered alarm reactions in *P. canalifrons*, whereas (*E*)-1-nitropentadec-1-ene did not affect the behavior of termite groups. The alarm reactions were characterized by rapid walking of activated termites and efforts to alert and activate other members of the group. Behavioral responses to alarm pheromone differed between homogeneous and mixed groups, suggesting complex interactions. Antennae of both soldiers and pseudergates were sensitive to the frontal gland secretion and to (*E*,*E*)-α-farnesene, but soldiers showed stronger responses. The dose responses to (*E*,*E*)-α-farnesene were identical for both soldiers and pseudergates, suggesting that both castes use similar receptors to perceive (*E*,*E*)-α-farnesene. Our data confirm (*E*,*E*)-α-farnesene as an alarm pheromone of *P. canalifrons*.

Introduction

Termites, as creatures generally living in permanent darkness, largely rely upon chemical communication during intraspecific interactions. Trail-following pheromones produced by the sternal gland (Matsumura et al. 1968; Bordereau et al. 1991; Laduguie et al. 1994; Peppuy et al. 2001), or the food-marking pheromone produced by the labial glands (Reinhard et al. 2002) are well known. Other means of chemical communication include alarm pheromones produced by the frontal gland of soldiers (Vrkoč et al. 1978; Roisin et al. 1990; Reinhard and Clément 2002), and sexual pheromones produced by tergal (Bordereau et al. 2002), posterior sternal (Peppuy et al. 2004), or sternal glands in alate imagoes (McDowell and Oloo 1984; Bordereau et al. 1991; Laduguie et al. 1994). In addition, there are several other glands whose functions are still unknown or hypothetical, such as the mandibular glands (Cassier et al. 1977; Šobotník and Hubert 2003), tarsal glands (Bacchus 1979), or epidermal glands (Šobotník et al. 2003).

When disturbed, termites communicate alarm mechanically via vibrations (Howse 1964, 1965; Connétable et al. 1999; Röhrig et al. 1999), or with alarm pheromones. With some exceptions (Maschwitz and Mülhenberg 1972; Traniello et al. 1984), pheromones mediate alarm communication in termite species with a developed frontal gland, i.e., in the families Serritermitidae, Rhinotermitidae, and Termitidae (Noirot 1969; Costa-Leonardo and Kitayama 1991). Although the involvement of the frontal gland

secretion in alarm communication has been proven for many species (Kriston et al. 1977; Kaib 1990; Roisin et al. 1990; Pasteels and Bordereau 1998; Reinhard and Clément 2002), a striking gap exists in our knowledge of the chemicals actually involved in alarm communication. Alarm pheromones have been identified only in three *Nasutitermes* species, including α-pinene and limonene in *N. rippertii,* carene and limonene in *N. costalis* (Vrkoč et al. 1978), and α-pinene in *N. princeps* (Roisin et al. 1990). The production of alarm pheromones may also be linked with soldier polymorphism: alarm pheromones are probably produced solely by small soldiers in *Schedorhinotermes lamanianus* (Kaib 1990) or by large soldiers in *Nasutitermes exitiosus* (Kriston et al. 1977).

The genus *Prorhinotermes* (Isoptera: Rhinotermitidae) is the only genus in the subfamily Prorhinotermitinae (Quennedey and Deligne 1975). Its crucial phylogenetic position within Rhinotermitidae as well as a peculiar combination of primitive and advanced characteristics makes it an attractive model to study. *Prorhinotermes* species have a linear ontogenetic scheme lacking a true worker caste; the work tasks are performed by temporarily specialized helpers, pseudergates, which retain capacity to become either alate imagos (through a single nymphal instar) or neotenic reproductives (by a single molt; Roisin 1988). Soldiers in *Prorhinotermes* originate from pseudergates or larvae through an intermediary presoldier instar (Roisin 1988; Hanus et al. 2006). They are abundant (up to 22%), they guard inside the nest and on its peripheries, but also act as defenders when the nest is being moved (Haverty 1977, Roisin et al. 2001). Soldiers' defense includes their piercing mandibles and a powerful frontal chemical weapon; they also perform vibratory alarm movements in response to disturbance (Deligne et al. 1981; Hanus et al. 2005).

The frontal gland secretion in soldiers of the genus *Prorhinotermes* contains predominantly (*E*)-1-nitropentadec-1-ene, with small amounts of sesquiterpenes (Vrkoč and Ubik 1974; Hanus et al. 2006; Piskorski et al. 2007). On average, the frontal gland of *P. canalifrons* soldiers contains 153 μg of (*E*)-1-nitropentadec-1-ene and 1.8 μg of (*E*,*E*)-α-farnesene, the latter representing about 65% of its sesquiterpenoid content (Piskorski et al. 2007). Whereas the defensive function of the frontal gland secretion, due to the large amounts of toxic (*E*)-1-nitropentadec-1-ene, is well established (Kuldová et al. 1999), its role in alarm communication and the contribution of (*E*,*E*)-α-farnesene remain hypothetical. The aims of the experiments described in this paper were as follows: (1) to determine whether the soldier frontal gland secretion is responsible for alarm communication in *P. canalifrons*; (2) to determine if (*E*,*E*)-α-farnesene mediates the alarm reaction; (3) to evaluate potential differences in alarm reaction among castes; (4) to verify the function of the putative alarm pheromone in conditions closer to natural ones, i.e., at the level of a whole colony. Thus, we studied the alarm reactions in homogeneous (formed by either pseudergates or soldiers) and heterogeneous termite groups (formed by pseudergates and soldiers), and subsequently in small complete colonies. As experimental stimuli, the whole frontal gland secretion, and solutions of synthesized (*E*)-1-nitropentadec-1-ene and (*E*,*E*)-α-farnesene were used. Electrophysiological responses of termite antennae were also recorded to investigate possible differences between castes in sensitivity to gland secretion, and (*E*,*E*)-α-farnesene.

Materials and Methods

Termites The colonies of *Prorhinotermes canalifrons* (Sjöstedt 1904) used for experiments originated from Saint-Denis (Réunion). The termites were collected in 2001 and since then were reared in containers in permanent darkness at 27°C and elevated humidity. Wet fine sand served as substratum. Colonies were continuously provided with decayed birch wood. The experimental design described below is summarized in Table 1.

Experimental Groups Termite groups of 4 different caste compositions were tested: (A) 40 pseudergates +10 soldiers (close to natural proportions, Haverty 1977), (B) 50

Table 1 The design of experiments: caste composition, stimuli used, number of repetitions, and number of individuals measured in experiments A–D

Experiment	Caste Composition	Stimuli	Individuals Measured per Repetition	No. of Repetitions per Stimulus	Individuals Measured per Stimulus	Individuals Measured
A	40 Ps+10 sold	bl, hex, npd, fg, far	10 Ps+5 sold	5	50 Ps+25 sold	250 Ps+125 sold
B	50 Ps	bl, hex, npd, fg, far	10 Ps	2	20	100 Ps
C	20 sold	bl, hex, npd, fg, far	10 sold	2	20	100 sold
D	Ps+sold+neo+pres+L	fg, far	Not evaluated	4	0	0

Ps pseudergate, *sold* soldier, *neo* neotenic, *pres* presoldier, *L* larva, *bl* blank control, *hex* hexane, *npd* (E)-1-nitropentadec-1-ene, *fg* frontal gland secretion, *far* (*E*,*E*)-α-farnesene

pseudergates, (C) 20 soldiers, and (D) incipient colonies. In experiments A and B, termites were transferred from the original colonies into experimental arenas 20–24 h prior to observation to allow to acclimatize after manipulation. This delay was reduced to 4–6 h only in experiment C because soldiers are care-dependent. The incipient colonies (experiment D) originated from groups of 60 pseudergates isolated and left to develop for 8 months. At the time of experimentation, these groups consisted of 25–35 pseudergates, 6–10 soldiers, 5–15 neotenics, 0–2 presoldiers, 0–5 larvae from the first to the third instar, and 0–8 eggs. The complete population of each small colony was carefully extracted from its original box and transferred to the experimental chamber inside the birch wood (see Fig. 1). The corridor connecting the chamber with the exterior was initially closed with a piece of filter paper, and was opened after 2 days. Behavioral tests were performed from the next day on.

Experimental Design All experiments were performed at 27°C under red light in Petri dishes (85 mm diameter) with wet filter paper as substratum (Fig. 1). A piece of birch wood served as a food and natural substrate. The test substance was loaded onto a piece of filter paper (7×3 mm) and introduced immediately into the Petri dish through a slit in the dish cap. The filter paper was hung out of reach of termites by a pin bridged over the slit.

The following stimuli were tested in experiments A–C: (1) untreated paper (blank control), (2) 1 μl of pure hexane (solvent control), (3) 31 μg of (*E*)-1-nitropentadec-1-ene (~0.2 frontal gland equivalent, FGE) in 1 μl of hexane, (4) one soldier frontal gland secretion (1 FGE), (5) 1.5 μg of (*E*,*E*)-α-farnesene (~1 FGE) in 1 μl of hexane. Each group was tested once for one stimulus and once for the control in random order. In experiment D, only two stimuli were tested: (4) frontal gland secretion, and (5) (*E*,*E*)-α-farnesene in random order with at least 2-day intervals between exposures (each stimulus tested once in every group).

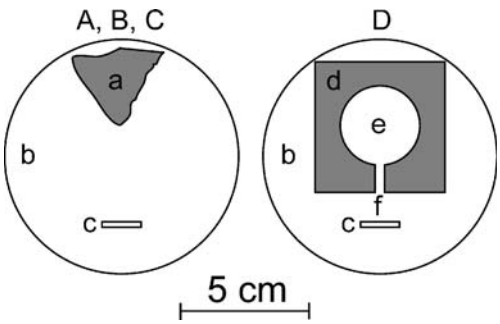

Fig. 1 Schematic drawing of the experimental design of behavioral bioassays: *left*, experiments A–C; *right*, experiment D. The arenas are drawn to scale; *a*, piece of birch wood; *b*, filter paper; *c*, slit in the lid of the Petri dish through which filter paper loaded with test solution was hung; *d*, birch wood test chamber; *e*, central arena where whole incipient colonies were placed, reaching from bottom to top of the dish; *f*, narrow corridor, the only connection between the central arena and the exterior

The frontal gland secretion of a soldier was obtained by decapitation, evacuation of the thoracic and abdominal part of the frontal gland reservoir with a slight pressure by forceps tip against the body, and then smashing the head on the test filter paper. For synthesis of (*E*)-1-nitropentadec-1-ene (>99%) (see Kuldová et al. 1999). (*E*,*E*)-α-farnesene (68%; from plant material; minor components incl. α-caryophyllene, hydrocarbon and sesquiterpene oxidation products) was provided by Anna-Karin Borg-Karlson, KTH, Sweden. Minor components included α-caryophyllene, sesquiterpene, and hydrocarbon oxidation products.

Recording The behavior of all termite groups was recorded with a Panasonic WV-CL920 camera and a Panasonic DVD hard drive recorder DMR-HS2. Each recording started 2 min before introduction of the stimulus and lasted for 7 min. The parameter evaluated in behavioral experiments was the speed of termite walking. New software, MouseTracer, was developed to track the position of the mouse cursor. The cursor was controlled by the experimenter, and the selected termite was followed on the screen. The cursor position, recorded 20 times per second of observation, was initially expressed in pixels and subsequently converted into millimeters.

The selection of termites to track in all experiments was designed to include all possible termite statuses at the beginning of the experiment: individuals close and far from the introduction slit, in the center and at the periphery of a termite group, individuals resting or walking in the arena, etc.

Statistics Experiment A was repeated five times for each stimulus, B and C twice, and then the data were merged for a particular stimulus. In each repetition of experiment A, the tracks of ten pseudergates and five soldiers were analyzed; ten individuals were tracked in experiments B and C. Thus, 50 pseudergates and 25 soldiers were analyzed in A, 20 pseudergates in B, and 20 soldiers in C for each stimulus. Experiment D was performed with four colonies, but the data were not evaluated statistically because termites often walked on the vertical walls of the chamber, which prevented them from being tracked.

Kruskal–Wallis rank tests and multiple comparisons of non-parametric data were used to compare the speed of particular castes before and after insertion of the stimulus, as well as the antennal responses in electroantennography (EAG) experiments compared with controls. The walking speeds between A, B, and C and the latency in response to olfactory stimuli were compared by means of nonparametric Mann–Whitney *U* tests. The curves in Fig. 2 were

obtained by using the moving average of the distances walked by the individual every 0.05 s, expressed as the average for every 5 s. Statistica® 7.1 was used for all calculations.

Electroantennography EAG recordings were performed by using individual antennae of pseudergates and soldiers with the antennal tip cut off. Glass Ag/AgCl microelectrodes filled with insect saline solution were used. Electrodes were connected to an amplifier (Syntech), and the tenfold amplified signal was fed to a PC via an IDAC 2 PC board (Syntech). (*E*,*E*)-α-farnesene was diluted in hexane in decadic steps (10 pg–10 μg/μl). From each concentration, 1 μl of stimulus solution was loaded onto a 1×0.5 cm piece of filter paper inserted in a Pasteur pipette. After solvent evaporation, the loaded odorant cartridges were sealed with parafilm and stored at −20°C until used. Prior to each experiment, the cartridges were allowed to warm up for 1 h at room temperature. Stimuli were delivered by injection of an air pulse (1 s, air flow 0.8 l/min) through an odorant cartridge into a continual air stream directed towards the antenna. Standard stimuli, i.e. cartridges with filter paper loaded with 100 ng of (*E*,*E*)-α-farnesene, were applied at the beginning and the end of each experiment to determine

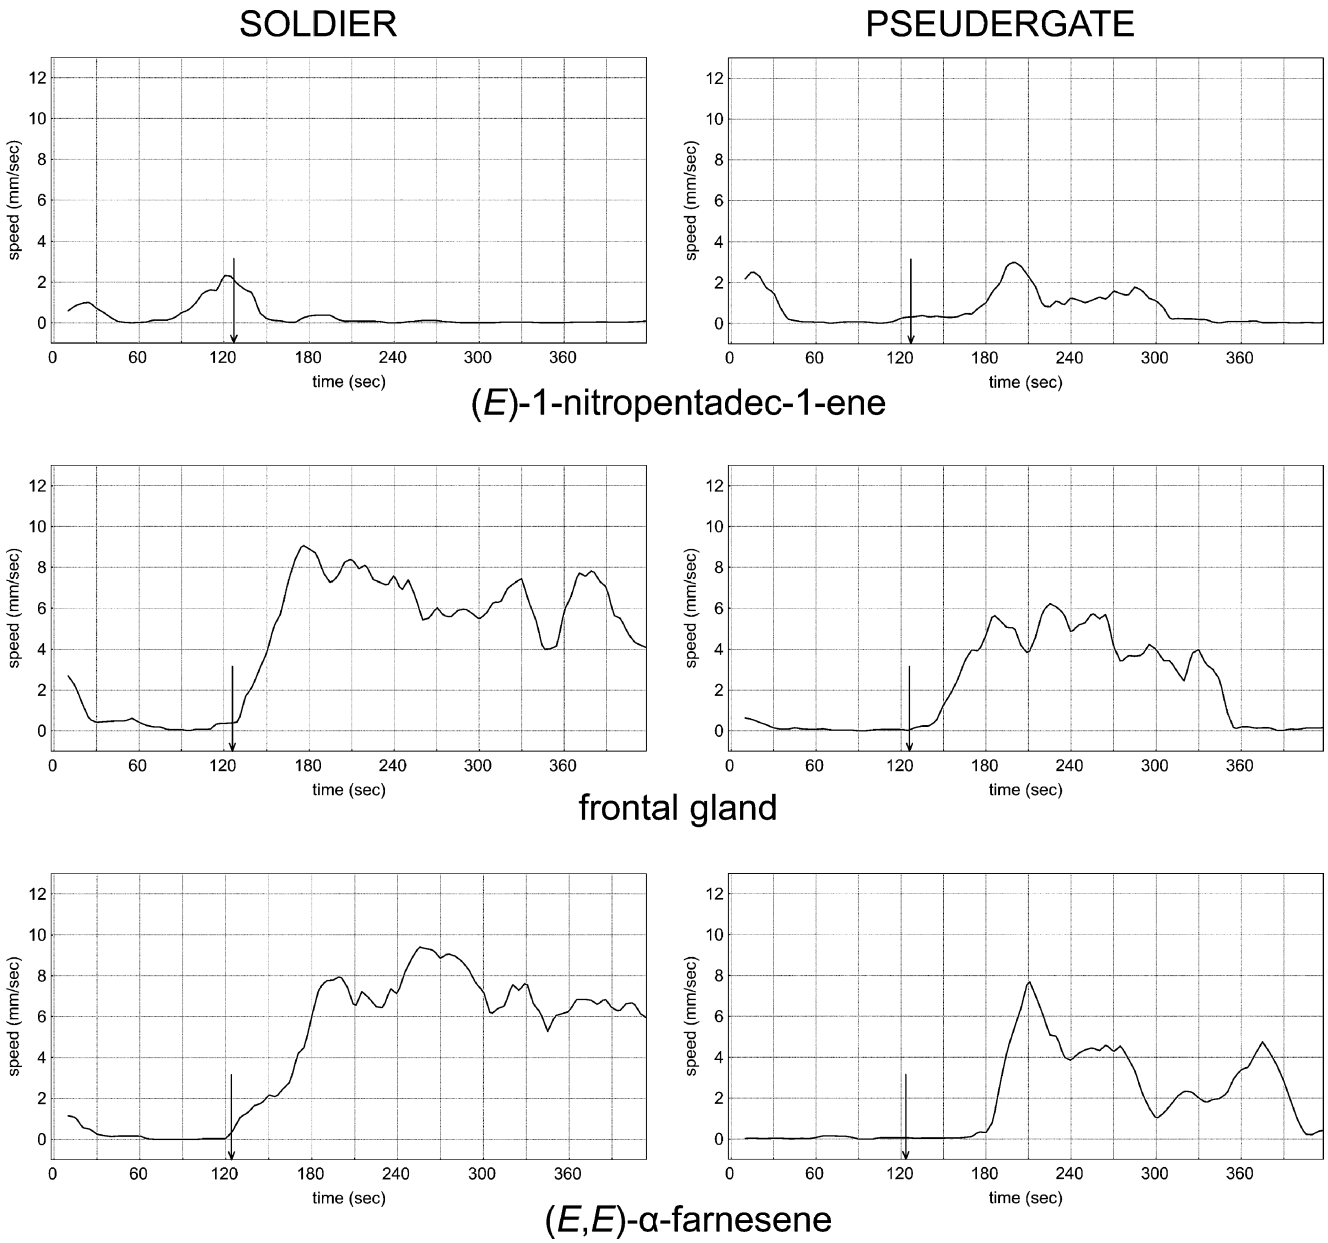

Fig. 2 Typical dynamic recordings of walking speed of soldiers and pseudergates exposed to different olfactory stimuli (experiment A). The curves represent a moving average of distances walked scored second by second. *Arrows* mark the insertion of the stimulus

possible changes in antennal sensitivity during EAG recordings and to allow normalization between experiments. The antennal responses (maximal negative deflection during stimulation in mV) were normalized to these standard stimuli and expressed in percent. Each stimulus was tested once on each antenna, with 19 different antennae per stimulus used; thus, the data analyzed represent 19 independent measurements for each stimulus.

Results

General Features of Alarm Behavior At the beginning of each experiment, most termites were quietly clustered near the piece of wood, and usually only a few individuals, predominantly soldiers, would slowly explore the arena. After insertion of an untreated filter paper, termite activity increased slightly for a while due to the disturbance, but decreased within a few seconds. Similar responses were elicited by hexane and (*E*)-1-nitropentadec-1-ene solution. On the other hand, insertion of a paper treated with frontal gland secretion or (*E*,*E*)-α-farnesene solution led to a long-lasting activation characterized by fast walking, scanning of the space with straightened antennae, zigzag searching for the odor source, mandibular opening and closing (in soldiers), and nestmate alerting. Activation led to marked change in termite distribution within the arena, namely the accumulation of termites below the odor source.

During nestmate activation, the alerting termites (usually soldiers, less commonly also pseudergates) searched for quiescent termites, touched them with their antennae, and subsequently performed a series of longitudinal vibrations. This behavior was usually repeated several times (most frequently 2–4 times during 3–10 s) until the alerting termite calmed down or until all nestmates were alerted. Soldiers reacted to alerting stimulation more easily than pseudergates: one alerting signal was usually enough to activate a soldier, whereas repeated alerting was often necessary to activate a pseudergate. The behavioral responses elicited by the frontal gland secretion did not differ qualitatively from those elicited by (*E*,*E*)-α-farnesene. Typical time courses of activation of soldiers and pseudergates are shown in Fig. 2.

Heterogeneous Groups of 40 Pseudergates +10 Soldiers—Experiment A The results of Experiment A are summarized in Fig. 3. Exposure to frontal gland secretion increased the walking speed in both pseudergates and soldiers ($P<10^{-6}$ for both): the average speed increased from 0.53 to 2.15 mm/s in pseudergates, and from 0.58 to 3.39 mm/s in soldiers. The same was observed for (*E*,*E*)-α-farnesene, which increased the speed of walking to 2.9 mm/s in pseudergates, and to 4.87 mm/s in soldiers ($P<10^{-6}$ for both). (*E*,*E*)-α-farnesene at the dose used apparently represented a more effective stimulus than the frontal gland secretion for both pseudergates and soldiers.

Soldiers generally reacted more quickly than pseudergates, as documented by individual measurements of 12 soldiers and 14 pseudergates exposed to (*E*,*E*)-α-farnesene: median value of the first maximum in walking speed was 20 s in soldiers and 40 s in pseudergates ($P<7\times10^{-3}$). With the exception of differences in reaction times, the responses of pseudergates and soldiers were similar. About 1 min after the introduction of the paper treated with (*E*,*E*)-α-farnesene or frontal gland secretion, all termites ran vigorously in the arena.

Homogeneous Groups of 50 Pseudergates or 20 Soldiers—Experiments B and C The responses of homogeneous groups of either pseudergates or soldiers were qualitatively similar compared to the mixed groups in experiment A: hexane and nontreated paper elicited no significant responses (Fig. 4). In contrast, the locomotion of soldiers and pseudergates was significantly faster after exposure to the frontal gland secretion or (*E*,*E*)-α-farnesene. The increase in speed in pseudergates did not differ from that in mixed groups. In soldiers, on the other hand, the increase was lower for the frontal gland secretion (1.51 vs. 3.39 mm/s in mixed groups; $P<6\times10^{-4}$) as well as for (*E*,*E*)-α-farnesene (2.63 vs. 4.87 mm/s in mixed groups; $P<10^{-6}$) when compared to observations in heterogeneous groups.

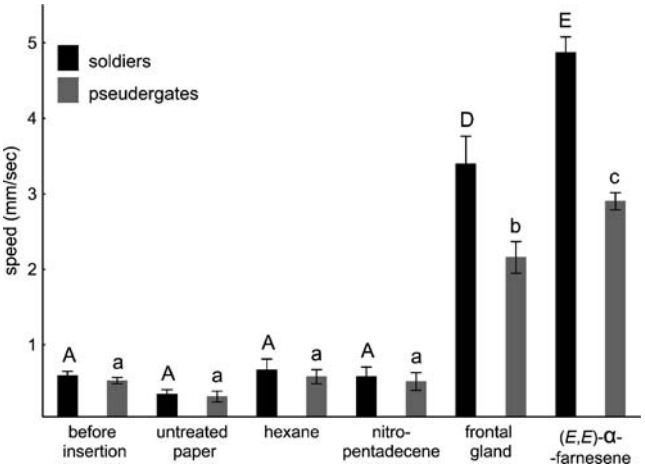

Fig. 3 Average walking speed of soldiers and pseudergates during behavioral bioassays with mixed groups (experiment A) exposed to various olfactory stimuli before (*the two columns on the left*, $n=125$ soldiers and 250 pseudergates) and after the insertion of the stimulus ($n=25$ soldiers and 50 pseudergates for each stimulus). *Columns* represent means, whiskers represent SEM. The *columns marked with different letters* are significantly different (Kruskal–Wallis test; $P<0.05$; multiple non-parametric comparison for unequal number of observations)

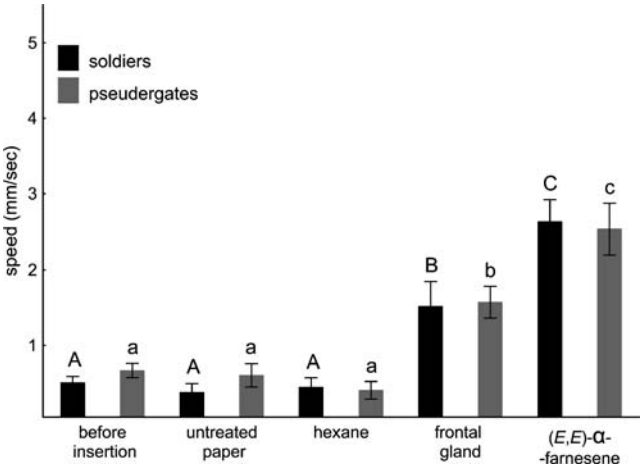

Fig. 4 Average speed of soldiers and pseudergates from single-caste groups (experiments B or C) exposed to different olfactory stimuli during behavioral bioassays. *Columns* represent means, whiskers represent SEM. The *columns marked with different letters* are significantly different (Kruskal–Wallis test; $P<0.05$; multiple non-parametric comparison for unequal number of observations)

Incipient Colonies—Experiment D Prior to the introduction of the test substances, members of all castes of incipient colonies were randomly distributed within the chamber with at least one soldier patrolling the corridor that connected the chamber with the outside. Introduction of (*E*,*E*)-α-farnesene or frontal gland secretion strikingly affected the walking speed of termites. The alerting behavior was also performed, predominantly by soldiers. The most prominent effect was the accumulation of the soldiers in the narrow corridor or in its vicinity, whereas members of other castes revealed a tendency to move to the parts of the chamber located farthest from the entrance or to climb up the chamber walls. Soldiers (and never a member of any other caste) were often seen to leave the corridor and perform zigzag searching; one to three soldiers were observed out of the chamber in four out of eight experiments recorded.

Electroantennography Antennae of both pseudergates and soldiers responded to frontal gland secretion and to (*E*,*E*)-α-farnesene (Fig. 5). The responses of soldiers to particular stimuli were slightly but significantly higher than that of pseudergates: the mean values for the standard stimulus were 0.253 mV in pseudergates and 0.327 mV in soldiers ($P<0.04$).

On the other hand, the responses of the two castes did not differ qualitatively: the dose response curves expressed as percent of the standard were identical for both castes (Fig. 5). The EAG response threshold to (*E*,*E*)-α-farnesene (compared to air control) was 100 ng for both castes. Above this threshold, the EAG response increased with the doses of (*E*,*E*)-α-farnesene: no EAG saturation was observed for the biologically relevant concentrations tested. The EAG response to the frontal gland secretion from a single soldier was approximately equivalent to that elicited by 1 μg of (*E*,*E*)-α-farnesene.

Discussion

Our results show that the frontal gland secretion is involved in alarm signaling in *P. canalifrons*. However, the major constituent of the frontal gland secretion, (*E*)-1-nitropentadec-1-ene, has no alarm effect. The function of this highly toxic compound (see Kuldová et al. 1999) can, therefore, be considered as purely defensive. In contrast, (*E*,*E*)-α-farnesene triggered several changes in behavior including increase in walking speed, searching for the odor source (zigzag running), attraction of both soldiers and pseudergates to the source (experiments A, B, and C), or attraction of soldiers and withdrawal of members of other castes from it (experiment D), and alerting of nestmates, performed predominantly by soldiers. Thus, (*E*,*E*)-α-farnesene clearly functions as an alarm pheromone in *P. canalifrons*. Together with the dominant (*E*)-1-nitropentadec-1-ene, isomers of α-farnesene also have been documented in species-specific mixtures in the frontal gland secretions of other *Prorhinotermes* species, *P. simplex* and *P. inopinatus* (Piskorski et al. 2007). As in *P. canalifrons*, we predict that

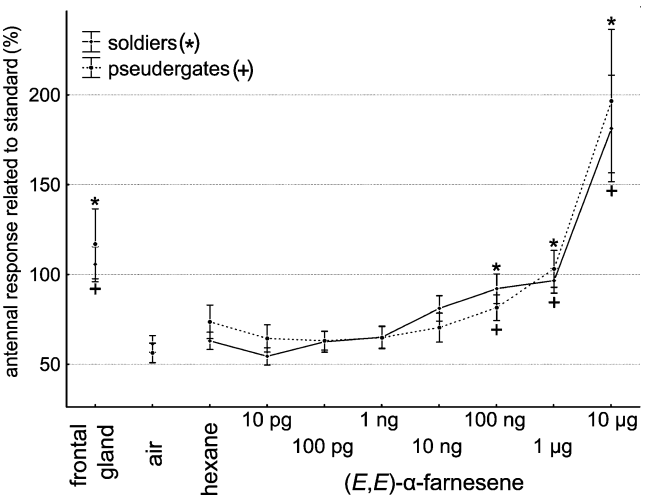

Fig. 5 EAG responses recorded from antennae of soldiers and pseudergates exposed to control stimuli (air and hexane), to the content of the soldier frontal gland, and to (*E*,*E*)-α-farnesene in seven doses. The responses are related to the value of response to a standard stimulus, i.e., 100 ng of (*E*,*E*)-α-farnesene. Nineteen measurements were performed for each stimulus. Points represent means, whiskers represent SEM. The values marked with *asterisks* (for soldiers) or *crosses* (for pseudergates) are significantly different from the air control (Kruskal–Wallis test; $P<0.05$; multiple non-parametric comparison)

these compounds will mediate alarm communication in these two species.

Behavioral effects of farnesene isomers have been recorded from numerous insect species. For example, (*E*,*E*) and/or (*Z*,*E*) isomers of α-farnesene act as sexual or trail pheromones in several insect orders, including many ant genera (e.g., Cammaerts 1973; Attygalle and Morgan 1983; Van der Meer 1983; Detrain et al. 1987). (*E*)-β-farnesene has been shown to be an alarm pheromone of aphids (Dawson et al. 1990) and a kairomone for their predators (ladybirds; Al Abassi et al. 2000; Francis et al. 2004). It has also been found in soldiers of *Reticulitermes* species (Quintana et al. 2003).

Although (*E*,*E*)-α-farnesene mediated an alarm response in both soldiers and pseudergates of *P. canalifrons*, soldiers were more sensitive, showing a stronger response in both behavioral tests and EAG. Similar EAG dose response curves suggests that both castes may use the same type of receptors. Thus, the difference in antennal sensitivity is probably based on differences in numbers of sensillae rather than on differences in sensitivity of olfactory receptor neurons tuned to (*E*,*E*)-α-farnesene. The numbers of sensillae between soldiers and pseudergates were not compared, but the soldiers' antennae are longer due to an increase in the number of antennal segments during soldier development from pseudergates (see Hanus et al. 2006).

The fact that soldiers are more sensitive to the alarm pheromone than pseudergates reflects their different social roles within termite societies. In this respect, the higher latency of response to chemical alarm in pseudergates can also be understood as caste specialization. The lower sensitivity and longer latency may ensure that pseudergates are not disturbed by stimuli that eventually appear as not dangerous, and rely upon soldiers to be alerted. The lower sensitivity of pseudergates is compensated by soldier nestmate alerting behavior mediated by mechanical means. Interestingly, the behavioral responses of soldiers to the alarm pheromone were more pronounced in heterogeneous groups containing both soldiers and pseudergates. In the absence of pseudergates, soldiers may exhibit lower activity simply because there are no other castes to alert.

A curious phenomenon that has been repeatedly observed in experiments with alarm pheromones is the accumulation of termites near the source of odor (Roisin et al. 1990, Reinhard and Clément 2002). We suggest that this response may be an artifact of the situation during testing because this was never observed when more natural conditions were used, i.e., in experiment D.

In both behavioral and EAG tests, the responses of both castes to the frontal gland content of one soldier were lower than to the equivalent dose of (*E*,*E*)-α-farnesene in hexane solution. This is probably due to (1) incomplete emptying of the gland on the tested paper or/and (2) different physical properties of the two solutions: hexane, being more volatile than (*E*)-1-nitropentadec-1-ene (which constitutes over 90% of the secretion), may enhance the evaporation of (*E*,*E*)-α-farnesene and thus volatilize higher amounts of alarm pheromone during the experiment. When considering the lower threshold dose of the alarm pheromone for sensorial and behavioral responses of pseudergates and soldiers, approximately 10% of the total amount of (*E*,*E*)-α-farnesene in one soldier frontal gland, one has to keep in mind that many soldiers participate in the alarm communication in a colony. It can thus be initiated and mediated by only a partial emptying of the frontal gland reservoir of a number of soldiers.

Termite soldiers are specialized for fulfilling defensive tasks to such a degree that they are not able to feed themselves and are fully dependent on the pseudergates' care. Their fundamental importance in *Prorhinotermes*, documented by their high proportion in the colony compared to other termite species (7–22%; Haverty 1977), comprises a wide variety of functions that include guarding the nest and foraging groups, direct physical defense, initiation and mediation of alarm by both vibratory and chemical means, and egg evacuation after an attack on the nest (Roisin et al. 2001; Hanus et al. 2005). Nevertheless, the role of pseudergates (or true workers in other termite species) in colony defense should not be overlooked because in many cases, they play a crucial role in defense (Thorne and Haverty 1991; Shelton and Grace 1996; Clément and Bagnères 1998).

Acknowledgement We are grateful to Jakub Janda (Prague, Czech Republic) for the development of the MouseTracer software. We acknowledge Anna-Karin Borg-Karlson (Stockholm, Sweden) for the gift of (*E*,*E*)-α-farnesene. We also thank Jean-Pierre Bourguignon (Halle, Belgium) for the production of the test chambers. This research was supported by FRFC (postdoctoral stay of J.Š., project no. 2.4597.05) and by the Grant Agency of the Academy of Sciences of the Czech Republic (project no. A600550614). T. Bourguignon was supported by a predoctoral fellowship from the FRIA, Belgium. We thank two anonymous reviewers for constructive suggestions.

Molecular Characterization and Expression Pattern of Two Pheromone-Binding Proteins from *Spodoptera litura* (Fabricius)

Wei-Ming Xiu · Yao-Zhen Zhou · Shuang-Lin Dong

Received: 1 December 2007 / Revised: 5 February 2008 / Accepted: 11 February 2008 / Published online: 18 March 2008

Abstract Pheromone perception is thought to be mediated by pheromone-binding proteins (PBPs) in the lymph surrounding the olfactory receptors. We cloned and characterized two PBP genes (*SlitPBP1* and *SlitPBP2*) from the common cutworm, *Spodoptera litura* (F.; Lepidoptera: Noctuidae), which encode PBPs belonging to two different PBP groups. Western blot analysis of the crude antennal extracts with SexigPBP1 antibody revealed a single immunoreactive band (much stronger in male than in female) of ~16 kDa, in agreement with the calculated values for SlitPBPs. From genomic DNA, two introns and a similar exon/intron structural pattern were identified in each PBP genes, but the introns differed in length within and between PBP genes. The expression patterns of two *SlitPBP* genes, with respect to tissue distribution and sex, were further investigated by reverse transcriptase-polymerase chain reaction (RT-PCR) and real-time PCR. Although the two PBP genes were expressed only in the antennae of both sexes, reflecting the antennal specificity of PBPs, the transcription levels of PBP genes differed between the sexes and the genes. The transcription levels of *SlitPBP1* and *SlitPBP2* in females were only 2.1% and 7.0%, respectively, relative to those in males, and the levels of PBP2 compared with PBP1 were 31.4% and 95.3% in males and females, respectively. These differential expression levels might suggest different roles played by the two SlitPBPs in the perception of sex pheromone both in males and females.

Introduction

Pheromone communication in moths is extremely sensitive and selective to discriminate extremely similar compounds or isomers (Hansson 1995). Perception of pheromones in moths and other insects is mediated by specialized pheromone-sensing organs, the sensilla trichodea, located mainly on the antenna. An early step in perception involves pheromone-binding proteins (PBPs), which are localized in the lymph of the sensilla on the moth antennae (Vogt and Riddiford 1981; Steinbrecht et al. 1995; Vogt et al. 2002). The first PBP was identified by its ability to bind the sex pheromone in the silk moth, *Antheraea polyphemus* (Vogt and Riddiford 1981). Since then, PBPs have been identified from various moth species (Krieger et al. 1996; Robertson et al. 1999; Picimbon and Gadenne 2002; Abraham et al. 2005; de Santis et al. 2006; Forstner et al. 2006; Xiu and Dong 2007). These proteins display considerable diversity, sharing 32–92% amino acid identity (Abraham et al. 2005). PBPs are thought to transport the relatively hydrophobic sex pheromones through the lymph surrounding the sensory dendrites to specific receptor proteins on the membrane of olfactory neurons (Prestwich 1996). Several PBPs have been demonstrated to bind pheromonal compounds (Du and Prestwich 1995; Plettner et al. 2000; Bette et al. 2002; Klusák et al. 2003; Maida et al. 2003; Lautenschlager et al. 2007).

Recently, several occurrences of multiple PBPs from a single moth species have been reported, and in each case, the different PBPs were encoded by distinct loci (Maïbèche-Coisné et al. 1998; Maida et al. 2000; Bette et al. 2002; Picimbon and Gadenne 2002; Abraham et al. 2005; de Santis et al. 2006; Forstner et al. 2006; Xiu and Dong 2007). Considering the multicomponent nature of moth sex pheromone constitution, it has been suggested that PBPs in moths might be involved in discriminating among pheromone components. Ligand-binding experiments in some moths, especially in the gypsy moth, *Lymantria dispar* (L.), have indicated that the various PBPs showed specificity in binding to their respective pheromone components (Du and Prestwich 1995; Plettner et al. 2000; Bette et al. 2002; Maida et al. 2003). This suggests a potential strategy in pest control by interfering with the expression of a single PBP in a moth species.

The common cutworm, *Spodoptera litura* (F.; Lepidoptera: Noctuidae), and the beet armyworm, *Spodoptera exigua* (Hüber), are important congeneric pests of various agricultural crops. They are sympatric in many parts of China and other Asian countries. The sex pheromones for these species have been identified and used successfully in population forecasting and pest control by mating disruption and mass trapping (Nemoto et al. 1980; Wakamura and Takai 1995; Srinivas and Rao 1999). The sex pheromone of *S. litura* comprises *Z*9, *E*11-14:Ac, *Z*9, *E*12-14:Ac, *Z*9-14:Ac, and *E*11-14:Ac (Tamaki et al. 1973, 1976; Sun et al. 2003), whereas that of *S. exigua* is composed of *Z*9, *E*12-14:Ac, *Z*9-14:OH, *Z*9-14:Ac, and *Z*9,*E*12-14:OH (Wakamura et al. 1989; Mitchell and Tumlinson 1994; Dong and Du 2002). Although the two species employ chemically similar pheromone components and share two of them, they are reproductively isolated in field environments, and traps that are baited with two components of each species (with one component in common) selectively attracted only one species in field trials (our unpublished data). Therefore, it would be interesting to compare differences in pheromone perception between the two species.

Previously, we identified and described two PBPs from *S. exigua* (Xiu and Dong 2007). In the present study, we report the identification of two PBPs from *S. litura* (SlitPBPs); their tissue distribution pattern; and relative expression levels in male and female antennae. We also report the genomic sequences of both genes.

Methods and Materials

Insect Rearing and Tissue Collection *S. litura* were reared at 27°C (14:10 hr, L:D) in the laboratory on an artificial diet (Huang et al. 2002) and separated by sex as pupae. Antennae were collected from 3-d-old male and female moths. They were excised at the base and immediately transferred into Eppendorf tubes immersed in liquid nitrogen. The same procedure was used for collecting heads (without antennae), thoraces, abdomens, and legs. All tissues were stored at –75°C until used experimentally.

Nucleic Acid Manipulation Total RNA was extracted by homogenizing antennae or other tissues of male and female moths by using the SV total RNA isolation system kit (Promega, Madison, WI, USA) following the manufacturer's instructions. Total RNA was transcribed into single strand cDNA that served as templates for PCR amplification by extension of an oligo$(dT)_{18}$ primer with MMLV reverse transcriptase (Promega) at 42°C for 60 min. The reaction was stopped by heating at 95°C for 5 min.

Genomic DNA was prepared from an individual fourth instar larva. The larva was ground in liquid nitrogen and homogenized with 300 µl DNA extraction buffer [(100 mM Tris–HCl, pH 8.0; 50 mM ethylenediaminetetraacetic acid (EDTA); 200 mM NaCl; 1% sodium dodecyl sulfate (SDS)]. The homogenate was transferred to an Eppendorf tube, gently mixed with 20 µl Proteinase K (20 mg/ml), and incubated at 56°C for 3 hr. The tube was centrifuged for 10 min at 12,000×*g*. The supernatant was transferred to a new tube, and DNA was extracted from it with an equal volume of phenol:chloroform: isoamyl alcohol (25:24:1) followed by an equal volume of chloroform:isoamyl alcohol (24:1). Each time, the sample was centrifuged for 5 min at 12,000×*g* to collect the aqueous phases. Two-and-one-half volumes of chilled ethanol were added to the aqueous supernatant for DNA precipitation. The pellets were washed in 70% ethanol, briefly vacuum-dried, and the DNA was redissolved in 50 µl TE buffer (10 mM Tris–HCl, pH 8.0; 1 mM EDTA, pH 8.0; 100 µg/ml RNase A).

Molecular Cloning and Sequencing The cDNAs that encode PBPs of *S. litura* were amplified from antennal cDNA of males. A pair of degenerate primers (Table 1) was designed to match amino acid regions of FWK(R)EG(E)Y and HE(D)LN(K)WA from the alignment of PBP sequences from *Heliothis virescens* (Krieger et al. 1993, GenBank X96861), *Helicoverpa zea* (Callahan et al. 2000, GenBank AF090191), *Agrotis ipsilon* (Picimbon and Gadenne 2002, GenBank AY301986), *Agrotis segetum* (LaForest et al. 1999, GenBank AF134253), and *Mamestra brassicae* (Maïbèche-Coisné et al. 1998, GenBank AF051142 and AF051143). These were the same degenerate primers used to clone *S. exigua* PBPs from a previous study (Xiu and Dong 2007). Amplification was carried out in a PCR machine PTC-200 (MJ Research, Waltham, MA, USA) and included negative controls under the following conditions: 94°C for 3 min; 9 cycles at 94°C for 50 sec, 65°C for 1 min, and 72°C for 30 sec, with a decrease of the

annealing temperature by 1°C per cycle. This was followed by 25 cycles at 94°C for 50 sec, 55°C for 1 min, and 72°C for 30 sec, and final incubation for 10 min at 72°C. The reaction was performed in 50 μl with 3 μl single-stranded cDNA, 2.0 mM $MgCl_2$, 0.2 mM deoxyribonucleotide triphosphate, 1.5 μM of each primer, and 2.5 U Taq polymerase (Promega).

A rapid amplification of cDNA ends (RACE) procedure was employed to amplify the 5′ and 3′ end of the coding region using SMART RACE cDNA Amplification Kit (Clontech, Mountain View, CA, USA) following the kit instructions. Gene-specific primers (GSP; Table 1) for 5′-RACE and 3′-RACE were derived from the sequence of PCR products. Amplification conditions were 94°C for 2 min; 28 cycles at 94°C for 30 sec, 65°C for 30 sec, and 72°C for 3 min.

Regions of the PBP gene were amplified from genomic DNA by PCR to ascertain the exon/intron structure of the genes. Specific primer pairs (Table 1) were chosen for the amplification. For *SlitPBP1*, touchdown PCR reactions were performed as follows: 94°C for 3 min; 6 cycles at 94°C for 50 sec, 58°C for 50 sec, and 72°C for 2 min, with a decrease of the annealing temperature by 1°C per cycle. Subsequently, 34 cycles at 94°C for 50 sec, 52°C for 50 sec, and 72°C for 2 min and followed by incubation for 10 min at 72°C. For *SlitPBP2*, the reactions were: 94°C for 3 min; 40 cycles at 94°C for 50 sec, 64°C for 50 sec, and 72°C for 2 min and followed by incubation for 10 min at 72°C. LA Taq polymerase (TaKaRa, Otsu, Shiga, Japan) was used following manufacturer's instructions.

PCR products were analyzed by 1.5% agarose-gel electrophoresis, and DNA purification was performed with a Wizard PCR Preps DNA purification kit (Promega). Purified products were subcloned in a T/A cloning plasmid by using the pGEM-T easy vector system (Promega) following manufacturer's instructions. Plasmid DNA was transformed into DH5α-competent cells. Positive clones (on the basis of restriction enzyme cleavage sites and PCR amplification) were sequenced by using dye-terminator chemistry and reactions on an ABI 377 automated sequencer (Applied Biosystems, Foster City, CA, USA).

Sequence Analysis Sequences were identified by using the NCBI-BLAST network server (Altschul et al. 1990). The putative signal peptides and their cleavage sites were predicted with the SignalP V 3.0 program (Bendtsen et al. 2004; http://www.cbs.dtu.dk/services/SignalP/). The hydrophobicity profile was determined by the method of Kyte and Doolittle (1982). The sequence data were aligned and compared with Clustal X (1.81) (Thompson et al. 1997). The phylogenetic tree was constructed with Neighbor Joining (NJ) by the MEGA3.1 program (Kumar et al. 2004). Bootstrap analysis used 1,000 replications.

Protein Extraction and Immunological Detection of SlitPBPs To test the expression of the PBPs in *S. litura*, antennae of 3-d-old males and females were excised separately. Each sample of 200 antennae was homogenized in ice-cold homogenizers in 100 μl of 20 mM Tris–HCl (pH 8.0). The homogenized samples were centrifuged for 20 min at 12,000×*g* at 4°C, and the supernatants were centrifuged again under the same conditions. Total protein concentration was estimated according to the method of Bradford (Bradford 1976).

Total antennal proteins (40 μg) were separated by 15% SDS-polyacrylamide gel electrophoresis (PAGE) under reducing conditions (Laemmli 1970), and the proteins were

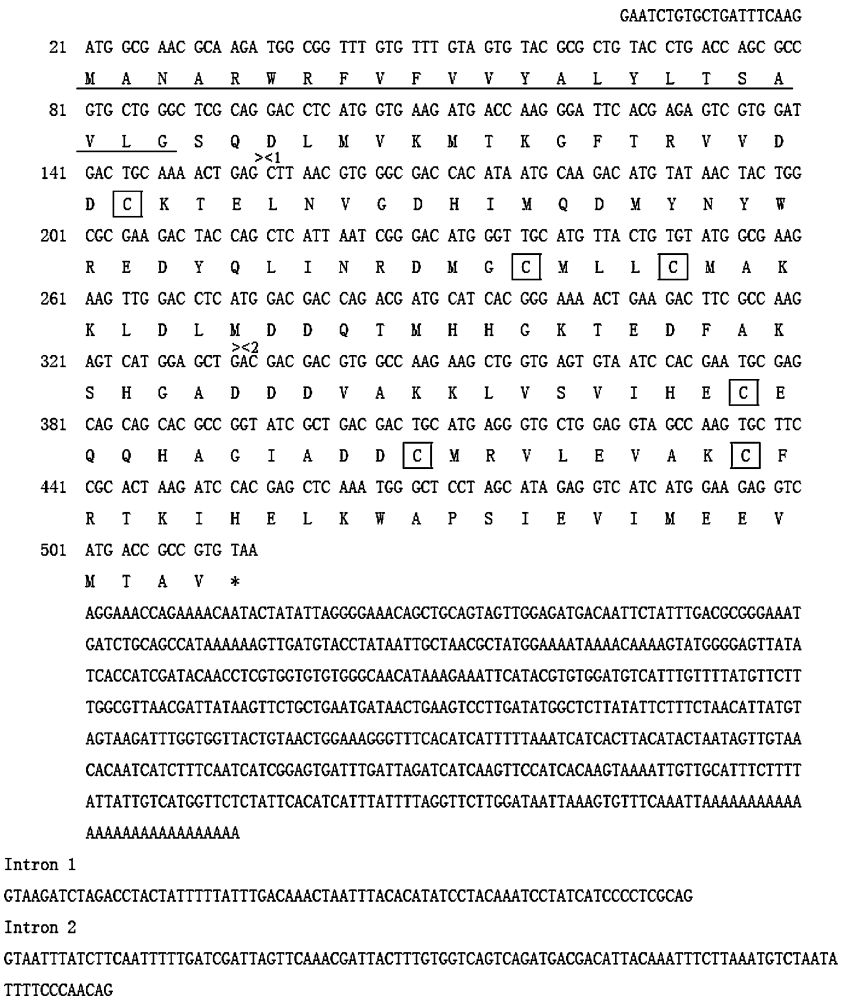

Fig. 1 cDNA sequence and predicted amino acid sequence of SlitPBP1. The stop codon is indicated with an *asterisk*. The signal peptide is *underlined*. The six conserved cysteines are *boxed*. transferred to PVDF membranes (Millipore, Bedford, MA, USA). After transfer, the membranes were blocked with 5% dried nonfat milk powder in PBST buffer (PBS plus 0.05% Tween 20, pH 7.4), and incubated with mouse primary antiserum against SexigPBP1 (the antiserum was prepared by our laboratory) in PBST at an antibody dilution of 1:2,000 for 2 hr. After several washes with PBST, horseradish peroxidase (HRP)-conjugated goat anti-mouse IgG as secondary antibody was applied for 2 hr, and 3,3′,5,5′-tetramethylbenzidine (TMB) was used as the staining substrate.

Distribution Pattern of SlitPBP Expression Tissue localization of expression of *SlitPBP*s was assessed by RT-PCR with the cDNA templates from antennae and other tissues of male and female moths, and genomic DNA. Specific primer pairs (Table 1) were derived from the cDNA sequences, spanning at least one predicted intron region, thus allowing us to distinguish genomic contaminants in the cDNA preparation. For testing the integrity of the cDNA templates, a control primer pair (Table 1) from the coding region of the *S. litura* β-actin gene (GenBank DQ494753) was used. PCR began at 94°C for 3 min, then 5 cycles at 95°C for 50 sec, 54°C for 50 sec, and 72°C for 2 min (with a decrease of the annealing temperature by 1°C per cycle); followed by 35 cycles at 95°C for 50 sec, 49°C for 50 sec, and 72°C for 2 min; with a final 10 min incubation at 72°C. PCR products were analyzed on 1.5% agarose gels.

Real-Time PCR Analysis of SlitPBP Expression Real-time PCR was performed in an ABI Prism 7000 Sequence Detection System (Applied Biosystems) with SYBR green dye bound to double strand DNA at the end of each elongation cycle (SYBR Green Realtime PCR Master Mix; TOYOBO, Osaka, Japan). Each pair of PCR primers was designed to span a cDNA exon–exon border to avoid amplification of potential traces of genomic DNA (Bohbot and Vogt 2005). *SlitPBP1* primers (Table 1) amplified a 169-bp product from cDNA. *SlitPBP2* primers (Table 1) amplified a 130 bp fragment from cDNA. As an endoge-

nous control to normalize the results of a variable target gene and to correct for sample-to-sample variation, the amplification size of β-actin gene primers (Table 1) was 220 bp.

Real-time PCR was conducted in 25 μl reactions that contained 12.5 μl of 2×SYBR Green PCR Master Mix, 0.5 μl of each primer (10 μM), 2.5 μl of sample cDNA, and 9 μl sterilized ultrapure H_2O (Millipore). To check reproducibility, test samples, endogenous control, and "no sample control" were done in triplicate. Cycling parameters included 94°C for 3 min, 40 cycles at 94°C for 30 sec, and

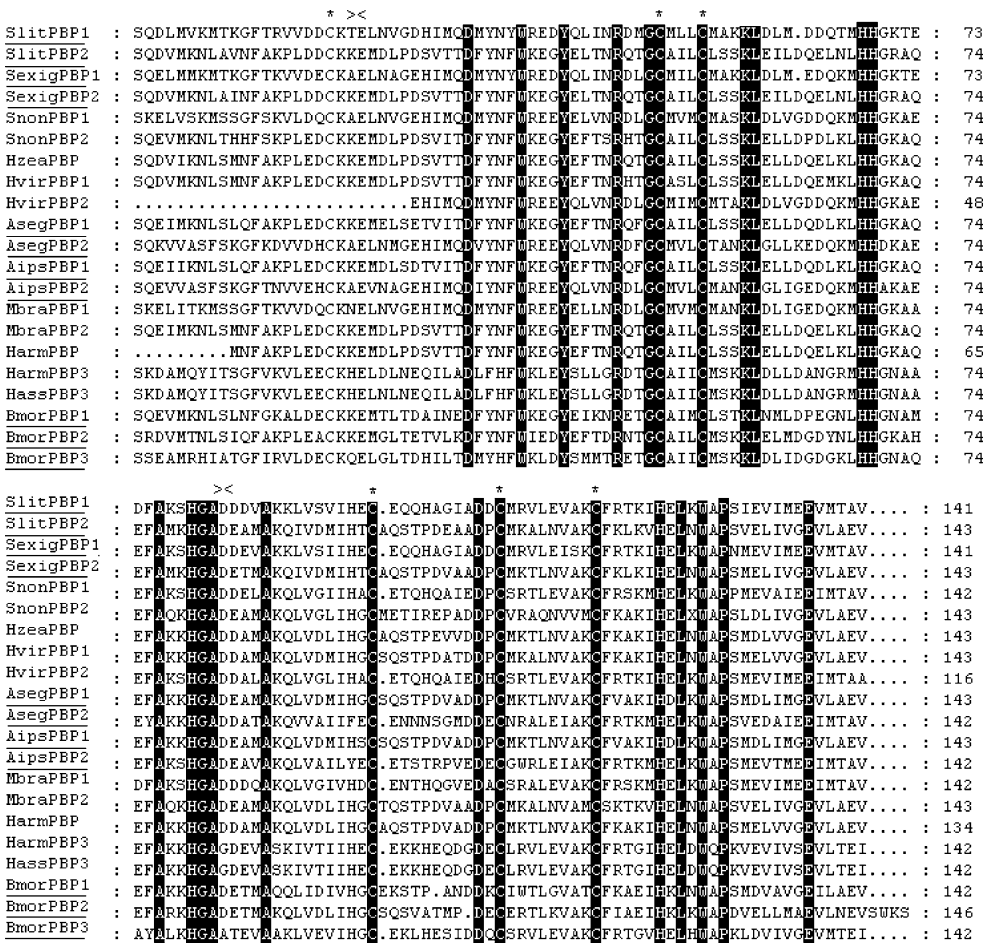

Fig. 3 Alignment of the mature SlitPBP1 and SlitPBP2 from *S. litura* with their orthologs from *Bombyx mori* and nine other species of Noctuidae: SlitPBP1 and SlitPBP2 are at the top, followed by SexigPBP1 (*S. exigua*, AY540316), SexigPBP2 (*S. exigua*, AY545636), SnonPBP1 (*Sesamia nonagrioides*, AY485219), SnonPBP2 (*S. nonagrioides*, AY485220), HzeaPBP (*Helicoverpa zea*, AF090191), HvirPBP1 (*Heliothis virescens*, X96861), HvirPBP2 (*H. virescens*, AY301988), AsegPBP1 (*A. segetum*, AF134253–AF134294), AsegPBP2 (*A. segetum*, AY301987), AipsPBP1 (*Agrotis ipsilon*, AY301985), AipsPBP2 (*A. ipsilon*, AY301986), MbraPBP1 (*Mamestra brassicae*, AF051143), MbraPBP2 (*M. brassicae*, AF051142), HarmPBP (*Helicoverpa armigera*, AJ278992), HarmPBP3 (*H. armigera*, AF527054), HassPBP3 (*Helicoverpa assulta*, DQ286414), BmorPBP1 (*Bombyx mori*, X94987), BmorPBP2 (*B. mori*, EMBL AM403100), and BmorPBP3 (*B. mori*, EMBL AM403101). Conserved amino acids in all PBPs are shown in a *black background*. Positions of six conserved cysteine residues are indicated by *asterisks*. Sites of the two introns are marked with "><", and the names of PBPs with intron data available are *underlined*

64.5°C for 45 sec. The products were analyzed by sequencing, agarose gel electrophoresis, and performing a melting curve, which indicated that each reaction did not produce nonspecific amplification.

Relative quantification was performed by using the comparative $2^{-\Delta\Delta C_T}$ method (Livak and Schmittgen 2001) to identify the amount of PBP mRNA in female antennal tissue relative to the amount in male tissue. All data were normalized to endogenous actin levels from the same individual sample. In the analysis of the relative fold-change, the male sample, which was one of the experimental samples, was taken as the calibrator (Mittapalli et al. 2006). Thus, the relative fold-change was assessed by comparing the expression level of *SexigPBP* in female moths to that in males. Calculations for relative quantification were performed, according to the instructions of the User Bulletin no. 2 from Applied Biosystems (Relative Quantification of Gene Expression; ABI Prism 7700 Sequence Detection System).

For a valid $\Delta\Delta C_T$ calculation with the comparative $2^{-\Delta\Delta C_T}$ method for relative quantification, the amplification efficiencies of the target and reference must be approximately equal. To confirm this, a pilot experiment was conducted to look at how ΔC_T ($C_{T,\text{Target}} - C_{T,\text{Actin}}$) varies with template dilution. Briefly, four serial tenfold dilutions of cDNA from each sample were amplified. For each dilution, amplifications were performed in triplicate with primers for PBP and actin. The average C_T was calculated for both PBP and actin and the ΔC_T was determined. A plot of the log cDNA dilution versus ΔC_T was made.

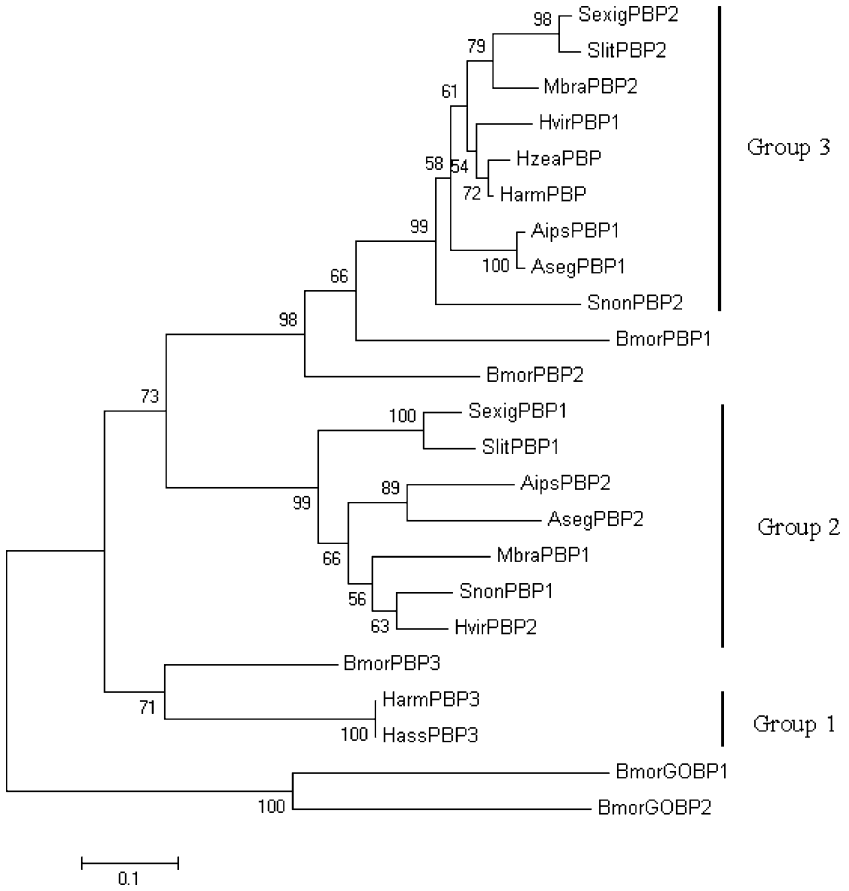

Fig. 4 Phylogenetic analysis based on SlitPBP1 and SlitPBP2 amino acid sequences. The tree was made with the neighbor-joining method with multiple alignments of amino acid sequences from Fig. 3 BmorGOBP1 and BmorGOBP2 from *Bombyx mori* were defined as the outgroups. Bootstrap analysis used 1,000 replications. The *bar* indicates phylogenetic distance value

Results

Identification of cDNA and Genomic DNA Sequences Encoding *S. litura* PBPs

The RT-PCR approach performed with a pair of degenerate primers identified two cDNA fragments of 275 and 281 bp, namely, *SlitPBP1* and *SlitPBP2*, respectively. A RACE procedure was further employed to obtain full-length sequences of the two genes from *S. litura*. The sequences of *SlitPBP1* and *SlitPBP2* (Figs. 1 and 2) were deposited in GenBank with the accession numbers DQ004497 and DQ114219, respectively.

The isolated cDNA clone encoding SlitPBP1 was 1,085 bp long and contained a 492-bp open reading frame for a polypeptide of 164 amino acids. The initial 23 amino acids are predicted as a signal peptide followed by the native protein of 141 amino acids with a molecular mass of 16,285 Da and an isoelectric point of 5.14. The isolated cDNA clone encoding SlitPBP2 (804 bp) comprised the complete PBP precursor consisting of a 27-amino acid signal peptide followed by the mature protein of 143 amino acids with a molecular mass of 15,998 Da and an isoelectric point of 4.92. The two PBPs display similar hydropathy profiles (not shown), and the presence of putative signal sequence suggest that these proteins are secreted into the extracellular fluid.

We aligned the mature amino acid sequences of SlitPBP1 and SlitPBP2 with PBPs from *Bombyx mori* (Lepidoptera: Bombycidae) and nine species of Noctuidae (Fig. 3). Both SlitPBP1 and SlitPBP2 have conserved motifs characteristic of lepidopteran PBPs, including the six cysteine residues that are believed to form three disulfide bridges, and the hydrophobic domains. The two SlitPBPs can be classified into different PBP groups (group 2 and group 3) by phylogenetic analysis and are closest phlylogenetically to PBPs from *S. exigua* (Fig. 4). Similarity analysis on the amino acid sequences of PBPs further confirmed the phylogenetic result. The two SlitPBPs share only 45% identity, but are much more identical to PBPs of the same group from other moth species. SlitPBP1 displays high identities with SexigPBP1 (87%), MbraPBP1 (70%), and SnonPBP1 (68%), whereas SlitPBP2 is more identical with SexigPBP2 (95%), MbraPBP2 (87%), and HvirPBP1 (84%; Table 2).

To understand the exon/intron structure of the genes, the two PBP genes were cloned and sequenced from the genomic DNA preparation. Both *SlitPBP1* and *SlitPBP2* contain two introns, and present a similar exon/intron structure. The two introns in *SlitPBP1* are located between Glu45 and Leu46 (intron 1, 76 bp) and inside the codon for Asp105 (intron 2,

[a] Numbers in upper right (bold-faced font) are % identity of amino acid sequences and in lower left (normal font) show the number of residues that match exactly (identical residues) between the two sequences. The shaded table entries indicate the identities among PBPs of same group. PBP names are the same as in Fig. 3.

104 bp; Fig. 1). The introns in *SlitPBP2* are located between Glu49 and Met50 (intron 1, 437 bp) and inside the codon for Asp110 (intron 2, 2008 bp; Fig. 2). The ends of the introns have a typical GT–AG structure (Figs. 1 and 2).

SDS-PAGE and Western Blot Analysis of SlitPBPs To confirm the two SlitPBPs identified by the molecular means, SDS-PAGE and Western blot analysis with protein extracts from *S. litura* antenna were conducted (Fig. 5). An antenna-specific protein band was detected with the same molecular weight as that predicted from cloned SlitPBPs (~16 kD), and this protein reacted strongly with antibody against SexigPBP1. In addition, the targeted band intensity in male antennae was much higher than that in female antennae, in agreement with male-based detection of the female-produced *S. litura* sex pheromone.

Tissue Distribution of Expression RT-PCR experiments were performed by using specific primers (Table 1) to determine the tissue distribution of the PBPs from *S. litura* (Fig. 6). RT-PCR products of the predicted size were observed exclusively in reactions with antennal cDNA of both sexes. No specific product was observed with head (without antennae), thorax, abdomen, or leg cDNA. The integrity of the cDNA templates prepared from different tissues was verified by primers specific for the *actin* gene. In all cDNA preparations, an *Actin* amplification product of the correct size was amplified. Larger bands that might have been generated from amplification of genomic DNA were not found. Therefore, *SlitPBP1* and *SlitPBP2* are only expressed in antennae.

PBP Gene Expression Between the Sexes Real-time PCR was performed to compare the transcription levels of *SlitPBP1* and *SlitPBP2* from antennae of male with female moths. For each sex, cDNA was synthesized from mRNA isolated from pools of 200 antennae. To validate the $\Delta\Delta C_T$ calculation, a pilot experiment was conducted to look at how ΔC_T ($C_{T,Target} - C_{T,Actin}$) varies with a tenfold serial dilution of template cDNA. The results indicated that the absolute value of the slope of the entire dilution curve is close to zero (data not shown). Therefore, the efficiencies of the target and reference genes are similar, and the $\Delta\Delta C_T$ calculation method can be used for the relative quantification.

The levels of transcription of PBP genes in antennae were higher in male than in female moths. The amounts of *SlitPBP1* and *SlitPBP2* mRNA in female antennae were about 2.1% and 7.0%, respectively, relative to those in male antennae. The transcription level of *SlitPBP2* was 31.4% of that of *SlitPBP1* in male moths, but *SlitPBP1* and *SlitPBP2* had similar amounts (100:95.3) in female tissues (Table 3).

Discussion

Two novel PBPs were identified from the antennae of *S. litura.* They bear all the hallmarks of the PBP family including a signal peptide, a major hydrophobic domain, and particularly the six conserved cysteine residues among Lepidopteran OBPs. These six cysteine residues are connected by three interlocking disulfide bridges in the native OPPs (reviewed by Pelosi et al. 2006). Western blot analysis with antiserum against SexigPBP1 indicates a single protein band of the correct size in both male and female antennae, further supporting the identification of the two SlitPBPs. The identification of these two SlitPBPs adds new members to the moth PBP family, and enables future studies on structure–function relationship in PBPs, partic-

ularly with respect to their discriminating ability among different pheromone components.

PBPs had been long regarded as specific to male antennae since their first identification in *A. polyphemus* (Vogt and Riddiford 1981; Laue and Steinbrecht 1997). However, PBP expression in female antennae now has been detected in many moth species (Krieger et al. 1996; Nagnan-Le Meillour et al. 1996; Callahan et al. 2000; Picimbon and Gadenne 2002; Maida et al. 2005; de Santis et al. 2006; Xiu and Dong 2007). In our present study with *S. litura*, we also found that both PBPs are also expressed in female antenna (Fig. 6). In fact, PBPs have been detected in antennae of all female moths examined so far when RT-PCR is used, a method far more sensitive than Western blot analysis. Therefore, it seems all female moths might express PBP in the antenna, although the expression levels might be lower than in male antennae and could vary according to species. Several studies have shown female autodetection of sex pheromone by electroantennography assay (Ljungberg et al. 1993; Ochieng et al. 1995; Schneider et al. 1998; Fan et al. 2003). The possible capacity for females to have a feedback control of their pheromone release has been proposed by Vogt et al. (2002). Nevertheless, the function and behavioral significance of PBPs in female moths remains elusive.

It is commonly recognized that the discrimination of pheromone components is performed by highly specific receptor proteins on the dendrite membrane of the olfactory neurons (Krieger et al. 2005; Nakagawa et al. 2005). In addition, the finding of multiple PBPs in a single insect species suggests that PBPs may also play a role in the differentiation of pheromone components by different binding capacity with pheromones. Quantification of the relative expression levels of each PBP could provide some clue for elucidating the functions of different PBPs. Unfortunately, the traditional immunoblot method with a PBP antibody does not differentiate different PBPs. It lacks selectivity among PBPs, even from different moth species. RT-PCR with specific primers can differentiate PBPs, but it is not a quantitative method. In the present study, we quantified the relative expression levels of the two SlitPBPs by using real-time PCR, and found that the expression levels of PBP1 is three times higher than that of PBP2 in male antennae, and this relative expression between PBP1 and PBP2 agrees with the quantitative ratio (100:27) of two

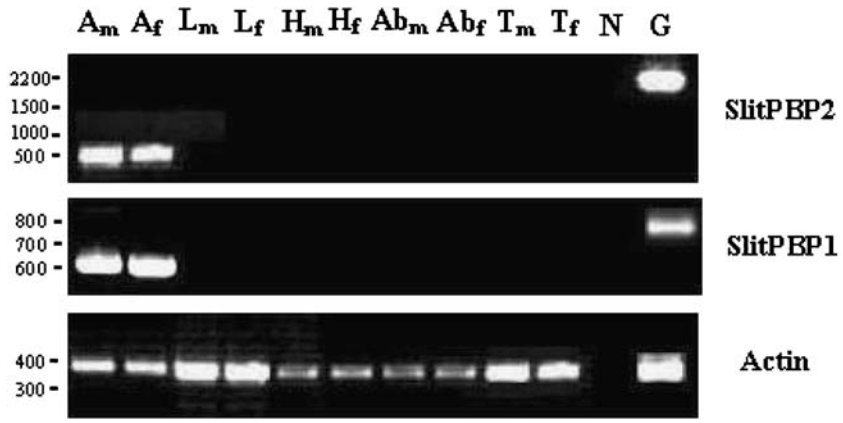

Fig. 6 Tissue-specific expression of *SlitPBP1* and *SlitPBP2*. RT-PCRs were performed by using RNAs isolated from the different tissues. Amplification products were analyzed on agarose gels and visualized by UV illumination after staining with ethidium bromide. Based on the primer design, the sizes of the expected PCR-products were 617 bp for *SlitPBP1*, 507 bp for *SlitPBP2*, and 377 bp for *Actin* (control). A_m Male antenna, A_f female antenna, H_m male head (without antenna), H_f female head (without antenna), T_m male thorax, T_f female thorax, Ab_m male abdomen, Ab_f female abdomen, L_m male leg, L_f female leg, *N* no-template (negative control) ensures the specificity of the amplifications, *G* genomic DNA template reaction indicates the relative position of PCR product derived from genomic DNA contamination in experimental samples. The position of molecular weight markers (bp) is indicated on the *left side*

main active sex pheromone components (*Z*9,*E*11-14:Ac to *Z*9,*E*12-14:Ac) in the female sex pheromone gland in *S. litura* (Sun et al. 2002). However, it is unlikely that the two PBPs selectively bind to two different pheromone components, respectively, because in *S. exigua*, *Z*9,*E*12-14:Ac is the most abundant pheromone component, and the expression level of *SexiPBP1* is also much higher than that of *SexiPBP2* (Xiu and Dong 2007). Binding assays between PBPs and pheromone components would provide a clearer picture of whether and to what extent binding selectivity exists in *S. litura* and *S. exigua*.

Insects appeared in the geological record about 400 million years ago (Mya) and include more than 800,000 identified species with upper estimates ranging from 1.5–30 million species (Erwin 1982; Kristensen 1991; Vogt et al. 2002). The Noctuidae are thought to have evolved as a taxon as early as 100 Mya (Pashley and Ke 1992). The two *SlitPBPs* and other moth PBP genes share the same exon/intron number and conserved exon/intron boundaries and positions (Fig. 3), which suggests a common PBP ancestor of these genes. A previous phylogenetic analysis of deduced amino acid sequences revealed three distinct groups of Noctuid PBPs (Xiu and Dong 2007). We elected to name these group-1 through group-3, with group-1 being the most ancestral. The clustering suggests that two duplication events might have occurred during noctuid PBP gene evolution, but we hypothesized that these duplications occurred before the differentiation of the Noctuidae (Xiu and Dong 2007). The two duplication events lead to the three distinct PBP groups, and group-2 and group-3 PBP have been found commonly in the Noctuidae, whereas Group-1 PBP have been identified rarely in these species (Fig. 4).

In contrast to the similarities among the amino acid sequences of PBPs of each group, the introns of PBPs display greater variation, particularly in their lengths (Table 4). First, both introns of group-2 PBP genes in *S. litura* and *S. exigua* are only about 100 bp, much shorter than introns from group-2 PBP genes of other species. Second, when compared with the sequences of two *Agrotis* moths, introns in group-3 PBP genes are much longer than those in group-2 genes. These differences indicate that the introns are under weaker selective pressure than exons in the evolution of moth PBPs. More generalized conclusions on introns and their implications in PBP evolution can be proposed when additional intron data become available from additional noctuid species.

Table 4 Intron lengths of known PBPs of the Noctuidae and Bombycidae

Family	Species	PBP Group in Noctuidae	PBP Name	GenBank Accession Number	First Intron (bp)	Second Intron (bp)	Second Intron/First Intron in Length
Bombycidae	*B. mori*		BmorPBP1	Gene Scaffold010822	701	427	
			BmorPBP2		782	630	
			BmorPBP3		229	701	
Noctuidae	*A. ipsilon*	Group-2	AipsPBP2	AY973627	458	564	1.23

Bidens pilosa L. Exhibits High Sensitivity to Coumarin in Comparison with Three Other Weed Species

Received: 11 September 2007 / Revised: 8 February 2008 / Accepted: 11 February 2008 / Published online: 13 March 2008

Abstract Nine natural plant compounds were screened for phytotoxicity to *Bidens pilosa* L. a troublesome weed in field and plantation crops. The sensitivity of three other weed species to coumarin, the most active identified compound, was also evaluated. Coumarin, at a concentration of 500 μM, had little effect on germination and growth of *Senna obtusifolia* L., *Euphorbia heterophylla* L., and *Ipomoea grandifolia* L. when compared with its effects on *B. pilosa* L. In a concentration range of 10–100 μM, coumarin caused a dose-dependent inhibition of germination and growth of *B. pilosa* L. The measurements of some parameters of energy metabolism revealed that coumarin-treated root tissues exhibited characteristics of seedlings in an earlier stage of growth, including higher respiratory activity and higher activities of alcohol dehydrogenase and lipoxygenase. These results suggest that coumarin inhibition of germination and growth of *B. pilosa* L. was not a consequence of an impairment of energy metabolism. Rather, it seems to act as a cytostatic agent, retarding germination. At concentrations above 50 μM, coumarin increased lipoxygenase activity and the level of conjugated dienes of root extracts, suggesting that it may induce oxidative stress in seedling roots.

COX	cytochrome oxidase
DTT	dithiothreitol
EDTA	ethylene diamide tetracetic acid
KCN	potassium cyanide
MDA	malondialdehyde
TBA	2-thiobarbituric acid
TCA	trichloroacetic acid

Introduction

Bidens pilosa L., an annual native of tropical America, is a dicot weed of the *Asteraceae* family. The species is a troublesome weed in field and plantation crops in more than 40 countries (Holm et al. 1977). In Brazil, it is responsible for yield losses of several crops, particularly soybean. It was demonstrated that *B. pilosa* L. first evolved resistance to herbicides known as acetolactase synthase inhibitors in 1993, and there were estimates that the resistant biotype continues to increase its distribution and prevalence (Christoffoleti and Foloni 1999). Because of increasing incidence of weeds evolving resistance to many commercial herbicides, there is growing interest in the development of alternative methods for weed control based on natural products. Plants produce thousands of secondary products that represent a large reservoir of novel chemical structures with biological activity. The use of plant species

with weed-suppressing ability thus has been considered for biological weed management in crop production (Putnam and Duke 1974; Macías 1995; Wu et al. 1999; Duke et al. 2000; Vyvyan 2002; Khanh et al. 2006). Numerous secondary plant products of the phenolic, flavonoid, and terpenoid classes have been implicated as compounds responsible for plant growth suppression (Reigosa et al. 1999; Vaughn and Spencer 1993; Dudai et al. 1999; Duke et al. 2000; Chon and Kim 2004; Kohli et al. 2006). However, there are fewer studies that are concerned with modes of action. Mitochondrial respiratory metabolism is essential to produce energy and precursors for biosynthesis of new cellular structures. An effect on respiratory metabolism could be a mode of action of natural compounds in suppressing the germination and growth of weeds.

In view of this, the aim of the present work was to identify which among nine compounds exerts high and selective phytotoxicity on *B. pilosa* L. We chose representative compounds of the phenolic and terpenoid classes, namely, caffeic, *p*-coumaric, ferulic, protocatechuic, and vanillic acids, coumarin, flavone, camphor, and eucalyptol. The effects of coumarin, the most active identified compound, on biochemical processes, critical for seed germination and seedling growth, were also evaluated. For the latter purpose, respiratory activity and the activity of alcohol dehydrogenase (EC 1.1.1.1) in seedling roots during postgerminative growth were measured. Some parameters of oxidative stress were also evaluated, including lipoxygenase activity (EC 1.13.11.12) and the content of malondialdehyde and conjugated dienes.

Methods and Materials

Reagents Camphor, caffeic acid, eucalyptol, *p*-coumaric acid, coumarin, ferulic acid, flavone, protocatechuic acid, vanillic acid, NAD^+, linolenic acid, and 2-thiobarbituric acid (TBA) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Reagents were of the purest grade available.

Seed Germination and Growth Seeds of *B. pilosa* L., *Euphorbia heterophylla* L., *Senna obtusifolia* L., and *Ipomoea grandifolia* L. were purchased from a commercial supplier (Cosmos Agrícola Produtos e Serviços Rurais Ltda, Brazil). Seeds were surface-sterilized in a 1.0% sodium hypochlorite solution. After washing in distilled water, seeds were placed on a double sheet of germination paper in plastic germination boxes (gerbox; 110×110 mm), moistened with 5–12 ml of distilled water or plant natural compound solutions at a concentration of 500 μM. Ferulic, caffeic, vanillic, and protocatechuic acids were dissolved in distilled water. Camphor, eucalyptol, flavone, and coumarin were dissolved in a 0.1% dimethylsulfoxide solution. Flavone was assayed at a concentration of 250 μM because of its low solubility in the 0.1% dimethylsulfoxide solution. Coumarin was assayed in a concentration range of 10 to 100 μM. Controls were performed to exclude the interference of dimethylsulfoxide, but no significant changes in seedling growth were found. Each treatment was applied to three plates (replicates), and each replicate consisted of 50 seeds distributed over gerbox. Experiments were repeated four to six times. Boxes were placed in a growth chamber programmed for the following regime for *B. pilosa* L.: 8/16 hr L/D, 30°/20°C. *E. heterophylla* L. seeds were allowed to germinate and grow at 25°C and on a 12/12 hr L/D photoperiod. The regimes for *S. obtusifolia* L. and *I. grandifolia* L. were 30°C and 12/12 hr L/D photoperiod. The photon flux density of the growth chamber was approximately 230 μmol m^{-2} s^{-1} photon flux. A seed was considered germinated when the radicle was 2.0 mm or longer. Seeds that had germinated at 2, 4, or 6 d were selected for growth tests. Seedlings were removed, dried on filter paper, and the primary roots were excised for measurements of their length and fresh weight. Data were expressed as centimeters or milligrams per root. The mean germination time was calculated according to Eq. 1 (Labouriau and Osborn 1984):

$$\bar{t} = \sum n_i t_i \Big/ \sum n_i \qquad (1)$$

$\bar{t}$ Mean germination time
n Number of germinated seeds between the times t_{i-1} and t_i

Respiration of Excised Primary Roots Oxygen consumption of primary roots from *B. pilosa* L. seedlings was measured polarographically at 25°C with a Clark-type electrode positioned in a closed plexi-glass chamber. Primary roots were removed from seedlings and rinsed in distilled water. For each measurement, samples of six roots were cut into segments 5–10 mm long as measured from the growth apex, weighed, and placed immediately in the oxygen electrode vessel that contained 2 ml of nutrient solution (pH 5.8) containing 2 mM $Ca(NO_3)_2$, 2 mM KNO_3, 0.43 mM NH_4Cl, 0.75 mM $MgSO_4$, and 20 μM NaH_2PO_4 (Larkin 1987). For estimating the contribution of the mitochondrial cytochrome oxidase (COX; KCN-sensitive respiration) and mitochondrial alternative oxidase (AOX) plus extramitochondrial oxidases (KCN-insensitive respiration) to the overall O_2 uptake, 270 μM potassium cyanide (KCN) were added to the reaction medium. Oxygen uptake was monitored for 12–15 min. Uptake rates were calculated from the polarographic records considering an initial concentration of dissolved oxygen of 240 μM at

25°C (Estabrook 1967) and referred to the fresh weight of the roots.

Alcohol Dehydrogenase Activity Alcohol dehydrogenase activity was assayed in root extracts from seedlings grown in the absence of coumarin for 2, 3, or 4 d or in the presence of coumarin (10–50 μM) for 4 d. Primary roots (approximately 0.2 g fresh weight) were excised from the seedlings, weighed, and transferred to a mortar, thoroughly mixed with 3.0 ml of a medium that contained 50 mM Tris–HCl (pH 7.4), 1.0 mM ethylene diamide tetracetic acid, and 2.0 mM dithiothreitol. Extracts were centrifuged for 20 min at 20,000×*g* and 5°C. The supernatant was decanted and used as the enzyme source. Alcohol dehydrogenase activity was measured according to Lee (1982). The reaction medium contained 50 mM Tris–HCl (pH 7.4), 1.0 mM NAD^+, and 200 μl of enzyme extract. The reaction was initiated by the addition of 120 μM *n*-propanol. Enzyme activity was evaluated as the initial rate of NAD^+ reduction, which was calculated from the increase in absorbance at 340 nm. Enzyme activity was expressed as μmol min^{-1} (g fresh weight)$^{-1}$.

Lipoxygenase Activity Lipoxygenase activity was assayed in the root extracts from seedlings grown in the absence of coumarin for 2, 3, or 4 d or in the presence of coumarin (10–50 μM) for 4 d. Primary roots (approximately 0.2 g fresh weight) were weighed and transferred to a mortar and thoroughly mixed with 1.5 ml of a cold 50 mM K-phosphate (pH 7.0) solution containing 0.1% Triton X-100 (*v*/*v*). Extracts were centrifuged for 10 min at 12,000×*g* and 5°C. The supernatant was decanted and used as the enzyme source. Lipoxygenase was measured polarographically with a Clark-type oxygen electrode according to Siedow and Girvin (1980). The reaction medium contained 200 mM K-phosphate (pH 7.0) and 200 μl of enzyme extract. The reaction was initiated by the addition of linolenic acid (3.0 mM final concentration), dissolved in Tween 20. Oxygen uptake was monitored for 12–15 min, and the enzyme activity was expressed as μmol O_2 min^{-1} (g root fresh weight)$^{-1}$. Controls were run to exclude solvent effects.

Lipid Peroxidation Products The level of lipid peroxidation in primary root extracts was measured in terms of malondialdehyde (MDA) and conjugated diene contents. Approximately 200 mg of excised roots were homogenized in 4.0 ml of 96% (*v*/*v*) ethanol. The content of malondialdehyde (MDA) was assayed in 3.0 ml of the homogenate (Heath and Packer 1968). An equal volume of 10% trichloroacetic acid that contained 0.5% TBA was added to the homogenate. The mixture was heated to 95°C for 30 min and cooled quickly in an ice bath. After centrifuging at 10,000×*g* for 10 min, absorbance of the supernatant at 532 nm was read. The value for nonspecific absorbance at 600 nm was subtracted. The concentration of MDA was calculated by using its extinction coefficient of 155 mM^{-1} cm^{-1} and expressed as nmol (g root fresh weight)$^{-1}$.

For the conjugated diene measurement, a 1.0-ml aliquot of homogenate was mixed into an equal volume of 96% ethanol and centrifuged at 12,000×*g* for 10 min (Boveris et al. 1980). Absorbance of the supernatant was read at 234 nm, and the nonspecific absorbance at 500 nm was subtracted. Concentration of the conjugated dienes was calculated by using the extinction coefficient of 2.65×10^4 M^{-1} cm^{-1} and expressed as μmol (g root fresh weight)$^{-1}$.

Statistical Analysis The data shown in the graphs and tables were expressed as means±standard errors (SEM) of independent preparations. Data were analyzed with Student's *t* test or analysis of variance (ANOVA), significant differences between means being identified by Duncan's test. The comparisons are given in the text as probability values (*P*). $P\leq0.05$ being adopted as the minimum criterion of significance. The ID_{50} was computed by numerical interpolation by means of a cubic spline function. Statistical analyses were performed by using the Statistica™ software package.

Results

Effects on Germination and Growth The present work revealed different effects and potencies for each tested compound on *B. pilosa* (Table 1). Germination and seedling growth inhibition among the cinnamic acid derivatives varied greatly. At 500 μM, ferulic acid reduced germination to 42% of the control at the second day, but when germination occurred, the lengths and the fresh weights of the seedling roots were not modified. After 2 days, no significant modifications were observed. Vanillic acid, in contrast, did not affect seed germination, but reduced the growth of seedling roots at the fourth day. Caffeic, *p*-coumaric, and protocatechuic acids were inactive.

The actions of monoterpenes were also variable. Whereas eucalyptol was inactive, camphor inhibited both germination and growth of *B. pilosa*. At 500 μM, it reduced germination by 81% and 40% on the second and fourth days, respectively. The lengths and the fresh weights of the seedling roots were 39% and 51% reduced, respectively, on the second day. On the fourth day, the corresponding values were 19% and 11%.

Flavone, at 250 μM, had weak activities on *B. pilosa*. Germination was 13% reduced at day 4, but the lengths and

the fresh weights of the seedling roots of germinated seeds were not modified.

Coumarin was the most phytotoxic among all assayed compounds. At the 500 μM concentration, it completely suppressed germination of *B. pilosa*.

Effects of Coumarin on Germination and Growth of E. heterophylla, I. grandifolia, and S. obtusifolia To evaluate whether the phytotoxicity of coumarin is species specific, the effects of 500 μM coumarin on germination and growth of *I. grandifolia*, *S. obtusifolia*, and *E. heterophylla* were examined (Table 2). Germination of *S. obtusifolia* was completely inhibited by the second day, but by the fourth day, the number of germinated seeds was not different from that of the control. No significant modification was found in the germination of *E. heterophylla* and *I. grandifolia*, although coumarin affected seedling growth. The lengths of primary roots of *E. heterophylla* and *S. obtusifolia* were reduced without significant reduction in fresh weights, whereas in *I. grandifolia*, a reduction in both growth parameters was observed by the second day. Comparison among species reveals that coumarin was more phytotoxic

Table 2 Germination percentage, length, and fresh weight of primary roots of *E. heterophylla* L., *I. grandifolia* L., and *S. obtusifolia* L. incubated for 2 or 4 d in 1% (*v*/*v*) DMSO or in 500 μM coumarin

to *I. grandifolia* than to *E. heterophylla* and *S. obtusifolia*. However, the phytotoxicity of coumarin on *B. pilosa* was significantly higher (at the same concentration [500 μM] ,it completely suppressed germination of this weed [Table 1]). This finding led us to perform a more extensive investigation of coumarin effects on *B. pilosa*.

Effects of Coumarin on Germination and Growth of B. pilosa When *B. pilosa* seeds were incubated in the presence of coumarin in the concentration range of 10–100 μM for 6 d, both seed germination and seedling root growth were significantly inhibited (Fig. 1). At d 2, complete suppression of seed germination was observed with coumarin at the 50 μM concentration or higher (Fig. 1a). The calculated ID_{50} were 10.6±2.1 μM, 23.8±4.5 μM, and 21.3±4.4 μM for germination, root length, and root fresh weight, respectively. At subsequent periods (d 4 and 6), germination and root growth were also reduced, though to lesser degrees. The ID_{50} for germination was increased to 46.5± 2.7 and 89.9±2.1 μM on the fourth and sixth day of incubation, respectively. Mean germination time increased from 88.4±4.5 hr in the control to 94.0±2.7, 105.8±2.6, 122.8±1.1, and 129.1±2.8 hr with 10, 25, 50, and 100 μM coumarin, respectively. Root fresh weight was reduced to a lesser extent compared to reduction of root length. At d 6, for example, coumarin up to 50 μM had not affected root fresh weight, while an inhibitory action on root length was observed with 10 μM coumarin.

After 4 d of incubation, the first leaves were visible, indicating that photosynthesis had started to contribute to seedling energy metabolism. Thus, the subsequent experiments were performed with seedlings grown for a maximum of 4 d, assuring that the contribution of mitochondrial respiration to seedling energy metabolism was predominant.

Effects of Coumarin on Respiratory Activity of Excised Primary Roots and on Activities of Alcohol Dehydrogenase and Lipoxygenase in Primary Root Extracts Respiratory activity of primary roots and activity of alcohol dehydrogenase and lipoxygenase in the control series (absence of coumarin) were measured in seedlings grown for 2, 3, and 4 d. As shown (Fig. 2), all these parameters were higher shortly after the emergence of primary roots (d 2) and decreased progressively during the subsequent growth period. From the second to the fourth day, the overall O_2 consumption rates were reduced by 40% on a fresh-mass basis. The relative contribution of the KCN-sensitive respiration to the overall respiration decreased from 73.9% at d 2 to 68.9% at d 4. The decline in the activities of alcohol dehydrogenase and lipoxygenase during the growth period was more accentuated (Fig. 2). At d 3 and 4, alcohol dehydrogenase activity was, respectively, 33.2% and 8.6% of that one found on d 2. Lipoxygenase activity decreased

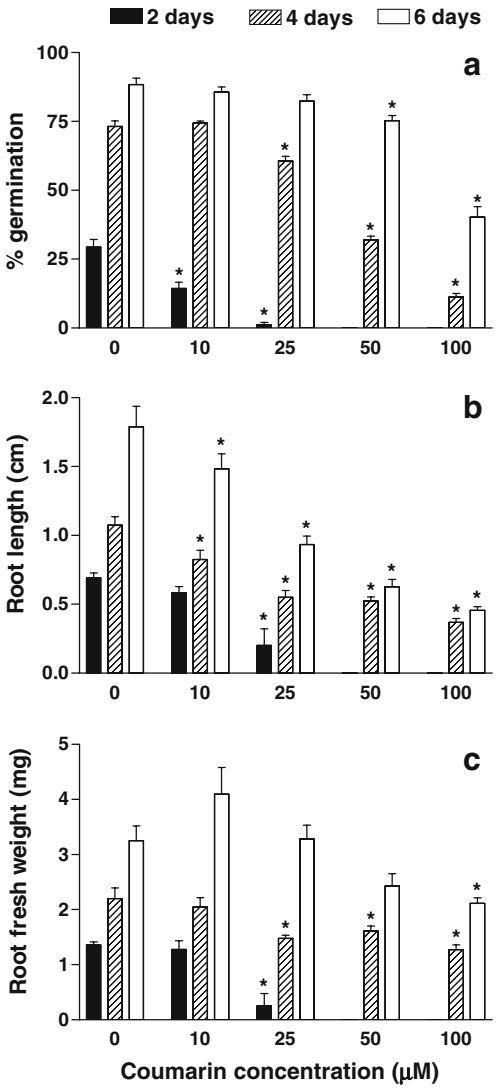

Fig. 1 The effects of coumarin on germination (**a**), root length (**b**), and root fresh weight (**c**) of *Bidens pilosa* L. Seeds were germinated and grown on the following regime: 8 hr light, at 30°C, 16 hr dark, at 20°C, photon flux density of approximately 230 μmol m^{-2} s^{-1}. Coumarin (10–100 μM) was added to the nutrient solution, and at each experimental interval (2, 4, or 6 d), roots were excised and their lengths and fresh weights were measured. All values are means of three to five independent experiments. *Error bars* are SEM. Significant differences between coumarin-treated and untreated seedlings were identified by ANOVA with Duncan's testing (*$P<0.05$)

28.4% on d 3 and 14.3% on d 4 relative to the value found on the second day.

The effects of coumarin at a concentration range of 10–100 μM were evaluated only in seedlings grown for 4 d (Fig. 3). At shorter time intervals, insufficient material was available for measurements because of the strong inhibition in seedling growth.

In contrast to what happened with germination and seedling growth (Fig. 1), overall respiration rates of root apices from seedlings grown for 4 d were stimulated in a dose-dependent manner by coumarin up to 50 μM

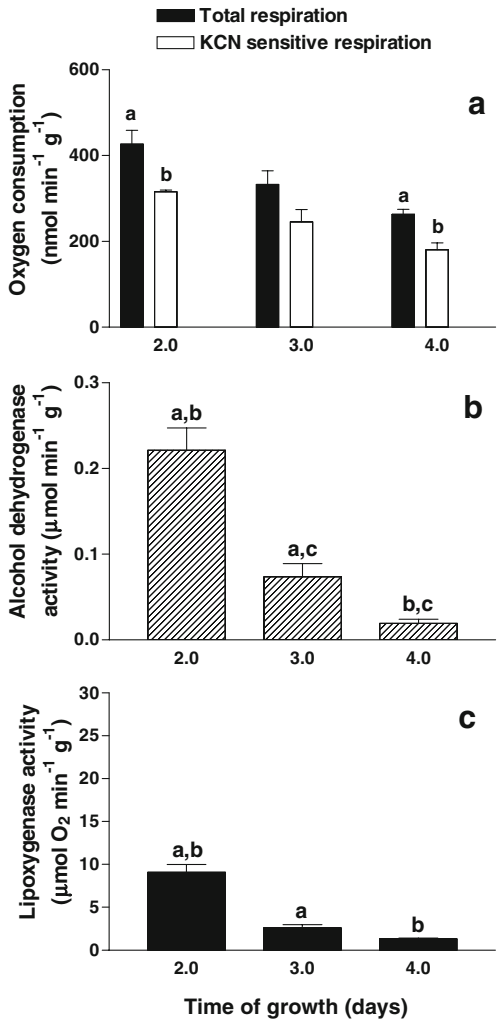

Fig. 2 Time course of respiration rates (**a**), alcohol dehydrogenase (**b**), and lipoxygenase (**c**) activities in roots of *B. pilosa* L. seedlings. In **a**, primary root tip samples were removed from seedlings and added without delay to the oxygen electrode vessel, containing 2.0 ml of nutrient medium in the absence or presence of 270 µM KCN. Oxygen consumption was followed polarographically over approximately 12–15 min. Total respiration: rate of oxygen consumption in the absence of inhibitors; KCN-sensitive respiration: difference between the rates of oxygen consumption measured in the absence and presence of KCN; Alcohol dehydrogenase activity (**b**) was measured in reaction medium containing 1.0 mM NAD^+ and 120 µM *n*-propanol. Lipoxygenase activity (**c**) was measured polarographically in the presence of 3.0 mM linolenic acid. Each data point is the mean value of four (**a**), three (**b**), or three (**c**) independent experiments. *Error bars* are SEM. *Pairs of letters* indicate statistical significance as determined by ANOVA with Duncan's testing ($P<0.05$)

(Fig. 3a). KCN-sensitive respiration was similarly stimulated, so that its relative contribution to overall respiration was not modified. It constituted 68.9% of overall respiration in the control condition and 67.8, 68.3, 70.8, and 66.4% in the presence of 10, 25, 50, and 100 µM coumarin, respectively.

Activities of alcohol dehydrogenase and lipoxygenase in root extracts from seedlings grown for 4 d were also stimulated in a dose-dependent manner by coumarin. The activity of alcohol dehydrogenase increased 4.6- and 9.3-fold, in the presence of 25 and 50 µM coumarin, respectively (Fig. 3b). Under the same conditions, the lipoxygenase activity increased 5.7- and 14.7-fold, compared to untreated seedlings (Fig. 3c).

To examine the possibility that lipoxygenase stimulation was a response to a cellular oxidative stress condition, we measured the content of malondialdehyde (MDA) and conjugated dienes in roots of seedlings grown in the presence of 25 and 50 µM coumarin (Table 3). An increment of nearly fourfold in conjugated dienes content

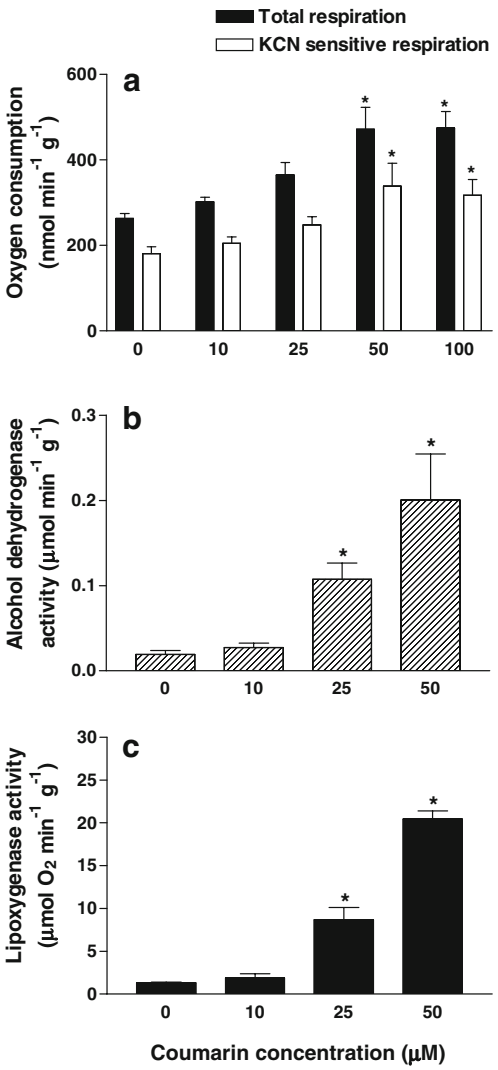

Fig. 3 Effects of coumarin on respiration rates (**a**), alcohol dehydrogenase (**b**), and lipoxygenase (**c**) activities in roots of *B. pilosa* L. seedlings. Seedlings were grown for 4 d in the absence or presence of coumarin (concentration range 10–100 µM). Respiration rates and the activities of lipoxygenase and alcohol dehydrogenase were measured as described in legend of Fig. 2. All values are the means of 4 (**a**), 3–4 (**b**), or 3 (**c**) independent experiments. *Error bars* are SEM. Significant differences between coumarin-treated and untreated seedlings were identified by ANOVA with Duncan's testing (*$P<0.05$)

Table 3 Effects of coumarin (25 and 50 μM) on the content of malondialdehyde (MDA) and conjugated dienes in primary roots from *Bidens pilosa* seedlings grown for 4 days

Coumarin Concentration	MDA (N=3)	Conjugated Dienes (N=6)
μM	nmol (g root fresh weight)$^{-1}$	μmol (g root fresh weight)$^{-1}$
0	14.3±2.4	3.18±0.21[a]
25	8.85±0.8	3.78±0.49[b]
50	12.3±1.4	15.68±2.06[a,b]

Values are expressed as mean±SE. Pairs of letters in each column indicate statistical significance as determined by ANOVA with Duncan's testing (P<0.05)

was found in 50 μM-treated seedlings, with no significant changes in MDA content.

Discussion

The study revealed different effects and potencies on *B. pilosa* for each compound tested. Coumarin was the most phytotoxic. Among the cinnamic derivatives, only ferulic and vanillic acids were active. Cinnamic acid derivatives possess in their structures a phenyl group with different substituents. Ferulic and vanillic acids possess in common the methoxyl substituent, which is absent in the other cinnamic acid derivatives. This group seems to be a critical factor in the inhibition of germination and growth of *B. pilosa*. This characteristic seems uncommon in other plant species such as *Arabidopsis thaliana* (Reigosa and Pazos-Malvido 2007) and *Amaranthus retroflexus* (Reigosa et al. 1999). In those studies, radicle growth of both species was reduced by ferulic and vanillic acids and also by *p*-coumaric and protocatechuic acids, which do not possess a methoxy group substituent.

Activities of the monoterpenes eucalyptol and camphor were also different. Both terpenes possess in common a hydrocarbonated cyclical structure and an oxygenated substituent, an ether function in eucalyptol and a ketone function in camphor. Camphor's higher solubility (Vaughn and Spencer 1993; Fischer et al. 1994) could have exerted some influence on its *B. pilosa* activity. Solubility did not seem to be a differential factor for coumarin and flavone activity. Both compounds are practically insoluble in water, but despite the fact that they are structurally related, flavone had weak activities on *B. pilosa*. The benzopyranone group of coumarin is an integral part of the structure of flavone, which possesses a phenyl substituent in position 2 of the benzopyranone group. This substituent apparently suppresses biological activity of the benzopyranone group in *B. pilosa*. This interpretation is consistent with the work of Richard et al. (1950), which demonstrated that the introduction of substituents in positions 3 and 4 of the benzopyranone group reduces the inhibitory potential of derivatives on the growth of *Avena* roots.

The phytotoxicity of coumarin seems to be species specific, as *E. heterophylla*, *S. obtusifolia*, and *I. grandifolia* were less sensitive. Coumarin and its derivatives are produced by plants of almost all families and are found on the surfaces of leaves, seeds, and fruits (Zobel and Brown 1995; Chon et al. 2003; Chon and Kim 2004; Khanh et al. 2006). There are a number of reports concerning the effects of coumarin on crop species, the responses also being species specific and concentration dependent (Murray et al. 1982). For example, at 680 μM, coumarin completely inhibits root growth of *Cucumis sativus* and *Zea mays* seedlings, but causes only slight inhibition of *Pisum sativum* root growth (Kupidlowska et al. 1994). Inhibition of *Triticum turgidum* ssp. *durum* seed germination was reported to occur at concentrations above 200 μM (Abenavoli et al. 2004, 2006). From this study, it is clear that *B. pilosa* has high sensitivity to coumarin in comparison with most assayed weed or crop species.

Several explanations for coumarin inhibitory action on germination have been proposed, including inhibition of cellulose synthesis (Hara et al. 1973), auxin-like activity (Jansson and Svensson 1980), inhibition of photosynthesis (Moreland and Novitzky 1987), uncoupling of mitochondrial oxidative phosphorylation (Knypl 1964; Yakushkina and Starikova 1978), blocking of the cell cycle (Zobel and Brown 1995), antimitotic action (Podbiekowska et al. 1994), inhibition of cell division and cell elongation (Svensson 1972), and inhibition of amino acid transport and protein synthesis (Van Sumere et al. 1972). The simplest explanation for the observed reduction in root seedling growth associated with increased KCN-sensitive respiration is that in *B. pilosa*, coumarin is acting as an uncoupler of mitochondrial oxidative phosphorylation. In this context, the observed increase in alcohol dehydrogenase activity would be interpreted as a compensatory increase of anaerobic ATP synthesis. However, comparisons between the metabolic parameters measured in seedlings grown in the presence of coumarin for 4 days and those of the control series (absence of coumarin) measured at days 2, 3, and 4 point to an alternative mechanism. Respiratory activity and the activities of alcohol dehydrogenase and lipoxygenase in the control series were higher shortly after the emergence of primary roots (d 2) and decreased progressively during the growth period. These results suggest that ATP production was provided by alcohol dehydrogenase activity only in the early stage of root growth with subsequent predominance of the mitochondrial ATP-generation pathway. The decline in KCN-sensitive respiration observed during the growth period

may represent a reduction in ATP demand due to progressive reduction in the root relative growth.

From these observations, it is plausible to suggest that the observed higher root respiration and alcohol dehydrogenase and lipoxygenase activities of seedlings grown for 4 days in the presence of coumarin are not consequences of an impairment on energy metabolism, but represent the metabolic status of seedlings at a different physiological age, i.e., in an earlier stage of growth. Coumarin probably acted by inducing a delay in seed germination and seedling growth. This conclusion is corroborated by the observation that the mean values of all parameters measured in seedlings grown in the presence of 50 μM coumarin for 4 days were statistically equal to those of seedlings grown for 2 days in the absence of coumarin. The only exception was the lipoxygenase activity, which was substantially higher in the presence of 50 μM coumarin.

Although the exact mechanism of germination and growth inhibition remains to be elucidated, our results corroborate the hypothesis that coumarin acts as a cytostatic agent, as suggested by its reported effects on mitosis and cell division (Svensson 1972; Podbiekowska et al. 1994; Zobel and Brown 1995).

Coumarin at higher concentrations also exerts an additional phytotoxic action in *B. pilosa* as indicated by the higher activity of lipoxygenase and the high content of conjugated dienes in root extracts. Activation of lipoxygenase is believed to be one of the immediate responses to changes in cell membrane structure induced by different agents including oxygen reactive species that can be generated in response to a variety of stress conditions (Siedow 1991; Porta and Rocha-Sosa 2002; Blokhina et al. 2003). The MDA content was presumably not increased because the products of lipid peroxidation were further oxidized or metabolized (Beuge and Aust 1978; Muscari et al. 1990). The hypothesis that coumarin induces a condition of oxidative stress was also suggested by Abenavoli et al. (2003, 2006) based on changes in antioxidant enzyme activities in durum wheat (*Triticum turgidum*) seedlings. In this plant species, however, the effects occurred at a concentration of 1,000 μM.

From the present study, it can be concluded that coumarin has a strong and selective ability to suppress the germination and growth of *B. pilosa* and might be effectively exploited as a natural herbicide. For example, the use of plants with high coumarin content (Macías et al. 1993; Chon et al. 2003; Chon and Kim 2004; Khanh et al. 2006) could be used in intercropping systems to reduce *B. pilosa* germination and growth.

Increased Terpenoid Accumulation in Cotton (*Gossypium hirsutum*) Foliage is a General Wound Response

Stefan Opitz · Grit Kunert · Jonathan Gershenzon

Received: 4 December 2007 / Revised: 8 February 2008 / Accepted: 12 February 2008 / Published online: 2 April 2008

Abstract The subepidermal pigment glands of cotton accumulate a variety of terpenoid products, including monoterpenes, sesquiterpenes, and terpenoid aldehydes that can act as feeding deterrents against a number of insect herbivore species. We compared the effect of herbivory by *Spodoptera littoralis* caterpillars, mechanical damage by a fabric pattern wheel, and the application of jasmonic acid on levels of the major representatives of the three structural classes of terpenoids in the leaf foliage of 4-week-old *Gossypium hirsutum* plants. Terpenoid levels increased successively from control to mechanical damage, herbivory, and jasmonic acid treatments, with *E*-β-ocimene and heliocide H_1 and H_4 showing the highest increases, up to 15-fold. Herbivory or mechanical damage to older leaves led to terpenoid increases in younger leaves. Leaf-by-leaf analysis of terpenes and gland density revealed that higher levels of terpenoids were achieved by two mechanisms: (1) increased filling of existing glands with terpenoids and (2) the production of additional glands, which were found to be dependent on damage intensity. As the relative response of individual terpenoids did not differ substantially among herbivore, mechanical damage, and jasmonic acid treatments, the induction of terpenoids in cotton foliage appears to represent a non-specific wound response mediated by jasmonic acid.

Introduction

Plants produce a broad range of defense chemicals that act as deterrents or toxins against herbivores and pathogens. Several different strategies have evolved concerning the deployment of such compounds. When the synthesis of defense chemicals occurs solely after initial attack, this reduces metabolic costs (Gershenzon 1994), as defenses are produced only when needed. Such induced defenses have ecological advantages (Agrawal and Karban 1999) and might be a useful strategy for plants that are sporadically attacked. However, plants that risk frequent and heavy damage may be better protected by investing in constitutive defense compounds (Wittstock and Gershenzon 2002). The accumulation of constitutive defenses within plants usually conforms to expectations of the 'optimal defense theory' (ODT), which predicts that the highest protection level will be found in parts with the highest fitness value such as young tissues and reproductive organs (McKey 1979; Rhoades 1979). This has been shown for a variety of plant secondary metabolites from different classes such as alkaloids (Hartmann and Zimmer 1986; Baldwin 2001), glucosinolates (Porter et al. 1991. Brown et al. 2003), furanocoumarins (Berenbaum and Zangerl 1999), phenylpropanoids (Harborne 1991; Opitz and Schneider 2002), and terpenes (Gershenzon and Croteau 1991). Under abiotic or biotic stress, plants often exhibit induced responses by enhancing the accumulation of constitutive compounds in certain tissues that increases their deterrence or toxicity to

enemies (Baldwin 1988; Wittstock and Gershenzon 2002; Vazquez-Flota et al. 2004). These changes also may be rationalized as a way for plants to reduce the costs of defense by producing high concentrations of constitutive defenses only when and where these are needed. However, more information is required to understand how the levels of constitutive defenses change under different stresses in plants on an organ-by-organ basis.

Among the vast number of defensive compounds in plants, terpenoids form the largest group with over 25,000 known structures (Buckingham 1994). Some of the best-studied examples for constitutive plant defenses are terpenoid volatiles such as monoterpenes (C_{10}), which are considered defensive against herbivores and pathogens (Gershenzon and Dudareva 2007). Monoterpenes are frequently constituents of oils and resins that are accumulated in complex secretory structures such as glandular trichomes, secretory cavities, or resin ducts (Fahn 1979). Among the most comprehensively studied systems are monoterpenes in the glandular trichomes of peppermint (Gershenzon et al. 2000; McConkey et al. 2000). However, less is known about the accumulation of other classes of terpenes.

Cotton (*Gossypium hirsutum*) is particularly suitable for the study of terpenoid accumulation because a large variety of terpenes are produced constitutively in all photosynthetically active parts of the plant and stored in subepidermal glands. Beside monoterpenes, *G. hirsutum* produces sesquiterpenes (C_{15}; Elzen et al. 1985) and terpenoid aldehydes, such as hemigossypolone (C_{15}) and the heliocides H_1 to H_4 (C_{25}; Fig. 1; Hedin et al. 1992). All three classes of terpenoids in cotton are biosynthetically related (Stipanovic et al. 1977, 1978a; Davis and Essenberg 1995). The precursor of sesquiterpenes, farnesyl diphosphate, is formed by addition of a C_5 isopentenyl diphosphate unit to geranyl diphosphate, the precursor of all monoterpenes. The C_{25} heliocides are formed from Diels–Alder-type reactions of the C_{15} hemigossypolone (derived from δ-cadinene) to the monoterpene myrcene for the formation of heliocides H_2 and H_3 or the monoterpene *E*-β-ocimene for the formation of heliocides H_1 and H_4 (Fig. 2).

The accumulation of terpenoid aldehydes in cotton leaves was shown to be increased after herbivory (Bezemer et al. 2004), and these compounds have been considered to function as feeding deterrents on generalist herbivores such as *Spodoptera exigua* (McAuslane et al. 1997). The heliocides specifically have been correlated with anti-feedant effects and are locally and systematically induced in response to herbivore attack (Karban and Carey 1984; Croxford et al. 1989; Alborn et al. 1996). However, besides the terpenoid aldehydes, little information is available on the accumulation of other terpenes found in subepidermal glands. In studying the control of terpenoid accumulation in cotton, it is of interest to determine if higher concentrations arise from increases in gland number or from increases in the amount of terpenoids per gland (McAuslane et al. 1997). Increasing numbers of subepidermal glands in cotton leaves were observed after attacks of spider mites and caterpillars (McAuslane et al. 1997; Agrawal and Karban 2000).

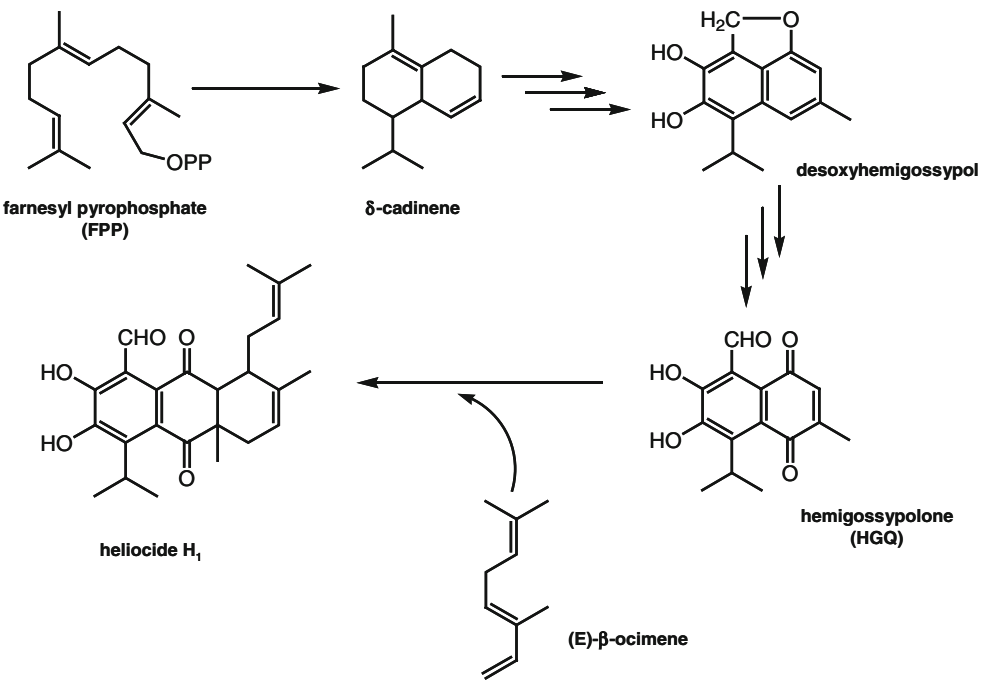

Fig. 2 Proposed scheme for the biosynthesis of heliocide H_1 in cotton

To learn more about the control of terpenoid accumulation in cotton, we compared the response of plants to herbivore damage, mechanical damage, and the application of jasmonic acid (JA), a ubiquitous mediator of defense responses in the plant kingdom (Browse 2005). Differences in the reaction of plants to these treatments were investigated with respect to plant growth, gland production, and accumulation of major compounds from three classes of terpenoids: terpenoid aldehydes, monoterpenes, and sesquiterpenes at the level of the individual leaf. We also examined how the accumulation was influenced by the number of glands in the total foliage or the relative filling of glands with terpenoids.

Methods and Material

Plants G. hirsutum L. of a single variety, 'Deltapine acala 90' (Delta and Pine Company—Hollandala, MS, USA), were reared in a growth chamber under high light intensity [1 mmol $(m^2)^{-1}$ s^{-1} of photosynthetically active radiation], a 15-h light period, 28°C/23°C (day/night), and 65% relative humidity. Plants were established in pots containing 'Seramis'-clay granulate (Masterfood GmbH, Verden/Germany), which were watered daily and fertilized weekly with a complete fertilizer [1 g/l Flory 3 (N/P/K, 15:10:15), Euflor/Germany]. Under these conditions, optimal growth and production of the various terpenoids was obtained.

For all experiments, leaves were numbered sequentially such that number 1 refers to the first true leaf initiated right after the cotyledons (Fig. 3). In this study, leaves 1–7 were investigated and collectively referred to as total foliage.

Herbivores Eggs of the generalist herbivore, *Spodoptera littoralis* (Boisd.; Lepidoptera, Noctuidae), Egyptian cotton worm, were obtained from Syngenta (Basel, Switzerland). After hatching, larvae were reared in 2-l plastic boxes

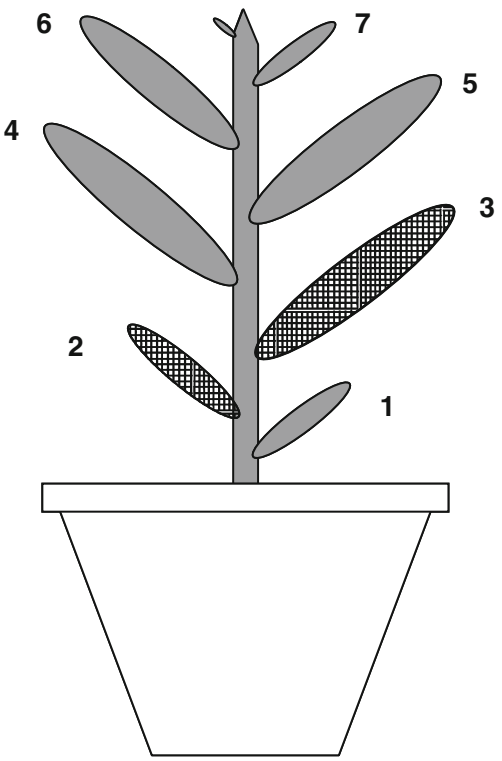

Fig. 3 Sketch of a *Gossypium hirsutum* plant at the end of experiment 1, approximately 1-month-old. Leaves are numbered according to the order of development. *Grid pattern* indicate leaves, which were damaged either mechanically or by caterpillars of *Spodoptera littoralis*

containing artificial diet, which consisted of 500 g of bean flour, 500 ml water, 9 g ascorbic acid, 5 g ethyl-4-benzoic acid, 0.6 ml α-tocopherol, 9 ml Mazola germ oil, 4 ml 3.7% formaldehyde, and 650 ml 7.5% agar solution. Fresh diet was applied every third day. Larvae were reared at constant 20°C, 50–60% relative humidity, and ambient light conditions. Two weeks after hatching, larvae reached the third instar and were used for the study.

Experiment 1

Treatment of Cotton Plants Three weeks after germination, when plants had developed four to five true leaves, the length of the midrib of leaf 4 was determined as a good measure for growth stage. Next, 24 plants at comparable growth stage were transferred into a second growth chamber (Vötsch, Germany) with abiotic conditions identical to the chamber where plants were reared. Here, plants were maintained separately in 250-ml plastic pots and watered twice a day to ensure adequate water supply. After 24 h, plants were divided into four treatment groups of six individuals each. Plants of one group were damaged mechanically three times on leaf 2 on the first day and three times on leaf 3 on the fourth day by using a fabric pattern wheel. In every case, leaves were scratched four times in parallel to the midrib (two times on each side). For a second group, three caterpillars of *Spodoptera littoralis* were caged on each plant on leaf 2 during the first day and on leaf 3 during the fourth day until larvae consumed at least one third of the available leaf material. Plants of the third group were watered with a 100-μM JA solution in water (Sigma) during the first day. JA concentrations in this range are commonly used to induce the biosynthesis of secondary products in plants (Koch et al. 1999; van Poecke and Dicke 2002). Afterward, this solution was replaced by pure tap water. A control group of plants was not treated at all. One week after the start of treatments, all true leaves were harvested separately, frozen in liquid nitrogen, and stored at −20°C until further analyses.

Foliar Glands Just after removal, all leaves were scanned to calculate leaf areas by using the program ImageJ (Wayne Rasband, National Institutes of Health, USA). In this procedure, herbivore-damaged leaves were used as templates to reconstruct the areas of undamaged leaves. In addition, surface view pictures were taken of two circular 24-mm^2 sections from the center of each leaf half with a stereomicroscope connected to a digital camera. In doing so, leaves were illuminated from below with a lamp to visualize filled subepidermal glands as pigmented spots. After the number of filled glands was counted, gland densities for 24-mm^2 sections were calculated. Based on these sections, gland numbers and gland densities per leaf and per total foliage were extrapolated. These values were slightly underestimated because of higher gland densities at leaf edges (personal observations).

Analysis of Monoterpenes and Sesquiterpenes True leaves were separately analyzed for their content of constitutive terpenes. Depending on available material, 30–100 mg of ground frozen leaf were extracted with 300–500 μl pentane/*n*-hexane 1:1. Additionally, 2 μg of nonylacetate were added as internal standard before extracts were shaken for 3 h at room temperature. After extracts were cooled to 4°C, they were filtered through cotton and Na_2SO_4 to remove remaining water. A subset of extracts was analyzed qualitatively by gas chromatography–mass spectrometry (GC–MS) on a Hewlett-Packard 6890 gas chromatograph (injector temperature 220°C; 1 μl splitless injection) coupled to a Hewlett-Packard 5973 quadrupole mass selective detector. Separations were performed on a DB-5MS column (30 m×0.25 mm×0.25 μm film; Agilent Technology) with 2 ml min^{-1} helium as the carrier gas. The following temperature gradient was used: 40°C for 3 min, increased to 90°C at 5°C/min, further increased to 140°C at 40°C/min, followed by an increase to 160°C at 4°C/min, maintained at 160°C for 3 min, and a final heating to 300°C for 3 min. Mass spectrometry was performed with an ionization potential of 70 electron volts and a scan range of *m*/*z* from 50 to 300. Compound identification was based on comparisons with mass spectra in the Wiley and National Institute of Standards and Technology (NIST) libraries or on direct comparison of mass spectra and retention times with available standards. For quantification, all samples were analyzed on a Hewlet-Packard 6890 gas chromatograph and a flame ionization detector (temperature 250°C). The separation procedure was identical to the method for GC–MS analysis. Terpenes were quantified by using nonylacetate and corrected with response factors according to Scanlon and Willis (1985). Concentrations and levels of terpenes per subepidermal gland were calculated for single leaves and for total foliage. Eight individual monoterpenes and sesquiterpenes were analyzed, which represent more than 90% of the total terpenes in *G. hirsutum*.

Analysis of Terpenoid Aldehydes True leaves were separately analyzed for their content of terpenoid aldehydes according to Stipanovic et al. (1988). Depending on available material, 30–100 mg of ground frozen material were extracted ×3 with 3 ml of ethyl acetate/*n*-hexane (1:3) and 50 μl of 10% HCL. Extracts were shaken at 5°C for 3 h. Afterwards, extracts were removed from the leaf material, evaporated with nitrogen, and redissolved in 40% H_2O and 60% solvent B (see below) from the following high-performance liquid chromatography (HPLC) proce-

dure. Reversed phase HPLC analysis was performed on a Chromolith LC-18 column (Merck; 5 μm; 100×4 mm) with single wavelength detection at 272 nm. The column was eluted with H_2O + 0.05% trifluoracetic acid (solvent A) and EtOH/MeOH/MeCN/EtOAc/iPrOH, 26.6:7.4:40.5:6.1:19.4 (solvent B), with the following gradient: 50% B (0 min)–50% B (5 min)–61% B (5.1 min)–61% B (20 min). Flow rate was held constant at 2 ml min^{-1}, and temperature was kept at 25°C. Five compounds, the hemigossypolone (C_{15}) and the heliocides 1–4 (C_{25}), were identified by their retention times according to the literature (Stipanovic et al. 1988) and additionally by liquid chromatography–mass spectrometry (LC–MS) measurements. Quantification was done by using standard curves of purified compounds. Concentrations and levels per subepidermal gland were calculated for single leaves and for the total foliage. Hemigossypolone and the four heliocides represent approximately 90% of the total terpenoid aldehyde content. As a sesquiterpene aldehyde, hemigossypolone was included in our analysis with other terpenoid aldehydes rather than with the sesquiterpenes. In comparison to other cotton varieties (Bezemer et al. 2004), the terpenoid aldehyde gossypol (C_{30}) was found only in traces by LC–MS and was not quantified.

Experiment 2

Eighteen 2-wk-old plants at the growth stage of two true leaves were chosen and prepared for treatments in a way comparable to the first experiment. Plants were divided into three groups. Plants of one group were damaged mechanically nine times on leaves 1 and 2 during six consecutive days by using a mechanical fabric pattern wheel (procedure see experiment 1). For a second group, two caterpillars of *Spodoptera littoralis* were caged on each plant on one cotyledon during day 1, on leaf 1 during day 3, and on leaf 2 during day 5 until larvae consumed at least one third of the available leaf material. A control group was not treated at all. One week after the start of treatments, leaf 4 from each plant was harvested. Leaf areas and gland number per leaf were determined according to experiment 1. Afterwards, leaves were frozen in liquid nitrogen and stored at −20°C until further analyses of mono- and sesquiterpenes. Levels of terpene classes were calculated based on the levels of eight individual compounds that represent more than 90% of the accumulated monoterpenes and sesquiterpenes in *G. hirsutum.*

Statistics—Experiment 1

Total Foliage The effects of mechanical damage, herbivory, and JA application on foliage area, levels of total monoterpenes, sesquiterpenes, and terpenoid aldehydes, as well as on levels of individual major terpenoids, were analyzed with analyses of variance. Data were tested for normality and equal variances. For normally distributed data, one-way analyses of variance (ANOVAs) were used. Differences between treatments and controls were tested for significance by using Dunn's post hoc tests. Data not normally distributed were analyzed by using Kruskall–Wallis one-way ANOVAs on ranks and Dunn's post hoc tests. Analyses were performed with Sigma Stat 2.03. The effect of foliage area and treatment on the total number of glands was tested by analysis of codeviance. Generalized linear models (GLM) with the log link as link function were performed. To deal with overdispersion, a quasi-Poisson distribution was used in the models instead of Poisson distribution. The models were simplified by removing non-significant terms and by factor-level reduction (Crawley 2002). These analyses were performed in *R*, version 2.4.1. All data are presented as mean ± SE except when it is mentioned otherwise.

Single Leaves The effects of leaf position, treatment, and their interactions on levels of terpenoids per gland were tested by using nested two-way ANOVA. For this purpose, terpenoid data were root- or log-transformed to normalize them. For single leaf positions, the effects of the treatments on the leaf area were tested with one-way ANOVAs. The effect of leaf area and treatment on the total number of glands was tested by analysis of codeviance (GLM see above). To analyze the effect of leaf area and treatment on gland density, levels of terpenoids per gland and terpenoid concentrations per milligram fresh leaf material ANCOVAs were used. These analyses were performed in *R*, version 2.4.1. Changes in per gland concentrations of individual terpenoids at specific leaf positions after treatments were tested with Sigma Stat 2.03. For normally distributed data, one-way ANOVAs were used. Differences between treatments and controls were tested for significance by using Dunn's post hoc tests. Data not normally distributed were analyzed using Kruskall–Wallis one-way ANOVAs on ranks and Dunn's post hoc tests.

Statistics—Experiment 2

Single Leaves The effect of the treatments on the areas of leaf 4 was tested with one-way ANOVA. The effect of leaf area and treatment on the total number of glands was tested by analysis of codeviance (GLM see above). To analyze the influence of leaf area and treatments on the accumulation of mono- and sesquiterpenes an ANCOVA was achieved. All analyses were performed in *R*, version 2.4.1.

Results

Experiment 1

Terpenoid Accumulation in Total Cotton Foliage after Induction The accumulation of terpenoid classes among the four different treatments was first compared on the basis of total foliage (Fig. 4). For monoterpenes, sesquiterpenes, and terpenoid aldehydes, there was a gradual increase in the following order: control, mechanical damage, herbivory, and JA treatment (ANOVA on ranks: monoterpenes, $H=9.420$, $P=0.024$; sesquiterpenes, $H=14.140$, $P=0.003$; terpenoid aldehydes, $H=19.760$, $P<0.001$). Levels of all three classes were elevated in herbivore-damaged (Dunn's tests: monoterpenes, $Q=2.572$; sesquiterpenes, $Q=2.490$; aldehydes, $Q=2.939$; all $P<0.05$) and JA-treated plants (Dunn's tests: monoterpenes, $Q=2.735$; sesquiterpenes, $Q=3.674$; aldehydes, $Q=4.164$; all $P<0.05$) in comparison to the controls.

All individual compounds showed the same pattern that was seen for total terpenoid accumulation: a gradual increase from control to mechanical damage, herbivory, and JA treatment. In 11 out of 13 compounds, this increase was significant (Table 1) for herbivore and JA-treated plants compared to the control plants, while mechanically damaged plants showed tendencies for increased accumulation. Among monoterpenes, considerable differences in accumulation after treatment were shown. (*E*)-β-ocimene increased up to eightfold after both herbivory and JA treatment in comparison to controls, whereas myrcene levels slightly but significantly increased after herbivory and JA treatment, and the amounts of α- and β-pinene did not show significant differences between treatments and control. Little variation in the induction pattern occurred when comparing individual sesquiterpenes. Levels of all major sesquiterpenes, including β-caryophyllene, α-humulene, γ-bisabolene, and β-bisabolol doubled after herbivory and were 2.0–2.6-fold higher after JA treatment in comparison to control plants. Among terpenoid aldehydes, considerable differences appeared. Whereas the amounts of hemigossypolone were doubled, levels of heliocides, especially H_1 and H_4, increased much more after herbivory and JA treatment compared to the controls. Heliocide H_4, for example, showed up to a ninefold increase after herbivory and up to a 15-fold increase after JA treatment in comparison to control plants. For H_1, these increases were approximately five- and tenfold, respectively. Meanwhile, the highest levels of H_2 and H_3 were found in the JA-treated plants, reaching up to 3.3-fold that of control levels.

Growth and Subepidermal Gland Production of Cotton Foliage ANOVA showed an effect of the treatments on the total leaf area ($F=10.44$, $P<0.001$). Whereas controls, mechanically and herbivore-damaged plants were highly comparable in size (mean, 496–513 cm^2), JA-treated plants (mean=306 cm^2) showed a reduction in the total area of foliage down to 60% that of the controls (Bonferoni post hoc test. $P<0.05$).

Because of significantly smaller leaves in the JA-treated plants, the effect of treatment on the production of subepidermal glands was tested by using a GLM with leaf area as a covariable. For all treatments, this covariable showed an impact on the number of glands ($t=8.113$, $P<0.001$; Fig. 5). In comparison to the controls, an increase in the number of glands was found for herbivore-damaged plants ($t=4.147$, $P<0.001$) and for plants that were treated with JA ($t=5.585$, $P<0.001$). Because there were no differences between mechanically damaged and non-treated plants, the data of both groups were combined in this analysis.

Single Leaf Analysis To assess more precisely plant response to the treatments, analyses were carried out at the level of individual leaves. For all treatments, the distribution of leaf areas followed a consistent pattern within plants with the biggest leaves at intermediate positions (Fig. 6a). Whereas no differences in leaf area

were evident among mechanically damaged, herbivore-damaged, and control plants, plants treated with JA exhibited significant smaller areas for leaves 3–6 in comparison to corresponding control leaves (ESM Tables 3 and 4). Because of the negative impact of JA treatment on the leaf area, the following analyses of the effect of treatments on gland and terpenoid production were performed by using leaf area as covariable (statistical results see ESM Tables 3 and 4).

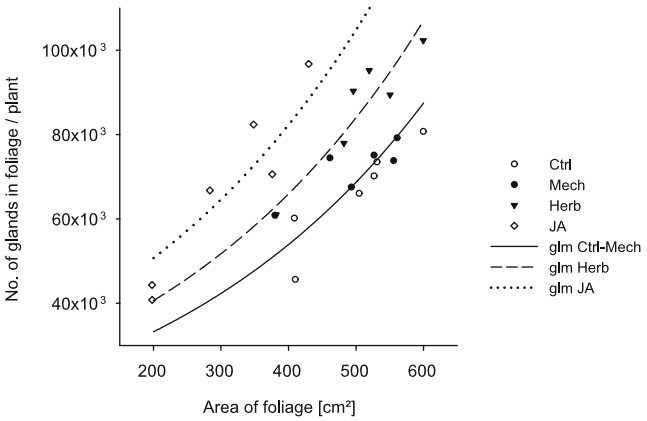

Fig. 5 Effect of leaf area and treatment on the number of glands in the total foliage of 4-week-old cotton plants, which were either damaged at leaves 2 and 3 mechanically (*Mech*), fed upon by larvae of *Spodoptera littoralis* (*Herb*), treated with jasmonic acid (*JA*), or left as untreated controls (*Ctrl*) 7 days previously. Regressions were drawn based on transformed data from a generalized linear model (*GLM*) with a quasi-Poisson error distribution. Data for control and mechanically damaged plants were combined due to factor level reduction

Gland number per leaf revealed a similar distribution pattern among leaves for all treatments: The oldest leaf 1 contained the lowest gland number, which increased gradually toward leaf 5 and again decreased in the expanding leaves 6 and 7 (Fig. 6b). Young leaves (5–7) of herbivore-treated plants showed significantly elevated numbers of glands in comparison to corresponding leaves of control plants. Lower but still significant increases in gland numbers were found for leaves 2, 3, and 7 (youngest leaf) of plants that were treated with JA compared to control leaves. Mechanical damage showed nearly no effect on gland number.

Changes in leaf area and gland numbers after treatment should have an impact on gland densities. Independent of treatment, gland densities increased gradually from the oldest leaf 1 toward the youngest leaf 7 (Fig. 6c). This pattern was enhanced in herbivore-damaged and JA-treated plants because of significantly higher gland densities in young leaves (5, 6, 7) compared to those leaves from the control plants. Mechanical damage did not cause an increased gland density in any leaf.

To analyze how terpenoid production was altered by treatment, total terpenoid levels per gland were calculated. Treatments had a considerable effect on the pattern of terpenoids per gland among leaves (Fig. 6d). Control plants showed highest levels in the oldest leaf and lowest levels in the youngest one. In contrast, mechanically and herbivore-

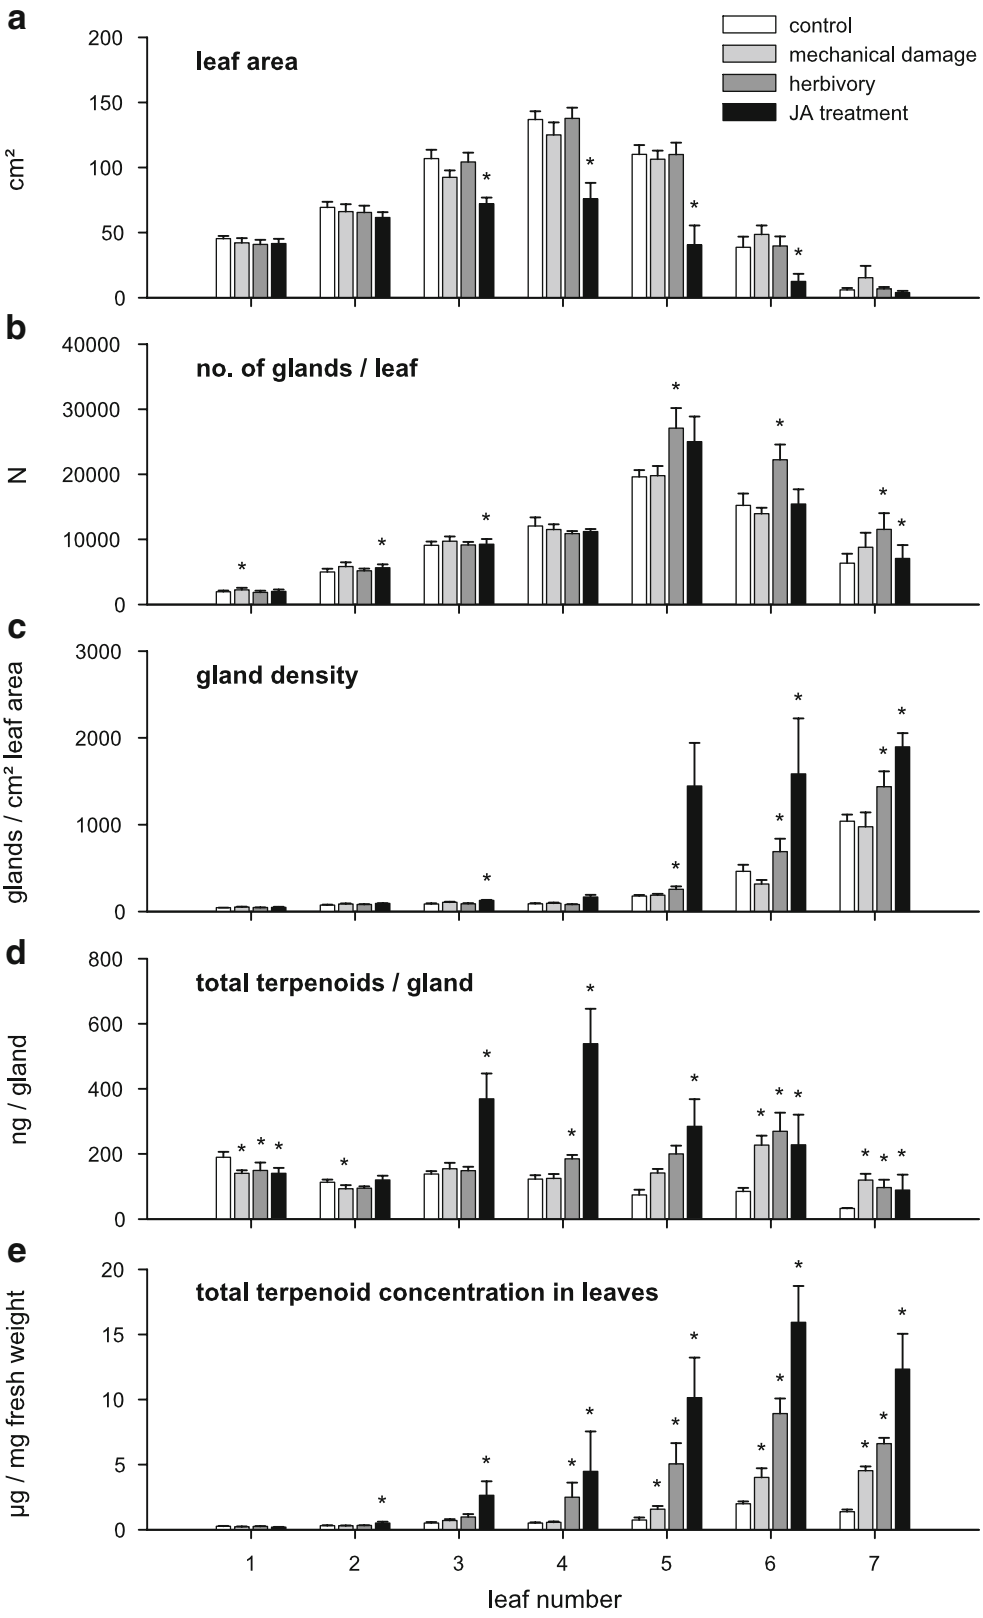

Fig. 6 Mean (±SE, N=3–6) leaf area, number of glands, gland density, terpenoid level per gland, and terpenoid concentration of 4-week-old cotton plants, which were either damaged at leaves 2 and 3 mechanically (Mech), fed upon by larvae of *Spodoptera littoralis* (Herb), or treated with jasmonic acid (JA) 7 days previously. Areas of herbivore-damaged leaves 2 and 3 were extrapolated from remaining leaf material. For each leaf position, *asterisks* indicate significant differences from corresponding control leaves based on one-way ANOVAs (**a**), on analyses of codeviance with leaf area as covariable (**b**), and ANCOVAs with leaf area as covariable (**c**–**e**). *P<0.05

damaged plants exhibited highest values in younger leaves, having significantly elevated total terpenoid levels in comparison to those of control leaves. Plants that were treated with JA showed significantly elevated levels of total terpenoids per gland in young and intermediate leaves in comparison to the controls.

The increase in total terpenoid and gland production caused by the treatments as well as altered leaf areas had a considerable impact on the pattern of the total terpenoid concentrations in leaves. Total terpenoid concentrations showed a consistent distribution pattern among leaves for all treatments (Fig. 6e). There was a gradual increase starting from the oldest leaf 1 toward the youngest leaves 6 and 7. All treatments enhanced this pattern by causing significantly higher concentrations in intermediate and young leaves in comparison to the leaves of corresponding control plants. The lowest effect was found for mechanically damaged plants, whereas plants treated with JA reached the highest concentration with mean levels of approximately 16 μg terpenoids per milligram fresh weight.

The analyses of individual terpenoids revealed a significant impact of treatment, leaf position, and interactions between these two factors on levels of all compounds per gland (Table 2). The lowest effects of treatment were found for the monoterpenes α- and β-pinene, whereas the biggest changes appeared for (*E*)-β-ocimene and heliocides 1 and 4. Differences of single terpenoid levels per gland among leaves appeared to be biggest for (*E*)-β-ocimene and heliocides 4, but in case of the latter, this was due to its unusual absence in leaves 2 and 3 (Fig. 7). Significant interactions between treatment and leaf position revealed that changes in levels of total and single terpenoids of induced plants were not consistent in all leaves, which is illustrated in Fig. 7. As with total terpenoid levels per gland (Fig. 6d), mechanical damage and herbivory caused significantly elevated accumulation of individual compounds per gland in the youngest leaves in comparison to control plants. In contrast, JA treatment induced elevated levels in young but also in intermediate leaves compared to control leaves. JA treatment led to the highest increases of most compounds, especially for heliocides, in comparison to those in the corresponding leaves of control plants.

Experiment 2

Morphological and Chemical Changes in Young Leaves after Induction In addition to herbivore-treated plants and untreated controls, this supplementary experiment also included mechanically damaged plants that were injured more frequently and over a longer period than in experiment 1. ANOVA showed an effect of the treatments on areas of young leaves (leaf 4; $F=5.97$, $P=0.012$; Fig. 8a, ESM Table 5). Herbivory reduced the areas of these leaves in comparison to those of the corresponding leaves of the control plants ($t=-3.445$, $P=0.004$). Therefore, the effect of mechanical damage and herbivory on the production of glands were tested by using a GLM with leaf area as a covariable. For both treatments, leaf area showed an impact on the number of glands ($t=2.256$, $P=0.041$). In comparison to the control plants, a significant increase in the number of glands was found for mechanically damaged plants ($t=2.599$, $P<0.021$) and an even more pronounced

increase for herbivore-treated plants (t=3.938, P=0.002; Fig. 8b).

The accumulation of mono- and sesquiterpenes in leaf 4 after treatment followed a comparable pattern: a gradual increase from control to mechanical damage and herbivory (ANOVA: monoterpenes, F=8.13, P=0.004; sesquiterpenes, F=27.43, P<0.001; Fig. 8c,d). Levels of monoterpenes were elevated after herbivory in comparison to the controls (t=4.029, P=0.001). Levels of sesquiterpenes were elevated after mechanical damage (t=5.115, P<0.001) and herbivory (t=7.197, P<0.001) in comparison to the controls.

Discussion

Cotton (*G. hirsutum*) accumulates a large variety of terpenes constitutively, including monoterpenes (C_{10}), sesquiterpenes (C_{15}), and terpenoid aldehydes (C_{15}, C_{25}, and C_{30}). This study is the first to describe the accumulation of all three of these classes after actual or simulated herbivory. Increased levels of terpenoids were observed in the total foliage 1 week after mechanical damage, feeding by *Spodoptera littoralis* caterpillars, or treatment with JA, in comparison to the untreated controls. A closer look revealed that, after damage to older leaves (leaves 2 and 3 numbered from the base), the increase was restricted mainly to young leaves (leaves 5–7). Similarly, studies on cotton that investigate the effects of herbivory by larvae of *S. exigua* and the wireworm *Agriotes lineatus* also showed elevated concentrations of terpenoid aldehydes in young cotton leaves (McAuslane et al. 1997; McAuslane and Alborn 1998; Bezemer et al. 2004). Such an induction pattern is in agreement with ODT, which predicts that an increase in the accumulation of defense chemicals occurs preferentially in plant parts with the highest fitness value such as young tissues or reproductive organs (McKey 1979; Frischknecht et al. 1987; Ohnmeiss and Baldwin 2000).

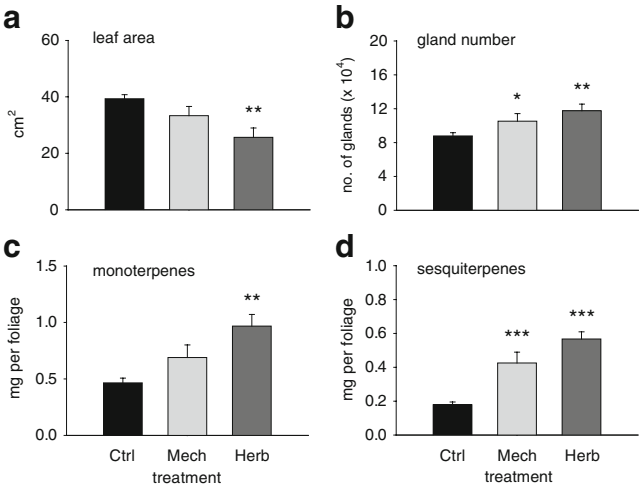

Fig. 8 Mean (±SE, N=6) leaf area, number of glands, and monoterpene- and sesquiterpene levels of leaf 4 from 3-week-old *Gossypium hirsutum* plants, which were either damaged mechanically at leaves 1 and 2 (*Mech*), fed upon by larvae of *Spodoptera littoralis* (*Herb*) on one cotyledon, leaves 1 and 2, or left as untreated controls (*Ctrl*). *Asterisks* indicate significant differences from corresponding control leaves based on one-way ANOVAs (**a**), on analyses of codeviance with leaf area as covariable (**b**), and ANCOVAs with leaf area as covariable (**c**, **d**). *P<0.05; **P<0.01; ***P<0.001

All three classes of cotton terpenoids are stored in subepidermal pigment glands found in leaves and other organs. After treatment, *G. hirsutum* displayed two ways to achieve elevated terpenoid accumulation: (1) production of additional glands and (2) increased filling of existing glands (Fig. 6). We showed that production of additional glands was restricted to leaves that were still under development or newly formed after treatment. This trend also has been observed after attack by spider mites or larvae of *S. exigua* on cotton (McAuslane et al. 1997; Agrawal and Karban 2000). In other plants, such as birch and tomato, an elevated number of defense structures like glandular trichomes is also produced in young leaves after induction by herbivores (Boughton et al. 2005; Valkama et al. 2005). Besides the fact that, according to ODT, plants have been selected to increase their resistance to herbivores especially in young tissue, the formation of subepidermal pigment glands in cotton might be necessarily restricted to newly developing leaves because of developmental constraints.

In counting the number of cotton leaf glands under a stereomicroscope, we may have overestimated the production of new glands after treatment if herbivory triggered the filling of pre-existing glands that were unpigmented (H. T. Alborn, personal communication). However, by using several microscopic techniques, we did not find any evidence for unfilled glands in the leaves analyzed. Therefore, we assume that actual or simulated herbivory does indeed induce increased numbers of glands in cotton.

The increased filling of existing glands with terpenoids was shown in the youngest leaves of induced plants for all major terpenoid classes. However, considerable differences in the magnitude of this additional accumulation were observed among individual terpenoid compounds. Among terpenoid aldehydes, levels of heliocides H_1 and H_4, showed the highest increase after treatments. Other studies on cotton species also have demonstrated that these two

heliocides increase more than H_2, H_3, and hemigossypolone (HGQ) after herbivory by *Spodoptera* species (McAuslane et al. 1997; McAuslane and Alborn 1998; Agrell et al. 2004; Bezemer et al. 2004). Here, we showed that levels of (*E*)-β-ocimene increased in a magnitude similar to H_1 and H_4, and that this compound increased most among monoterpenes and sesquiterpenes. Interestingly, (*E*)-β-ocimene is a direct precursor in the formation of H_1 and H_4, combining with hemigossypolone in a Diels–Alder-type reaction (Stipanovic et al. 1978a; Fig. 2). Therefore, in non-treated plants, the biosynthesis of this monoterpene could represent a limiting step in the production of the appropriate heliocides. This proposition is supported by the fact that, in cotyledons of *G. hirsutum*, which do not contain any heliocides, hemigossypolone is present (S. Opitz, unpublished), but (*E*)-β-ocimene is absent. A comparable regulation mechanism that involves myrcene could determine the levels of H_2 and H_3 (Stipanovic et al. 1977, 1978b).

Our study compared the terpenoid content of total cotton foliage after three different treatments and showed a gradual increase in terpenoid levels in the following order: mechanical damage with a fabric pattern wheel, herbivory by *S. littoralis* caterpillars, and application of JA. However, a single incidence of mechanical injury is hard to compare with continuous feeding damage by an insect. Studies on lima bean have demonstrated that both the intensity and frequency of mechanical damage can alter the reaction of a plant (Mithöfer et al. 2005). This is consistent with the results of experiment 2 where more frequent mechanical damage caused significantly higher numbers of glands (Fig. 8), a response not detectable after the less frequent mechanical damage in experiment 1 (Fig. 5 and 6). However, in both experiments, herbivory induced stronger reactions of plants than mechanical damage. Elicitors found in the regurgitate of herbivores are known to trigger the biosynthesis of defense metabolites (Alborn et al. 1997). If such elicitors play a role in cotton defense reactions, mechanical injury may never result in terpenoid accumulation comparable to that caused by herbivory.

The strongest increase in both terpenoid and gland production appeared in plants that were treated with JA, a ubiquitous plant hormone known to mediate defense responses to biotic and abiotic stresses (Browse 2005). A previous study with cotton showed that the application of the methylated derivative, methyl jasmonate, induced the synthesis and emission of volatile terpenes, a response also observed for herbivore-damaged plants (Rodriguez-Saona et al. 2001). Obviously, JA plays an important role in mediating damage-induced signaling in *G. hirsutum*. Given the effects of exogenous application, herbivory can be assumed to trigger elevated internal levels of JA as in other species (Baldwin et al. 1997; Creelman and Mullet 1997). For example, in tobacco, lima bean, or maize, internal JA levels were determined in ranges of single nanograms per gram fresh weight, showing 20- to 40-fold increases within the first hours after induction (Baldwin et al. 1997; Koch et al. 1999; Schmelz et al. 2003). However, internal JA levels of cotton still need to be investigated. If the irrigation of plants with 100 μM JA in our study led to a non-physiological high internal concentration of JA, this could explain why JA treatment induced terpenoid accumulation to a greater extent than herbivory. We observed additionally that JA inhibited leaf development, a response also seen in other plants (Sembdner and Parthier 1993).

Studies on the induction of chemical defense in plants after herbivory always raise questions about the specificity of such reactions to particular enemies. Certain plants have been shown to induce different spectra of defenses in response to different herbivores (Turlings et al. 1998; Traw and Dawson 2002; Delphia et al. 2007). However, in this study, we did not find substantial differences in the pattern of induction among treatments for the major terpenoids measured (see Table 1). The amounts of single compounds varied in magnitude, leading to changes in the terpenoid profile, but these profile changes tended to be comparable among treatments. The induction of elevated terpenoid accumulation in leaves of *G. hirsutum* may thus be a non-specific reaction of plants to damage. Similar non-specific reactions to damage are known for terpenes in other species (Banchio et al. 2005), as well as for alkaloids (Frischknecht et al. 1987; Baldwin et al. 1997), phenolics (Cipollini 1997), and glucosinolates (Bodnaryk 1992).

The fact that cotton plants react to damage with elevated levels of terpenoids accumulated in the subepidermal pigment glands of their foliage suggests that these compounds function in plant defense. Caterpillar species such as *S. exigua* or *Heliothis virescens* prefer feeding on glandless instead of glanded cultivars of *G. hirsutum*, thus supporting the argument that the gland terpenes play a key role in defense of cotton against herbivores (Montandon et al. 1986; McAuslane and Alborn 2000). Leaf material from plants of glanded cultivar lines that had been induced by herbivory showed increased deterrent or toxic effects on *Spodoptera* species compared to material from uninduced plants, a finding thought to be due to their elevated contents of terpenoid aldehydes (Alborn et al. 1996; McAuslane et al. 1997; Anderson et al. 2001). Indeed, terpenoid aldehydes such as gossypol, hemigossypolone, and the heliocides H_1 and H_2 exhibit strong toxicity to caterpillars of *H. virescens* and *Pectinophora gossypiella* after addition to artificial diet (Elliger et al., 1978). While the feeding deterrent effects of induced cotton foliage are usually attributed to elevated terpenoid aldehydes contents (Hedin et al. 1992; McAuslane et al. 1997; McAuslane and Alborn 2000), we showed that cotton plants also increase their

levels of monoterpenes and sesquiterpenes. Thus, these compounds may also participate in defense against herbivores. A sesquiterpene, caryophyllene oxide has been demonstrated to synergize the negative effect of gossypol, the dominant terpenoid aldehyde in roots and seeds of cotton, on larval development of *H. virescens* (Gunasena et al. 1988). Additionally, caryophyllene retarded the growth and delayed the time of development of these larvae. Other studies have shown that single sesquiterpenes such as β-bisabolene impair the development of insect herbivores and deter them from feeding (Bowers et al. 1976; Gonzalez-Coloma et al. 1995; Zipfel 2007).

Beside their function against herbivores, terpenoids are also considered to play a defensive role against fungi or pathogens. Because plants are exposed especially to infestation at wound sites, the elevated terpenoid levels in damaged leaves might have a critical role in helping plants to cope with pathogens. For cotton, studies have shown that certain terpenoid aldehydes possess antifungal and anti-pathogen activities (Zhang et al. 1993; Abraham et al. 1999). A good example for the antibiotic activity of terpenoids in other species comes from conifers where the growth and germination of bark beetle associated pathogens is inhibited (Keeling and Bohlmann 2006). In addition, analyses of terpene-rich essential oils from a variety of plant species have shown antibacterial and antifungal activities, indicating the potential role of these substances in plant defense (Oyedeji and Afolayan 2005; Ozer et al. 2007).

In summary, our results demonstrate that elevated levels of terpenoids in cotton leaves after real and simulated herbivory represent a general wound response that is mediated by JA. The increase in terpenoids is due to the production of additional glands, in which terpenoids are stored, as well as the increased filling of existing glands. As all three classes of terpenoids (monoterpenes, sesquiterpenes, and terpenoid aldehydes) were elevated after damage, these substances may act synergistically in defense against herbivores or pathogens (Stipanovic et al. 1988).

Acknowledgment We thank Bettina Raguschke and Carsten Köhler for help with the preparation of all leaf samples; Steffen Harzsch for microscopic work; Sybille Unsicker, Susanne Textor, Michael Reichelt and Jan-Willem Dekraker for discussing the manuscript; the gardeners of our institute for growing the plants; and Syngenta Crop Protection AG for providing us with *Spodoptera littoralis* eggs. Financial support was provided by the Deutsche Forschungsgemeinschaft (DFG: Az. OP 93/1-1) and the Max Planck Society.

Behavioral Responses of Adult *Sitophilus granarius* to Individual Cereal Volatiles

Giacinto S. Germinara · Antonio De Cristofaro · Giuseppe Rotundo

Received: 7 August 2007 / Revised: 12 February 2008 / Accepted: 12 February 2008 / Published online: 14 March 2008

Abstract The antennae of *Sitophilus granarius* (L.) (Coleoptera: Curculionidae) adults detect a wide variety of compounds in the odor blend of various cereal grains (Germinara et al., *Tec. Molit.*, 53:27–34, 2002). In the present study, we looked at the behavioral responses of the granary weevil to 20 of these individual volatiles (aliphatic alcohols, aldehydes, ketones, and aromatics) in a two-choice pitfall olfactometer, using the aggregation pheromone and propionic acid as the attractant and repellent controls, respectively. Five doses, ranging from 1 μg to 1 mg, of each compound were tested. At least one concentration of eight compounds attracted beetles but required doses 1,000- to 5,000-fold higher than the concentration of aggregation pheromone to elicit a response. Three compounds, while attractive at lower concentrations, acted as repellents at higher doses. Twelve compounds were repellent at concentrations similar to the quantity of propionic acid that significantly repelled beetles. The data show that granary weevil adults have the ability to respond behaviorally to a wide range of cereal volatiles and that responses may change as a function of concentration. The results suggest that host finding behavior of weevils will depend on the balance of positive and negative volatile stimuli from grain as the relative concentrations of volatiles may change during storage. An understanding of how the weevils respond to such changes could be useful for the development of effective integrated pest management strategies.

Introduction

The granary weevil, *Sitophilus granarius* (L.) (Coleoptera: Curculionidae), is a serious pest of stored grains worldwide. Infestations not only cause significant losses due to the consumption of grains; they also result in elevated temperature and moisture conditions that lead to an accelerated growth of molds, including toxigenic species (Sauer et al. 1984; Magan et al. 2003). Recent legislation that limits the use of fumigants and broad-spectrum contact insecticides, with increasing consumer demand for safe food, makes the control of such storage pests difficult. Furthermore, as larvae develop within the grains, any effective control strategy requires the early and accurate monitoring of adult weevils.

The use of semiochemicals has stimulated interest, as they may be used to improve current monitoring as well as direct means of controlling stored-product insect pests (Phillips 1997; Cox 2004). In the case of *S. granarius*, there is a male-produced aggregation pheromone, 1-ethylpropyl-(2*S*,3*R*)-3-hydroxy-2-methylpentanoate (Phillips et al. 1989; Chambers et al. 1996) that is attractive to both sexes (Faustini et al. 1982). Phytophagous insects also use volatiles from plant materials to locate suitable substrates (Dickens 1984; Visser 1986), and it has been shown that extracts from carob pods and peanuts (Collins et al. 2004, 2007; Wakefield et al. 2005) as well as specific components attract granary weevil adults (Collins et al. 2007). *S.*

granarius adults orient to volatile blends emitted by grains of several cereal species (Levinson and Kanaujia 1981; Rietdorf and Steidle 2002), and the presence of phagostimulatory compounds are considered crucial in the infestation process by this pest (Kanaujia and Levinson 1981). Male and female *S. granarius* respond to various extracts from stored winter wheat (Levinson and Kanaujia 1982) and to lipid fractions that consist mostly of triacylglycerols and fatty acids (Nawrot et al. 1995).

Despite this behavioral evidence and the identification of many volatiles emitted by grains of several cereal species (Maga 1978; Zhou et al. 1999; Sides et al. 2001), little attention has been given to the response of weevils to individual compounds. Chambers et al. (1996) showed that a wheat extract mixture was electroantennographically (EAG) active but showed no specific peaks of activity in using the combined gas chromatography–electroannographic detection approach. In light of the results, they suggested that the EAG response to the whole extract must be due to small contributions from a large number of components. In previous studies, we observed that both male and female *S. granarius* antennae responded to a wide range of synthetic compounds found in cereal volatiles (Germinara et al. 2002) and that adults were repelled by propionic acid (Germinara et al. 2007). In this study, we examined the behavioral response of granary weevil adults to different doses of individual, EAG-active compounds present in cereal volatiles in the search for candidate semiochemicals useful for weevil pest management.

Materials and Methods

Insects *S. granarius* were reared on whole wheat kernels for several generations in continuous dark at 23±2°C and 60±5% relative humidity (r.h.). Adult beetles, of mixed sex and age, were used for the experiments.

Odor Stimuli Test compounds (Table 1; Sigma-Aldrich, Milan, Italy) were selected based on their presence in cereal grains (Maga 1978; Zhou et al. 1999) and their EAG activity to granary weevil adults (Germinara et al. 2002). Solutions (decimal dilutions from 100 to 0.1 μg/μl) were prepared with mineral oil (Sigma-Aldrich) to reduce the rate of evaporation.

Solutions (0.1 ng/μl to 5 μg/μl) of the aggregation pheromone 1-ethylpropyl-(2*S*,3*R*)-3-hydroxy-2-methylpentanoate (Novapher, San Donato Milanese, Italy; chemical purity 91%) and propionic acid (100 μg/μl; Sigma-Aldrich; chemical purity >99.9%) were used as positive controls for attractant and repellent compounds, respectively. Solutions were stored at −20°C until needed.

Table 1 Chemical purity of synthetic compounds known to occur in natural cereal volatiles that were tested in a behavioral assay using the granary weevil, *S. granarius*

Compound	Purity (%)
Aliphatic alcohols	
1-Butanol	99
1-Pentanol	99
1-Hexanol	99
3-Methyl-1-butanol	99
Aliphatic aldehydes

Hexanal	98
Heptanal	95
(*E*)-2-Hexenal	95
(*E*,*E*)-2,4-Heptadienal	88
(*E*,*E*)-2,4-Nonadienal	85
(*E*,*E*)-2,4-Decadienal	85
Aliphatic ketones	
2-Pentanone	99
2-Hexanone	99
2-Heptanone	98
2,3-Butanedione	97
Aromatics	
3-Methoxy-2-methyl-4-pyrone (maltol)	99
Furfural	99
Phenylacetaldehyde	90
3-Methoxy-4-hydroxy-benzaldehyde (vanillin)	97

Pitfall Bioassays The behavioral response of *S. granarius* adults to individual odor stimuli was measured by using a two-choice pitfall bioassay, similar to those described by Phillips et al. (1993) and Pike et al. (1994). The test arena was a steel container (32 cm diameter×7 cm high) with two diametrically opposed holes (3 cm diameter) located 3 cm from the side wall. Test or control (10 μl) stimuli were adsorbed onto a filter paper disk (0.7 cm diameter) suspended at the center of each hole by a cotton thread taped to the lower surface of the arena. Glass flasks (500 ml) were positioned under each hole, and the inside surfaces of their necks were coated with mineral oil to prevent captured insects from returning to the arena. The floor of the arena was covered with filter paper (Whatman No. 1) to provide a uniform surface and to facilitate insect movements (Pike et al. 1994). Twenty insects, deprived of food for at least 4 h, were placed under an inverted Petri dish (3 cm diameter×1.2 cm high) at the center of the arena and allowed 30 min to acclimate. They were then released and tested for 3 h in the dark at 25±2°C and 60±5% r.h. Experiments were carried out between 10:00 A.M. and 4:00 P.M. During the assay, the arena was covered with a steel lid to prevent insects from escaping. Insects were given a choice between a specific dose of the test stimulus

(1, 10, 100, 500, and 1,000 μg) and mineral oil, used as a control. Propionic acid was tested only at 1,000 μg, as this concentration has a strong repellent effect to adult granary (Germinara et al. 2007). To determine the optimal dose for insect attraction to the aggregation pheromone in our experimental device, we tested 0.001, 0.005, 0.05, 0.1, 0.25, 0.5, 5.0, and 50 μg. There were six replicates of each assay, and insects were only used once.

In each trial, a response index (RI) was calculated by using $RI=[(T-C)/Tot]\times 100$, where T is the number responding to the treatment, C is the number responding to the control, and Tot is the total number of insects released (Phillips et al. 1993). Positive values of RI indicate attraction to the treatment, while negative ones indicate repellence. The significance of the mean RI in each treatment of the two-choice pitfall bioassay was evaluated by the Student's t test for paired comparisons (Phillips et al. 1993). Data were submitted to linear regression analysis to evaluate the effect of the dose on the insects' response. The most significant positive or negative mean values of RI were first analyzed by an analysis of variance and subsequently ranked by using the least significant difference (LSD) multiple range test ($P=0.05$).

Results

The control repellent propionic acid 1 mg dose gave a significant RI (−57.2±2.9; $P<0.001$). The aggregation pheromone elicited significant positive responses from 5 to 250 ng, whereas it induced a significant negative response at 50 μg (Fig. 1).

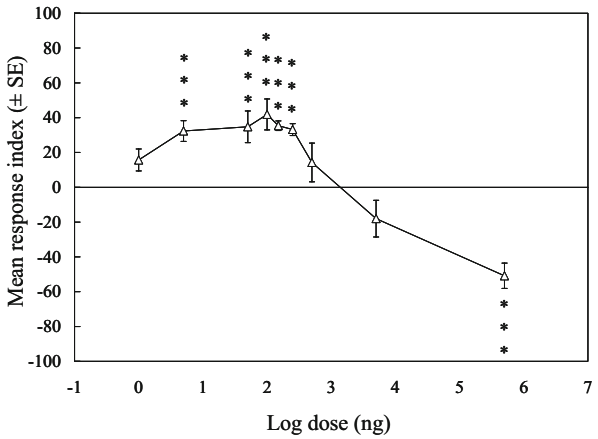

Fig. 1 Response of *S. granarius* to increasing doses of 1-ethylpropyl-(2*S*,3*R*)-3-hydroxy-2-methylpentanoate (aggregation pheromone) in two-choice pitfall bioassays. $N=6$. Significant response to experimental stimulus: *** $P<0.001$ (paired-sample t test)

Of the four aliphatic alcohols tested, 1-butanol and 3-methyl-1-butanol elicited significant positive responses at the 500 μg dose, while 1-hexanol elicited a significant negative response at the three highest doses tested (Table 2). 1-Pentanol was an attractant between 1 and 100 μg but was a repellent at 1 mg (Table 2). Pentanal was the only aliphatic aldehyde that caused significant attraction (at 100 and 500 μg), whereas six others had a repellent effect, particularly at high doses. (*E*,*E*)-2,4-Heptadienal was an attractant at 10 and 100 μg, whereas it elicited significant negative responses at the two highest doses (Table 2).

The four aliphatic ketones acted as significant repellents for granary weevil adults over the dose range tested, with the level of repellency generally increasing with an increase in dose (Table 2).

The aromatics 3-methoxy-4-hydroxy-benzaldehyde (vanillin), 3-methoxy-2-methyl-4-pyrone (maltol), and phenylacetaldehyde were attractants, but the concentrations that elicited a significant response varied depending on the compound (Table 2). In contrast, phenylacetaldeyde and furfural significantly repelled beetles at the highest dose tested.

In the case of compounds that induced significant positive or negative responses, regression analyses showed a dose-dependent relationship for eight of those with repellent properties but none for those that attracted *S. granarius* (Table 2). Both the highest positive ($F=3.57$; $df=8$; $P<0.01$; Table 3) and negative ($F=3.95$; $df=15$; $P<0.001$; Table 4) RI values differed among attractant and repellent compounds.

Discussion

Our results show that many cereal volatiles, known to be detected by antennal sensilla of *S. granarius* (Germinara et al. 2002), also elicit a significant behavioral response at one or more of the doses tested. Over the range of concentrations tested, five compounds (1-butanol, 3-methyl-1-butanol, pentanal, maltol, and vanillin) acted uniquely as attractants, while twelve [1-hexanol, butanal, hexanal, heptanal, (*E*)-2-hexenal, (*E*,*E*)-2,4-nonadienal, (*E*,*E*)-2,4-decadienal, 2,3-butanedione, 2-pentanone, 2-hexanone, 2-heptanone, and furfural) acted only as repellents. However, in the case of 1-pentanol, (*E*,*E*)-2,4-heptadienal, and phenylacetaldehyde, granary weevils were attracted to low concentrations but repelled by higher ones, thus showing the ability of the species to detect and respond differentially to variations in concentration of host volatiles.

The number of compounds present in the volatiles emitted from stored grains, as well as their concentrations,

will change over time (Zhou et al. 1999; Sides et al. 2001). Thus, viewed from an ecological perspective, our results should be considered within the context of resource utilization by the granary weevil. Some of the volatiles that attract *S. granarius* have been identified in the aroma of freshly broken grains of several cereal species (Maga 1978) and, consequently, may act as kairomones. For example, pentanal, 1-pentanol, and phenylacetaldehyde, all of which attracted beetles, increase with time following storage (Heiniö et al. 2002). Similarly, the attractant vanillin could result as a biotransformation product of ferulic acid (Kavitha et al. 2005), while (*E*,*E*)-2,4-heptadienal could be an oxidation product of linolenic acid (Nielsen et al. 2004), a minor fatty acid in wheat (Morrison 1987). Thus, once these volatiles increase above a certain concentration, they act as attractants, which could explain the preference for aged wheat kernels over fresh ones (Levinson and Kanaujia 1981). It is of interest to note that, while higher concentrations of host volatiles are required to elicit a response from granary beetles, as seems also the case for *Oryzaephilus surinamensis* (L.) and *Oryzaephilus mercator* (Fauvel) (Pierce et al. 1990), the RIs for (*E*,*E*)-2,4-heptadienal, vanillin, and maltol at their most attractive dose were similar to that of the aggregation pheromone (Table 3). A number of

these compounds may also be used as kairomones by other species: pentanal, vanillin, and maltol are attractive to *Sitophilus oryzae* (L.) (Phillips et al. 1993); pentanal attracts *O. surinamensis* and *O. mercator* (Pierce et al. 1990), whereas phenylacetaldehyde is an attractant for several Lepidopteran species (El-Sayed 2006), including *Ephestia cautella* (Walker) and *Plodia interpunctella* (Hübner) (Olsson et al. 2005), as well as *Ephestia kuehniella* Zeller (Olsson et al. 2006).

3-Methyl-1-butanol has been implicated as a kairomone for other stored-product insects, such as the larvae of *Tribolium castaneum* (Herbst) (Sinha 1990), adults of *O. surinamensis*, *O. mercator*, *Cryptolestes ferrugineus* (Stephens), *Ahasverus advena* (Waltl), *Cathartus quadricollis* (Guérin) (Pierce et al. 1991), and *E. kuehniella* (De Cristofaro et al. 2000). Unlike Sinha 1990, we also found that it attracted the granary weevil. This difference may be explained by the fact that we tested lower concentrations. This observation, together with the fact that certain compounds, similarly to the aggregation pheromone, are attractants at low concentrations but have a repellent effect at higher ones (Table 2), highlights the necessity of testing a range of doses.

Similarly, repellent compounds may serve as reliable cues of habitat quality for the granary weevil. The production of hexanal, commonly used as an indicator of lipid oxidation in cereals (Piggot et al. 1991), increases over time in stored native oats (Heiniö et al. 2002) and raw oat flour (Molteberg et al. 1996). There will also be an increase of (*E*,*E*)-2,4-decadienal and (*E*,*E*)-2,4-nonadienal due to the oxidation of linoleic acid, the major fatty acid of wheat lipids (Grosh and Schieberle 1991). Similarly, 2-heptanone is the major ketone formed when raw oat flour is stored (Molteberg et al. 1996) and, along with other ketones, is a typical metabolite of mold-infested cereals (Pasanen et al. 1996; Magan and Evans 2000). The idea that these could provide reliable cues for *S. granarius* is supported by the observed positive correlations between the concentration and repellency (Table 2). Furthermore, the optimal doses of (*E*,*E*)-2,4-nonadienal, (*E*)-2-hexenal, 2-pentanone, 2-heptanone, (*E*,*E*)-2,4-decadienal, and furfural were as effective as the repellent control, propionic acid.

The results reported here are of significance from a management perspective. Specific blends of synthetic attractants may be used to monitor and/or trap the granary weevil. These could be deployed alone or in combination with the aggregation pheromone of *S. granarius* as (1) synergistic or additive effects have been reported for several species (Landolt and Phillips 1997), including the congeners *Sitophilus zeamais* (Walgenbach et al. 1987) and *S. oryzae* (Phillips et al. 1993), and (2) some olfactory cells may respond to both host-plant volatiles and pheromones (De Cristofaro et al. 2004; Ansebo et al. 2005). An alternative method may be to use repellent compounds to mask and/or alter odors emitted from stored grains to reduce the granary beetle's ability to detect suitable food and oviposition sites.

The results of this study suggest that host finding by the granary weevil is a complex process that depends on the balance of positive and negative stimuli that change over time. Consequently, a clear understanding of the biological activity of different cereal volatiles, individually and in combination, will be essential for developing semiochemical-based granary weevil management strategies. Furthermore, as noted above, considerable attention will not only have to be given to the selection of the actual compounds but also to the specific concentration to be used. Furthermore, one must also consider the impact that these blends might have on other species that utilize the same resources to ensure that compounds to repel one pest is not an attractant for another. For example, while hexanal, heptanal, and (*E*,*E*)-2,4-nonadienal (at low doses) repel the granary weevil, they have been reported as attractants for *O. surinamensis* and *O. mercator*, two secondary pests of stored grain and processed cereals (Pierce et al. 1990). Such differential responses to the same semiochemicals that originate from a heterogeneous food substrate undoubtedly play an important role in niche partitioning within the stored-grain ecosystem (Phillips et al. 1993). However, a failure to understand these interactions when deploying lures to control one species may lead to an increase in the density of other pests.

Enantiospecific Effect of Pulegone and Pulegone-Derived Lactones on *Myzus persicae* (Sulz.) Settling and Feeding

Katarzyna Dancewicz · Beata Gabrys · Iwona Dams · Czesław Wawrzeńczyk

Received: 7 September 2007 / Revised: 2 January 2008 / Accepted: 8 February 2008 / Published online: 14 March 2008

Abstract The effect of pulegone chiral center configuration on its antifeedant activity to *Myzus persicae* was examined. Biological consequences of structural modifications of (*R*)-(+)- and (*S*)-(−)-pulegone, the lactonization, iodolactonization, and incorporation of hydroxyl and carbonyl groups were studied, as well. The most active compounds were (*R*)-(+)-pulegone (**1a**) and δ-hydroxy-γ-spirolactones (5*S*,6*R*,8*S*)-(−)-6-hydroxy-4,4,8-trimethyl-1-oxaspiro[4.5]decan-2-one (**5b**) and (5*R*,6*S*,8*S*)-6-hydroxy-4,4,8-trimethyl-1-oxaspiro[4.5]decan-2-one **(6b)** derived from (*S*)-(−)-pulegone (**1b**). The compounds deterred aphid probing and feeding at preingestional, ingestional, and postingestional phases of feeding. The preingestional effect of (*R*)-(+)-pulegone (**1a**) was manifested as difficulty in finding and reaching the phloem (i.e., prolonged time preceding the first contact with phloem vessels), a high proportion of probes not reaching beyond the mesophyll layer before first phloem phase, and/or failure to find sieve elements by 20% of aphids during the 8-hr experiment. The ingestional activity of (*R*)-(+)-pulegone (**1a**) and hydroxylactones **5b** and **6b** resulted in a decrease in duration of phloem sap ingestion, a decrease in the proportion of aphids with sustained sap ingestion, and an increase in the proportion of aphid salivation in phloem. δ-Keto-γ-spirolactone (5*R*,8*S*)-(−)-4,4,8-trimethyl-1-oxaspiro[4.5]decan-2,6-dione **(8b)** produced a weak ingestional effect (shortened phloem phase). The postingestional deterrence of (*R*)-(+)-pulegone **(1a)** and δ-hydroxy-γ-spirolactones (5*R*,6*S*,8*R*)-(+)-6-hydroxy-4,4,8-trimethyl-1-oxaspiro[4.5]-decan-2-one (**5a**), **5b**, (5*S*,6*R*,8*R*)-6-hydroxy-4,4,8-trimethyl-1-oxaspiro[4.5]decan-2-one (**6a**), **6b**, and δ-keto-γ-spirolactone **8b** prevented aphids from settling on treated leaves. The *trans* position of methyl group CH_3–8 and the bond C5–O1 in lactone **6b** appeared to weaken the deterrent activity in relation to the *cis* diastereoisomer (**5b**).

Introduction

Substances that alter insect behavior have attracted much attention as potential crop protection compounds that, at least in part, might replace traditional pesticides (Unelius et al. 2006); they comprise repellents, oviposition inhibitors, antifeedants, etc. The most widely known antifeedants belong to different chemical groups and come from natural sources (Ley and Toogood 1990; Wawrzyniak 1996; Simmonds 1998). Plant terpenoids are one of the major classes of secondary metabolites synthesized by plants that are toxic, unpalatable, or at least repellent to herbivores. As such, they function as defensive agents (Pickett 1991; Harrewijn et al. 2001; Wittstock and Gershenzon 2002). Discovery of insect control substances include, among others, ajugarin, azadirachtin, and polygodial. The sesquiterpenoid polygodial was successfully applied in the field against bird cherry-oat aphid *Rhopalosiphum padi*. It gave results similar to those obtained with the broad-spectrum

pyrethroid cypermethrin (Pickett et al. 1994). Monoterpenoids are components of many plant essential oils and often show insecticidal, feeding deterrent, and repellent activities (Simmonds 1998). Citral appeared toxic to Mediterranean fruit fly *Ceratitis capitata*, American cockroach *Periplaneta americana*, and housefly *Musca domestica* (Salvatore et al. 2004; Choi et al. 2006; Price and Berry 2006) and repellent to termites *Coptotermes formosanus* (Zhu et al. 2001) and mosquitoes *Aedes aegypti* (Oyedele et al. 2002).

Annual world crop loss due to aphids is estimated at 2% of all losses attributed to insect feeding (Wellings et al. 1989). Apart from removing vital fluids from plant sieve elements, aphids are effective vectors of virus diseases: approximately 60% of all plant viruses are spread by aphids. According to Blackman and Eastop (1985), the peach aphid *Myzus persicae* (Sulz.) can infest plants belonging to over 40 different families that include many economically important ones, and it has the ability to transmit more than 100 plant viruses. Elimination or at least reduction of penetration of plant tissues by aphids may save plants from infection by pathogenic agents (Martin et al. 1997).

Aphids respond to many monoterpenoids. The repellent properties of linalool and α-terpineol to *Myzus persicae* were reported by Hori (1998, 1999). Gutierrez et al. (1997) found that geraniol inhibited *Myzus persicae* settling on host plants. (*S*)-Limonene restrained phloem sap ingestion and had other negative effects on the behavior of the peach potato aphid (Halarewicz-Pacan et al. 2003). Citral and linalool had repellent effects that were manifested in a significant decrease in time spent on leaves, decreased total and mean time of penetration, and lower numbers of probes compared to controls. Citral, linalool, (*S*)-limonene, α-ionone, and camphene reduced the total and mean probing time of aphids and settling on the leaves (Gabrys et al. 2005).

Our interest in pulegone and its likely antifeedant effect on *Myzus persicae* was inspired by reports on the compound's broad spectrum biological activity. Pugelone is repellent to birds, including the common starling *Sturnus vulgaris*, red-winged blackbird *Agelaius phoeniceus*, and Northern bobwhite *Colinus virginianus* (Avery et al. 1996; Mason and Epple 1998). It is also toxic to the German cockroach *Blatella germanica*, *Musca domestica*, and storage pests [rice weevil *Sitophilus oryzae*, red flour beetle *Tribolium castaneum*, and the sawtoothed grain beetle *Oryzaephilus surinamensis* (Franzios et al. 1997; Lee et al. 2003)]. Pulegone downgrades reproduction and development of the pea aphid *Acyrthosiphon pisum*, probably by killing aphid symbionts *Buchnera* sp., which is attributed to its bactericidal activity (Harrewijn et al. 2001). The fungicidal effect of pulegone has also been reported (Gata-Gonçalves et al. 2003).

Pulegone is the major component of essential oils of several species of *Mentha* (e.g., *M. pulegium*, *M. arvensis*, *M. longifolia*, and *M. spicata*) and occurs in two isomeric forms: (*R*)- and (*S*)-pulegone (Phatak and Heble 2002; Vetere et al. 2002; Conover and Lyons 2005). The enantiomers of a chiral compound may differ significantly in respect to their interaction with biological receptors, thus resulting in a different biological activity (Juza et al. 2000). The biological activity depends not only on the stereochemistry but is related also to the presence of various functional groups. Often, natural antifeedants are lactones with one or more additional functional groups (Ley and Toogod 1990; Wawrzeńczyk et al. 1997). From the practical point of view, the use of plant-derived antifeedants on a large scale is not justified economically. Synthetic analogs of natural compounds are more accessible for application.

The aim of this work was to assess the effect of pulegone chiral center configuration on its antifeedant activity to *Myzus persicae* and to study the biological consequences of structural modifications of (*R*)-(+)- and (*S*)-(−)-pulegone: the lactonization, iodolactonization, and incorporation of hydroxy and carbonyl groups. The biological study included various aspects of aphid host plant selection and acceptance processes. The behavioral responses of *Myzus persicae* to pure and structurally modified pulegone enantiomers were investigated to reveal the biological basis of their deterrent activity.

Methods and Materials

Chemicals (*R*)-(+)-Pulegone (>98%), (*S*)-(−)-pulegone (>99%), (1*S*,2*R*,5*S*)-(+)-isopulegol (>99%), and (1*R*,2*S*,5*R*)-(−)-isopulegol (>99%) were purchased from Aldrich and Fluka. Test lactones **3**–**8** (Fig. 1) were synthesized from optically pure isomers of pulegone and isopulegol. The synthetic methodology for compounds **3**–**6**, based on the orthoacetate modification of the Claisen rearrangement and iodolactonization of γ,δ-unsaturated acids or acidic lactonization of epoxy esters, was described earlier (Dams et al. 2004a,b). δ-Hydroxy-γ-spirolactones **5**–**6** were oxidized with pyridinium dichromate to the corresponding δ-keto-γ-spirolactones **7**–**8** (Dams et al. 2004b). The structures of synthesized lactones were determined on the basis of spectroscopic and crystallographic methods. The enantiomeric purity of the final products was higher than 97% as determined by gas chromatography by using chiral columns: CP-Cyclodextrin-β-2,3,6-m-19, 25 m×0.25 mm×0.25 μm and Chirasil-Val-L, 25 m×0.25 mm×25 μm. It was not possible to obtain pure enantiomers of **6a** and **6b**. To evaluate their activity, it was necessary to use **6a**/**6b** mixtures. The activity of **6a** was studied as a mixture **5a**/**6a**=28%:72% and **6b**–**5b**/**6b**=28%:72%.

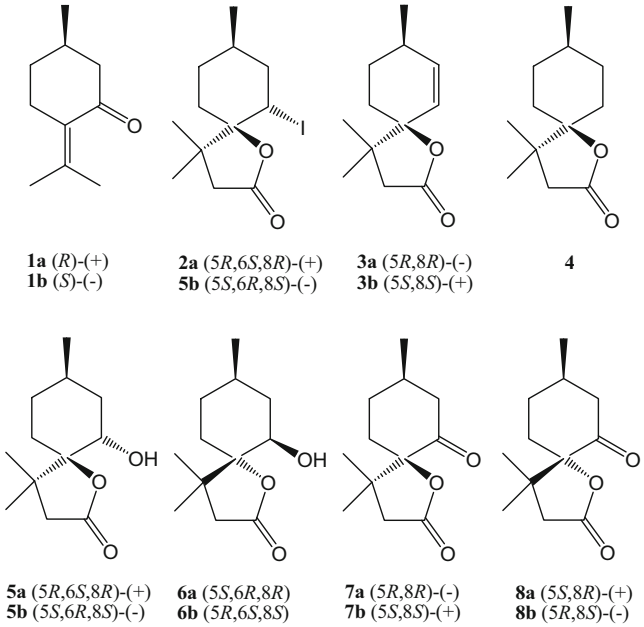

Fig. 1 Structures of pulegone and pulegone-derived lactones. **1a** (*R*)-(+)-pulegone, **1b** (*S*)-(−)-pulegone; **2a** (5*R*,6*S*,8*R*)-(+)-6-iodo-4,4,8-trimethyl-1-oxaspiro[4.5]decan-2-one, **2b** (5*S*,6*R*,8*S*)-(−)-6-iodo-4,4,8-trimethyl-1-oxaspiro[4.5]decan-2-one; **3a** (5*R*,8*R*)-(−)-4,4,8-trimethyl-1-oxaspiro[4.5]dec-6-en-2-one, **3b** (5*S*,8*S*)-(+)-4,4,8-trimethyl-1-oxaspiro[4.5]dec-6-en-2-one; **4** 4,4,8-trimethyl-1-oxaspiro[4.5]decan-2-one; **5a** (5*R*,6*S*,8*R*)-(+)-6-hydroxy-4,4,8-trimethyl-1-oxaspiro[4.5]-decan-2-one, **5b** – (5*S*,6*R*,8*S*)-(−)-6-hydroxy-4,4,8-trimethyl-1-oxaspiro-[4.5]decan-2-one; **6a** (5*S*,6*R*,8*R*)-6-hydroxy-4,4,8-trimethyl-1-oxaspiro[4.5]decan-2-one, **6b** (5*R*,6*S*,8*S*)-6-hydroxy-4,4,8-trimethyl-1-oxaspiro[4.5]decan-2-one; **7a** (5*R*,8*R*)-(−)-4,4,8-trimethyl-1-oxaspiro[4.5]decane-2,6-dione, **7b** (5*S*,8*S*)-(+)-4,4,8-trimethyl-1-oxaspiro[4.5]decane-2,6-dione; **8a** (5*S*,8*R*)-(+)-4,4,8-trimethyl-1-oxaspiro[4.5]decane-2,6-dione, **8b** (5*R*,8*S*)-(−)-4,4,8-trimethyl-1-oxaspiro[4.5]decane-2,6-dione

Aphids, Plants, and Compound Application Aphids (*Myzus persicae*) and plants (Chinese cabbage *Brassica pekinensis*) were reared in laboratory at 20°C, 65% RH, and 16:8 L/D photoperiod. Compounds were applied to the adaxial surface of leaves as 0.1% ethanolic solutions, 0.01 ml/cm^2 of the leaf according to a method described by Polonsky et al. (1989). All biological assays were performed 1 hr after compound application to allow evaporation of the carrier solvent. Iodolactones were not studied in electronic penetration graph (EPG) experiments due to their instability.

Behavioral Responses of Aphids The antifeedant effect of pulegone and its structural analogs was assessed by watching the settling behavior of freely moving aphids and by electronically monitoring aphid stylet activities in plant tissues (probing behavior).

Settling of *Myzus persicae* was studied by using the "half-leaf test" (Polonsky et al. 1989). Compounds were applied to one half of a leaf; the other side of the midrib was coated with 0.1% ethanol and considered the "control." Aphids were offered a choice between equal areas of treated and control surfaces. Aphids that settled on each side of the midrib (i.e., aphids that did not move and had their antennae directed backwards, indicating probing) were counted at 15-, 30-min, 1-, 2-, and 24-hr intervals after access to the leaf (8 replicates, 20 viviparous apterous females/replicate). The relative index of deterrence was calculated after Powell et al. (1997): $R=(C-T)/(C+T)$. C represents the number of aphids settled on the control half of the leaf and T=the number of aphids settled on half of the leaf coated with the tested compound. R values may range from "−1" (indicating a good attractant) to "1" (indicating a good deterrent). Statistical differences in settling/no settling between treatment and control were tested for each substance by Student's *t*-test.

Myzus persicae probing behavior was monitored by using electronic registration of aphid stylet penetration in plant tissues referred to as EPG. This technique is commonly used in insect–plant studies. Aphids and plants become incorporated into an electric circuit; the circuit is closed when aphids insert their stylets into plant tissues. A weak voltage is applied through the circuit, and all changes in electrical properties are recorded as EPG waveforms that can be correlated with aphid activities and stylet position in plant tissues (Tjallingii 1994). The values of parameters derived from EPG recordings, e.g., the duration of probing, duration of phloem sap ingestion, number of probes, etc., reflect the suitability of a food source to the aphids (Mayoral et al. 1996). After attachment of the wire electrode, aphids were starved for 1 hr before the start of an experiment. The probing behavior of 16 apterous females was tested per substance and monitored continuously for 8 hr with a four-channel DC EPG recording device. Signals were analyzed with Probe 2.1 software provided by W.F. Tjallingii. The following EPG patterns were distinguished: np (non penetration—aphid stylets remained outside of the plant), A, B, C, F (pathway phase—penetration of non-phloem tissues), E1 (salivation into sieve elements), and E2 (ingestion of phloem sap). The E1/E2 transition patterns were included in E1. A number of sequential (i.e., describing the sequence of events during the recording) and non-sequential (i.e., referring to frequency, total, and average duration of patterns) parameters were calculated (Van Helden and Tjallingii 1993). Results were analyzed statistically with analysis of variance (Kruskal–Wallis test) by using Statistica 6.1 (StatSoft axxp505b946905ar28).

Results

(R)-(+)-Pulegone and its Analogs Significantly fewer aphids settled on the leaf halves coated with (*R*)-(+)-pulegone (**1a**), (+)-δ-iodo-γ-spirolactone (**2a**), δ-hydroxy-γ-spirolactones *cis*(5*R*,6*S*,8*R*)-(+)-**5a** and *trans*(5*S*,6*R*,8*R*)-**6a** than on

control leaf halves. The relative indices of deterrence after 24-hr observation were 0.43, 0.72, 0.25, and 0.31, respectively. The unsaturated γ-spirolactone (5*S*,8*R*)-(−)-γ-spirolactone (**3a)** showed strong deterrent properties during the first 2 hr of an experiment (R=0.82). However, this activity had ceased by 24 hr (Fig. 2).

The most distinctive modification of aphid behavior during probing (EPG experiments) was observed on plants treated with (*R*)-(+)-pulegone (**1a**) (Table 1, Fig. 2). Total time of probing was significantly shorter on treated leaf halves—72% of 8-hr experimental time—compared to 90% for control plants. Aphids penetrated mainly peripheral tissues (78% of penetration time compared to 47% on control tissue). The time before reaching phloem vessels was nearly twice as long with non-penetration accounting for one third of that time. On (*R*)-(+)-pulegone-treated plants, aphid probes that preceded the first phloem phase were numerous (2.6 times as many as on the control half of leaves), but the probing was short, usually not longer than 2–10 min (83% of all probes). Moreover, some aphids failed to reach phloem vessels. Among those that got through to the phloem, most did not ingest sap for longer than 10 min (i.e., there was no sustained sap ingestion in more than 30% of aphids). The high proportion of salivation during penetration of phloem vessels (18% of all activities in sieve elements) was noteworthy. In 44% of aphids, recurrent alterations between E1 and E2 during every period of phloem phase were observed (the E1/E2 transition patterns were included in E1; data not shown). In general, aphid behavior generally did not change on leaf halves treated with δ-hydroxy-γ-spirolactones **5a** and **6a** compared to control leaf halves. However, on these plants, as on plants treated with (*R*)-(+)-pulegone (**1a**), aphids usually did not show sustained sap ingestion during the first contact with phloem vessels (Table 1).

(S)-(−)-Pulegone and its Analogs Significantly fewer aphids settled on leaf halves treated with (5*S*,6*R*,8*S*)-(−)-δ-iodo-γ-spirolactone (**2b)**, δ-hydroxy-γ-spirolactones: *cis* (5*S*,6*R*,8*S*)-(−)-**5b**, *trans* (5*R*,6*S*,8*S*)-**6b**, and *trans* (*5R,8S*)-(−)-δ-keto-γ-spirolactone **(8b)** than on control leaf halves. The relative indices of deterrence after 24-hr were 0.34, 0.49, 0.48, and 0.67, respectively (Fig. 3).

Aphid probing on plants treated with (*S*)-(−)-pulegone (**1b**) was similar to that on control plants. The most noticeable changes occurred after application of hydroxylactone **5b** (Table 2). Although aphid stylet penetration was not inhibited on **5b**-treated leaf halves, the total duration of phloem activities was reduced by a half, and fewer aphids showed sustained sap ingestion compared to controls [62 vs. 100% on control leaf halves or 94% on (*S*)-(−)-pulegone-treated plants]. The time to reach phloem elements was doubled, the duration of first phloem sap ingestion period was half, and the proportion of salivation in all activities in sieve elements was five times greater than on the control half of the leaves. On **8b**-treated plants, 81% of aphids reached phloem vessels, but the duration of first phloem phase was half as long as on control plants. On **6b**-treated plants, the first phloem phase was delayed by more than 2 hr on average, 32% fewer aphids reached sieve elements, and the proportion of salivation in the phloem phase was six times greater compared to controls. None or few aphids showed sustained sap ingestion during first phloem phase on plants treated with (*S*)-(−)-pulegone and lactones **5b**, **8b**, and **6b**. Thirty-two percent (**6b**) and 38% (**5b**) of aphids failed to ingest phloem sap for longer than 10 min at a time (Table 2).

Discussion

Behavioral Aspects of Feeding Deterrent Activity of Pulegone and its Analogs Frazier and Chyb (1995) suggested that insect feeding can be inhibited at three levels: preingestional, immediate effect associated with host finding and host selection processes involving gustatory receptors; ingestional, related to food transport and production, release, and digestion by salivary enzymes; and postingestional, long-term effects involving various aspects of digestion and absorption of food. Aphids differ from chewing herbivores with respect to the location of their main gustatory receptors. Mouthparts lack external chemoreceptors, and the taste organ is located in the hypopharynx, i.e., the hypopharyngeal gustatory organ; hence the ingestion of sap is crucial for recognition and acceptance of a host plant (Wensler and Filshie 1969; Ponsen 1987; Harrewijn 1990). Before reaching the phloem vessels of host food plants, aphids ingest small samples of parenchyma cell contents for gustatory purposes (Martin et al. 1997). Gabrys and Tjallingii (2002) showed that aphids can distinguish a host from a non-host plant before reaching sieve elements. Because aphid-probing behavior cannot be observed directly, the parameters derived from EPG recordings are used as reliable indicators of preingestional and ingestional factors that affect feeding. Long penetration

times of non-phloem tissues compared to total penetration time, a large number of short vs. long probes before the first phloem phase, a relatively long time to first phloem phase within a probe, and a failure to find sieve elements may be interpreted as preingestional effects of antifeedants on aphids that restrain probing at the level of non-phloem tissues. Short (<10 min) probes are limited either to the epidermis (<2 min; Van Hoof 1958) or do not reach beyond the mesophyll layer (2−10 min; Gabrys et al. 1997). Similarly, the short total and mean duration of phloem sap ingestion and the high proportion of salivation during penetration of phloem vessels may point to feeding deterrence at the ingestional level (Mayoral et al. 1996; Gabrys and Pawluk 1999). Particularly, prolonged salivation is characteristic of aphid behavior on resistant plant cultivars or non-host plants (Van Helden and Tjallingii 1993; Wilkinson and Douglas 1998; Gabrys and Pawluk 1999).

In this study, pulegone and some of its structural analogs were found to deter aphid probing and feeding at the preingestional [(*R*)-(+)-pulegone], ingestional [(*R*)-(+)-pulegone, δ-hydroxy-γ-spirolactones **5b** and **6b**, δ-keto-γ-spirolactone **8b**], and postingestional [(*R*)-(+)-pulegone (**1a**), δ-hydroxy-γ-spirolactones **5a**, **5b**, **6a**, **6b**, and δ-keto-γ-spirolactone **8b**] levels.

The preingestional effect of (*R*)-(+)-pulegone (**1a**) was characterized by aphid difficulties in finding and reaching phloem tissues. These difficulties were manifested in: prolonged time preceding the first contact with phloem vessels (2.5 times as long as on controls), greater number of probes not reaching beyond mesophyll layers before first phloem phase (3.6 times as many as on controls), and a failure to find sieve elements by 20% of aphids during 8-hr experiments. Azadirachtin- and *S*-limonene-derived lactone have similar effects on *Myzus persicae* during the pre-phloem phase (Nisbet et al. 1993; Halarewicz-Pacan et al. 2003). On non-host plants or resistant varieties of crop plants, aphid probing may also be impeded at the level of peripheral tissues. Caillaud (1999) showed that *Acyrthosiphon pisum* did not reach or ingest phloem sap from non-host plants. There were only short probes to the mesophyll. Likewise, *Aphis gosypii* on resistant lines of *Cucumis melo* showed a high number of short probes that never reached phloem vessels (Garzo et al. 2004). Pathway activities of cabbage aphid *Brevicoryne brassicae* were suppressed on the non-host plant *Vicia faba* and accidental host plants *Thlaspi arvense* and *Lunaria annua* (Gabrys and Pawluk 1999).

The ingestional effect of (*R*)-(+)-pulegone (**1a**) was characterized by a decreased duration of phloem sap ingestion (by as much as 50% compared to controls),

decreased proportion of aphids with sustained sap ingestion (by 30%), and increased proportion of salivation in aphid activities in phloem (about 12 times). Furthermore, the ingestional effect of feeding deterrence was observed after application of δ-hydroxy-γ-spirolactones **5b** and **6b**. There was a decrease in the total duration of phloem phase, the duration of first phloem phase, and the proportion of phloem phase in activities related to stylet penetration (**5b**). Between 30–40% of aphids failed to ingest sap for longer than 10 min on **6b**- and **5b**-coated leaves, respectively, and the duration of salivation into sieve elements was five times longer than on control leaves. Weak ingestional effects occurred with δ-keto-γ-spirolactone **8b**-treated leaves and were manifested in shortened phloem phase. Ingestion of the phloem sap for longer than 10 min reflects the acceptance of a plant by an aphid (Tjallingii and Mayoral 1992). The mechanism of resistance of plant varieties or cultivars to aphids is manifested in the reduction of time in sap ingestion (Cole et al. 1993; Sauge et al. 1998; Powell 2004). The presence of azadirachtin in the phloem sap results in the termination of feeding (Nisbet et al. 1993). A decrease in the duration of sap ingestion is a good indicator of the deterrent properties of specific chemical compounds—shown via the use of artificial diets by Givovich and Niemeyer (1995). Frequent interruptions of E2 in phloem phases and the relatively high proportion of salivation in aphid activities in phloem are possible responses of aphids to resistance mechanism in plants (Tjallingii 2001). Increased salivation duration is often reported in aphids that feed on resistant varieties of crop plants (Van Helden and Tjallingii 1993; Mayoral et al. 1996; Wilkinson and Douglas 1998). Sauge et al. (1998) found frequent alterations between E1 and E2 patterns during the phloem phase of *Myzus persicae* on resistant varieties of peach, and Van Helden and Tjallingii (1993) in *Nasonovia ribis-nigri* on lettuce. In the present study, such interesting phenomenon occurred after the application of (*R*)-(+)-pulegone (**1a**). Miles (1990) and Miles and Oertli (1993) suggest that aphid saliva may neutralize plant resistance factors in the phloem. Tjallingii and Cherqui (1999) showed that the watery saliva secreted into phloem elements contained various proteins, including detoxification enzymes. Leszczynski (2001) is of the opinion that the enzymes present in the saliva may help to metabolize toxic allelochemicals encountered during sap ingestion.

The postingestional deterrence by pulegone and some of its analogs may be assumed because of their influence on aphid settling. The effect of (*R*)-(+)-pulegone (**1a**) was long-term and discouraged aphids from settling on plants 24 hr after application, suggesting a role in postingestional activity. The δ-hydroxy-γ-spirolactones **5a** and **6a** derived from (*R*)-(+)-pulegone (**1a**) were probably also postingestional antifeedants. Application of these compounds did not affect aphid behavior during the pre-pholem or phloem phase of stylet penetration; however, aphids refused to settle on leaf halves treated with these compounds or with **5b**, **6b**, or **8b** within 24 hr after treatment. The postingestional effect of these terpenoids will require a separate study into their influence on digestive physiology and/or metabolism in aphids.

Structure–Activity Relationships The starting point for our experiments were two optical isomers of natural monoterpenoid pulegone: (*R*)-(+)- and (*S*)-(−)-pulegone. We found that only (*R*)-(+)-pulegone (**1a**) was deterrent to *Myzus persicae*; (*S*)-(−)-pulegone (**1b**) had no effect on aphid probing or feeding behavior. (*R*)-(+)-pulegone **(1a)** appears to be a feeding deterrent with the broadest spectrum of activity of the compounds studied. It affected aphid behavior during the initial, intermediate, and final (sap ingestion) phases of probing. (*R*)-(+)- and (*S*)-(−)-pulegone were the initial substrates for the synthesis of the bicyclic lactones with a *p*-mentane system, various functional groups, and different configuration of chiral centers. The incorporation of iodine into the bicyclic spirolactones (i.e., **2a** and **2b)** had the most dramatic impact on activity of all of the structural modifications. The deterrence indices of **2a** and **2b** were twice and four times as high as those of (*R*)-(+)-pulegone (**1a**) and (*S*)-(−)-pulegone (**1b**), respectively. Lactones with hydroxy and carbonyl groups were also active (**5a**, **5b**, **6a**, **6b**, and **8b**); however, there were differences in the activity levels among the enantiomers. Generally, lactones synthesized from (*S*)-(−)-pulegone (**1b**) were more active (e.g., hydroxylactones **5b** and **6b**) and showed broad spectrum deterrence while **5a** and **6a** deterred aphid settling but had no effect during the preingestive and ingestive stages of aphid probing. There was also a difference in activity between two diastereoisomeric hydroxylactones **5b** and **6b**, with the **5b** having broader spectrum of activity. The *trans* position of methyl group CH_3–8 and the bond C5–O1 in the lactone ring of **6b** appeared to weaken the deterrent activity in relation to diastereoisomer **5b** with *cis* configuration.

Our comparative study of the biological activity of enantiomeric pairs of pulegone and pulegone-derived lactones shows a correlation between chiral center configuration and expression of biological activity. Chirality is a unique character of most known biological processes, and enantiomers of bioactive molecules show different activities toward living organisms (Avalos et al. 2000). These studies confirm other reports that suggest that (*R*)-(+)-pulegone is a more bioactive compound than the (*S*)-isomer. For example, the hepatotoxicity and pneumotoxicity of pulegone is attributed to (*R*)-configuration of pulegone (Chan 2001). Addition of a lactone moiety and a hydroxyl group to (*S*)-

(−)-pulegone introduced antifeedant properties not possessed by the inactive substrate, thus confirming the importance of the lactone moiety to expression of biological activity. Similar effects were obtained in feeding deterrence studies of pulegone and pulegone-derived spirolactones toward the Colorado potato beetle *Leptinotarsa dacemlineata* Say, lesser mealworm *Alphitobius diaperinus* Panzer, confused flour beetle *Tribolium confusum* Duv., grain weevil *Sitophilus granarius* L., and khapra beetle *Trogoderma granarium* Ev. (Szczepanik et al. 2005; Wawrzenczyk et al. 2005).

Abstract Elaphoside-A [*p*-vinylphenyl (β-D-glucopyranosyl)-(1→3)-β-D-allopyranoside], a Mediterranean fruit fly oviposition deterrent, was previously isolated from an Argentine collection of the fern *Elaphoglossum piloselloides*. In order to establish the structural requirements for the observed oviposition inhibition, we synthesized and characterized 4 known and 21 new aromatic glycosides structurally related to elaphoside-A. Their effects on the oviposition behavior of *Ceratitis capitata* females are discussed.

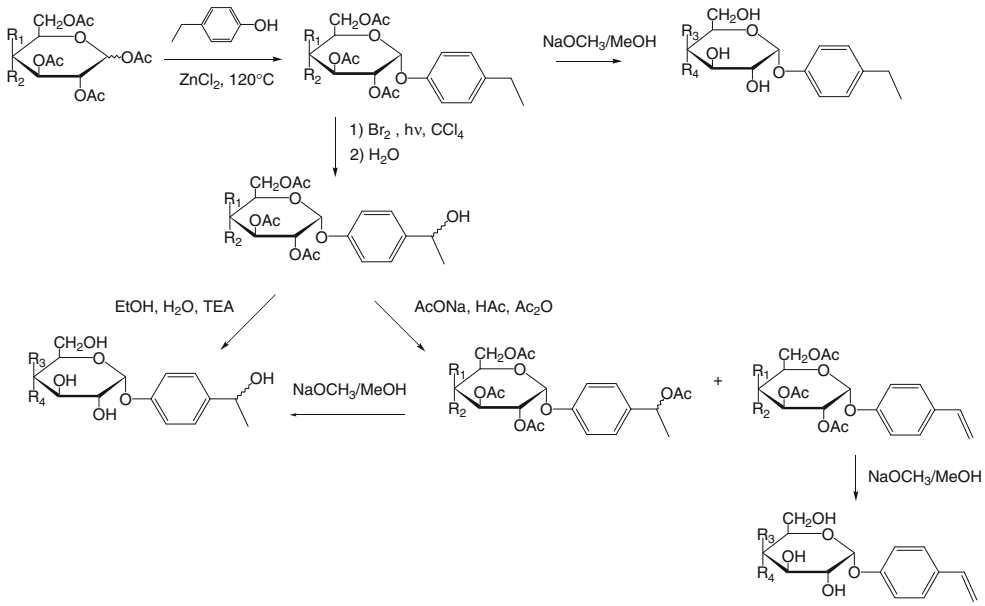
Introduction

The influence of chemical agents on the ovipositional behavior of insects can be used to control pests as well as vector insects. Some natural products display oviposition-deterrent activity against different insects. A chromene from *Blepharispermum subsessile* (Compositae) is an oviposition deterrent for *Phthorimacea operculella* (Kulkarni et al. 1987). Essential oils from medicinal plants have been successfully tested as oviposition deterrents on *Thrips tabaci* (Koschier and Sedy 2003) and the *Anopheles stephensi*, *Aedes aegypti*, and *Culex quinquefasciatus* mosquito species (Prajapati et al. 2005). The ovipositional response of the fruit fly *Anastrepha suspensa* (Loew) to stimulants and deterrents was studied by Szentesi et al. (1979). Factors that affect the oviposition behavior of some tephritid fruit flies include host-plant odor as well as the physical and chemical characteristics of the oviposition substrate, such as size, shape, color, and presence of deterrent chemicals.

The Mediterranean fruit fly *Ceratitis capitata* (Tephritidae) causes important economic damage in the north of Argentina and other countries; therefore, substances that affect their behavior can be used in the development of pest-control agents. Previously, it was reported that elaphoside-A [*p*-vinylphenyl (β-D-glucopyranosyl)-(1→3)-β-D-allopyranoside], a bitter-tasting styrene glycoside isolated from the methanol extract of the fern *Elaphoglossum piloselloides*, partially inhibited the oviposition of *C. capitata* when incorporated into the surface of an artificial fruit at a concentration of 6 μg/cm^2. The number of eggs laid on treated artificial fruit was 48% lower than that oviposited on control (nontreated) fruit at the mentioned dose (Socolsky et al. 2003). In order to determine the structural requirements



Scheme 1 Synthesis of α-ANOMERS. When R_1=OAc, R_2=H, R_3=OH and R_4=H, the scheme is illustrated for α-D-galactopyranosyl derivatives. When R_1=H, R_2=OAc, R_3=H and R_4=OH, α-D-glucopyranosyl derivatives are obtained, and when R_1=H, R_2=*O*-2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl, R_3=H and R_4=*O*-β-D-galactopyranosyl, α-lactose derivatives are obtained

for activity, a synthetic scheme (Scheme 1) was designed by varying the sugar moiety and the alkyl substituent at the *para* position of the aromatic ring to obtain 25 glycosides (**1**–**25**) structurally related to the active natural product (Fig. 1). In addition, four compounds (**26**–**29**) were obtained by chemical modification and degradation of elaphoside-A. Compounds **1**–**10**, **12**–**22**, and **24**–**29** were tested for their capacity to inhibit the oviposition of *C. capitata* in comparison with elaphoside-A and the commercial *p*-vinylanisole (**30**).

Methods and Materials

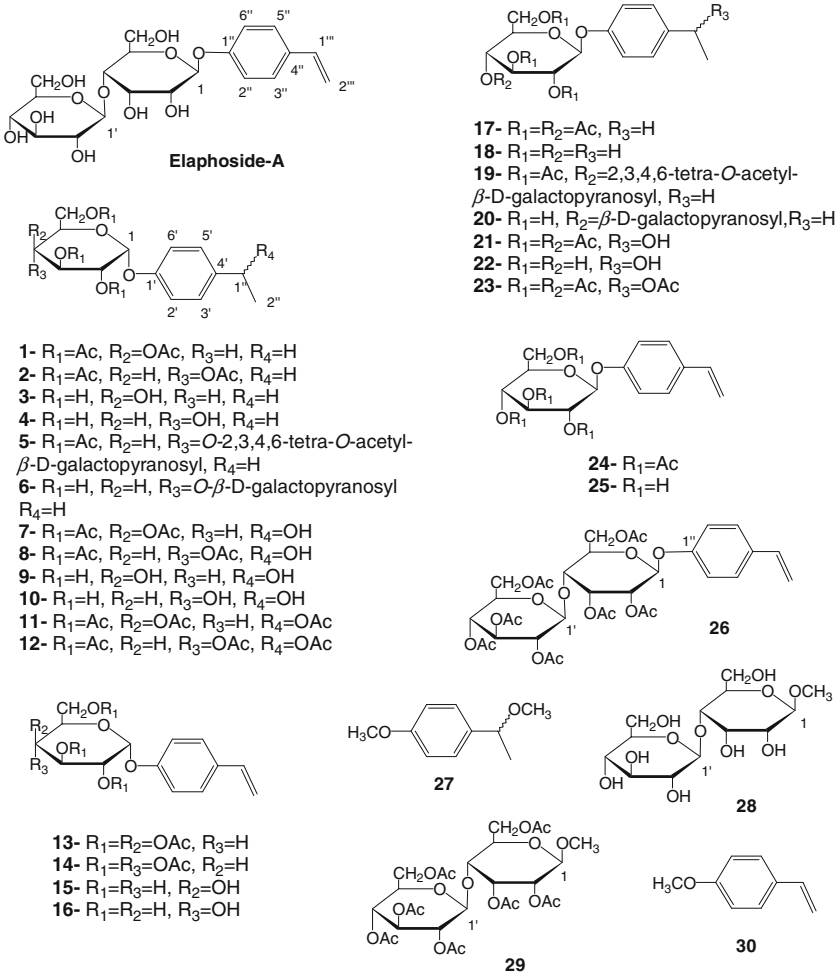
General Infrared spectra were recorded on a Shimadzu FT/IR-8400S. Optical activities were determined on a JASCO P-1030 polarimeter. Nuclear magnetic resonance (NMR) spectra were recorded on a Varian Gemini 200, Varian Unity 300, Bruker 500 or Varian Unity 600, with tetramethylsilane (TMS) as internal standard. Low- and high-resolution mass spectra were measured on a JEOL JMS AX-500 spectrometer. Column chromatography was performed over silica gel (230–400 Mesh, Merck) with hexane-AcOEt or toluene-EtOH gradients as mobile phases. For thin-layer chromatography, silica gel precoated aluminum plates (Kiesel gel 60 F254, Merck) were employed. The visualization of spots was accomplished by spraying the plates with a H_2SO_4 solution followed by heating. High-performance liquid chromatography (HPLC) separations were performed using C8 and C18 Phenomenex columns (*Luna*, 5 μm, 10×250 mm) with pure methanol or methanol–water mixtures as mobile phases.

Insects A colony of *C. capitata* was initiated with pupae obtained from infested oranges from the northwest of Argentina. Adults were fed on an artificial diet made of water and a mixture of sugar and yeast hydrolysate (3:1). They were maintained in a rearing room with a photoperiod 12L:12D, at 24±2°C and 60±10% relative humidity.

Oviposition-Deterrent Activity Artificial fruits (oviposition substrates) were prepared by boiling a mixture of peach juice (500 ml), agar (15 g), and sodium benzoate (one teaspoonful) as preservative (Fig. 2). This agar solution was poured into cylindrical molds, allowed to gel, and sliced. The agar cylinders were then wrapped in plastic wrap Rolopac to avoid dehydration. The surface of the wrapped cylinder was pricked with a needle and treated with an acetone or methanol solution of the sample to be tested. An amount of 15 μg/cm^2 of the test compound was deposited. Control cylinders were impregnated only with the solvent that was then removed in vacuo. Three groups of *C. capitata* adults were selected from the laboratory colony. Each group, consisting of seven male–female pairs, was placed in a small cage and covered with voile (a light, almost transparent cloth made of silk). Two agar cylinders (sample and control) were placed over the voile, and females oviposited on one or the other according to their preference (Fig. 2). After 4 days, eggs were gently rinsed from the agar and counted.

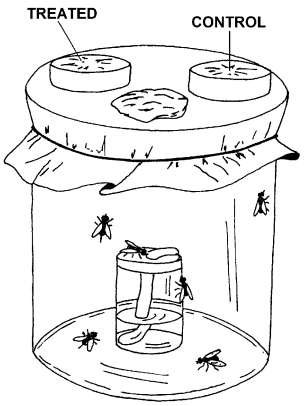
Statistical Analysis Results are reported as mean±SEM. Differences in the mean values were evaluated using the *t* test for all pairwise comparisons. In all statistical analyses, *P* values>0.05 were considered not significant.

Fig. 1 Chemical structures of the compounds evaluated for oviposition-deterrent activity



Synthesis of Aromatic Glycosides All synthetic compounds were prepared by previously reported methods (Conchie et al. 1957; Clingman 1964; Cannizzaro et al. 1998; Burger et al. 2004). The selected sugars were the monosaccharides D-glucose, D-galactose, and the disaccharide lactose. The synthetic scheme for the α-anomeric compounds is presented in Scheme 1. To obtain the β-anomeric compounds of glucose, *p*-toluenesulfonic acid was used as catalyst for the first reaction step instead of $ZnCl_2$. The β-anomeric glycoside of lactose was obtained by the Paulsen condensation method (Burger et al. 2004).

Fig. 2. Experimental setup for oviposition bioassay. Agar cylinders with peach juice were employed as artificial fruits. One of them contains the compound of interest on the surface (*treated*) and the other does not (*control*). They are placed over the cage containing the flies



Aromatic Glycosides Tested in Bioassays The synthetic compounds **1**–**25** (Fig. 1) were purified by reverse-phase HPLC, and their structures were established by spectroscopic methods (1 and 2D NMR, high-resolution mass spectrometry (MS), and infrared (IR)). NMR data are compiled (see Appendix).

Compounds **26**–**29** Compound **26,** *p*-vinylphenyl (2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyl)-(1→3)-2,4,6-tri-*O*-acetyl-β-D-allopyranoside was obtained by acetylation of elaphoside-A (Socolsky et al. 2003). Compounds **27**, *p*-(1-metoxyethyl) anisole obtained as a racemic mixture, and **28,** methyl (β-D-glucopyranosyl)-(1→3)-β-D-allopyranoside, were products of methanolysis of elaphoside-A. Finally, compound **29**, methyl (2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyl)-(1→3)-2,4,6-

tri-*O*-acetyl-β-D-allopyranoside, was obtained by acetylation of the methylated sugar.

Results and Discussion

For all compounds, the ^{1}H NMR spectra showed two doublet signals characteristic of a *para*-disubstituted benzene ring. One of them was located between 7.38 and 7.10 ppm (2H, d, $J\approx8$ Hz), and the other between 7.12 and 6.92 ppm (2H, d, $J\approx8$ Hz). The ethyl group of compounds **1**–**6** and **17**–**20** produced a quartet located between δ 2.60 and 2.47 (2H, q, $J\approx8$ Hz), and a triplet in the 1.21–1.04 ppm range (3H, t, $J\approx8$ Hz). The signals for the 1″-hydroxyethyl substituent of compounds **7**–**10**, **21**, and **22** were located in the δ 4.88–4.75 range (1H, q, $J\approx6.5$ Hz) and 1.48–1.32 (3H, d, $J\approx6.5$ Hz). Regarding the vinyl group of compounds **13**–**16**, **24**, and **25**, three characteristic signals were observed in the proton spectrum at δ 6.66 (1H, dd, $J\approx18$, 11 Hz), 5.65–5.63 (1H, dd, $J\approx18$, 1 Hz), and 5.18–5.10 ppm (1H, dd, $J\approx11$, 1 Hz). Finally, the 1″-acetoxyethyl substituent of compounds **11**, **12**, and **23** showed three signals at δ 5.86 5.83 (1H, q, $J=6.5$ Hz), δ 2.17–2.04 (3H, s), and δ 1.52–1.51 (3H, d, $J=6.5$ Hz). The proton NMR spectra of compounds **1**–**25** showed characteristic signals for the sugar moieties glucose, galactose, and lactose. Compounds **7**–**12** and **21**–**23** were obtained as mixtures of C-1″ epimers; therefore, in their ^{1}H and ^{13}C NMR spectra, some signals were duplicated. As the diastereomers' mixtures could not be resolved by high-resolution chromatographic methods, these compounds were tested as a 1:1 mixture of both epimers; therefore, the final concentration of each epimer was 7.5 μg/cm^2.

The previously described synthetic glycosides **1**–**10**, **12**–**22**, **24**, and **25** (Fig. 1) were evaluated in the bioassay (Fig. 2) in order to determine the structural requirements for oviposition-deterrent activity, taking into account that elaphoside-A is a very active compound. Our aim was to investigate how the activity is influenced by hydroxylation of the vinyl group and different sugar residues attached to

Table 1 Effect of aromatic glycosides on the oviposition-behavior of *C. capitata*

Compound	Number of Eggs Laid on the Control Fruit [a]	Number of Eggs Laid on the Treated Fruit [a]	Io=(100*T*/*C*)−100

Numbers represent mean±SEM, $n=3$. Means within a row followed by the same letter are not significantly different ($P>0.05$, paired *t* test)

the styrene moiety and acetylation of the sugars. We also tested the activity of products **26**–**29** obtained by derivatization and degradation of elaphoside-A (Fig. 1). The effects of elaphoside-A and *p*-vinylanisole (**30**) were evaluated under the same experimental conditions for comparison.

Oviposition-Deterrent Activity The results are summarized in Table 1. To facilitate their interpretation, an oviposition index was defined as Io=(100*T*/*C*)−100, where *T* is the number of eggs laid in the treated artificial fruit, and *C* is the number of eggs deposited in the control fruit. This index takes negative values for oviposition deterrents and positive values for oviposition attractants.

As shown (Table 1), the only compounds that inhibit oviposition at a rate close to that of the natural product elaphoside-A are **27** (racemic mixture) and **30**, indicating that the presence of a methoxy group attached to the aromatic ring confers activity to the compound. It is noted that the effect of each enantiomer in mixture **27** could not be assessed since the racemate could not be resolved.

None of the synthetic glycosides was as active as elaphoside-A, although the α-anomeric compounds **4**, **6**, **7**, **10**, and **16**, as well as the β-anomeric peracetylated glycoside of the disaccharide lactose (**19**), were fairly active, with Io<−30. Acetylation of elaphoside-A led to a loss of activity. An Io=−47.9 was determined for elaphoside-A, while nonsignificant effects were displayed by the peracetylated analog **26**. Accordingly, pairwise comparison of effects produced by the peracetylated glycosides **2**, **5**, **8**, **13**, **14**, and **24** (Io, 0.9, −1.3, −7.7, −13.5, −7.0, and −6.4, respectively) with those of the corresponding non-acetylated analogs **4**, **6**, **10**, **15**, **16**, and **25** (Io, −35.8, −32.8, −33.2, −28.6, −30.6, and −16.3, respectively), indicated that acetylation produced decrease or loss of the activity. In contrast, pairwise comparison of the effects produced by the α-anomers of glucose **4**, **10**, and **16** (Io, −35.8, −33.2, and −30.6, respectively) with those of the corresponding β-anomers **18**, **22**, and **25** (Io, −9.5, 7.9, −16.3, respectively) indicates that the former are more deterrent than the latter.

To evaluate the changes in activity when the vinyl group, present in the natural product elaphoside-A, was chemically modified, glycosides carrying the substituents ethyl (**1**–**6**, and **7**–**20**), 1″-hydroxyethyl (**7**–**10**, **21**, and **22**), and 1″-acetoxyethyl (**12**) were evaluated in the bioassay. As shown (Table 1), different effects were observed in each case, and thus, no structure–activity relationships could be derived.

While elaphoside-A (Io=−47.9) and the most active synthetic glycoside, *p*-ethylphenyl α-D-glucopyranoside **4** (Io=−35.8), are bitter-tasting substances, their peracetylated derivatives **26** (Io=−9.4) and **2** (Io=+0.9), respectively, had no apparent taste. Thus, taste may play a role in the election of the oviposition substrate by *C. capitata*.

Acknowledgments We thank Ms. Y. Okamoto from Tokushima Bunri University for measuring the HR-MS spectra, Dr. M. Tanaka (TBU) for recording some of the NMR spectra, and Mr. J. Caram for drawing Fig. 2. C. Socolsky thanks Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET) for a grant. Dr. N. D'Accorso is a research member of CONICET. This work was supported in part by a Grant-in-Aid for Scientific Research (B) N° 14403014 from the Ministry of Education, Science, Sports and Culture (Japan), CONICET, ANPCyT (project 06-13922), Universidad de Buenos Aires (UBA), and Consejo Nacional de Investigaciones de la Universidad Nacional de Tucumán (CIUNT), Argentina.

A Floral-Derived Compound Attractive to the Tephritid Fruit Fly Parasitoid *Diachasmimorpha longicaudata* (Hymenoptera: Braconidae)

Eric Rohrig · John Sivinski · Peter Teal · Charles Stuhl · Martin Aluja

Received: 30 October 2007 / Revised: 20 December 2007 / Accepted: 23 January 2008 / Published online: 15 March 2008

Abstract Many adult hymenopteran parasitoids, even host-feeding species, consume the nectar of flowering plants. Previous field studies had identified plants attractive (*Lobularia maritima* L.) and unattractive (*Spermacoce verticillata* L) to certain opiine braconids (Hymenoptera). Under laboratory conditions, *Diachasmimorpha longicaudata* (Ashmead), a parasitoid of tephritid fruit fly larvae and representative opiine, responded in flight tunnels to *L. maritima* but not to *S. verticillata.* Volatile chemicals of the two flowers were collected and analyzed by using capillary gas liquid chromatography and mass spectral analysis. Acetophenone was isolated from *L. maritima* but not from *S. verticillata.* In flight tunnels, *D. longicaudata* were exposed to 10 concentrations (doses) of acetophenone. Female parasitoids showed a significant attraction to several acetophenone doses, with concentrations of 25 and 50 ng the most attractive. No odor source, either floral or floral-derived, was attractive to male parasitoids. Reliable trapping systems for parasitoid species, particularly species such as *D. longicaudata* used for augmentative biological control, would be a valuable monitoring tool. At present, there are few, if any, florally derived synthetic lures for attracting hymenopteran parasitoids.

Introduction

Understanding the population dynamics of target pests and their natural enemies is critically important in Integrated Pest Management (IPM) (Kogan 1998; Suckling et al. 2002). Attraction and trapping techniques are among the simplest means of determining pest and natural enemy distributions and densities in the field, and this information, combined with known insect biology, can help determine what controls should be applied, when and where to use them, and the status of non-target organisms that might be affected (Prokopy 1985). Among the controls best timed and placed through the use of trapping-demographic data is the inundative release of beneficial insects (Jewitt and Carpenter 2001). It is particularly important to monitor the dispersal and survival of the mass-released predators/parasitoids so that adjustments can be made to the releases, and their efficacies estimated.

At present, most pest-insect attractants are based on sex pheromones, and majority of these are female-derived chemicals that capture males (Foster and Harris 1997). Sex pheromones are also emitted by female, and more rarely male, parasitic Hymenoptera (Sivinski and Petersson 1997; Kainoh 1999), and can also be used as attractants (Rice and Jones 1982; Jewett and Carpenter 2001; Suckling et al. 2002). However, compounds associated with hosts, or

environments where hosts might be found, may be more generally attractive to a presumably largely non-virgin and sexually unresponsive female parasitoid population. For example, among tephritid fruit fly parasitoids, *Fopius arisanus* (Sonan) and *Diachasmimorpha longicaudata* (Ashmead) females are attracted to fruit volatiles (Messing and Jang 1992; Eben et al. 2000; Altuzar et al. 2004), the latter particularly to decaying fruit and associated fungi (Greany et al. 1977). Yet another tephritid parasitoid *Psyttalia fletcheri* Silvestri responds to decaying fruits and leaves of pumpkins and cucumbers (Messing et al. 1996). Nishida (1956) earlier found that stem tissues of cucurbits are attractive to *P. fletcheri*, and Messing et al. (1996) suggest that the attractiveness to leaf and stem tissues may be due in part to "green leaf volatiles", a suite of common leaf-derived compounds known to be attractive to other braconid species (Whitman and Eller 1990).

Flowers of many species of plants produce odors that are also highly attractive to various natural enemies (Andersen 1987; Maini and Burgio 1999; Ventura et al. 2000; Landolt et al. 2001). Although nectar feeding, and to a lesser extent pollen consumption, is common in the parasitic Hymenoptera (Jervis et al. 1993), there has been little if any use of floral-derived compounds as attractants. However, there may be advantages to the use of such compounds. Like host odors, but unlike male-produced sex pheromones, flower volatiles might be more consistently appealing to the mated females that likely constitute the bulk of many parasitoid populations.

In the course of a previous field comparison, flowers that were attractive (*Lobularia maritima* L.) and unattractive (*Spermacoce verticillata* L.) to an economically significant subfamily of Braconidae, the Opiinae, were preliminarily identified (Rohrig 2006). In the present experiments, the flight tunnel responses of *D. longicaudata,* a widely used tephritid biological control agent and representative opiine, to the two flowering plants and to a compound uniquely identified from *L. maritima* volatiles were determined. These plants and the model insect are described below.

Spermacoce verticillata, "shrubby false buttonweed" (Rubiaceae) is native to the West Indies, but can be found in Florida and Texas as well as west Africa, the tropical Americas, and the south Pacific. Habitats consist of open or disturbed sandy zones and pinelands where it grows as a shrub. *Spermacoce verticillata* is a perennial dicot whose small white flowers form dense clusters at the upper stem nodes. Flowers have a mean corolla depth of 1.5 mm, a width of 1.0 mm, and possess a honey guard at the interior base of the corolla (Sivinski et al. 2006). The nectar is a major food source for the mole cricket ectoparasitoids *Larra bicolor* F. and *Larra analis* F. (Hymenoptera: Sphecidae) in Florida (Frank and Parkman 1999).

Lobularia maritima, "alyssum" (Brassicaceae), was introduced from the Mediterranean region and now ranges throughout most of the United States including Hawaii. This plant is a hardy, non-weedy, annual dicot herb that flowers consistently from fall through spring in subtropical areas. Small cruciform-stalked white flowers grow in clusters randomly throughout the plant that attract large numbers of parasitic Hymenoptera (Chaney 1998). On average, corollas are 0.67 mm wide by 1.4 mm deep (Sivinski et al. 2006).

Lobularia maritima nectar increases the longevity of several ichneumonoid parasitoids, both in the laboratory and in the field (Johanowicz and Mitchell 2000; Berndt and Wratten 2005). While *L. maritima* flowers increase the longevity and realized fecundity of the egg parasitoid *Trichogramma carverae* Oatman and Pinto (Begum 2004), this is only true of the white flower variety (Begum et al. 2004). This was the variety used in the present experiments.

Due to availability and its wide use as a biological control agent, *D. longicaudata* was chosen to examine the response of a representative opiine to the floral volatile. While a variety of chalcidoids, diapriids, figitids, and ichneumonoids parasitize Tephritidae (e.g., Sivinski et al. 2000), braconids of the subfamily Opiinae are typically the most numerous and diverse members of the guilds that attack frugivorous species (Purcell 1998). Opiinae are solitary, koinobiont, larval/egg-prepupal endoparasitoids of Cyclorrhapha Diptera (Bess et al. 1961; Lopez et al. 1999; Wharton 1999). Several species are considered important regulators of fruit fly populations (Wharton 1989) and have been introduced, and frequently established, throughout the world (Ovruski et al. 2000).

Diachasmimorpha longicaudata is one of the most widely used of these opiine tephritid biological control agents (Ovruski et al. 2000). Adult females use their relatively long ovipositor to parasitize a number of second- and third-instar fruit fly species' larvae in a wide variety of host fruits (Wharton 1989; Sivinski et al. 2000). The species was originally discovered in the Indo-Philippine region where it attacked *Bactrocera* spp. (Wharton and Marsh 1978), and in 1947 was introduced into Hawaii for the control of oriental fruit fly, *Bactrocera dorsalis* (Hendel) (Clancy and Dressner 1952). In 1972, *D. longicaudata* was established in Florida to control the Caribbean fruit fly, *Anastrepha suspensa* (Loew), and it subsequently reduced populations by ~40% (Baranowski et al. 1993).

In addition to wide-spread introductions, *D. longicaudata* has been mass-reared and inundatively released, either alone or in combination with sterile male flies, for the control of *Ceratitis capitata* (Wong et al. 1991), and various *Anastrepha* spp. (Sivinski et al. 1996; Montoya et al. 2000). In Florida, such releases suppressed *A. suspensa*

populations by as much as 96% and have been considered as a means of supporting "fly-free" zones to facilitate citrus exports.

Methods and Materials

Diachasmimorpha longicaudata were obtained from a >5-yr-old colony at the USDA-CMAVE and reared as described by Sivinski et al. (1996). Parasitoids were maintained in a climate-controlled room with a temperature range of 21–24°C and a relative humidity of 65–80%.

Chemical Analysis Preliminary chromatographic examinations of volatile chemicals collected from cut and attached flower were similar. Therefore, due to the handling ease, flowers used for compound identification were cut from the plant stem as close to floral tissue as possible, and the cut end was surrounded with cotton wool soaked in water. Flower heads were placed in a glass volatile collection chamber (Heath and Manukian 1992). This system consists of a chamber (30 cm long and 4 cm outside diameter [OD]) that has a sintered glass frit at the upwind end and a joint outlet with a single-port collector base. Humidified charcoal filtered air was pushed into one end of the chambers and over the flower heads. Air was pulled out the other end via a vacuum system. Air exiting the chamber passed through a volatile collection filter that contained 50 mg of Super-Q® (Refined Technologies, Woodland, TX, USA) to collect and hold any volatiles. Afterwards, collection filters were eluted with three aliquots of 100 µl methylene dichloride to remove volatile compounds.

Extracts of samples were analyzed by capillary gas liquid chromatography (GC) using a Hewlett Packard 5890 (Palo Alto, CA, USA) equipped with a cool on-column injector and flame ionization detector. The column, a 30 m×0.25 mm (i.d.) SE-30 capillary column (Alltech Assoc., New Gloucester, ME, USA), was attached to a 10-m length of 0.25-mm (id) deactivated fused silica as a retention gap, which was in turn attached to a 10-cm length of 0.5 mm id deactivated fused silica in the injector. Helium (linear flow velocity 18 cm/sec) was used as a carrier gas. The oven temperature and injector temperatures were programmed to go from 60°C (held for 5 min) to 200 °C at a rate of 10°C/min. Mass spectral analysis was accomplished with an HP6890 GC equipped with a DB-5 MS® column (30 m×0.25 mm ID×0.25 µm,) linked to an HP 5973 mass spectrometer. Both electron impact (70 eV) and chemical ionization (isobutene reagent gas) spectra were obtained. Helium was the carrier gas, and a splitless injector (injector temperature of 240°C, split valve delay of 0.5 min) was used. The oven temperature was held at 35°C for 1 min, then programmed to increase at a rate of 10°C/min to 230°C, which was held for 10 min. The ion source temperature was 230°C. Tentative identifications were made by comparison of fragmentation patterns with patterns available in the NIST-MS library and libraries developed at USDA-CMAVE (Gainesville, FL, USA). Identifications were confirmed by comparison of chromatographic retention times and mass spectra of natural compounds with those of commercially available standards analyzed on the same instrument.

Electroantennagrams To determine if male and female *D. longicaudata* had a sensory response to *L. maritima* volatiles (see results), extracts were analyzed with a GC interfaced to both flame ionization (FID) and electroantennograph detectors. In this manner, antennal responses were matched with FID signals for compounds eluting from the GC. Volatile extracts were prepared in the manner described above, and 1-µl aliquots were analyzed on a Hewlett-Packard (HP) 5890 Series II gas chromatograph equipped with an HP-5 column (30 m×0.32 mm ID×0.25 mm) (Agilent, Palo Alto, CA, USA). The oven temperature was held at 40 °C for 5 min, then programmed to increase to 10°C /min to 220°C and held at this temperature for 5 min. Helium was used as a carrier gas at a flow rate of 2.0 ml/min. A humidified air stream was delivered over the antenna is at 1 ml/min.

The antennae were excised by grasping the scape with jeweler's forceps (No. 5, Miltex Instrument Company Inc, Switzerland) at the base, and the antennae were removed from the head of either male or female wasps. The extreme distal and proximal ends of the antennae were held between gold electrodes in conductivity gel (Syntech, Hilversum, The Netherlands). The electroantennal detector (EAD) and FID signals were concurrently recorded with a GC-EAD program (Syntech GC-EAD 2000, Hilversum, The Netherlands), which analyzed the amplified signals on a PC.

Flight Tunnel Bioassays To determine the response of *D. longicaudata* to various odor sources, parasitoids were observed in three identical flight tunnels. These flight tunnels were constructed of clear Plexiglas and measured 128 cm long×32×32 cm, and were located inside two climate-controlled greenhouses. Natural sunlight illuminated the chambers. Although the greenhouses were climate controlled, extremes of outside temperatures caused the internal temperature to fluctuate between 21° and 27°C and relative humidity between 60% and 85%. Airflow and air speed were maintained at 0.3 to 0.4 m/s by using a variable speed fan at the downwind end. This was the speed that stimulated the most flight in *D. longicaudata* in previous investigations (Messing et al. 1997). Odors were released into the anterior end of the tunnel. Two separate chambers that contained either an odor source or a blank-air control

were housed outside of the flight tunnel. Chambers were constructed from 114-l all-glass aquaria (31×61×61 cm). Lids were constructed of clear Plexiglas and fit tightly to prevent outside air from entering the chambers. Purified air was passed through the sample chambers at 0.3 m/s regulated with adjustable flow meters (Aalborg Instruments, Monsey, NY, USA) and into the flight tunnel. Each chamber was connected to a trap inside the front end of the tunnel. The traps were located midway between the top and bottom of the tunnel, and were constructed from clear cylindrical plastic vials (9×5 cm) placed horizontally. Both cylinders had orange colored snap tight lids and had a 1.3-cm hole in the center to allow air to exit. This provided an opening for the parasitoids to enter in search of the odor source.

Traps, washed initially with a mild detergent, were changed with each new odor source, and the tubing connecting the traps to volatile-source container was washed with detergent after each replication.

In all flight tunnel experiments, 25 presumably mated (sexes held together for 3–7 d) parasitoids were used per day. All parasitoids had access to water, but food was withheld for 24 hr before use in experiments to enhance response to potential food sources. Flight tunnels were checked hourly from 0900 to 1700 hours. A parasitoid inside a trap was recorded as a positive response, and was removed and returned to the tunnel after counting. Each day, the tubes connecting the odor chambers to the traps were switched to prevent positional effects.

Ripe mango fruit, *Mangifera indica* L., and the flowering plants were tested as odor sources. Mangos are attractive to *D. longicaudata* in flight tunnel tests (Eben et al. 2000) and were used as a positive control. Flowering plants were in full bloom and contained in 2-l plastic pots. Each of the three odor sources was tested individually against a blank control of clean odorless air. There were 10 replicates for males alone and 10 for females alone, each replicate lasting a day. In addition, there were 10-d-long replicates of 25 females and 25 males together with *L. maritima* as the odor source. This was done to ensure that any sexual dimorphism in response was not due to undetermined environmental factors present during separate-sex replications.

Acetophenone was loaded on 11-mm sleeve stopper natural red rubber septa by dissolving the synthetic material at various doses in methylene chloride and filling the large well of the septa with 100 µl of solution. Septa were air-dried for 24 hr and stored in a freezer, except during use in the wind tunnels. During flight tunnel tests, septa were placed in glass airtight containers (2 l) that served as the odor chambers.

All volatile loaded septa were run against blank septa loaded with 100 µl of methylene chloride and air-dried as a control. To find the dose that elicited the greatest response, various concentrations were exposed to parasitoids. An initial dose of 1 mg did not produce a response, and increasingly lower doses were tested until there was no significant response. Each dose was initially run for 3 d in sequential decreasing order from highest to lowest. Only females were in the wind tunnel. Acetophenone doses used were as follows: 1 mg, 100 µg, 50 µg, 10 µg, 1 µg, 100 ng, 50 ng, 25 ng, 10 ng, 1 ng. If any response was seen, then that volatile dose was run for 10 d with females and 10 d with males.

Statistical Analyses Statistical analyses were conducted by using SAS programming (SAS Institute Inc. 2001). Polynomial regression analysis (PROC GLM) was used to examine flight responses over time and the interactions of "time of day ×volatile source" on response. Analysis of variance (PROC ANOVA) followed by means separation through the Waller test was employed to compare the mean responses to various doses. Note that the protocol for all wind tunnel experiments included the return of captured females to the population inside the tunnel. While this was a simple means of controlling for insect density and environmental history, the summed captures could include multiple responses by a particular insect. This led us, when comparing a particular volatile to its control, to employ the most conservative method available, the nonparametric "paired sign test" (Zar 1974) where a consistently greater response over 10 replicates to a particular source yields a P value of 0.01. Mean and variance data should be interpreted in terms of "responses" and not "insects responding".

Results

Volatile Identification Gas chromatographic analysis of volatiles from the flowers of each plant revealed the presence of surprisingly few compounds (Fig. 1a). After subtraction of compounds present in volatiles from both species, only three were unique to volatiles collected from *L. maritima*, and only a single compound was common to those collected from intact flowers and from excised flowers. Mass spectral analysis (both electron impact (EI) spectra and chemical ionization (CI) spectra) of the unique compound indicated a mass of 120 amu with significant losses of 15 (CH_3), 28 (CH_2O). Tentative identifications were made by comparison of fragmentation patterns with patterns available in the NIST-MS library and libraries developed at USDA-CMAVE (Fig. 1a). Acetophenone (Fig. 1b) (8.96 min; C8H8O, molecular weight 120.15 g/mol [US EPA, 1987]) showed a large peak in *L. maritima* volatiles and was not present in those of *S. verticillata*.

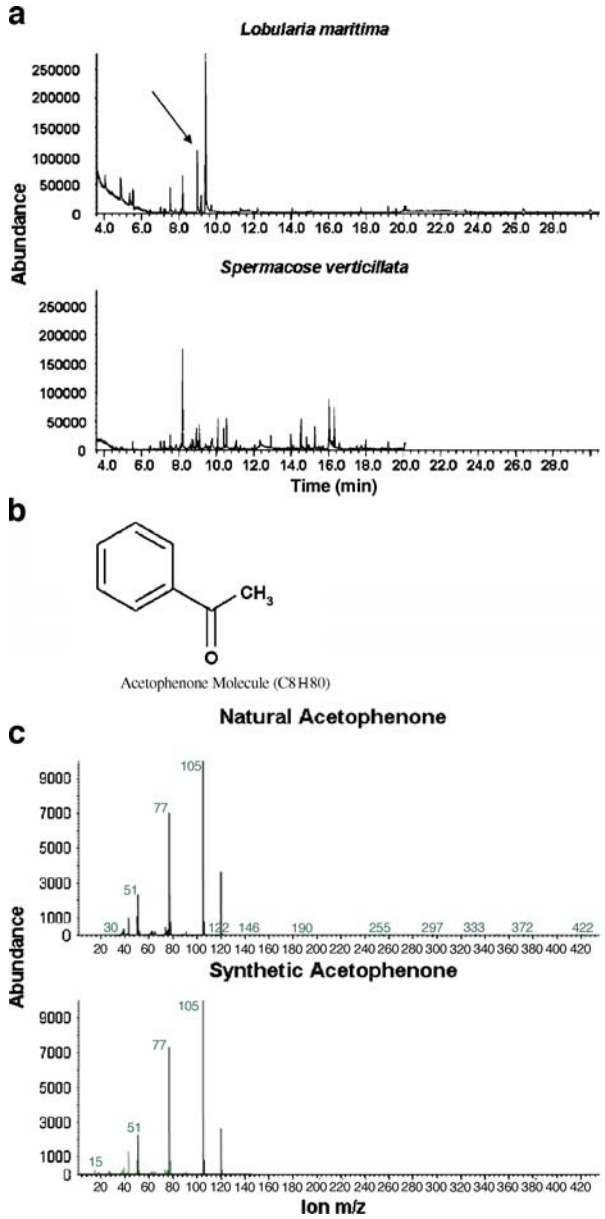

Fig. 1 (**a**) GC analysis of chemical constituents of two flowering plant, *Lobularia maritima* and *Spermacoce verticillata*, volatiles as revealed by mass spectra. The arrow indicates the unique presence of acetophenone in *L. maritima.* (**b**) Acetophenone molecule. (**c**) A mass spectroscopy comparison between the putative acetophenone collected from *L. maritima* and a known synthetic standard

Identification was confirmed by comparison of GC retention times and MS of natural compounds with those of commercially available standards analyzed on the same instruments (Fig. 1c).

Electroantennagrams Both male and female *D. longicaudata* registered a neuronal response that correlated to the putative acetophenone peak present in *L. maritima* volatile extracts (Fig. 2). Of the three females tested, their average responses over three exposures to volatiles were areas (mV/time) of 1.2, 0.7, and 1.5. Of the three males tested, their average responses over three exposures were 0.4, 0.6, and 1.1.

Flight Tunnel Bioassays Males showed no significant response to any odor source. In several instances, they were caught in isolation traps, but in general, they exhibited occasional walking and flying behaviors at the rear of the flight tunnel away from the odor source.

Females had different responses to various volatiles (F=240.5, df=9, 1430, P=0.001), and were more likely to be trapped by some volatiles than by their corresponding controls (F=35.8, df=1, 1430, P=0.001). Responses differed over time in a non-linear fashion (F=67.3, df=1, 1430, P=0.001) (Fig. 3). However, the responses over time were similar among treatments, i.e., there was no significant interaction between type of volatile and the temporal pattern of response (F=0.68, df=1, 1430, P=0.41).

Because it was impractical to control the amount of volatiles emitted by fruit and flowers, there was no direct comparison of these non-formulated volatile sources. Both mango and *L. maritima* significantly elicited female responses, but *S. verticillata* did not (Fig. 4). These tests

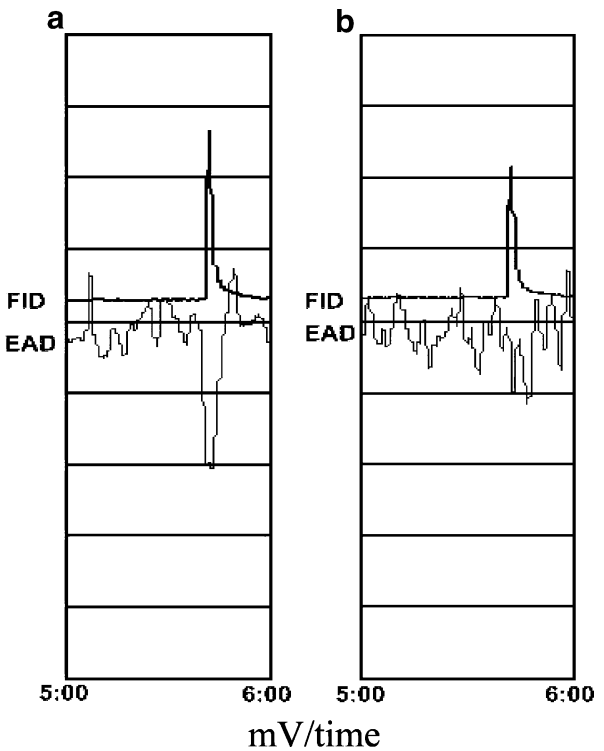

Fig. 2 Neuronal responses of (**a**) female and (**b**) male *Diachasmimorpha longicaudata* to the acetophenone present in volatile extracts of *Lobularia maritima* flowers. The darker line represents the presence of acetophenone as revealed by gas chromatography and the lighter line the response of neurons to the same volatile sample

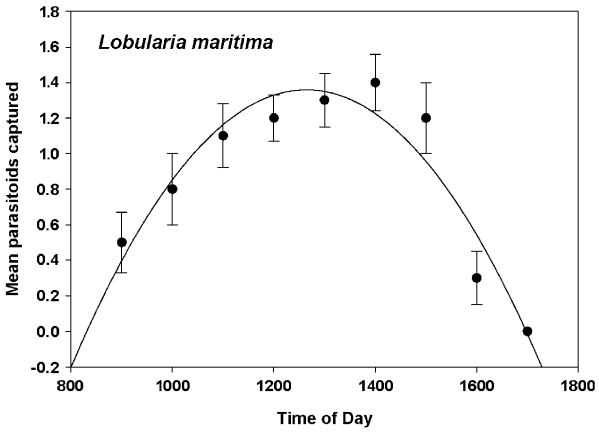

Fig. 3 Mean (SE) windtunnel captures of female *Diachasmimorpha longicaudata* over time in response to flowering *Lobularia maritima*

were followed by exposures of parasitoids to formulated doses of acetophenone, the compound present in *L. maritima*, but absent in *S. verticillata*. Of the 10 doses tested, four elicited a response from parasitoids (Fig. 4). Acetophenone concentrations of 100, 50, 25, and 10 ng all showed significant attraction, with 25- and 50-ng doses being the most attractive (F=3889, df=3, P=0.003; Fig. 5). Acetophenone doses of 1 mg, 100, 50, 10, and 1 µg, and 1 ng elicited no response in female parasitoids in the wind tunnel.

When both males and females were simultaneously exposed in the wind tunnel to *L. maritima* flower volatiles, no males entered the isolation chambers, but female response was similar to the single-sex experiment with *L. maritima* (mean of 0.9 [SE 0.07] responses/hourly observation period; paired sign test, greater response to volatile source equal to 10 of 10; P=0.01).

Discussion

These experiments provide additional evidence that not all flowers are equally attractive to any one particular species of parasitoid (Jervis et al. 1993). In the field, *L. maritima* caught more Braconidae, specifically unidentified Opiinae, than did *S. verticillata* (Rohrig 2006). This difference was substantiated in flight tunnel tests that found a significant flight response by the opiine *D. longicaudata* to *L. maritima* but not to *S. verticillata*. In addition to this corroborative evidence in support of the generality that there is variance in the diversity of parasitoids attracted to flowers, there were several novel/unusual findings. These included: (1) the suggestion that there may be broad phylogenetic preferences for certain flowers, i.e., the common response of at least two allopatric opiines to the pair of flower species (Rohrig 2006); (2) the identification of a compound from a flower volatile that is attractive to a hymenopteran parasitoid; and (3) the sexual dimorphic response to *L. maritima*, with only females attracted to either the complete flower volatiles or the isolated compound unique to *L. maritima*.

Direct comparisons of parasitoid olfactory response to different live flowers can lead to ambiguous results. Although the sizes of the plants used and the overall area of flowers present were similar (Rohrig 2006), the amounts of volatiles released may have been different. Even within a species, odor concentration can vary among flower parts and change diurnally as well as seasonally (Bergstrom et al. 1995). The identification of the attractive compounds present in floral odors can help overcome this obstacle. Once isolated, compounds can be presented in fixed amounts, thereby reducing variation in the odors encountered by the test insects. Thus, the identification of

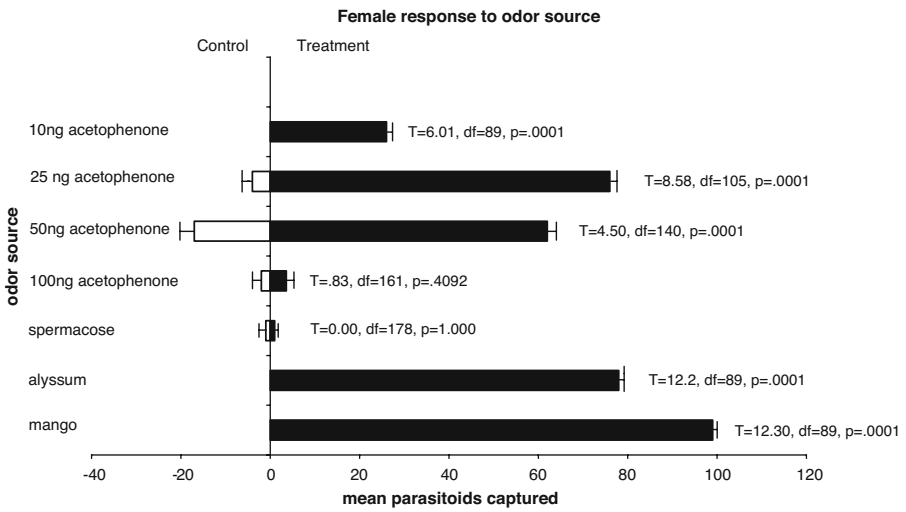

Fig. 4 Mean (SE) of summed captures/replicate of females *Diachasmimorpha longicaudata* exposed to various volatiles and their corresponding blank air controls

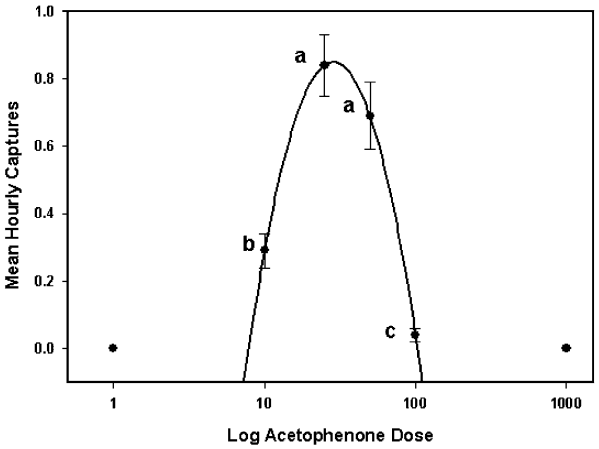

Fig. 5 Mean (SE) captures of female *Diachasmimorpha longicaudata* exposed to various doses of acetophenone. The regression line fits only those doses that elicited a significant response. Means that share a letter are not significantly different

acetophenone as a compound both unique to *L. maritima* and attractive to *D. longicaudata* supports the difference in attractiveness observed between the two whole plants. The isolation of acetophenone also allowed estimation of optimal release rates.

Diachasmimorpha longicaudata had a sexually dimorphic response to all volatiles that elicited flight; male parasitoids were not attracted to any. This was true when the sexes were tested both separately and together, so that unnoticed environmental cues present during single-sex experiments cannot be responsible for the sexual difference. Males did exhibit oriented flight and entered the isolation traps in response to virgin females + fruit + honey solutions in experiments conducted in the same wind tunnels (C. S., unpublished data). Thus, the lack of response in the present experiments was due to the volatiles used and not because of male inability to perform in the flight tunnel environment.

Messing and Jang (1992) had previously found that female *D. longicaudata* responded to various host fruit stimuli to a greater extent than did males. Similar sexually dimorphic responses to plant materials are not restricted to hymenopteran parasitoids. For instance, females of the tachinid *Eucelatoria bryani* Sabrosky are attracted to many more plant volatiles, including those of flowers, than are males (Martin et al. 1990).

There are several possible explanations of why female, and not male *D. longicaudata*, are attracted to acetophenone. For instance, females may have unique nutritional needs that flower nectar provides. Acetophenone possess a flowery smell and is used in the perfume industry in fragrances such as vanilla, honeysuckle, and jasmine (USEPA 1987). It is emitted as a volatile by several flowers including *Centaurea scabiosa* L., a species frequently visited by butterflies (Andersson et al. 2002), *Elsholtzia argyi* Dong (Peng and Yang 2005), and *Calanthe sieboldi* Decne (Awano et al. 1997). In the laboratory, *D. longicaudata* feeds avidly on juices of fruits that would be commonly encountered while searching fallen fruit for hosts (Sivinski et al. 2006). Ground-foraging female parasitoids, however, would also be in the general vicinity of flowers and could visit them to obtain additional other nutrients (Koptur 2005). The relatively ambiguous laboratory evidence that flowers are an important adult food sources for *D. longicaudata* does not offer strong support for this conclusion (Sivinski et al. 2006). Maximum longevities were significantly extended in the presence of flowers (including the presently examined species), but there was no difference between the mean longevities of parasitoids provided with flowers and those given only water.

Females might also mistake acetophenone for a host-fruit volatile or a male-produced pheromone. It has been isolated from Rambutan fruit (*Nephelium lappaceum* L.; Ong et al. 1998) and guava pulp (*Psidium guajava* L.) (Idstein and Scherier 1985), and is also produced by a number of diverse insects as a semiochemical (Kohnle et al. 1987; Schulz et al. 1993; Aldrich et al. 1995; Birkett et al. 2004). The latter hypothesis likely can be discarded since neither acetophenone nor closely related compounds are present in the male-produced sex pheromone (Nancy Epsky, unpublished data).

However, female *D. longicaudata* might mistake the flower volatile for a fruit cue. Tephritids use odor to locate fruit, and the same ability would be useful to fruit fly parasitoids (Eben et al. 2000). Males of both fruit flies and their natural enemies may not have been subject to the same selection pressures as females to develop sensitivity to fruit odor stimuli. For example, when 4-ethyl-acetophenone in the peel of navel oranges (*Citrus sinensis* Osbeck) was used as an odor source in electroantennogram studies of *Ceratitis capitata* (Weid.), the Mediterranean fruit fly, it elicited a significant voltage spike in females, but not in males (Hernandez et al. 1996). Levinson et al. (2003) found that female *C. capitata* sensilla were significantly more responsive to orange odor than male sensilla. Electroantennagrams showed that male *D. longicaudata* sensed acetophenone, but it did not elicit a behavioral response.

Regardless of the significance of the acetophenone response, it may lend itself to improved traps and ultimately better control procedures. There are no efficient synthetic lures and traps available to monitor opiine parasitoid populations in the field (Messing 1992). At present, most monitoring and delineation of fruit fly parasitoids is accomplished through laborious and time-consuming fruit sampling (Montoya et al. 2000; Sivinski et al. 2000). An improved trapping system would prove valuable in several ways. It could be used to determine the presence of

parasitoids in a given area as well as help understand their population dynamics. Traps could provide important wasp dispersal and patch retention information that might improve the application of parasitoids for inundative biological control. Knowing when and where to release parasitoids, as determined by previous trapping in various locations, could be crucial to their application in new sites, whether the goal is permanent establishment or mass releases.

Field testing of acetophenone is needed to examine its usefulness. Although only female wasps were attracted, females are the agents of mortality, and their distribution in time and space is generally of primary interest. It may be that acetophenone by itself will not be sufficiently attractive, but it could prove to have a role in a more efficacious mixture of compounds that could include other floral volatiles, fruit odors (Eben et al. 2000), fungal/bacterial odors (Greany et al. 1977), and pheromones.

Acknowledgments We thank Dr. Ru Nguyen, Dr. Nancy Epsky, and Dr. Rob Meagher, for advice and review. We also thank the late Barbara Dueben for help on the chemical and bioassay aspects of this work. Tim Holler and Amy Moses provided a constant supply of parasitoids. We also thank Gina Posey for help with computer issues and the preparation of the graphs.

Received: 2 July 2007 / Revised: 24 November 2007 / Accepted: 9 December 2007 / Published online: 4 March 2008

Abstract Plants defend themselves against herbivores and pathogens with a suite of morphological, phenological, biochemical, and biotic defenses, each of which is presumably costly. The best studied are allocation costs that involve trade-offs in investment of resources to defense versus other plant functions. Decreases in growth or reproductive effort are the costs most often associated with antiherbivore defenses, but trade-offs among different defenses may also occur within a single plant species. We examined trade-offs among defenses in closely related tropical rain forest shrubs (*Piper cenocladum*, *P. imperiale*, and *P. melanocladum*) that possess different combinations of three types of defense: ant mutualists, secondary compounds, and leaf toughness. We also examined the effectiveness of different defenses and suites of defenses against the most abundant generalist and specialist *Piper* herbivores. For all species examined, leaf toughness was the most effective defense, with the toughest species, *P. melanocladum*, receiving the lowest incidence of total herbivory, and the least tough species, *P. imperiale*, receiving the highest incidence. Although variation in toughness within each species was substantial, there were no intraspecific relationships between toughness and herbivory. In other *Piper* studies, chemical and biotic defenses had strong intraspecific negative correlations with herbivory. A wide variety of defensive mechanisms was quantified in the three *Piper* species studied, ranging from low concentrations of chemical defenses in *P. imperiale* to a complex suite of defenses in *P. cenocladum* that includes ant mutualists, secondary metabolites, and moderate toughness. Ecological costs were evident for the array of defensive mechanisms within these *Piper* species, and the differences in defensive strategies among species may represent evolutionary trade-offs between costly defenses.

Introduction

In response to strong selective forces exerted by a broad array of enemies, which include insect herbivores, vertebrate herbivores, and pathogens (Coley et al. 1985), plants employ a variety of morphological, biochemical, and biotic defenses (Maxwell et al. 1972; Johnson 1975; Coley 1983; Kursar and Coley 1992; Harborne 2001). Differences in plant palatability that result from these defenses contribute to substantial variation in the extent of herbivore damage to plants (Coley 1983). However, each kind of defense is potentially associated with allocation costs (Levin 1976; Herms and Mattson 1992; Gershenzon 1994; Bergelson and Purrington 1996; Koricheva 2002; Strauss et al. 2002).

Many studies have addressed intraspecific trade-offs between defense and other plant metabolic functions (Zangerl et al. 1997). Because most plants produce several

different defenses (reviewed in Romeo et al. 1996), intraspecific trade-offs may occur between defenses (e.g., between chemical and biotic defenses or between two different chemical defenses; Mattson et al. 1988; Steward and Keeler 1988; but see Koricheva et al. 2004). In this case, rather than reducing plant allocation of resources to reproduction or growth, plants may express the costs of heightened defense production by diverting resources from one defense to another. These trade-offs among different defenses are referred to as "ecological costs" (Heil 2002) since reducing a given defense only incurs costs under the appropriate ecological conditions.

Evolutionary trade-offs among defenses may also be evident between closely related species because sympatric plant species that differ in the type or quantity of their defenses may be at a selective advantage when defending themselves against specialist herbivores that have evolved resistance (Cates and Rhoades 1977). Producing multiple defenses may be selectively advantageous either because of synergistic action, where the effect of a combination of defenses exceeds the sum of the effect of all individual defenses (e.g., Berenbaum and Neal 1985; Berenbaum et al. 1991; Calcagno et al. 2002; Dyer et al. 2003), or because multiple defenses may protect a plant against a diverse suite of enemies (Hay et al. 1994; Lindroth and Hwang 1996; Nelson and Kursar 1999; Dyer et al. 2003; Koricheva et al. 2004).

Ant–plant associations ranging from obligate mutualisms to loose facultative relationships are common (Heil and McKey 2003) and have long been used as model systems in the study of plant defense (e.g., Janzen 1966; Rehr et al. 1973; Dyer et al. 2001). Allocation of resources to production of domatia, food bodies, nectar, or other ant rewards in these systems presumably incurs some costs (Folgarait and Davidson 1995; Dyer et al. 2001; Heil et al. 2002). Leaf toughness and production of secondary metabolites are two widely distributed defenses in tropical plants (Coley and Barone 1996). Several studies have shown that toughness is an effective defense (Feeny 1970; Coley 1983; Sagers and Coley 1995; Coley and Barone 1996), but relatively few studies include toughness in examinations of ecological costs. Plant secondary metabolites are often effective in reducing herbivory (reviewed by Harborne 2001) but can be metabolically costly to produce (Gershenzon 1994; Zangerl et al. 1997; Dyer et al. 2001; reviewed by Bergelson and Purrington 1996, and Strauss et al. 2002), potentially necessitating trade-offs in resource allocation. For example, allocation of limited plant resources may necessitate trade-offs between allocation of carbon to ant rewards, construction of structural carbohydrates to enhance toughness, and/or chemical defense. Similarly, nitrogen may be allocated to ant rewards, nitrogen-based chemical defenses, or the enzymes and physiological machinery necessary to produce tougher leaves or higher levels of chemical defense. Plant species or individuals that invest in ant mutualisms often show reduced chemical defense when compared to closely related species or individual plants within a species that lack ant defenders (Rehr et al. 1973; Dyer et al. 2001; Heil et al. 2002).

By using field experiments and surveys, we examined relative efficacies of and trade-offs among three ecologically important tropical plant defenses: ant mutualists, secondary metabolites, and leaf toughness. Three closely related species in the genus *Piper* [*P. imperiale* (Miq.) C. DC., *P. cenocladum* C. DC., and *P. melanocladum* C. DC.) served as a model system. The phytochemistry of the diverse tropical genus *Piper* is variable and well documented (reviewed by Parmar et al. 1997; Dyer et al. 2004a). All species investigated to date (more than 112) produce mixtures of secondary metabolites, and the compounds discovered include alkaloids/amides/imides, lignans, neolignans, terpenes, propenylphenols, steroids, kavapyrones, chalcones, flavones, flavanones, and piperolides (Dyer et al. 2004a). The three *Piper* species utilized are closely related (as part of the sect. *Macrostachys* clade, Tepe et al. 2004), and share many species of generalist and specialist herbivores (Marquis 1991; L. Dyer, personal observations). They display a unique combination of ant mutualism, chemical defense, and leaf toughness. *Piper cenocladum* is defended by ant mutualists and nitrogen-containing chemicals, *P. imperiale* has a facultative relationship with ants, but its chemistry has not previously been investigated, and *P. melanocladum* has no relationship with ants, and its chemistry was previously unknown. The relative leaf toughness of all three has not previously been measured.

We tested for inter- and intra-specific trade-offs between multiple putative plant defenses and their effects on herbivory in order to address these two general questions: How is intra- and interspecific variation in plant defense associated with herbivory by specialists and generalists? Are ecological costs of different types of defense evident within and among these three *Piper* species?

We predicted that generalist herbivores would respond more to chemical defenses, while small, specialists would be deterred by ant defenders or leaf toughness (Dyer et al. 2004b). We expected to find trade-offs in allocation of resources to toughness, ant associations, and chemical defense within and among the three *Piper* species.

Materials and Methods

Study System *Piper cenocladum* is a tall (to 5 m) understory plant with large, long-lived leaves (Letourneau and Dyer 1998) found in the lowland wet forest of Costa Rica (Burger 1971). This species has defenses in the form of

amide/imide secondary metabolites (Dodson et al. 2000) and resident obligate ant mutualists (Risch and Rickson 1981; Risch 1982). *Piper cenocladum* leaves contain two imides and one amide [Appendix, structures 1–3: piplartine (1), 4′-desmethylpiplartine (2), and cenocladamide (3); Dodson et al. 2000] in relatively high concentrations of up to 3.8% dry weight (Dyer et al. 2004b). Piplartine is cytotoxic in vitro (Duh et al. 1990), and all three compounds in combination act synergistically to directly and indirectly affect the fitness and feeding preferences of generalist and specialist herbivores from a wide range of taxa (Dyer et al. 2003). *Pheidole bicornis* Forel (Hymenoptera: Formicidae: Myrmicinae) ant colonies are housed inside of *P. cenocladum* sheathing leaf bases (petioles), and the plants produce amino acid and lipid rich opalescent food bodies on the adaxial sides of the petioles (Risch and Rickson 1981). These food bodies comprise the majority of the ants' diet (Fischer et al. 2002). In return, the ants remove insect eggs, vines, and small particles from the surface of the leaves, and kill small lepidopteran larvae and stem boring weevils (Risch et al. 1977; Letourneau 1983; Letourneau and Dyer 1998). When plants are not inhabited by ants, the production of these food bodies declines, and amide production increases threefold or greater (Dodson et al. 2000; Dyer et al. 2001).

Piper imperiale is a large shrub or small tree to 6 m tall found in moist, shaded forest areas (Burger 1971). This species is characterized by large leaves and tubercles on stems and leaves but in many ways is morphologically and ecologically similar to *P. cenocladum* (Burger 1971). Several species of ants facultatively inhabit the sheathing leaf bases, but the plants produce no food bodies inside of the domatia. Whether the ants benefit the plants in any way is unknown.

Piper melanocladum is a small understory shrub to 1.6 m tall, with thick, glabrous, shiny lanceolate leaves (Burger 1971). It has small, partially open leaf bases, and has no demonstrated relationship with ants. We describe the first characterization of the nitrogen-based secondary metabolites of *P. imperiale* and *P. melanocladum*.

Field Survey This study took place in two lowland tropical wet forests at Tirimbina Rainforest Center and Estacion Biologica La Selva, Heredia Province, Costa Rica. La Selva is located at 10°25′N 84°05′W at circa 100 m elevation on the Caribbean slope. Tirimbina is located nearby at circa 210 m elevation, 10°24′4″ N, 84°6′29″ W.

We sampled *P. imperiale* (N=81), *P. cenocladum* (N=84), and *P. melanocladum* (N=94) plants along trails at Tirimbina and La Selva. Because *P. imperiale* and *P. cenocladum* reproduce vegetatively through fragmentation (Dyer et al. 2004c), individuals that we collected were separated by at least 5 m. On each plant, we chose the first fully mature leaf from the top of the plant for our measurements to standardize leaf age. We measured leaf toughness by using a modified penetrometer described by Feeny (1970). This device measures leaf toughness as the force, measured in grams of sand, needed to punch a 5-mm steel rod through a taut leaf. Immediately after removing the leaf from the plant, we took three toughness measurements, two on one side of the midrib and one on the other side. These measurements were made near the leaf tip, thus avoiding all major veins. The mean of these three toughness values was used in all analyses.

We used a translucent grid to measure the percent area removed from each leaf by each of the following major *Piper* herbivores: *Atta cephalotes* (leaf-cutter ants; Hymenoptera: Formicidae: Myrmicinae), katydids (Orthoptera: Tettigoniidae), beetles (Coleoptera: Chrysomelidae and Curculionidae), *Quadrus cerealis* caterpillars (Lepidoptera: Hesperiidae), and at least two species of *Eois* caterpillars (Lepidoptera: Geometridae), which were grouped together. Each type of herbivore damage is easily discernible based upon the pattern and shape of damage. Total percent damage was calculated for each leaf as the sum of damage by all herbivore types.

Imide Isolation and Quantification Imides were isolated from *P. imperiale* and *P. melanocladum*, and their structures were determined with the methods for *P. cenocladum* described by Dodson et al. (2000). All imide structures were confirmed by synthesis (Appendix). A randomly selected subset of *P. imperiale* (N=30), *P. melanocladum* (N=44), and *P. cenocladum* (N=34) leaves were air-dried and analyzed to determine secondary chemical content. Each leaf was extracted ×2 with ethanol overnight. The resultant extract was resuspended in a 3:1 water/ethanol mixture and exhaustively extracted with chloroform in a separatory funnel. Combined extracts were dried, resuspended in chloroform, and analyzed by gas chromatography. Standards for analysis were synthesized at Mesa State College (Appendix). For a more detailed description of extraction and GC methods, see Dodson et al. (2000) and Dyer et al. (2001).

Atta cephalotes Bioassays To determine the effectiveness of the newly identified *P.* imides as defenses, we performed a feeding choice experiment with *Atta cephalotes* colonies. We modeled our experiment on those performed by Folgarait et al. (1996). We presented foraging *A. cephalotes* colonies with a selection of leaf fragments coated with different compounds. Treatments applied to experimental leaf fragments included piplaroxide (**5**), the newly discovered compounds (**6**) and (**4**), and a control that contained

only methanol (all imides were in methanol solution). Treatments were applied to *Hyeronima alchorneoides* Allemao (Euphorbiaceae) leaves (a species shown to be palatable to *A. cephalotes*; Folgarait et al. 1996) and allowed to dry. Randomly distributed *A. cephalotes* colonies were simultaneously presented with five fragments of each of the four treatments (for a total of 20 leaf fragments per trial) in a cafeteria-style display. These trials continued for 15 min or until all 5 fragments of one of the treatments had been removed by the ants. It was repeated with 22 different colonies (N=22).

We modified this *A. cephalotes* feeding trial to use *P. imperiale* leaf ethanol extracts, which would contain most secondary metabolites and other ethanol-soluble compounds produced by the plant, and to force the ants to cut fragments from a large leaf section, so that their mouthparts would be exposed to any secondary metabolites during the cutting process. We applied an extract of *P. imperiale* to leaves of *Hieronyma alchorneoides* and compared the amount of leaf material removed from leaves treated with extract to control leaves. Fresh and dry mass measurements from 144 strips of *H. alchorneoides* were used to create a conversion factor for estimation of the dry mass of fresh leaf strips used in feeding choice trials (dry mass=0.2512 (fresh mass) +0.0054, R^2=0.83). Leaves were cut into paired strips (two from each leaf) weighing 0.25 g fresh weight, avoiding all major veins, and the leaf area for each strip was measured with a LICOR leaf area meter (leaf area mean ± SE=12.27±0.15 cm^2). We cut a pair of treatment and control leaf strips from the same leaf, applied *P. imperiale* extract at high or low concentrations of 0.0095% leaf dry weight compound 4 (Appendix) and 0.0051% leaf dry weight compound 5 (Appendix) (N=42), or 0.0024% leaf dry weight compound 4 (Appendix) and 0.0013% leaf dry weight compound 5 (Appendix) (N=36; dissolved in 0.24 and 0.06 ml ethanol, respectively) to the treatment leaf strip and a corresponding amount of ethanol to the control leaf strip and allowed the extract to dry. These concentrations are an order of magnitude lower than those found in *P. imperiale* leaves, and so should measure the lower limits of ant abilities to detect and respond to secondary metabolites. Leaves were placed in pairs (one control leaf and one leaf treated with *P. imperiale* extract) in an actively foraging column of leaf-cutter ants (modeled after the methods of Folgarait et al. 1996). Each trial was allowed to continue for 2 hr or until the ants had removed all of one leaf strip. Leaf strips were large enough that ants cut small (approximately 1 cm^2) sections to carry away. After each trial, final leaf weight and leaf area were measured.

Statistical Analyses Because we were not able to transform the percent herbivory data to meet requirements of normality for parametric statistics due to the low frequency of occurrence of herbivory, we used two methods of analyses to test for differences among *Piper* species in herbivory by different herbivores. First, to examine qualitatively host choice by herbivores, we categorized leaves as experiencing herbivory or escaping from herbivory, and we performed chi-square tests for contingency tables to test for differences among plant species in the frequency of escape from herbivory. We then quantitatively examined the extent of feeding by herbivores once feeding was initiated (i.e., excluding all plants lacking herbivory) by performing an analysis of covariance (ANCOVA) with plant species as the independent variable, herbivore damage as the dependent variable, and toughness as a covariate, followed by Tukey's multiple range tests. For this analysis, we removed all zero herbivory values from the data set and log transformed damage and toughness values to meet assumptions of residual normality and homogeneity of variance. The covariate and the interactive term were insignificant in all tests. In combination, these two analyses compare both the frequency of herbivory and the amount of herbivore damage among plant species. Both of these analyses were repeated for all damage types (total herbivory, *A. cephalotes*, tettigoniid, beetle, *Eois*, and *Q. cerealis*). To test for interspecific differences in toughness and concentration of amides/imides, we performed an analysis of variance (ANOVA) followed by Tukey's multiple range test.

We used logistic regression to examine intraspecific relationships among chemical defense (with chemical defense content used as a predictor variable), toughness, and herbivory by different herbivores. One test was performed for each type of herbivore (with the exception of *Q. cerealis* and *A. cephalotes*, which were excluded because of rarity) and for total percent herbivory. Damage by each type of herbivore was classified as either present or absent. We tested for evidence of intraspecific trade-offs among different defenses by examining correlations between average leaf toughness and amide content for each *Piper* species.

Due to intrinsic difficulties in analyzing cafeteria-style feeding choice data (Lockwood 1998, and works cited therein) and nonnormality of the data, we analyzed the first *A. cephalotes* bioassay feeding preference data by using log-linear models (Floyd 2001). Each leaf fragment treatment was used as a variable in specified models. We used the maximum likelihood method for parameter estimation of linear models and Chi-square statistics for hypothesis testing (Folgarait et al. 1996). Because we were interested in testing specific hypotheses, we used nonhierarchical models to test the significance of leaf treatments as predictors of *A. cephalotes* preference. For the second *A. cephalotes* bioassay feeding preference experiment that

used leaf extracts, two paired *t* tests were used to test for differences in the leaf area and mass removed from control and *P. imperiale* leaf extract treated leaf strips, for each concentration of extract.

Results

Secondary Metabolites *Piper imperiale* contains two imides (Appendix, structures 4, 5). The first imide, compound 4, is an analog of piplartine, a compound we previously found in *P. cenocladum*. Compound 4 (5′-desmethoxydihydropiplartine) has not been isolated previously from a species of *Piper*, and is accompanied by its epoxide deviative, compound 5, which has been isolated previously from *P. tuberculatum* by Capron and Wiemer (1996) and is named piplaroxide. Total imide content ranged from 0.0044% to 0.029% dry weight. *P. imperiale* did not have alkaloids but contained at least five different sesquiterpenes (Appendix, Experimental).

We isolated compounds **4** and **5** (piplaroxide; Appendix) as well as the 4′-desmethyl analog of piplaroxide from *P. melanocladum*. The latter compound is also new to the genus *Piper* and has structure **6** (Appendix). These imides are present at high levels (ranging from 0.016% to 0.40% dry weight) in the leaves. No other defensive compounds were detected in *P. melanocladum* (Appendix, Experimental).

Piper cenocladum total amide/imide content ranged from 0.17% to 1.068% leaf dry weight. This range of concentrations is consistent with ranges reported in other studies with this species where synergy (Dyer et al. 2003) and trade-offs (Dodson et al. 2000) have been demonstrated. No other defensive compounds were detected in *P. cenocladum* (Appendix, Experimental).

Interspecific Differences The three *Piper* species were different in their leaf toughness ($F_{2,\ 256}$=168.2, P<0.001; Fig. 1a). *Piper melanocladum* is the toughest species with a penetrometer value of 559.3±13.9 g, nearly twice as tough as the least tough *P. imperiale* (296.6±6.7 g). The toughness of *P. cenocladum* was intermediate (389.9±13.9 g). The concentration of amides/imides in *P. cenocladum* was higher than that in *P. melanocladum*, which in turn was higher than that in *P. imperiale* ($F_{2,\ 100}$=107.18, P<0.001; Fig. 1b).

When leaves were categorized as either experiencing or escaping herbivory, *Piper* species had significant differences in frequency of leaves escaping damage from beetles, *Eois*, and all herbivores combined (Fig. 2a; beetle: X^2=17.3, df=2, P<0.001; *Eois*: X^2=13.1, df=2, P=0.001; total: X^2=21.4, df=2, P<0.001). The number of individuals escaping total herbivory and beetle herbivory was lowest for *P. imperiale*, while the number of individuals escaping *Eois* herbivory was lowest for *P. cenocladum*. *Piper melanocladum* individuals escaped all three types of herbivory more frequently than the other two *Piper* species. Damage by *Atta cephalotes* and *Q. cerealis* was rare (N=4 for each herbivore), indicating that these herbivores avoid all three *Piper* species. Tettigoniids showed no preference for one *Piper* species over another (X^2=4.0, df=2, P=0.1).

Once a plant is attacked by an herbivore, the extent of damage differs among *Piper* species and among herbivores. When individuals with no herbivore damage were omitted from the analysis, beetle and total herbivore damage were significantly different between *Piper* species (Table 1, Fig. 2b). Herbivores fed more on *Piper imperiale* than on *P. cenocladum* or *P. melanocladum* (Fig. 2b). Beetles

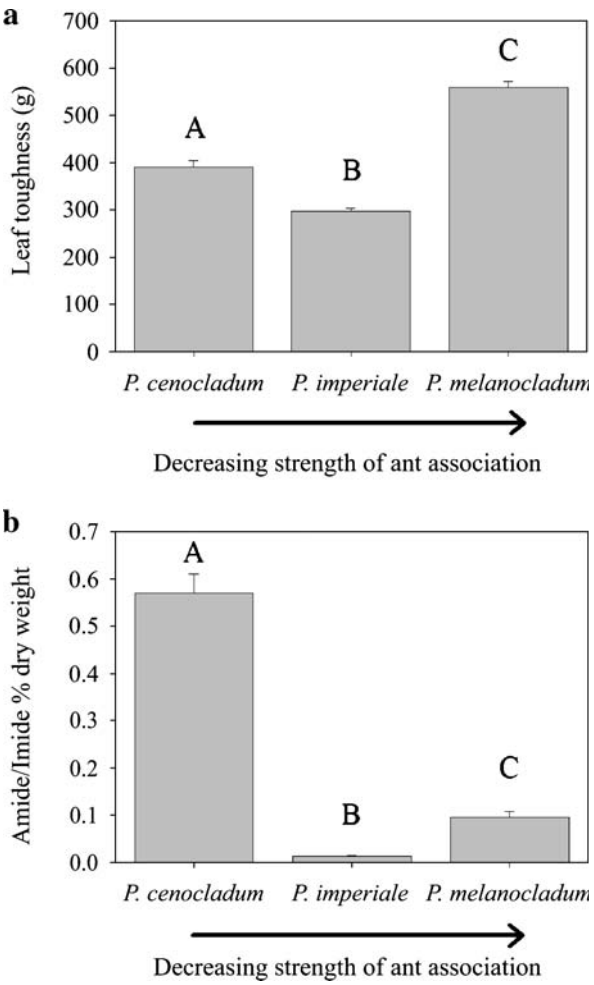

Fig. 1 Differences in: **a** mean leaf toughness (±1 SE) and **b** mean amide/imide content (±1 SE) among three species of *Piper* shrubs (*P. cenocladum*: N=84, *P. imperiale*: N=84, *P. melanocladum*: N=94). Data were analyzed using analysis of variance followed by Tukey's multiple range test; *different letters* above *Piper* species indicate significant differences

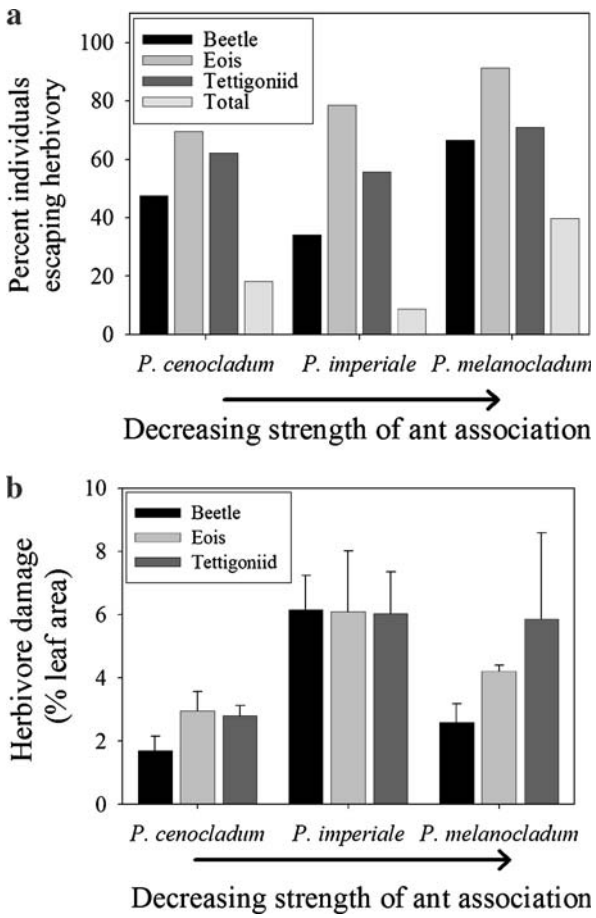

Fig. 2 Naturally occurring interspecific variation in herbivory for three closely related species of tropical shrubs, *Piper* spp. **a** Percentage of individuals completely escaping herbivory. Chi-square tests for contingency tables were utilized to test for differences between plant species in the frequency of escape from herbivory. Beetle, *Eois* and total herbivory differed significantly between *Piper* species (*P. cenocladum*: N=84, *P. imperiale*: N=84, *P. melanocladum*: N=94). A value of 100% indicates all individuals of that species escaped herbivory from a particular herbivore taxon. Total herbivory includes escape from all categories of herbivory, thus, it is always has a lower percentage than other categories. **b** Percent herbivory (±1 SE) on individual plants that did not escape herbivores. Analysis of Covariance (with toughness as a covariate) was utilized to test for differences in herbivory between species. *P. cenocladum*: N=72, *P. imperiale*: N=67, *P. melanocladum*: N=56)

showed a significant preference for *P. imperiale* over *P. cenocladum* but did not differentiate between *P. melanocladum* and the other two *Piper* species (Table 1). *Piper* damage by *Atta cephalotes* and *Q. cerealis* was excluded from the analysis due to small sample size. Levels of damage by *Eois* and tettigoniids were not significantly different among *Piper* species (Table 1).

Intraspecific Relationships Among Secondary Metabolites, Toughness, and Herbivory Secondary metabolite content in *P. melanocladum* was negatively correlated with levels of tettigoniid herbivory on leaves that experienced herbivory (R=−0.63, P=0.05). No other correlations between herbivory and secondary metabolites were found. We found no intraspecific relationships between toughness and herbivory (Table 2), but intraspecific variance was low compared to interspecific variance (Fig. 1a). We also found no evidence for trade-offs between toughness and secondary metabolites in the three species (*P. cenocladum* N=34, R=−0.22, P>0.05; *P. imperiale* N=30, R=0.033, P>0.05; *P. melanocladdum* N=44, R=0.10, P>0.05).

Atta cephalotes Feeding Trial In *P. imperiale* and *P. melanocladum*, compound **4**, piplaroxide (**5**), and compound **6** are clearly deterrent to *A. cephalotes* (Table 3, Fig. 3). The loglinear model revealed significant associations in removal of different leaf disks based on this deterrence. The (compound **4**×compound **6**) and (compound **4**×piplaroxide) interactions are significant since the frequencies of removal of both disk types are low in each case. In addition, associations between removal of control and treatment disks reflect the fact that the likelihood of the control disk being taken while the treatment disk was not taken was high, and the likelihood of the control disk being left while the treatment disk was taken was low. Whole leaf extract of *P. imperiale* was also deterrent to *A. cephalotes* (Fig. 4). Ants removed less leaf area and mass of leaves treated with leaf extracts in high (T=−2.38, df=41, P=0.02; T=−2.86, df=41, P=0.007) and low (T=−2.60, df=35, P=.01; T=−2.10, df=35, P=0.04) concentrations.

Discussion

We found evidence for ecological costs of the different defense mechanisms in the three *Piper* species studied. Secondary metabolites and their concentrations differed among species, along with toughness and the strength of the association of the plants with ants. *Piper melanocladum*, which has no ant association and low levels of chemical defense, has tough leaves. *Piper cenocladum* has the strongest association with ants and the highest levels of chemical defenses, but the leaves of this species are not likely to use toughness as a deterrent. *Piper imperiale* has tender leaves, low levels of defenses, and a loose association with ants. In addition to these contrasting suites of defenses, it is possible that there are trade-offs between the traits measured here and chemical defenses that are unknown or were not quantified, such as the sesquiterpenes that are present in *P. imperiale*. A comparison of toughness for the non-ant plant, *P. melanocladum*, with the ant-plants, *P. cenocladum* (obligate) and *P. imperiale* (facultative), provides support for the hypothesis that ant plants invest less in other defenses (Fig. 1a; Dyer et al. 2001; Heil et al.

Table 1 Qualitative differences in frequency of herbivory

Damage Type	Mean±SE (*N*)			*F* (*df*)
Plant Species (Total *N*)	*P. imperiale* (81)	*P. cenocladum* (84)	*P. melanocladum* (94)	
Total percent damage	9.6±1.21 (72)	4.5±1.1 (67)	5.0±1.4 (56)	9.6** (2)
Beetle percent damage	6.1±1.1% (52)	1.7±0.4% (43)	2.6±0.6% (31)	10.7** (2)
Tettigoniid percent damage	6.0±1.3 (35)	2.8±0.8 (31)	5.9±2.7 (27)	3.0* (2)
Eois percent damage	6.1±1.9 (17)	3.0 0.6 (25)	4.2 1.7 (8)	1.4 (2)
A. cephalotes percent damage	(0)	22.9±20.8 (3)	1.0 (1)	–
Q. cerealis percent damage	26.9±23.9 (2)	2.4 (1)	6.6 (1)	–

[a] Analysis of covariance
[b] Only herbivores experiencing herbivory were included in analyses, thus *N* varies by damage type and different types of herbivory do not add up to total percent damage.
*$P<.06$
**$P<.0001$

2002). On the other hand, the hypothesis that ant plants invest less than non-ant plants in chemical defenses, such as amides/imides, is only supported when comparing concentrations of these compounds in *P. imperiale* and *P. melanocladum* (Fig. 1b).

The effectiveness of different defensive mechanisms in these three species varies widely and differs according to the taxon of the attacking herbivore. The strong negative relationship between herbivory and toughness across the three species supports the findings of previous studies that demonstrate that toughness is an important defense (Coley 1983; Sagers and Coley 1995; Coley and Barone 1996). When choosing among multiple host species, generalist and oligophagous herbivores may avoid extremely tough species. In an examination of different types of anti-herbivore defenses and other plant characteristics across 46 tropical tree species, Coley (1983) found that leaf toughness was the plant characteristic most correlated with reduced herbivory. However, all patterns of herbivory cannot be accounted for with differences in leaf toughness. Specialist *Eois* caterpillar damage is higher on *P. cenocladum* vs. the other two species, although *P. cenocladum* is of intermediate toughness. *Eois* feeding may be deterred by both toughness (in *P. melanocladum*) and secondary metabolite content (in *P. imperiale*). Alternatively, as relatively specialized feeders, *Eois* species, some of which sequester imides/amides (Dyer et al. 2003), may be adapted to the defensive compounds in *P. cenocladum*. Tettigoniids, which are relatively generalized feeders, do not appear to have a host preference possibly because they feed on the young, expanding leaves of these species, which may have low toughness and secondary metabolite content (Kursar and Coley 1992).

Intraspecific variation in leaf toughness is not associated with changes in total herbivory, suggesting that feeding preferences within a single plant species may be motivated by other factors, such as nutrient content or secondary metabolism. Indeed, individual *Piper* species with lower levels of chemical defenses in their tissues may be preferred by insect enemies, such as leaf-cutter ants. We have shown here that piplaroxide (**5**) and compounds **4** and **6** (found in *P. imperiale* and *P. melanocladum*) are strongly deterrent to

A. cephalotes (see also Capron and Wiemer 1996). In previous studies, we demonstrated also that the three imides/amides found in *P. cenocladum* deter feeding by *A. cephalotes* and act synergistically against a variety of herbivores (Dyer et al. 2003). Clearly, the imide/amide nitrogen-based defenses are effective deterrents to leaf-cutter ants, and the presence of these compounds is a likely explanation for why these *Piper* species are avoided by *A. cephalotes*.

The two sister species, *P. cenocladum* and *P. imperiale* exhibit different patterns of defense, tolerance, and trade-offs among defenses, despite the fact that these two species are morphologically similar, unresolved in molecular phylogenies (Tepe et al. 2004), and share almost identical herbivore fauna. In *P. imperiale*, herbivory is common, as the species appears to be investing few resources in defense and relying on tolerance. Dyer et al. (2004c) found that asexual reproductive success of *P. imperiale* was not affected by herbivory, which is consistent with a tolerance hypothesis. *Piper imperiale* fragments placed on the surface of lowland rainforest soils to simulate asexual reproduction through natural fragmentation appeared tolerant of high

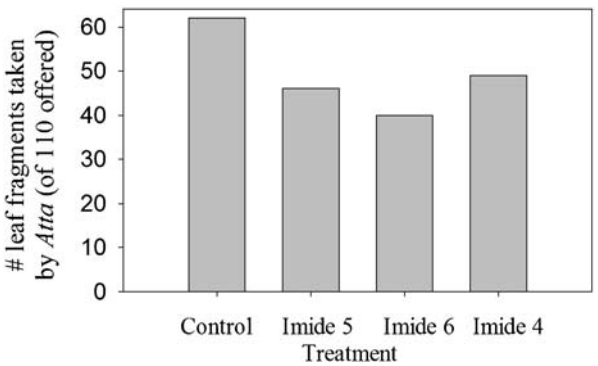

Fig. 3 The frequency of experimental leaf fragment removal by leafcutting ants, *Atta cephalotes* (Hymenoptera). Experimental fragments were treated with imides from two species of tropical shrubs, *P. imperiale* and *P. melanocladum*, and control fragments were treated only with solvent. A loglinear model uncovered significant associations between removal of pairs of leaf fragments with different solutions applied (e.g., when high numbers of control fragments were removed, low numbers of piplaroxide fragments were removed). Based on significant associations in this model, all defensive imides were deterrent to *A. cephalotes*. Imide 4=1-[(2E)-3-(3′,4′-dimethoxyphenyl)prop-2-enoyl]-5,6-dihydropridin-2(1H)-one; Imide 5=piplaroxide; Imide 6=3-[(2*E*)-3-(4-hydroxy-3-methylphenyl)prop-2-enoyl]-7-oxa-3-azabicyclo[4.1.0]heptan-2-one

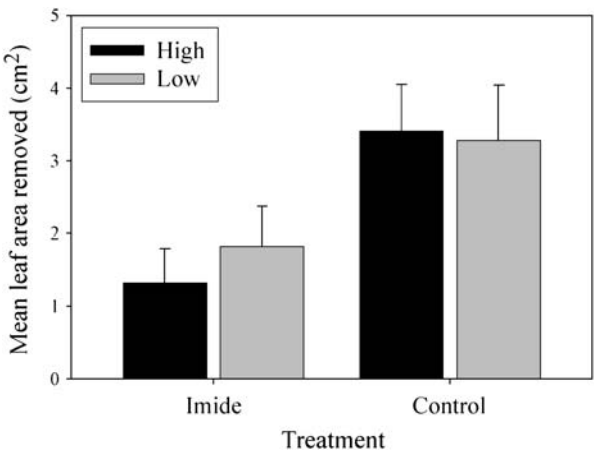

Fig. 4 Mean leaf area (±1 SE) removed from leaves of the tropical shrub, *P. imperiale*, by foraging leaf-cutter (*Atta cephalotes*; Hymenoptera) workers. Large leaf fragments were treated with *P. imperiale* extracts at high ($T=-2.38$, d.f.=41, $P=0.02$) and low ($T=-2.60$, d.f.=35, $P=0.01$) concentrations and ants were presented with a control leaf and a treatment leaf during a 2 h trial

levels of herbivory present on fragments before planting. In contrast, *P. cenocladum* exhibits high allocation of resources to defense, which may reflect low tolerance of herbivory in this species. *Piper cenocladum* relies primarily on vegetative fragmentation for reproduction (Greig 1993), and Dyer et al. (2004c) showed that *P. cenocladum* asexual reproductive success is reduced by natural herbivory on and artificial damage of the leaves of fragments. Prevention of herbivory by chemical and ant defense is associated with increased asexual reproductive fitness. One might predict that such high investment in defense would lead to trade-offs among different defenses. In *P. cenocladum*, a trade-off between secondary metabolite content and ant defense is indicated by a threefold increase in amide concentrations when ants are excluded from *P. cenocladum* plants (Dodson et al. 2000). In the current study, this increase in secondary metabolite content was not correlated with *Eois* herbivory, which is consistent with other studies that demonstrate that amides/imides do not protect *P. cenocladum* plants from feeding by specialized herbivores (Dyer et al. 2004b). There is evidence that the *Ph. bicornis* ant mutualists effectively protect plants against specialized herbivores, but they have little effect on large, generalist herbivores such as katydids or other caterpillars, which may be deterred by increased amide/imide concentrations (Dyer and Letourneau 1999; Dyer et al. 2001, 2004b). Although we found that *P. cenocladum* exhibits moderate investment in leaf toughness, we were unable to detect any correlations between toughness and herbivory in this species. Nevertheless, investment in leaf toughness could make it difficult for rare herbivores such as hesperiids (Lepidoptera) and *Atta* (Hymenoptera) from adding this plant species as a consistent food resource.

In summary, we have demonstrated a wide variety of defensive mechanisms among three closely related species of tropical shrubs. It is clear that redundancy in defense provides the plant with protection against a variety of herbivores. Previous work demonstrated intraspecific trade-offs between chemical and ant-mediated defense in *P. cenocladum*, but our interspecific results here were consistent with both the trade-off hypothesis as well as the alternative hypothesis that there are no trade-offs between indirect biotic and direct chemical defenses in plants (Heil et al. 2002). We were also unable to measure trade-offs between defense and other functions, but tough leaves may come at the expense of lower rates of growth or reproduction. Studies of chemical redundancy, ecological costs of antiherbivore defense, and interspecific variation in defensive attributes should consider the complex interaction between forces that select for optimum levels of defense against a variety of different herbivores and trade-offs between defenses, growth, and reproduction that allow plants to minimize the cost of defense.

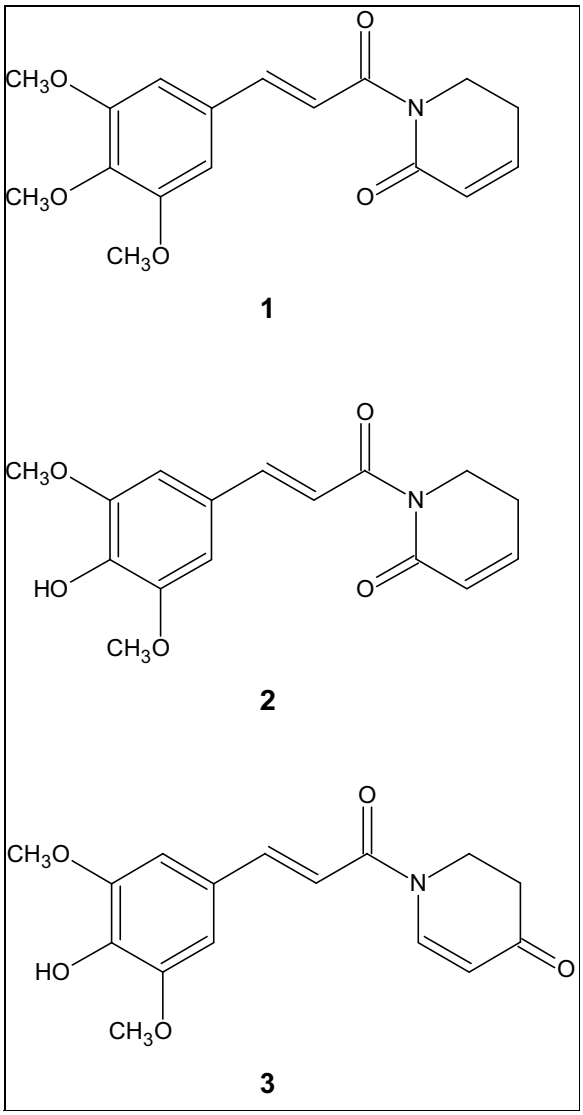
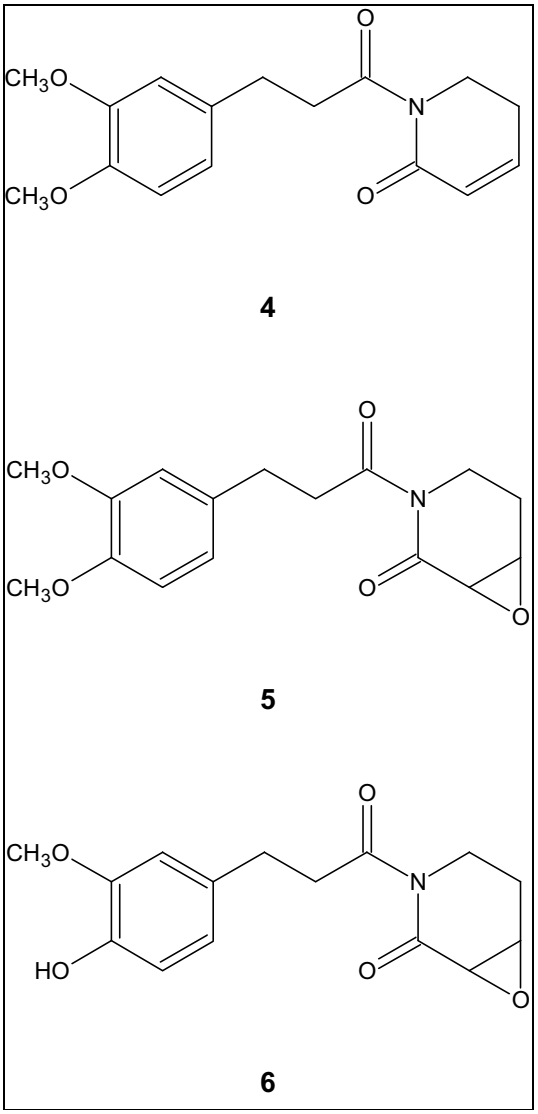
Structures 1–3. Defensive metabolites isolated from *Piper cenocladum*



Structure 4–6. Defensive metabolites isolated from *Piper melanocladum*



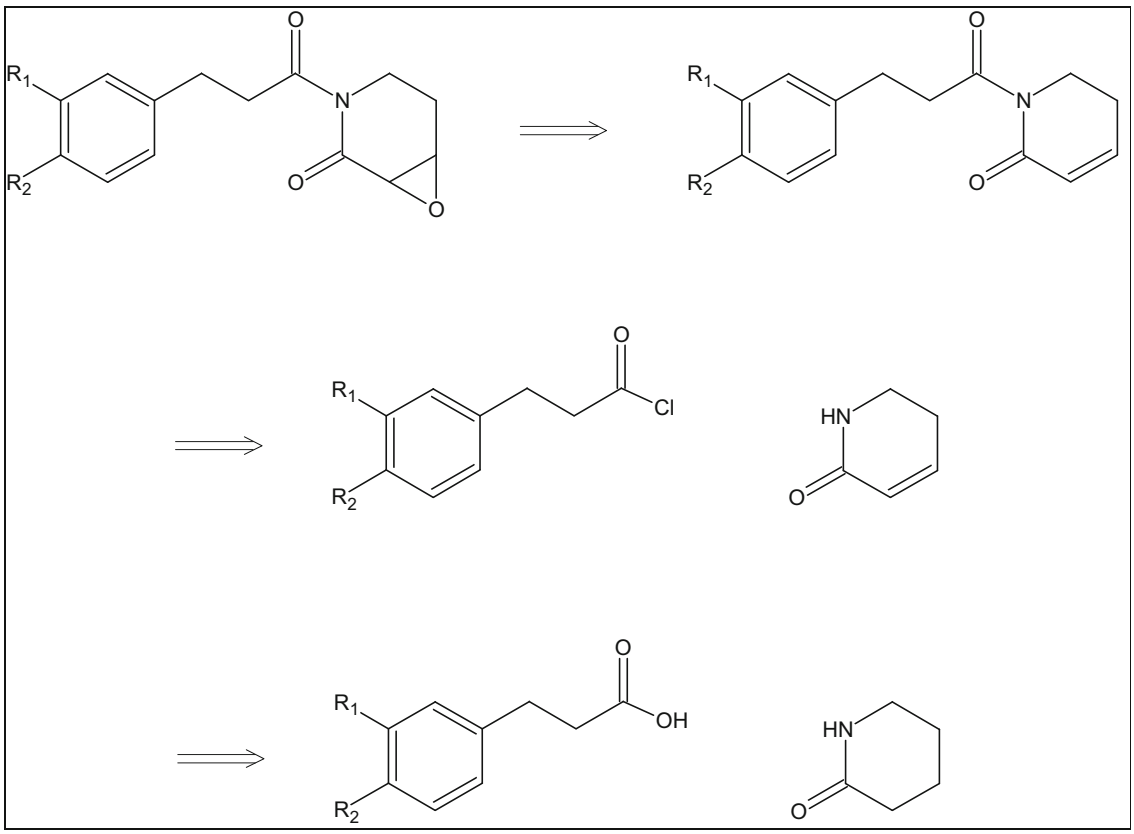
Synthesis of **4, 5, and 6** (Schemes 1, 2, 3, 4, 5, 6 and 7): The syntheses of 1-[(2E)-3-(3′′,4′′-dimethoxyphenyl)prop-2-enoyl]-5,6-dihydropridin-2(1H)-one (**4**), 3-[(2*E*)-3-(3,4-dimethylphenyl)prop-2-enoyl]-7-oxa-3-azabicyclo-[4.1.0] heptan-2-one (piplaroxide, **5**) and 3-[(2*E*)-3-(4-hydroxy-3-methylphenyl)prop-2-enoyl]-7-oxa-3-azabicyclo[4.1.0]-heptan-2-one (**6**) were accomplished via similar convergent approaches. These involved the synthesis of an appropriate functionalized pyridinone piece and its coupling with an appropriately activated acid derivative.

Experimental

General Information All ^{1}H NMR and ^{13}C NMR spectra were recorded at 300 MHz. All flash chromatography was performed on Aldrich silica gel (200–400 mesh, 60 Å). Tetrahydrofuran (THF) was redistilled from sodium/benzophenone. Dichloromethane (CH_2Cl_2) was redistilled from CaH_2. All other reagents and solvents were used as received unless otherwise noted.

1-(Methoxymethyl)piperidin-2-one (13) A 500-ml round bottom flask was flushed under N_2 while δ-valerolactam was melted on the oven. δ-Valerolactam (15.147 g, 153 mmol) and distilled THF (160 ml) were added to the flask, and the mixture was cooled on an ice bath for 10 min. After cooling, 2.25 M n-BuLi (50 ml) was added to the mixture slowly via syringe. CH_3OCH_2Cl (11.8 g, 157 mmol) was added to the flask, and the mixture stirred at room temperature for 2 h. The reaction mixture was transferred to a separatory funnel with hexane (50 ml), and washed with water (2×100 ml) and brine (1×50 ml). The combined aqueous layers were extracted with CH_2Cl_2 (5× 50 ml). The combined organic layers were washed with brine (1×60 ml), dried over anhydrous magnesium sulfate, and filtered. The solvent was removed under reduced pressure to yield a yellow liquid (15.2 g), which was purified via vacuum distillation (92–94°C @ 4 mm Hg) using a Vigeroux fractionating column to yield **13** as a colorless liquid [10.3 g, 49% yield; ^{1}H NMR ($CDCl_3$): δ 4.77 (2H, s), δ 3.32 (2H, t, *J*=5 Hz), δ 3.26 (3H, s), δ 2.39 (2H, t, *J*=5 Hz), δ 1.78 (4H, m). ^{13}C NMR ($CDCl_3$): δ 171.1, δ 77.1, δ 56.0, δ 46.2, δ 32.4, δ 23.1, δ 21.3].

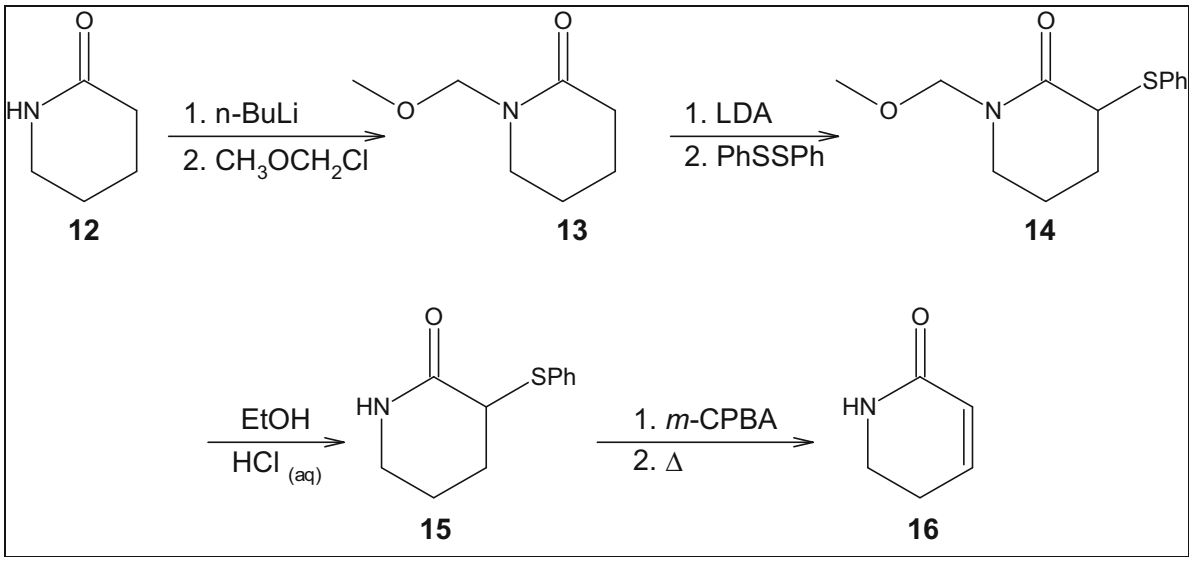
1-(Methoxymethyl)-3-(phenylthio)piperidin-2-one (14) A 250-ml three-necked round bottom was oven dried, fitted with an addition funnel and a septum, and flushed under N_2. Distilled THF (30 ml) and diisopropylamine (8 ml) were added to the flask and the solution stirred on ice for 10 min. 2.25 M n-BuLi (24 ml) was added through the septum via syringe and the mixture stirred on ice for 10 min. The mixture was cooled to −78°C in a dry ice/isopropanol bath. Compound **13** (4 g, 27.9 mmol) was dissolved in distilled THF (15 ml) and added to the reaction through the dropping funnel over 10 min. The mixture stirred at −78°C for an additional 45 min. A mixture of phenyldisulfide (6.01 g) and HMPA (4.8 ml) in distilled THF (15 ml) was added to the reaction mixture over 20 min. The reaction stirred at −78°C for an additional 40 min and was then allowed to warm to room temperature. The reaction mixture was transferred to a separatory funnel with water (60 ml) and extracted with diethyl ether (3× 60 ml). The combined ether layers were washed with 3 M NaOH (1×40 ml), water (1×40 ml), 3 M HCl (1×40 ml), water (1×40 ml), and brine (1×40 ml). The solution was dried over magnesium sulfate, filtered, and evaporated to yield **14** as an orange oil [6.25 g, 89% yield; ^{1}H NMR ($CDCl_3$): δ 7.54 (2H, m), δ 7.29 (3H, m), δ 4.83 (2H, q, *J*=



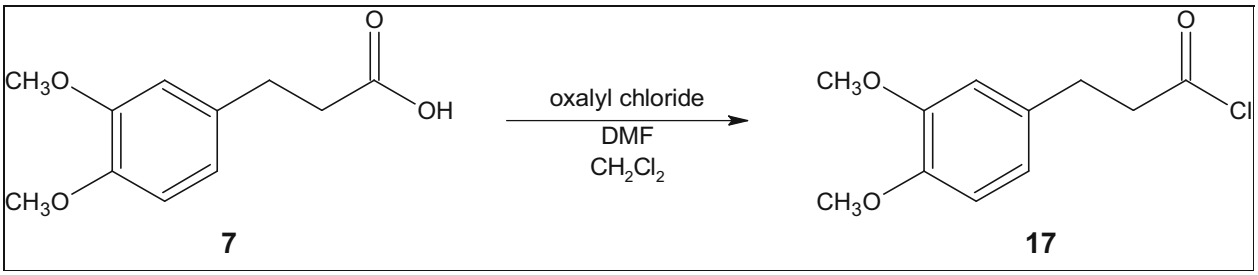
Scheme 1 Convergent retrosynthesis of "*Piper* amides" isolated from *P. melanocladum*

10 Hz), δ 3.89 (1H, t, *J*=5.5 Hz), δ 3.39 (2H, m), δ 3.30 (3H, s), δ 2.06 (3H, m), δ 1.7 (1H, m). ^{13}C NMR ($CDCl_3$): δ 169.8, δ 134.4, δ 132.7, δ 129.1, δ 127.7, δ 77.5, δ 56.2, δ 49.0, δ 45.9, δ 28.4, δ 20.4].

3-(Phenylthio)piperidin-2-one (15) Compound **14** (10 g) was placed in a 1-l round bottom flask with 95% ethanol (270 ml) and conc. HCl (54 ml). The reaction mixture was heated at reflux for 6 h. The volume was reduced to 100 ml



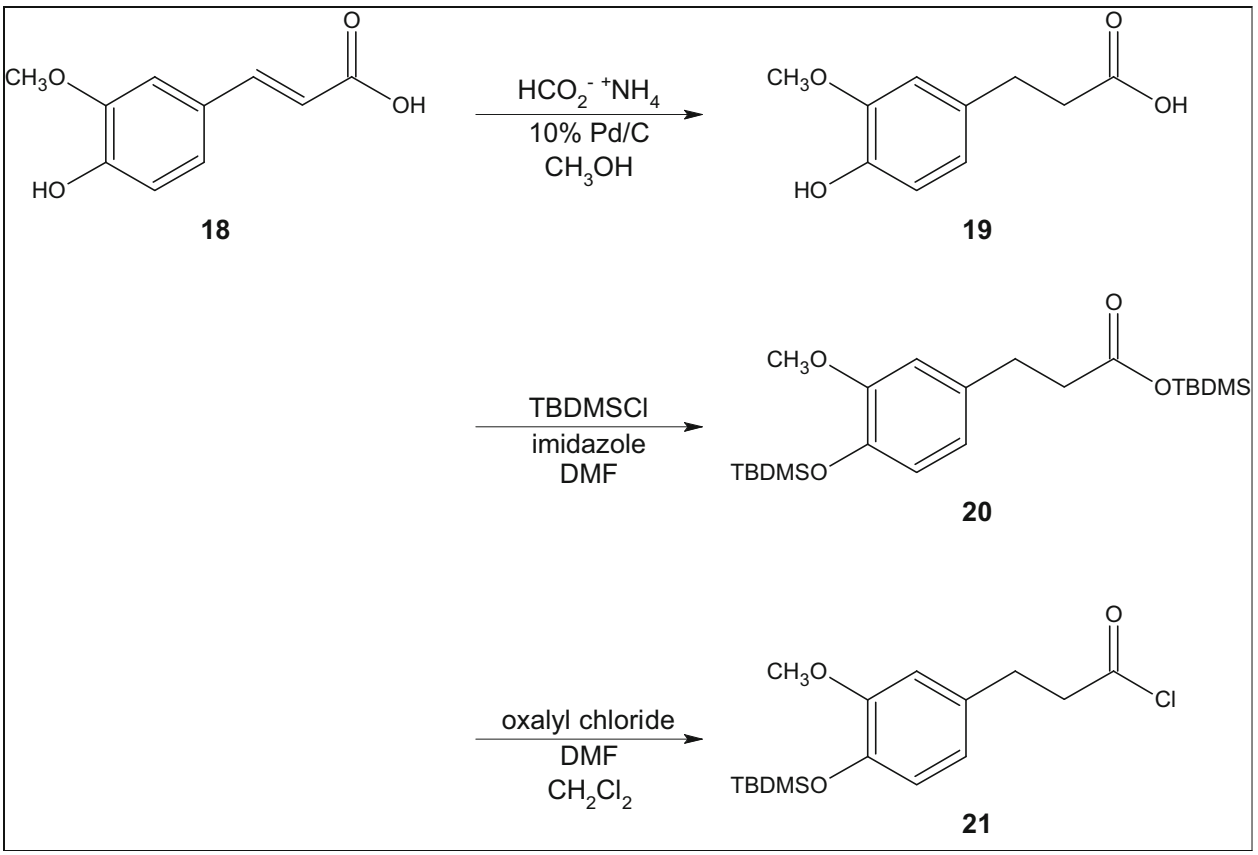
Scheme 2 The dihydropyridinone moiety was prepared from δ-valerolactam (**12**). The lactam nitrogen was protected (**13**) by treating the lithium salt of the lactam with chloromethyl methyl ether (MOMCl). The enolate of compound **13** was generated by treating the protected lactam with two equivalents of LDA in THF at −78°C and sulfenylated in the α-position with phenyl disulfide (PhSSPh). After deprotection of the sulfenylated lactam (**14**), the sulfide was oxidized to the sulfoxide and subjected to thermal elimination to produce 5,6-dihydropyridin-2(1*H*)-one (**16**)



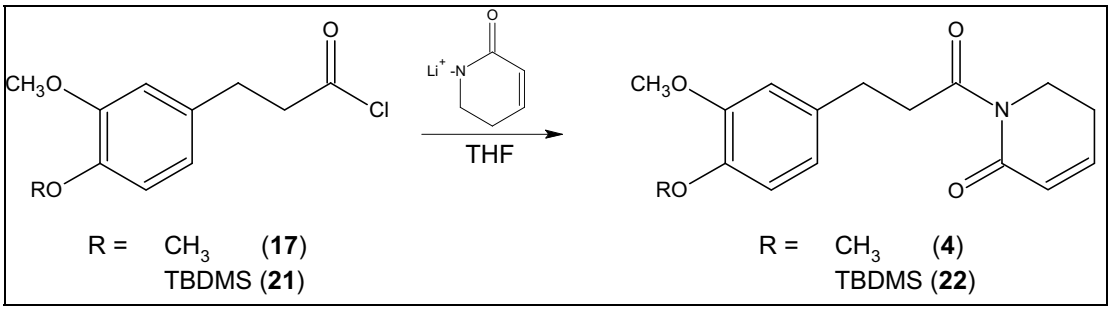
Scheme 3 The hydrocinnamoyl derivatives were prepared from appropriate carboxylic acid precursors. Consequently, commercially available 3,4-dimethoxyhydrocinnamic acid (**7**) was converted to 3,4-dimethoxyhydrocinnamoyl chloride (**17**) by treating the acid with oxalyl chloride in dichloromethane using catalytic amounts of dry DMF

under reduced pressure, and the mixture was extracted with CH_2Cl_2 (2×250 ml). The acid layer was neutralized with 6 M NaOH and extracted with CH_2Cl_2 (2×250 ml). Each CH_2Cl_2 layer was washed with saturated $NaHCO_3$ (2× 80 ml) and brine (1×80 ml). The combined organic layers were dried over sodium sulfate, filtered, and evaporated to yield a brown residue (7.4 g). The residue was recrystallized from ethyl acetate/hexane to yield **15** as an off-white solid [5.3 g, 64% yield; ^{1}H NMR ($CDCl_3$): δ 7.54 (2H, m), δ 7.31 (3H, m), δ 6.05 (1H, broad s), δ 3.83 (1H, t, *J*=6 Hz), δ 3.32 (2H, t, *J*=4 Hz), δ 2.03 (3H, m), δ 1.74 (1H, m)]. ^{13}C NMR ($CDCl_3$): δ 170.4, δ 134.1, δ 132.9, δ 129.1, δ 127.8, δ 48.4, δ 42.5, δ 28.3, δ 20.2.

5,6-Dihydropyridin-2(1H)-one (16) Compound **15** (3.0 g) was weighed into a 250-ml round bottom flask. CH_2Cl_2 (100 ml) and saturated $NaHCO_3$ (20 ml) were added to the flask, which was then cooled on an ice bath for 10 min.



Scheme 4 In the case of the 4-hydroxy-3-methoxy derivative, the appropriate acid (**19**) was first obtained via catalytic transfer hydrogenation of commercially available ferulic acid (**18**) with ammonium formate using 10% Pd/C in methanol. The free phenolic hydroxyl group was then protected as the TBDMS ether (**20**) using *t*-butyldimethylsilyl chloride and imidazole in dry DMF. Protection was necessary to avoid polymerization during and after the formation of the acyl halide. While this step also introduced a TBDMS group at the carboxyl oxygen, this group was directly converted to the acyl chloride (**21**) by treating the silyl ester with oxalyl chloride in dichloromethane using catalytic amounts of DMF



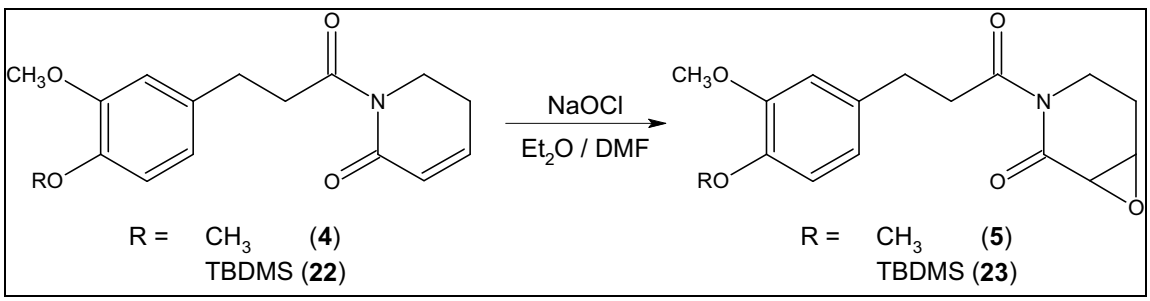
Scheme 5 In all cases, the next step involved the coupling of compound **16** with the appropriate acyl halide. Thus, the lithium salt of compound **16** was generated by treatment with KHMDS in dry THF and condensed with ether **17** or **21** to yield **4** or **22**, respectively

Seventy-seven percent 3-chloroperbenzoic acid (3.1 g) was added in five portions over 10 min. The mixture was vigorously stirred on an ice bath 1 h. The reaction mixture was transferred to a separatory funnel with CH_2Cl_2 (200 ml) and washed with saturated $NaHCO_3$ (2×30 ml). The solution was dried over sodium sulfate, filtered, and evaporated to yield a brown residue (3.2 g). Toluene (50 ml) was added to the brown residue and the solution was heated at reflux for 1 h. The solvent was removed under reduced pressure, and the brown oil was purified via flash chromatography (EtOAc) to yield compound **16** [1.25 g, 90% yield; ^{1}H NMR ($CDCl_3$): δ 6.64 (1H, m) δ 6.45 (1H, broad s), δ 5.89 (1H, m), δ 3.42 (2H, m), δ 2.34 (2H, m)]. ^{13}C NMR ($CDCl_3$): δ 166.6, δ 141.9, δ 129.2, δ 39.7, δ 23.9.

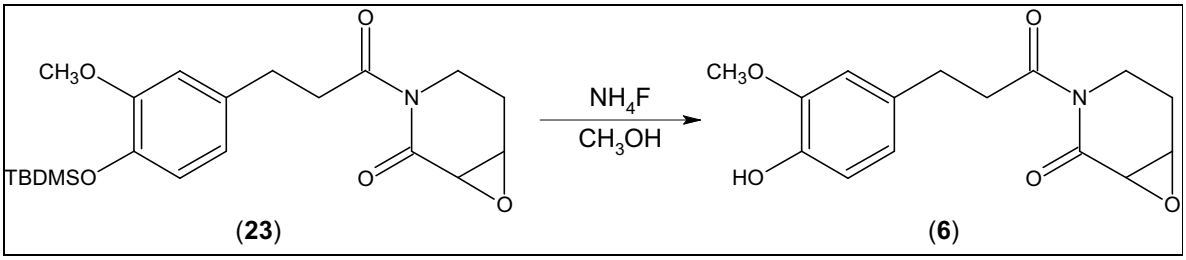
3-(3,4-Dimethoxyphenyl)propanoyl chloride (17) A 100-ml round-bottomed flask was flushed with N_2 and charged with **7** (2.1 g, 10 mmol), freshly distilled dichloromethane (40 ml), and dry DMF (four drops). Oxalyl chloride (1.75 ml, 20 mmol) was added slowly via pipet. The flask was fitted with a drying tube ($CaCl_2$), and the mixture was stirred at RT for 22 h. The volatiles were removed under reduced pressure to yield **17** as a pale yellow oil sufficiently pure for use [2.3 g, 100%; ^{1}H NMR ($CDCl_3$): δ 6.82–6.69 (3H, m, ArH), δ 3.87 (3H, s, -OCH_3), δ 3.86 (3H, s, -OCH_3), δ 3.19 (2H, t, J=7.4 Hz, -CH_2-), δ 2.96 (2H, t, J= 7.4 Hz, -CH_2-). ^{13}C NMR ($CDCl_3$): δ 173.22, δ 149.09, δ 147.94, δ 131.22, δ 120.30, δ 111.61, δ 111.43, δ 55.99, δ 55.94, δ 48.92, δ 30.75].

3-(4-Hydroxy-3-methylphenyl)propanoic acid (19) A mixture of **18** (2.0 g, 10 mmol), ammonium formate (2.0 g, 32 mmol), and 10% Pd/C (0.1 g) in methanol (50 ml) was stirred under N_2 at RT for 24 h. Celite filter aid (0.5 g) was added, and the mixture was vacuum filtered. The volatiles were removed under reduced pressure. The residue was transferred to a separatory funnel with the aid of 1 M HCl (50 ml) and dichloromethane (50 ml). The organic layer was isolated, and the aqueous solution was extracted with more dichloromethane (1×50 ml). The combined organic layers were washed with brine, dried over anhydrous $MgSO_4$, and filtered. The volatiles were removed under reduced pressure to yield **19** as a pure white solid [1.9 g, 95%; ^{1}H NMR ($CDCl_3$): δ 11.17 (1H, br s), δ 6.84 (1H, d), δ 6.71 (2H, m), δ 5.54 (1H, br s), δ 3.87 (3H,s), δ 2.89 (2H, t), δ 2.65 (2H, d). ^{13}C NMR ($CDCl_3$): δ 179.11, δ 146.50, δ 144.14, δ 132.14, δ 120.91, δ 114.47, δ 110.97, δ 55.94, δ 36.07, δ 30.41].

tert-Butyldimethylsilyl 3-(4-t-butyldimethylsilyloxy-3-methyoxyphenyl)propanoate (20) A mixture of **19** (2.7 g, 14 mmol), TBDMSCl (4.52 g, 30 mmol) and imidazole (4.1 g, 60 mmol) in dry DMF (12 ml) was stirred under N_2 at RT for 5 days. The mixture was poured into a separatory funnel with diethyl ether (75 ml) and hexanes (25 ml). The mixture was washed with water (1×50 ml), saturated $NaHCO_3$ (1×50 ml), and water (1×50 ml), and brine (1× 50 ml). The organic solution was dried over anhydrous $MgSO_4$ and filtered. Solvents were removed under reduced



Scheme 6 The corresponding epoxides (**5** and **23**) were prepared via epoxidation of the respective alkenes by treatment with NaOCl in a mixture of diethyl ether and DMF



Scheme 7 Finally, compound **6** was prepared after deprotection of **23** with methanolic NH_4F

pressure to yield a colorless oil. The remaining volatiles were removed under high vacuum to yield **20** as a pure, pale yellow oil [5.77 g, 99%; ^{1}H NMR ($CDCl_3$): δ 6.74 (1H, d), δ 6.68 (1 H, d), δ 6.63 (1H, d of d), δ 3.78 (3H, s), δ 2.85 (2H, t), δ 2.62 (2H, t), δ 0.98 (9 H, s), δ 0.90 (9H, s), δ 0.23 (6H, s), δ 0.13 (6H, s). ^{13}C NMR ($CDCl_3$): δ 173.57, δ 150.81, δ 143.36, δ 134.22, δ 120.84, δ 120.35, δ 112.38, δ 55.53, δ 37.78, δ 30.88, δ 25.82, δ 25.63, δ 18.52, δ 17.67, δ −4.58, δ −4.74].

3-(4-t-butyldimethylsilyloxy-3-methyoxyphenyl)propanoyl chloride (21) A 250-ml round-bottomed flask was flushed with N_2 and charged with **20** (5.768 g, 13.6 mmol), freshly distilled dichloromethane (25 ml), and dry DMF (five drops). Oxalyl chloride (1.80 ml, 20.6 mmol) was added slowly via pipet. The flask was fitted with a drying tube ($CaCl_2$), and the mixture was stirred at RT for 20 h. The volatiles were removed under reduced pressure to yield **21** as a pale yellow oil sufficiently pure for further use [2.3 g, 100%; ^{1}H NMR ($CDCl_3$): δ 6.77 (1H, d), δ 6.66 (1H,d), δ 6.62 (1H,d), δ 3.79 (3H, s), δ 3.18 (2H, t), δ 2.93 (2H, t), δ 0.98 (9H, s), δ 0.13 (6H, s). ^{13}C NMR ($CDCl_3$): δ 173.25, δ 151.03, δ 143.91, δ 132.09, δ 121.09, δ 120.45, δ 112.38, δ 55.58, δ 48.95, δ 30.84, δ 25.80, δ 18.52, δ −4.56].

1-[3-(3,4-Dimethoxyphenyl)propanoyl]-5,6-dihydropyridin-2(1H)-one (4) A 100-ml three-necked, round-bottomed flask was oven dried and flushed with N_2 while cooling. Freshly distilled THF (15.6 ml) and a solution of KHMDS (8.2 ml, 0.5 M in toluene) were added to the flask and cooled on ice for 10 min. Compound **16** (0.4 g, 4 mmol) was dissolved in THF (4.5 ml) and added dropwise to the reaction mixture, which was then stirred on ice for 10 min. Compound **17** (1.0 g, 4.4 mmol) was added to the reaction mixture, which was then stirred on ice for 10 min. The reaction mixture was transferred to a separatory funnel with water (20 ml), ethyl acetate (30 ml), and hexane (10 ml). The organic layer was isolated and washed with saturated $NaHCO_3$ (2×20 ml), 0.1 M HCl (1×20 ml), and brine (1× 20 ml). The organic solution was dried over sodium sulfate, filtered, and the solvent was evaporated to yield an orange oil (800 mg). The oil was purified via flash chromatography (4:1 EtOAc/hexane) to yield compound **4** as a white solid [470 mg, 40% yield; ^{1}H NMR ($CDCl_3$): δ 6.86 (1H, d of t), δ 6.78 (3H, s), δ 5.97 (1H, d of t), δ 3.96 (2H, t), δ 3.86 (3H, s), δ 3.84 (3H, s), δ 3.24 (2H, t), δ 2.93 (2H, t), δ 2.37 (2H, m); ^{13}C NMR ($CDCl_3$): δ 175.7 (s), δ 165.5 (s), δ 149.0 (s), δ 147.5 (s), δ 145.3 (d), δ 133.8 (s), δ 126.0 (d), δ 120.4 (d), δ 111.9 (d), δ 111.2 (d), δ 56.0 (q), δ 55.9 (q), δ 41.2 (t), δ 41.1 (t), δ 30.8 (t), δ 24.7 (t). LREIMS *m/z* (rel. int.): 289 (37), 192 (51), 164 (100), 151 (50). HRMS: Found *m/z* 289.1315, calculated for $C_{16}H_{19}O_4N$ 289.1314. Anal. Calcd. for $C_{16}H_{19}NO_4$: C, 66.42; H, 6.62; N, 4.84. Found: C, 66.52; H, 6.62; N, 4.65.

3-[3-(3,4-dimethoxyphenyl)propanoyl]-7-oxa-3-azabicyclo [4.1.0]heptan-2-one (5) A 250-ml round-bottomed flask was charged with **4** (3.47 g, 12 mmol), DMF (100 ml) and Et_2O (100 ml). The mixture was cooled to 5°C on an ice bath. Cold, 6% $NaOCl_{(aq)}$ (Clorox, 20 ml, 24 mmol) was added, and the resultant mixture was vigorously stirred for 10 min. The reaction mixture was then transferred to a separatory funnel with 5% $Na_2S_2O_3$ (100 ml) and Et_2O (50 ml). The layers were mixed and separated. The aqueous layer was further extracted with Et_2O (2×100 ml). The combined organic layers were then washed with brine (1× 100 ml) and dried over anhydrous $MgSO_4$. The volatiles were evaporated under reduced pressure to yield **5** as a pale solid that was sufficiently pure for further use (1.23 g, 34%). Further purification can be accomplished via recrystallization from 95% EtOH [^{1}H NMR ($CDCl_3$): δ 6.77 (3H, br s), δ 4.32 (3H, dddd), δ 3.87 (3H, s), δ 3.85 (3H, s), δ 3.68 (1H, dd), δ 3.56 (1H, d), δ 3.21 (2H, m), δ 3.15 (1H, dd), δ 2.90 (2H, t), δ 2.41 (1H, dm), δ 1.98 (1H, dddd). ^{13}C NMR ($CDCl_3$): δ 174.8 (s), δ 169.7 (s), δ 148.8 (s), δ 147.4 (s), δ 133.5 (s), δ 120.4 (d), δ 111.9 (d), δ 111.2 (d), δ 56.0 (q), δ 55.9 (q), δ 53.6 (d), δ 52.5 (d), δ 41.5 (t), δ 35.8 (t), δ 30.6 (t), δ 24.0 (t). LREIMS *m/z* (rel. int.): 305 (24), 192 (35), 164 (100), 151 (62). Anal. Calcd. for $C_{16}H_{19}NO_5$: C, 62.94; H, 6.27; N, 4.59. Found: C, 63.05; H, 6.08; N, 4.54.

1-[3-(4-t-Butyldimethylsilyloxy-3-methyoxyphenyl)-propanoyl]-5,6-dihydropyridin-2(1H)-one (22) A 250-ml three neck, oven dried, round bottom was cooled while flushing with N_2. KHMDS (0.5 M in toluene, 28.4 ml) was

added and the flask cooled on an ice bath for 10 min. Compound **16** (1.38 g, 14 mmol) was dissolved in THF (30 ml) and added dropwise to the reaction mixture which then stirred for 10 min. Compound **21** (4.5 g, 14 mmol) was added to the reaction which then stirred for 10 min. The reaction mixture was transferred to a separatory funnel with water (50 ml), ethyl acetate (75 ml), and hexanes (15 ml). The water layer was removed and the organic layer was washed with saturated $NaHCO_3$ (2×50 ml), 0.1M HCl (1× 50 ml), and brine (1×50 ml). The solution was dried over sodium sulfate, filtered, and evaporated to yield a brown oil (5.2 g). The oil was purified via flash chromatography (1:1 EtOAc/hexanes) to yield compound **22** [2.2 g, 42% yield; ^{1}H NMR ($CDCl_3$): δ 6.86 (1H, d of t), δ 6.70 (3H, m), δ 5.97 (1H, d of t), δ 3.95 (2H, t), δ 3.77 (3H, s), δ 3.21 (2H, t), δ 2.90 (2H, t), δ 2.36 (2H, m), δ 0.97 (9H, s), δ 0.12 (6H, s). ^{13}C NMR ($CDCl_3$): δ 175.81, δ 165.44, δ 150.73, δ 145.26, δ 143.26, δ 134.64, δ 125.97, δ 120.72, δ 120.66, δ 112.68, δ 55.55, δ 41.14, δ 41.08, δ 30.94, δ 25.82, δ 24.72, δ 18.51, δ 14.28, δ -4.55].

3-[3-(4-t-Butyldimethylsilyloxy-3-methoxyphenyl)-propanoyl]-7-oxa-3-azabicyclo[4.1.0]heptan-2-one (23) A 250-ml round-bottomed flask was charged with **22** (1.34 g, 3.44 mmol), DMF (36 ml) and Et_2O (36 ml). The mixture was cooled to 5°C on an ice bath. Cold, 6% $NaOCl_{(aq)}$ (Clorox, 20 ml, 17.2 mmol) was added, and the resultant mixture was vigorously stirred for 1 h. The reaction mixture was then transferred to a separatory funnel with 5% $Na_2S_2O_3$ (180 ml) and Et_2O (90 ml). The layers were mixed and separated. The aqueous layer was further extracted with Et_2O (2×90 ml). The combined organic layers were then washed with brine (1×180 ml) and dried over anhydrous $MgSO_4$. The volatiles were evaporated under reduced pressure to yield **23** as a pale orange oil that was sufficiently pure for further use (1.27 g, 91%). Further purification can be accomplished via flash chromatography on silica [1:1 EtOAc/hexanes; ^{1}H NMR ($CDCl_3$): δ 6.75–6.64 (3H, m), δ 4.32 (1H, dddd), 3.78 (3H, s), 3.68 (1H, dd), 3.55 (1H, d), 3.18 (2H, m), 3.13 (1H, dd), 2.34 (1H, dm), δ 1.98 (1H, dddd), 0.98 (9H, s), 0.13 (6H, s)].

3-[3-(4-hydroxy-3-methoxyphenyl)propanoyl]-7-oxa-3-aza-bicyclo[4.1.0]heptan-2-one (6) A mixture of **23** (1.27 g, 3.12 mmol), ammonium fluoride (0.579 g, 15.6 mmol), and methanol (75 ml) was heated at reflux for 5 min. The reaction mixture was transferred to a separatory funnel with the aid of water (90 ml). The aqueous layer was extracted with CH_2Cl_2 (2×90 ml). The combined organic extracts were washed with brine (1×90 ml) and dried over anhydrous $MgSO_4$. The volatiles were evaporated under reduced pressure to yield a tan solid. This was recrystallized from EtOAc-hexanes to yield **6** as an off-white solid [0.41 g, 48%; ^{1}H NMR ($CDCl_3$): δ 6.83–6.70 (3H,m), δ 5.47 (1H,s), δ 4.35 (1H, ddt), δ 3.87 (3 H, m), δ 3.68 (1 H, br t), δ 3.56 (1H, d), δ 3.21 (2H, t), δ 3.21 (1H, m), δ 2.90 (2 H, t), δ 2.40 (1H, m), δ 1.98 (1H, ddd). ^{13}C NMR ($CDCl_3$): δ 175.1 (s), δ 169.9 (s), δ 146.6 (s), δ 144.2 (s), δ 133.0 (s), δ 121.2 (d), δ 114.3 (d), δ 111.2 (d), δ 56.0 (q), δ 53.5 (d), δ 52.4 (d), δ 41.5 (t), δ 35.7 (t), δ 30.6 (t), δ 23.9 (t). LREIMS *m/z* (rel. int.): 291 (13), 178 (23), 150 (100), 137 (50). ES(+)MS *m/z* 292.1 [M+H], 314.1 [M+Na]. Anal. Calcd. for $C_{15}H_{17}NO_5$: C, 61.85; H, 5.88; N, 4.81. Found: C, 62.16; H, 6.11; N, 4.81.

Other potential compounds All three species were screened for basic alkaloids using a standard acid/base partitioning technique followed by TLC with visualization using the alkaloid specific spray reagent, iodoplatinic acid, and found to be negative. Each species was examined by GC-MS using the same conditions described above for imide/amide quantitation. *Piper cenocladum* and *P. melanocladum* were found to be devoid of compounds other than the imides/amides described (other peaks in the chromatograms had areas at least 1,000 times less than the imides/amides). *Piper imperiale* was found to contain a series of seven peaks with areas similar to or greater than the imides described. The mass spectra of all of these compounds are consistent with sesquiterpenes or mono-oxygenated sesquiterpenes. Five peaks had mass spectra that were excellent matches to the library spectra of copaene, cyclopropylazulene, (-) spathulenol, ledrol, and caryophyllene oxide. The peak for caryophyllene oxide was the largest in the chromatogram. Lack of standards for these compounds precluded confirmation of their identities and quantification. Other classes of natural products were not actively pursued.

Received: 31 January 2007 / Revised: 31 January 2008 / Accepted: 8 February 2008 / Published online: 16 April 2008

Abstract Females of the European beewolf, *Philanthus triangulum*, possess a large glove-shaped gland in the head, the postpharyngeal gland (PPG). They apply the content of the PPG to their prey, paralyzed honeybees, where it delays fungal infestation. Here, we describe the chemical composition of the gland by using combined GC-MS, GC-FTIR, and derivatization. The PPG of beewolves contains mainly long-chain unsaturated hydrocarbons (C23–C33), lower amounts of saturated hydrocarbons (C14–C33), and minor amounts of methyl-branched hydrocarbons (C17–C31). Additionally, the hexane-soluble gland content is comprised of small amounts of an unsaturated C25 alcohol, an unknown sesquiterpene, an octadecenylmethylester, and several long-chain saturated (C25, C27) and unsaturated (C23–C27) ketones, some of which have not yet been reported as natural products. Surprisingly, we found a dimorphism with regard to the major component of the PPG with some females having (*Z*)-9-pentacosene, whereas others have (*Z*)-9-heptacosene as their predominant component. The biological relevance of the compounds for the prevention of fungal growth on the prey and the significance of the chemical dimorphism are discussed.

Introduction

Hymenoptera possess a huge variety of exocrine glands (e.g., Hölldobler and Wilson 1990). The chemistry and function of different types of these have been studied for a number of social species, whereas comparatively little is known from solitary bees and wasps. Recently, a postpharyngeal gland (PPG) has been described from a species of digger wasp (Strohm et al. 2007), the European beewolf, *Philanthus triangulum* Fabricius 1775 (Hymenoptera: Crabronidae, formerly Sphecidae, Melo 1999). The occurrence of this gland is surprising since the PPG was assumed to be restricted to ants (Hölldobler and Wilson 1990; Schoeters and Billen 1997; Lenoir et al. 1999) where it functions in generating the colony odor (e.g., Hefetz et al. 1992, 1996; Soroker et al. 1994, 1995, 1998; Vienne et al. 1995; Dahbi et al. 1998; Lenoir et al. 1999, 2001; Oldham et al. 1999; Soroker and Hefetz 2000; for a review of other proposed functions, see Eelen et al. 2006).

In beewolves, the PPG has a unique function in protecting the larval provisions from microbial attack (Strohm and Linsenmair 2001; Herzner and Strohm 2007; Herzner et al. 2007a). Female European beewolves hunt

and paralyze honeybees, bring them to their nest burrow, and provision one to six bees in a brood cell as larval food for one progeny. Due to the humid and warm conditions in the brood cell, the highly nutritive provisions are prone to detrimental microbial attack (Strohm and Linsenmair 2001). Early fungus infestation inevitably destroys the food resources, and larvae are killed by fungal toxins or starve to death. Observations in special cages (Strohm and Linsenmair 1994–1995) revealed that beewolf females intensively lick the bodies of the paralyzed bees and apply the secretion from the PPG to the bees' surface (Strohm and Linsenmair 2001; Herzner et al. 2007a). This treatment has the effect of delaying fungus growth for 2 to 3 days, which is a highly relevant effect given the short larval feeding period of only 8 to 11 days. The primary mechanism of this delay is not a direct chemical effect of the secretion on fungi, but the prevention of water condensation on the bees that in turn impairs the germination and growth of fungal spores (Herzner and Strohm 2007). Male European beewolves also have a PPG that is even larger than in females (Herzner et al. 2007b). However, it serves as a reservoir for the scent marking pheromone that males apply to their territories to attract females (Kroiss et al. 2006).

Despite the advanced understanding of the function of the secretion of the PPG of female European beewolves, there has been no detailed investigation of its chemistry. Therefore, we analyzed the chemical composition by using combined gas chromatography-mass spectrometry (GC-MS), gas chromatography-Fourier transform infrared spectroscopy (GC-FTIR), fractionation, and derivatizations.

Materials and Methods

Sampling Beewolf females were taken either from a field population close to the Biocenter of the University of Würzburg, Germany, or from a laboratory population kept at the University of Würzburg (daughters of field caught females). They were all mated with actively provisioned nests with honeybees and were between 1 and 4 weeks old. To identify the chemicals of the PPG, females that were freshly killed by CO_2 were decapitated, and their PPGs were removed from the heads by grasping the hypopharynx with tweezers and gently pulling the attached gland out through the mouth (Strohm et al. 2007). The glands were immersed immediately in 0.25 ml *n*-hexane (Fluka Chemie GmbH, Buchs, Switzerland) that had been distilled prior to use. For the identification of the components in the PPG, the glands of four females were pooled. This enabled us to identify minor components that were not reliably detectable in the extracts of individual PPGs. In order to have an easier method to obtain the content of the PPG, we investigated whether extracts of whole heads differed in composition from dissected glands. There was a large amount of hydrocarbons in the PPG, and extracts of entire heads were identical to extracts of the dissected glands. There were no additional peaks detectable and the proportions were the same (see Herzner et al. 2007b for an analogous procedure for male PPGs). Thus, as an easier alternative to the dissection of the PPG, entire heads were extracted. To obtain data on PPG content variability, we analyzed individual extracts made from the heads of 37 females. Heads of freshly killed females were cut off and extracted in distilled hexane for 4 h. An internal standard (octadecane, Sigma, St Louis, MO, USA) was added to assess the absolute amount of compounds in the PPG (although octadecane could be detected in pooled samples, it was not detectable in individual samples and was therefore employed as an internal standard).

Identification Identification of the chemicals was accomplished by GC-MS. Head extracts were fractionated by solid phase extraction (SPE, Chromabond, unmodified silica, 3 ml, 500 mg, Macherey-Nagel, Düren, Germany) with hexane as the first and dichloromethane as the second eluent to separate nonpolar and polar fractions. Alkanes were characterized by comparison of mass spectra and retention indices with those of purchased standard alkanes (Aldrich, Deisenhofen, Germany). Corresponding alkenes were tentatively identified by their typical mass spectra, their retention indices, and (depending on availability) with commercially available (Aldrich) and synthesized standards. Dimethyl disulfide (DMDS) derivatization was carried out to determine the position of double bonds according to the method of Dunkelblum et al. (1985). The configurations of the double bonds were determined by using GC-FTIR (Attygalle 1994). Methyl-branched alkanes were identified by using MS databases and diagnostic ions, and by determining retention indices (Carlson et al. 1998). Details on the identification of polar compounds are given in the results section.

For the identification of the hydrocarbons, we used a Hewlett Packard HP 6890 Series GC System coupled to a Hewlett Packard HP 5973 Mass Selective Detector (Agilent Technologies, Böblingen, Germany). The GC was equipped with a DB-1 fused silica capillary column (30 m×0.25 mm i.d., 0.25 μm film thickness; J & W, Folsom, CA, USA). Temperature was programmed from 100°C to 300°C with a 6°C/min heating rate, held for 20 min at 300°C. Helium was used as carrier gas with a constant flow of 1 ml/min. Injection was carried out at 300°C in the splitless mode for 2 min. The electron impact mass spectra (EI-MS) were recorded with an ionization voltage of 70 eV and a source temperature of 230°C. The software ChemStation (Agilent Technologies) for windows was used for data acquisition.

GC-FTIR spectra were obtained by using an HP 5890 GC (Agilent Technologies) coupled to an FTS 575C Tracersystem (BioRad, Hercules, CA, USA). The GC was equipped with the same column as described above. Temperature was programmed from 80 to 270°C with a 4°C/min heating rate. Helium was used as carrier gas with a constant flow of 1–2 ml/min. Injections were carried out by using a split/splitless injector at 250°C in the splitless mode for 60 s. Injection volume was 0.1 µl. IR spectra were recorded by scanning 256 times in a frequency range from 4,000 to 700 cm^{-1} with a resolution of 1 cm^{-1}. Data system was a Dell Optiplex GX110-PC with BioRad WinIR Pro (Version 2.7) Tracer Software and Sadtler IRSearchMaster.

Data Handling and Statistical Analysis Because the relative amounts of compounds constitute compositional data, they were transformed to logcontrasts according to Aitchison (1986): $Z_{ij}=\log_{10}(Y_{ij}/g(Y_j))$ where Z_{ij} is the standardized peak area i for individual j, Y_{ij} is the peak area i for individual j, and $g(Y_j)$ is the geometric mean of all peaks for individual j, prior to statistical analysis. Several peaks had to be combined for the quantitative analysis of individuals because they were not always clearly separated in the chromatograms. To test for differences in the proportions of components between groups, we subjected the transformed data to exact tests for two independent groups (SPSS 13.0, SPSS Inc. 2004).

Results

Identification and Analysis of Hydrocarbons in the PPG The chromatograms of the crude hexane extracts of the PPG showed a total of 53 peaks that represented 62 different compounds (Fig. 1, Table 1). The mean amount of all compounds was 337±292 µg (minimum, 36.7 µg; maximum, 1,410 µg, N=37). All alkanes as well as (*Z*)-9-tricosene, (*Z*)-9-pentacosene, and (*Z*)-9-heptacosene were identified by comparison of mass spectra and retention indices with those of available standards. The location and configuration of double bonds of other alkenes were determined with DMDS derivatives and GC-FTIR data (band at 721 cm^{-1}: *cis* configuration of RCH=CHR′; Attygalle 1994). Some components could, however, not be completely characterized (location of methyl groups or double bond, configuration of double bond) due to the small amounts in the extracts. One component could not be identified at all. There were more unsaturated (81.5%) than saturated compounds in the nonpolar fraction of the PPG extract from beewolf females.

Identification of the Constituents in the Polar Fraction The polar fraction contained a group of uncommon constituents.

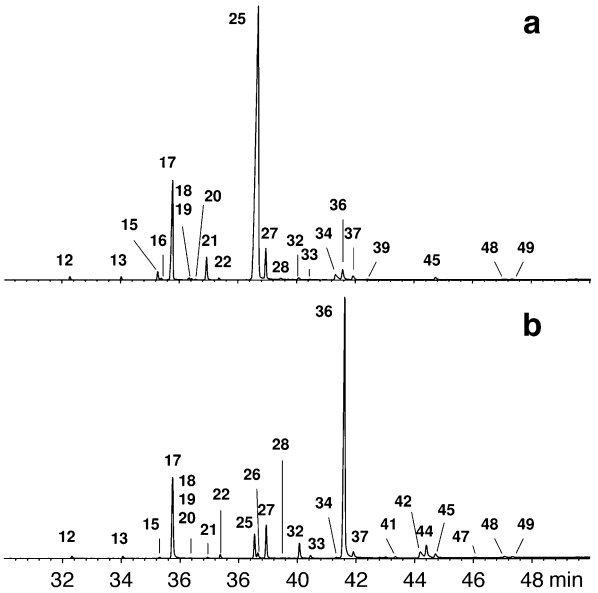

Fig. 1 Total ion chromatograms of the hexane extract of the PPG from individual female European beewolves, *Philanthus triangulum*, with **a** (*Z*)-9-pentacosene (C25-type) and **b** (*Z*)-9-heptacosene (C27-type) as the predominant hydrocarbon peak. Numbers correspond to the numbers in the peak list (Table 1). Some compounds listed in Table 1 were present in quantities too low to be visible in these chromatograms

Hydrogenation of double bonds with H_2 and palladium on carbon (Attygalle 1998) as well as DMDS adducts were used to obtain sufficient information by mass spectrometry to identify these compounds. 18-Heptacosen-10-one was identified by comparison with an already published mass spectrum (Yasui et al. 2003). The mass spectrum of this compound showed a molecular ion of *m/z* 392 and two diagnostic fragment ions at *m/z* 155 for $[C_9H_{19}–CO]^+$ and at *m/z* 265 for $[C_{17}H_{33}–CO]^+$ indicating the carbonyl position at C10. After hydrogenation of this unsaturated ketone, the resulting 10-heptacosanone as well as the 10-heptacosanone of the untreated extract showed identical mass spectra (*m/z*: 155 $[C_9H_{19}\text{-}CO]^+$, 267 $[C_{17}H_{35}\text{-}CO]^+$, 394 M^+) and identical retention indices (2,868) with that already published by Yasui et al. (2003). 14-Tricosen-6-one was characterized by its diagnostic masses (*m/z*: 99 $[C_6H_{11}\text{-}CO]^+$, 265 $[C_{17}H_{33}\text{-}CO]^+$, 336 M^+). Also, hydrogenated 14-tricosen-6-one was tentatively identified as 6-tricosanone by comparison with a commercially available MS library (NIST 2.0, Stein et al. 2001). The double bond positions in these and additional unsaturated ketones were determined from mass spectra of DMDS adducts. Additionally, three unsaturated and one saturated ketone were tentatively identified as 15-tetracosen-7-one, 16-pentacosen-8-one, 17-hexacosen-9-one, and 8-pentacosanone. The corresponding alcohol 16-pentacosen-8-ol was tentatively identified by its diagnostic masses after hydrogenation of the polar fraction

Table 1 List of compounds in the postpharyngeal gland of females of the European beewolf, *Philanthus triangulum*

Peak No.	RI	Compound Name	Diagnostic MS Ions

[a] Identification with available standards.

with lithium aluminum hydride (Attygalle 1998; Table 1). (*Z*)-9-Octadecenylmethylester was characterized by using a commercially available standard (Aldrich). Finally, a compound with a typical sesquiterpene mass spectrum was found in small amounts in the polar fraction of the extract. We could not determine the type of functional group in this sesquiterpene.

Chemical Dimorphism One alkene dominated the composition of the PPG, and surprisingly, this major compound differed among individuals (Fig. 2, Table 2). Among the 37 females whose PPG content was analyzed, 29 had (*Z*)-9-pentacosene and eight had (*Z*)-9-heptacosene as their major peak (from here on referred to as the C25- and C27-type, respectively). The frequency of the two types differed significantly from equality (χ^2=15.4, *df*=1, *P*<0.001). By using exact tests for independent samples to assess whether the proportions of other components were also affected by the major peak, we revealed that 14 of the 21 peaks differed significantly between the C25- and the C27-type (Table 2). Generally, the C27-type had larger proportions of components with longer chain lengths.

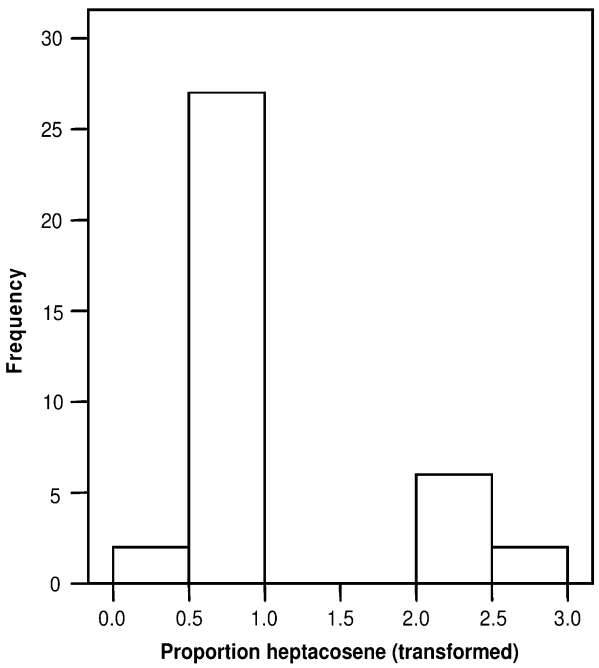

Fig. 2 Frequency distribution (population of *N*=37) of individual female European beewolves, *Philanthus triangulum*, based on the proportion of (*Z*)-9-heptacosene in their PPG secretion (values transformed to logcontrasts (Aitchison 1986): $Z_{ij}=\log_{10}(Y_{ij}/g(Y_j))$ where Z_{ij} is the standardized peak area *i* for individual *j*, Y_{ij} is the peak area *i* for individual *j*, and $g(Y_j)$ is the geometric mean of all peaks for individual *j*). There is a clear bimodal distribution, i.e., some individuals have a large proportion of (*Z*)-9-heptacosene, whereas some have a small proportion; there are no intermediate types

Discussion

The PPG secretion of beewolf females contains predominantly unbranched unsaturated long chain hydrocarbons (C23–C33, mainly either C25 or C27), smaller amounts of saturated hydrocarbons (C14–C33), and small or trace amounts of methylalkanes (C17–C31), unsaturated ketones (C23–C27), saturated ketones (C25, C27), a sesquiterpene, an unsaturated C18 methylester, and an unsaturated C25 alcohol.

The secretion of the PPG of beewolf females is involved in the preservation of their honeybee prey that serves as larval food (Herzner and Strohm 2007). Females apply large amounts of the PPG secretion to the prey prior to oviposition (Strohm and Linsenmair 2001; Herzner et al. 2007a). The prevalence of unsaturated hydrocarbons in the PPG of beewolf females is probably related to the preservation function. The preservation seems to be mainly accomplished by a physical mechanism (Herzner and Strohm 2007): the secretion prevents the condensation of water on the bees and in this way renders the microclimatic conditions unsuitable for the growth of fungi. Possibly, the PPG secretion covers structures on the paralyzed bee that would otherwise function as effective nuclei for the condensation of water. Scanning electron microscopy revealed that the PPG secretion forms a contiguous layer over the whole surface of the prey (Herzner and Strohm 2007). A hydrocarbon mixture of predominately alkenes might be an ideal means to build up such layers, because at the temperatures that prevail in beewolf brood cells, the unsaturated hydrocarbons might be in a more or less liquid state and can be spread easily over the bee surface.

The composition of hydrocarbons on the cuticle of paralyzed honeybees is dramatically modified due to the treatment by beewolf females (Herzner et al. 2007a, b). Untreated honeybees and most other insects bear predominantly saturated straight or branched hydrocarbons (e.g., Howard and Blomquist 1982, 2005; Schmitt et al. 2007). Less frequently, alkenes constitute large proportions of cuticular hydrocarbons (e.g., on a termite, Howard et al. 1978; on an aphid parasitoid, Liepert and Dettner 1996; on workers of European hornets, Ruther et al. 2002; on stingless bee foragers, Abdalla et al. 2003; on diapausing butterfly pupae, Kaneko and Katagiri 2004; or on nesting females of the burrowing bee, Simmons et al. 2003). The reasons for the prevalence of saturated hydrocarbons in some species and unsaturated hydrocarbons in other species are unknown. Possibly, the physicochemical properties of the surface can be adjusted to specific requirements by a particular mixture of saturated and unsaturated compounds (e.g., Gibbs and Pomonis 1995; Gibbs 1998).

In addition to the ubiquitous alkanes and alkenes that we found in the PPG, we also identified long chain unsaturated

Table 2 Mean proportions of selected hydrocarbons and ketones from the postpharyngeal glands of individual female European beewolves, *P. triangulum*, that had either (*Z*)-9-pentacosene (C25-type) or (*Z*)-9-heptacosene (C27-type) as the major component[a]

[a] Table entries include mean and one standard deviation (SD) of the proportion (%) of the components for females of the C25 (*N*=29) and of the C27-type (*N*=8), as well as the difference (C25–C27) and the significance level for the difference according to an exact test (*P*, significant differences in bold).
[b] Differences were calculated from the original data, rounding of values produced some rounding error.

ketones, some of which had not yet been described as natural products. Only (*Z*)-18-heptacosen-10-one and 10-heptacosanone had previously been reported as components of a contact sex pheromone from females of the white-spotted longicorn beetle, *Anoplophora malasiaca* (Yasui et al. 2003). The function of these compounds in the secretion of beewolf females is unclear. Besides a not-completely identified sesquiterpene, (Z)-9-octadecenylmethylester, and 16-pentacosen-8-ol, these ketones are the only identified components in the PPG of beewolf females that have a functional group. They might be likely candidates to exhibit an antifungal effect. However, in bioassays, no direct antifungal effect of the PPG content could be detected (Herzner et al. 2007a). Male European beewolves have some of the same ketones and a slightly shorter unsaturated ketone in their marking secretion (Schmitt et al. 2003; Kroiss et al. 2006). Their exact function in males is also unknown (see below).

The estimated amount of hydrocarbons in the secretion of the PPG differed considerably among females. This might be due to differences in physiological status, size, and age. Interestingly, the mean (approximately 330 μg) and maximum (approximately 1,400 μg) amounts match the quantities found on honeybees that were embalmed with the PPG secretion by beewolf females. Bees are each embalmed with approximately 110 μg (Herzner et al. 2007a) and females provision on average three bees per day and a maximum of ten bees per day (Strohm and Linsenmair 1997). Thus, an average female has available the necessary amount of PPG secretion for the embalming of the average number of bees caught on 1 day. Likewise, the maximum amount found in some individuals would be sufficient to embalm the maximum number of bees that the most successful females hunt per day. Moreover, according to a three-dimensional reconstruction based on histological sections, the maximum volume of the gland was estimated to be 3–4 μl (Strohm et al. 2007). The comparatively large size of the gland is explained by the need to provide enough secretion for the treatment of several prey items per day. The supply with such large amounts of unsaturated hydrocarbons might be costly and might represent a considerable part of the cost of parental care in this species (Strohm and Linsenmair 1999, 2000; Strohm and Marliani 2002).

Remarkably, beewolf females show a striking dimorphism with regard to the chemical composition of the PPG

secretion. The major component is either (*Z*)-9-pentacosene or (*Z*)-9-heptacosene, and there are no intermediate individuals. Both compounds are widespread among aculeate Hymenoptera and other insects (e.g., Ruther et al. 2002; Simmons et al. 2003). Most other components of the PPG secretion also differ between the two morphs, in that C27-types tend to have larger proportions of long-chain compounds. Possibly, the whole metabolism of hydrocarbons is adjusted to longer chain lengths in the C27-types. Why females have either (*Z*)-9-pentacosene or (*Z*)-9-heptacosene as the major compound is unclear. Preliminary analyses (E. Strohm, G. Herzner, M. Kaltenpoth, unpublished data) suggest that there is no effect of age or physiological status on the expression of the major component. One proximate explanation could be that conditions during development differ between the females and cause differential gene activation [for example, the synthesis of (*Z*)-9-heptacosene might be induced by high temperatures because of the presumably higher melting point, e.g., Gibbs et al. 1998; Rouault et al. 2000]. However, our study specimens were bred under identical temperature conditions in the same climate chamber with the same diet (honeybees from the same population) and, nevertheless, showed this dimorphism. Furthermore, an analysis of beewolf females from different populations ranging from northern Germany to the southern valleys of the Alps not only showed both types of females, but also revealed that they occurred in similar proportions (Strohm et al. 2008). Together with the lack of intermediate individuals, this might suggest that the dimorphism has a genetic basis. Such a dimorphism would have to be balanced because otherwise one morph would disappear at least from some populations either because it has a selective disadvantage or because of genetic drift. One possible explanation for a balanced dimorphism is a spatial difference in the suitability of the two alleles. Such spatial heterogeneity might either be generated by differences in abiotic or biotic conditions. There are specialized cuckoo wasps that enter the nests and oviposit on the bees (Strohm et al. 2001). These wasps seem to employ chemical mimicry in order not to leave traitorous signs in the nest. Most notably, the chemical mimicry only refers to the C27-type of females (Strohm et al. 2008). Thus, the C27-type might be disadvantaged with regard to the rate of parasitism, but this could be balanced by other advantages. Again, this hypothesis is weakened by the fact that the proportions of both types of individuals are similar over a wide geographical range despite probable differences in the abundance of the cuckoo wasps.

Compared to the content of the PPG of males of the European beewolf (Schmitt et al. 2003; Kroiss et al. 2006), females have fewer components with functional groups and lower proportions thereof, whereas the composition of the alkanes and alkenes is similar. The function of the secretion of the male PPG is also quite different. Males use this secretion to scent mark their territories and to attract receptive females (Simon-Thomas and Poorter 1972; Evans and O'Neill 1988; Strohm 1995; Strohm and Lechner 2000; Schmitt et al. 2003). The marking secretion is stored in and delivered from the PPG (Kroiss et al. 2006). Therefore, the compounds with functional groups may play a role in the attraction of females (Herzner et al. 2005; Kroiss et al. 2006) and may also convey some additional information on male quality and suitability as a mate (Herzner et al. 2006; Kaltenpoth and Strohm 2006).

In summary, females of the European beewolf, *P. triangulum*, have large amounts of mainly unsaturated hydrocarbons in their PPG. The composition of the secretion is probably shaped by its function as an antifungal coating of the prey, paralyzed honeybees. Thus, the function of the PPG of beewolf females differs entirely from this gland in ants. However, the general chemistry is consistent with that found in ants. This supports earlier arguments based on morphology, ultrastructure, and behavioral context (Strohm et al. 2007) that the PPGs of these two taxa are homologous. Comparison of physiological aspects of the PPGs of ants and beewolves, as well as the investigation of other aculeate Hymenoptera is necessary to obtain further insights into the evolution and function of the PPG in this group of insects.

Acknowledgments We are grateful to Gerhard Krammer (Symrise AG) for conducting the GC-FTIR analysis. This study was supported in part by the Deutsche Forschungsgemeinschaft (SFB 554, TP B3, STR 532/1–2).

Developmental and Geographical Variation in the Chemical Defense of the Walkingstick Insect *Anisomorpha buprestoides*

Aaron T. Dossey · Spencer S. Walse · Arthur S. Edison

Received: 15 November 2007 / Revised: 11 February 2008 / Accepted: 19 February 2008 / Published online: 10 April 2008

Abstract *Anisomorpha buprestoides*, a walkingstick common in the southeastern United States, sprays chemicals that irritate and repel threatening insects, birds, or mammals. The active chemical in this substance was initially identified as a monoterpene dialdehyde. This compound can be present in several stereoisomeric forms, and subsequent studies have revealed that *A. buprestoides* produces at least three diastereomers: anisomorphal, dolichodial, and peruphasmal. However, no inquiry has been made to date into the geographical or developmental dependence of this variation. We report here that different populations of adult *A. buprestoides* spray either anisomorphal, or peruphasmal, or a mixture of the two stereoisomers. Additionally, offspring of a peruphasmal-producing population produced a variable mixture of anisomorphal and dolichodial but switched to peruphasmal upon reaching sexual maturity. This appears to be the first report of a developmentally regulated change in walkingstick insect chemical defense. Our results suggest a more complex role of these substances in the overall chemical ecology of walkingstick insects.

Introduction

Many living organisms rely on the use of chemical compounds for communication. Insects are particularly well-known for their chemical signaling and defense (Eisner et al. 2005). Many of the over 2,500 known species of walkingstick insects (Order Phasmatodea; Bedford 1978) produce noxious defensive secretions. However, the defensive chemistry of only a few species to date has been elucidated (Schneider 1934; Meinwald et al. 1962; Eisner 1965; Smith et al. 1979; Chow and Lin 1986; Ho and Chow 1993; Bouchard et al. 1997; Eisner et al. 1997; Schmeda-Hirschmann 2006; Dossey et al. 2006, 2007).

Defensive secretions from other types of insects are known to serve multiple functions (Blum 1996). For example, components of defensive secretions have been found to possess alarm pheromone activity in termites (Order Ispotera) and cockroaches (Order Blattodea) (Roisin

et al. 1990; Farine et al. 1997). Developmental changes in defensive secretion production have also been observed in insects such as true bugs (Order Hemiptera) (Blatt et al. 1998) and grasshoppers (Order Orthoptera) (Blum 1996). It has been postulated that walkingstick insect secretions could serve functions beyond warding off predators (Tilgner 2002), but so far, no studies have addressed this hypothesis.

We recently analyzed single defensive secretions from individual immature *Anisomorpha buprestoides* walkingsticks (Dossey et al. 2006) by using a novel 1-mm-high temperature superconducting NMR probe (Brey et al. 2006). This spray contained three monoterpene diastereomers: anisomorphal (Meinwald et al. 1962), dolichodial (Cavill and Hinterberger 1961; Cavill and Whitfield 1964; Cavill et al. 1976), and peruphasmal (Fig. 1a); glucose was also secreted with the monoterpenes (Dossey et al. 2006). Anisomorphal and dolichodial were produced in proportionally high concentrations compared with peruphasmal, which was present in only trace amounts. The ratios of anisomorphal and dolichodial varied from animal to animal and as a function of time (Dossey et al. 2006).

In two independent studies of *A. buprestoides* defensive spray, only anisomorphal was reported from *A. buprestoides* collected at Archbold Biological Research Station (Highlands Co., FL, USA) (Meinwald et al. 1962; Eisner et al. 1997). There were two major differences between the animals we worked with (Dossey et al. 2006) and those from the previous reports: (1) age/life stage and (2) geographical source of the animals from which spray was collected. Interestingly, *A. buprestoides* exists in various regionally specific color forms in Florida, USA (Hetrick

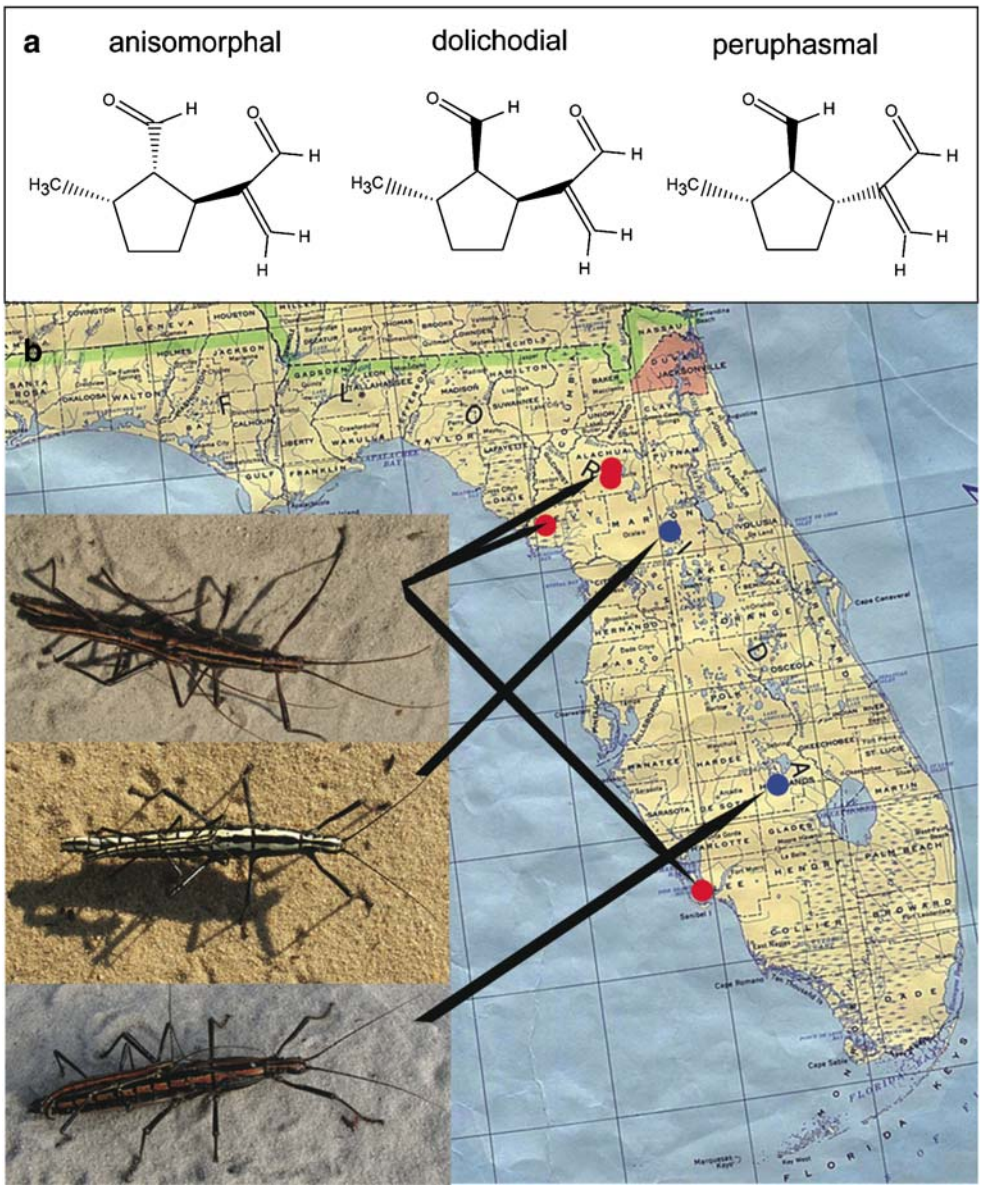

Fig. 1 Defensive spray variability in adult *A. buprestoides*. **a** The three monoterpene isomers produced by *A. buprestoides*. The relative configuration of dolichodial and anisomorphal were previously reported (Pagnoni et al. 1976). We have verified these studies and determined the relative configuration of peruphasmal (Wang et al., unpublished). **b** Geographic locations and photographs of color forms of *A. buprestoides* studied. The brown form (*top photo*) was found in two Gainesville locations (GNV and UFNA; 18 animals analyzed), GH (18 animals), and SI (three animals). The white-striped form (*middle photo*) was found in the ONF (15 animals). The orange-striped form (*bottom photo*) was found in AB (21 animals). The *colored dots* indicate collecting locations: *Blue dots* represent adult populations that only produced anisomorphal and *red dots* represent populations that produce peruphasmal or a mixture of peruphasmal and anisomorphal. One of the animals analyzed at Archbold produced about 25% dolichodial (Fig. 3), but that was the only significant amount of dolichodial found in the entire geographical study. No obvious dependence on gender of the animals was observed. Photographs by Aaron T. Dossey. The Florida map is courtesy of the University of Texas Libraries, The University of Texas at Austin

1949, Thomas 2001). The insects collected from Archbold for the current study all had a pair of orange dorsal stripes. Insects collected in Ocala National Forest (Florida, USA) were from a population with bright white dorsal stripes (Hetrick 1949). Aside from the stripes, the bodies of the Archbold and Ocala color forms are black. The bodies and dorsal stripes for *A. buprestoides* found at most other locations are usually brown with dark brown bodies and tan dorsal stripes. For simplicity, we refer to these color forms as the brown form (Fig. 1b, top photo), the white-striped form (Fig. 1b, middle photo), and the orange-striped form (Fig. 1b, bottom photo).

Here, we report both a developmental study and a geographical survey of the monoterpene dialdehydes used by *A. buprestoides* for defense. Additionally, we use ^{13}C labeling and ^{1}H NMR to demonstrate that *A. buprestoides* can synthesize its own defensive monoterpene dialdehyde from glucose. These results shed some light on the possible biological mechanisms behind the isomeric heterogeneity of defensive monoterpene dialdehyde production observed within this species.

Methods and Materials

Field Collections Individual secretions were collected in the field from sexually mature adult animals, as evidenced by the smaller males riding on the backs of larger females. The samples were frozen in the field and later analyzed by using NMR and gas chromatography-flame ionization detection (GC-FID). Each sample was an individual spray collected in a 1.5-ml glass vial held on top of the defensive gland while lightly agitating the insect. Samples were kept on ice and transported back to our lab for storage and analysis. The gender and location of each animal were recorded and are available in Supplementary Table S1. Global positioning satellite coordinates for collecting sites are as follows: Gainesville Airport "GNV": 29° 44′ 3″ N, 82° 16′ 27″ W; University of Florida Natural Area "UF-NA": 29° 38′ 1″ N, 82° 22′ 11″ W; Gulf Hammock "GH": 29° 14′ 46″ N, 82° 43′ 43″ W; Archbold Research Station "AB": 27° 10′ 50″ N, 81° 21′ 2″ W; Ocala National Forest "ONF": 29° 3′ 00″ N, 81° 38′ 50″ W; Sanibel Island "SI" two locations: 26° 27′ 5″ N, 82° 00′ 57″ W and 26° 27′ 37″ N, 82° 09′ 25″ W.

Developmental Study Eggs from the peruphasmal-producing GNV population of *A. buprestoides* were collected and reared in the laboratory. The hatchling animals were separated into their own plastic containers and reared as previously described (Dossey et al. 2006). Briefly, individuals were kept in separate containers, fed variegated privet (*Ligustrum sinense*), and raised from hatchling to adult. Defensive secretions were obtained as described for field collections of large animals or with a glass pipette placed directly over the defensive gland for very small animals. The secretions were extracted directly into methyl *tert*-butyl ether (MTBE) and analyzed by gas chromatography with mass spectrometric (GC-MS). The genders of the insects used in this study are available in Supplementary Table S2.

Isotopic Labeling An adult male *A. buprestoides* was fed 10–50 μl of 400 mM $^{13}C_6$ D-glucose (Cambridge Isotope Laboratories, Inc.) alternated every other day with variegated privet (*L. sinense*) for about 1 month. The glucose was given as a drop on the end of a blunt syringe needle and was readily accepted by the insect (Supplementary Video S1). Defensive secretions were collected periodically to monitor incorporation of ^{13}C into the defensive monoterpene. ^{13}C enrichment can easily be identified by large couplings between about 120 and 160 Hz (depending on the type of C–H bond) of the carbon-bound proton resonances in a standard ^{1}H 1D spectrum. This enrichment was quantified by using 1D ^{1}H NMR by dividing the sum of the integrals of the ^{13}C coupled "satellites" (e.g., pairs of coupled resonances) on each side of aldehyde ^{1}H resonances by the integral of the center ^{12}C-bound ^{1}H resonance.

Analytical Methods One-dimensional ^{1}H NMR spectra were collected as previously described (Dossey et al. 2006) on secretions dissolved directly with D_2O and subsequently analyzed with a custom built 1-mm HTS probe (Brey et al. 2006). GC-MS and flame ionization detection (GC-FID) were done as in (Dossey et al. 2006). Briefly, gas chromatography utilized He carrier gas (1.4 ml/min) and columns connected in series: a deactivated guard (L=8 cm, ID=0.53 mm), an HP-1MS retention-gap (L=2 m, ID=0.25 mm, df=0.25 mm), and a J&W DB-5 analytical (L=30 m, ID=0.25 mm, df=0.25 mm). Cool on-column or split-less injections (1 μl) were at 40°C and 200°C, respectively, and the oven program was isothermal at 40°C for 5 min, heated to 200°C at 11°C/min, and held 10 min, then heated to 250°C at 25°C/min and held 15 min. The FID was 260°C with N_2 make-up gas. Mass spectra were recorded with a Finnigan MAT Magnum® ion trap with 70-eV electron impact or isobutane chemical ionization over m/z 40–400; transfer-line and manifold temperatures were 240 and 220°C, respectively. Retention relative to tetradecane internal standard: peruphasmal, 0.81; dolichodial, 0.82; and anisomorphal, 0.83.

Results

Walkingstick Insects are Herbivores Thus, one explanation for chemical variability could be due to exogenous

synthesis of defensive compounds; if so, the different stereoisomers might be trivially explained as a consequence of diet. We note that dolichodial is also produced by ants (Cavill and Hinterberger 1961) and plants (Cavill and Hinterberger 1961; Pagnoni et al. 1976). To rule this out, we fed a few microliters of 400 mM $^{13}C_6$ D-glucose (see Supplementary Video S1) to a male walkingstick, alternating daily with food plant (privet—*Ligustum sinense*). We continued this feeding protocol for approximately 30 days and periodically analyzed the defensive secretions by NMR and mass spectrometry. Peruphasmal was enriched by 14%, 20%, and 25% in ^{13}C after 2, 3, and 4 weeks, respectively, clearly demonstrating that *A. buprestoides* can biosynthesize their own defensive monoterpene (Fig. 2).

Another explanation for chemical variability could be geographic location, so we sampled a total of seventy-five *A. buprestoides* from six different regions in Florida (Fig. 1b). As mentioned, *A. buprestoides* has at least three different color forms that are found in different geographical locations (Hetrick 1949; Thomas 2001). Figure 1b shows photographs of each color form, geographical collecting locations, and a summary of the defensive spray composition from insects in each location. Quantitative results are shown in Fig. 3. The white-striped (Hetrick 1949) and orange-striped forms collected in the Ocala National Forest and Archbold Research Station, respectively, secreted only anisomorphal, consistent with the original studies (Meinwald et al. 1962; Eisner et al. 1997). The brown forms, collected in Gainesville, Gulf Hammock and Sanibel Island, were more heterogeneous, producing only anisomorphal (28 animals), only peruphasmal (five animals), or a mixture of anisomorphal and peruphasmal (six animals). With one exception (Fig. 3), no adult *A. buprestoides* produced more than a trace amount of dolichodial.

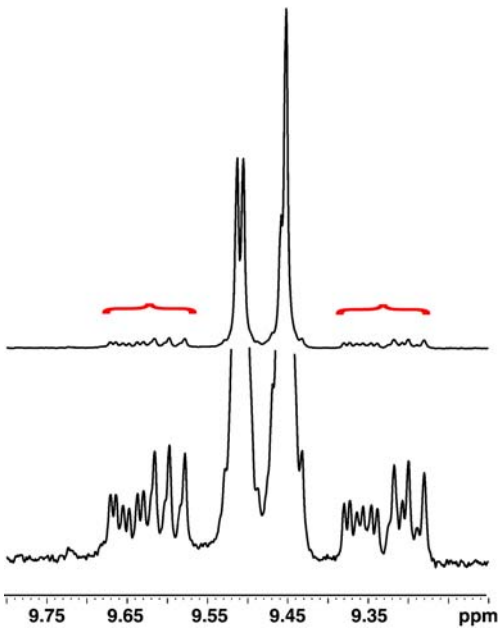

Fig. 2 Isotopic labeling of *A. buprestoides*. Animals were fed 10–50 µl of 400 mM uniformly labeled ^{13}C glucose alternated with plants for 15–30 days. This sample was collected on day 17, and 14% of the carbons in peruphasmal were labeled with ^{13}C, demonstrating that the insects can synthesize their own venom. The ^{13}C incorporation increased to 25% at 30 days (not shown). The spectrum shown is an expansion of the aldehyde region; the *top* shows the full intensity of the peaks, and the *bottom* is the same spectrum vertically expanded to show details of the ^{13}C satellites, indicated by *brackets*. The satellite resonances result from large one-bond ^{13}C–^{1}H scalar coupling, and the amount of ^{13}C incorporation can be easily determined from the ratio of the sum of the integrals of the satellite resonances to the integral of the central, ^{12}C-bound, resonances. A video showing the feeding is available as Supplementary Material, video S1

In our previous study, we found significant but variable amounts of dolichodial in immature *A. buprestoides* (Dossey et al. 2006). Because we found almost no dolichodial in the adult populations (Fig. 3), we investigated the role of development in the chemical composition of defensive secretions. Fourteen animals (ten males, three females, and one, which died before gender could be determined) were reared from hatchlings to adults as described in "Methods and Materials". These were offspring of adults collected from a peruphasmal-producing Gainesville population (GNV). Defensive secretions were collected and analyzed by GC-MS over a period of about 3 months (Fig. 4). Immature hatchlings (Fig. 4a) produced significant but variable amounts of dolichodial and anisomorphal but only trace amounts of peruphasmal, consistent with our previous findings (Dossey et al. 2006). We observed a consistent trend within each individual animal of increasing amounts of dolichodial after about 2 months of development (see yellow and orange circles in Fig. 4b and Supplementary Table S2 with a complete table of results). To our surprise, upon reaching sexual maturity, all animals stopped producing dolichodial and anisomorphal and started secreting only peruphasmal. Additionally, hatchlings reared in identical conditions but from another brown form population (Gulf Hammock, FL, USA) produced anisomorphal as adults (data not shown). This verified that peruphasmal was not the only isomer produced by adults reared under these conditions. Interestingly, these developmental changes in isomer production corresponded to the same sub-adult developmental stage when the males would normally mount the backs of females, the standard behavior for *A. buprestoides*.

Discussion

The results illustrate several aspects of the chemical defense system utilized by *A. buprestoides*. First, it is able to synthesize its own defensive monoterpene *de novo* from D-glucose. We hypothesize that the variability in the defensive

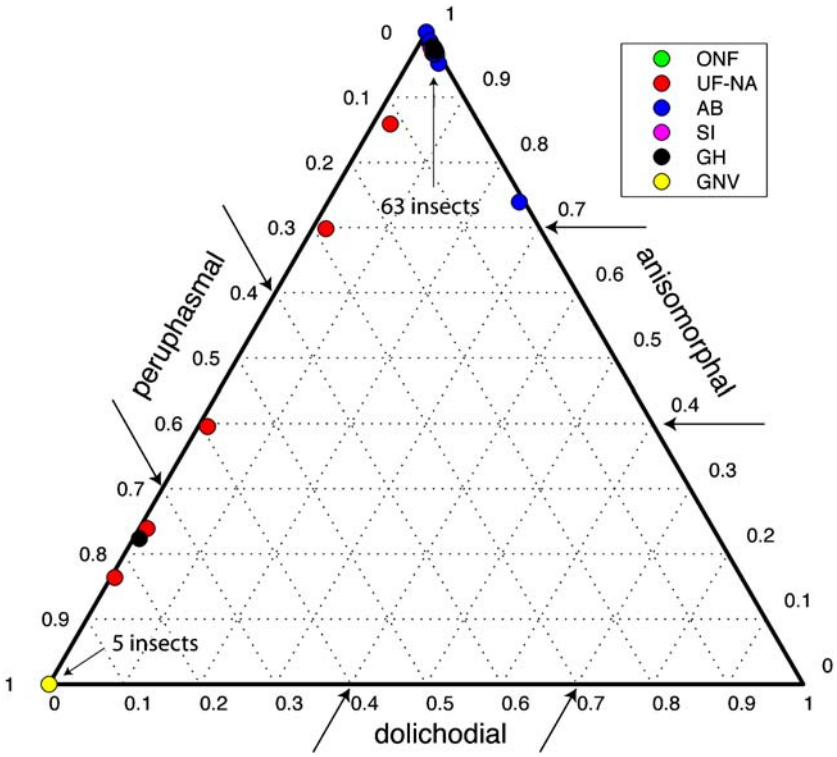

Fig. 3 Field milkings of individual adult *A. buprestoides*. Single defensive secretions were collected from animals in six different geographic locations in Florida (see Fig. 1b for abbreviations). The samples were frozen and analyzed by GC-FID and/or NMR as described in "Methods and Materials", and the total amount of anisomorphal, peruphasmal, and dolichodial for each animal was normalized to 1. The *arrows* on ternary plot axes indicate the direction that each component is plotted (e.g., anisomorphal is *horizontal*). With the exception of one sample with 25% dolichodial from AB, all other samples contained predominantly anisomorphal (63 insects), peruphasmal (five insects), or a mixture of anisomorphal and peruphasmal (six insects)

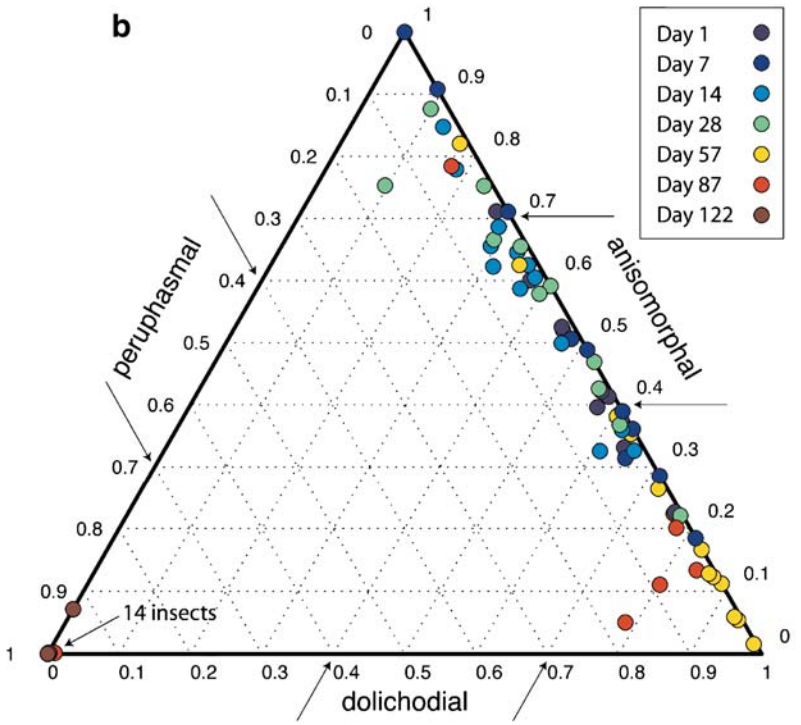

Fig. 4 *A. buprestoides* defensive secretions as a function of development. Fourteen animals (ten males, three females, and one undetermined) from a peruphasmal-producing GNV population (Figs. 1b and 3) were raised from hatchling to adult in individual containers. Individual secretions were collected from 1- to 3-day-old hatchlings (**a**) and at subsequent intervals ranging from 1 to 5 weeks, and secretions were analyzed by GC-MS. **b** Ternary plot of normalized anisomorphal, peruphasmal, and dolichodial concentrations, as described in Fig. 3. The data from *Day 1* were from 1- to 3-day-old hatchlings. By *Day 122*, all animals had reached sexual maturity. Photograph by Aaron T. Dossey

secretion composition likely results from variation in insect biosynthetic enzyme expression, primary sequence, or both. Such a system could evolve independently of food plant selection. However, further experiments are needed to determine whether enzymes or other non-protein mechanisms such as acid/base catalysis are responsible for the variability. Second, different populations of *A. buprestoides* produce different ratios of monoterpene dialdehydes in their defensive secretions, which also suggests an underlying genetic mechanism. Population dependent variability also could be the result of group isolation and, considering drastic differences between different color forms, the early stages of speciation. Since these insects do not fly, gene flow across their geographic range is probably slow, and certain populations are likely to become genetically isolated over time. However, a complete population genetic study of this species has not been pursued and is beyond the scope of the current study.

Finally, the composition of the monoterpene dialdehydes in *A. buprestoides* defensive spray is dependent on developmental life stage, showing both a trend to increased levels of dolichodial at about 2 months and an abrupt transition to ~100% peruphasmal by about 4 months (Fig. 4b). In the geographic study, we also found that adult *A. buprestoides* may sometimes produce anisomorphal or a combination of anisomorphal and peruphasmal, depending on which population they come from. In contrast, although dolichodial can be a major component of the spray before animals reach sexual maturity (Fig. 4b; Dossey et al. 2006), it is present only in trace amounts in adults (Fig. 3). One possible explanation for these observations is adaptive response to different predatory environments. For example, it is possible that young *A. buprestoides* encounter smaller invertebrate predators such as other insects or spiders. These may be more sensitive to dolichodial. Adult *A. buprestoides* are probably more vulnerable to attack by large vertebrate animals such as birds or mammals. It is possible that these animals are less sensitive to dolichodial and more sensitive to anisomorphal and peruphasmal. The developmental changes in *A. buprestoides* defensive spray chemistry also suggest their possible use as pheromones. *A. buprestoides* have an unusual behavior among insects: Males begin to copulate with the females before the females are fully grown, with one or two molts remaining. It is, therefore, possible that *A. buprestoides* defensive compounds also function as mating pheromones to regulate this behavior. In fact, many walkingstick species do not produce any secretion from their thoracic defense glands or produce secretions that are not irritating, at least to humans (Tilgner 2002). However, these hypotheses have yet to be tested. Overall, the findings of this study emphasize the value of extensively sampling natural products over both development and geographic range at individual organism resolution in order to more fully understand underlying chemical biodiversity and ecology.

The Iridoid Glucoside, Antirrhinoside, from *Antirrhinum majus* L. has Differential Effects on Two Generalist Insect Herbivores

Clifford W. Beninger · Renée R. Cloutier · Bernard Grodzinski

Received: 21 November 2007 / Revised: 25 January 2008 / Accepted: 28 January 2008 / Published online: 15 April 2008

Abstract The iridoid glucoside, antirrhinoside, is constitutively distributed throughout *Antirrhinum majus* L. in a manner consistent with its possible role as an allelochemical, but there is no evidence that it has a defensive function with respect to insect herbivory. To address this question, two generalist herbivores, *Lymantria dispar* L. (gypsy moth) and *Trichoplusia ni* Hübner (cabbage looper) were chosen for feeding trials on excised whole leaves of *A. majus* and in artificial diet assays. In leaf excision feeding trials, fourth instar gypsy moth rejected, without sampling, the leaves of *A. majus* regardless of what node the leaf was excised from. In contrast, fourth instar cabbage looper readily fed on the excised leaves, and antirrhinoside was not found in their bodies or feces (frass) as determined by thin layer and high-pressure liquid chromatography. In the leaf and diet assays, a second major leaf iridoid in *A. majus*, antirrhide, was found in both cabbage looper and gypsy moth frass. In diet feeding assays, the growth of gypsy moth and cabbage looper were not inhibited by methanol extracts, iridoid fractions, or pure antirrhinoside at concentrations of 0.6% in diet, but cabbage looper growth was enhanced. At an antirrhinoside concentration of 3.3% in diet, gypsy moth growth was reduced, whereas cabbage looper growth again increased significantly relative to the control. It is likely that antirrhinoside functions as defense against herbivory for one generalist insect herbivore but also, at low concentrations, enhances the growth of another.

Introduction

Antirrhinoside is a monoterpene iridoid glucoside characteristic of species in the tribe Antirrhineae of the family Scrophulariaceae (Kooiman 1970) that includes *Antirrhinum majus* L. (Scarpati et al. 1968), various *Linaria* spp. (Ilieva et al. 1992; Bianco et al. 2004), *Cymbalaria* spp. (formerly placed in *Linaria*; Bianco et al. 1997; Serafini et al. 2004), *Asarina* spp. (Gowan et al. 1995; Voitsekhovskaja et al. 2007), *Kickxia* spp. (Handjieva et al. 1995; Al-Rehaily et al. 2006), and *Maurandya antirrhiniflora* Willd. (Boros et al. 1991). The taxonomy of genera within the Scrophulariaceae currently is the subject of debate. Recently, in a study based on molecular phylogenetics, *Antirrhinum* was placed in the Plantaginaceae family (Albach et al. 2005). This reassignment may indicate a closer relationship to *Plantago lanceolata* L., which has the iridoids catalpol and aucubin (Fig. 1). Catalpol is structurally similar to antirrhinoside, and it is found at high concentrations in new foliage, whereas aucubin predominates in older leaves (Klockars et al. 1993).

We have shown previously (Beninger et al. 2007) that for *A. majus* L., the iridoid glucoside, antirrhinoside, is likely phloem mobile and is allocated constitutively at much higher concentrations in young leaves, buds, and flowers, reaching 20% of the dry weight of those tissues, whereas the lowest concentrations are found in the root tissue. While antirrhinoside is present in all tissues of *A. majus*, a second major iridoid, antirrhide, is found only in the leaves. The relative concentrations of these two

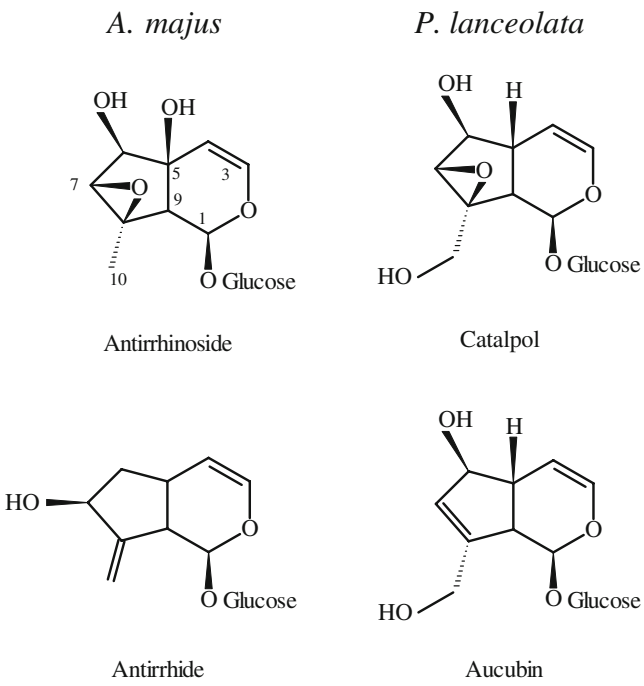

Fig. 1 Chemical structures of antirrhinoside and antirrhide found in *A. majus* and catalpol and aucubin found in *P. lanceolata*

iridoids change with time: as leaves age, antirrhinoside declines and the concentration of antirrhide increases (Beninger et al. 2007).

While much is known about the biosynthesis of antirrhinoside (Breinholt et al. 1992; Damtoft et al. 1993, 1995) there is, to our knowledge, little known of the function of this compound with regard to plant homeostasis or possible plant–plant and plant–animal interactions. The suggestion that it may be involved in homeostasis comes from a comparative study of two species within the Scrophulariaceae. Voitsekhovskaja et al. (2007) found that in *Asarina barclaiana* Pennell, antirrhinoside accounted for 39% of the total carbon transported in the phloem, whereas in *Alonsoa meridionalis* O. Kuntze, which does not have antirrhinoside, sugars, predominantly sucrose, were loaded into the phloem. From this, they concluded that antirrhinoside as well as sucrose in *A. barclaiana* may function to increase the osmotic pressure within the phloem. In another species within the Scrophulariaceae, *Asarina scandens* (Cav.) Penn., Gowan et al. (1995), by using ^{14}C labeling found that antirrhinoside accounted for up to 25% of the label relative to sucrose in lamina and petiole tissue. However, the potential of antirrhinoside as an allelochemical is not known. Other iridoids such as catalpol, catalposide, aucubin, loganin, and asperuloside negatively affect the growth of larval gypsy moth (Bowers and Puttick 1988, 1989). Indirect evidence for antirrhinoside acting as an allelochemical is the finding that it is sequestered by two species of moths that are aposematic as larvae and adapted to feeding on high antirrhinoside-containing plants (Boros et al. 1991). Antirrhinoside, however, was not found in the cryptic adults of the two species.

The purpose of the present study was to determine if antirrhinoside from *A. majus* would affect the feeding and growth of generalist insect herbivores. To accomplish this, two broadly polyphagus herbivores were chosen: gypsy moth (*Lymantria dispar* L.) and cabbage looper (*Trichoplusia ni* Hübner). Cabbage looper is a generalist that feeds on more than 160 species of plants in 36 families (Sutherland and Greene 1984) and may have encountered iridoid containing plants in its diet, as it has been known to be problematic in greenhouse production of *A. majus* (Naegele and Johnson 1962; Sutherland and Greene 1984). Gypsy moth is also considered a generalist that feeds on trees and shrubs in a number of families, but appears not to favor those that contain alkaloids (Barbosa and Krischik 1987).

Larval insects were presented with excised leaves from *A. majus* with different concentrations of antirrhinoside taken from different heights on the plant. Larvae were then tested in artificial diet experiments where methanol extract, iridoid fraction, and pure antirrhinoside isolated from *A. majus* were incorporated into diet. The fate of the two major iridoids in *A. majus*, antirrhinoside and antirrhide, was then determined by thin layer chromatography (TLC) and high-pressure liquid chromatography (HPLC) examination of the larval bodies and feces (frass) of the two species.

Methods and Materials

Plant Material The snapdragon cultivar used in this study was Potomac Ivory White. Seed were provided by PanAmerican Seed™ (Chicago, IL, USA) and sown and grown as described previously in Beninger et al. (2007). Briefly, seeds were sown in a soil-less growth medium (Pro-mix GPX®; Premier Horticulture Ltée/LTD Rivière du Loup, QC) in "128 cavity plug trays" (Landmark Co. Plastic, Akron, OH, USA). Germination took place on a greenhouse misting bench at 22/15°C day/night temperature regime under natural light conditions. After 3–4 wk, snapdragon seedlings were transplanted into a hydroponic basket with Leca as substrate and placed in 1.8-l containers filled with aerated nutrient solution as described by Johnstone et al. (2005). Hydroponic single-plant units were positioned in a growth chamber with a 12-hr photoperiod and provided 350±50 μmol m^{-2} sec^{-1} of photosynthetically active radiation at plant canopy height. Day/night temperatures were approximately 23.5/18°C. Plants were fertilized with a commercial hydroponic formulation (1.15 g of 6:11:35 N/P/K supplemented with 0.85 g of $CaNO_3$ per liter; Plant Products Ltd., Brampton, ON, Canada) with a pH of 6.0 and electrical

conductivity of 1.9 mS/cm. Each main stem was supported by a galvanized wire stake (gauge 12). Seedlings received a half strength nutrient solution for 5 d after transplant. Thereafter, seedlings received full strength nutrient solution, and the solution level was maintained during the experiment. Leaves for the insect bioassays and extraction of the iridoid fraction were excised at commercial maturity.

Insects Cabbage looper eggs and larvae were obtained from Agriculture and Agri-Food Canada, Southern Crop Protection & Food Research Centre, London, ON, Canada. Gypsy moth eggs were obtained from the Canadian Forest Service Insect Production Unit, Great Lakes Forest Research Centre, 1219 Queen St. E., Sault Ste. Marie, ON, Canada. Larvae were reared to the appropriate stage on BioServ® (Frenchtown, NJ, USA) gypsy moth and cabbage looper (general purpose Lepidoptera) artificial diets.

Isolation of the Iridoid Fraction from Leaf Tissue Freeze-dried, ground leaf tissue was loaded into a glass column (6.0×36.0 cm) and extracted sequentially with hexane, ethyl acetate, and methanol. The methanol fraction was found by HPLC to contain the iridoids. A 2.0×30.0-cm glass column was packed with a slurry of chlorophorm/methanol/water 6:3:1 and chromatographic silica (Fisher Scientific 100×200 mesh) and equilibrated with the same solvent system. One gram portions of powdered dry leaf crude methanol extract were dissolved in 2.0 ml methanol and loaded onto the column, which was then eluted with chloroform/methanol/water 6:3:1. Most of the chlorophyll and carotenoids were washed off the column, while the iridoids remained adhered to the silica. The mobile phase was changed to 100% methanol, which eluted the iridoids, and then this fraction was rotary evaporated until dry. It was taken up in 2.0 ml of methanol and loaded onto the top of a Sephadex LH-20 (Sigma-Aldrich®, Oakville, ON, Canada) 2.5×24.0-cm glass column, which had been equilibrated with 100% methanol and eluted with the same solvent. The column was monitored with a hand-held UV lamp at 366 nm (Model UVGL-58 Mineralight Lamp) and the blue band that contained the iridoids collected (Fig. 2a). This was rotary-evaporated to dryness, taken up in 2.0 ml of water, frozen at −80°C, and freeze-dried for use in the diet bioassays.

Isolation of Antirrhinoside Antirrhinoside is not available commercially and therefore must be purified from plant tissue. Flowers of *A. majus* contained the highest concentrations of antirrhinoside, with no antirrhide or chlorophyll to complicate purification. Flowers from mature Potomac Ivory White plants, which were grown as above, were removed from the flower spike (or inflorescence) and immersed in liquid N_2, frozen at −80°C, and then freeze-dried. Dried flowers were ground to a fine powder, loaded into a glass column (6.0×36.0 cm), and extracted as above for the leaves. The methanol extract contained antirrhinoside by HPLC analysis, and was rotary-evaporated to dryness, recovered in methanol, and dried under a stream of N_2. Finally, the methanol extract was taken up in water, frozen at −80°C, freeze-dried, and stored at −20°C before use. One gram portions of the methanol extract were fractionated on a Sephadex LH-20 column (2.5×24.0 cm) that had been equilibrated with 100% methanol and eluted with the same solvent. The column was monitored with a hand-held UV lamp at 366 nm. The first band collected was blue under UV and contained antirrhinoside in high concentration by HPLC analysis. This band was collected, concentrated by rotary evaporation, and streaked on 1,000-μm thickness, 20.0×20.0-cm silica gel preparative TLC plates (Analtech Inc., Newark, DE, USA). The blue band under UV was scraped from the plate, placed in 10.0-ml centrifuge tubes to which methanol had been added until close to the top, and centrifuged for 5 min at 3,000 rpm. The supernatants were collected, combined, and rotary-evaporated to dryness, after which, they were taken up in 2.0 ml of methanol and applied to the top of a Sephadex LH-20 column (1.5×24.0 cm) equilibrated, and eluted with 100% methanol for final purification. Purity of the isolated antirrhinoside used in the diet assays was then determined by HPLC analysis (Fig. 2b).

Preparation of Tissue for HPLC Analysis Leaf material, insects, and frass were frozen at −80°C and freeze-dried. These were placed into 1.5-ml Eppendorf tubes and two stainless steel beads (Montreal Biotech Inc. 3.17 mm) added to each tube to which 1.0 ml of methanol was added. Tissues were homogenized in a Retsch® MM300 tissue homogenizer (Newtown, PA, USA) for 5 min at 30 cycles per second, removed, centrifuged at 14,000 rpm for 3 min, and the supernatant passed through a 0.2-μm syringe filter (Whatman International Ltd., Maidstone, UK) into HPLC vials for analysis.

TLC Analyses TLC analysis of the extracts was carried out by co-chromatography with purified standards. Extracts and pure compounds were spotted onto 20.0×20.0-cm, 250 μm Avicell microcrystalline cellulose plates (Analtech Inc.) 2.0 cm from the bottom of the plates, allowed to dry, and placed in a TLC tank with *n*-butanol/acetic acid/H_2O 4:1:5 as the mobile phase. Plates were removed after the solvent front had reached within 2.0 cm of the top of the plate. After removal from the tank, plates were allowed to dry and sprayed with diphenylamine/aniline/H_3PO_4 spray (Markham 1982) and heated with a heat gun (Hejet, model HJ300 Pamran Co. Inc., Waukesha, WI, USA.) to visualize the iridoids.

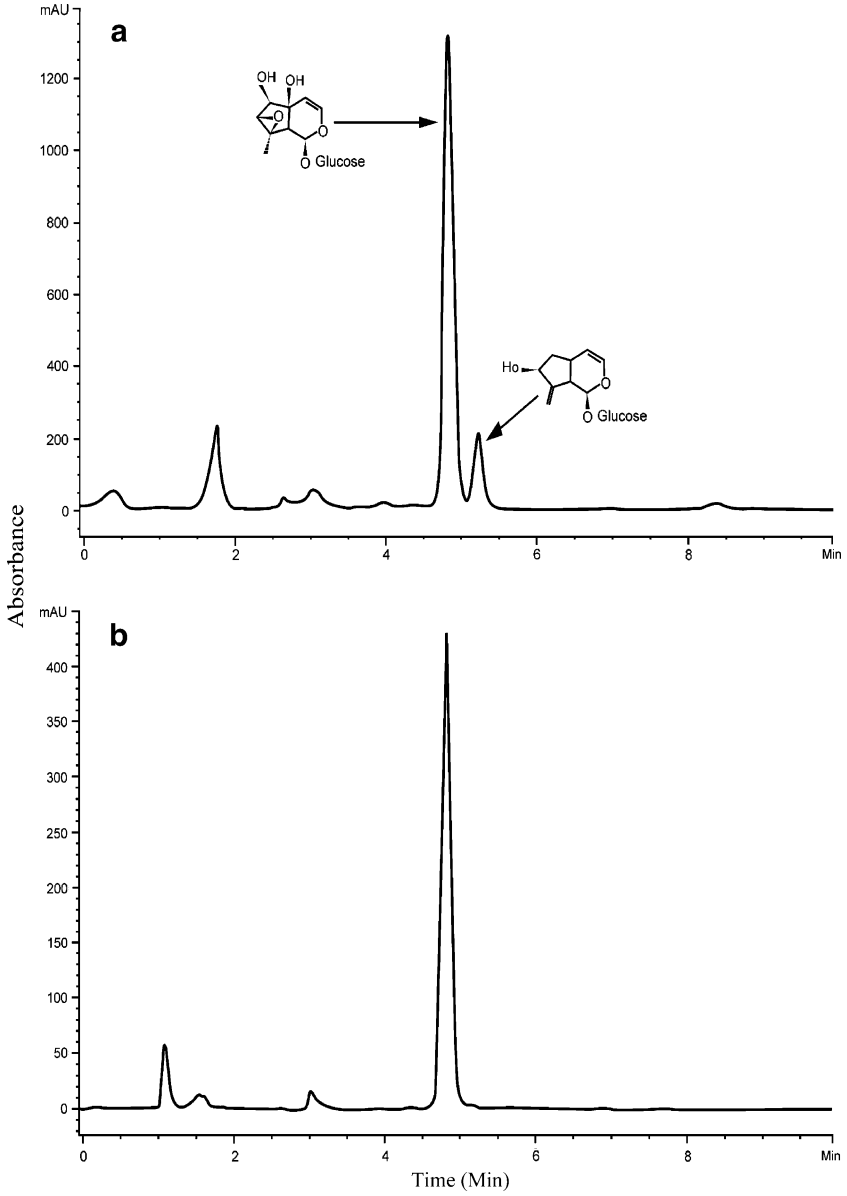

Fig. 2 **a** HPLC chromatogram of the purified iridoid fraction from *A. majus* leaves; **b** purified antirrhinoside from *A. majus* flowers

HPLC Analyses HPLC analyses were performed with an Agilent model 1100 HPLC equipped with a degasser, quad pump, autosampler, and diode array display (Agilent Technologies Canada Inc., Mississauga, ON, Canada). The column used was a CapCell Pak AG 120 C18 (4.6× 250.0 mm, 5-μm particle size; Shiseido Co. Ltd. Japan), and the HPLC had ChemStation software. The solvent system used was isocratic with 8% acetonitrile in water with a scan of 200 to 600 nm and quantification wavelength of 205 nm.

Excised Leaf-Feeding Experiments with Larvae Axillary leaves and lateral stems originate from slightly enlarged areas of the main stem of *A. majus*, defined as nodes. Nodes are numbered from the base of the stem, with the lowest node number being closest to the base. Leaves from nodes 4, 8, and 12–14 (N=5 from each node for each experiment) were excised at the point where the petiole joins the main stem. The cut ends of the petioles were placed in 1.5-ml Eppendorf tubes filled with distilled water through holes that had been cut in the lids. Eppendorf tubes and leaves were then placed on top of an empty 20.0-ml glass scintillation vial for support, and these were placed inside clear plastic Magenta® tissue culture boxes (Model GA7, 77.0×77.0×97.0 mm, Magenta Corporation, Chicago, IL, USA). Insects at the fourth instar stage were placed directly on the leaves (two per leaf) and the Magenta® boxes placed into an environmental chamber (12-hr photoperiod, day/night temperatures were approximately 23.5/18°C). Leaves from nodes opposite the

leaves that were presented to cabbage looper were analyzed by HPLC for their iridoid concentrations as an approximation of initial iridoid concentrations in leaves presented to the insects. The remaining leaf tissues that had been fed on by cabbage looper were also examined by HPLC to give a final concentration. A change would give an indication whether local leaf iridoid synthesis was altered by insect feeding over the 24-hr period. Leaves from node 10 (N=10) were also removed, one half of which was prepared as above and analyzed by HPLC to give an estimate of initial iridoid concentrations. The other half was treated exactly as leaves presented to the insects, except that no insects were placed on them. These were controls to determine what effects leaf excision may have on leaf iridoid chemistry. Ten insects for each leaf-feeding experiment were set aside and fed artificial diet for 24 hr only under the same environmental conditions as those fed leaves.

After 24 hr, insects were removed, and if leaves were fed on, they were prepared as above and analyzed by HPLC. Frass from cabbage looper leaf assays was allowed to air dry due to the difficulty in removing it from the Magenta® boxes while moist. When dry, frass was removed and subjected to HPLC analysis. Frass from artificial diet fed gypsy moth was freeze-dried before HPLC analysis.

Artificial Diet—Feeding Experiments with Larvae Gypsy moth and cabbage looper artificial diets were obtained from BioServ® (Frenchtown, NJ, USA). Extracts, fractions, and pure antirrhinoside were weighed to give the appropriate concentrations and then dissolved in 2:1 acetone/water, sonicated, and added to the artificial liquid diet. Control diet had only acetone/water 2:1. Diet was poured into Petri dishes, allowed to cool, and individual plugs were removed with cork borers of different sizes that were then placed in 29.6-ml Solo® cups to which the insect larvae (N=20 per treatment) were added. The cups were placed in an environmental chamber with the same light and temperature conditions as for the leaf assays. Diet was replaced every 2 d (or as needed), and larvae were weighed every 3 d. Gypsy moth larvae and frass from the 0.6% iridoid fraction and 3.3% antirrhinoside treatment were frozen, freeze-dried, and prepared as above for HPLC analysis.

Statistical Analyses The SAS® (2005) statistical software package was used. One-way analyses of variance with Student Newman–Keuls means differences tests were used to determine differences in iridoid concentrations in different leaf tissues, larvae, and frass using the PROC GLM, Means SNK. Differences in larval weights were analyzed in the same manner. The probability of a type I error rate was set at 0.05% for all analyses.

Results

Isolation of Iridoids Chemical structures of the compounds to be discussed are given (Fig. 1). Figure 2a,b shows the HPLC traces of the purified iridoid fraction from the leaves and antirrhinoside isolated from the flowers of *A. majus*. The bulk purification techniques outlined above gave better than 90% pure iridoid fraction and antirrhinoside.

Excised Leaf-Feeding Experiments with Larvae Cabbage looper larvae fed readily on the excised leaves of *A. majus* regardless of from where in the canopy the leaf was taken. For example, leaves from the fourth node are the oldest and contain the lowest levels of antirrhinoside and highest levels of antirrhide, whereas leaves taken from nodes 12–14 are relatively young and have the highest levels of antirrhinoside and lowest levels of antirrhide (Beninger et al. 2007). Gypsy moth did not feed on the leaves of *A. majus* and were active, moving around inside the culture boxes. Therefore, iridoid concentrations in leaves, larvae, and frass from this assay are not reported. In contrast to cabbage loopers that fed on the leaves and increased in weight (Fig. 3a), the gypsy moth larvae lost (about 13%) weight (Fig. 3b) and did not excrete frass over the 24-hr period of the experiment.

There was no significant difference in the amount of antirrhinoside, antirrhide, or total iridoids between the estimated initial and the actual final concentrations in the leaves that had been fed on by cabbage looper (Table 1). However, for the leaf taken from node 10, which was a control to examine the effect of excision on iridoid concentration, the amount of antirrhinoside increased significantly, whereas the concentration of antirrhide remained the same (Fig. 4). When the bodies and frass of cabbage looper fed *A. majus* leaves were analyzed by HPLC, antirrhinoside was not detected in either. However, antirrhide, while undetected in the body, was found at low concentrations in the frass (Table 2). This was confirmed by co-chromatography with TLC and HPLC with purified compounds and by HPLC peak UV signatures.

Artificial Diet—Feeding Experiments with Larvae Neither cabbage looper nor gypsy moth was adversely affected by methanol extract, iridoid fraction, or antirrhinoside at concentrations of 0.6% (Figs. 5a and 6a). However, cabbage looper showed significantly enhanced growth when feeding on antirrhinoside alone at the above concentration, and the same effect was seen when fed antirrhinoside at a concentration of 3.3% in diet (Fig. 5b). When fed antirrhinoside at 3.3%, gypsy moth larval weight was significantly reduced at all periods from the start of the experiment and was reduced by almost 50% by the end of the experimental period (Fig. 6b), although no larvae died.

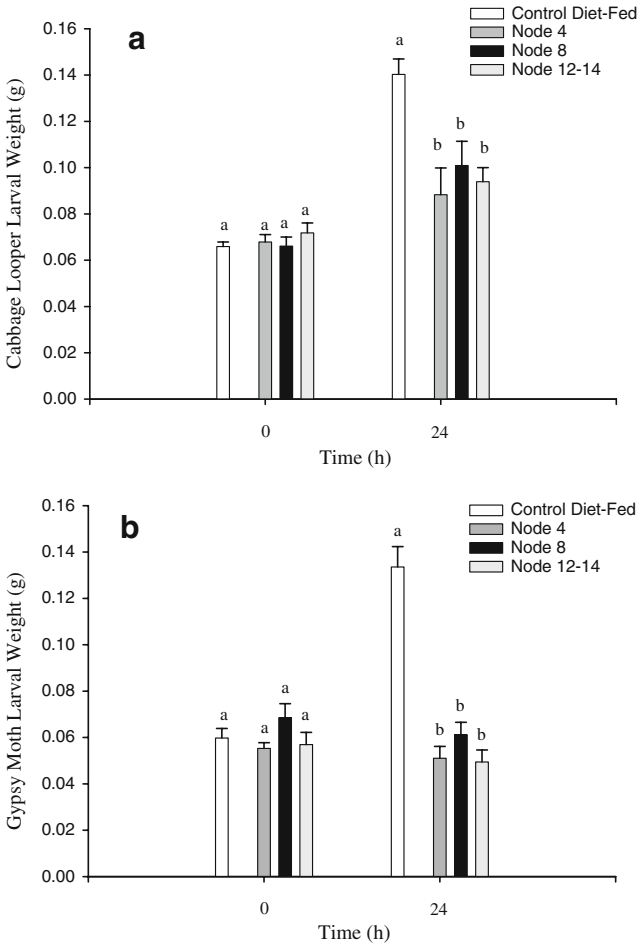

Fig. 3 **a** Larval weights of cabbage looper fed for 24 hr on artificial diet and excised *A. majus* leaves. **b** Larval weights of gypsy moth fed for 24 hr on artificial diet and excised *A. majus* leaves. Means with the *same letter above bars* at a given time period are not significantly different ($P>0.05$)

Bodies and frass of gypsy moth were also analyzed by HPLC and TLC, and antirrhinoside was not found. However, antirrhide was identified in the frass by its characteristic R_f and spot color with TLC (see Beninger et al. 2007), but the concentrations were too low for quantification.

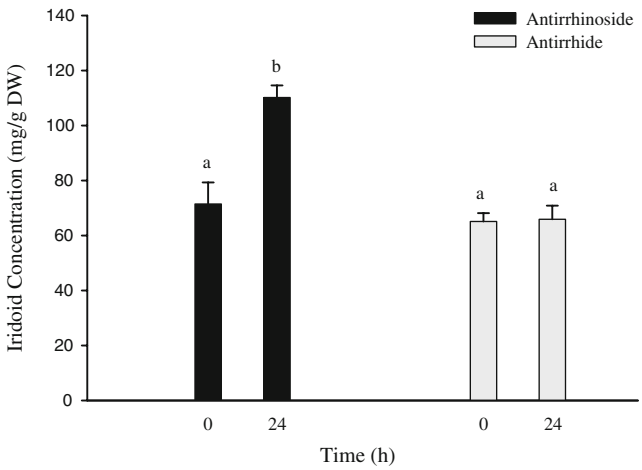

Fig. 4 Initial (based on opposite leaves) and final concentrations of iridoids in excised leaves not fed on by cabbage looper ($N=10$). Means with the *same letter above bars* at a given time period are not significantly different ($P>0.05$)

Peaks eluted with the same retention time as antirrhinoside in both cabbage looper and gypsy moth bodies; however, their UV signature from HPLC analysis and characteristic spot color on TLC was absent (data not shown). These peaks and UV signatures were found also in cabbage looper and gypsy moth bodies fed control diet, so they are likely a component of the artificial diet.

Discussion

Antirrhinoside is an iridoid glucoside that is produced constitutively in *A. majus* but whose concentration changes in leaves, depending on age (position in the canopy), relative to antirrhide, the other major iridoid found in *A. majus* (Høgedal and Mølgaard 2000; Beninger et al. 2007). A body of research has been published on the relationship between generalist and specialist insect herbivores that feed on the ribwort plantain (*Plantago lanceolata* L.; Bowers 1983, 1984; Bowers and Puttick 1988, 1989; Klockars et al. 1993; McCloud and Berenbaum 1999), which contains two major iridoids, catalpol, and aucubin (Fig. 1).

Table 1 Initial (based on opposite leaves) and final concentrations (mg/g DW) of iridoids for *A. majus* leaves fed to cabbage looper larvae

	Initial			Final		
	Node number					
	4	8	12–14	4	8	12–14
Antirrhinoside	64.07 (6.0)	106.31 (10.6)	150.51 (16.7)	74.21 (11.4)	107.69 (10.7)	125.53 (14.1)
Antirrhide	59.12 (5.8)	56.77 (5.7)	43.01 (3.3)	53.90 (1.9)	52.23 (3.0)	36.47 (1.0)
Total iridoids	123.18 (10.7)	163.09 (16.1)	193.52 (16.1)	128.1 (12.9)	159.92 (12.7)	162.01 (14.2)

Means with SE in parentheses. There were no significant differences between initial and final concentrations for leaves removed from different nodes ($P>0.05$).

Table 2 Concentration (mg/g DW) of iridoids recovered in frass of cabbage looper fed *A. majus* leaves

	Node from which Leaf Was Excised		
	4	8	12–14
Iridoid			
Antirrhinoside	nd	nd	nd
Antirrhide	6.97 (2.59)	4.32 (1.80)	6.98 (2.54)

Means with SE in parentheses. There were no significant differences in the concentration of antirrhide in the frass ($P>0.05$).
nd not detected

Because of the widespread occurrence and ease of cultivation of *P. lanceolata*, as well as the availability of the commercial standards catalpol and aucubin, this plant has become a model system to study the role of iridoids in insect–plant interactions. However, the relationship between the iridoid glucosides antirrhinoside and antirrhide in *A. majus* and their possible effects on insect herbivory are unknown. While antirrhide is found only in the leaves, antirrhinoside is found in all plant parts at 19–23% of the dry weight in new leaves and flowers, respectively (Beninger et al. 2007). The value of *A. majus* as a model system for studying the biological activity of iridoids is worthy of more careful examination because *A. majus* is a species for which a considerable amount of genetic and developmental information is known.

In the present study, we found different responses for two generalist herbivores in feeding trials with excised leaves. Fourth instar cabbage looper readily fed on leaves that contained total iridoid concentrations that varied from 12.3% to 19.4% of the dry weight of the leaf (Table 1) depending on where they were excised from in the canopy. In a study of potential host plants of cabbage looper, Soo Hoo et al. (1984) found that 60% survival to adulthood was

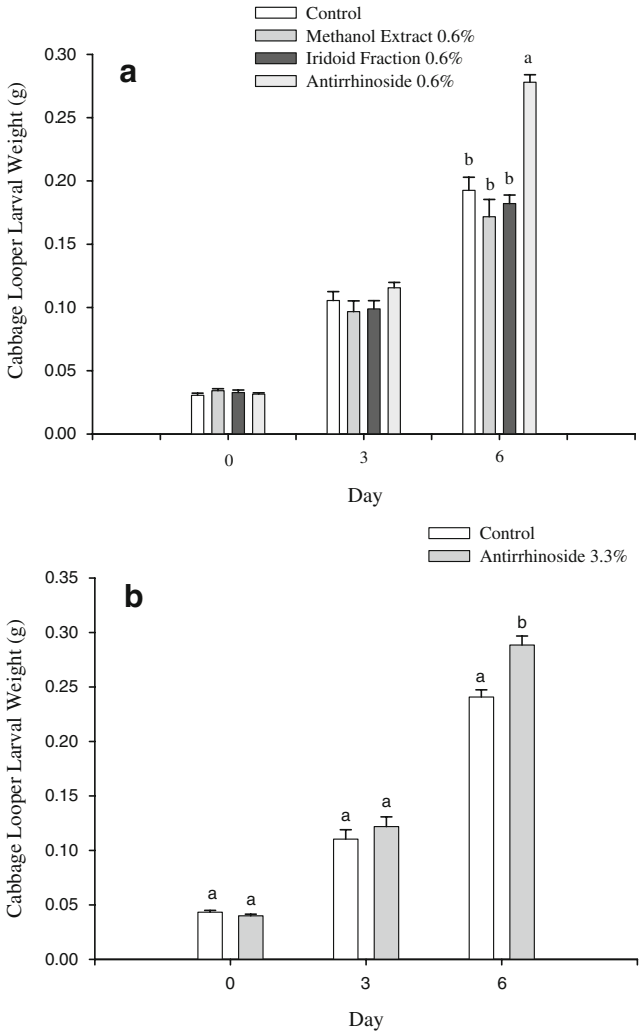

Fig. 5 **a** Larval weights for cabbage looper fed methanol extract, iridoid fraction, and pure antirrhinoside in artificial diet at 0.6%. **b** Larval weights for cabbage looper fed pure antirrhinoside at 3.3% in artificial diet. Means with the *same letter above bars* at a given time period are not significantly different ($P>0.05$)

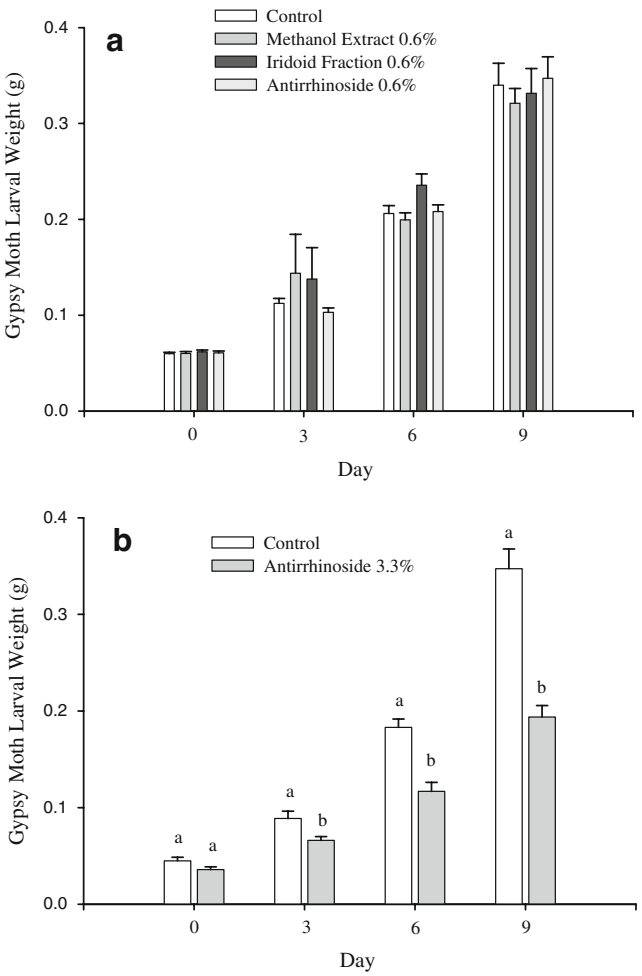

Fig. 6 **a** Larval weights for gypsy moth fed methanol extract, iridoid fraction and pure antirrhinoside in artificial diet at 0.6%. **b** Larval weights for gypsy moth fed pure antirrhinoside at 3.3% in artificial diet. Means with the *same letter above bars* at a given time period are not significantly different ($P>0.05$)

possible when fourth instars were placed on *Penstemon virgatus* Gray, which contains the iridoids catalpol, globularin, and scutellarioside-II (L'Empereur and Stermitz 1990). However, when first instars were placed on these plants, none survived to the second instar stage, which may indicate that the earliest instar of cabbage looper is more sensitive to iridoids. In our study, fourth instar cabbage looper fed leaves of different ages gained the same amount of weight, although not as much as the control larvae fed artificial diet only (Fig. 3a). This indicates that the role of antirrhide when present in leaves with antirrhinoside is unknown yet may be significant.

To our knowledge, before the present work, there has been no study that has tested directly whether antirrhinoside is anti-feedant or toxic to lepidopteran larvae. There is some evidence that it is nontoxic to specialists that feed on antirrhinoside-containing plants, as it is sequestered as a defense against predation. For example, the larvae of *Meris paradoxa* and two *Lepipolys* species are specialists on *Maurandya antirrhiniflora*, whose leaves contain concentrations of antirrhinoside similar to *A. majus*, and sequestered this compound at 3–11% dry weight of larvae (Boros et al. 1991). These larvae are aposomatic, but the adults are cryptic and do not sequester antirrhinoside. In contrast, cabbage looper is a generalist with cryptic larvae that do not sequester antirrhinoside.

In *P. lanceolata*, where the iridoids catalpol and aucubin are found, catalpol has been shown to reduce growth more than aucubin when fed to the generalist *Spodoptera eridania* (Stoll; southern armyworm; Puttick and Bowers 1988). Aucubin differs from catalpol only in the absence of the epoxide ring. Antirrhide in *A. majus* also lacks an epoxide ring (Fig. 1). Catalpol is similar to antirrhinoside, differing only in the lack of an oxygen at the 5-position and substitution of an oxygen at carbon 10. In this study, we did not feed pure antirrhide to cabbage looper because in the iridoid fraction from *A. majus*, it occurs only at low concentrations (Fig. 2a) relative to antirrhinoside and elutes very close to it in the HPLC analysis. The only method we have found to purify this compound from leaves is by semi-preparative HPLC, which gives small amounts that cannot be incorporated into artificial diet at physiologically relevant concentrations.

For leaves fed on by cabbage looper, antirrhinoside production did not appear to be induced in 24 hr, as the concentration remained unchanged (Table 1). This can be explained if *A. majus* is similar to *P. lanceolata* in which local induction of the iridoid catalpol was not apparent until 6 d after the specialist *Junonia coenia* Hübner was placed on the plants (Fuchs and Bowers 2004). As antirrhinoside in *A. majus* is likely phloem mobile, induction may have to occur at the whole plant level and result in the reallocation of antirrhinoside to damaged tissue from other leaves, a response which could not be determined within the experimental time period with excised leaves in our study. However, the excised leaves that were not fed on had significantly more antirrhinoside after 24 hr (Fig. 4). This may have been a local response to damage due to excision, but it is unclear why leaves that were fed on did not show a similar response. Cabbage looper is known to "trench" leaves to release compounds from the phloem tissue (Doussourd and Denno 1994), but this behavior was not observed in our experiments.

In diet-feeding experiments, cabbage looper fed pure antirrhinoside showed increased growth relative to controls. It should be noted that the antirrhinoside concentrations in diet are well below what can be expected in most leaves of *A. majus* (Høgedal and Mølgaard 2000; Beninger et al. 2007). However, when feeding on the concentrations of antirrhinoside and antirrhide found in leaves (Fig. 3a, Table 1), there was no deleterious effect on growth with regard to leaf position, although growth was significantly lower than larvae fed artificial diet.

Gypsy moth did not feed on the excised leaves (Fig. 3b) and was not affected when fed 0.6% antirrhinoside in diet (Fig. 6a), but at 3.3%, growth was significantly reduced (Figure 6b). In a study of the iridoids catalpol and aucubin, Bowers and Puttick (1988) found that these compounds both reduced gypsy moth final weights by approximately 50% at a concentration in diet of only 0.18% dry weight. The fact that gypsy moth was unaffected by antirrhinoside at 0.6% may be due to structural differences between catalpol and antirrhinoside or that some laboratory strains of gypsy moth are less sensitive to iridoids in their diet (Bowers and Puttick 1989).

Antirrhinoside and antirrhide were not found in the body of gypsy moth in our study, but antirrhide was present in the frass at concentrations too low for HPLC quantification. However, its characteristic R_f and spot color was found in TLC analysis. In another study, gypsy moth was found to excrete catalposide, but this was not detected in the body of the larvae (Bowers and Puttick 1986). Previously published choice studies with gypsy moth larvae either showed no preference for control vs. iridoid-containing diet or a preference for diet that contained iridoids that was dependant on the *type* of iridoid (Bowers and Puttick 1988). In another study, Bowers and Puttick (1989) found no preference for catalposide-containing diet at a concentration of 0.18% over control, but at high (7.2%) vs. low (0.18%) catalposide diet, responses varied, with the low concentration sometimes preferred and in other cases the high concentration. From these studies, the varied response of gypsy moth to iridoids in diets may indicate that it cannot reliably detect and avoid these compounds. The lack of feeding response when presented with excised leaves of *A. majus* was probably not due to gypsy moth's ability to

identify and avoid iridoids, as the leaves were not sampled by biting. In leaves, antirrhinoside accumulates mainly in vacuoles and is translocated in the phloem of leaf tissue (Voitsekhovskaja et al. 2007). It is unlikely that it is present on the leaf surface and that rejection of the leaves by gypsy moth may be a reaction to leaf volatiles or chemical components in the wax of the surface that can be detected with contact chemoreceptors on the tarsi or mouthparts (Bernays and Chapman 1994).

When feeding on *A. majus* leaves, cabbage looper is exposed to both antirrhinoside and antirrhide of differing concentrations (Table 1), dependant on the location of the leaves within the canopy. There was no effect of leaf position on growth (Fig. 3a), but growth was reduced relative to the diet-fed controls. In addition, growth of cabbage looper was unaffected when fed iridoid fraction at 0.6% in artificial diet, yet growth was enhanced when fed antirrhinoside alone (Fig. 5a,b) at 0.6% and 3.3% in diet. This indicates that when feeding on these two iridoids together in leaf or diet that the increase in weight observed when feeding on antirrhinoside alone is suppressed.

In summary, we have shown previously (Beninger et al. 2007) that antirrhinoside in *A. majus* is consistent with it being a phloem mobile compound whose distribution and concentration in various organs suggest that it functions as an allelochemical. In the current study, we have shown that one generalist herbivore, gypsy moth, rejects leaves of *A. majus*, and its growth is negatively affected when fed antirrhinoside in diet at a concentration that is lower than it would normally encounter in leaves of the plant. This defense may only be effective against some generalist herbivores, as cabbage looper growth is increased when fed on diet containing antirrhinoside alone. However, when feeding on the concentrations of antirrhinoside and antirrhide that are found in leaves, cabbage looper growth is reduced compared to control diet-fed larvae. The co-occurrence and relative concentrations of antirrhinoside and antirrhide in leaves of *A. majus* could therefore have significant effects on insect herbivores. Future research should focus on the combined effect of these two compounds.

Acknowledgments This research was supported in part by a Natural Sciences and Engineering research grant awarded to Bernard Grodzinski. We also thank the following funding agencies: Flowers Canada (Ontario) Ltd. and Ontario Ministry of Agriculture, Food and Rural Affairs and an Ontario Centres of Excellence Research Award. In addition, we are grateful for the laboratory assistance given by the undergraduate summer research assistant Amanda J. Niederkorn.

RAPID COMMUNICATION

Defense-Inducing Volatiles: In Search of the Active Motif

Martin Heil · Ulrich Lion · Wilhelm Boland

Received: 6 February 2008 / Accepted: 18 March 2008 / Published online: 12 April 2008

Abstract Herbivore-induced volatile organic compounds (VOCs) are widely appreciated as an indirect defense mechanism since carnivorous arthropods use VOCs as cues for host localization and then attack herbivores. Another function of VOCs is plant–plant signaling. That VOCs elicit defensive responses in neighboring plants has been reported from various species, and different compounds have been found to be active. In order to search for a structural motif that characterizes active VOCs, we used lima bean (*Phaseolus lunatus*), which responds to VOCs released from damaged plants with an increased secretion of extrafloral nectar (EFN). We exposed lima bean to (*Z*)-3-hexenyl acetate, a substance naturally released from damaged lima bean and known to induce EFN secretion, and to several structurally related compounds. (*E*)-3-hexenyl acetate, (*E*)-2-hexenyl acetate, 5-hexenyl acetate, (*Z*)-3-hexenylisovalerate, and (*Z*)-3-hexenylbutyrate all elicited significant increases in EFN secretion, demonstrating that neither the (*Z*)-configuration nor the position of the double-bond nor the size of the acid moiety are critical for the EFN-inducing effect. Our result is not consistent with previous concepts that postulate reactive electrophile species (Michael-acceptor-systems) for defense-induction in Arabidopsis. Instead, we postulate that physicochemical processes, including interactions with odorant binding proteins and resulting in changes in transmembrane potentials, can underlie VOCs-mediated signaling processes.

Introduction

Plants respond to herbivore damage with the release of volatile organic compounds (VOCs) that signal the presence of herbivore prey to predators and parasites and thereby serve as an indirect defense mechanism (e.g., Heil 2008). Research has demonstrated that these VOCs can also be perceived by neighboring plants or intact, systemic parts of the damaged plant (Baldwin et al. 2006; Heil 2008). Particularly, green-leaf volatiles (GLVs) have been associated with induced resistance in intact plants (Arimura et al. 2000; Engelberth et al. 2004; Farag et al. 2005; Ruther and Kleier 2005; Kost and Heil 2006;). However, little is known about the identity of VOCs that are active in this context or about a structural motif that active VOCs might have in common. In an attempt to explain the inducing activity of such VOCs on gene expression, it has been suggested that GLVs with an α,β-unsaturated carbonyl group such as (*E*)-2-hexenal can trigger defense responses in Arabidopsis through their activity as reactive electrophile species (Almeras et al. 2003).

In the present study, we used lima bean (*Phaseolus lunatus* L.) to search for traits that characterize defense-inducing VOCs. Lima bean responds to herbivore damage with the jasmonate-mediated production of VOCs and extrafloral nectar (EFN), an aqueous, sugar-containing secretion on nonreproductive plant organs that attracts predatory arthropods (mainly ants). The natural blend of VOCs that is released from a herbivore-damaged lima bean induces EFN secretion in intact neighboring plants (Kost and Heil 2006) and serves as a within-plant signal (Heil and Silva Bueno 2007). Among the quantitatively dominant VOCs that are released from induced lima bean, however, only (*Z*)-3-hexenyl acetate significantly induced EFN secretion when used as pure compound (Kost and Heil 2006). In the present study, we applied different structurally related esters to lima bean plants and monitored their EFN secretion.

Materials and Methods

Plants were cultivated from seeds collected in the coastal area of Puerto Escondido, Oaxaca, México (15°55.596 N and 097°09.118 W, elevation 15 m). Seedlings were cultivated under ambient conditions in 250 ml pots filled with soil from the original growing site. The plants were watered daily and fertilized 6 weeks after germination with commercial fertilizer: 10 ml per plant of a solution of 3 mg l^{-1} of "Fertilisante foliar de alta concentración" (Grupo Bioquímico Mexicano, Aaltillo, Coah., Mexico). Experiments were conducted with plants of an age of 8–10 weeks. The following compounds were dissolved in Lanolin paste (all at 0.1 μg μl^{-1}): (A) (*Z*)-3-hexenyl acetate, (B) (*E*)-3-hexenyl acetate, (C) (*E*)-2-hexenyl acetate, (D) 5-hexenyl acetate, (E) (*Z*)-3-hexenyl isovalerate, (F) (*Z*)-3-hexenyl butyrate, (G) 2-ethylhexanol, (H) (*E*)-2-hexanal, (I) decanal, and (K) nonanal (Lanolin paste and all compounds were purchased from Sigma Aldrich). Each 0.25 g paste per plant was applied on green plastic stripes (MAX Binde-band) attached to the plant in order to avoid direct contact of the paste with the plant. The plants were then packed in perforated PET foil bags (Bratenschlauch, Toppits, Minden, Germany) and in nets to protect them from EFN consumers. Amounts of VOCs released from the lanolin paste into the plants' headspace under these conditions were monitored in a parallel experiment that used a closed-loop stripping system as described previously (Kost and Heil 2006). EFN secretion was quantified from the five youngest leaves 24 h later. In short, EFN concentration was measured with a portable refractometer, and nectar volume was measured with glass capillaries (Kost and Heil 2006) to calculate the total amount of soluble solids secreted, which in the case of lima bean EFN are mainly glucose, fructose, and sucrose. Leaves were then collected and dried to calculate EFN secretion as soluble solids secreted per gram leaf dry mass and per 24 h. Plants to which Lanolin paste without any compound added had been applied served as controls (Lanolin control, LC). Per day, two groups each comprising all 11 treatments were investigated, and in total eight plants per treatment were used.

Results and Discussion

Amounts of VOCs released from the lanolin paste into the plant's headspace resembled those released from an induced plant, i.e., all individual VOCs were present at 80–130% of the amount of (*Z*)-3-hexenyl acetate that is released under comparable conditions from five induced leaves of lima

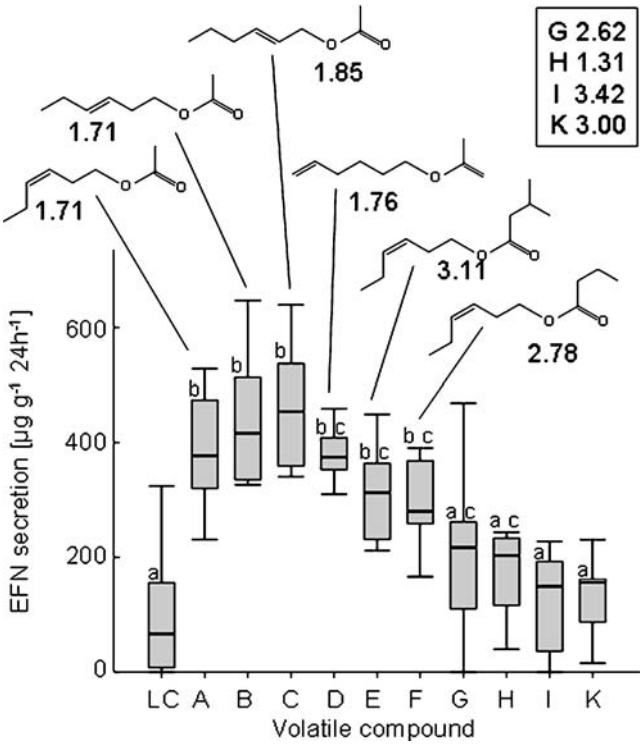

Fig. 1 EFN secretion in μg soluble solids secreted per gram leaf dry mass and per 24 h is depicted. Plants were exposed for 24 h to (*A*) (*Z*)-3-hexenyl acetate, (*B*) (*E*)-3-hexenyl acetate, (*C*) (*E*)-2-hexenyl acetate, (*D*) 5-hexenyl acetate, (*E*) (*Z*)-3-hexenyl isovalerate, (*F*) (*Z*)-3-hexenyl butyrate, (*G*) 2-ethylhexanol, (*H*) (*E*)-2-hexanal, (*I*) decanal, and (*K*) nonanal dissolved in Lanolin paste. Plants to which pure Lanolin paste had been applied served as controls (*LC*). Lower and upper whiskers represent the 5% and the 95% percentile, lower and upper margins of boxes the 25% and the 75% percentile, the *lines within boxes* indicate medians. *Different letters appearing above boxes* mark treatment effects that differ significantly from each other ($P<0.05$ according to LSD posthoc analysis), and structures of compounds leading to a significant induction of EFN secretion as compared to the control are graphically presented. LogP values of all compounds were calculated with ChemDraw Ultra 6.0 and are given under the structures (compounds *A–F*) and in the insert (*G–K*)

bean (data not shown, for amounts of VOCs released from an induced plant see Kost and Heil 2006). The different VOCs to which lima bean plants had been exposed affected their EFN secretion significantly (General linear model: $F_{77,10}=10.05$, $P<0.001$). Compounds A–F consisted of acyl hexenols in which the configuration and position of the double bond was systematically shifted from the polar head to the aliphatic terminus of the molecule. Moreover, the importance of the size of the acyl moiety was evaluated by using acetates, butyrate, and isovalerate of (*Z*)-3-hexenol. Although only one of the tested VOCs is naturally released from lima bean, exposure to the six compounds (A–F) elicited EFN secretions that were significantly higher than those of the controls (LSD posthoc analysis: $P<0.05$, see Fig. 1). These compounds were (*Z*)-3-hexenyl acetate, (*E*)-3-hexenyl acetate, (*E*)-2-hexenyl acetate, 5-hexenyl acetate, (*Z*)-3-hexenyl isovalerate, and (*Z*)-3-hexenyl butyrate. Hence, EFN secretion by lima bean can be induced by VOCs that are not released naturally from this species, while several VOCs that are released from induced plants did not significantly change EFN secretion in previous experiments (Kost and Heil 2006).

How are VOCs perceived by plants, and via which mechanisms do they affect defense expression patterns? It has been suggested that molecules with an α,β-unsaturated carbonyl group can trigger defenses in Arabidopsis through their activity as reactive electrophile species (Almeras et al. 2003). In principle, VOCs could also be perceived by binding to specific receptor-proteins or to odorant binding proteins with a preference for a class of compounds, similar to animal olfactory systems.

Apparently, neither the configuration nor the position of the double bound is a critical factor. Compounds reported to prime or induce gene activity or phenotypic defenses in intact corn plants comprise (*Z*)-3-hexen-1-ol, (*Z*)-3-hexenal, and (*Z*)-3-hexenyl acetate (Engelberth et al. 2004; Farag et al. 2005; Ruther and Kleier 2005). We found that (*Z*)-3-hexenyl acetate, (*E*)-3-hexenyl acetate, (*E*)-2-hexenyl acetate, and 5-hexenyl acetate all elicited particularly high EFN secretion rates in lima bean. The majority of these substances lack an α,β-unsaturated carbonyl group, which thus cannot be a generally required motif. In addition, a compound such as 5-hexenyl acetate cannot yield an electrophile such as (*E*)-2-hexenal via the sequence of ester hydrolysis, oxidation, and isomerization, as it is principally possible for (*E* or *Z*)-3-hexenyl acetate or (*E* or *Z*)-2-hexenyl acetate. Moreover, unlike (Z)-3-hexenyl acetate the potential end product of the transformation sequence, (*E*)-2-hexenal, had only a weak effect on the nectar flow. Similarly, the observation that (*Z*)-3-hexenyl acetate and (*E*)-3-hexenyl acetate elicited almost identical EFN secretion rates contradicts the involvement of classical receptor proteins, since these usually require a specific stereochemistry of the interacting molecule. We further calculated LogP values to check for putative importance of the compound's lipophilicity but did not find any clear relation between the EFN-inducing activity of a compound and its octanol-water partition coefficient (Fig. 1).

More studies are required to understand which VOCs induce plant defenses via which mechanism. However, our results point to a new mechanism. Changes in transmembrane potentials—occurring through modulations of ion fluxes—are involved in early signaling events in the cellular response to stress (Maffei et al. 2007), and exposition to VOCs indeed changes membrane potentials in intact lima bean leaves (M. Maffei, personal communication). It is thus tempting to speculate that the dissolving of VOCs in the membranes coupled to interactions with membrane proteins, similar to the odorant binding proteins of insects (Campanacci et al. 2001), leads to changes in transmembrane potentials and thereby induces gene activity. This hypothesis gains support from the observation that the induction of EFN secretion by VOCs appears to be a gradual one rather than a clear 'yes-or-know' response. Several of the compounds that are released naturally from lima bean showed a trend towards an increase in EFN secretion, although the difference was not significant: EFN secretion in response to Linalool was on average higher by 40% than in control plants, and DMNT ((3*E*)-4,8-dimethylnona-1,3,7-triene) increased EFN secretion by 50% (see Table 1 in Kost and Heil 2006). Similarly, plants exposed to ethylhexanol or (*E*)-2-hexanal in the present study showed a trend towards higher EFN secretions than controls (Fig. 1). EFN responds to a comparably wide variety of structures, and slight changes in the molecular structure gradually alter the induction effect. This observation is best explained by a comparably simple physicochemical process, whose detailed nature remains to be elucidated.

How can signals evolve that apparently lack chemical specificity? The answer might be simply that plants seldom are exposed to GLVs or chemically related compounds that are not released from attacked plants. In evolutionary terms, the probability of this situation was probably too low to cause any selection towards a more specific signal perception.

Acknowledgments We thank Ralf Krüger, Susann Schiwy, and Juan Carlos Silva Bueno for help with the experiments and plant cultivation. Financial support by the DFG (grant He3169/4–2), CONACYT (Consejo National de Ciencias y Tecnologia) and the Max-Planck-Gesellschaft is gratefully acknowledged.

Olfactory Responses of the Predatory Mites (*Neoseiulus cucumeris*) and Insects (*Orius strigicollis*) to Two Different Plant Species Infested with Onion Thrips (*Thrips tabaci)*

Satoshi Tatemoto · Takeshi Shimoda

Received: 17 October 2007 / Revised: 2 February 2008 / Accepted: 20 March 2008 / Published online: 15 April 2008

Abstract Responses of *Neoseiulus cucumeris* (a predatory mite) and the predatory insect *Orius strigicollis* to volatiles associated with two different plant species infested with onion thrips, *Thrips tabaci*, were examined in a Y-tube olfactometer. Both predators species showed a significant preference for volatiles from infested cucumber leaves without *T. tabaci* over clean air. However, they were not attracted to volatiles from uninfested cucumber leaves, artificially damaged cucumber leaves, or volatiles from *T. tabaci* plus their visible products collected from cucumber leaves. These results suggest that both predator species are capable of exploiting herbivore-induced volatiles from *T. tabaci*-infested cucumber leaves as a foraging cue. Neither predator was attracted to volatiles from uninfested spring onion leaves, infested spring onion leaves without *T. tabaci*, or volatiles from *T. tabaci* plus their visible products collected from spring onion leaves. Interestingly, they avoided volatiles from artificially damaged spring onion leaves. A possible explanation for the non-significant olfactory responses of the predator species to spring onion plants with infestation damage of *T. tabaci* is discussed.

Introduction

Attraction of carnivorous arthropods to herbivore-induced volatiles from favored combinations of plants and prey herbivores has been well documented in many tritrophic interactions (Takabayashi and Dicke 1996; Dicke et al. 1998; Dicke 1999a, b; Shiojiri et al. 2002). Such phenomena have received attention from the viewpoints of carnivore foraging or plant indirect defense against herbivorous arthropods. However, the olfactory responses of carnivorous arthropods to less favored plant–prey combinations have been less well documented (Takabayashi et al. 2000). What carnivore response is elicited by herbivore-induced volatiles from less favored plant species with infestation damage by a favored herbivore species remains an intriguing question. The answer should give us a better understanding of carnivore foraging decisions in response to herbivore-induced volatiles when the target prey is a polyphagous insect that can exploit a wide range of plant species.

Onion thrips (*Thrips tabaci)* are highly polyphagous and a major pest of vegetable crops (Kendall and Bjostad 1987; Edelson et al. 1989; Doederlein and Sites 1993; Shelton et al. 1998), fruits (Tsuchiya 2001, 2002), and flowers (Childers 1997) in many parts of the world. This pest is characterized as the only vector of the tospovirus, Iris Yellow Spot Virus, which causes symptoms that include straw-colored spindle-shaped lesions on host plant leaves

(Kritzman et al. 2001; Doi et al. 2003). Of the various biological control agents potentially applicable to *T. tabaci*, the generalist predatory mite *Neoseiulus cucumeris* is widely available in many countries from commercial sources (Hoy and Glenister 1991; Brødsgaard and Hansen 1992; Williams 2001; Shipp and Wang 2003). The generalist predatory bug *Orius strigicollis* is also an important natural enemy in Japan (Yasunaga 1997; Hinomoto et al. 2004) and in Taiwan (Wang et al. 2001).

The efficacy of biological control of *T. tabaci* by employing these generalist predators is influenced by plant species. For example, *N. cucumeris* is a good candidate for biological control of cucumber pests (Gillespie 1989; Brødsgaard and Hansen 1992). This also seems to be true for *O. strigicollis* since the species is commonly found on crops belonging to the Cucurbitaceae, as well as on members of the Leguminosae and Solanaceae (Yasunaga 1997; Wang et al. 2001). In contrast, attempts to use biological controls for spring onion and other *Allium* plants that use either of these predator species have largely failed (Tatemoto, unpublished data; Okazaki, personal communication). Thus, a *T. tabaci*-infested cucumber plant is a plant–prey combination favored by *N. cucumeris* and *O. strigicollis*, whereas a *T. tabaci*-infested spring onion plant is a less favored combination for predators. This relationship might be associated with the increased production of sulfur compounds by spring onion in response to physical damage, including herbivory, since these compounds have possible toxic and/or repellent effects on many insects (Dugravot et al. 2004, 2005).

The main purpose of this research was to study whether each of the two predator species shows different olfactory responses to two different plant species, i.e., cucumber and spring onion plants, infested with *T. tabaci*. Although each predator was attracted to volatiles from *T. tabaci*-infested cucumber plants, they were not attracted to volatiles from spring onion plants infested with *T. tabaci*. We give a possible explanation for the different olfactory responses to different plant–prey combinations.

Materials and Methods

Plants Cucumber (*Cucumis sativus* cv. Sharp 1) and spring onion (*Allium fistulosum* cv. Koutou) were cultivated individually in plastic pots (12-cm diam., 10-cm deep) in a climate-controlled plant growth chamber (25±2 °C and L16/D8 at approx 8,000 lux). First to third fully open leaves of 24- to 37-day-old cucumber plants were used for the experiments. Additionally, 29- to 41-day-old spring onion plants with the roots attached were used for the experiments.

Mites and insects T. tabaci were collected from spring onion plants at Higashi-Hiroshima, Hiroshima Prefecture, Japan in 2004. They had been reared on spring onion plants in a climate-controlled chamber (25±2°C and L16/D8). *N. cucumeris* were obtained from a commercial source (Ishihara Sangyo Corp., Osaka, Japan) in 2004. Insects were reared on the stored food mites *Tyrophagus putrescentiae* in wheat bran in a climate-controlled room (25±2°C and L16/D8) for more than 1 year. To obtain starved predators, adult females of *N. cucumeris* were introduced into a sealed glass tube (38 ml), containing a piece of moist filter paper and maintained at 25±2°C and L16/D8 for 20–24 h prior to the experiments. *O. strigicollis* was obtained from a commercial source (Arysta Life Science Corp., Tokyo, Japan) in 2005 and 2006. Insects were reared in a climate-controlled room (25±2°C and L16/D8) for 2–7 days on *Ephestia kuehniella* eggs and *Kalanchoe blossfeldiana* leaves as food and oviposition materials, respectively. Other conditions and procedures for obtaining starved predators were the same as those for *N. cucumeris*. Neither predator species had experienced the volatiles from cucumber, spring onion, or those from *T. tabaci* during mass rearing to assess their innate olfactory responses to the volatiles.

Olfactometer experiments All experiments were conducted in Y-tube olfactometers (Takabayashi and Dicke 1992) with 10-cm arm length, 12-cm stem length, and 4-cm i.d. The air was first cleaned by passing it through granular activated charcoal (1 l) in a glass bottle before sending it to the sample and control odor source bottles (1 l). Air (ca. 4 l/min) containing each odor was sent to either of the arms of the olfactometer. At the commencement of each bioassay, a predator was placed on the start point of a steel Y-shaped wire that was fixed at the center of the Y-tube. We regarded the observation as complete when the predator reached one end of the wire arm. Predators that did not pass the finish line of either arm within 5 min (termed "no choice" subjects) were excluded from the statistical analysis detailed below. Following every five bioassays, the arm containing the sample odor source was switched with that containing the control odor source. In each experiment, 60–70 predators were tested for more than 3 days.

Responses of predators to volatiles associated with cucumber plants We investigated the behavioral responses of *N. cucumeris* and *O. strigicollis* to the four different types of sample odor sources associated with cucumber plants discussed below.

Experiment 1 Uninfested cucumber leaves vs. clean air. Detached cucumber leaves (three to five) with the petioles attached (ca. 4 g in total) were placed onto a moist filter paper (Advantec No. 2, 9-cm diam.) within a plastic container (15×10 cm, 5-cm deep).

Leaves were kept for 20–24 h in a laboratory (25±2°C and L16/D8). Both leaves and the moist filter paper were used as the odor source. A moist filter paper was prepared as the control odor source.

Experiment 2 Infested cucumber leaves without *T. tabaci* vs. clean air. Detached cucumber leaves (three to five) with petioles attached (ca. 4 g in total) were infested with approximately 100 *T. tabaci* individuals (ca. 20–34 individuals per leaf) at the adult and larval stages (approx. 50 of these were second-instar larvae) for 20–24 h. *T. tabaci* and their visible products were removed from the infested leaves with a fine paintbrush just before the bioassays. Leaves were washed with dH$_2$O and were carefully dried with paper wipes (Kimwipe S-200). These infested leaves plus a moist filter paper were used as the sample odor source. A moist filter paper was prepared as the control odor source. Other conditions and procedures were the same as in Experiment 1.

Experiment 3 *T. tabaci* and their products from cucumber leaves vs. clean air. About 100 living *T. tabaci* individuals at the adult and larval stages (approx. 50 of these were second-instars) and their visible products were carefully removed with a fine paintbrush from *T. tabaci*-infested cucumber leaves just before the bioassays. The thrips and their products collected on a moist filter paper were used as the sample odor source. A moist filter paper was prepared as the control. Other conditions and procedures were the same as in Experiment 1.

Experiment 4 Artificially damaged cucumber leaves vs. clean air. Just before the bioassays, the detached cucumber leaves (three to five) with the petioles attached (ca. 4 g in total) were rubbed with fine sandpaper (No. AA240, Sankyo Rikagaku Corp., Saitama, Japan). The mechanically damaged leaves plus a moist filter paper were used as the sample odor source. The moistened filter paper was prepared as the control odor source. Other conditions and procedures were the same as in Experiment 1.

Responses of predators to volatiles associated with spring onion The behavioral responses of *N. cucumeris* and *O. strigicollis* to the four different types of sample odor sources associated with spring onion plants were investigated. In our preliminarily investigation, a strong sulfurous smell was noticed within several hours of detaching the roots from spring onion plants, which seemed to generate undesirable data in the experiments detailed below. Thus, to minimize physical damage, we used whole spring onion plants with the roots attached.

Experiment 5 Uninfested spring onion plants vs. clean air. Eight to 14 whole spring onion plants (approx. 15 cm in height, ca. 4 g in total), with the roots attached, were maintained for 20–24 h before the experiments. The plants plus a moist filter paper were used as the odor source. A moist filter paper was prepared as the control. Other conditions and procedures were the same as in Experiment 1.

Experiment 6 Infested spring onion plants without *T. tabaci* vs. clean air. Eight to 14 whole spring onion plants with the roots attached (ca. 4 g in total) were infested with a total of approximately 100 *T. tabaci* individuals (seven to 13 individuals per plant) in the adult and larval stages (approx. 50 of these were second-instars) for 20–24 h. *T.* tabaci and their visible products were removed from the infested leaves with a fine paintbrush just before bioassay. Infested plants and a moist filter paper were used as the sample odor source. Moistened filter paper was prepared as the control odor source. Other conditions and procedures were the same as in Experiments 2 and 5.

Experiment 7 *T. tabaci* and their products from spring onion plants vs. clean air. Immediately preceding bioassay, approximately 100 *T. tabaci* consisting of about a 50:50 mixture of adult and larval stages and their products) were removed from infested spring onion plants with a fine paint brush. The thrips and their visible products collected on a moist filter paper were used as the sample odor source. A moistened filter paper was prepared as the control odor source. Other conditions and procedures were the same as in Experiments 3 and 5.

Experiment 8 Artificially damaged spring onion plants vs. clean air. Eight to 14 whole spring onion plants except for the attached roots (ca. 4 g in total) were rubbed with fine sandpaper just before the bioassays. These mechanically damaged plants plus a moist filter paper were used as the sample odor source.

A moistened filter paper was prepared as the control. Other conditions and procedures were the same as in Experiments 4 and 5.

Chemical analysis of volatiles Each sample odor source used in Experiments 1–8 were placed into lidded glass bottles (2 l). Before collection of volatiles, a steady flow (200 ml/min) of clean air, purified by passing it through silica gel, molecular sieves, and activated charcoal (1 l each), was circulated through each glass bottle for 10 min. Headspace volatiles from each odor source were collected by using a Tenax TA Thermal Desorption Tube (180 mg, 60/80 mesh; Gerstel), connecting each lidded glass bottle (30 min) by sending clean air (100 ml/min checked by using a flow meter). Collected volatiles in each sample were analyzed by using a gas chromatography–mass spectrometry (GC–MS) system (GC: Agilent Technologies 6890 with an HP-5MS capillary column: 30-m long, 0.25-mm i.d., and 0.25-μm-file thick; injection temperature: 250°C; MS: Agilent Technologies 5973N mass selective detector, 70 eV) with Thermodesorption Autosampler System and Cold Injection System (TDS A 2 and CIS 4: Gerstel). The oven temperature of the GC–MS was programmed to rise from 40°C (9-min hold) to 280°C at 10°C/min. The TDS A 2 and CIS 4 temperatures were programmed to rise from 20°C (1-min hold) to 280°C at 60°C/min and from −150°C (0.5-min hold) to 300°C at 12°C/min, respectively. The observed compounds were tentatively identified by comparing their mass spectra and retention times with those of mass spectra in the database (Wiley Library) along with our authentic data regarding volatile compounds from herbivore-infested plants or physically damaged plants in our laboratory (e.g., Ozawa et al. 2000; Shimoda et al. 2005). However, (*Z*)-3-hexen-1-ol, (*Z*)-3-hexenyl acetate, (*E*)-2-hexenal, linalool, methyl salicylate, methyl propyl disulfide and dipropyl disulfide were double-checked and positively identified by using synthetic samples of purity ranging from 97% to 99% (Wako Pure Chemical Industries).

Statistical analysis The results from each olfactometer experiment were subjected to a χ^2 test (Sokal and Rohlf 1995). The null hypothesis was that predators exhibited a 50:50 distribution over the two odor sources. The Kruskal–Wallis test followed by the Mann–Whitney *U* test, weighted by the Bonferroni correction, were used to compare the results of the chemical analysis. Each analysis was performed with JMP (version 5.0.1J for Windows, SAS Institute Inc., Cary, NC, USA) or StatView (version 5.0J for Windows, SAS Institute Inc., Cary, NC, USA).

Results

Olfactometer experiments When presented with a choice between uninfested cucumber leaves and clean air, neither predator species discriminated between the odor sources (Experiment 1; *N. cucumeris*: χ^2=0.021, *df*=1 and *P*=0.884;

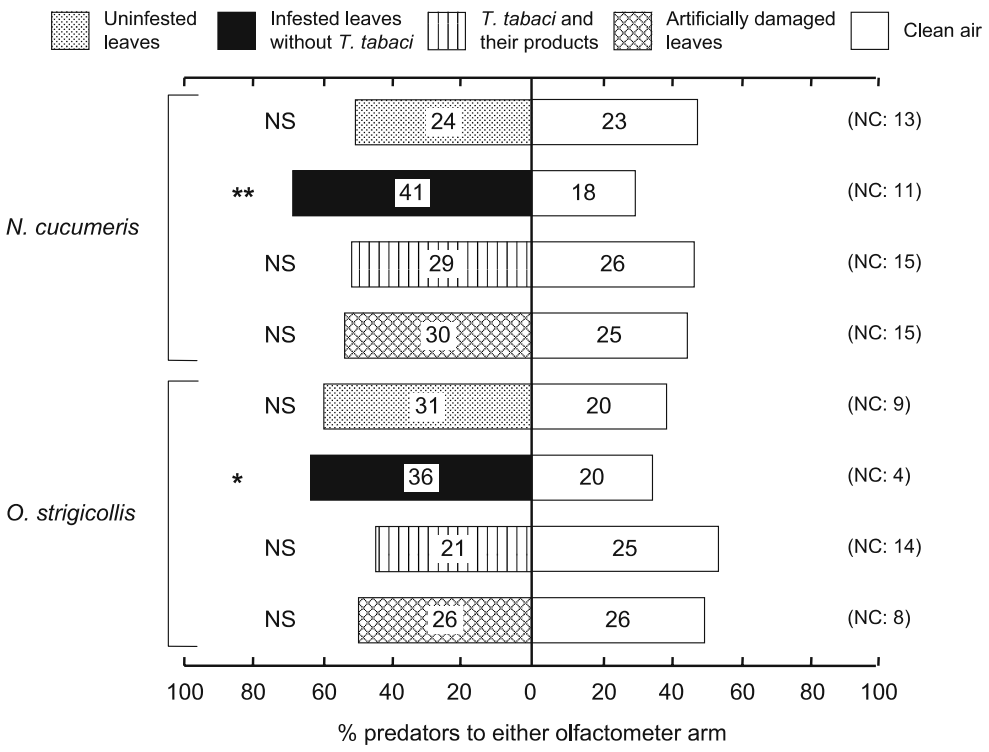

Fig. 1 Responses of *N. cucumeris* and *O. strigicollis* when offered (Experiment 1) uninfested cucumber leaves vs. clean air; (Experiment 2) infested cucumber leaves without *T. tabaci* vs. clean air, (Experiment 3) *T. tabaci* and their products from cucumber leaves vs. clean air, and (Experiment 4) artificially damaged cucumber leaves vs. clean air. The χ^2 test was used to evaluate whether the results differed from a 50:50 distribution between the two olfactometer arms (*single asterisk P*< 0.05, *double asterisk P*<0.01, *NS P*>0.05). Predators that did not reach the end of either olfactometer arm within 5 min (no choice: *NC*) were excluded from the statistical analysis. For further explanation, see the text

O. strigicollis: χ^2=2.373, *df*=1 and *P*=0.123; Fig. 1). The predators showed no significant preference for volatiles from *T. tabaci* and their products from cucumber leaves (Experiment 3; *N. cucumeris*: χ^2=0.164, *df*=1 and *P*=0.686; *O. strigicollis*: χ^2=0.348, *df*=1 and *P*=0.555) or volatiles from artificially damaged cucumber leaves (Experiment 4; *N. cucumeris*: χ^2=0.455, *df*=1 and *P*=0.5; *O. strigicollis*: χ^2=0, *df*=1 and *P*=1) over clean air. In contrast, each predator species showed an olfactory preference for infested cucumber leaves without *T. tabaci* (Experiment 2; *N. cucumeris*: χ^2=8.966, *df*=1 and *P*<0.01; *O. strigicollis*: χ^2=4.571, *df*=1 and *P*<0.05).

When presented with a choice between uninfested spring onion plants and clean air, neither predator species discriminated between these odor sources (Experiment 5; *N. cucumeris*: χ^2=0.021, *df*=1 and *P*=0.884; *O. strigicollis*: χ^2=0.077, *df*=1 and *P*=0.782; Fig. 2). The same tendency was observed in each predator species when *T. tabaci* plus visible products vs. clean air was compared (Experiment 7; *N. cucumeris*: χ^2=0.424, *df*=1 and *P*=0.515; *O. strigicollis*: χ^2=0.296, *df*=1 and *P*=0.586). Neither of the two predator species showed a significant preference for volatiles from infested spring onion plants without *T. tabaci* (Experiment 6; *N. cucumeris*: χ^2=0.276, *df*=1 and *P*=0.599; *O. strigicollis*: χ^2=0.296, *df*=1 and *P*=0.586). When artificially damaged spring onion plants were offered vs. clean air, more predators chose the latter odor source (Experiment 8; *N. cucumeris*: χ^2=16.490, *df*=1 and *P*<0.001; *O. strigicollis*: χ^2=8.963, *df*=1 and *P*<0.01).

Chemical analysis of volatiles Uninfested cucumber leaves emitted trace amounts of two green leaf volatiles (*Z*)-3-hexen-1-ol and (*Z*)-3-hexenyl acetate (Table 1). Artificially damaged cucumber leaves emitted a small amount of (*E*)-2-hexenal in addition to these two compounds. Infested cucumber leaves without *T. tabaci* emitted small amounts of (*E*)-β-ocimene, (*E*)-4,8-dimethyl-1,3,7-nonatriene, linalool, and methyl salicylate in addition to the three green leaf volatiles. There was a significant difference among the three odor sources as to the amounts of (*Z*)-3-hexen-1-ol and (*Z*)-3-hexenyl acetate.

Uninfested spring onion plants emitted small amounts of methyl propyl disulfide, dipropyl disulfide, and two unidentified volatile sulfur compounds (Table 2). Trace amounts of (*E*)-β-ocimene and linalool also were found in the headspace of the odor source due to slight infestation damage by *T. tabaci* accidentally occurring in the plant growth chamber before collection of volatiles. Artificially damaged spring onion plants also emitted these sulfur volatile compounds and herbivore-induced volatile compounds in addition to an unidentified sulfur compound. Infested spring onion plants without *T. tabaci* emitted a small amount of methyl salicylate in addition to the seven volatile compounds found in the headspace of artificially damaged spring onion plants. Artificially damaged spring onion plants emitted a significantly greater amount of dipropyl disulfide than the uninfested spring onion plants. Infested spring onion plants without *T. tabaci* were intermediate between these odor sources in the amount of this compound.

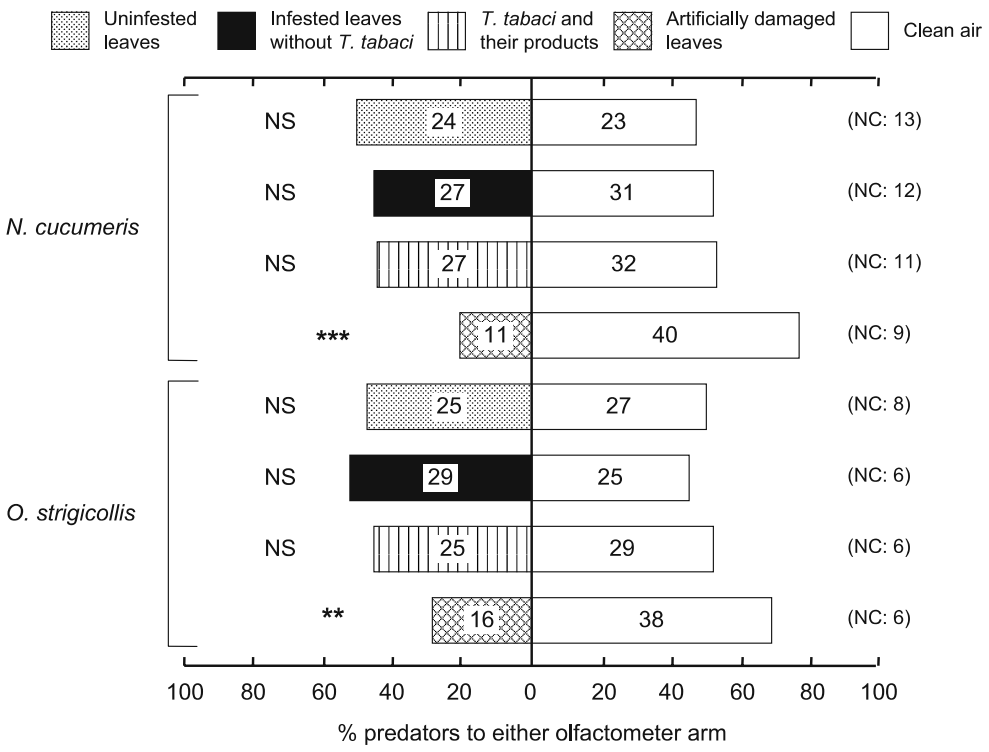

Fig. 2 Responses of *N. cucumeris* and *O. strigicollis* when offered (Experiment 5) uninfested spring onion plants vs. clean air, (Experiment 6) infested spring onion plants without *T. tabaci* vs. clean air, (Experiment 7) *T. tabaci* and their products from spring onion plants vs. clean air, and (Experiment 8) artificially damaged spring onion plants vs. clean air. The χ^2 test was used to evaluate whether the results differed from a 50:50 distribution between the two olfactometer arms (*double asterisk P*<0.01, *triple asterisk P*<0.001, *NS*:*P*>0.05). Predators that did not reach the end of either olfactometer arm within 5 min (no choice: *NC*) were excluded from the statistical analysis. For further explanation, see the text

Table 1 Mean ion intensities (±SE×10^8) of volatile compounds detected in the headspace of cucumber leaves subjected to different treatments

Compound	Uninfested (N=5)	Damaged (N=5)	Infested (N=5)	Statistics (Kruskal–Wallis test or U test)
(*E*)-2-hexenal	ND	0.07±0.03[a]	0.06±0.04[a]	z=−0.111, df=1, P=0.911
(*Z*)-3-hexen-1-ol	0.43±0.39[a]	15.02±6.97[b]	1.65±0.56[a]	H=11.260, df=2, P<0.01
(*Z*)-3-hexenyl acetate	0.10±0.07[a]	5.54±0.18[b]	0.07±0.07[a]	H=10.526, df=2, P<0.01
(*E*)-β-ocimene	ND	ND	0.18±0.02	
(*E*)-4,8-dimethyl-1,3,7-nonatriene	ND	ND	0.07±0.03	
Linalool	ND	ND	0.10±0.07	
Methyl salicylate	ND	ND	0.25±0.08	

Values with a different letter following the same compound are statistically significant (Kruskal–Wallis test followed by U test, weighted by the Bonferroni approach, P<0.01).
Uninfested Uninfested cucumber leaves, *Damaged* artificially damaged leaves, *Infested* infested cucumber leaves without *Thrips tabaci* or their products, *ND* not detected in the chemical analysis (excluded from statistical analysis)

Compared to infested cucumber leaves without *T. tabaci*, infested spring onion plants without *T. tabaci* emitted similar amounts of herbivore-induced volatile compounds (U test, linalool: z=−0.74, df=1 and P=0.459; methyl salicylate: z=−0.313, df=1 and P=0.754; (*E*)-β-ocimene: z=−0.731, df=1 and P=0.465); although the latter odor source did not produce (*E*)-4,8-dimethyl-1,3,7-nonatriene (see Tables 1 and 2).

Discussion

N. cucumeris and *O. strigicollis* showed similar responses to volatiles associated with cucumber plants. Both predators were attracted to volatiles from infested cucumber leaves without *T. tabaci*, although they had not previously experienced the volatiles. Neither insect was attracted to the volatiles from uninfested cucumber leaves, artificially damaged cucumber leaves, or *T. tabaci* plus their visible products collected from infested cucumber leaves. These results suggest that *N. cucumeris* and *O. strigicollis* may have the ability to exploit herbivore-induced volatiles from *T. tabaci*-infested cucumber leaves as a foraging cue. Olfactory attraction evoked by volatile infochemicals from herbivore-infested plants has been reported in the tritrophic interaction among *N. cucumeris*, the western flower thrip *Frankliniella occidentalis*, and cucumber plants (Janssen et al. 1998), and among *N. cucumeris*, the rust mite *Aceria tulipae*, and tulip bulbs (Aratchige et al. 2004). There are no reports of studies of the olfactory response of *O. strigicollis* to herbivore-infested plants. However, olfactory attraction to herbivore-infested plants has been reported in closely related predatory bug species such as *Orius laevigatus* (Venzon et al. 1999; Bennison et al. 2002), *Orius tristicolor* (James and Price 2004), *Anthocoris nemoralis* (Scutareane et al. 1996), and *Anthocoris nemorum* (Drukker et al. 1995).

There were only four herbivore-induced volatile compounds detected in the volatile blend of infested cucumber leaves without *T. tabaci* among the odor sources used in Experiments 1–4 (linalool, methyl salicylate, (*E*)-β-ocimene, and (*E*)-4,8-dimethyl-1,3,7-nonatriene). At least one of these volatiles probably was involved in attracting each predator

Table 2 Mean ion intensities (±SE×10^8) of volatile compounds detected in the headspace of spring onion plants subjected to different treatments

Compound	Uninfested (N=5)	Damaged (N=5)	Infested (N=5)	Statistics (Kruskal–Wallis test or U test)
(*E*)-β-ocimene	0.03±0.03[a]	0.07±0.05[a]	0.29±0.2[a]	H=2.759, df=2, P=0.252
Linalool	0.04±0.04[a]	0.16±0.1[a]	0.09±0.03[a]	H=1.689, df=2, P=0.43

Values with a different letter following the same compound are statistically significant (Kruskal–Wallis test followed by U test, weighted by the Bonferroni approach, P<0.01).
Uninfested Uninfested spring onion plants, *Damaged* artificially damaged spring onion plants, *Infested* infested spring onion plants without *Thrips tabaci* or their products, *Unidentified 1*, *2*, and *3* unidentified sulfur components (retention time: 9.09, 12.61, and 16.68 min respectively), *ND* not detected in the chemical analysis (excluded from statistical analysis)

species to infested cucumber leaves without *T. tabaci*. Each of these four compounds contributes to attraction of the predatory mite *Phytoseiulus persimilis* to lima bean plants infested with the two-spotted spider mite *Tetranychus urticae* (Dicke et al. 1990a; de Boer et al. 2004). Linalool and methyl salicylate are also involved in attracting the predatory mite *Neoseiulus californicus* to *T. urticae*-infested lima bean plants (Shimoda et al. 2005). Further, methyl salicylate plays a key role in attracting the anthocorid predatory bug *A. nemoralis* to psyllid-infested pear leaves (Drukker et al. 2000b). In contrast, behavioral and chemical analyses suggest that (*Z*)-3-hexen-1-ol, (*Z*)-3-hexenyl acetate, and (*E*)-2-hexenal (green leaf volatiles) emitted from infested cucumber leaves without *T. tabaci* do not play a role in the attraction of predator species to the odor source.

In *Allium* species, physical damage, including herbivory, leads to increased release of volatile sulfur compounds that can act as repellents against many insects (Auger et al. 1989; Dugravot and Thibout 2006). In the current study, volatiles from artificially damaged spring onion plants were avoided by both predator species, while those from uninfested spring onion plants did not affect their behavior. A significantly greater amount of dipropyl disulfide was a principal sulfur component in the headspace of the former odor source but less significant in the latter odor source. Thus, we consider dipropyl disulfide is a prime candidate for the predator repellent. There were at least four other sulfur compounds in the headspace of artificially damaged spring onion plants. Further studies are needed to identify the key compound(s).

Neither predator species responded positively to infested spring onion plants without *T. tabaci*. One likely explanation is that the volatiles might include both predator attractants and repellents. (*E*)-β-ocimene, linalool, and methyl salicylate were emitted from the odor source; similar amounts of the same compounds also were produced by infested cucumber plants without *T. tabaci*. Methyl salicylate was not emitted from either uninfested or artificially damaged spring onion plants. These results suggest that at least one of the three herbivore-induced volatile compounds, especially methyl salicylate, from infested spring onion plants without *T. tabaci* might be attractive to the predator species. However, this attraction might be offset by the function of dipropyl disulfide as a predator repellent because similar amounts of this compound were emitted from infested spring onion plants without *T. tabaci*, as well as from artificially damaged spring onion plants (Table 2). The attraction of carnivorous arthropods to herbivore-induced volatiles can be interfered with other volatile infochemicals from plants, herbivores, and/or their products. For example, volatiles from rosemary leaves can inhibit attraction of *O. laevigatus* to herbivore-induced volatiles from chrysanthemum buds infested with *F. occidentalis* (Bennison et al. 2002). Whether or not the predatory mite *P. persimilis* prefers or avoids volatiles from lima bean leaves infested with *Spodoptera exigua* caterpillars can be affected by the relative contribution of herbivore-induced volatiles (attractive volatiles) and fecal volatiles (repellent volatiles) in the total blend from the odor source (Shimoda and Dicke 1999).

The success of biological control against *T. tabaci* indicates that *T. tabaci*-infested cucumber is a favored plant–prey combination for *N. cucumeris* and *O. strigicollis* (Gillespie 1989; Brødsgaard and Hansen 1992). In contrast, the repeated failure of the biological control suggests that *T. tabaci*-infested spring onion may be less favored by the predators (Tatemoto unpublished data; Okazaki, personal communication). Although these two odor sources were not simultaneously compared in this study, we can infer that each generalist predator has the potential to discriminate, by olfactory means, a favored plant–prey combination from a less favored one. No positive response to spring onion plants with infestation damage by *T. tabaci* would appear to be reasonable for their successful foraging because their survival, development, and/or oviposition are presumably affected by sulfur compounds from the less favored plants, as reported in other insects adapted to *Allium* species (Venugopal and Narayanan 1981; Auger et al. 1989; Dugravot et al. 2004; Dugravot and Thibout 2006). Although the olfactory responses of several predatory mites or parasitoid wasps can be affected by their previous experience of herbivore-infested plants (Dicke et al. 1990b; Turlings et al. 1993; Vet et al. 1993; Drukker et al. 2000a; De Boer et al. 2005; Maeda et al. 2006), it is debatable whether unfavorable experience with *T. tabaci*-infested spring onion increases the olfactory response of each investigated predator species to the odor source. Further study is needed to answer the question, as well as to show their different performances on the two plant–prey combinations investigated in this study.

Our data associated with cucumber plants support previous studies that show that herbivore-induced volatiles play a role in indirect plant defenses against herbivorous arthropods, i.e., recruiting carnivorous natural enemies as bodyguards (Karban and Baldwin 1997; Dicke et al. 2003; Choh et al. 2004), as well as in predators' foraging decisions. However, this indirect defense via herbivore-induced volatiles was not seemingly observed in spring onion plants, which might be associated with their direct defense. Sulfur compounds produced by spring onions, as well as other *Allium* plants, may prevent herbivory by many generalist herbivore insects (Auger et al. 1989; Hori and Harada 1995; Dugravot and Thibout 2006). Because *T. tabaci* can easily exploit spring onions, it would appear to be important for the plant to provide an efficient indirect defense to cope with herbivores. However, our results

suggest that defensive sulfur volatiles in spring onion may inhibit the activities of generalist carnivore insects as biological agents against *T. tabaci*. This opens the interesting question of whether there is an efficient indirect defense (e.g., by the aid of specialized predators or parasitoids) against *T. tabaci* in spring onion plants. This remains to be investigated.

Acknowledgments We thank Junji Takabayashi, Rika Ozawa, and Hiromichi Nitta for their constructive comments during the study. We also express gratitude to Kouichi Yamaguchi for providing us with the predatory mites. This study was supported by a Grant-in-Aid for Scientific Research (No. 19380188) of the Japan Society for the Promotion of Science.

Attraction to Herbivore-induced Plant Volatiles by the Host-foraging Parasitoid Fly *Exorista japonica*

Ryoko T. Ichiki · Yooichi Kainoh · Soichi Kugimiya · Junji Takabayashi · Satoshi Nakamura

Received: 14 November 2007 / Revised: 25 February 2008 / Accepted: 5 March 2008 / Published online: 9 April 2008

Abstract Responses of the tachinid fly *Exorista japonica* Townsend to odors from corn plants infested with the fly's host, the larvae of the noctuid moth *Mythimna separata* (Walker), were examined in a wind tunnel. Naïve female flies showed a higher rate of landing on *M. separata*-infested corn plants from which the host larvae had been removed than on artificially damaged or intact corn plants. When paper impregnated with a solution of headspace volatiles collected from host-infested plants was attached to intact plants, females landed on the plants at a high rate. Females also responded to intact plants to which had been attached with paper impregnated with a synthetic blend of nine chemicals identified previously in host-infested plants. There was an optimum concentration of the synthetic blend for the females' landing. Of the nine chemicals identified previously, four [(*E*)-4,8-dimethyl-1,3,7-nonatriene, indole, 3-hydroxy-2-butanone, and 2-methyl-1-propanol] released only by host-infested plants were classified as a host-induced blend. The other five [(*Z*)-3-hexen-1-yl acetate, (*E*)-2-hexenal, hexanal, (*Z*)-3-hexen-1-ol, and linalool] were classified as a non-specific blend released not only by infested plants but also by artificially damaged or intact plants. In the wind tunnel, *E. japonica* females did not respond to intact plants to which paper containing a solution of non-specific blend or host-induced blend was attached. However, they showed a high level of response to a mixture of the non-specific and host-induced blends. These results indicate that naïve *E. japonica* use a combination of non-specific and host-induced blends as an olfactory cue for locating host-infested plants.

Introduction

Olfactory cues play a major role in the host-finding behavior of parasitoids (Vinson 1976; Van Alphen and Vet 1986; Godfray 1994). Particularly, the volatiles produced by plants infested with herbivorous hosts are important cues for host finding by a number of hymenopteran parasitoids (e.g., Turlings et al. 1990; Vet and Dicke 1992; Potting et al. 1995; Takabayashi et al. 1995; Fukushima et al. 2002; Shiojiri et al. 2006) and by several types of dipteran parasitoid (Roth et al. 1982; Roland et al. 1989, 1995; Mondor and Roland 1997; Kainoh et al. 1999; Stireman 2002). These so-called herbivore-induced plant

volatiles (HIPVs), which are released in response to herbivore attacks, are considered to be an indirect plant defense against herbivores (for review see Turlings and Wäckers 2004) because the feeding of the parasitoids that are attracted reduces the damage caused by the herbivores. However, it remains largely unknown which specific chemicals, or chemical blends, in HIPVs actively attract parasitic insects, except in the case of several hymenopteran species such as *Encarsia formosa* Gahan (Birkett et al. 2003) and *Opius dissitus* Muesebeck (Wei and Kang 2006). The chemical attractant of only one of the species of tachinid fly, *Cyzenis albicans* (Fallén), has been identified (Roland et al. 1995).

The tachinid fly *Exorista japonica* Townsend is a gregarious and polyphagous endoparasitoid that attacks a wide range of lepidopteran pests in Japan, including the noctuid moth *Mythimna separata* (Walker), the fall webworm *Hyphantria cunea* Drury, and the gypsy moth *Lymantria dispar* (Linnaeus) (Shima 2006). The female fly lays a macrotype egg directly on the host's cuticle. The hatched larva enters the host's body cavity, develops within the body, and finally kills the host (Nakamura 1994). A previous study showed that *E. japonica* females were attracted to corn plants placed together with the larvae of *M. separata* in a wind tunnel (Kainoh et al. 1999). We hypothesized that the flies use chemical cues from host-infested plants. To test this hypothesis, we investigated the attraction of *E. japonica* to intact, artificially damaged, or *M. separata*-infested corn plants in a wind tunnel. We then examined the flies' attraction to the headspace volatiles of an *M. separata*-infested plant. Previously, we had identified a series of volatile chemicals in headspace samples from *M. separata*-infested corn plants (Takabayashi et al. 1995). We classified these volatiles into two groups: (1) the "host-induced blend" of chemicals released from corn plants infested by the host larvae and (2) the "non-specific blend" of chemicals released not only from plants infested by the hosts but also from artificially damaged or intact plants. Here, we investigated which synthetic blend was responded to by *E. japonica* in a wind tunnel.

Methods and Materials

Insects

Larvae of *M. separata* were obtained from a stock culture and reared on an artificial diet in accordance with the method of Hattori and Atsusawa (1980). The colony of *E. japonica* originated from parasitized final-instar larvae of *H. cunea*, which had been collected at Tsukuba, Ibaraki, Japan (36°2′ N, 140°5′ E) in September and October 2004. This colony was maintained by using final instars of *M. separata* as the hosts. Within 2 days after adult emergence, a female was mated once with a male in a cage (30×28×25 cm) with two windows of nylon mesh. The mated female was transferred to a cylindrical plastic cage (8-cm diameter, 14-cm high) with a sugar cube and water and kept alone until the experiments were begun. Because the active time of oviposition by *E. japonica* is 5–10 days after emergence (Nakamura 1994), females aged 5–10 days were used in the experiments. To eliminate the effects of oviposition experience and learning of odors, naïve females were used. All procedures were conducted at 25°C under a photoperiod of 16:8 h (L/D) and 60% relative humidity (RH).

Plants

Corn plants (*Zea mays* Linnaeus, 'Honey-bantam Peter 619', Sakata Seed Co., Kanagawa, Japan) used for the wind tunnel bioassay were individually grown from seeds in soil in plastic pots (300 ml) in a greenhouse for more than 1 month (27±2°C, 50–70% RH, 16 L:8 h D). Corn plants used for collecting the headspace volatiles of host-infested plants were grown in a field from seeds during the summer for more than 1 month. Seedlings 30- to 40-cm high were used for the experiments.

Collection of Headspace Volatiles

Corn plants were cut at 5-cm high from the ground. To avoid desiccation, the cut ends of the stem were covered with moist cotton wool and then aluminum foil. Corn plants were individually provided with ten final-instar larvae of *M. separata* in the cage in a laboratory. After 5 h, the host larvae had consumed approximately 20% of the total surface area of the leaves. After the larvae and frass had been removed from the plants, headspace volatiles from the infested plants were collected in accordance with methods of the previous studies (Takabayashi et al. 1991, 1995), as follows. One glass tube (4-mm diameter×160-mm long) containing 100 mg Tenax TA (GL Science, Tokyo, Japan) was attached to the inlet, and one to the outlet, of a glass bottle (2 l) in which the five infested corn plants (100 g) were placed. A water aspirator was connected to the glass tube of the outlet and sucked for 1 h to collect the corn headspace volatiles. Volatiles trapped on the Tenax TA in the glass tube attached to the outlet of the glass bottle were extracted with ether (5 ml). Collection of headspace volatiles of infested plants was replicated five times using 25 corn plants (500 g) and 250 hosts in total, and all the extracts were mixed together as a headspace volatile solution (20 g leaves/ml). All sample solutions were kept in a freezer until use for bioassay.

Chemicals

Nine chemicals were used to prepare the synthetic blends (Table 1). The nine had been identified as being released in relatively large amounts from corn plants infested by the final (sixth) instars of *M. separata* (Takabayashi et al. 1995). We used gas chromatography-mass spectrometry (GC-MS) analysis to confirm that the nine chemicals were recorded in the headspace of infested corn plants (data not shown).

(*E*)-4,8-dimethyl-1,3,7-nonatriene, indole, 3-hydroxy-2-butanone, and 2-methyl-1-propanol were found only in corn plants infested by final instars (Takabayashi et al. 1995). We called the blend of these four chemicals the host-induced blend. (*Z*)-3-hexen-1-yl acetate, (*E*)-2-hexenal, hexanal, (*Z*)-3-hexen-1-ol, and linalool were compounds commonly found in infested, artificially damaged, or intact plants at relative amounts of at least 5% (Takabayashi et al. 1995). We called the blend of these five chemicals the non-specific blend. Additionally, we called the blend of all nine chemicals the "mixed blend." These three blends were prepared by dissolving each of the synthetic chemicals in 1 ml of hexane at the amounts (in μg) listed in Table 1. The amounts of each chemical were determined based on their relative percentage amounts detected in the headspace of host-infested plants (Takabayashi et al. 1995).

Linalool has two stereoisomers, (*R*)-(−)-linalool and (*S*)-(+)-linalool. Our enantioselective GC analysis by chiral column (β-DEX 225, 30 m×0.25 mm ID, 0.25-μm film thickness; Supelco, Sigma-Aldrich, St. Louis, MO, USA) of the headspace volatiles from *M. separata*-infested corn plants revealed that the plants released mainly (*S*)-(+)-linalool, with only a marginal amount of (*R*)-(−)-linalool. Because pure (*S*)-(+)-linalool was not available, we used racemic linalool (Tokyo Chemical Industry Co., Ltd., Tokyo, Japan) here. (*E*)-4,8-dimethyl-1,3,7-nonatriene was synthesized by a known reaction (Maurer et al. 1986). The other chemicals were purchased from Wako Pure Chemical Industries, Ltd., Osaka, Japan.

Table 1 Chemical composition and purity of synthetic non-specific, host-induced, and mixed blends

Compounds	Amount (μg)	Purity (%)
Non-specific blend[a]		
Linalool	8.3	95
(*Z*)-3-hexen-1-ol	8.4	97
Hexanal	9.2	95
(*E*)-2-hexenal	16.6	97
(*Z*)-3-hexen-1-yl acetate	19.7	98
Total	62.2	
Host-induced blend[b]		
2-methyl-1-propanol	1.2	99
Indole	3.2	98
(*E*)-4,8-dimethyl-1,3,7-nonatriene	3.4	>95
3-hydroxy-2-butanone	7.4	95
Total	15.2	
Mixed blend[c]		
Total	77.4	

[a] Five chemicals are released not only from *Mythimna separata*-infested corn plants but also from artificially damaged or intact plants (Takabayashi et al. 1995). A total of 62.2 μg was dissolved in 1 ml of hexane

[b] Four chemicals are released only from *M. separata*-infested corn plants (Takabayashi et al. 1995). A total of 15.2 μg was dissolved in 1 ml of hexane

[c] All the nine chemicals were mixed together as a mixed blend. A total of 77.4 μg was dissolved in 1 ml of hexane

Wind Tunnel Bioassay

The flight response of female flies to several target plants was examined in a wind tunnel. The tunnel was 50-cm high×50-cm wide, 1.5-m long, and 5-mm thick. Air was drawn through the tunnel at 30 cm/s, and the light intensity on the tunnel floor was 2,600 lx. A target plant was placed on the upwind side of the tunnel. A mated female fly was introduced to the tunnel on a sugar cube, which was placed on a platform (9-cm diameter, 20-cm high) 1 m downwind from the target. When the female did not take off from the platform within 5 min or did not land on the plant within 5 min after having taken off, we regarded her as not having been attracted to the target plant and replaced her with a new female. The target plant and the odor source were replaced with fresh ones after every two or three females. The following four experiments were conducted in the wind tunnel.

Experiment 1: Response to Infested, Artificially Damaged, or Intact Corn Plants

A corn plant was cut 5 cm above the ground, and the cut end was placed in an Erlenmeyer flask (200 ml) with 150 ml water. The opening of the flask was filled with cotton wool. To make an infested plant sample, the cut corn in the flask was provided with ten final instars of *M. separata*. After 5 h, we removed the larvae and their frass. To make an artificially damaged plant sample, the leaves of the cut corn in the flask were damaged with a hole punch (5 mm diameter) 30 min before the bioassay. We made 30 holes per plant to damage approximately 20% of the total surface area of the leaves. To make an intact plant sample, the cut corn in the flask was kept without hosts for 5 h after cutting. The flight responses of the female flies to the 3 target plants were assayed on five separate days using a total of 75 females.

Experiment 2: Response to Headspace Volatiles of Infested Corn Plants

The headspace volatile solution (20 g leaves/ml) was diluted to concentrations of 10^{-1} and 10^{-2} with ether. Each diluted solution (100 μl) was separately absorbed onto green drawing paper (2×10 cm). After solvent evaporation (30 s), the paper was fixed to the intact plant with a clip. As a control, 100 μl of ether was similarly tested. The flight responses of females to three doses (0.02, 0.2, and 2 g leaves) of the headspace volatiles and the control were assayed on six separate days using a total of 104 females.

Experiment 3: Response to Synthetic Mixed Blends at Different Doses

To examine whether the parasitoid could detect synthetic volatiles and to determine the optimum dose, we assayed the responses of *E. japonica* to the mixed blend. The original mixed blend solution (7.7×10^{-2} μg/μl) was diluted to concentrations of 10^{-1} and 10^{-2} with hexane. Each diluted solution (100 μl) was absorbed separately onto the green paper and tested in the same way. As a control, 100 μl of hexane was similarly tested. The flight responses of females to three doses of the mixed blends (7.7×10^{-2}, 7.7×10^{-1}, and 7.7 μg) and a control were examined on seven separate days using a total of 100 females. GC-MS analysis showed that a synthetic blend dose of 7.7×10^{-1} μg gave an ion intensity roughly identical to that in the headspace volatile from between 2 and 20 g of leaves.

Experiment 4: Response to Synthetic Host-induced and Non-specific Blends

The host-induced and non-specific blends were prepared. Each of the two blends was diluted to a concentration (host-induced blend: 1.5×10^{-3} μg/μl; non-specific blend: 6.2×10^{-3} μg/μl) the same as the one determined to be the most attractive as a component of the mixed blend in experiment 3 (Fig. 3). Each diluted solution (100 μl) was absorbed onto the green paper to give a dose of 1.5×10^{-1} or 6.2×10^{-1} μg, respectively. The host-induced and non-specific blends also were combined to make a different mixed blend (3.87×10^{-3} μg/μl); this mixed blend solution (200 μl) was absorbed onto the green paper to give a dose of 7.7×10^{-1} μg. As controls, 100 μl of hexane was used for the host-induced and non-specific blends and 200 μl of hexane for the mixed blend. The landing rates of the females to the three types of synthetic blend and the controls were examined on eight separate days using a total of 150 females.

Statistical Analyses Differences in the rates at which flies landed on the three types of test plant, the plants with papers containing headspace volatiles, and the plants with papers containing the different doses of synthetic mixed blends were subjected to the χ^2 test and then compared by Ryan's multiple-range test for proportions. Landing rates on the plants by flies were also compared among the infested plants, the headspace volatiles, and two types of synthetic mixed blends by using the χ^2 test. Fisher's exact probability test was used to compare the landing rates of flies between the plant treated with the three types of synthetic blend and the controls. We used the software package R, version 2.4.1 (R Development Core Team 2006) to do these statistical analyses.

Results

Experiment 1: Response to Infested, Artificially Damaged, or Intact Corn Plants

A significantly higher proportion of naïve female flies (80.0%) landed on the *M. separata*-infested corn plants than on the intact corn plants (32.0%; Ryan's multiple-range test for proportions after χ^2 test, $P<0.05$; Fig. 1). The females responded in an intermediate way to the artificially damaged plants (56.0%), but this result was not significantly different from that with intact plants ($P>0.05$).

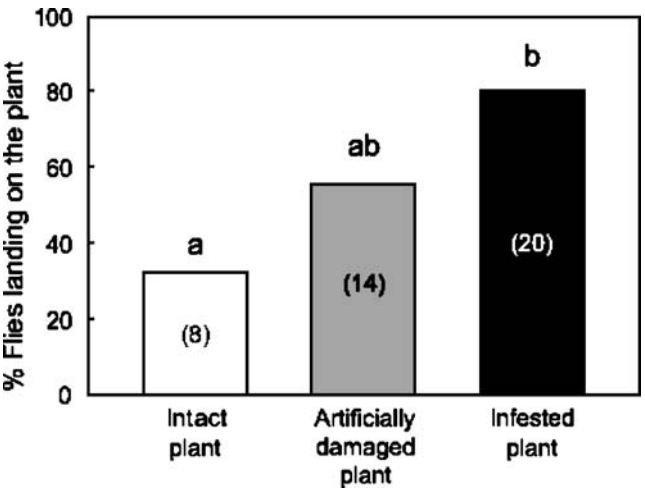

Fig. 1 Flight response of naïve females of *E. japonica* to intact, artificially damaged, and *M. separata*-infested corn plants in the wind tunnel. For each target plant, 25 females were used. *Numbers in bars* indicate the numbers of flies that reached the target plants. *Different letters above bars* indicate significant differences between values (Ryan's multiple-range test for proportions after χ^2 test, $P<0.05$)

Experiment 2: Response to Headspace Volatiles of Infested Corn Plants

When the intact plant was treated with volatile solution prepared from the headspace volatiles of the host-infested plants, more naïve females landed on the treated targets than on the controls (Fig. 2). The responses to the 0.2- and 2-g doses of the volatile solutions (73.1% and 76.9% of females landing on the plant) were significantly greater than that to the control (38.5%; Ryan's multiple-range test for proportions after χ^2 test, $P<0.05$). At the lowest dose of the volatile solution (0.02 g), the response rate declined slightly (69.2%) and was not significantly different from the response to the control ($P>0.05$).

Experiment 3: Response to Synthetic Mixed blends at Different Doses

Naïve females were attracted to the intact plants treated with the synthetic mixed blend solution prepared from the nine chemicals but not to the control plants (Fig. 3). Among the three doses of the blend, the middle dose of 7.7×10^{-1} μg was most attractive (72.0% of females landing on the plant). The response of the females to the middle dose was significantly higher than that to the control (32.0%; Ryan's multiple-range test for proportions after χ^2 test, $P<0.05$). The responses were lower to the other two doses, 7.7×10^{-2} (56.0%) and 7.7 μg (48.0%); these responses were not significantly different from the response to the control ($P>0.05$).

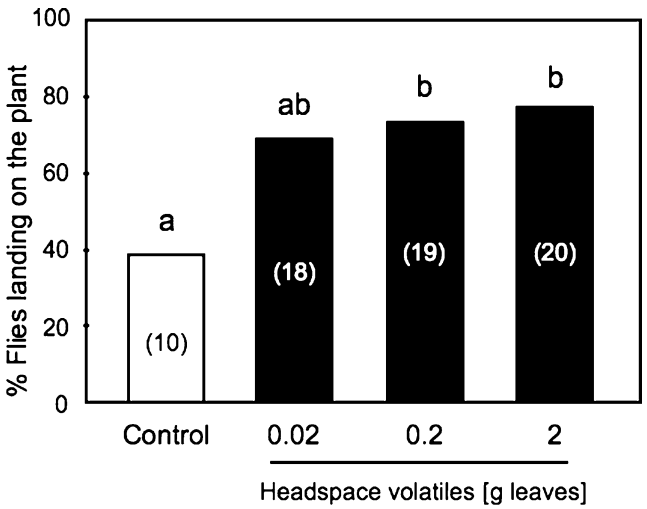

Fig. 2 Flight response of naïve females of *E. japonica* in the wind tunnel to plant volatiles collected from the headspace of *M. separata*-infested corn plants. For each odor source, 26 females were used. *Numbers in bars* indicate the numbers of flies that reached the target plants. *Different letters above bars* indicate significant differences between values (Ryan's multiple-range test for proportions after χ^2 test, $P<0.05$)

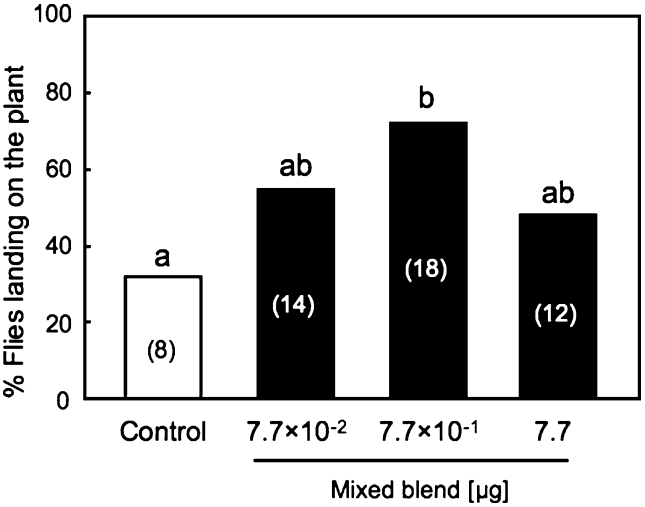

Fig. 3 Flight response of naïve females of *E. japonica* to mixed blend of nine chemicals from *M. separata*-infested corn plants in the wind tunnel. For each odor source, 25 females were used. *Numbers in bars* indicate the numbers of flies that reached the target plants. *Different letters above bars* indicate significant differences between values (Ryan's multiple-range test for proportions after χ^2 test, $P<0.05$)

Experiment 4: Response to Synthetic Host-induced and Non-specific Blends

When the intact plant was treated with the synthetic non-specific blend, naïve females showed a low landing rate (40.0%; Fig. 4). The landing rate in response to the non-specific blend was not significantly different from that to the control (20.0%; Fisher's exact probability test, $P=0.217$). The females also did not respond significantly more to intact plants treated with the synthetic host-induced blend (40.0%) than to the control (28.0%; $P=0.551$). In contrast, the females showed a high landing rate (76.0%) in

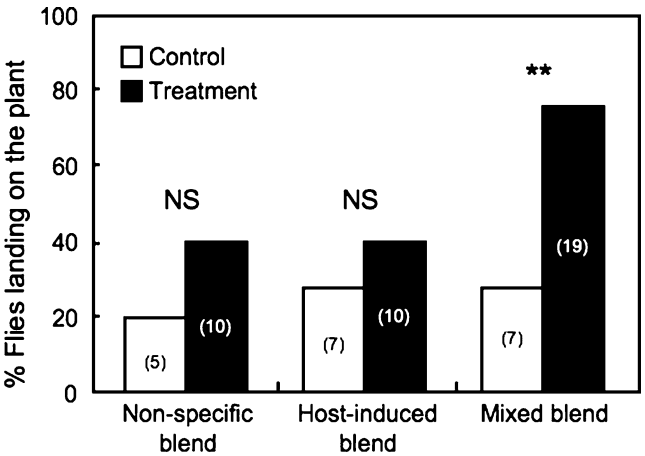

Fig. 4 Flight response of naïve females of *E. japonica* to non-specific blend (1.5×10^{-1} μg), host-induced blend (6.2×10^{-1} μg), and mixed blend (7.7×10^{-1} μg) in the wind tunnel. In each case, 25 females were used. *Numbers in bars* indicate the numbers of flies that reached the target plants. *Asterisks* indicate significant differences between treatment and control (Fisher's exact probability test, $P<0.05$)

response to intact plants treated with the mixed blend that combined the non-specific and host-induced blends. The landing rate in response to the mixed blend was significantly greater than that to the control (28.0%; P=0.002).

Comparison of Responses to Infested Corn Plants, Headspace Volatiles, and Synthetic Mixed Blends We compared the responses of the flies to four odor sources: *M. separata*-infested corn plants (Fig. 1), the most attractive dose of headspace volatiles (2 g; Fig. 2), the most attractive dose of synthetic mixed blend composed of the nine chemicals (7.7×10^{-1} μg; Fig. 3), and the synthetic mixed blend combined with the non-specific and host-induced blends (Fig. 4). The responses were not significantly different from each other (χ^2 test, χ^2=0.45, df=3, P=0.93).

Discussion

Our results demonstrated that the naïve females of *E. japonica* were attracted to volatiles emitted from corn plants infested by *M. separata* larvae. Our previous study (Kainoh et al. 1999) reported that naïve *E. japonica* females had lower responses to infested plants than did oviposition-experienced females: When female flies were tested with *M. separata*-infested corn plants together with the host larvae in a wind tunnel, the rate of landing on the plants within 2 min after takeoff was 33.3% (5 of 15) in naïve females and 70.6% (12 of 17) in females conditioned by oviposition on hosts. However, when naïve females were observed for 5 min after takeoff and tested on infested plants from which the host larvae had recently been removed, the rate of landing on infested plants by naïve females was found to be 80.0% (Fig. 1). Therefore, the observation period used in our previous bioassays may have been too short for us to detect fully the reactivity of naïve females to the infested plants. *E. japonica* females appear to have innate sensitivity to the plant volatiles, but this sensitivity may be still lower in naïve females than in oviposition-experienced females. In hymenopteran parasitoids, the sensitivity of females generally increases with exposure to the host or a host product (e.g., McAuslane et al. 1991; Turlings et al. 1992). To eliminate the effects of oviposition experience and learning of odors, we used naïve females in these experiments.

Naïve females of *E. japonica* responded to intact corn plants attached only with headspace volatiles or only with synthetic volatiles that reflected the infested plants (Figs. 2, 3, and 4); they responded in the absence of other potential host-searching cues such as frass or other host secretions, suggesting that the volatiles alone from the host–plant complex are adequate olfactory cues for this tachinid to locate host-infested plants.

In the Tachinidae, attraction to herbivore-infested plants themselves or to their extracts has been demonstrated in several species (Roth et al. 1982; Roland et al. 1989, 1995; Mondor and Roland 1997; Kainoh et al. 1999; Stireman 2002). However, attraction to a synthetic chemical has been confirmed in only one species of microtype tachinid. *C. albicans* had a high rate of response to borneol among the ten volatile compounds identified from a crude extract of garry oak (*Quercus garryana* Dougl. ex Hook.) foliage, which was known to be attractive to this tachinid fly (Roland et al. 1995). Here, we demonstrated that *E. japonica* was attracted to a mixture of several synthetic chemicals. A mixed blend of nine synthetic chemicals identified from the *M. separata*-infested plants was attractive to naïve females of *E. japonica* (Fig. 3). The middle dose of the mixed blend (7.7×10^{-1} μg) was most attractive among the three doses tested, and the landing rate in response to this dose of the mixed blend did not differ from that in response to the infested plants or the headspace extract, suggesting that this dose was optimal for attracting *E. japonica*. In addition, *E. japonica* responded to neither the non-specific blend nor the host-induced blend but showed a high rate of response to a mixture of the non-specific and host-induced blends at the optimum dose (Fig. 4). These results indicate that a combination of non-specific and host-induced blends is essential for the attraction of *E. japonica*. An example of the reciprocal effects of non-specific and host-induced blends had been reported in the learned response of *Cotesia kariyai* Watanabe to plant volatiles (Fukushima et al. 2002).

E. japonica attacks 49 lepidopteran species in Japan (Shima 2006). Some host species such as *H. cunea* and *L. dispar* are polyphagous and attack many plant species (see Japanese Society of Applied Entomology and Zoology 2006). In order for this generalist parasitoid to locate hosts on a multitude of species, it seems to utilize volatile compounds common to various species. Components of the non-specific blend, namely (*Z*)-3-hexen-1-yl acetate, (*E*)-2-hexenal, hexanal, and (*Z*)-3-hexen-1-ol, called green leaf volatiles (GLV), are commonly released from various plants after physical damage, as well as by herbivory (e.g., Takabayashi et al. 1995; Turlings et al. 1998; Hoballah et al. 2002; Chamberlain et al. 2006). Some parasitic wasps are attracted by these GLV (Takabayashi et al. 1991; Wickremasinghe and Van Emden 1992). Our data suggest that the presence of the non-specific blend, composed mainly of GLV, was essential for *E. japonica* to land on the infested plants. However, it is likely that the GLV alone are insufficient to attract *E. japonica* because this parasitoid showed moderate responses to both the artificially damaged plants (Fig. 1) and the non-specific blend (Fig. 4). The GLV appear to have an additive effect on the attraction of *E. japonica* with the host-induced blend. Our data suggest that

the presence of the host-induced blend was also important for *E. japonica* to land on the infested plants. The homoterpene (*E*)-4,8-dimethyl-1,3,7-nonatriene in the host-induced blend is released from several plant species, including corn (Turlings and Tumlinson 1992; Takabayashi et al. 1995; Hoballah et al. 2002; Birkett et al. 2003), bean (Dicke et al. 1990; Wei and Kang 2006), and cotton (Röse et al. 1996), in response to herbivory, and it attracts some parasitic wasps such as *E. formosa* (Birkett et al. 2003) and *O. dissitus* (Wei and Kang 2006). This homoterpene is one of common HIPVs found in several host–plant complexes and is a highly reliable indicator of host presence. Therefore, it may be the most likely candidate for the chemical that attracts the generalist *E. japonica*. By exploiting mixtures of such common HIPVs and GLV as chemical cues, in nature, *E. japonica* may efficiently search for a variety of hosts on plants.

Acknowledgments We thank Dr. Hajime Sugie of the National Institute for Agro-Environmental Sciences for kind assistance on chemical analyses. We also thank Mr. Kazufumi Hanyu of the Graduate School of Life and Environmental Sciences, University of Tsukuba for valuable comments and Ms. Chieko Yokokura of the *Japan International Research Center for Agricultural Sciences* for technical assistance. This work was supported by a Research Fellowship (to Ryoko T. Ichiki) through the Japan Society for the Promotion of Science.

Flight Tunnel Responses of Female Grape Berry Moth (*Paralobesia viteana*) to Host Plants

Dong H. Cha · Stephen P. Hesler · Charles L. Moser · Satoshi Nojima · Charles E. Linn Jr. · Wendell L. Roelofs · Gregory M. Loeb

Received: 16 November 2007 / Revised: 24 January 2008 / Accepted: 28 March 2008 / Published online: 26 April 2008

Abstract Semiochemicals play important roles in mate and host recognition of herbivorous insects, such as moths, and flight tunnels have been an effective tool in the identification of these bioactive compounds. However, more work has been carried out on pheromones than on host plant cues, and few examples exist where flight tunnel evaluations of host cues have resulted in a lure that is attractive under field conditions. Our goal was to determine whether the flight tunnel could be used to evaluate the response of a specialist moth, grape berry moth (GBM), to its host plant (grapevines), by incorporating ecological and physiological aspects of GBM biology. We found grape shoot tips and mature leaves were more attractive to female GBM than unripe and ripe berries or flowers. Under optimized flight tunnel conditions, approximately 80% of tested females flew upwind and closely approached or landed on the most preferred target. Mating status, wind speed, the time of day, and the presence/absence of patterns that resemble grape tissues on the top of the flight tunnel all significantly affected the responses of female GBM. Consideration of these factors in flight tunnel assays will aid in the development of a synthetic lure that can be used to monitor female moths in the field.

Introduction

Moth species in the family Tortricidae cause economic losses in agricultural and horticultural crops and forests in temperate regions worldwide (Van der Geest and Evenhuis 1991). Semiochemicals play important roles in both mate and host recognition in these moths (Ridgway et al. 1990; Bruce et al. 2005). Sex pheromones have been identified in over 60 tortricids (Arn 1991) and used in the field for control or monitoring purposes. Similarly, host plant volatiles that are involved in host recognition or oviposition have been studied with a focus on female tortricids (Reed and Landolt 2002; Ansebo et al. 2004; Hern and Dorn 2004; Natale et al. 2004; Tasin et al. 2005, 2006a, b, 2007). Most of the behavioral components of these studies have been carried out in flight tunnels since this type of bioassay is a useful method to evaluate the responses of flying insects to semiochemicals (Howse et al. 1998). However, most of the research using flight tunnels has been looking at responses to sex pheromones, and there is considerably less on responses to host plant cues (e.g., Cardé 1984). This could be because male moths generally have more obvious behavioral responses to pheromone, whereas females have rather subtle behavioral responses to host cues (Tasin et al. 2006b), thus making identification of such bioactive compounds difficult. This may explain why few flight tunnel evaluations of host cues, especially for lepidopterans, have resulted in a lure that works in the field (e.g., Ansebo et al. 2004). In addition, plants generally emit a greater number of volatile compounds than found in insect pheromones, making identification of key compounds more difficult. This situation has been improved

recently with the development of volatile collection systems, such as solid phase microextraction in combination with gas chromatographic-electroantennographic detection (e.g., Zhang et al. 1999; Nojima et al. 2003a, b).

Grape berry moth (*Paralobesia viteana*) (GBM), a major specialist pest of cultivated grape in the Eastern USA, is crepuscular in activity (Taschenberg 1945). Although the female-produced sex pheromone of GBM has been known for several decades (Roelofs et al. 1971) and used to monitor male flight activity, male captures in these pheromone traps have proven to be poorly correlated with female activity (Hoffman 1990; Weigle et al. 1999). Consequently, trap catch data from pheromone traps have not been useful for timing management decisions. As a first step towards developing a host-plant-based lure that is effective in the field, our goal was to determine whether female GBM respond to plant sources in the flight tunnel by comparing response to different grape tissues (flowers, unripe berries, ripe berries, mature leaves, and shoot tips) since knowing the most attractive plant part would help in future studies to identify bioactive volatile cues used for host location. We also examined the effects of time of day, ceiling pattern, wind speed, and mating status on female behavioral responses.

Materials and Methods

Insect Grape berry moths were reared in cages placed in walk-in environmental chambers at 26°C and 60% RH under an 18:6 (L:D) photoperiod. Adult moths were fed with 50% honey and water impregnated in cotton. They mated freely in rearing cages (45 cm height × 77 cm width × 45 cm diameter) and oviposited on seedless grape (*Vitis vinifera*, red flame variety). First and second instars were transferred to diet cups (30 ml, WinCup Inc., Stone Mountain, GA, USA) and reared on semi-synthetic diet (Nagarkatti et al. 2000) consisting of grapes, pinto beans, and commercially available tobacco hornworm diet (Bio-Serve, Frenchtown, NJ, USA). Pupae were sexed and set up in cohorts for flight tunnel bioassays. Each cohort was set up with 10–15 female pupae in a Plexiglas cage (30 cm height × 30 cm width × 30 cm diameter) and provided with 50% honey and water. For mated cohorts, females were housed in cages with 15 to 20 males (one antenna clipped for distinction from females) and a grape cluster to increase mating. Both 3-day-old virgin females and 5-day-old mated females were used for flight tunnel bioassays.

Flight Tunnel The response of female GBM to host plants under different conditions was assessed by using two different, but similarly designed flight tunnels. Both flight tunnels were 2 m in length by 0.6 m in width and 0.6 m in height with a fan installed at the upwind end to create a steady airflow into the tunnel and an exhaust hood at the downwind end to evacuate odor from the flight tunnel and laboratory through a vent. The upwind and downwind ends of the tunnel consisted of two layers of cheesecloth to prevent escape of moths. The first tunnel was constructed with glass doors on one long side and a white panel on the other and a Plexiglas floor and ceiling. A black stripe floor pattern (1.5 cm width stripes every 19 cm perpendicular to the direction of airflow) over a white surface was installed under the Plexiglas floor. Light was provided from above with eight 40-watt incandescent bulbs. Light intensity was reduced to 25 lx (using a rheostat and measured with a Sunlight Illumination Meter, Weston Instruments Inc., Archbald, PA, USA) to mimic dusk conditions. We used this tunnel initially to quantify the most attractive grape tissue type to female GBM, and to investigate the importance of diel periodicity, additional optomotor cues, and wind speed. We conducted subsequent bioassays in an all-glass flight tunnel to minimize volatile contamination in anticipation of future work to identify specific volatile cues used by female GBM. The second flight tunnel was used to determine the effect of mating status on the flight response of female GBM. Light (again at 25 lx) was provided by eight 25-watt incandescent bulbs, and the pattern on the glass floor was made up of randomly distributed dark green paper circles (10 cm diameter) on a white background. During the experiments, temperature and relative humidity of the first flight tunnel was 23.3°C (±0.64 STD) and 30.6% (±7.71 STD), and 23.0°C (±0.32 STD) and 23.6% (±0.16 STD) in the second.

We tested the response of small groups (four to six) of females in the trials conducted in the first flight tunnel, recording the behavior of each moth in the group for 15 min. Flight behavior was made by two observers. We tested single female moths for trials conducted in the second flight tunnel, recording behavior for 8 min per moth. We noted the time it took each moth to respond, and the behavior expressed: leaving the release cage or making an orientation flight (more than 50 cm of tight zigzag flight to within 10 cm of the target, similar behavior as observed in flights with pheromone lure) or contacting the target. For data analysis, we categorized each moth based on the best behavior that the moth displayed within the duration of each assay. Thus, moths that flew from the release cage were categorized as “no orientation” (no directed flight toward the target), “orientation,” or “landing”. The target for a particular trial was introduced at the upwind end in the center of tunnel (30 cm from upwind end) affixed on an acetone-washed copper tube stand, while females were introduced in the plume about 1.5 m downwind of the target in small metal screen cages. The pattern and movement of smoke from incense placed at the target end

of the tunnel was used to determine the female moth release point.

Response of Female Moths to Host plants We compared the response of female GBM to flowers, unripe berries, ripe berries, mature leaves, or shoot tips (three to four immature leaves with tendrils) of *Vitis labrusca* (variety concord). All grape plants were grown from cuttings in 1-gal pots under greenhouse conditions at 21–26°C, with supplemental light extending the day length to 14 to 16 h. They were fertilized weekly with water-soluble fertilizer (Peters 20–20–20, Scotts-Sierra Horticultural Products Co., Marysville, OH, USA). Grape tissue was harvested and immediately placed into a water pick just prior to the start of assays. The volume of each tissue type presented had an approximate area of 10×10×10 cm. A portion of the grapevine stem was retained for all types of tissue used in the flight tunnel. Control flights were performed by using the acetone-washed copper stand without water pick as a target. The effect of mating status on flight response of female GBM was examined by using concord shoot tips as the target. We performed both experiments (tissue type and mating status) under optimized flight tunnel conditions defined by experiments described below.

Effect of Environmental and Physiological Factors on Flight Tunnel Responses In all tests, except where noted, we used live concord shoot tips as a target. The effects of diel periodicity on female flight were tested by comparing flight responses of mated and unmated females to shoot tips at dusk (in our experiment, this was a 2-h period including the hour before and after the start of the scotophase) and 2–4 h before dusk. The response of female GBM with a ceiling pattern was assessed by adding pieces of dark green paper, cut in the shape of grape leaves, on the glass ceiling below the light source, thereby creating a pattern of dark shapes that filled approximately 25% of the surface. We tested the effect of wind speed by adjusting the fan with a rheostat to create velocities of 0.25, 0.5, or 0.66 m/s (measured with a vaneometer from Dwyer Instruments, Inc., Michigan City, IN, USA) at the point of release for the moths.

Statistical Analyses The effect of tissue type (N=238), time of day (N=46), wind speed (N=25), ceiling pattern (N=30), and mating status (N=127) was analyzed by using generalized linear models with orientation or landing as dependent variables and time, wind speed, ceiling pattern, tissue type, or mating status as fixed independent variables by using binomial distribution with logit link function and maximum likelihood estimation (Proc Glimmix, SAS Institute 2006). Test effects were compared by using contrast statements and mean % response and standard errors were estimated with lsmeans statement with ilink option and presented in the figures (Proc Glimmix, SAS Institute 2006). We interpreted our results as odds ratios where odds are defined as the ratio between probability of event and probability of no event (Allison 2001). Odds were calculated by exponentiating coefficients of independent variables in Proc Glimmix output.

Results

Orientation to Different Tissue Types Females responded differently to different tissue types in terms of orientation (P<0.001) and landing (P<0.001) (Fig. 1). Females displayed the greatest level of orientation and landing to shoot tips, but this was not statistically different from the response to mature leaves (P=0.27 for orientation, P=0.17 for landing). Shoot tips were more attractive to females than unripe berries (P=0.014 for orientation, P=0.051 for landing), which in turn were more attractive than ripe berries (P=0.012 for orientation, P< 0.001 for landing) and flowers (P=0.004 for orientation, P=0.011 for landing). Ripe berries were not different from flowers (P=0.13 for orientation, P=0.55 for landing) although they were more attractive from control with respect to orientation (P=0.014) but not landing. Attractiveness of flowers to females was not different than control (P=0.26 for orientation, P=0.63 for landing).

Effects of Diel Periodicity on Flight Behavior The proportion of females that oriented to (P=0.010) and landed on

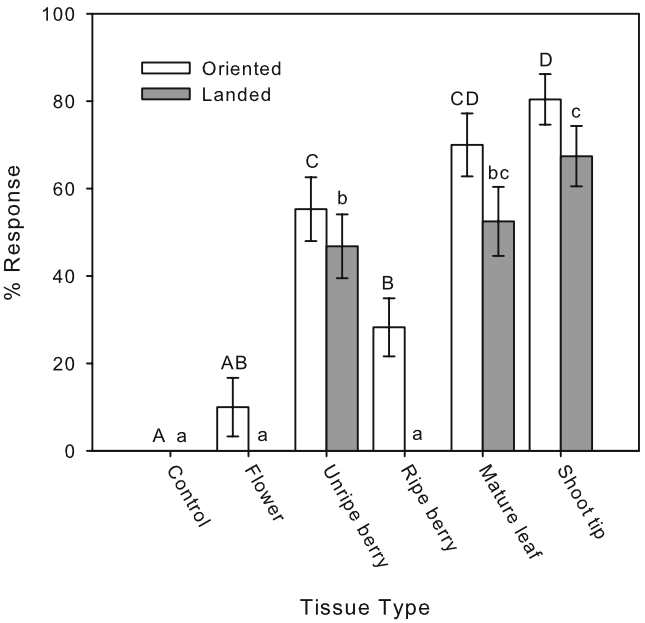

Fig. 1 Flight tunnel response (%) of female GBMs to different parts of the host plant, *V. labrusca*. Different *letters* (*capital letters* for orientation response and *small letters* for landing response) on *bars* indicate significant differences (P<0.05). Error bars=±1 SE

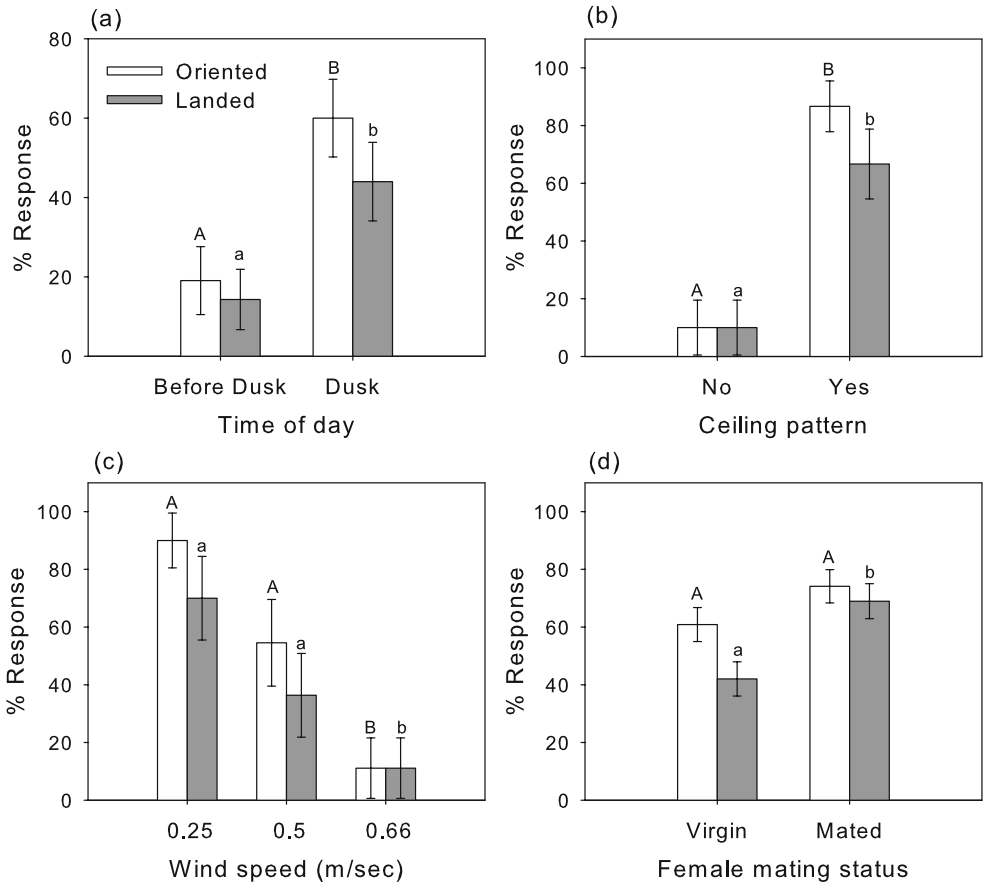

Fig. 2 Flight tunnel response (%) of female GBMs to shoot tips of *V. labrusca* when **a** flown at dusk (between 1 h before and after dusk time) or 2–4 h before dusk, **b** flown with or without a ceiling pattern, **c** flown at different wind speeds (0.25, 0.5, and 0.66 m/s), and **d** either virgin or mated. Different *letters* (*capital letters* for orientation response and *small letters* for landing response) on *bars* indicate significant differences ($P<0.05$). Error bars=±1 SE

shoots ($P=0.043$) was significantly higher at dusk than moths flown 2–4 h before dusk (Fig. 2a).

Effects of Flight Tunnel Environment The addition of a ceiling pattern to the flight tunnel increased the proportion of females orientating ($P=0.014$) to and landing on ($P=0.041$) grape shoots compared to the control (Fig. 2b). The effect of wind speed was marginally important for both orientation ($P=0.050$) and landing ($P=0.103$) responses of females to grape shoots (Fig. 2c) with significantly fewer females responding at 0.66 m/s than at the lower wind speeds.

Effect of Mating Status on Female Flight Behavior The mating status of females did not affect the orientation response ($P=0.150$) but more mated females landed at the source than virgins ($P=0.015$) (Fig. 2d).

Discussion

We compared attractiveness of different grape tissue types to female GBM as a first step in our effort to identify attractive host volatiles. Under the optimized flight tunnel condition determined by this study, we found that shoot tips and mature leaves are the two most attractive tissue types to female GBM. This appears somewhat counter intuitive, given that females lay eggs mostly on grape clusters. However, it is possible that they use shoot odors (shoot tips and mature leaves) to orient to the vines over long distances (several meters or more) but use different cues, including visual and chemotactile cues, to locate oviposition sites once within the canopy. We found that adjusting flight tunnel factors, such as wind speed and optomotor cues, along with consideration of biological factors, such as diel periodicity and mating status, can significantly impact on the orientation and landing responses of females. We observed that females had four to six times greater chance of locating the target around dusk than 2–4 h before dusk, which is not really surprising given that GBM is a crepuscular species and oviposition activity also peaks at dusk (Taschenberg 1945; Greg Loeb, unpublished data). Our findings are similar to those reported for the European grapevine moth, where responses to the host plant in the flight tunnel were significantly lower 6 h prior to dusk than at dusk (Hurtrel and Thiery 1999).

The addition of a ceiling pattern in addition to the existing one on the floor significantly increased orientation and landing female responses. In a previous study, male

spruce budworm moths responded better to sex pheromone in a flight tunnel with a ceiling compared to a floor pattern (Sanders et al. 1981). However, we did not compare the response of females when only a ceiling pattern was used.

In our study, the behavior of females improved as wind speed decreased. This might be because wind speed affects plume structure, which is important in the flight of moths (Willis and Baker 1984; Vickers and Baker 1992). In addition, the size of the odor active space and the maximum distance of communication decrease at higher wind speed (reviewed in Elkinton and Cardé 1984). Moreover, GBM is small and does not appear to be a strong flyer, and may have difficulty maintaining upwind flight in even moderate wind. Indeed, Botero-Garces and Isaacs (2004) found that movement of marked GBM in the field was greatly reduced at wind speeds of 0.6 m/s.

Mating is an important event in a moth's life and brings about many physiological and behavioral changes (Thompson and Pellmyr 1991). Our interest was to test whether mated and unmated females showed different flight responses to host plants in the flight tunnel. We found that mated females had a better chance of landing on grape shoots compared to unmated female moths, although there was no difference in the incidence of orientation. There is the potential that our results from the mating status experiment are confounded because mated moths were 5 days old while unmated moths were 3 days old. However, in separate experiments evaluating orientation to volatile blends, unmated 3-day-old females were not different than unmated 5-day-old females (Dong Cha, unpublished data), suggesting a minimal confounding effect between age and mating status in our experiment. In addition, the importance of mating status in the behavior of other Tortricidae moths (e.g., oviposition site selection of eastern spruce budworm moth described by Wallace et al. (2004)) supports our result.

Other studies with tortricid moths also have shown a similar increase in landing response by mated females (Hurtrel and Thiery 1999; Yang et al. 2005; Masante-Roca et al. 2007). This might be because mated females are ready to oviposit, and landing may indicate a transition from host searching to oviposition-related behaviors. Increased levels of landings by mated females could have resulted from being previously exposed to odors of grape clusters present in our cohort mating cages. Improved flight response in mated females pre-exposed to tansy flower volatile has been reported in European grapevine moth (Hurtrel and Thiery 1999). However, in our environmental chamber, air moved freely among rearing and cohort chambers, so mated and unmated moths should have shared all the volatiles in the air. Thus, it would appear probable that physiological and neurological changes that follow mating could explain the increased probability of females landing.

The flight tunnel has proved to be an essential tool in developing a synthetic lure for the sex pheromone where the bioassay system relates well to what is happening in the field. Our finding showing that female GBM respond to host plant volatiles, especially under optimized flight tunnel conditions, suggests it has potential to develop synthetic host plant lures. We will be using this approach for future tests on isolated volatiles, as these tools will help in our efforts to improve a GBM monitoring system for use in management of this key grape pest.

Acknowledgements We thank Sara Villani, Eric Smith, Shinyoung Park, Rachel Tucker, Mike Colizzi, Jessica Worden, and Kevin Conley for their support on various aspects of this research, but particularly their efforts in maintaining the GBM colony and setting up mating cohorts. This research was supported by USDA NRI grant no. 2005–35302–16154 and USDA Viticultural Consortium.

Belowground Chemical Signaling in Maize: When Simplicity Rhymes with Efficiency

Ivan Hiltpold · Ted C. J. Turlings

Received: 14 December 2007 / Revised: 13 March 2008 / Accepted: 18 March 2008 / Published online: 29 April 2008

Abstract Maize roots respond to feeding by larvae of the beetle *Diabrotica virgifera virgifera* by releasing (*E*)-β-caryophyllene. This sesquiterpene, which is not found in healthy maize roots, attracts the entomopathogenic nematode *Heterorhabditis megidis*. In sharp contrast to the emission of virtually only this single compound by damaged roots, maize leaves emit a blend of numerous volatile organic compounds in response to herbivory. To try to explain this difference between roots and leaves, we studied the diffusion properties of various maize volatiles in sand and soil. The best diffusing compounds were found to be terpenes. Only one other sesquiterpene known for maize, α-copaene, diffused better than (*E*)-β-caryophyllene, but biosynthesis of the former is far more costly for the plant than the latter. The diffusion of (*E*)-β-caryophyllene occurs through the gaseous rather than the aqueous phase, as it was found to diffuse faster and further at low moisture level. However, a water layer is needed to prevent complete loss through vertical diffusion, as was found for totally dry sand. Hence, it appears that maize has adapted to emit a readily diffusing and cost-effective belowground signal from its insect-damaged roots.

Introduction

Plants defend themselves against herbivores either directly with the use of toxins, repellents, or morphological structures (Karban et al. 1997; Karban and Baldwin 1997; Schoonhoven et al. 1998; Agrawal and Rutter 1998; Baldwin and Preston 1999; Dicke et al. 2003), or indirectly by attracting the enemies of herbivores (Dicke and Sabelis 1988; Agrawal 1998; Dicke and Hilker 2003; Turlings and Wäcker 2004). The role of volatiles in the attraction of such natural enemies was first brought to light in studies on the interactions between arthropods and plant leaves. Results revealed that herbivore attack induces emissions of volatile organic compounds (VOC) attractive to parasitoids and predators (Dicke and Sabelis 1988, Turlings et al. 1995; De Moraes et al. 1998), and this role of induced volatiles in tritrophic interactions has also been demonstrated under realistic field conditions (Bernasconi et al. 1998; De Moraes et al. 1998; Thaler 1999; Kessler and Baldwin 2001). While the aboveground portion of a plant is obviously essential for photosynthesis and reproduction, the root system is also of vital importance. Little is known about possible indirect defense mechanisms against root feeders, but several studies now have demonstrated that roots also are able to recruit enemies of herbivores by releasing chemical cues into soil. These chemicals can attract entomopathogenic nematodes (Boff et al. 2001; van Tol et al. 2001; Bertin et al. 2003), predatory mites (Aratchige et al. 2004), and even parasitoids (Neveu et al. 2002). In *Zea mais* L., feeding by larvae of the western corn rootworm (WCR), *Diabrotica virgifera virgifera* LeConte (Coleoptera: Chrysomelidae), results in the release of a few sesquiterpenoids, dominated by (*E*)-β-caryophyllene (EβC), which is attractive to the entomopathogenic nema-

tode (EPN) *Heterorhabditis megidis* Poinar (Rhabditida: Heterorhabditidae) (Rasmann et al. 2005).

Western corn rootworm is the most destructive pest of maize in the United States and its introduction in Europe (Miller et al. 2005) also has generated concern among maize growers in the Old World (Vidal et al. 2005). Several strategies have been used worldwide to control WCR populations, of which crop rotation has thus far been the most effective (Levine et al. 1992). However, certain US populations have developed an extended diapause (Tollefson 1988; Levine et al. 1992) or the ability to develop on soybean roots (O'Neil et al. 2002), and other control measures are being considered. Some potential biological control agents have been identified (Toepfer and Kuhlmann 2004). Field results with such agents have been variable (Jackson 1996; Journey and Ostlie 2000; McCoy et al. 2002), but EPNs are the most promising (Gaugler et al. 1997; Kuhlmann and Burgt 1998). EPNs are obligate parasites that kill insect hosts with the aid of mutualistic bacteria (Forst and Nealson 1996; Burnell and Stock 2000). The effectiveness of *H. megidis*, a promising nematodes against WCR, is strongly correlated with the emission of EβC (Rasmann et al. 2005). A good understanding of the mechanism by which EβC attracts EPNs could help to improve their efficacy.

The release by the roots of only one dominant compound in response to herbivory contrasts strongly with insect-damaged maize leaves, which release a complex blend of green leaf volatiles, aromatic compounds, and various terpenoids (Degen et al. 2004). We hypothesized that this difference between roots and leaves is due to the chemical properties of EβC, which might make it particularly suitable for belowground diffusion. To test this, we compared the diffusion of EβC with those of other typical maize volatiles that the roots could potentially emit.

Materials and Methods

Experiments were carried out in clean sand that had been passed through a 2mm sieve and autoclaved to obtain a homogeneous, air-dried, and VOC-free medium. Deionized water was added in precise quantities to obtain specific humidity levels. Humidity was 10% in all initial experiments, and was obtained by adding 50ml deionized water to 450g of sand in a Teflon-box (12 × 10 × 4cm; 480cm^3, internal dimensions), maintaining constant porosity at about 90%. The box was put on a thermal tray, maintaining the temperature at 12°C. A 0.2mm diameter cylinder made of ultra-fine metal mesh (2300 mesh; Small Parts Inc., USA) was inserted into the sand, thereby creating a hole in which a solid-phase microextraction (SPME) fiber could be safely inserted. Automated sampling was performed with a 100μm polydimethylsiloxane SPME fiber (Supelco, Buchs, Switzerland) within 12h with a multipurpose sampler (MPS2, Gerstel GmbH & Co. KG, Germany) (Koziel et al. 2000; Gorecki and Namiesnik 2002; Vas and Vekey 2004). At 30min intervals, the adsorbed compounds were analyzed by retracting the fiber from the sand and inserting it for 3min in the injector of an Agilent 6890 Series gas chromatograph heated at 230°C (G1530A) coupled to a quadrupole-type mass-selective detector (Agilent 5973;

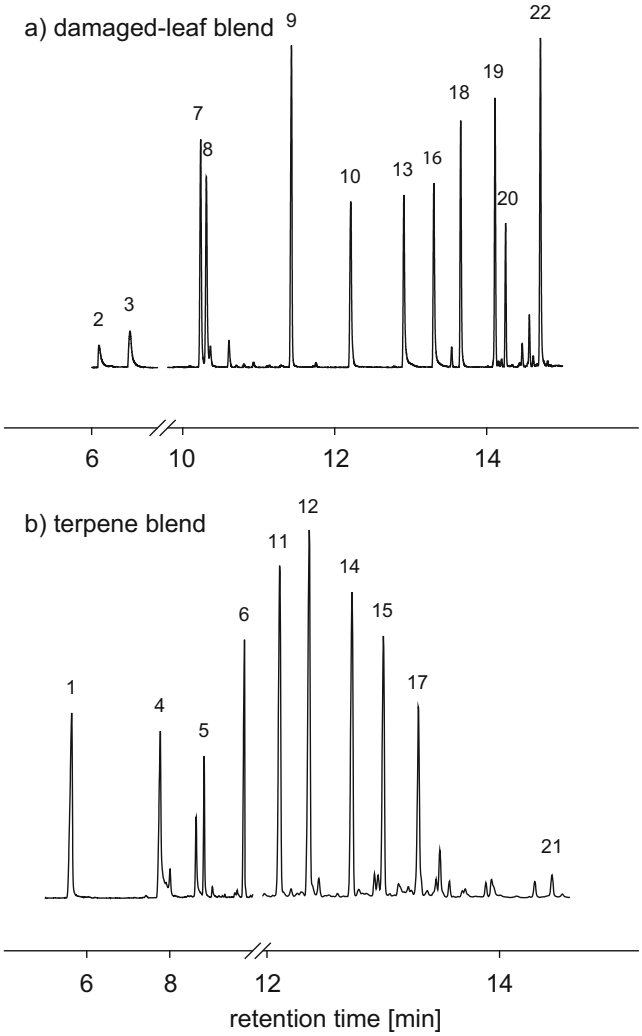

Fig. 1 Representative GC-MS chromatograms obtained by sampling just above the two synthetic blends that were used for the diffusion experiments. **a** analysis after collection with a 100μm polydimethylsiloxane SPME fiber of a synthetic mix of typical leaf volatiles. **b** analysis after collection with a 75μm corboxen™-polydimethylsiloxane SPME fiber of a blend of selected terpenoids. Labeled peaks are as follow: (*1*) (+)-α-pinene, (*2*) (E)-2-hexenal, (*3*) (Z)-3-hexenol, (*4*) β-myrcene, (*5*) cis-ocimene, (*6*) and (*9*) linalool, (*7*) β-myrcene, (*8*) (Z)-3-hexenyl acetate, (*10*) methyl salicylate, (*11*) (−)-α-cubebene, (*12*) (−)-α-copaene, (*13*) indole, (*14*) and (*19*) EβC, (*15*) α-humulene, (*16*) methyl anthranilate, (*17*) valencene, (*18*) geranyl acetate, (*20*) (E)-β-farnesene, (*21*) caryophyllene oxide and (*22*) ($^+/_-$)-trans-nerolidol

transfer line 230°C, source 230°C, ionization potential 70eV). The desorbed volatiles were separated on a polar column (HP1-MS, 30m, 0.25mm ID, 0.25μm film; Agilent Technologies, USA) using helium as a carrier gas (constant pressure of 127.9kPa). Following injection, the column temperature was maintained at 40°C for 1min and then increased 20°C min^{-1} to 250°C, where it was held for another 12min. After the first 30min sampling period, a synthetic mixture of typical caterpillar-induced leaf volatiles (0.2μg for each compound) (Turlings and Ton 2006) dissolved in 5μl of pentane (>99%; Acros Organic) (Fig. 1a) was injected 3cm into the sand. The injection site was located 0.5cm from the edge of the tray, opposite the fiber insertion site. Measurements with the fiber were done at four distances (1.5, 3, 6, and 10cm) from the injection point, and were replicated 5 times for each distance.

The results of the first experiment prompted an additional similar diffusion test with a blend that mainly comprised terpenoids (Fig. 1b). The set-up was the same as described above except that we sampled only at 10cm from the source and a 75μm Corboxen™-polydimethylsiloxane SPME fiber was used, because of its higher affinity for terpenes.

Diffusion also was assessed in a standard soil (type 5M, LUFA Speyer, Germany) that was first autoclaved. Experiments were conducted with the two synthetic blends described above (Fig. 1) following the same experimental set-ups as for the sand experiments, but sampling was only done at 10cm of the release point.

The effect of moisture level on EβC diffusion was determined by measuring horizontal diffusion of a synthetic version injected at 0.2μg/5μl pentane. Porosity of sand was maintained constant by adding a fixed mass of medium (500g) into the Teflon box. The ratio between sand and water was adjusted to obtain moisture levels of 0%, 1%, 5%, or 10% water.

All experiments were replicated five times. Chromatograms were analyzed with ChemStation (version D.00.00.38, Agilent Technologies), and peak areas of VOCs were compared with analysis of variance (ANOVA) and *t*-test. Differences among compounds and humidity levels were determined by using a Bonferroni post hoc test. All analyses were run on SigmaStat (version 2.03, Access Softek Inc.).

Results

Diffusion of Typical Maize Leaf Volatiles At concentrations of 0.2μg/5μl, the amount and number of VOCs adsorbed onto the SPME fiber decreased drastically with sampling distance (Fig. 2). At 10cm, only three terpenes EβC, β-myrcene, and (*E*)-β-farnesene were detected (Fig. 3). Of these, EβC diffused best (one-way ANOVA, $N = 5$, $F_{2,14} = 6.95$, $P = 0.01$) and was detected longer after the injection.

Diffusion of Terpenoids in Sand All terpenoids, with the exception of caryophyllene oxide diffused readily through sand and were detected 10cm from the source, but the amounts detected were considerably different for the different compounds. Data shown in Fig. 4 include only the four terpenes that are emitted by WCR-damaged maize roots (Rasmann et al. 2005). Of these, β-copaene diffused best, followed by EβC, which diffused equally well as the structurally similar α-humulene (one-way ANOVA, $N = 5$, $F_{2,14} = 21.57$, $P < 0.001$). As we did not detect any diffusion of caryophyllene oxide, we omitted this compound from the statistical analyses.

Diffusion of Terpenes in Soil Differences in how the terpenes diffused in soil were similar to those in sand, but the amount of each chemical recovered at 10cm from the source was considerably lower (Fig. 4). Again, β-copaene

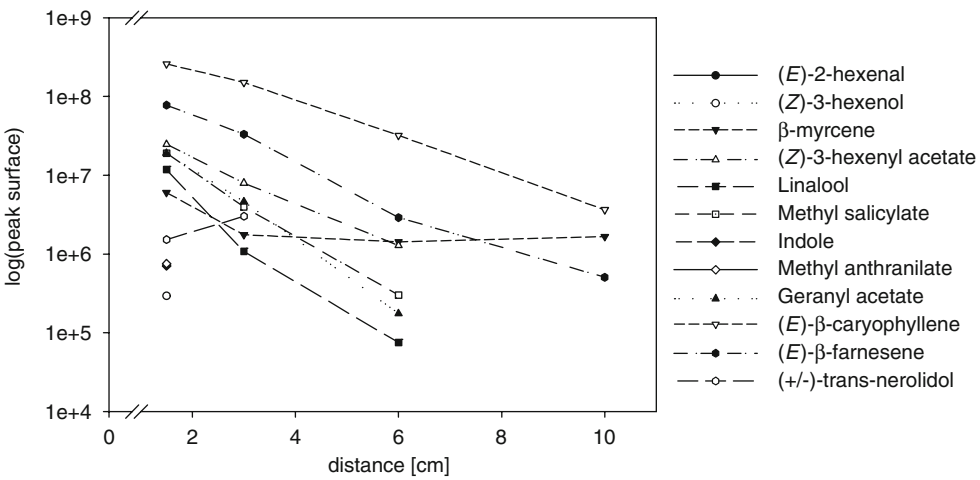

Fig. 2 Diffusion of a synthetic blend along 10cm in a sand medium. VOCs were sampled 1.5, 3, 6, and 10cm from the odor source. Only terpenes were diffused as far as 10cm. All the other compounds were not detected at distances of more than 6cm. Trans-nerolidol, methyl anthranilate and indole were detected only 1.5cm from the source. Detection directly at the release point was not possible because of fiber saturation

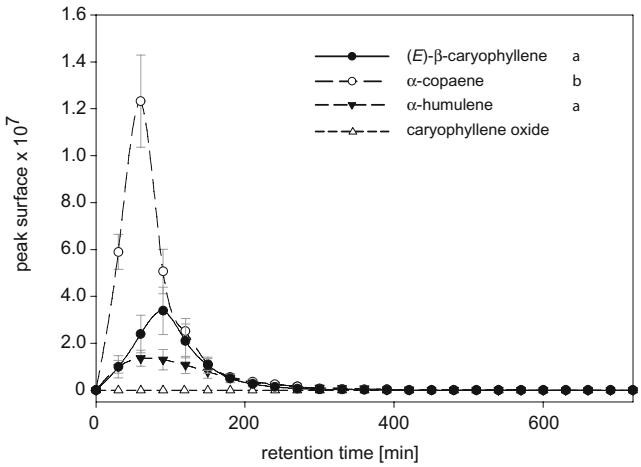

Fig. 3 Diffusion of an authentic terpenoids blend measured at 10 cm from the source. GC-MS peak surfaces of EβC, α-copaene and α-humulene reached their maximum at 72, 30, and 128 min (mean time) after injection, respectively. Maximum GC-MS peak surfaces differed significantly (one-way ANOVA, N=5, $F_{2,14}$=6.95, P=0.01). Letters next to the compound names indicate significant differences between compounds (Bonferroni posthoc test)

diffused better than EβC (*t*-test, $N = 5$, $P = 0.039$). α-Humulene and caryophyllene oxide were not detected in soil.

Moisture Level and EβC Diffusion The amount of water present in the sand strongly affected EβC diffusion. An almost twofold larger amount of EβC was detected at a humidity level of 1% than at 10% humidity. However, a water layer is needed to avoid loss by vertical diffusion: no EβC was detected when the sand was completely free of water (Fig. 5, one-way ANOVA, $N = 5$, $F_{2,14} = 21.47$, $P < 0.001$). As we did not detect EβC in dry sand, results for this treatment were omitted from the statistical analyses.

Discussion

The results support our hypothesis that EβC is particularly well-suited as a belowground signal because of its diffusion properties. The only other maize-produced compound that diffused better than EβC was α-copaene. All other compounds were consistently detected at lower amounts away from the release point or not detected at all. The limited detection of these other compounds could be explained by early evaporation (vertical diffusion), which is likely to be the case for compounds with low molecular weight (Lowell and Eklund 2004) such as (*E*)-2-hexanal and (*Z*)-3-hexanol. Besides vertical diffusion, adsorption onto colloids (polar particles) within the media could slow down or stop both vertical and horizontal diffusion. Although adsorption is expected to be relatively low in sand (Ruiz et al. 1998), silicates on the surface of sand particles, and also the aqueous phase of the medium, could adsorb many of the compounds that were tested. This was evident from a study in which a blend of induced maize volatiles was pushed through a silica-filter, and several of the volatiles that did not diffuse in the current study were found trapped on the filter (D'Alessandro and Turlings 2005). As adsorption does not alter chemical properties, adsorption of VOCs onto static silicates could enhance the establishment of a chemical gradient over a longer period of time (McGechan and Lewis 2002), thus allowing EPNs to follow a chemical trail towards potential hosts.

Terpenes were the best diffusing compounds, possibly explaining why WCR-damaged maize roots exude mainly terpenes, even though maize is able to synthesize many other VOCs (Figs. 2 and 4). EβC clearly diffuses better than α-humulene, the other sesquiterpene released by maize roots, but we detected up to two times more β-copaene in

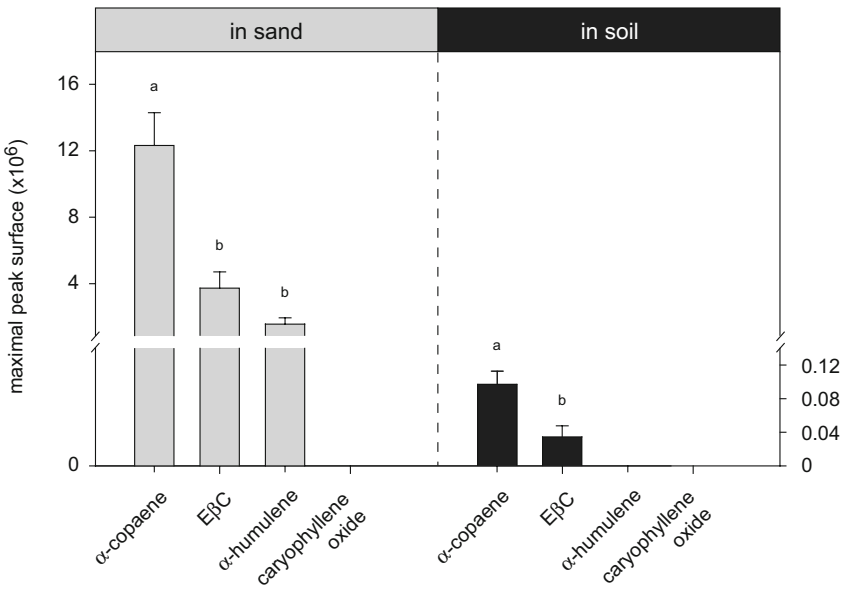

Fig. 4 Diffusion of terpenoids in sand and in soil. VOCs were sampled 10 cm from the odor source. In sand, α-copaene diffused significantly better than the other compounds (one-way ANOVA, N=5, $F_{2,14}$=21.47, P<0.001). The same pattern of diffusion was observed in soil (*t*-test, N=5, P=0.039). Undetected compounds were excluded from the statistic

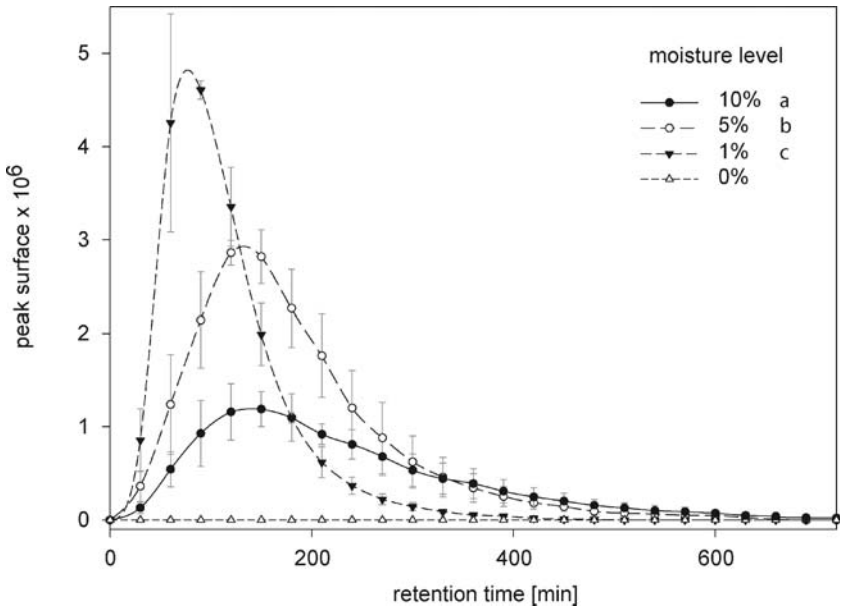

Fig. 5 Diffusion of EβC under different moisture levels measured at 10 cm from the source. Peak surfaces of EβC with 1%, 5%, and 10% of water in sand reached their maximum at 80, 140, and 160 min after injection, respectively. Diffusion velocity tended to increase with lower moisture levels, but there was no statistical difference among the three moisture levels (data not shown) (one-way ANOVA, N=5, $F_{2,14}$=2.17, P=0.19). Maximum GC-MS peak surfaces differed significantly (one-way ANOVA, N=5, $F_{2,14}$=21.47, P<0.001). *Letters* indicate significant differences between compounds (Bonferroni post hoc test). As no diffusion was detected in dry sand (0%), it was excluded from the statistical analyses

sand 10cm from the source than EβC, and this difference was similar in soil (Fig. 4, in soil). That β-copaene diffuses better than EβC (Fig. 4) may reflect their respective adsorption strengths onto the substrate. The most likely explanation why roots emit EβC rather than β-copaene as a belowground signal comes from what is known about their respective biosyntheses. While there is much speculation and some disagreement about the evolution and function of VOCs (Firn and Jones 2000; Peñuelas and Llusia 2004; Owen and Penuelas 2005, 2006; Firn and Jones 2006), researchers agree on at least one principle: production of such herbivore-induced plant volatiles can require considerable resource investment. It has been reported that some plants may allocate up to 10% of their carbon for the production of VOCs (Firn and Jones 2006). Considering this potential cost, plants can be expected to have adapted the energetically cheapest solutions. The precursor for the maize sesquiterpenes is the same, farnesyl diphosphate (FPP). When WCR larvae feed on roots, this triggers a cascade of reactions that lead to the production of two different enzymes. The first reacts with FPP to catalyze the production of EβC and α-humulene, and the second reacts with the same precursor, but forms β-copaene and approximately 50 other compounds (T. Köllner, personal communication), (Fig. 6). Because of the production of these additional compounds, a plant produces nine times more EβC than β-copaene with the same number of FPP molecules. Hence, even if EβC diffusion is half as

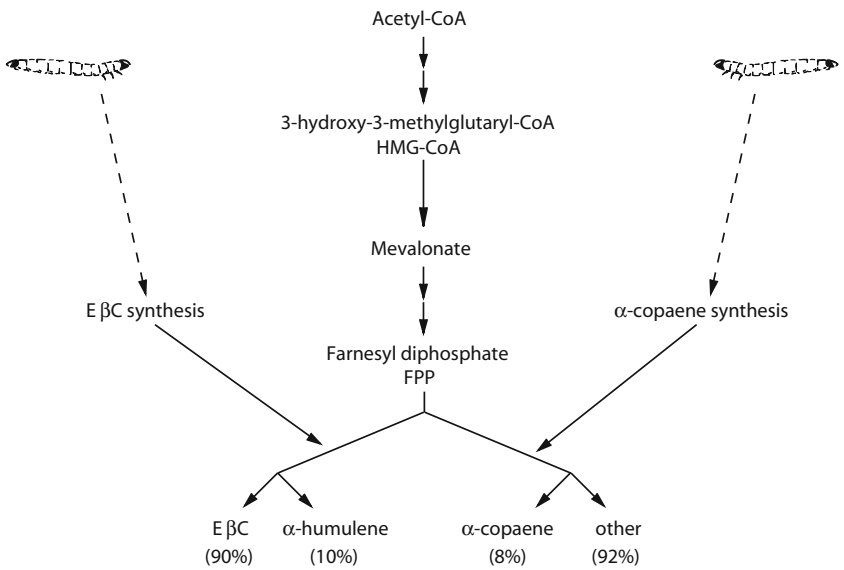

Fig. 6 Schematic model of the metabolic pathway for EβC synthesis. When WCR larvae feed on roots this triggers a cascade of reactions resulting in the production of two different enzymes that lead to two separate pathways of volatile synthesis. The ratio in which the volatiles are produced from these pathways implies a much more cost-effective production of EβC than of β-copaene (T. Köllner, personal communication)

efficient as β-copaene, the fact that it is far less expensive for the plant to produce should counterbalance this difference.

The moisture level of the substrate strongly affected EβC diffusion (Fig. 5). The detected abundance and the velocity of horizontal diffusion were negatively correlated with the water volume present in the sand. Porosity was maintained constant. Therefore, the addition of water reduced the gaseous phase volume. Thus, the results confirm the notion that the diffusion of EβC occurs in the gaseous phase, which was expected because of its poor solubility in water. Low moisture levels enhance horizontal diffusion of EβC, but a complete lack of water dramatically reduces it. This is best explained by a need for a thin layer of water to avoid quick vertical evaporation of the sesquiterpene.

EβC is a common compound and has been identified from various plant species (e.g., Rodriguez-Saona et al. 2001; Tholl et al. 2005; Calyecac-Cortero et al. 2007; Cheng et al. 2007; Helmig et al. 2007). Its function, as for most plant volatiles, remains unclear. Sesquiterpenes in general may have anti-microbial or insecticidal effects (e.g., Erasto et al. 2006; Liu et al. 2006; Sabulal et al. 2006; Ji et al. 2007), but at the dose emitted by maize roots it is unlikely to be effective against insects (Rasmann et al. 2005). Interestingly, EβC is also emitted from maize silk and has been implicated in the attraction of adult *Diabrotica* beetles (Hammack 2001), but recent behavioral assays suggest that other plant compounds are considerably more important for adult attraction (Tòth et al. 2007). Belowground sesquiterpenes (strigolactone) also have been found to play a role in the symbiosis between roots and arbuscular mycorrhiza as fungi branching factor (Akiyama et al. 2005) and in germination of *Striga*, *Alectra*, and *Orobanche* species (Butler 1995). Hence, it is important to stress that multiple functions and modes of selection for EβC or other sesquiterpenes must be considered. The recently identified sequiterpene-synthase gene TPS23, which is responsible for EβC production in maize (Köllner et al. 2008), was found to be highly conserved, implying an important function for the plant. There is little information about herbivore-induced root volatiles from other plants. A comparison among the emissions from maize, cotton, and cowpea roots in response to feeding by *Diabrotica balteata* larvae has revealed the typical release of EβC by maize roots, a more complex mixture of terpenoids emitted from cotton roots, including α-copaene, but no detectable amounts of EβC, whereas no volatiles were detected from attacked cowpea roots (Rasmann and Turlings 2008). Nematodes are most attracted to damaged maize roots and far less to damaged cowpea roots (Rasmann and Turlings 2008), which is in accordance with an important role for EβC in the attraction.

This study set out to explain why the induced emission of volatiles in maize roots is basically limited to just one dominant sesquiterpene, EβC. The hypothesized explanation that this compound would be particularly suited as a belowground signal because of its diffusion properties was confirmed. The only maize-produced compound that appeared to be even better at diffusing in the substrates tested was β-copaene, another sesquiterpene. A plausible reason why the plant has evolved to emit EβC is that β-copaene is more costly to produce. Given the logic behind these explanations, we should perhaps now turn the question around and wonder why the leaves emit such complex blends if they could be so much simpler.

Acknowledgments We thank all the members of the E-vol lab at the University of Neuchâtel for their support, in particular Matthias Held, Russell E. Naisbit, and Sarah Kenyon. We also thank Jean-Michel Gobat for advice on the experimental design, Violaine Jourdie for stimulating discussions and Marie-Eve Wyniger for assistance with the chemical analyses. This project was funded by the Swiss Confederation's innovation promotion agency (CTI project no. 7487.1 LSPP-LS).

Sex Pheromone of the American Warble Fly, *Dermatobia hominis*: The Role of Cuticular Hydrocarbons

Claudia Cristina Gulias Gomes · José Roberto Trigo · Álvaro Eduardo Eiras

Received: 26 July 2007 / Revised: 24 March 2008 / Accepted: 26 March 2008 / Published online: 29 April 2008

Abstract Chemical communication between adults of the American warble fly, *Dermatobia hominis* (Diptera: Oestridae), was investigated by electroantennography and behavioral bioassays. Significant electroantennographic responses were recorded from both sexes to hexane-soluble cuticular lipids from either sex. Olfactometer tests indicated an attraction between males and females, and between females. Copulatory behavior of males with a white knotted string treated with female extract confirmed production of a sexual stimulant by females. Such behavior was not observed in tests with male extract, demonstrating that the pheromone acts also as a sex recognition factor. Cuticular hydrocarbons of sexually mature female and male *D. hominis* were identified by Gas chromatography–mass spectrometry and consist of a mixture of saturated *n*-, monomethyl-, and dimethylalkanes in both sexes. Sexual dimorphism was characterized by a higher relative concentration of dimethylalkanes in males and the presence of alkenes only in females.

Introduction

During the last five decades, pheromone production has been confirmed in more than ten species of muscoid Diptera of importance in human and animal health within the families Muscidae, Calliphoridae, and Sarcophagidae (Howard and Blomquist 1982; Eiras 2001). Most of these compounds are sex pheromones isolated from the cuticle (Lockey 1980; Howard and Blomquist 1982). Such information has improved understanding of the biology of these taxa and has provided new insight for control methods. Similar research, however, is lacking for many other Diptera, including the American warble fly, *Dermatobia hominis* (L.) (Diptera: Oestridae), an important mammal parasite in Neotropical regions.

Dermatobia hominis has an unusual biology. Gravid females use other dipterous species to transport their eggs to suitable hosts, and adults have non-functional mouthparts and live just a few days, surviving on nutritional reserves from the larval stage (Hall and Wall 1995). Larvae are able to penetrate intact mammalian skin and develop in subcutaneous tissue until the third instar. Mature larvae leave the host and pupate below ground (Guimarães and Papavero 1999). Adults emerge after 4 to 8 wk; males emerge 1 to 2 days before females (Barbosa et al. 2000). The highest percentage of female insemination was measured in the laboratory with flies between 24–30 h after emergence, and sexual vigor of males decreases after 3 days of age (Banegas and Mourier 1967).

Parasitism by the American warble fly affects cattle production, with economic losses in Brazil estimated between

US $200–260 million per year, mainly as a consequence of leather devaluation and control costs (Guimarães and Papavero 1999; Grisi et al. 2002). Application of broad-spectrum injectable or topical insecticides is the main control strategy employed to reduce larval infestation (Hall and Wall 1995; Oliveira et al. 1999). Alternative methods of management of *D. hominis* are desired because excessive use of insecticides represents a risk to environmental, human, and animal health.

The process of orientation and copulatory behavior of *D. hominis* adults in the field is still poorly understood. Aggregation behavior is common among species in the Oestridae (Catts et al. 1965; Anderson et al. 1994), and males of *D. hominis* have been observed to aggregate in trees (Guimarães 1966). Olfactometer tests suggested that female odors do not regulate male orientation or play a minor role in this behavior (Banegas and Mourier 1967). However, most sex pheromones produced by muscoids have been characterized as short-range attractants, sexual stimulants, or contact sex/species recognition factors. Usually, they are alkanes or alkenes and are produced by females (Uebel et al. 1975a, b; 1978a, b; Sonnet et al. 1979; Bolton et al. 1980; Carlson et al. 1974, 1998, 2007). In this study, we investigated the role of intraspecific chemical communication in the copulatory behavior of *D. hominis*. The cuticular lipids of each sex were identified to assist in the future identification of the sex pheromone.

Methods and Materials

Insects Third instars of *D. hominis* were collected from cattle hides in two slaughter houses located in Contagem and Betim, Minas Gerais, Brazil. Larvae and pupae were maintained in humidified sawdust at 28°C, 60%±10% RH, and L/D 12:12 h. Pupae were placed individually in sawdust in plastic vials (3-cm height×2.5-cm diameter) and covered with a thin layer of white polystyrene beads (1-2 mm diameter) to provide contrast with adult fly color. Emergence time was monitored with a video camera to determine the age of each adult. Insects were removed from the sawdust within a few hours after emergence and kept separate until the beginning of tests. All insects used in experimental trials were 1 to 3 days old.

Cuticular Hydrocarbon Extracts Insects were anesthetized by using low temperature (−20°C) and then immersed individually in 500 μl *n*-hexane (Merck, 99% purity, Darmstadt, Germany) for 10 min. All samples were stored at −20°C and used within a maximal period of 1 week unless specified otherwise. Combined extracts used for the olfactometer bioassay (three insect equivalents) and mass spectrometric analyses (nine insect equivalents) were concentrated to 100 μl after they were pooled. The remaining individual extracts were kept separately for later chemical analysis. All samples were concentrated just before each test.

Electroantennography Hexane extracts of one male equivalent (1 ME) or one female equivalent (1 FE) were concentrated under a stream of N_2 to ~100 μl and transferred onto a strip of filter paper (40×5 mm). After solvent evaporation, the filter paper was placed into a 15-cm long Pasteur pipette. Glass electrodes were filled with 0.1 N aqueous KCl solution, and silver electrodes fitted within. The head and tip of one arista of *D. hominis* was cut off and mounted between the reference and recording glass electrodes, respectively. A purified and humidified air stream of 30 cm/s was directed continually over the preparation, and a pulse stimulus of 0.3-s duration was added to the air stream every 2 min (Stimulus Controller C5-05, Synthec, Hilversum, The Netherlands). Electroantennographic signals were amplified and transferred to a personal computer (IDAC Box Model ID-01B, Synthec). The electroantennography (EAG) analyses were performed sequentially by using the following stimuli: air, hexane, 1 ME of hexane extract, and 1 FE of hexane extract (ten females and ten males analyzed in response to each stimulus). Stimuli were tested three times per insect, and baseline was also recorded. EAG deflections were measured and stored numerically as millivolts. Results were normalized as a percentage of the control (hexane), which was by definition set at 100% (Synthec program for Windows version 2.6) and compared with the Kruskal–Wallis test (Zar 1999), followed by Dunn's post-test (Siegel and Castellan 1988).

Behavioral Bioassays Attractiveness of male and female *D. hominis* to conspecific adults was evaluated in a four-arm linear olfactometer system. Each olfactometer arm was composed of three chambers: (1) a transparent central tube (plexiglass tube 500 mm long×90-mm diameter), (2) another transparent plexiglass tube at the downwind end (100 mm long) with a rotating screen to control insect release, and (3) a polyvinylchloride (PVC) tube at the upwind end (200 mm long×100-mm diameter), with an entrance for the stimulus located above. The PVC tube was isolated from the central tube by gauze screen. Each olfactometer arm received air from a single air conducting system (PVC tubes), which involved air pumped from outside by an extractor fan, purified by an activated charcoal filter, heated, and finally, humidified before passing simultaneously into each arm of the olfactometer (Fig. 1).

The olfactometer was arranged over a metal stand covered with white-striped paper. Each olfactometer arm was shielded on both sides from visual stimulation by white

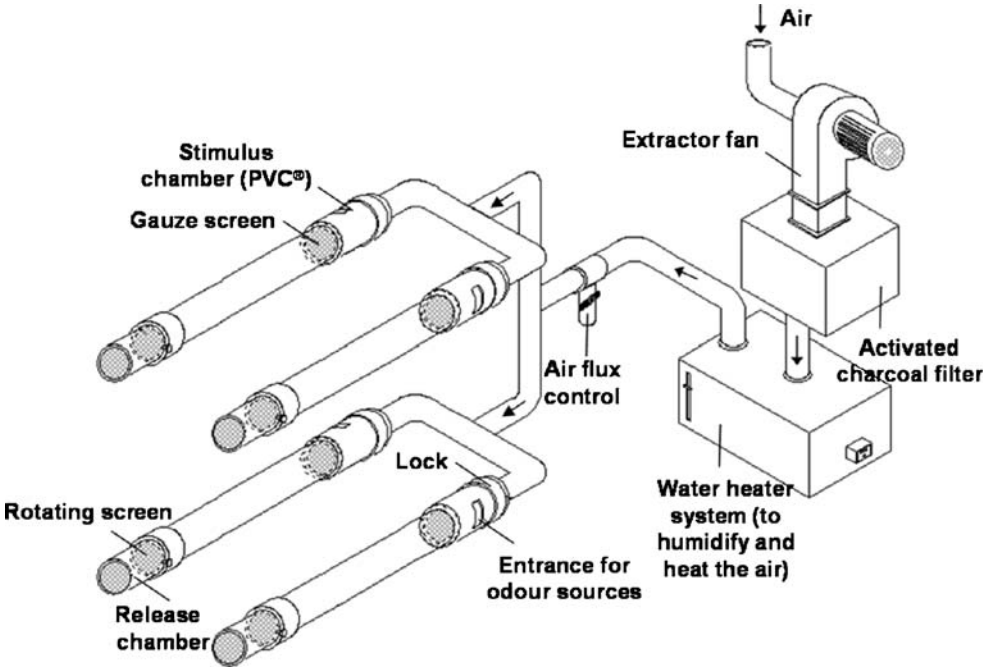

Fig. 1 Schematic drawing of the four-arm linear olfactometer system

and yellow cardboard. They were used in sequence, and after four replications, all the equipment was cleaned with water and 5% Extran® (MA 02, Neutral, Merck) detergent solution before starting a new battery of tests. Although not confirmed by chemical analysis, the capacity of the detergent solution to remove contaminants from the equipment was considered adequate because the responses to control stimuli remained low and uniform among the battery of tests. The experimental area was illuminated by two 20-W light bulbs above each set of two olfactometer arms, providing 1,200-lx light intensity. The experimental area was maintained at 27°C±1°C, 60%±10% RH, L/D 12:12 h, and 0.1–0.15 m/s wind speed.

Behavioral stimuli consisted of male and female adults of *D. hominis*, as well as hexane extracts (1 FE, 1 ME, 3 FE, and 3 ME). Before presentation of the stimulus, each responding adult was acclimated 15 min in the release chamber in the olfactometer air stream. Stimulus insects were placed in a screened cage (20×20×20 mm) and allowed to become stationary before being transferred to the PVC chamber. Extracts were concentrated under a gentle stream of N_2 to 100 µl and transferred onto a strip of filter paper (20×20 mm). After solvent evaporation, the filter paper was placed on a support in the middle of the PVC chamber. After the release chamber was opened, the maximum linear location of the test fly in either direction in the central tube was recorded during a period of 5 min. The maximal distance (centimeter) attained by each fly in the direction of the stimulus was taken as a measure of attraction. Responses to each stimulus and its control (pure air) were recorded from 30 different insects of each sex. Results were analyzed by the Kruskal–Wallis test and compared by the Mann–Whitney test (Zar 1999).

Production of a short-range pheromone by females was investigated in behavioral tests by using fly models (dummies) in a glass tube (400 mm long×50 mm diameter). Dummies were constructed of male and female *D. hominis* anaesthetized at –20°C or a white knotted string impregnated with conspecific body extracts (<24 hours old). One test male and one dummy were released at opposite ends of the glass tube. The side of each dummy was sealed with Parafilm® to keep dispersion of the odor plume toward the direction of the test male. Male behavior was observed during an initial 5 min period (phase 1). Behavioral data recorded were (1) contact, characterized as a short pouncing contact with the dummy, and (2) copulation attempt, characterized by mounting and exposure of the genitalic surstyli. In the absence of an orientated mount, contact between dummy and test male was induced by bending the tube during a subsequent 5-min period (phase 2). The only behavioral event recorded during phase 2 was copulation attempt. The effects of visual and tactile stimuli, which could induce copulatory behavior, were controlled by testing flies with white knotted string washed previously with hexane. Thirty replications of each treatment and control were conducted. Statistical analyses of the number of contacts and copulatory attempts were performed by using Fisher's test (Zar 1999).

Analysis and Identification of Cuticular Hydrocarbons

Chemical analyses were carried out with extracts of nine females and nine males concentrated to 100 µl in a N_2

stream. Aliquots of 1 µl of each sample were injected in splitless mode into an HP6890 gas chromatograph coupled to an HP5973 mass selective detector (GC–MS; Hewlett Packard, Palo Alto, CA, USA). The GC was equipped with an HP-5MS capillary column (Hewlett Packard; 30-m×0.25-mm×0.25-µm film thickness). The oven temperature was increased from 60°C to 230°C at 20°C/min and then from 230°C to 320°C at 2°C/min, where it was maintained for 10 min. The injector and detector temperatures were 250°C and 300°C, respectively. Helium was used as the carrier gas (1.2 ml min^{-1}). All samples were analyzed separately and by co-injection with consecutive *n*-alkane standards for determination of Kovats Retention Index (KI). Individual components were identified by their KI (Carlson et al. 1998) and by fragmentation patterns (Nelson et al. 1981; Pomonis 1989; Carlson et al. 1999). Peaks with areas less than 0.5% relative to the major peak were not considerated in GC–MS analysis. Alkenes were derivatized with dimethyldisulfide for determination of double-bond position (Francis and Veland 1981). The relative percentages of hydrocarbons were calculated by analysis of individual extracts of ten males and ten females with a Shimadzu 17A GC (Shimadzu, Osaka, Japan) equipped with a DB-1 capillary column (J&W, Folsom, CA, USA; 30-m×0.5-mm×0.5-µm film thickness) and a flame ionization detector. The temperature program was the same as described above; injector and detector temperatures were 330°C and 340°C, respectively. Hydrogen was used as the carrier gas (1.5 ml/min). Data acquisition and processing were performed with an HP G1030 data system (version B.00.01).

Volatile Entrapment To confirm the volatility of cuticular hydrocarbons identified from hexane extracts of *D. hominis*, volatiles were collected from ten living specimens of each sex during a 12-h photophase period, considering that the species has diurnal habits. The insects used in the bioassay were 24–48 h old to ensure that specimens were sexually mature and active. A blank test was run as a control. Volatiles were collected from *D. hominis* in a glass chamber (135-mm high×60-mm-diameter base×45-mm-diameter top) with two lateral arms (30-mm long×10-mm diameter), which served as the entrance and exit for the air stream. This air stream was produced by an air compressor system (1 l/min) and was purified by using an activated charcoal and silica filter (130-mm long×30-mm diameter) before entering the aeration chamber. The air stream exited through a glass column containing 0.1 g of Super Q adsorbent (100–120 mesh, Alltech, Deerfield, IL, USA). The experimental area was maintained at 24°C and 23%± 5% RH. Adsorption samples were extracted with diethyl ether (99% chemical purity, Merck) to a volume of 1 ml and concentrated under a stream of N_2 to 100 µl. One microliter of each sample was analyzed by GC–MS, as described above.

Results

Electroantennography Hexane extracts of conspecifics elicited significant EAG responses from female and male *D. hominis* (Kruskal–Wallis test; female, $H=41.95$, $df=4$, $P<0.001$; male, $H=43.71$, $df=4$, $P<0.001$; Figs. 2 and 3). Responses were higher in females than in males (Figs. 2 and 3).

Behavioral Bioassays Olfactometer assays showed significant responses by females and males to females, as well as by females to males. The mean distances attained by insects in these treatments were similar (Fig. 4). Males were not attracted to males. In tests where attraction was observed, on average, 60% of the insects moved from their initial position within the olfactometer. In the control groups, this percentage was only 27%. Attraction was not observed with extracts of one or three equivalents of either sex (data not shown).

The total percentages of copulatory attempts (phases 1 and 2 combined) observed in the bioassays of males with an anesthetized female or with a white knotted string treated with female extract were similar ($P=0.671$; Fig. 5), although in the latter case, most copulatory attempts occurred after contact was induced. The number of males that made contact with an anesthetized female ($N=11$) did not differ significantly from the number that contacted hexane-washed females ($N=7$; $P=0.398$). However, nine of the 11 touches with an anesthetized female were followed by a copulatory attempt. No attempts were observed after contact was made with hexane-washed females. In the bioassays with white knotted string treated with 1 FE, only one contact was made, followed by a copulatory attempt.

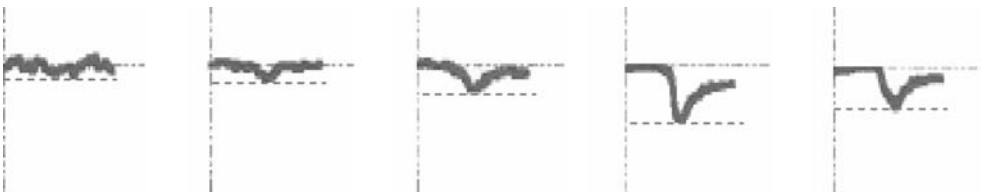

Fig. 2 Example of electroantennographic responses of male *Dermatobia hominis* antennae to hexane cuticle extracts of conspecifics (1 FE = 1 female equivalent; 1 ME = 1 male equivalent). From left to right: baseline, air, hexane, 1FE, 1ME

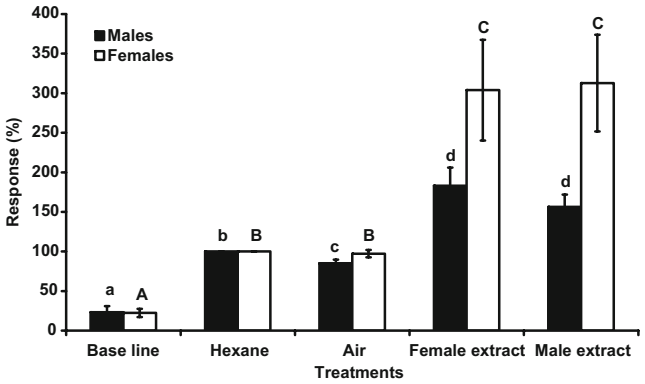

Fig. 3 Electroantennographic responses (mean ± SD) of female and male *Dermatobia hominis* (N=10 for each sex) to hexane cuticle extracts of conspecifics (one insect equivalent). EAG signals were measured as millivolts and normalized by using the response to hexane as a reference (set at 100%). Significant differences among treatment within female and male responses are indicated by *different letters* (lower case letters for males and capital letters in females)

Neither a contact nor a copulatory attempt was observed with untreated white knotted string. In the treatments with anesthetized males or white knotted string treated with 1 ME, no copulatory attempt was observed during phase 1 (Fig. 5). After contact was induced (phase 2), a male tried to copulate with a male control washed with solvent.

Analysis and Identification of Cuticular Hydrocarbons Analysis of the chemical composition of hexane extracts of male and female *D. hominis* revealed the presence of linear and branched hydrocarbons with chains varying from 23 to 41 carbons in males and 21 to 39 carbons in females (Table 1). The alkanes present consisted of linear and mono- or dimethyl-branched chains. The *n*-alkanes were the most abundant type of hydrocarbon, with approximately 43.1% of the total in males and 39.3% in females. Of these percentages, only 3.4% and 5.5%, respectively, were chains with an even number of carbons. Heptacosane (C_{27}) was a major component, representing 20.8% and 18.7% of the total hydrocarbons in males and females, respectively. Tricosane (C_{23}) and pentacosane (C_{25}) were found in relatively greater concentrations in females, as opposed to nonacosane (C_{29}), hentriacontane (C_{31}), and tritriacontane (C_{33}), which were found in relatively larger concentrations in males.

The methyl alkanes consisted of a homologous series of externally and internally branched isomers. The location of the branches in the monomethyl-alkanes varied from position 3 to position 19. Isomers with internal branches beyond position 9 co-eluted, resulting in a KI between XX31, the XX33 (XX are the primary digits of the KI) in chains with an odd number of carbons (from 9-MeC_{xx} to 19-Me C_{xx}, where "$_{xx}$" are the carbon numbers), and XX27 and XX29 in chains with an even number of carbons (from 10-MeC_{xx} to 14-Me C_{xx}, where "$_{xx}$" are the even carbon numbers). Male and female *D. hominis* had relatively similar percentages of monomethyl alkanes, representing 25.7% and 30.9% of total hydrocarbons, respectively. However, the biggest concentration of monomethyl alkanes in females occurred with compounds that had parent chains of 27, 29, and 31 carbons, whereas in males, the biggest concentration occurred with compounds that had parent chains with 35, 37, 39, and 41 carbons.

Dimethyl alkanes represented 25% and 7.4% of the total composition of hydrocarbons in males and females, respectively. Most of these occurred as a homologous

DiMe dimethyl, *Me* methyl, $C_{xx:1}$ unsaturated compound

[a] Abbreviated names of co-eluting compounds are joined by a plus sign. The co-eluting compounds follow the order of elution.

[b] Calculated by gas chromatography–flame ionization detector

[c] Carbon number; *question mark* unknown carbon number

[d] Kovats Index; the asterisk indicates estimated KIs; the compounds were identified by their mass spectrum and by comparison with the corresponding homolog series.

[e] Diagnoses based on comparisons with mass spectral data from Nelson et al. (1981), Pomonis (1989), and Carlson et al. (1998 and 1999). For methyl-branched alkanes, ion clusters occur as even/odd mass pairs depending on the branching point (Nelson et al. 1972). For brevity, only the higher fragment of each pair is listed.

series with internal branches initiated mainly at positions 9, 11, and 13, with three methylene units between the branches; they occurred from C_{27} to C_{41} odd parent chains. A second homologous series, present in relatively low amounts from C_{25} to C_{27} odd parent chains, was composed of 3, *x*-dimethyl alkanes, where the *x* was represented by carbons 7, 9, or 11. 5,*x*-Dimethyl alkanes also occurred with C_{25} and C_{27} parent chains, but in this case, *x* varied between carbons 9, 11, 13, 15, and 17.

Alkenes comprised 22.3% of the total composition of hydrocarbons in females. The double bond was at positions 7 and 9. The compounds 7-tricosene (7-$C_{23:1}$) and 7-pentacosene (7-$C_{25:1}$) were abundant, representing 11% and 7.3% of the total female hydrocarbons. Unidentified peaks comprised only 6.2 % of relative abundance in males, whereas all peaks were identified in females.

Analysis of trapped volatiles revealed that *n*-alkanes and monomethylated alkanes with chain lengths ranging from 23 to 31 carbons (females) and from 25 to 31 carbons (males) could be collected in the headspace (Table 2). All of these compounds were always present in the cuticular extracts of adults in relative concentrations above 1%. Volatiles collected from females were uniquely characterized by 7-tricosene (7-$C_{23:1}$), tricosane (C_{23}), 7-pentacosene (7-$C_{25:1}$), monomethyl pentacosanes, hexacosane (C_{26}), and 5-methyl-heptacosane (5-Me C_{27}). Volatiles collected from males were characterized by several compounds shared with females but also hentriacontane (C_{31}), which was present in extracts of both the sexes, but at a low concentration in the female extract.

Discussion

This study offers the first evidence for sex pheromones in a species in the Oestridae. The bioassays with dummies indicated the occurrence of chemical communication in the copulatory process of *D. hominis* and confirmed the presence of chemical components in the female extract that function as a sexual stimulant. The increase in copulatory attempts observed only after contact of the males was induced with either the anesthetized females or the white knotted string models suggests that chemical stimulation occurs over short distances or by means of contact receptors. Preliminary bioassays demonstrated that white knotted string treated with female extract stimulates males to copulate even after storage for 1 month at −20°C. This indicates that the sexual stimulant is of low volatility and is stable. The presence of a sexual stimulant, however, does not exclude the possibility of an attractive stimulant, as the majority of sex pheromones are multi-component (Wyatt 2003). Olfactometer tests with air flow indicated attractiveness of males to females. This intraspecific attractiveness has been observed in some muscoids, such as *Musca domestica* L. (Murvosh et al. 1965), *Musca autumnalis* Degreer (Chaudhury et al. 1972), *Haematobia irritans* L.,

and *Stomoxys calcitrans* L. (Howard and Blomquist 1982). Most of these studies reported low attractiveness (Murvosh et al. 1965; Howard and Blomquist 1982), although the use of the identified synthetic pheromone, (*Z*)-9-tricosene, against both male and female *M. domestica* in the field has become universal because of its effectiveness when combined with pesticides (Carlson and Beroza 1973). Considering the large variation that we measured in the responses of individual male *D. hominis*, the attraction to the chemical source can also be interpreted as low intensity. Probably for this reason, Banegas and Mourier (1967) concluded that no pheromone was involved or had little importance in the process of orientation by *D. hominis* males. It is also probable that attraction behavior was not observed in the bioassay with glass tube because there was no air flow, which may increase chemical dispersion. On the other hand, in our study, the use of Parafilm® to seal the glass tube or to provide a barrier on the anesthetized dummies could be considered as a potential source of contamination. This material is composed of hydrocarbons (Millar and Sims 1998), and identical compounds were later identified in hexane cuticular extracts from females. A background odor could affect the response of olfactory receptors cells of males. However, if the action of a longer range pheromone was influenced by other molecules present in the glass tube environment, no interference was observed at short range because physical contact with the dummies stimulated courtship.

The absence of attractiveness of male and female *D. hominis* to extracts at one and three insect equivalents could be attributed to an extract concentration that was insufficient to duplicate the odor plume generated by a live insect. The importance of how a stimulus is presented was discussed by Geier and Boeckh (1999) in which they compared the liberation of an extract of human skin odor with a heating system (60°C) or with filter paper. The results demonstrated that, to achieve similar responses, it was necessary to use 300 times the concentration on the filter paper than was used in the heating system. This type of methodology could be used in future studies of *D. hominis* attractiveness, especially because of the difficulty in obtaining large numbers of adults.

The absence of copulatory attempts by males with models treated with extract of conspecifics males indicates the action of a sexual recognition factor in the chemical composition of the species. This type of factor has been demonstrated in other studies of sexual pheromones of flies as the hydrocarbon 19,23-dimethyl-1-tritriacontene, produced by males of *Glossina morsitans* Westwood (Diptera: Glossidae) that inhibits mating activity when applied to the body of conspecifics females (Carlson and Schlein 1991). Previous laboratory studies of courtship behavior of *D. hominis* males (unpublished data) demonstrated reduced number of homosexual copulatory attempts. These data corroborate the presence of a sexual recognition factor and suggest that recognition occurs at a distance and is not limited to physical contact between the insects. The presence of odor receptors on male antennae responsive to the extract of conspecifics males (EAG results) supports the existence of biologically active volatile compounds in the male extract. The presence of a sexual recognition factor in the male cuticle might explain the lack of response of males when conspecifics males were tested in the olfactometer bioassays. In this case, the sexual recognition factor would have an inhibitory function.

Eletroantennographic analyses also demonstrated the presence of odor receptors in female antennae to compounds in extracts of both sexes. Behavioral bioassays have supported these results by demonstrating the attraction of

D. hominis females to both males and females. The intraspecific attraction of females by males has not received much attention previously. Most research has focused on sex pheromones produced by females and behavioral assays that demonstrate the short-range orientation of males. Fletcher et al. (1966) reported a male pheromone of *Cochliomyia hominivorax* (Coquerel; Diptera: Calliphoridae) that elicited "exploratory searching movements" on females. Male aggregation has been observed to *D. hominis* and *C. hominivorax* (Guimarães 1966; Krafsur 1978). If these sites of aggregation work as "mating stations," a pheromone component that elicits "exploratory activity" or signals the meeting site could help females to locate males. Production of a social aggregation pheromone (alcohols, ketones, and alkenes) has been described for several *Drosophila* species (Diptera: Drosophilidae; Symonds and Wertheim 2005). *Cis*-vaccenyl acetate, produced by male *D. melanogaster* Meigen, induces antagonistic behaviors: aggregation of males and females, female sexual receptivity, and inhibition of courtship in the male (Mehren 2007), suggesting that many interesting questions remain to be explored with fly pheromone perception. Another poorly explored area is the attraction between conspecific females. Although the biological significance of this interaction remains obscure, it has been observed in *M. domestica* and *H. irritans* (Murvosh et al. 1965; Howard and Blomquist 1982).

Analysis of cuticular hydrocarbon extracts of male and female *D. hominis* disclosed the chemical nature of the sexual pheromone of the species, and the volatile entrapment technique demonstrated the volatility of some of the cuticular components of adults. It is possible that these blends are involved in the process of attraction as observed in the olfactometer tests. Most of the cuticular hydrocarbons of the American warble fly have been reported for other insects (Lockey 1980; Nelson et al. 1981; Trabalon et al. 1992). Heptacosane characterizes the chemical profile of this species, as it is the major component of the cuticular hydrocarbons and similar in relative concentration in extracts from both of the sexes. On the other hand, sexual dimorphism was evident because of the large concentration of dimethyl alkanes in males and alkenes in females. Alkenes have been identified as sex stimulants in females of various species of flies, such as *H. irritans* (Bolton et al. 1980), *M. autumnalis* (Uebel et al. 1975a), *S. calcitrans* (Sonnet et al. 1979), and three species of the genus *Fannia* (Diptera: Muscidae; Uebel et al. 1975b; 1978a, b). In *M. domestica*, in addition to stimulating copulation, alkenes reportedly had an attractive function as well, based on results of olfactometer and decoy tests (Carlson et al. 1974). The alkenes in *D. hominis* females, therefore, are possible candidates for its sex pheromone, with potential to have a sex stimulant and an attractive function. Identification of *D. hominis* cuticular hydrocarbons in this work serves as the basis for the identification of components with pheromonal activity, which can also include the methyl and dimethyl alkanes. These data could also be used in studies of chemotaxonomy that attempt to characterize populations of different regions or countries.

Acknowledgment We thank Célia M. Sá for invaluable technical help with chromatography and Gabriela R. Chaves for indispensable assistance in collecting *D. hominis* larvae. We are also grateful to Steven J. Seybold and reviewers for their comments on the manuscript. This work is part of a Ph.D. thesis and was supported by CAPES fellowship to C.C.G.G., and FAPESP grant 98/01065-7 and CNPq fellowship to J.R.T.

Abstract The peacock blenny, *Salaria pavo* (Risso 1810), typically breeds in rocky shores of the Mediterranean and adjacent Atlantic coast. Males defend a territory around a hole or cavity wherein females deposit eggs that the male guards until hatching. A pair of exocrine glands on the anal fin (anal glands) of males produces a putative pheromone involved in attraction of reproductively competent females to the nest. We used behavioral assays to assess species-specific attraction of reproductively competent females to putative male pheromones, including the anal gland pheromone. Additionally, chromatographic fractions of anal glands and male-conditioned water were tested for olfactory potency in females by electro-olfactogram analysis (EOG). In a flow-through tank or fluviarium, reproductive females were attracted to male-conditioned water and to the anal gland macerate from conspecifics but not to those of a closely related heterospecific. In addition, attraction of reproductive females to conspecific anal gland macerate occurred only during their initial upstream movement in the fluviarium; this was an ephemeral response when compared with the response to male-conditioned water that attracted females throughout the entire period of observation (5 min). Reproductive females also were attracted during the entire period of observation to water-conditioned by conspecific males whose anal glands had been removed. However, the attraction was more variable than that to water conditioned by intact males. Moreover, females were not attracted to male (without anal glands) odor during their initial upstream movement in the fluviarium. Finally, non-reproductive females were not attracted to the conspecific anal gland macerate. The EOG responses of females to molecular weight fractions and solid-phase extraction and high-performance liquid chromatography fractions of anal gland macerates and male-conditioned water (with and without anal glands) suggest that the anal glands release hydrophilic odorants that consist mainly of molecules smaller than 500 Da. Furthermore, males released potent odorants that do not originate from the anal glands. We hypothesize that females respond to a multi-component male pheromone to find mates. The putative anal gland pheromone is possibly comprised of hydrophilic odorants, whereas the other component(s), presumably of gonadal origin, may be less water-soluble.

Introduction

Hormonal pheromones (steroids, prostaglandins, and/or their metabolites) are generally involved in the reproduction of teleost fishes (reviewed in Stacey and Sorensen 2006), but relatively little is known about either chemical signaling behavior or specialized pheromone glands. In the goldfish, *Carassius auratus* L., which has been extensively studied with respect to reproductive hormonal pheromones, gonadal steroids and prostaglandins released via the urine and gills of females and detected by nearby males, seem to function primarily as timing cues to synchronize spawning (Stacey and Sorensen 2006 and references therein). These cues can be regarded as unspecialized metabolic by-products that are not specifically released to affect the behavior and physiology of the receiver. However, the controlled release of urine by sexually receptive females seems to represent a specialization for delivery of prostaglandin pheromones to mark the spawning site and attract males at short range (Appelt and Sorensen 2007).

More specialized chemical communication seems to exist in species for which the physical environment and/or the reproductive strategy have favored the use of sex pheromones in mate-finding. For example, in the benthopelagic African catfish, *Clarias gariepinus* Burchell 1822, which spawns at night in flooded deltas, the seminal vesicle produces steroid glucuronides that attract females (Resink et al. 1987, 1989; Lambert and Resink 1991). Furthermore, species with mating systems that typically involve male territoriality, nest defense, and paternal investment seem to have evolved specializations for sex pheromone production. In the black goby, *Gobius niger* L., and round goby, *Neogobius melanostomus* Pallas 1814, mesorchial glands in the testis (nonspermatogenic portions with a high density of Leydig cells) produce primarily 5β-reduced androgens that seem to act as hormonal pheromones that attract females (Colombo et al. 1980; Murphy et al. 2001; Belanger et al. 2004; Arbuckle et al. 2005; Gammon et al. 2005). Blennies (Blenniidae) share a similar reproductive strategy with gobies (Gobidae). Steroid glucuronides secreted during the breeding season by the testicular blind pouches (tubular evaginations of the spermatic ducts that do not function as sperm reservoirs) have been hypothesized to act as hormonal pheromones by analogy with the black goby and the African catfish (Lahnsteiner et al. 1993). External exocrine glands in male blennies produce a putative pheromone that attracts females (Laumen et al. 1974; Barata et al. 2008).

Combtooth blennies form the largest family of true blennies (suborder Blennioidei) and include more than 300 species of demersal fishes, living in littoral zones all over the world (Zander 1986). Blennies are polygynandric, and their general breeding pattern consists of males defending a territory wherein females deposit adhesive eggs on the inner surface of cavities (crevices, holes, empty shells, or other nesting cavities), which are guarded by the males until the eggs hatch (Gibson 1969; Almada and Santos 1995). During the spawning season, male peacock blennies, *Salaria pavo* (Risso 1810), and other blennies (e.g., *Salaria* spp. and *Parablennius* spp.) develop a pair of anal glands on the first two rays of the anal fin (Zander 1975; Papaconstantinou 1979). These glands seem involved in the production of a putative pheromone (Laumen et al. 1974) that attracts reproductively competent females and, thereby, increases male reproductive success (Barata et al. 2008). To act as mate-finding sex pheromone, species-specific attraction of reproductive females to the anal gland pheromone, but not of non-reproductive females, would be expected; however, this prediction has not yet been tested. In addition, it remains unclear whether the anal glands are the only source of a sex pheromone involved in female attraction.

In the current study with *S. pavo*, we used behavioral assays to test: (1) whether attraction of reproductively competent females to putative male pheromones is species-specific; (2) whether males release pheromones from locations besides the anal glands; and (3) whether non-reproductive females are attracted to the anal gland pheromone. Initial steps were made to chemically characterize the male-derived odorants by combining chromatographic techniques with assessment of olfactory potency by electro-olfactogram analysis (EOG).

Methods and Materials

Origin and Maintenance of Fish Male and female *S. pavo* were caught in Ria Formosa (southern Portugal) where breeding occurs from May to September (Almada et al. 1994). At this location, holes in bricks that clam culturists use to delimit their fields are used as shelters and as male nests during the breeding season. At low tide, between March and July, *S. pavo* inside the brick holes were caught by shaking the bricks over a plastic container with water. Males and females in the container were caught with a small net and carried inside buckets to the Ramalhete Experimental Station (University of Algarve) in Ria Formosa. At the end of the studies all fish were released at their place of capture.

Hetero-specific stimuli (see below) were derived from *Salaria fluviatilis* (Asso 1801), captured in Lake Banyoles (Catalonia, Spain). Official permission was issued by local authorities to Dr. Joaquim Pou Rovira (Environmental Sciences Department of the University of Girona, Spain) who caught the fish by an electro-fishing technique. The apparatus was custom-made and turned on only when in close proximity to *S. fluviatilis* observed swimming over stones along the shore of the lake. None of the collected

fish died, and the electro-fishing method had no adverse effects on the lake wildlife. The fish were transported from Girona to the Ramalhete Experimental Station by car in appropriate containers with oxygen-saturated water. After the experiments, *S. fluviatilis* were donated to the Vasco da Gama Aquarium (Lisbon, Portugal) for keeping and breeding.

Up to four male and up to 30 female blennies were maintained in aquaria (70 l of aerated seawater for *S. pavo* at 22 to 28°C and aerated freshwater for *S. fluviatilis* at 24± 2°C; 12-hr photoperiod) with sand and stones on the bottom. Gray polyvinyl chloride (PVC) tubes (15 cm length and 3 cm diameter) were provided as nests for the males, and when required, a net partition separated the males to avoid aggression, especially among *S. fluviatilis* males. *Salaria pavo* were fed daily with commercially available frozen mussels, *Mytilus* spp., and *S. fluviatilis* with *Artemia* spp., small shrimp, *Paleomon serratus*, and trout muscle. Female *S. pavo* were acclimated to these conditions for at least 7 d before use in behavioral assays and were kept separate from those males that were used to obtain macerates of anal glands or male-conditioned water (see below). Both species behaved normally, including sexual behavior and spawning.

Behavioral Assays To assess female attraction to male-derived chemical stimuli, behavioral assays were carried out in a flow-through tank or fluviarium made of glass, similar to that described by Bjerselius et al. (1995a,b). The test area (length × width, 450×320 mm) with a 120-mm deep water column was limited upstream and downstream by two plastic nets (5-mm mesh), and the two inner sides were painted with non-toxic grey paint (Arialcin, Corporação Industrial do Norte S.A., Maia, Portugal). At the downstream edge of the test area, a 'fish box' made of transparent acrylic (with holes allowing water passage) was placed where individual females were introduced. The fish box opened to the test area *via* a remotely operated gate. Particle- and charcoal-filtered natural seawater was pumped into the fluviarium forming a continuous laminar flow (12 l/min) through the test area. Tests with a food dye showed that the dye remained in a non-turbulent plume that expanded, largely due to diffusion, as it was carried downstream. Male-related substances and control water were delivered (10 ml/min) into the test area with a peristaltic pump, *via* one of the two gray PVC tubes (7 cm length and 5 mm diameter) on each side of the inflow water. Each tube was placed 3 mm above the bottom of the fluviarium and 1 cm away from the plastic mesh limiting the upstream edge of the test area. Dye delivered into either side (water injected in the opposite side) showed a plume that expanded downstream but remained within the same side of the test area; the dye front reached the fish box at the downstream edge of the test area within 2 min.

The fluvarium was illuminated from below with infrared light. A black and white infrared-sensitive CCD camera (Ikegami ICD 47/47E IR camera) fitted with a 4- to 10-mm zoom lens with an infrared filter was placed 650 mm above the test area. The camera was connected to a black and white video monitor (Panasonic WV-BM1410) and to a computer in an adjacent room for video-tracking of female position and movement. The infrared illumination underneath the test area produced a white background on the video image over which the fish appeared dark gray. Although infrared light was used to track the fish, all experiments took place during the day.

The EthoVision Pro 3.1 system (Noldus Information Technology, Wageningen, The Netherlands) was used for video tracking (25 frames/sec) of females in the test area of the fluviarium. The position of each fish was recorded at a rate of 5/sec. Data filtering was then applied to separate genuine displacement from slight body movement. To calculate mean linear velocity (cm/sec) and mean angular velocity (mean rate of directional change per distance; deg/cm), movement was considered only when the fish traveled at least one third of its length (standard length) between two consecutive data points. To discriminate between the states of motion and no motion (to calculate the time in motion and number of movements), transition from no motion to motion was defined as when linear velocity exceeded one-third body length per second, whereas the reverse transition was defined as when linear velocity decreased to below one-sixth body length per second.

Female attraction to a given chemical stimulus was assessed by calculating a reaction value $(\mathrm{Rv} = [(S - C)/(S + C)] \times 100)$, which represents the difference between the time that each female spent moving in the stimulus side (S) and in the control (C) side (each side was considered as half of the test area along the water flow axis) normalized to the total time in movement. Thus, a positive Rv indicates attraction to a given chemical stimulus. Reaction values were calculated during their initial upstream movement (immediately after leaving the fish box) in the test area and over the total observation period (5 min). Reaction values based on the total time (moving + not moving time) spent in either side of the test area were also calculated. However, these values are not shown, since they all were positively correlated with Rv values based on time moving. To assess whether female locomotory pattern could be affected by the type of chemical stimulus in the fluviarium, female movements were analyzed during their initial upstream swim by the latency to reach the upstream edge of the test area, number of movements, mean linear velocity (cm/sec), and mean angular velocity (deg/cm).

To test whether female attraction to putative male pheromones is species-specific, four groups of reproductive

female *S. pavo* were tested (to male-conditioned water or anal gland macerate from conspecifics, or to equivalent chemical stimuli from heterospecifics, i.e., *S. fluviatilis*). To test whether *S. pavo* males release female-attractive pheromones that do not originate in the anal gland, one group of reproductive females was tested with water conditioned by males after excision of their anal glands. To test whether non-reproductive females are attracted or not to the anal gland pheromone from conspecifics, two groups of females were tested [to anal gland macerate or to a macerate of food (mussels, *Mytilus* spp., positive control)]. Water-only controls were used to test whether females had any preference for either side of the fluvarium.

Selection of Females and Experimental Procedure On each day, females were classified as reproductive or non-reproductive on the basis of abdomen distension (qualitative scale from 0 to 3) and sexual behavior. Up to five females from the stock tanks were placed in another tank with one male and a nesting site (PVC tube) and their behavior observed for 10 min. Females with distended abdomens (scale=2 or 3) that also exhibited conspicuous courtship (i.e., display of nuptial coloration and rapid flickering of the pectoral fins while opening and closing the mouth in synchrony; Patzner et al. 1986; Gonçalves et al. 1996) were considered reproductively competent. Non-courting females with flat abdomens (0 or 1) were considered non-reproductive. Most females with a distended abdomen exhibited courtship behavior toward the male, whereas the females with flat abdomens neither approached the male nor exhibited courtship. Many females with distended abdomens spawned soon after the experiment, and their abdomens became flat; a few females with flat abdomens spawned, and then only several days later after their abdomen had become distended. Previous work (E.N. Barata and R.M. Serrano, unpublished data) has shown that the gonadosomatic index (gonadal weight/fish weight×100) of courting females with a distended (scale=2 or 3) abdomen was greater (mean±SEM=7.1±0.4%, N=12) than that of non-courting females with a flat (scale=0 or 1) abdomen (2.8±0.2%, N=15).

Replicates with individual females (tested only once) started 1–2 hr after lights-on and were carried out for up to 6 hr; female courtship and spawning has been observed during daylight (Patzner et al. 1986; Gonçalves et al. 1996; Barata et al. 2008). In each replicate, one female was placed in the fish box of the fluviarium, and after 5 min of acclimation, the gate was lifted and the fish's swimming behavior recorded for 5 min. Females that did not move within 5 min were excluded from the analysis. Delivery of chemical and control stimuli started 2 min before lifting the gate. Between replicates (15 min), the water in the fluviarium was fully replaced, and the chemical and control stimuli were delivered into opposite sides of the test area; on each day, only one type of treatment was used. After each replicate, the length (standard length, SL) and weight of females were measured, and they were placed in aquaria with males before being released back to their natural environment. The size (SL) of females in different treatments did not differ significantly (overall mean±SD=67.8±8.7 mm; N=246).

Statistical Analysis of Female Behavior One-way analysis of variance (ANOVA) was used to compare time and locomotory parameters (latency to reach the upstream edge of the test area, number of movements, mean linear velocity, and mean angular velocity) of female initial upstream movement among groups of reproductive females tested with water conditioned by intact conspecific males (N=26), water conditioned by conspecific males without anal glands (N=24), water conditioned by intact heterospecific males (N=27), and control water (N=47). The same statistical analysis was used to compare locomotory parameters between reproductive females tested with anal gland macerates from conspecifics (N=37) and heterospecifics (N=29), and between non-reproductive females tested with conspecific anal gland macerate (N=33) and food macerate (N=23). The mean reaction values (during the initial upstream movement and over the total observation period) in each female group were tested for significant difference from zero (P<0.05) by Student's t test.

Male-Conditioned Water and Anal Gland Macerate for Behavioral Assays Six *S. pavo* males [standard length (SL)=100±8 mm (mean ± SD); body weight (BW)=14.4±4.1 g] and six *S. fluviatilis* males [SL=83±5 mm (mean ± SD); BW=10.7±2.6 g] with fully developed anal glands were placed individually in small glass tanks (30×15×19 cm) with aerated artificial seawater (35 ppt, Instant Ocean®, Spectrum Brands, Cincinnati, OH, USA) or dechlorinated tap-water, respectively. The volume of water used was normalized to the fish's weight (5 g/l). Each container was placed next to a similarly sized glass tank with three conspecific females. The water was conditioned for 24 hr at 24°C. Males were anaesthetized by immersion in water containing MS222 (0.3 g/l; 3-aminobenzoic acid ethyl ester, Sigma-Aldrich, Madrid, Spain), and the anal glands of each male were excised with small scissors cutting the base of the two anal-fin rays bearing the glandular tissue. This procedure is almost as simple as fin clipping, and no visible bleeding occurs. An antiseptic cream (Betadine®) was applied to the wound. Anesthetized fish recovered within 5–10 min and were then placed back in the stock tanks where they exhibited normal behavior. For *S. pavo*, 36 hr later, water was conditioned by the same six males (without their anal glands). In both species,

anal gland regeneration was seen after 3–4 wk. Male-conditioned water was filtered (<150 μm), and a similar volume of water from each male (with or without anal glands, respectively) was pooled. Control water was treated in the same way, except that it did not hold any fish. Male-conditioned water and control water were stored at −20°C. Immediately before use, thawed male-conditioned water was diluted in seawater collected at the inflow of the fluviarium and delivered into the test area at 0.05 mg fish/ml (equivalent to 100-fold dilution of the original conditioned water).

The excised anal glands [*S. pavo*, weight=27.2±6.6 mg (mean ± SD), *N*=6; *S. fluviatilis*, weight=9.9±3.7 mg, *N*=6] were pooled and macerated in distilled water (1 mg/ml) followed by filtration (<0.45 μm). Salt (Instant Ocean) was added to the anal gland macerate and control distilled water to obtain a salinity equivalent to that of seawater (35 ppt), and aliquots were stored at −20°C until use. The anal gland macerate was diluted in seawater and delivered into the test area at a concentration of 0.1 μg/ml. Mussels (*Mytilus* spp.) were macerated in the same way and tested at 0.1 mg/ml with non-reproductive females.

Isolation of Male Odorants We assessed the molecular-weight range and relative hydrophilicity of odorants from the anal gland. To estimate the molecular-weight range, fully developed glands [33.5±6.7 mg (mean ± SD), *N*=6] and two portions of skin (35.1±5.9 mg) from the lateral-dorsal area of the body (as control) were removed from anesthetized males as previously described. Tissues were pooled and macerated in distilled water (1 mg/ml) and filtered (<0.45 μm). Part of each pooled macerate (including a water-only control) was frozen at −20°C for later use. The remainder was ultra-filtered by centrifugation at 4°C through 10 kDa, then through 3 kDa filters (Centriprep YM-10, Amicon, Millipore, Madrid, Spain), and finally through a 500 Da filter (Ultrafiltration Membranes 500, Amicon Limited, Stonehouse, UK) according to the manufacturer's instructions. Each fraction was kept at −20°C until use (see below).

To assess the involvement of non-polar, hydrophobic molecules, two different solid-phase extraction (SPE) sorbents were used. Fully developed anal glands [78.4±2.8 mg (mean ± SD), *N*=6] and anal-fin rays (73.1±5.1 mg, *N*=6) were removed and macerated in distilled water (1 mg/ml) as described previously. Half of each filtered (<0.45 μm) macerate was frozen at −20°C, and the other half was passed through two different SPE columns. Part of the anal gland macerate was passed through C18 columns (500 mg packed in 6-ml glass cartridges, IST—Isolute Sorbent Technology, Glamorgan, Hengoed, UK), which are used to separate and concentrate non-polar organic compounds from water (e.g., steroids; see Scott and Ellis 2007 and references therein). The remainder of the macerate was passed through columns with layered phases of C2 over ENV+ (C2/ENV+, 500/200 mg packed in 6-ml glass cartridges, IST), which are used to trap a wider range of compounds from water (Ingvarsdóttir et al. 2002). Both column types were previously activated with HPLC grade methanol (2 ml) followed by washing with distilled water (2 ml). The substances retained on the column were eluted with bi-distilled ethanol (2 ml). The macerate of anal fin rays was passed through the C2/ENV+ columns only. Water-only control separations were also carried out with both types of column. Both filtrate and eluate were kept at −20°C until use (see below).

Extracts of water conditioned by breeding males with fully developed anal glands (before and after excision) were fractionated by HPLC and the olfactory potency of fractions assessed on females. Males with fully developed anal glands [length=116±6 mm (mean ± SD), *N*=6; weight=25.1±2.8 g, gland area=18.6±2.7 mm^2] were captured during the breeding season (late May). Males with partially developed anal glands [length=110±3 mm (mean ± SD); weight=20.8±1.8 g, gland area=12.8±2.4 mm^2] captured during April were used to assess whether excision of their undeveloped anal glands affects the olfactory potency of male-conditioned water. Artificial seawater was conditioned as described previously (5 g fish/l), and C2/ENV+ columns were used to extract male-conditioned water (approximately 1 l of fish-conditioned water or control water per column) before and after anal gland excision (as described above). Male-conditioned water and control water were stored at −20°C until use. Ethanol eluates of male-conditioned water were dried under a stream of nitrogen, re-dissolved in methanol, and aliquots (20 μl of each eluate) were fractionated with a Shimadzu LC-10AD HPLC system equipped with a reverse-phase C18 column (250×4.6 mm, Phenomenex, UK). Eluting compounds were detected by UV (254 nm). Gradient elution (1 ml/min) was used (100% water, 0–3 min; 0–100% methanol, 3–28 min; 100% methanol, 28–60 min), and 5-min fractions were collected. These were then evaporated under high vacuum and kept at −20°C until assessment of their olfactory potency (see below).

Recording of the EOG and Data Analysis To our knowledge, EOGs have not been recorded before in blennies. Perhaps, this is because the vast majority lives in seawater, and nostrils lack a lamellar olfactory rosette at the bottom of the olfactory chamber as typical of many fishes. Instead, female *S. pavo* have two adjacent olfactory lamellae that extend from the dorso-lateral wall of the olfactory chamber (J. Araújo, O. Lopes, and E.N. Barata, unpublished data).

To reduce the shunting effect of seawater, recording of the EOG in females was carried out in 12 ppt seawater (females were pre-adapted to this salinity in two steps over at least 5 d before recording). Females were anesthetized by immersion in water that contained 100 mg/l MS222 followed by subcutaneous injection of 30 μl/10g Saffan™ (Schering-Plough Animal Health, Welwyn Garden City, UK) and placed on a padded V-clamp. Aerated seawater (12 ppt) was pumped over the gills (approximately 100 ml/100 g fish weight per minute) *via* a plastic tube inserted into the mouth. Attempts to record EOGs from exposed olfactory epithelium by cutting the skin and bone surrounding the olfactory chamber were not successful. Recording of EOGs was achieved by positioning the stimulus delivery tube and recording electrode as described by Murphy et al. (2001). L-Cysteine (10^{-5} M) was used as standard stimulus instead of L-alanine. The olfactory chamber was continually irrigated with 12 ppt seawater *via* a gravity-fed system (4 ml/min), which terminated in a small glass tube (stimulus delivery tube) positioned in the exhalent nostril, creating a reversed water flow (into the exhalent nostril and out of inhalant nostril). Odorant-containing water was introduced into this flow *via* a three-way valve for 10 sec. The resulting EOG was recorded differentially with electrodes made from boro-silicate glass micropipettes (tip diameter, 0.2 mm) filled with 3 M NaCl in 1% agar. The recording electrode was placed inside the inhalant nostril at a position that gave the largest response to the standard stimulus (10^{-5} M L-cysteine); the olfactory response to amino acids (data not shown) was similar to that described for other species (Hara 1994). The reference electrode was placed lightly on the skin of the head. The fish was grounded *via* an Ag–AgCl pellet electrode placed under the head. The DC signal was connected to solid-state electronics *via* Ag–AgCl electrodes (in contact with 3 M KCl). The signal was filtered (low-pass 30 Hz), amplified (2,000- to 5,000-fold) with a CP122 AC/DC strain gauge amplifier (Grass Instrument Division, Astro-Med, Inc., West Warwick, RI, USA); see Velez et al. (2005) for further details. Larger females (between 7 and 10 cm SL) were chosen because the nostrils of smaller females were too small. The reproductive condition of the females was not assessed before or after the experiment. Most females survived the experiment, and after 1–2 wk in aquaria at 35 ppt, they were released at their place of capture.

All stimuli were dissolved in diluted seawater (12 ppt). Before dilution, the ethanol of the SPE eluates was evaporated, and the macerated tissues and their respective filtrates were lyophilized. Groups of related stimuli were tested on the same females, e.g., eluates of water conditioned by males before and after anal gland excision. The order in which the stimuli were given varied among fish. Macerates, centrifugal fractions, and SPE fractions from tissue were applied at 0.1 mg/ml; SPE eluates and HPLC fractions of fish-conditioned water were given at 50 mg fish/ml. Concentrations below these did not evoke responses consistently higher than that of blank (stimulus-free background water treated in exactly the same way as stimulus solutions). Between groups of related stimuli, responses to background water 'blank' and to 10^{-5} M L-cysteine were recorded.

In general, the form of the recorded EOG was typical of fish, i.e., a rapid negative deflection at stimulus onset, which was followed by a period of adaptation in the continued presence of the stimulus. However, this adaptation was sometimes rapid, and the signal returned to baseline levels in the presence of the stimulus soon after the initial peak, and sometimes more slowly, only returning to baseline after the cessation of the stimulus. In each case, however, only the amplitude of the initial peak was measured in millivolts. The mean of the preceding and following response to background water 'blank' was subtracted from each response, which was then normalized to the mean of the preceding and following responses to 10^{-5} M L-cysteine (also blank-subtracted); the statistical analysis was done on these normalized EOG responses. Data were tested for normality and homogeneity of variance and, if necessary, were $\log_{10}(n+1.5)$-transformed to reduce variance heterogeneity between groups.

Centrifugal (molecular weight) fractions of macerated skin and anal glands were tested on different groups of five females, and fractions of the same tissue were tested on the same female. Due to heterogeneity of variances among the variables that could not be eliminated through data transformation, non-parametric statistical tests were used. Friedman's ANOVA test was used to compare EOG responses within each group of females to fractions from extracts of the same tissue (skin or anal gland), whereas the Mann–Whitney *U* test was used to compare female EOG responses to equivalent fractions of the two male tissues (skin and anal gland).

One-way repeated measures ANOVA followed by the Tukey Honest Significance Difference test (Tukey HSD) was used to compare (1) the EOG responses of five females to macerated male tissues (fully developed anal glands and fin rays) and corresponding SPE fractions (eluate and filtrate) and (2) the EOG responses of six females to SPE eluates of water conditioned by males with fully developed and partially developed anal glands, before and after the excision of the glands. Student's *t* test for paired samples was used to compare the EOG responses (five females) to equivalent HPLC fractions of eluates of water conditioned by males before and after anal gland excision.

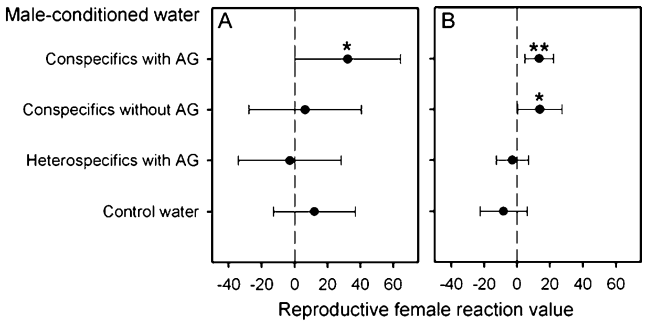

Fig. 1 Reaction values (mean±95% CL) of *Salaria pavo* reproductive females in the fluviarium with water conditioned by conspecific males with anal glands (with AG, N=26); water conditioned by the same males after anal gland excision (without AG, N=24 females); water conditioned by *Salaria fluviatilis* males with anal glands (heterospecifics with AG, N=27); and control water (N=47) during **a** the initial upstream movement (*t_{25}=2.07, P<0.05) and **b** during entire 5-min period of observation (*t_{23}=2.11, P<0.05; **t_{25}=3.13, P<0.01). The variance of female reaction values for conspecific males without anal glands was significantly larger than that of reaction values for intact conspecific males during the entire 5-min period of observation ($F_{24,26}$=2.14, P<0.05)

Results

Behavioral Responses of Females Females in the fluviarium left the fish box and, with successive upstream swimming bouts, reached the edge of the test area close to the stimulus or the control side of the device. After this initial upstream movement, females stayed at the upstream edge for a while (sometimes swimming against the net limiting the test area or across the upstream edge), then swam downstream, eventually moved across the test area, and swam upstream again; females repeated these movements in the test area several times between periods of stillness.

Reproductive females tested with water conditioned by intact conspecific males swam initially upstream along the side, or in the water column, carrying the chemical substances. In contrast, reproductive females tested with water conditioned by conspecific males without anal glands, intact heterospecific males, or control water did not show a preference for either side (Fig. 1a). During the entire 5-min observation, females swam preferentially along the side of the fluviarium containing either water conditioned by conspecific males with or without the anal glands, whereas no preference was shown with water conditioned by intact heterospecific males or control water (Fig. 1b). However, the variability of female reaction values in response to water conditioned by conspecific males without anal glands was greater than that to water conditioned by intact conspecific males (Fig. 1b). During the initial upstream movement, the locomotion parameters were not different among the four groups of reproductive females (Table 1). Furthermore, the time that females spent moving in the test area over the entire observation period was not different [conspecific males with anal glands, 166.7± 9.0 sec (mean ± SEM); conspecific males without anal glands, 163.4±9.5 sec; intact heterospecific males, 153.5±11.4; control water, 140.9±10.3 sec; $F_{3,120}$=1.25, P=0.295].

For the anal gland macerates from conspecifics, reproductive females initially swam upstream along the stimulus side of the fluviarium but did not show a preference for either side when the stimulus was from heterospecific males (Fig. 2a). During the total observation period, however, females showed no preference for either side in response to either treatment (Fig. 2b). Non-reproductive females tested for the macerate of anal glands from conspecific males did not show a preference during the initial upstream movement or throughout the total observation period. However, non-reproductive females swam preferentially along the stimulus side of the fluviarium in response to the mussel positive control during both initial upstream movement and the total observation period (Fig. 2a, b). The locomotory parameters of initial upstream movement (Table 2) and time

Table 1 Parameters (mean ± SEM) that characterize the initial upstream movement of *Salaria pavo* females in the fluviarium (male-conditioned water)

Parameter[a]	Control[b]	Conspecifics with anal glands[c]	Conspecifics without anal glands[d]	Heterospecifics with anal glands[e]
Latency to up-stream edge (sec)	15.2±2.2	22.9±4.8	22.3±5.1	15.2±2.3
Linear velocity (cm/sec)	8.7±0.5	7.7±0.6	7.4±0.7	7.4±0.5
Angular velocity (deg/cm)	5.6±0.5	5.2±0.7	5.5±0.7	4.8±0.4
Number of movements	4.7±0.5	7.0±1.2	7.7±1.6	5.6±0.7

[a] The locomotion parameters were not significantly different among the four groups of females (one-way ANOVA): latency to up-stream edge of the test area, $F_{3,120}$=1.50, P=0.219; mean linear velocity, $F_{3,120}$=1.43, P=0.238; mean angular velocity, $F_{3,120}$=0.42, P=0.737; number of movements, $F_{3,120}$=2.15, P=0.100.
[b] Reproductive females without any male-related stimulus (control) (N=47 females).
[c] Reproductive females tested to water conditioned by conspecific males with anal glands (N=26 females).
[d] Reproductive females tested to water conditioned by conspecific males without anal glands (N=24 females).
[e] Reproductive females tested to water conditioned by heterospecific males (*Salaria fluviatilis*) with anal glands (N=27 females).

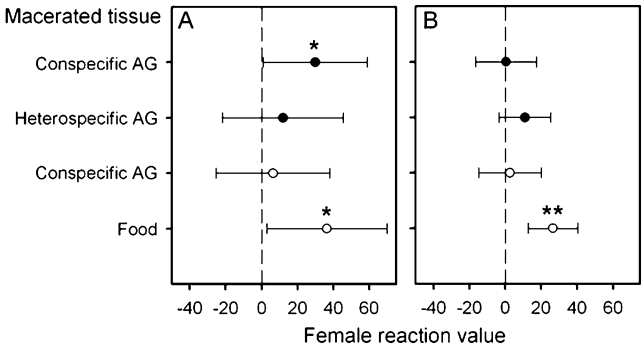

Fig. 2 Reaction values (mean±95% CL) of reproductive (*filled circles*) and non-reproductive (*open circles*) *Salaria pavo* females in the fluviarium with an anal gland macerate from conspecific males (reproductive, N=37; non-reproductive, N=33), an anal gland macerate from *Salaria fluviatilis* (reproductive, N=29), and a macerate of food (mussels), *Mytilus* spp. (non-reproductive, N=23) during **a** the initial upstream movement (*reproductive, t_{36}=2.17, P<0.05; non reproductive, t_{22}=2.78, P<0.05) and **b** the entire 5-min period of observation (**non-reproductive, t_{22}=4.02, P<0.01)

spent moving during the total observation period were not different among the four groups of females [reproductive females tested with conspecific anal glands, 129.1±6.9 sec (mean ± SEM); reproductive females tested with heterospecific anal glands, 127.6±6.6 sec; non-reproductive females tested with conspecific anal glands, 140.2±7.4; non-reproductive females tested with food-odor, 129.6± 5.7 sec; $F_{3,118}$=0.73, P=0.537].

EOG Responses to Anal Gland Odorants Females gave different amplitude responses to different molecular-weight fractions from the anal gland macerate (Friedman ANOVA, N=5, df=3, χ^2=14.76, P<0.005) and the skin macerate (Friedman ANOVA, N=5, df=3, χ^2=13.70, P<0.005; Fig. 3). The majority of the anal gland olfactory potency resided in the less than 500 Da fraction of the macerate. However, odorants with a molecular weight greater than 500 Da were also present. In the skin macerate, all olfactory activity was found in the <500 Da fraction. The anal gland macerate evoked larger EOG amplitudes than the skin macerate (Mann–Whitney U test, Z=2.40, P<0.05). Although not significantly different (Mann–Whitney U test, Z=1.78, P=0.07), the fraction containing substances less than 500 Da from the anal gland macerate evoked larger EOG amplitudes than that of skin macerate.

The olfactory potency of the C2/ENV+ eluate was not different from that of the original anal gland macerate. Both the macerate and the eluate evoked larger EOG amplitudes than the filtrate (Fig. 4). The olfactory potency of the fin-ray macerate was weaker than that of the anal gland, and the C2/ENV+ sorbent only extracted a fraction of the olfactory activity; olfactory potency of the eluate was less than that of the macerate. The sum of the EOG amplitudes elicited by either fraction was approximately equal to that of the untreated macerate (Fig. 4). The EOG responses to the anal gland macerate and corresponding C18 filtrate and eluate showed that the potency of the filtrate was stronger than that of the eluate and not significantly different from the original macerate (data not shown). This type of sorbent is, therefore, ineffective in extracting the odorants from the anal gland.

EOG Responses to Eluates of Male-Conditioned Water and their HPLC Fractions The eluate of water conditioned by males with fully developed anal glands elicited the largest EOG responses, and subsequent excision of the glands caused a decrease in olfactory potency (Fig. 5). In contrast, the olfactory potency of water conditioned by males with partially developed anal glands was not affected by their excision (Fig. 5). The eluate of water-only control elicited lower responses than the eluates of male-conditioned water (data not shown).

Table 2 Parameters (mean ± SEM) that characterize the initial upstream movement of *Salaria pavo* females in the fluviarium (macerated tissues)

Parameter[a]	Reproductive females		Non-reproductive females	
	Conspecific anal glands[b]	Heterospecific anal glands[c]	Conspecific anal glands[d]	Food macerate[e]
Latency to up-current edge (sec)	16.7±3.3	16.6±3.8	16.7±3.1	21.0±2.9
Linear velocity (cm/sec)	9.0±0.3	9.2±0.7	9.0±0.5	8.0±0.4
Angular velocity (deg/cm)	5.5±0.6	4.5±0.4	5.0±0.5	5.2±0.6
Number of movements	5.8±1.1	5.1±0.6	4.5±0.5	6.3±0.9

[a] The locomotion parameters were not significantly different among the four groups of females (one-way ANOVA): latency to up-stream edge of the test area, $F_{3,118}$=0.35, P=0.793; mean linear velocity, $F_{3,118}$=0.97, P=0.411; mean angular velocity, $F_{3,118}$=0.86, P=0.463; number of movements, $F_{3,118}$=0.90, P=0.445.
[b] Reproductive females tested to water with macerated anal glands from conspecific males (N=37 females).
[c] Reproductive females tested to water with macerated anal glands from heterospecific (*Salaria fluviatilis*) males (N=29 females).
[d] Non-reproductive females tested to water with macerated anal glands from conspecific males (N=33 females).
[e] Non-reproductive females tested to water with macerated mussels, *Mytilus* spp. (N=23 females).

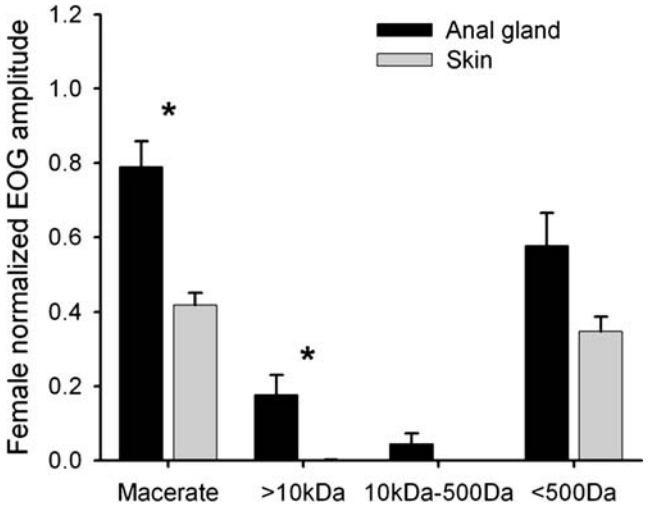

Fig. 3 Normalized EOG amplitudes (mean + SEM) of *Salaria pavo* females (N=5) to macerates and corresponding molecular weight fractions (>10 kDa, between 10 kDa and 500 Da, and <500 Da) of anal gland (*solid bar*) and skin (*gray bar*) extracts. Concentration of macerates and fractions: 0.1 mg/ml. Significant differences (Mann–Whitney U test) between equivalent fractions of the two tissues are indicated, *P<0.05)

The EOG responses to HPLC fractions of water conditioned by males with fully developed anal glands (Fig. 6) showed that the three 5-min fractions eluting between 0–15 min (F1–F3) elicited significantly higher EOG amplitudes than the same fractions after anal gland excision (t_4=7.43, P<0.01 for F1; t_4=5.18, P<0.01 for F2 and t_4=8.69, P<0.001 for F3). The percentage of methanol in the mobile phase increased from zero to about 48%

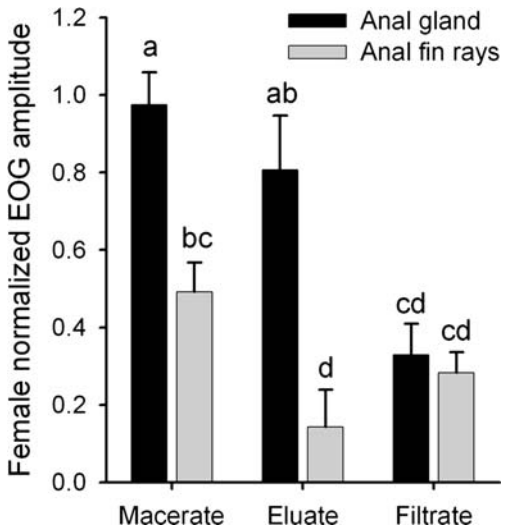

Fig. 4 Normalized EOG amplitudes (mean + SEM) of *Salaria pavo* females (N=5) to macerates and corresponding solid phase extraction fractions (eluate and filtrate) of male anal gland (*black bar*) and anal fin ray (*gray bar*) tissues. Concentration of macerates and fractions was 0.1 mg/ml. *Different letters above the bars* indicate significant differences (repeated-measures ANOVA, $F_{5,20}$=12.98, P<0.001, followed by Tukey HSD test, P<0.05). Solid phase extraction was performed with a 6-ml glass cartridge packed with C2/ENV+

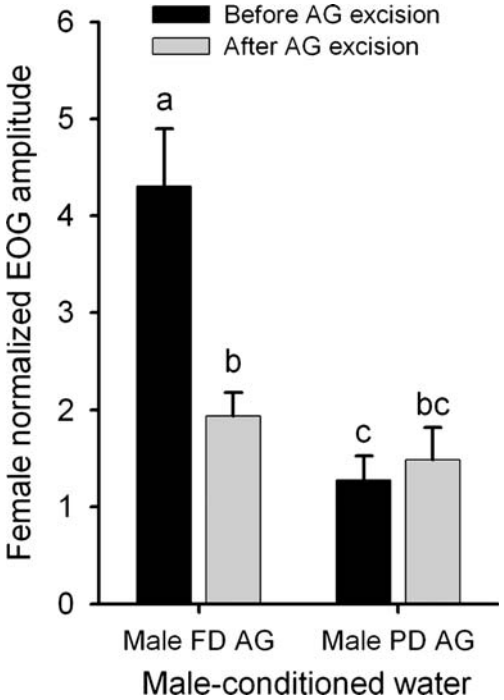

Fig. 5 Normalized EOG amplitudes (mean + SEM) of *Salaria pavo* females (N=6) to SPE eluates of male-conditioned water at 50 mg fish-weight/ml. Male-conditioned water before (*black bar*) and after (*gray bar*) removal of fully developed (*FD*) or partially developed (*PD*) anal gland (*AG*). *Different letters above the bars* indicate significant differences (repeated-measures ANOVA, $F_{3,15}$=185.88, P<0.001, followed by Tukey HSD test, P<0.01). Solid phase extraction was performed with a 6-ml glass cartridge packed with C2/ENV+

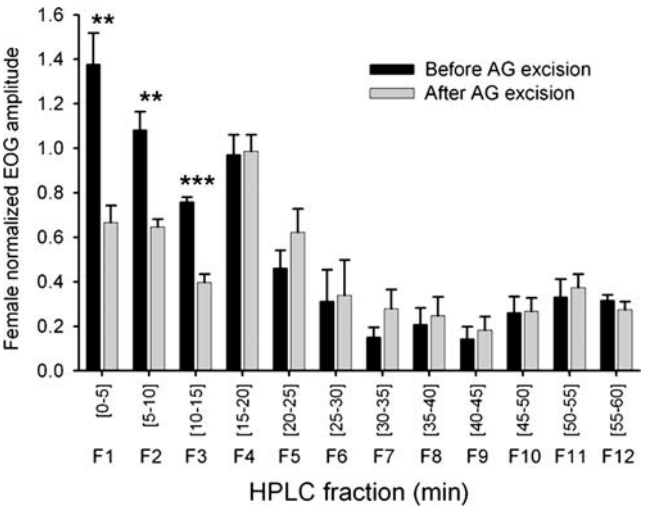

Fig. 6 Normalized EOG amplitudes (mean + SEM) of *Salaria pavo* females (N=5) to 5 min HPLC fractions (50 mg fish-weight/ml) of SPE eluates (extraction with 6-ml glass cartridge packed with C2/ENV+) of water conditioned by breeding males before (*solid bar*) and after (*gray bar*) excision of fully developed anal glands (*AG*). Significant differences (Student's t test for paired samples) are indicated,**P<0.01 or ***P<0.001)

during the elution of these fractions (F1, from 0% to 8%; F2, up to 28%; F3, up to 48%). The fraction eluting between 15 and 20 min (F4; up to 68% methanol in the mobile phase) also elicited relatively large EOG amplitudes, but no significant differences were found between before and after anal gland excision (t_4=0.24, P=0.82). The eight fractions eluting later than 20 min (F5 to F12) elicited relatively small EOG amplitudes without any differences (P>0.05) between males with or without anal glands. The chromatograms obtained at 254 nm could not be related to the pattern of EOG responses and, therefore, are not shown.

Discussion

We present new evidence on the putative pheromonal system of the peacock blenny and possibly other blenniids. First, reproductive females were attracted to male-conditioned water (whole male odor) and to anal gland macerates (anal gland odor) from conspecifics but not to those of heterospecifics, suggesting that attraction to putative male pheromones is species-specific. Second, although reproductive females were initially attracted to conspecific anal gland odor, this response was ephemeral compared with that to whole male odor. Furthermore, whole odor from males without anal glands attracted reproductive females over 5 min; however, female attraction was significantly more variable than that to whole odor from intact males, and during initial upstream movement, females were not attracted to odor of males without anal glands. These observations suggest that attraction of reproductive *S. pavo* females to conspecific males possibly involves a multicomponent pheromone that consists of the putative anal gland pheromone and another components not originating from the anal glands. Finally, non-reproductive females were not attracted to conspecific anal gland odor, thus supporting a role for the putative anal gland pheromone in mate-location and mate-choice as previously suggested (Barata et al. 2008).

Previous assays (Barata et al. 2008) carried out in Y-maze flow-through tanks (about tenfold larger than the fluviarium) showed that reproductively competent females are attracted to odor of intact males and anal gland odor but not to odor of males without anal glands or female odor. These results apparently contradict the current study in which reproductive females were attracted to odor of males without anal glands and initially attracted to anal gland odor. With respect to the anal gland, the difference could be due to different concentrations used in the two assays (at least 50-fold higher in the Y-maze than the fluviarium). However, differences in concentration cannot account for the different responses to male-conditioned water without anal glands (at least 16-fold lower in the fluviarium than the Y-maze).

Common to both assays is the preference of females to swim initially upstream along the side containing odor of intact males or anal gland odor, showing no preference for the side containing odor of males without anal glands. In the fluviarium, as in the Y-maze, females were not attracted to whole odor of males without anal glands during their initial upstream movement. However, in contrast to the Y-maze, females in the fluviarium could move freely between the two odor plumes, and therefore, attraction to odor from males without anal glands during the entire observation period could be assessed. The comparison of these two results suggests that the anal gland odor especially affects female spatial orientation when they initially swim towards the odor source, whereas whole male odor has the additional effect of arresting females within it. Possibly, in the natural environment, the anal gland odor initially attracts females to closer proximity where other components of male odor may be important in the mate-choice and/or to entice females into the nest. Intact male blennies get more visits from reproductive females and receive more eggs in their nests than males without anal glands (Barata et al. 2008).

The current study also shows that the majority of odorants released by the anal glands of breeding males are hydrophilic molecules smaller than 500 Da. In addition, breeding males release other, less hydrophilic odorants (especially olfactory-active in HPLC fraction F4) that do not originate from the anal gland. Possibly, the highly hydrophilic odorants in male water constitute the putative anal gland pheromone, whereas the less hydrophilic potent odorants constitute another male pheromone.

The anal glands of *S. pavo* consist of extensive integumental folds in the first two anal fin rays, with numerous clusters of secretory cells that differentiate during the breeding season. The ultra-structure of the secretory cells indicates intense glycoprotein synthesis, especially of neutral mucins (Serrano et al., unpublished data). Most of the proteinaceous material in the anal glands is hydrophilic, whereas only a relatively small amount is hydrophobic (Giacomello et al. 2006). Therefore, further studies should address whether proteins and/or enzyme products of such proteins (such as small peptides and/or amino acids) constitute the putative anal-gland pheromone. In some newts, male abdominal glands produce and release protein-derived peptides that are female-attractive pheromones (Toyoda et al. 2004; Kikuyama et al. 2005). Furthermore, skin glands of anuran males secrete peptide pheromones that attract conspecific females (Wabnitz et al. 2000; Kikuyama et al. 2005). In crustaceans and other marine invertebrates, there is increasing evidence for peptide-like pheromones and kairomones and substituted amino sugar kairomones derived from enzyme action on glycoproteins and proteoglycans (Rittschof and Cohen 2004). Whether

the anal gland pheromone of male blennies consists of peptides, peptide-derivatives of larger protein precursors synthesized by the anal gland secretory cells, or another type of hydrophilic molecule, its release together with mucus would suggest a sustained, slow release by males in their nest.

The less-hydrophilic potent odorants found in odor of breeding males with and without anal glands (HPLC fraction F4) may derive from the testes. Blennies have two testicular accessory organs that produce steroids, the testicular glands and the testicular blind pouches. In each testis, the testicular gland consists of irregularly arranged tubules formed by a monolayered epithelium of cells that secrete glycoproteins (acidic mucins—sialomucins) and steroid-producing cells (do not seem to produce steroid glucuronides) in the *interstitium* (Seiwald and Patzner 1989) that are the major source of 11-ketotestosterone (Oliveira et al. 2001). However, 11-ketotestosterone did not elicit significant EOG responses in females (data not shown). In contrast, secretory cells lining the epithelium of the blind pouches seem to produce mainly steroid glucuronides (Lahnsteiner et al. 1993). Although the blind pouch fluid is a potent odorant (data not shown), it is not known whether the odorants are steroid glucuronides that could act as sex pheromones by analogy with marine and freshwater gobies (Colombo et al. 1980; Murphy et al. 2001; Belanger et al. 2004; Arbuckle et al. 2005; Gammon et al. 2005).

Taken together, the results show that *S. pavo* males release a species-specific odor that attracts reproductively competent females. This odor consists of hydrophilic odorants from the anal gland and less hydrophilic odorants that possibly originate from the testes or blind pouches. Therefore, we suggest that male blennies release a complex multicomponent pheromone to attract reproductively competent females.

Acknowledgments This work was funded by the Treaty of Windsor (British Council/CRUP, grants B-14/03 and B-90/04) and by Ministry of Science and Higher Education and European Social Funds through the Portuguese National Science Foundation (FCT): project POCTI/BSE/45843/2002, and Ph.D. fellowship (SFRH/BD/6670/2001) to R. Serrano. Chemical Characterization of Territorial Marking Fluid of Male Bengal Tiger, *Panthera tigris*

B. V. Burger · M. Z. Viviers · J. P. I. Bekker · M. le Roux · N. Fish · W. B. Fourie · G. Weibchen

Received: 13 June 2007 / Revised: 15 February 2008 / Accepted: 2 March 2008 / Published online: 24 April 2008

Abstract The territorial marking fluid of the male Bengal tiger, *Panthera tigris*, consists of a mixture of urine and a small quantity of lipid material that may act as a controlled-release carrier for the volatile constituents of the fluid. Using gas chromatography and gas chromatography–mass spectrometry, 98 volatile compounds and elemental sulfur were identified in the marking fluid. Another 16 volatiles were tentatively identified. The majority of these compounds were alkanols, alkanals, 2-alkanones, branched and unbranched alkanoic acids, dimethyl esters of dicarboxylic acids, γ- and δ-lactones, and compounds containing nitrogen or sulfur. Several samples of the marking fluid contained pure (*R*)-3-methyl-2-octanone, (*R*)-3-methyl-2-nonanone, and (*R*)-3-methyl-2-decanone, but these ketones were partly or completely racemized in other samples. The γ-lactone (*S*)-(+)-(*Z*)-6-dodecen-4-olide and the C_8 to C_{16} saturated (*R*)-γ-lactones and (*S*)-δ-lactones were present in high enantiomeric purities. The chiral carboxylic acids, 2-methylnonanoic acid, 2-methyldecanoic acid, 2-methylundecanoic acid, and 2-ethylhexanoic acid were racemates. Cadaverine, putrescine, and 2-acetylpyrroline, previously reported as constituents of tiger urine, were not detected. The dominant contribution of some ketones, fatty acids, and lactones to the composition of the headspace of the marking fluid suggests that these compounds may be important constituents of the pheromone. Although it constitutes only a small proportion, the lipid fraction of the fluid contained larger quantities of the volatile organic compounds than the aqueous fraction (urine). The lipid derives its role as controlled-release carrier of the chemical message left by the tiger, from its affinity for the volatiles of the marking fluid. Six proteins with masses ranging from 16 to 69 kDa, *inter alia*, the carboxylesterase-like urinary protein known as cauxin, previously identified in the urine of the domestic cat and other felid species, were identified in the urine fraction of the marking fluid.

Introduction

The tiger, *Panthera tigris*, is the largest existing member of the Felidae. Of the six subspecies of tiger, the Bengal tiger, *P. tigris tigris*, occurs throughout India and Indochina (Ellerman and Morrison-Scott 1951). The wide geographical distribution implies a great adaptability to different environmental conditions; the only requisites for its

survival are some vegetative cover, a supply of water, and sufficient prey (Schaller 1967). Tigers are normally solitary animals but occasionally travel in groups of four to eight (Schaller 1967). They use different sounds, postures, and gestures to communicate with each other when they are together (Leyhausen 1960). Although vocal communication is the main form of communication, they vocalize relatively infrequently (Schaller 1967). Because of their nocturnal and solitary habits, they make extensive use of semiochemical communication, in which urine and feces appear to be the main vectors of the semiochemicals. Urine mixed with scent gland secretions is sprayed as a territorial marking fluid on conspicuous objects. Apparently, it is a common way of signaling that another tiger is in the vicinity, providing a visitor the opportunity to avoid conflict (Leyhausen and Wolff 1959). It is thought that these scent marks are a major source of information, revealing how recently a tiger has passed by, its gender, and in the case of a female, whether she is sexually receptive. Both sexes mark territories, but a male's territory may overlap several females' territories (Schaller 1967). Females scent mark intensively just prior to estrus. This behavior is reduced during estrus. Males, on the other hand, mark more frequently when females are in estrus than during other stages of the females' cycle (Smith et al. 1989). Another source of semiochemicals is the strong-smelling secretion produced by the anal glands, which, when mixed with the feces, is also used to mark territory. Because there is no connecting channel between the urinary tract and the anal gland (Hashimoto et al. 1963), it has been concluded that the marking fluid does not contain anal gland secretion (Brahmachary and Dutta 1987).

Brahmachary and Dutta (1979) described some of the chemical and physical properties of the animal's marking fluid. 2-Phenylethylamine (Brahmachary and Dutta 1979) and 2-acetylpyrroline (Brahmachary 1996) were identified as two of the compounds responsible for the characteristic odor of the animal's urine. This odor was less persistent in the absence of the lipid fraction of the fluid (Brahmachary et al. 1990). The lipid material consists of a complex mixture of, *inter alia*, long-chain free and esterified saturated and unsaturated fatty acids and alcohols with carbon chains of 14 to 22 carbon atoms (Poddar-Sarkar 1996).

In bioassays carried out during investigation into the semiochemical role of the urine of the cheetah, *Acinonyx jubatus* (Burger et al. 2006b), it was observed that whereas a male Bengal tiger showed minimal interest in the cheetah's urine and in various other odorants used as controls, it immediately attempted to overmark a mixture of a few of the synthetic constituents of its own marking fluid. These constituents have not been reported in earlier studies on the tiger's marking fluid, suggesting that some constituents of the marking fluid were not detected in previous studies. In this paper, we report our attempts at a comprehensive chemical characterization of the volatile organic fraction of the tiger's marking fluid and results of behavioral experiments with synthetic constituents of the marking fluid, as far as this was feasible with one pair of tigers in captivity.

In what follows, the lipid and aqueous fractions of the marking fluid will be referred to as the lipid fraction and urine, respectively.

Methods and Materials

General All Pyrex glassware used in the handling of biological material and extracts and in the preparation of reference compounds was heated to 500°C in an annealing oven to remove traces of organic material. Dichloromethane (Pestanal Grade, Riedel-de Haën, Seelze, Germany) was analyzed by gas chromatography (GC) and found to be pure enough for extraction purposes when used in small quantities. Syringes, stainless steel needles, and other tools were cleaned by rinsing with this solvent.

Collection of Marking Fluid A pair of Bengal tigers was available for the present study at the Tygerberg Zoo near Cape Town, South Africa. Shortly before completion of our research, the female had a cub, and although she must have been in estrus during the period the work was carried out, it is not known whether the intermittent collection of marking fluid from the male on occasion coincided with estrus in the female. Spraying behavior could not be induced in the female, but marking fluid was obtained from the 5-year-old male as follows. One edge of an aluminum sheet (100×500×2 mm) was folded over to form a small gutter on that side. A hole was made at one end in the bottom of the gutter while pressing the aluminum outward to form a funnel through which the marking fluid could flow into a 100-ml glass bottle. The collection device was thoroughly cleaned with soap and water, rinsed with methanol, and heated with an industrial paint stripper. The device was suspended on the outside of the steel mesh of the tiger's cage with the fluid-collecting channel facing toward the cage and at an angle that allowed the fluid to flow into the bottle. To induce the tiger to spray its marking fluid toward the collection device, various odorants (see "Results and Discussion") were applied to the back of the aluminum. Thus, a filter paper loaded with a dilute solution of a compound (1 µl in 1 ml of dichloromethane) or a mixture of compounds (10 µl in 2 ml of dichloromethane) was taped to the back of the aluminum. The collected marking fluid was stored at −20°C until it was used for the experiments.

Analytical Methods GC analyses were carried out with Carlo Erba 4200 and 5300 gas chromatographs equipped with flame ionization detectors and split/splitless injectors, operated at 220°C and 280°C, respectively, and with cool on-column injectors. Hydrogen was used as the carrier gas (50 cm/sec at 40°C).

The capillary columns used in this project were manufactured in the Laboratory for Ecological Chemistry (LECUS, Stellenbosch University) and were provided with integrated retention gaps of 1 to 2 m. Column A (glass, 40 m×0.25 mm inner diameter [i.d.]) was coated with 0.25 μm of the polar stationary phase AT-1000 (FFAP equivalent), column B (glass, 40 m×0.25 mm i.d.) coated with 0.25 μm of PS-089-OH (DB-5 equivalent), the enantioselective columns C (glass, 30 m×0.3 mm i.d.) with 0.25 μm of OV-1701-OH containing 10% heptakis(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin), D (glass, 30 m×0.3 mm i.d.) with 0.25 μm of PS-089-OH containing 10% heptakis(2,3-di-*O*-acetyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin, E (glass, 30 m×0.3 mm i.d.) with 0.25 μm of OV-1701-OH containing 10% of heptakis (2,3,6-tri-*O*-methyl)-β-cyclodextrin, and the preparative column F (fused silica, 32 m×0.53 mm i.d.) with 2.0 μm of PS-255 (DB-1 equivalent).

Extracts of the urine and solutions of reference compounds were injected in split mode at a column temperature of 30°C to cold trap the volatiles entering the column. Column A was then programmed at 2°C from 40°C to 250°C (hold 10 min) and column B at 2°C from 40°C to 280°C (hold 10 min). Enantioselective columns C and D were programmed at 1°C from 40°C to 200°C and to 220°C, respectively, and column E at 1°C from 40°C to 140°C. The preparative column F was programmed with an isothermal period during which the particular target analyte was collected.

Synthetic 3-methyl-2-alkanones were purified by preparative GC on column F, collecting fractions manually (Burger et al. 2008). Preparative chromatography on enantioselective column C gave the pure enantiomers of synthetic 3-methyl-2-octanone (**10**). A sample enriched 2:1 with respect to the (*R*)-enantiomer with the shorter retention time on column C was used for the synthesis of 2-methylheptanoic acid enriched with respect to the second-eluting (*R*)-enantiomer.

Electron impact mass spectra (EIMS) were obtained at 70 eV on a Carlo Erba QMD 1000 GC-mass spectrometry (MS) instrument by using columns A to E with helium as the carrier gas (28.6 cm/sec at 40°C). The GC-MS interface and ion source temperatures were 250°C and 180°C, respectively. Methane was used as reactant gas at a source-chamber pressure of about 2×10^{-4} torr to obtain low-resolution chemical ionization spectra.

Quantitative analyses were done with the above GC and GC-MS instruments with on-column sample introduction, using the 11 homologous ketones from 2-heptanone to 2-heptadecanone as external standards.

^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded in $CDCl_3$ on Varian VNMR-300 or ANOVA-400 spectrometers at 25°C, or on a Bruker AMX-400 instrument at 27°C. Chemical shifts are given in parts per million (δ) relative to $CDCl_3$ (7.26 and 77.04 ppm for ^{1}H and ^{13}C NMR, respectively).

Solvent Extraction of the Volatile Organic Constituents The urine and lipid fractions of the marking fluid were separated by centrifuging 58.47 g of the collected marking fluid for 15 min at 3,000 rpm. The aqueous layer (urine) was removed with a syringe. During further prolonged centrifugation of the lipid fraction, the temperature of the material increased to about 30°C, and a supernatant layer of clear, almost colorless oil was formed. This was separated from a further small volume of urine, which was combined with the previous urine fraction. The supernatant oil (0.45 g) and the combined urine fractions (58 g) were stored at −20°C until analyzed.

Using centrifugation to facilitate separation of the phases, the organic material was repeatedly extracted from a sample (33.8 g) of the urine with 3-ml aliquots of dichloromethane, monitoring the removal of the organic material by GC-MS analysis. The extraction was terminated after the 15th extraction cycle. The combined extracts (approximately 40 ml) were concentrated to about 60 μl by slow evaporation of the solvent under nitrogen atmosphere, without blowing nitrogen directly into the vial containing the extract (Reiter et al. 2003). As the solvent was evaporated, the extract was transferred to increasingly smaller vials. Aliquots of 1.0 μl of the concentrated solution were analyzed by GC and GC-MS.

A second sample of marking fluid was centrifuged to separate the lipid and urine fractions. The urine was subjected to five extraction cycles with methyl *tert*-butyl ether (Extra pure, Merck, Darmstadt, Germany). The combined extracts were concentrated under argon atmosphere to 50 μl. Aliquots were used for the determination of double-bond positions in the unsaturated constituents by dimethyl disulfide (DMDS) derivatization and GC-MS analysis (Vincenti et al. 1987).

A further urine sample (8.87 ml) was partitioned twice with methyl *tert*-butyl ether, and the combined extracts were concentrated to 7 μl and used for the quantitative determination of the sulfur content of the urine fraction by using elemental sulfur as the external standard.

Headspace Analysis A sample enrichment probe (SEP; MasChrom Analisetegniek, Stellenbosch, South Africa) was used to collect volatile organic constituents from the

headspace of both the unprocessed marking fluid and the urine fraction for GC and GC-MS analyses. This was done by exposing the sorptive phase of the SEP (28 mg of polydimethylsiloxane rubber) to the headspace of, for example, a fresh sample of the urine (e.g., 46.67 g) at 40°C for periods of 15 to 48 hr. The volatile compounds were desorbed at 220°C in the GC-MS injector, leaving the probe in the injector until completion of the analysis (Burger et al. 2006a).

Solventless Sample Introduction of the Lipid Fraction The lipid phase of the marking fluid was analyzed by GC and GC-MS for its volatile organic content using the injector-internal thermal desorption technique (Biedermann et al. 2005). Aliquots of approximately 3 to 4 mg of the lipid material were applied to the inside wall of an injector liner containing just enough silylated glass wool to prevent the lipid sample from running down the liner to the bottom of the injector. The liner was installed in the injector at 220°C, the carrier gas was turned on, and the analysis was completed in the usual manner.

Protein Analysis The urine fraction of the marking fluid used for protein analysis was kept frozen in an Eppendorf tube at −80°C until analyzed. The protein content of the urine was estimated according to Bradford (1976) using bovine serum albumin as the standard. Prior to gel electrophoresis, proteins from lipid-free urine were concentrated, and the proteins were precipitated by adding an equal volume of 20% trichloroacetic acid to each sample. The samples were left on ice for 1 hr and then centrifuged for 15 min at 4°C and 16,000×*g*. The supernatant was removed, the pellet was washed with 300 µl of ice-cold acetone, and the suspension was centrifuged as before. The supernatant was removed, and the pellet was dried, resuspended in sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (PAGE) loading buffer, denatured by heating at 65°C for 3 min, and loaded onto the gel. The proteins were analyzed by denaturing PAGE (12% SDS PAGE; Laemmli 1970) and stained with Coomassie blue according to Sambrook et al. (1989). In-gel digestion with trypsin was performed according to published methods (Shevchenko et al. 1996). The resulting partially digested peptides were separated on a Waters CapLC instrument fitted with an Atlantis dC18 column (150 mm×100 µm, bead size 3 µm). The peptides were loaded in 2% acetonitrile/0.2% formic acid (solvent A), and the column was eluted by using a linear gradient from 3% of solvent B (98% acetonitrile/0.2% formic acid) to 100% of solvent B in 50 min at a flow rate of 1.5 µl/min. MS/MS data of the eluting peptides were acquired from *m/z* 400 to 1,995 at 0.5 sec per scan and an interscan delay of 0.1 sec by nano-electrospray quadrupole time-of-flight MS (Waters API Q-TOF Ultima). The resulting data were analyzed by the Matrix software. Fragments were sequence identified by database searches against publicly available mammalian databases using the Mascot search engine (Perkins et al. 1999) and confirmed using the Basic Local Alignment Search Tool (BLAST; Altschul et al. 1990). Probability-based MOWSE (Perkins et al. 1999) scores were estimated by comparing searched results against an estimated random match population and were reported as $-10\times\log_{10}(P)$, with P as the absolute probability.

Reference Compounds Most of the compounds required for comparison with constituents of the marking fluid were purchased from Sigma-Aldrich (Cape Town) or other chemical suppliers or were synthesized during previous research projects. The syntheses of 3-methyl-2-octanone (**10**), 3-methyl-2-nonanone (**14**), (*R*)-2-methylheptanoic acid, 2-methylnonanoic acid (**77**), 2-methyldecanoic acid (**84**), 2-methylundecanoic acid (**89**), dimethyl succinate (**33**), dimethyl glutarate (**43**), dimethyl adipate (**55**), *N*-benzylidenepentylamine (**51**), *N*-pentylurea (**104**), *N*-benzylidene-2-phenylethylamine (**117**), and (*S*)-(+)-(*Z*)-6-dodecen-4-olide (**86**) are described in the Supplementary Information for this article.

Results and Discussion

In a project aimed at finding ways to count cheetah in the wild, Balme (2005) found that the animals were attracted to various perfumes, notably to Obsession for Men by Calvin Klein. To obtain territorial marking fluid for the present research, attempts were made to elicit territorial marking behavior by both the male and the female tigers, by applying different odorants to the back of the aluminum sheet that was used to collect the marking fluid. The male tiger reacted to dodecan-4-olide (**85**), (*Z*)-6-dodecen-4-olide (**86**), the perfume Elle (Paco Rabanne), and a synthetic mixture of the compounds that were identified early in the investigation (mixture A, Table 1) by spraying urine/marking fluid in the direction of the collection device, but it ignored DMDS, musk ambrette (Haarman & Reimer, Johannesburg), and the perfume Romance (Ralph Lauren). No clear relationship between the unpleasantness of an odor (to the human nose) and the reaction of the tiger was observed. As could be expected, the tiger marked more readily just after his cage had been cleaned. Marking behavior was stimulated most by the synthetic mixture and by the perfume Elle. The major constituents of this perfume were not detected in the marking fluid that was collected when this perfume had been used to induce spraying behavior, proving that the collected fluid was not contam-

inated by the stimulant. Generally, relatively small volumes of the marking fluid were recovered, largely because the tiger usually started spraying before having fully turned his back on the collection device. Nevertheless, on two occasions, it was possible to collect 100-ml quantities of fresh fluid. In contrast to the cheetah, *A. jubatus*, which avoided turning its back on its reflection in the shiny aluminum surface, the tiger sprayed more readily after having inspected the shiny surface than when it was presented with a surface sprayed with green lacquer.

When left standing, the marking fluid separated into two layers: a bottom urine layer and a small upper layer of off-white material. Centrifugation and separation of the urine from the upper layer produced a supernatant layer of clear, viscous oil.

Two sample preparation and introduction techniques were employed for GC and GC-MS analyses. The first of these, a simplified version of the recently developed high-capacity SEP (Burger et al. 2006a), was used to collect the volatile constituents from the headspace of the urine fraction and to introduce the resulting sample into the injector of the GC or GC-MS instrument. The implementation of the simplified version of the SEP technique does not require modification of the injector of the GC. In general practice and depending on the application, this technique could be more efficient than collection by solid-phase microextraction (SPME) by about two orders of magnitude (Burger and Herbert, unpublished results). The total ion chromatogram (TIC) obtained in a typical SEP analysis of the urine headspace is depicted in Fig. 1. The prominent peaks in the lower retention time range were from alcohols, aldehydes, ketones, and fatty acids, whereas γ-lactones (alkan-4-olides) and δ-lactones (alkan-5-olides) constitute some of the most prominent peaks at higher retention times. A comparison of the headspace analyses of the urine and of the whole marking fluid revealed that these liquids gave TICs with similar constituent profiles. For conventional GC and GC-MS analyses and for retention time comparison, the organic material was extracted from the urine fraction of the marking fluid with dichloromethane.

Biedermann et al. (2005) recently introduced a GC sample introduction technique, described as injector-internal thermal desorption, in which volatile organic analytes present in heavy, relatively nonvolatile oils are vaporized in the injector of the gas chromatograph, cold-trapped on the column, and analyzed in the usual manner. In this technique, the heavy oil serves as a nonvolatile solvent. If samples exceeding a critical volume are injected, the oil can run down the injector liner, and some volatile material could thus be lost. This could be a problem in quantitative analysis. However, this problem can be minimized by using a small plug of silylated glass wool in the liner to support the oil at that point. By using injector-internal thermal desorption as a sample introduction technique, excellent qualitative and quantitative results were obtained in GC and GC-MS analyses of the neat lipid fraction of the marking fluid.

The territorial marking fluid of the male Bengal tiger contained a complex mixture of compounds, distributed between the aqueous (urine) and lipid phases of the fluid. The analytical problems resulting from the presence of these two phases and particularly the coelution of a large percentage of the volatile organic constituents of the marking fluid were compounded by the presence of a number of fatty acids that eluted as broad distorted peaks from the apolar capillary columns. Therefore, most of the GC and GC-MS analytical work was done on a capillary column coated with the polar phase AT-1000 (FFAP equivalent) from which the carboxylic acids eluted as sharp peaks, minimizing overlap of the carboxylic acid peaks with those of other constituents. Polar compounds (e.g., amides) eluted later than related but less polar compounds with higher molecular masses (e.g., certain N- or C-alkyl-substituted amides) from this phase. AT-1000 is also slightly acidic, resulting in some of the nitrogen-containing compounds eluting as broad, fronting peaks or, in some cases, not eluting at all. Thus, although *N*-benzylidenepentylamine (**51**) was present in TICs obtained with this column and with column C, this compound and *N*-benzilidene-2-phenylethylamine (**117**) were identified by using the apolar column B.

Samples of the marking fluid collected over a period of 3 years ranged in size from a few milliliters to 100 ml. The fluid contained varying proportions of the lipid phase, and little or no lipid was present in the smaller samples that were collected, probably because some of the viscous lipid material adhered to the collection apparatus. Analytical techniques were developed that would give a reliable picture of the qualitative and quantitative composition of the animal's marking fluid. These techniques were then used to analyze fresh marking fluid that was free from contaminants and which contained a relatively high proportion of the lipid material to obtain a comprehensive picture of a typical sample of the fluid. Thus, crude samples were subjected to SEP-GC and -GC-MS analyses, after which the lipid material was separated from the urine and analyzed by GC and GC-MS by using solventless sample introduction. The organic material was exhaustively extracted from samples of the urine fraction with dichloromethane or methyl *tert*-butyl ether, and the extracts were analyzed by using split injection (GC and GC-MS) or on-column sample introduction (quantitative GC). The relevant qualitative and quantitative data are given in Table 1.

We tried to use DMDS derivatization of unsaturated compounds and GC-MS analysis of the derivatives (Vincenti et al. 1987) to determine the positions of double bonds in

Table 1 Compounds identified and quantified in the urine fraction, the headspace of the urine fraction, and the lipid fraction of the territorial marking fluid of the male Bengal tiger

Number in Fig. 1[a]	Compound[b]	Identification[c]	Quantitative data			Compounds in Mixture A	Compounds in Mixture B

[a] Compounds are listed in order of elution from column A (Fig. 1), although all compounds were not detected with each of the three analytical methods used.
[b] Stereochemical information on chiral compounds is given in Table 2.
[c] a GC-EIMS data, b retention time comparison with synthetic compounds, c not detected or values lower than 0.03 ng, d tentative identification, e retention time increment comparison, f GC-CI(CH_4)MS data, g double bond location by DMDS derivatization and GC-MS analysis, h nitrogen-containing compounds were collected by SEP from the headspace of the urine fraction and analyzed using the apolar capillary column B, i identified in the material collected by SEP from the headspace of several samples of the marking fluid. Extraction with methyl *tert*-butyl ether from a urine fraction (8.87 ml) and GC-MS analysis using sulfur as external standard gave a sulfur concentration of 80 ng/ml urine
[d] GC and GC-MS analyses of volatile organic constituents collected from the headspace of 46.67 g of urine for 20 hr at 40°C using a SEP. Quantitative data were normalized with respect to dodecan-4-olide as 100%.
[e] GC and GC-MS analyses of the volatile organic material extracted with dichloromethane from 33.8 g of the urine fraction of the marking fluid. Extract concentrated to 60 μl and 1 μl injected on-column. The 11 homologous ketones from 2-heptanone to 2-heptadecanone were used as external standards. Quantitative data in nanograms per 33.8 g of urine
[f] GC and GC-MS analyses using sample introduction by injector-internal thermal desorption of 3.28 mg of the 262.2 mg of lipid fraction separated from the above urine fraction. Alkanones were used as external quantitative standards. Quantitative data in nanograms per 262.2 mg of lipid material
[g] Stereochemistry not determined

the unsaturated constituents of the fluid. However, the major unsaturated compounds were not quantitatively derivatized and appeared unchanged in the TIC of the reaction product, and the minor unsaturated constituents were not detected, either as the unchanged compounds or as their derivatives. Using a larger sample of the extract and a larger excess of the reagents, the derivatives of the major unsaturated compounds were still formed in very low yields. No unchanged compounds were detected in the TIC, even when a large sample (6 μl) of the final product was analyzed. Fortunately, information on the positions of the double bonds in the unsaturated γ-lactone (**86**) and 9-hexadecenoic acid (**112**) was obtained in both of these experiments. In a repetition of the experiment with a sample of the lipid fraction, the iodine and probably also the DMDS were rapidly consumed and had to be replenished several times. Only the DMDS derivative of 9-hexadecenoic acid was detected in the product. Thus, some of the other compounds extracted from the urine or present in the lipid appear to interfere with the reaction. The double bond positional and geometric (*E/Z*) isomers of long-chain unsaturated compounds are not always completely resolved in capillary GC-MS analyses. Thus, although these compounds coeluted with authentic synthetic reference compounds, some of them are listed as tentatively identified in Table 1 if the positions of their double bonds could not be conclusively established.

A larger number of compounds were identified in the urine fraction by using the SEP sample introduction technique than by conventional injection of an extract of the urine. These differences are the result of the differences in sensitivity of these methods for compounds that differ in volatility and polarity. The SEP technique particularly facilitated the analysis of highly volatile constituents, and the profile of the volatiles obtained with this method probably gives a more accurate picture of the composition of the semiochemical message released by the tiger's marking fluid than information obtained by other methods. Regardless of the sampling technique used, GC-MS analysis showed the volatile fraction of the marking fluid to be complex, with a coelution of many constituents. Thus, although constituents were quantified by using GC data,

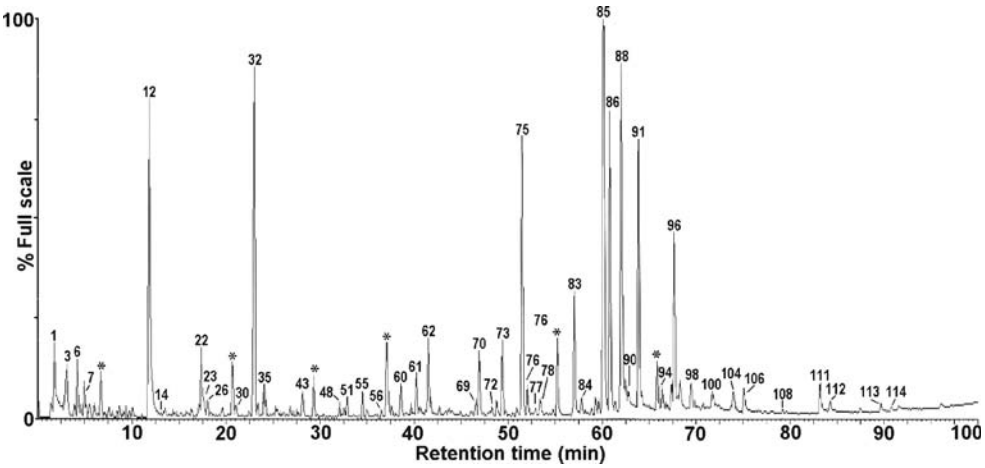

Fig. 1 TIC obtained by GC-EIMS analysis of the volatile organic compounds collected with a SEP at 40°C from 46.67 g of the urine fraction of the territorial marking fluid of the Bengal tiger on the glass capillary column A (40 m× 0.25 mm i.d.) coated with 0.25 μm of the polar stationary phase AT-1000 (FFAP equivalent). The column was programmed at 2°C from 40°C to 280°C. *Asterisk*, Unidentified or contaminants

qualitative and quantitative GC-MS data were considered to avoid incorrect assignment of peaks and to quantify overlapping or coeluting peaks. GC-MS data were also used to determine the enantiomeric composition of chiral compounds. Because samples collected on different occasions were normally not pooled for analysis and different sample preparations, different sample introduction techniques, and different columns were employed in this research, the quantitative results reported in Table 1 have to be considered with some circumspection. The different ratios in which some compounds, belonging to the same compound class, were present in the urine and lipid fractions have not yet been investigated. It is nonetheless clear that the overall qualitative and quantitative picture differs substantially from the published information on the composition of the marking fluid of the tiger discussed in the introduction.

A comparison of the results of the quantitative analyses of the urine and lipid fractions of one typical sample of the marking fluid reveals that if squalene is excluded from the equation, 0.45 g of the lipid fraction contains about seven times the amount of volatile organic material extracted from the associated urine fraction (58 g), illustrating the high affinity of the lipid material for the volatile organic constituents of the marking fluid, which probably enhances the lifetime of a territorial mark.

Perhaps the most remarkable feature of the results reported here is the large number of lactones present in the marking fluid. Some of these lactones have relatively low vapor pressures and will persist in territorial marks, although they may not be the major active constituents of the territorial marking pheromone. The major constituents of the headspace of the urine fraction and of the whole marking fluid were 2-heptanone (**6**), 2-nonanone (**11**), 2-undecanone (**32**), decanoic acid (**83**), (*Z*)-9-dodecenoic acid (**96**), hexadecanoic acid (**111**), dodecan-4-olide (**85**), (*Z*)-6-dodecen-4-olide (**86**), decan-5-olide (**75**), dodecan-5-olide (**88**) and, in some analyses, the nitrogen compounds *N*-benzylidenepentylamine (**51**), 2-phenylethylamine (**116**), and *N*-benzylidene-2-phenylethylamine (**117**). Cadaverine and putrescine, reported as constituents of tiger urine (Brahmachary 1986), were not detected in our study, possibly because animals in the wild will occasionally eat putrid meat containing these compounds, whereas the animals used in this project were only fed fresh chicken. 2-Acetylpyrroline, mentioned as a constituent of tiger urine in several publications (e.g., Brahmachary 1996), also was not detected in our study. However, Brahmachary (1996) suggested that this compound could possibly be an artifact formed by a Maillard reaction during sample preparation. The two imines, *N*-benzylidenepentylamine (**51**) and *N*-benzylidene-2-phenylethylamine (**117**), and *N*-pentylurea (**104**) identified in the present study might also be artifacts formed at the high temperature in the GC injector from amines and carbonyl compounds present in the tiger's marking fluid. This possibility was not investigated, but it could be responsible for the variable quantitative results obtained for these compounds under different analytical conditions. Elemental sulfur was not found in the sample of marking fluid under discussion, but it was present in most of the analyses of SEP-collected material. In a methyl *tert*-butyl ether extract of the urine fraction, it was present in a concentration of 80 ng/ml of urine. Elemental sulfur eluted from column A as a broad and fronting peak, extending over a retention time range of about 5 min, at about the retention time of tetradecan-5-olide (**100**). Sulfur has previously been identified in the urine of the cheetah, *Acynonix jubatus* (Burger et al. 2006b).

Except for a few minor terpenoids, the 3-methyl-2-alkanones and 2-methylcarboxylic acids, 2-ethylhexanoic acid, and a series of γ-alkylsubstituted γ-lactones and δ-alkylsubstituted δ-lactones were the only chiral constituents identified in the marking fluid. No information is available on the order of elution of the enantiomers of 3-methyl-2-alkanones from chiral columns. However, it is known that (*S*)-2-methylheptanoic acid, for example, elutes before the

(*R*)-enantiomer from the phase used in column C (Maas et al. 1994a). Thus, iodoform oxidation of the first-eluting enantiomer of 3-methyl-2-octanone produced the second-eluting (*R*)-enantiomer of 2-methylheptanoic acid. The first-eluting enantiomer of the ketone therefore has (*R*) configuration. In a repetition of this experiment with a 2:1 mixture of the ketone enantiomers, the presence of the other enantiomer of the ketone in the product served as retention time references and ruled out any possibility of incorrect interpretation of the results. By using GC-MS analysis of the SEP-collected volatiles on the enantioselective column C, in conjunction with cochromatography of the enriched material and racemic synthetic samples, and by using the base peak at *m/z* 72 in the mass spectra of these compounds for quantification, it was found that in some samples, these ketones had racemized, but that pure (*R*)-3-methyl-2-octanone (**10**), (*R*)-3-methyl-2-nonanone (**14**), and (*R*)-3-methyl-2-decanone (**26**) were present in most samples (Table 2).

In GC-MS analyses that used column C, the chiral carboxylic acids 2-methylnonanoic acid (**77**), 2-methyldecanoic acid (**84**), and 2-methylundecanoic acid (**89**) were all found to be racemates. 2-Ethylhexanoic acid (**62**) eluted from column E as the racemate. The enantiomeric 2-methylcarboxylic acids were separated on column C with resolutions (R_S) varying from 2.7 for 2-methylnonanoic acid to 2.5 for 2-methylundecanoic acid. These acids were eluted from the nonpolar enantioselective column D as broad and barely resolved peaks. It is unlikely that these acids were racemized during handling because they are expected to be less susceptible to racemization at pH 6.5 than the ketones discussed above.

The enantiomers of the saturated γ- and δ-lactones were resolved on column D with relatively high R_S values, ranging from 4.9 for the C_8 to 2.4 for the C_{16} γ-lactones and from 1.9 for the C_9 to 1.1 for the C_{16} δ-lactones. According to Maas et al. (1994b), the (*R*)-γ-lactones and (*S*)-δ-lactones under discussion elute before the respective (*S*)- and (*R*)-enantiomers from this phase. The elution order of the lactone enantiomers was confirmed by comparing published data (e.g., Mosandl et al. 1989) with analyses on column D of the headspace volatiles of strawberries and raspberries, which contain the enantiomers of some of the γ- and δ-lactones present in the marking fluid. The results of the enantioselective analyses of the lactones are given in Table 2. The enantiomeric ratios of the C_5 and C_6 lactones were not determined because they were present in insufficient concentrations. The majority of five marking fluid samples and two mixtures of, respectively, three and eight smaller samples contained the (*R*)-γ- and (*S*)-δ- lactones (enantiomeric ratios are given in order of elution) in such high enantiomeric purities that it can be assumed that these lactones are excreted as the pure enantiomers (see Table 2).

Table 2 Enantiomeric composition[a] of chiral constituents of the marking fluid determined by GC-MS using columns C, D, and E

Compounds	
γ-Lactones (*R*:*S*)	
C_8	72:28 to 58:42 (*n*=3, C[b])

C_{11}	100:0 (*n*=4)
2-Ethylhexanoic acid (column E)	
C_8	Racemic (*n*=3)

[a] The ratios were determined by integration of single ion plots of the base peaks of the individual compounds. The quantitative data are given in the order of elution of the enantiomers from column C or D. In some samples, one or both of the enantiomers coeluted with other constituents and could thus not be quantified, which accounts for the different numbers of samples (*n*) shown in the table.
[b] Enantioselective column C
[c] Enantioselective column D

The racemization of the chiral constituents of the marking fluid has not yet been investigated. However, some of these samples had spent 15 hr or more at 40°C for the SEP collection of volatiles for qualitative and/or quantitative analyses before the enantioselective analyses were done, and it is possible that the variation in enantiomeric ratios could be explained in terms of some racemization having taken place under these conditions.

The position of the double bond in the unsaturated γ-lactone, (*Z*)-6-dodecen-4-olide (**86**), was determined by MS analysis of its DMDS derivative. The (*S*)- and (*R*)-enantiomers (in the order of elution) were separated (R_S 1.6) on column D. In contrast to the saturated γ-lactones, the (*R*)-enantiomer eluted first from this column. (*S*)-(+)-

Table 3 Identification of proteins in the urine fraction of the marking fluid of the Bengal tiger

Bands from 1D SDS-PAGE (kDa)	MASCOT/BLAST result	Accession number	Theoretical molecular mass (kDa)	MASCOT MOWSE score[a]	Percentage coverage (number peptides identified)

[a] Probability-based MOWSE score: Ions score is $-10\times\mathrm{Log}(P)$, where P is the probability that the observed match is a random event. Protein scores are derived from ions scores as a nonprobabilistic basis for ranking protein hits. Individual ions scores indicating identity or extensive homology ($p<0.05$) for each of the proteins were as follows: Q81034_FELCA≥27; S57632≥27; EAX05759≥38; AAA37484≥37; AAF09245≥28; VBHU≥37.

(*Z*)-6-Dodecen-4-olide has recently been characterized in the interdigital secretion of the bontebok, *Damaliscus pygargus pygargus* (=*D. dorcas dorcas*; Burger et al., unpublished). The (*R*)-and (*S*)-enantiomers of this lactone are also present in the tarsal tuft of the black-tailed deer in a ratio of 89:11, respectively (Müller-Schwarze et al. 1978). In this animal, the lactone does not originate in the tarsal structure itself but is extracted from the animal's urine by the tarsal tuft (Müller-Schwarze et al. 1977).

Because only one pair of captive Bengal tigers was available for this research, little time was devoted to bioassays of the identified compounds. Nevertheless, we tested the major volatile constituent of the marking fluid, dodecan-4-olide, which elicited overmarking behavior, provided that bioassays were not done more often than about once per day. A small sample of synthetic marking fluid, the composition of which is given in Table 1 (mixture B), can be made available to researchers for field tests with tigers living in the wild.

The extraction of volatiles from the urine was complicated by the formation of a thin layer of semisolid material, probably denatured proteins, between the solvent and the urine. This solid material could not be fully characterized, but positive- and negative-ion electrospray time-of-flight MS revealed the presence of scores of compounds with molecular weights ranging from 80 to 750 Da. Although our primary goal was the identification of the volatile constituents of the marking fluid, we undertook an exploratory investigation into the possibility that proteins in the marking fluid could be involved in territorial marking in the tiger. The urine fraction of a sample of marking fluid contained proteins (0.318 mg/ml) with molecular weights ranging from 16 to 180 kDa. Nine electrophoretically separable protein bands were selected for peptide analyses, from which six proteins were identified (Table 3).

Eight peptides representing 16% coverage of the serum albumin precursor of *Felis silvestris catus* (Miyazaki et al. 2003) were identified in the urine of *P. tigris*, with a high degree of sequence conservation for albumin between these species. Serum albumin is the most abundant plasma protein in mammals. Lazar et al. (2004) identified urinary albumin in the Asian elephant (*Elephas maximus*), where it binds the pheromone component (*Z*)-7-dodecenyl acetate and releases it *via* a pH change.

Carboxylesterase-like urinary excreted protein, also known as cauxin, is secreted in the urine of the domestic cat (*F. silvestris catus*), bobcat (*Lynx rufus*), and the lynx (*L. lynx*; Miyazaki et al. 2003, 2006a), and according to Miyazaki et al. (2006a), this protein is not present in the urine of *Panthera* species. However, in the present study,

cauxin was identified as one of the component proteins in the urine fraction of the Bengal tiger. Six peptides representing 20% coverage of the cauxin sequence were identified. All peptides fell within the esterase-, lipase-, and coesterase-conserved domains of cauxin (covering 23% and 22% of these domains, respectively) and showed 100% homology to the published *F. silvestris catus* sequence (Fig. 2). Highly conserved amino acids in the substrate-binding pocket and the catalytic triad were also represented, further confirming the identity of cauxin. The function of cauxin is not known, but Miyazaki et al. (2006b) suggested that it might regulate the production of felinine (2-amino-7-hydroxy-5,5-dimethyl-4-thiaheptanoic acid), a putative pheromone precursor in the domestic cat. Carboxylesterase and *N*-acylsphingosine amidohydrolase (acid ceramidase) catalyze reactions that form long-chain carboxylic acids. Acid ceramidase has previously been identified in human urine (Bernardo et al. 1995). The presence of these enzymes possibly could explain the high fatty acid composition of the lipid fraction of the marking fluid. Two immunoglobulin peptides, (λ)- and (κ)-chain, were identified. These small polypeptide subunits are components of immunoglobulins, T cell receptors, CD1 cell surface glycoproteins, secretory glycoproteins, and major histocompatibility complex class I/II molecules and have previously been identified in the urine of rodents (Hurst et al. 2005). Transthyretin is known to act as a carrier protein for various molecules, including retinol (Monaco 2000), and has been identified in rat urine (Wait et al. 2001).

Healthy mammals excrete small amounts of urinary proteins, and usually proteinuria is an indicator of renal abnormality (Raila et al. 2005). However, several studies have proposed that urinary proteins are involved in chemical communication in mammals. The role of the major urinary proteins (MUPs) in the semiochemical communication of the house mouse, *Mus domesticus*, has been studied in great detail during the past decade (e.g., Novotny 2003). For example, it was found that MUPs bind dehydro-*exo*-brevicomin and 2-(*sec*-butyl)-4,5-dihydrothiazole (Bacchini et al. 1992), which elicits male aggression in the house mouse (Novotny et al. 1985). It has also been suggested that the pattern of MUPs present in male urine may act as a type of individuality barcode that signals the identity of the owner of a particular scent mark (Beynon and Hurst 2003). On the other hand, Miyazaki et al. (2006b) suggested that the excreted MUPs of the domestic cat act as an enzyme in the synthesis of putative pheromone precursors and not as carrier proteins.

Development of Tolerance to the Dietary Plant Secondary Metabolite 1,8-cineole by the Brushtail Possum (*Trichosurus vulpecula*)

Stuart McLean · Sue Brandon · Rebecca R. Boyle · Natasha L. Wiggins

Received: 20 January 2008 / Revised: 8 March 2008 / Accepted: 18 March 2008 / Published online: 10 April 2008

Abstract The common brushtail possum (*Trichosurus vulpecula*) is a generalist herbivore whose diet includes *Eucalyptus* leaves that are well defended by plant secondary metabolites (PSM) such as the terpene 1,8-cineole (cineole). We accustomed possums to a terpene-free diet, then challenged them with the addition of 2% cineole to the diet. Initially, there was a 50% reduction in total overnight food consumption associated with a marked decrease in the mass of the major feeding bout. After nine nights, however, cineole tolerance had developed as total food consumption had returned to the control amount. Compared to the control diet, the cineole diet was eaten in a larger number of smaller bouts, which were also eaten at a slower rate. The experiment was repeated with animals that had been accustomed to day-time feeding to take blood samples during feeding sessions. Feeding variables and blood concentration data for cineole were compared on the first and seventh day of the cineole diet. Although the total food consumed increased 2.5-fold after 7 days of the cineole diet, there was no increase in average blood cineole concentration, measured as the area under the concentration–time curve. This indicates that induction of liver enzymes resulted in greater pre-systemic metabolism of cineole and reduced bioavailability. The maximum tolerated blood concentration of cineole also increased, suggesting some adaptation of the central nervous system to the cineole aversive effects. This appears to be the first report in a vertebrate herbivore that consumption of a dietary PSM leads to metabolism induction and that this contributes to development of tolerance to the PSM. Overall, herbivores adapt to newly encountered dietary PSMs by immediate changes in feeding behavior followed by development of increased metabolism of PSM and probably diminished cellular responsiveness to effects.

Introduction

Woody plants produce a great variety of chemicals that appear to have no further role in plant metabolism but serve a number of external functions, including defense against attack by pathogens or herbivores (Fraenkel 1959; Bryant et al. 1991; Foley et al. 1999). These plant secondary metabolites (PSMs) act through a number of mechanisms to produce toxicity or other aversive effects on herbivores (Iason 2005). Mammalian herbivores must eat to live, and they have developed countermeasures that enable them to subsist on a diet of chemically defended plants. The countermeasures include regulation of intake to avoid consuming a quantity of PSM that would be damaging and biotransformation of absorbed PSMs into metabolites that are usually less toxic and more readily excreted (Dearing et al. 2005). The behavioral and physiological responses of mammalian herbivores can be represented as a continuum from avoidance to tolerance, with most animals lying between the extremes (Iason and Villalba 2006). The

coevolution of plant defenses and herbivore countermeasures has resulted in a balanced coexistence of plants and animals in wild communities, although poisonings can occur when stock animals eat plants that are novel (Provenza 1995; Pfister et al. 1997).

The enzymes in animals that metabolize PSMs are principally the cytochrome P450 oxidases (CYPs) and conjugating enzymes such as glucuronosyltransferase (Dearing et al. 2005). Although considered to have evolved in part as a response to plant toxins (Gonzalez and Nebert 1990), these enzymes are remarkably nonspecific and metabolize other non-nutrient compounds (xenobiotics), including drugs and industrial chemicals. A search of the literature shows that most studies of the enzymes that metabolize xenobiotics have been undertaken in the fields of pharmacology and toxicology.

Genetic and environmental factors determine the capacity of an individual animal to metabolize xenobiotics. For example, CYP genes differ widely in allelic forms and expression that leads to marked differences among and within species in enzyme activity (Gonzalez and Kimura 2003; Wilkinson 2004). In addition to this inherited variation, which is probably driven by evolved species foraging characteristics, a temporary change in enzyme activity can be produced by exposure to certain xenobiotics that can inhibit or induce various CYP enzymes (Hollenberg 2002). The activity of CYPs and other enzymes of xenobiotic metabolism are regulated by a complex system of nuclear receptors that bind to certain xenobiotics resulting in increased transcription and synthesis of xenobiotic metabolizing enzymes (Pascussi et al. 2004). Many PSMs are inducing agents (Zhou et al. 2003), and it is generally considered that the ability to increase xenobiotic metabolizing activity evolved in response to challenges from dietary chemicals (Ioannides 2002). The consequences of induction have been most extensively studied for drug metabolism. In particular, induction of metabolism of a drug, whether by the drug itself or another drug (Hollenberg 2002; Wang and LeCluyse 2003) or a herbal product (Ioannides 2002; Zhou et al. 2003), results in decreased blood levels of the drug and diminished therapeutic effect. The effects of dietary PSMs on drug metabolism have also been studied as food–drug interactions (Harris et al. 2003).

The hypothesis that continued feeding on a diet containing PSMs that can induce their own metabolism will enable increased consumption of the diet has been supported by a study of the larval tobacco hornworm (*Manduca sexta*). This insect herbivore increased its consumption of a nicotine diet over 36 hr, associated with induction of CYP metabolism of nicotine. Both effects were reversed by the CYP-inhibitor, piperonyl butoxide (Snyder and Glendinning 1996). There have been no direct studies in mammalian herbivores, however, to show whether induction of the metabolism of dietary PSM increases consumption of the PSM diet.

Feeding studies have shown that mammalian herbivores can develop a limited tolerance to the presence of a deterrent PSM in their diet. For example, the *Eucalyptus* terpene 1,8-cineole (cineole) acts as a dose-dependent deterrent when added to the diet of the common ringtail possum (*Pseudocheirus peregrinus*) and the common brushtail possum (*Trichosurus vulpecula*), but both animals increase their intake of cineole over several days until it reaches a maximum tolerable amount (Lawler et al. 1999; Boyle and McLean 2004). When brushtail possums were fed for 10 days a diet containing a mixture of four terpenes, including cineole, the hepatic CYPs were induced (Pass et al. 1999) and the *in vitro* microsomal metabolism of cineole was increased (Pass et al. 2001). This suggests that enhanced metabolism contributes to the development of tolerance to a cineole diet (pharmacokinetic tolerance), but it is also possible that animals become tolerant to the pharmacological effects of cineole (pharmacodyamic tolerance). Cineole has a depressant effect on the central nervous system (CNS; Dziba et al. 2006; McLean et al. 2007), and the CNS usually adapts to the presence of various types of drugs (e.g., alcohol, nicotine, and morphine; O'Brien 2006). Therefore, it also appears likely that CNS adaptation contributes to the development of tolerance to cineole.

The aim of this study was to examine the development of tolerance to cineole by the common brushtail possum and to determine whether this can be attributed to induction of metabolism or CNS adaptation, or both. This was approached by measuring and subsequently linking the common brushtail possum's behavioral and physiological responses to a cineole-containing diet.

Methods and Materials

Animals Approval for animal experimentation was granted by the University of Tasmania's Animal Experimentation Ethics Committee. Brushtail possums were trapped in the wild and housed in individual pens (2×2×2.5 m) with wooden nest boxes (28×28×26 cm) hung from the wire mesh walls. Possums were maintained on an artificial terpene-free basal diet of 46% apple, 35% silver beet, 10% carrot, 5% lucerne (ground to pass a 1-mm sieve), and 4% raw sugar (Wiggins et al. 2006). The constituents were chopped and mixed in a food processor, and the final diet was 20% dry matter. Food weights are given as wet matter. Food and water were provided each evening as possums are nocturnal. Animals were tested with the experimental feeding setups, and only those that became acclimated were used in the study. 1,8-Cineole (99%, Sigma, Castle

Hill, NSW, Australia) was mixed into the basal diet as required immediately before being offered to possums.

Experimental Design The study design was to monitor feeding and blood cineole concentrations in possums before and after tolerance had developed to a cineole diet. We have found previously that the antifeedant effect of cineole in the brushtail possum is associated with the concentration of cineole in the blood reaching a critical value. This indicates that it may be the aversive signal detected by the animal (Boyle et al. 2005). An increase in this critical concentration would be evidence of CNS adaptation. The relationship between cineole ingested and its blood concentration was used as a measure of the relative rate of cineole metabolism. The study first established the time-course of the development of tolerance to a diet containing added cineole. As possums are nocturnal, this was done by offering food at night with the animal freely moving around its pen. The development of tolerance was taken to be when total overnight food consumption returned to the pre-cineole level. The next study required blood sampling during feeding, which was done with animals that had been catheterized to enable blood sampling and that were acclimated to eating from their nest box during the day. Possums readily adjust to diurnal feeding but remain less active than at night, when it would be difficult to manage the blood sampling. After a control period of 3 d, cineole was added to the basal diet. Blood was taken on the first day of the cineole diet and again 1 wk later after tolerance had developed.

Night Feeding Possums (seven male, four female; body weight, 3.45±0.11 kg) were offered the basal diet (500 g wet weight) and water overnight. The stainless steel food dish was placed on a balance and housed in a plywood box. The box had a hinged lid with an opening in the top through which the food was presented. The box protected the dish and balance from being knocked over by the possum. The balance was connected to a laptop computer outside the pen, and the weight of food remaining was recorded every minute throughout the night. This method of monitoring feeding has been described previously (Boyle et al. 2005). Night-feeding experiments were commenced late afternoon (4–5 pm) and stopped at about 9 am the following morning (i.e., after about 16 hr). The time and weight recordings were used to monitor feeding throughout the night. Animals were offered the basal diet for at least three nights, then the same diet containing 2% cineole (wet weight) for nine nights. The possums had been maintained on a terpene-free diet for a minimum of 2 wk (median, 7 wk) before being offered the cineole diet.

Day Feeding Possums (four male, three female; body weight, 3.47±0.07 kg) were fasted overnight and taken in the morning in their nest box from their pen to the laboratory. The front opening of the nest box was fitted with a gate through which the possum could reach into a food dish but not leave the box, as described in Boyle et al. (2005). The weight of the food dish was recorded every minute on a laptop computer. Feeding experiments were commenced at 9 am and continued for 3 hr. After the experiment, the animal was returned to its pen in its nest box.

Based on the findings of the night-feeding experiments, 7 d were allowed for the development of tolerance to the cineole diet. The experiment was commenced with three control days, then 2% cineole was introduced into the diet, and blood samples were taken on the first and seventh cineole days. Because, at first, little of the cineole diet was eaten during the 3-hr experiment, the uneaten food was left overnight in the pen for the animal to continue eating. The night-feeding experiments had shown that, after a few days, most of the cineole diet was eaten by morning. The offering of uneaten food ceased on days 5 and 6 to re-establish daytime feeding before the second blood sampling experiment on day 7.

Blood Sampling and Analysis These methods have been described previously in detail in Boyle et al. (2005). At least 1 wk before experiments started, a vascular access port was implanted between the scapulae, and its catheter was placed in the jugular vein. On the day of an experiment, an infusion set needle was inserted into the port and the other end of the catheter left outside the closed lid of the nest box. Blood samples (0.1 ml) were taken when feeding commenced and continued every 5 min until 10 min after the bout finished. Between bouts, blood samples were taken every 15–30 min. Blood samples were stored in heparinized tubes at −18°C until analysis of cineole by gas chromatography (Boyle et al. 2002).

Data Analysis The time–weight data were used to calculate total food intake, the number and size of feeding bouts, and their duration. A feeding bout was arbitrarily defined by a consumption rate of more than 10 g in 1 min, although rests of up to 2 min were accepted as part of a bout. We had previously defined a bout as >3 g/min (Boyle et al. 2005), but this included intakes that were subsequently considered to be too small to be significant for the analysis of bouts. Since some food was consumed at slower rates, the total food intake was greater than the sum of the bouts, and the percentage eaten in bouts was calculated. The rate of food intake was calculated by dividing the amount eaten in a bout by the time taken.

The blood concentration of cineole (C) is expressed in nanogram per milliliter (1 ng/ml=6.494 nM). The concentration–time data were used to determine the maximum

concentration (C_{max}) and its corresponding time (T_{max}), and the area under the curve (AUC) during the 3-hr daytime-feeding experiment. In one experiment, the catheter failed after 85 min, so the AUC and total food intake for this and the other blood-sampling day for the same animal were calculated for this time. The relative bioavailability of cineole was estimated from the ratio AUC/amount of cineole ingested.

Data are expressed as mean±SE. Means were compared by one-way analysis of variance (ANOVA) or, when only two means were compared, Student's paired *t* test. When the ANOVA *F* test was significant ($P<0.05$), post-tests were conducted for linear trend or to compare pairs of means (Tukey's multiple comparison test), as appropriate. T_{max} data were extremely skewed and were compared as medians using Wilcoxon's matched pairs test. All comparisons were made with matched (repeated measures) tests since there was considerable individual variability in feeding behavior. Night-time and daytime experimental findings were compared in the six possums that underwent both procedures. GraphPad Prism software version 4 (San Diego, CA, USA) was used for calculating AUC, statistical analyses, and graphing.

Results

Night Feeding Seven possums were offered the basal diet (500 g) in the night feeding setup for seven nights. There was a significant increase in total food consumption over time (ANOVA, $F_{6,6}=6.59$, $P<0.001$), which post-testing showed was due to the increase after the first night and that, thereafter, food consumption was constant for each possum. For these seven possums, the last three nights before 2% cineole was added to the diet were used as the control period. An additional four possums were fed the control diet for just the three nights before the cineole diet. The total time spent feeding varied greatly between individual possums: On the last control night, the median was 7.9 hr and range 0.9 to 10.5 hr ($N=11$).

Figure 1 shows the total food eaten overnight for three control nights and nine nights of cineole diet, and Table 1 summarizes the analysis of feeding variables. There was no difference between the three control nights, but introduction of 2% cineole halved total food intake on the first night. Total intake of the cineole diet increased progressively, and by the third night, it was not significantly different from either the control or the cineole diet intake on nights 4–9. However, because the upward trend continued as shown in Fig. 1, data from cineole night 9 (the last night) were used to measure the adjustments associated with tolerance.

The number of feeding bouts did not change from control night 3 to cineole night 1, but nearly doubled after adaptation to the cineole diet (Table 1). The mass of the major feeding bout, which was usually the first bout, decreased about threefold when cineole was added to the diet. The mass eaten during the major bout had doubled by the third cineole night, and thereafter, it remained constant and was still only 60% of the amount on control night 3. The rate of eating also decreased from control night 3 to cineole night 1 and remained slower on subsequent cineole nights. Nearly all (96%) of the control diet was eaten in bouts of >10 g. This proportion fell to 70% when cineole was first introduced but returned to control levels by cineole night 9.

At the end of the night-feeding experiments, mean possum weights (3.52±0.13 kg) had not significantly changed ($t=1.83$, $df=10$, $P=0.097$).

Day Feeding In preliminary trials for 3–5 days, animals became used to daytime feeding from their nest box by the second day and, on subsequent days, did not increase total food consumption during the 3-hr feeding session. Therefore, a 3-d control period was used for the seven possums in the day-feeding experiments. During this control period, there was a non-significant increase in food consumption after the first day to a constant amount on days 2 and 3 (ANOVA, $F_{2,6}=2.12$, $P=0.149$).

Day and night feeding on the basal diet were compared in six possums that had been fed under both conditions. Total food intake during control day 3 (280±12 g) was about three quarters of that during control night 3 (404±39 g; $t=3.56$, $df=5$, $P=0.016$). However, as the time available for feeding was much less during the day (3 h) than the night (about 16 hr), the overall rate of feeding was greater during the daytime sessions. Moreover, the major feeding bout was larger during the day (183±11 g) than the night (128±22 g; $t=2.86$, $df=5$, $P=0.035$).

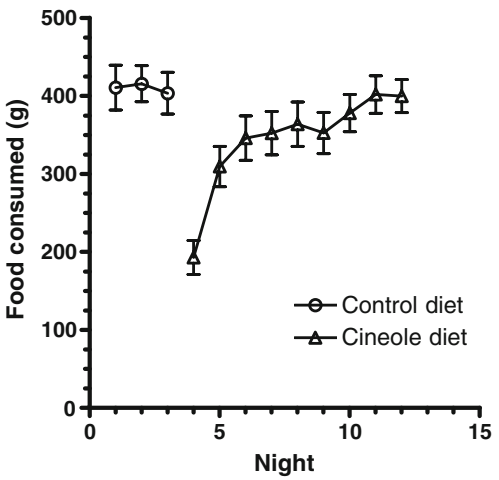

Fig. 1 Night feeding on basal diet (control) and 2% cineole in basal diet (cineole). Data are shown as mean±SE ($N=11$). Statistical analyses are given in Table 1

Table 1 Night-feeding variables

	Control night 3	Cineole night 1	Cineole night 9	Cineole nights 1 to 9; ANOVA F, P[a]

Seven animals were used to study the development of tolerance to cineole in day-feeding experiments. When cineole was added to the basal diet, total food consumption initially fell to about one fifth of the control amount (Table 2). The daytime consumption remained constant for the following 4 days, while the residual cineole diet was given to the animals for overnight consumption. Most of the diet was eaten overnight, and the total food consumption (day+night) was about 400 g, equivalent to that of the night feeding experiments.

Then, food was withheld on nights 5 and 6 to re-establish day-feeding behavior before the blood-sampling experiment on day 7. The amount eaten during the day remained similar from days 1 (64±5 g) to 5 (60±12 g), but after the overnight fast, it increased on day 6 to 134±25 g (t=4.93, df=6, P=0.003) and was not significantly greater on day 7 (157±18 g; t=1.28, df=6, P=0.248). After 7 days of cineole diet, the total amount eaten during the day had increased 2.5-fold to about half the control values (Table 2).

Although the number of bouts did not change significantly after cineole commenced, the major bout was smaller on cineole day 1 than on control day 3, but this increased to about half the control value on cineole day 7 (Table 2). The rate of consumption during the major bout also fell when cineole was introduced but rose to about the control level by day 7. The percentage of the total food intake that was eaten in bouts >10 g dropped by a third on cineole day 1 but had recovered to the control value by the seventh day of cineole.

At the end of the day-feeding experiments, possum weights had slightly increased to 3.72±0.13 kg (t=3.38, df=6, P =0.015).

Pharmacokinetics Figure 2 shows an example of blood concentration and feeding data for one possum on cineole days 1 and 7. The rate of feeding was usually constant during a bout, although sometimes it slowed, as can be seen in the first bout on day 1. The blood cineole concentration rose rapidly when feeding commenced and fell promptly

Table 2 Day feeding variables

	Control day 3	Cineole day 1	Cineole day 7	P cineole days 1 vs. 7
Total food eaten (g)	308±29	64±5	157±18	0.003
P vs. control		<0.001	<0.001	
Number of feeding bouts	3.6±0.4	2.6±0.5	3.7±0.8	0.066
P vs. control		0.134	0.853	
Amount consumed during major feeding bout (g)	181±9	29±4	96±13	0.001
P vs. control		<0.001	<0.001	
Rate of eating major bout (g/min)	7.01±0.73	3.38±0.77	6.17±0.61	0.002

Percentage eaten in bouts >10 g	98.1±0.6	67.3±5.2	96.2±1.7	0.003
P vs. control		0.001	0.295	

Data shown as mean ± SE (N=7). P values from paired t tests (df=6)

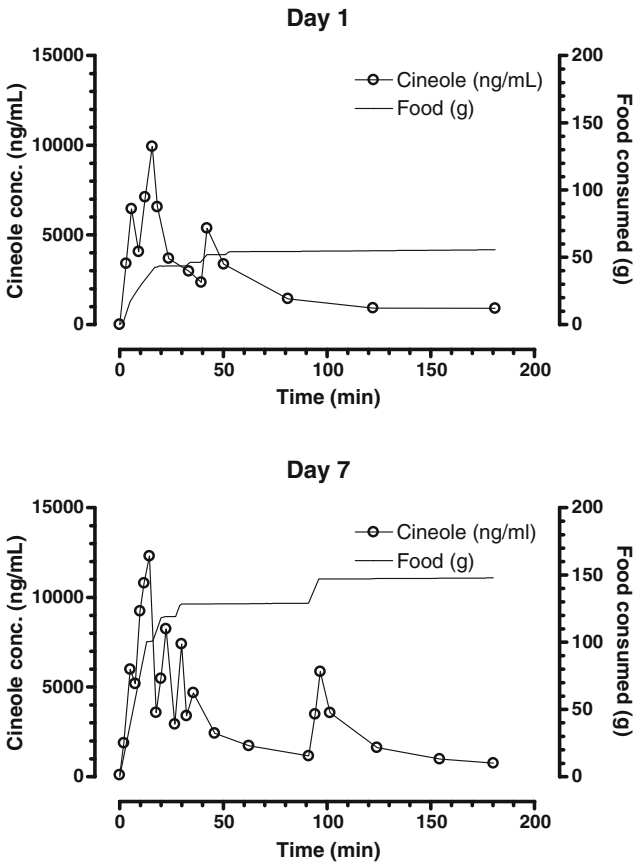

Fig. 2 Food consumption and blood concentrations of cineole on days 1 and 7 of the 2% cineole diet. Data are shown for a single possum

when feeding slowed or ceased. Table 3 compares the mean pharmacokinetic and feeding data for all possums. The total intake of food and, therefore, cineole increased from cineole day 1 to 7 (the slight discrepancy from food intake values in Table 2 is due to the adjustment required for one animal whose catheter blocked, ending the blood sampling after 85 min instead of 3 hr).

There was an increase in C_{max} on day 7 but no significant change in AUC. T_{max} was highly variable, but comparison of the median values showed that it occurred earlier on day 7 (15.8; range, 12–160 min) than day 1 (53.9; range, 3–43 min; Wilcoxon's matched pairs test, P=0.016). The ratio of AUC/cineole ingested decreased after 7 days, indicating that the bioavailability of cineole also fell.

Discussion

Night Feeding The night-feeding experiments confirmed the previously reported antifeedant effect of 2% cineole (Lawler et al. 1999; Boyle and McLean 2004). Full tolerance to cineole, defined by food intake returning to the pre-cineole amount, was evident by the ninth cineole night. Although total food intake was not significantly different from the control value on the third cineole night, the trend continued upwards until the eighth night (Fig. 1 and Table 1) indicating that about a week was required for full tolerance.

Breakdown of the feeding variables (Table 1) showed that the initial response to cineole was to reduce greatly the amount consumed in the major bout and to eat it more slowly, and to eat about half the total control amount of food and about a third of this in small quantities (<10 g). Similar changes to feeding behavior of brushtail possums have been found when increasing levels of cineole were added to a basal diet (Wiggins et al. 2003; Boyle and McLean 2004). Overall, after tolerance had developed, the total pre-cineole food intake was achieved by eating a larger number of smaller bouts and at a slower rate.

Day Feeding The day-feeding situation was quite different from night feeding, as it took place during the normal rest period for possums, the animals were confined in their nest boxes, and the time available for feeding was reduced to 3 hr. Nevertheless, feeding was active under these conditions, as two thirds of the overnight (16 hr) control diet intake was consumed, and the major bout was 40% greater than at night.

The addition of cineole to the diet resulted in a greater initial decrease in total food consumption than in the night experiments, most likely due to the shorter available feeding time. As with the night experiments, there was a commensurate decrease in the mass of the major bout and its rate of consumption and an increase in the amount of

Table 3 Pharmacokinetic data from day feeding on a 2% cineole diet

	Cineole day 1	Cineole day 7	P value
Total food eaten (g)	60±5	153±18	0.003
Total cineole ingested (mg)	1,202±97	3,061±358	0.003
C_{max} (ng/ml)	6,653±1,309	10,588±1,595	0.001
T_{max} (min)	61±20	20±5	0.067
AUC (min.ng/ml)	442,961±103,865	480,477±49,006	0.726
AUC/cineole ingested	345±52	160±11	0.008

Data shown as mean±SE (N=7). P values from paired t tests (df=6)

food eaten in quantities less than the defined bout size of 10 g. By the seventh day of the cineole diet, possums showed evidence of adaptation similar to that seen in the night experiments, i.e., increases in total food consumption and amounts eaten in the major bout and the percentage of food eaten in bouts. However, there were some differences from the night-feeding experiments, which were possibly due to the shorter feeding time: Total food consumption did not reach the control amount, and there was no increase in the number of bouts, but their rate of consumption did increase to about the control value.

Food consumption depends on the balance between positive drives (especially hunger) and the negative influences of satiety and the aversive effects of PSMs (Provenza 1995). The night-feeding experiments indicated that 7 days of the cineole diet would be sufficient for tolerance to develop. However, the development of pharmacological tolerance (whether pharmacokinetic or pharmacodynamic) depends on the amount of the drug ingested and the period of exposure (Hollenberg 2002; O'Brien 2006), and the lower daytime food consumption would also result in a lower daily cineole dose and a possible failure to develop tolerance.

The dilemma was to ensure that possums not only ate a sufficient quantity of the cineole diet over 7 d to maintain adequate nutrition and develop tolerance to cineole, as occurred with night feeding, but also were fasted long enough to develop a degree of hunger on cineole day 7 comparable to that on cineole day 1. This was achieved in two stages. For the first 4 days, possums were offered the remaining uneaten cineole diet for overnight consumption. Although daytime feeding remained low, total 24-hr food consumption equaled that of the night-feeding experiments, indicating that nutrition and cineole tolerance would also be similar. Then, food was withheld on nights 5 and 6 to re-establish day-feeding behavior before the blood-sampling experiment on day 7. The amount eaten during the day increased from days 5 to 6 but was not significantly greater on day 7. Thus, as for the control diet, it took 2 days to establish constant daytime feeding.

While it is not possible to compare directly the levels of hunger on days 1 and 7 of the cineole diet, the feeding behavior was in some respects (mass of major bout and percentage eaten in bouts) similar to that on cineole nights 1 and 9, respectively. This suggests that the conditions of the possums when first exposed to cineole and after tolerance had developed were comparable in the day and night experiments. Although total food consumption was less during the day than at night, there was no loss of body weight during the day-feeding experiments. Possibly, animals compensated by being less active overall during the periods of the daytime-feeding regime.

The fall in food consumption when cineole was introduced may have been an example of the general cautionary response of herbivores to a new diet (Provenza 1995) as much as to any direct aversive effect of cineole. However, the continuance of the low daily intake suggests that aversion was more important than unfamiliarity.

Pharmacokinetics Blood analyses offer insights into the mechanisms that underlie the development of tolerance to dietary cineole. The maximum blood concentration of cineole followed the largest feeding bout and indicated the highest concentration that would be tolerated to continue feeding. On the first day of cineole, C_{max} was 6,653±3,462 ng/ml or 43±22 μM, similar to the 52±14 μM found previously to be the critical concentration that caused immediate cessation of feeding (Boyle et al. 2005). After 7 d of the cineole diet, this critical concentration had increased by 60% to 10,588±4,220 ng/ml (69±27 μM). This may indicate that significant tolerance had developed to the aversive effects of cineole, although an increase in hunger cannot be discounted. However, on cineole day 7 and cineole night 9, the amount of cineole diet consumed in the major bout and its rate of consumption were similar, indicating that both the level of hunger and the critical aversive blood concentration of cineole would have been similar on both occasions, despite the differences in the feeding regimens. This supports the view that the increase in C_{max} associated with adaptation to a cineole diet is due at least in part to tolerance to its aversive effects.

There are two possible antifeedant effects of cineole for which pharmacodynamic tolerance could occur. Tolerance would be expected to develop to the CNS depressant effect of cineole, as mentioned in "Introduction." Another possible aversive effect is nausea (Provenza 1995), which is mediated at least partly via $5HT_3$ serotonergic receptors (Lawler et al. 1998). $5HT_3$ receptors characteristically show rapid desensitization with continued stimulation (Spiller 2002).

By day 7 of the cineole diet, the total cineole intake had increased 2.5-fold, but the AUC had not changed. The AUC is a measure of the completeness of absorption into the systemic circulation, and it increases in proportion to dose, provided that absorption is unchanged (Rowland and Tozer 1995). The fraction of a dose that reaches the general circulation, termed the bioavailability, is calculated from the ratio of AUCs after oral and intravenous administration, corrected for any differences in dose. We have found previously that cineole is absorbed rapidly and completely from the gut in the brushtail possum and that only a small fraction of an oral dose reaches the general circulation (McLean et al. 2007). This phenomenon is due to extensive pre-systemic metabolism of cineole by enzymes in the gut wall and liver during the absorption process (the 'first-pass effect'). In the present experiment, the AUC corrected for the amount of cineole ingested (AUC/cineole ingested) fell

by one half after 7 d of the cineole diet, indicating that there had been an increase in enzyme activity and pre-systemic metabolism of cineole resulting in a decrease in its bioavailability. Induction of liver enzymes is known to decrease the oral bioavailability of any drug that, like cineole, is rapidly metabolized in the liver (Rowland and Tozer 1995).

The increase in size of the major bout supports this view. The maximum tolerable dose of cineole, estimated from the major bout, was 163±22 mg/kg on cineole day 1 and 527± 80 mg/kg on day 7. This suggests that pre-systemic metabolism had greatly increased after 7 days, since there was not a proportionate (i.e., threefold) increase in blood cineole concentration (C_{max}). In fact, the expected increase in C_{max} is greater than threefold, since the bioavailability of cineole is increased after higher doses due to saturation of the enzymes responsible for pre-systemic metabolism (McLean et al. 2007).

A potential complication arises because ingestion of cineole through feeding takes longer than its administration as an oral dose, effectively prolonging the absorption time of dietary cineole. Slowing the absorption of a drug gives lower blood levels even if bioavailability is unchanged (Rowland and Tozer 1995). In addition, for a drug like cineole that has low bioavailability due to rapid first-pass metabolism, slow absorption would be expected to decrease further its bioavailability and therefore its blood concentrations. This is because slow absorption results in a lower concentration of cineole being presented to the enzymes in the gut wall and liver, resulting in less saturation of enzymes and more complete metabolism of the ingested cineole (effectively a consequence of the dose-dependent kinetics mentioned above).

Consistent with this, when possums were first presented with cineole, they ate the major bout more slowly, which would be expected to produce lower blood levels for the same amount of cineole ingested. This slower rate continued after tolerance had developed in the night-feeding experiments; that is, tolerance was in part due to a behavioral change in the rate of feeding. However, in the time-limited day-feeding experiments, the feeding rate on the major bout was decreased on day 1 but had returned to the pre-cineole level on day 7. As this change would tend to increase blood cineole levels, it is further evidence that the relatively low cineole concentrations were due to induction of the enzymes of first-pass metabolism.

We have demonstrated previously that a diet containing cineole and other terpenes induces the liver enzymes that metabolize cineole (Pass et al. 1999, 2001). There is a large literature on the induction of drug metabolism by herbal preparations and other drugs, and it is generally considered that the induction mechanism evolved in herbivores as a response to chemical defenses of plants. However, this is the first demonstration in a vertebrate herbivore that consumption of a dietary PSM leads to induction of its metabolism and a consequent increase in feeding.

Linking Behavioral and Physiological Data The behavioral feeding patterns demonstrated by brushtail possums offer support for our hypothesis that possums are able to develop a level of tolerance to a cineole diet. Their initial reduction in total intake, feeding bout mass, and intake rate when first exposed to a 2% cineole diet had, after 7 days, largely returned to the behavioral feeding patterns displayed on the control diet. Our findings also support the avoidance-tolerance model of Iason and Villalba (2006), as the increase in detoxification capacity and probably pharmacodynamic tolerance leads to a reduction in the behavioral strategy of avoidance.

We have also demonstrated that intake appears to be correlated highly with blood cineole concentrations – where large bouts of eating are mirrored by sharp peaks in blood cineole concentrations. The alteration of intake, intake rate, and bout mass should thus be a direct response to blood cineole levels, used as a behavioral regulatory mechanism. The evidence presented in this study indicates that brushtail possums can adapt to a dietary PSM initially by altering feeding behavior and subsequently by induction of the enzymes responsible for its metabolism, probably coupled with some decreased CNS sensitivity.

The unique combination of physiological and behavioral data measured in this experiment has not only enabled us to test the hypothesis of tolerance and metabolic induction in the brushtail possum, but it also provides support for the hypothesis proposed by Wiggins et al (2006) that the feeding decisions of generalist mammalian herbivores, specifically in relation to diet mixing, may largely be driven over a short-term, possibly minute-by-minute basis, in direct response to their exposure to blood concentrations of ingested dietary PSMs.

Acknowledgments We are grateful to the staff of the Central Animal House for assistance with feeding and maintenance of the possums, and to Drs. Barrie Wells and Chris Lee for implantation of vascular access ports and general veterinary care. The project was supported by a grant from the Australian Research Council. We thank the anonymous reviewers for their comments, which have improved this paper.

Abstract *Sesbania virgata* (Cav.) Pers (wand riverhemp) is a fast-growing tropical legume species that has been used for revegetation of riparian forests and rehabilitation of degraded areas and that exhibits an invasive behavior in certain regions of Brazil. Preliminary studies have shown that seed leachates inhibit the germination and development of seedlings of some crop species. In this study, we report that the seed leachates of *S. virgata* inhibit the growth of *Arabidopsis thaliana* and rice. The flavonoid (+)-catechin is found in high amounts in these leachates. It was active at concentrations of 50 μg ml^{-1}, and its effect was not distinguishable from the (+)-catechin obtained from a commercial source. We found that (+)-catechin is located in the seed coat and is rapidly released in high concentrations (235 μg per seed) at the beginning of imbibition. Quercetin was also detected in the seed coat of *S. virgata*, but it was not released from the seeds. Other phytotoxic compounds in the seed leachates were also detected. The fact that *S. virgata* releases high amounts of (+)-catechin, which also has antimicrobial activity, and other phytotoxins from its seeds at the earliest stages of its development might represent some adaptative advantage to the seedling that contributes to its invasive behavior and successful establishment in different soils.

Introduction

The seed stage is a crucial phase of plant development that allows plants to effectively establish in the natural environment. One strategy that enables the success of the early establishment of plants is the release of secondary metabolites and other low-molecular-weight compounds at germination, which can inhibit the proliferation of soil pathogens and the germination and growth of competing plants (Nelson 2004).

Some studies have examined how phytotoxic secondary metabolites exuded by the roots can influence the ability of a plant to become invasive in a new environment, such as the enantiomers (±)-catechin exuded by *Centaurea maculosa* Lam. (Bais et al. 2002) and lactones released by *Echinochloa crusgalli* (L.) Beauv. (Xuan et al. 2006). Although these studies have examined only those compounds that are exuded through the plant root tissues, seeds are also able to rapidly release allelochemicals after the beginning of the imbibition process that contribute to the invasive behavior of some species (Ndakidemi and Dakora 2003 and references therein).

The tropical legume *Sesbania virgata* (Cav.) Pers (Syn. *S. marginata* Benthan) is a perennial, fast-growing shrub native to South America. It is 2–4 m in height and occurs in

Central, Southeast, and South Brazil, Argentina, Uruguay, and Paraguay. It produces a lot of seeds with long-term viability that are dispersed within indehiscent legume fruits that float in the water (Pott and Pott 1994). It has been described as invasive in flood and damp soil, especially in inundated rice plantations (Kissmann and Groth 1999). This species has been used for revegetation of riparian forests, soil erosion control, and rehabilitation of degraded areas (Pott and Pott 1994).

Previous studies have demonstrated that *S. virgata* seed leachates can affect the germination and growth of the radicle of some crop species (lettuce, tomato, and radish; Simões and Braga, unpublished data). It also has been reported that the seeds of various other *Sesbania* species contain toxic compounds that are able to restrict the growth of other plant species (Buta 1983; Powell et al. 1990; Van Staden and Grobbelaar 1995). *Sesbania* species generally present abundant seed production and rapid growth, occurring naturally near rivers, in flood places, and in modified soils. *S. punicea* (Cav) Benth. is described as a noxious weed in South Africa, invading abandoned fields and out-competing natural vegetation, and forming a dense population. This behavior seems to be associated with the presence of the potent alkaloid sesbanimide in the seeds that can inhibit the seedling growth of several species (Gorst-Allman et al. 1984; Van Staden and Grobbelaar 1995). As reported by Singh et al. (2007), under field conditions, intercropping of *Sesbania* species with cultivated plants reduces the density of grass weeds. Due to its invasive behavior and demonstrated ability to release phytotoxins from its seeds, *S. virgata* may fit the seed-related allelopathic invasiveness pattern of this genus; however, the chemicals responsible for the phytotoxicity have not yet been identified.

Despite the fact that seed leachates of *S. virgata* contain large amounts of sugars released during the mobilization of the storage cell wall carbohydrates by the developing embryo (Buckeridge and Dietrich 1996), no microbial contamination has been observed during the germination process. This lack of a microbial presence suggests the release of antimicrobial compounds during the early stages of germination. As the phytotoxic compounds produced are unknown, the aim of the present work was to isolate and identify phytotoxins present in the *S. virgata* seed leachates. We tested compounds on *Arabidopsis thaliana* and rice under laboratory conditions. We report that (+)-catechin is the major compound released by *S. virgata* seeds.

Methods and Materials

Seed Germination Seeds of *S. virgata* were collected from natural populations in the region of São Paulo, Brazil. Six thousand seeds were selected, scarified, and placed on two Whatman 1 filter papers in 15-cm-diameter Petri dishes along with 0.7 ml of distilled water per seed (50 seeds per dish). The plates were incubated for 3 days at 25°C with a photoperiod of 12 h.

Extraction and Isolation During the third day of germination, seeds were removed from the Petri dishes, the leachates were collected, and the filter papers were washed ×3 with 105 ml of distilled water (representing three times the initial water volume added to each dish). The leachates of each dish were combined, filtered through a *nylon* membrane, freeze-dried, and weighed (6 g). The resultant powder was dissolved in 300 ml distilled water and extracted sequentially with the same volume of hexane and ethyl acetate (×3 each). The aqueous extract was freeze-dried and re-dissolved in methanol, and evaporated under a vacuum. The ethyl acetate extracts were chromatographed in a regular Merck silica gel 60 (0.063–0.200 mm) column (80×3 cm) and eluted with a gradient of dichloromethane (DCM) and MeOH (0→100% MeOH). Fifty fractions were collected and assembled according to their thin-layer chromatography (TLC) profiles to yield ten fractions (A–J). One of the largest phytotoxic fractions collected (fraction H, 110 mg) was re-fractioned in a flash chromatography system with a silica gel column (1×20 cm) and DCM/MeOH (9:1) as an isocratic solvent system.

Seeds removed from the Petri dishes were also freeze-dried, triturated with a Walita mixer, extracted ×3 with pure ethanol (0.7 ml per seed), evaporated, and partitioned with hexane, ethyl acetate, and methanol as described above. The ethyl acetate fraction (600 mg) was also submitted to a regular Merck silica gel 60 (0.063–0.200 mm) column (2× 20 cm) with a gradient with DCM and MeOH (0→100% MeOH). The 60 fractions collected were compiled into 15 fractions according to their TLC profiles, and one fraction (six) that contained pure quercetin was detected.

Circular Dichroism Spectroscopy and ^1H NMR Analyses Quercetin and catechin isolated from *S. virgata* seeds and leachates were identified by ^1H NMR spectra analyses in CD_3OD and compared to standards purchased from Sigma by using a Varian INOVA 400-MHz Fourier spectrometer. Catechin was also analyzed by its circular dichroism (CD) spectrum in methanol on an Aviv model 202 spectrometer and compared with the standard. (+)-Catechin showed a cotton effect at 280 nm ($\Delta\epsilon$=−1.511; Korver and Wilkins 1971).

Quantification of Isolated Compounds Seeds of *S. virgata* were germinated as described above, and every day, between the beginning of the imbibition and the final day

of germination (1–6 days), a set of 40 seeds was removed from the Petri dishes. Tissues were separated (seed coat, endosperm, and embryo), freeze-dried, and extracted ×3 with ethanol (0.7 ml per seed). Ethanol was evaporated, and the extracts were suspended in 1 ml distilled water and partitioned with 1 ml ethyl acetate (×4). After drying, extracts were solubilized in MeOH (high-performance liquid chromatography, HPLC, grade) and injected into a C18 Dionex Acclaim column (150×4.6 mm) in an HPLC mass spectrometry (HPLC-MS) consisting of a system P680 pump, an ASI-100 autosampler, and a UVD170U UV detector coupled to a Thermo Finnigan Surveyor MSQ mass spectral detector. The samples were eluted with acetic acid (0.1%) in water (eluent A) and 0.1% acetic acid in methanol (eluent B) in a linear gradient from 10% of B (3 min) to 90% of B (90 min). Compounds were quantified by using Sigma standards for catechin and quercetin chromatographed under the same conditions. Leachates obtained from each germination day were also collected and extracted with ethyl acetate and analyzed by HPLC-MS as described above.

Phytotoxicity Bioassays Seeds of *A. thaliana* (L.) Heynh. ecotype Columbia (Col-0) purchased from Lehle Seed Co. (Texas, USA) were surface-sterilized with 20% commercial sodium hypochlorite (0.4% active chloride) for 2 min, washed ×4 in sterile distilled water, and further germinated on solid Murashige and Skoog (1962) basal medium in Petri dishes at 25±2°C and a 16:8 h L/D photoperiod. After 5 days, the *A. thaliana* seedlings were relocated to sterile 12-well plates (one plant per well) that contained 1 ml of liquid MS basal media. They were placed on an orbital shaker under the growth conditions described above to oxygenate the roots properly. Six replicates were used per treatment. After 1 day, catechin and other fractions obtained from *S. virgata* seed leachates and a commercial standard of (+)-catechin (Sigma) were applied to the liquid MS containing the *A. thaliana* seedlings. The substances were dissolved in methanol or ethanol, and 10 μl of the extracts containing different concentrations were applied to the wells. Controls were performed using only the solvents. After 7 days, the length and biomass of the plant root tissues were evaluated.

Seeds of inundated rice (*Oryza sativa* L.) cultivar IAC 106 (Instituto Agronômico de Campinas, SP, Brazil) were washed rapidly with 80% ethanol and then surface sterilized with 20% commercial sodium hypochlorite (0.4% active chloride) for 20 min. After that, seeds were washed three times with sterile distilled water then immersed in a 0.2% fungicide solution (Derosal Bayer) for 30 min and subsequently washed three times with sterile distilled water. Rice seeds were germinated in 250-ml flasks that contained solid MS basal medium at 25±2°C with 16:8 h L/D photoperiod. After 6 days, seedlings were transferred to tubes (2.3×15 cm) that contained 2 ml of liquid MS basal medium (one seedling per tube). The bioassay was performed as described for *A. thaliana.*

Statistical Analyses All statistical analyses were performed by using Winstat software (Microsoft, USA). Growth parameters were subjected to analysis of variance (ANOVA), and significant differences between means were determined by using *LSD* test at 1% probability.

Results

Fractions A–J obtained from the ethyl acetate extract of the seed leachates caused significant reduction in root length and root biomass in *A. thaliana* plants grown in MS media when compared to the controls (Fig. 1). The ^{1}H NMR spectrum from one of the largest fractions collected (H) and also from the G fraction was identical to that of the standard bioflavonoid catechin. When fraction H was rechromatographed, two of the 20 fractions were pure catechin (F2 and F3, containing 23 and 17 mg, respectively). ^{1}H NMR of these fractions confirmed that the isolate compound from *S. virgata* seed leachates was catechin, and the CD spectrum analyses revealed that the molecule was the enantiomer (+)-catechin (data not shown).

Different concentrations of (+)-catechin isolated from *S. virgata* seed leachates were tested against *A. thaliana* seedlings, and activity was compared with commercial (+)-catechin. Statistical analyses (*LSD*, ANOVA, P=0.01) showed that there were no differences between the treatments with catechin from Sigma and from *S. virgata* (Fig. 2). The effect of the concentrations of 50 and 100 μg ml^{-1} on root length was not different from the effect of methanol alone on control plants (Fig. 2a); however, differences were detected in root biomass of plants among these treatments (Fig. 2b). (+)-Catechin appeared to be phytotoxic to root tissues of *A. thaliana* at the concentration of 50 μg ml^{-1}. The concentrations of 200 and 500 μg ml^{-1} were toxic, causing a darkening of the plant roots, a total inhibition of lateral root formation (not shown), and drastic reduction in root biomass (Fig. 2).

Toxicity of (+)-catechin purified from *S. virgata* seed leachates was also observed on rice, and this level of toxicity was similar to that found with catechin purchased from Sigma. With both, toxicity was detected only in the response of root biomass (Fig. 3). This effect was statistically different from control plants when a concentration of 100 μg ml^{-1} of catechin or higher was used (Fig. 3b). Root damage, however, was observed even with the lowest concentration (50 μg ml^{-1}).

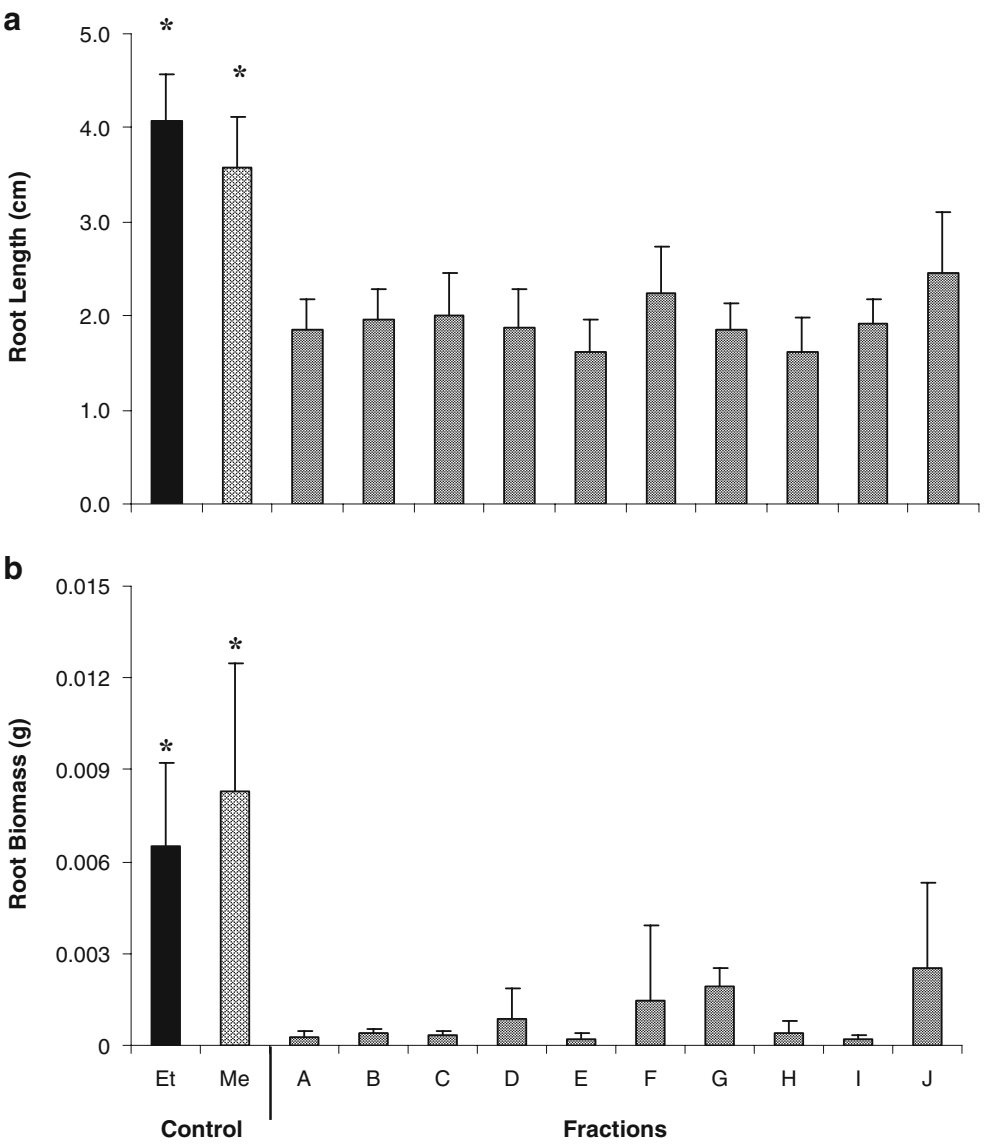

Fig. 1 Root length (**a**) and root biomass (**b**) of *A. thaliana* seedlings grown for 7 days in liquid MS media containing one of the fractions A–J collected from the *S. virgata* seed leachates' chromatography. Each fraction was administered at a concentration of 200 μg ml^{-1} of MS media. Control plants were treated with the same volume of ethanol (*Et*) used to solubilize fractions A–D or methanol (*Me*) used to solubilize fractions E–J. The *asterisk* indicates a significant difference between the means of the treatments and the controls determined by the test *LSD* (ANOVA, $P=0.01$). *Bars* represent the SD of the means ($N=6$)

The flavonoid quercetin was isolated from the seed extracts (25 mg), but it was not exuded by *S. virgata* seeds (Fig. 4). It was phytotoxic to *A. thaliana* (data not shown). Both (+)-catechin and quercetin are located in the seed coat tissues of *S. virgata*; these compounds were not detected by HPLC-MS analyses in the extracts of the embryo or endosperm tissues (data not shown).

During the germination of *S. virgata*, we found that (+)-catechin was rapidly released from the seed coat tissues on the first day of imbibition at levels up to 235 μg per seed (Fig. 4). After this first release, levels in the seed leachates decreased from the second day of imbibition. Based on the data of Fig. 4, the amount of (+)-catechin released from one seed was estimated as higher than 400 μg until the sixth day after the beginning of imbibition. The quantity of catechin and quercetin in the seed coat also decreased during germination, but the amount of (+)-catechin in the seed coat was considerably lower than that measured in the seed leachates (Fig. 4).

Discussion

High concentrations of constitutive phenolic compounds in the seed coat have been reported in *Sesbania* species. Some are rapidly released during imbibition and are found in the soil surrounding germinating seeds (Ceballos et al. 1998). We found that (+)-catechin was rapidly released from seed coat tissues of *S. virgata* on the first day of imbibition at much higher (approximately ten times) levels than those reported for other species of *Sesbania* (Ceballos et al. 1998) and *Lespedeza* (Buta and Lusby 1986).

Catechin has shown phytotoxic effects on a variety of plants, but the level of phytotoxicity varies depending

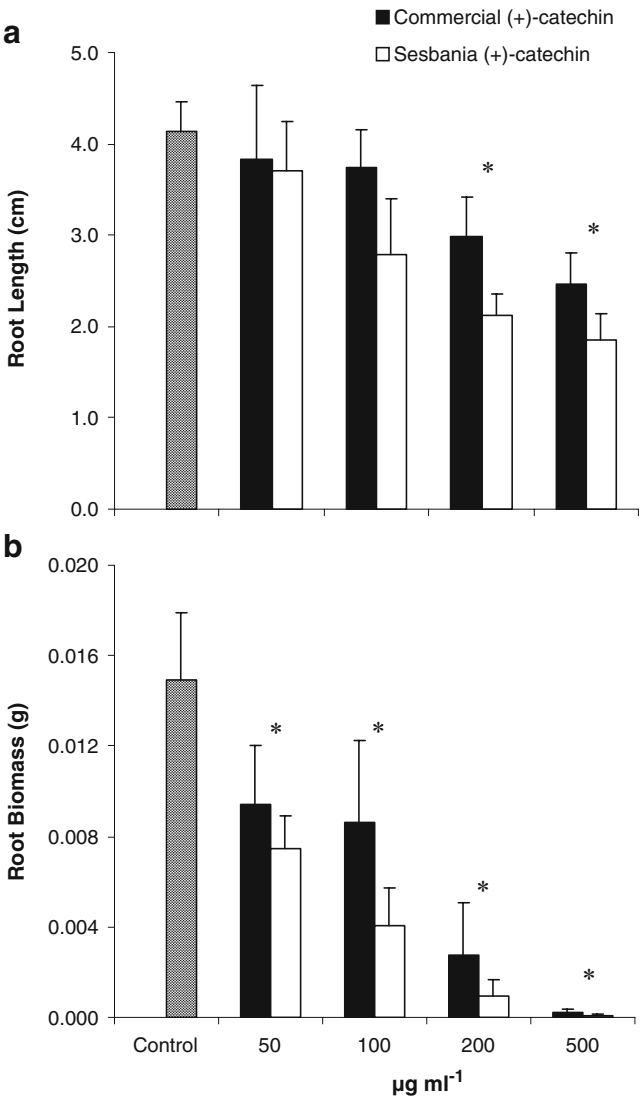

Fig. 2 Effect of different concentrations of (+)-catechin derived from *S. virgata* seed leachates and commercial (+)-catechin on the length (**a**) and root biomass (**b**) of *A. thaliana* seedlings after 7 days of treatment. Control plants were treated only with methanol. The *asterisk* indicates a significant difference between the means of the treatments and the control determined by the test *LSD* (ANOVA, P=0.01). *Bars* show the SD of the means (N=6)

on the species tested and the experimental conditions (Buta and Lusby 1986; Bais et al. 2002, 2003; Iqbal et al. 2003; Perry et al. 2005a; Thelen et al. 2005; D'Abrosca et al. 2006; Thorpe 2006; Weir et al. 2006; Furubayashi et al. 2007). In addition, (+)-catechin has antimicrobial activity and inhibits the growth of the pathogenic soil bacteria *Erwinia carotovora*, *E. amylovora*, *Xanthomonas campestris*, and *Pseudomonas fluorescens* (Veluri et al. 2004). (±)-Catechin also acts as an autoregulator of seed germination and seedling development in *Centaurea maculosa* and *Lespedeza* sp. (Buta and Lusby 1986; Perry et al. 2005b). Seed germination in *S. virgata* seems not to be affected by its coat leachates, but additional experiments are needed to definitively determine this.

The inhibitory effect of (+)-catechin isolated from seed leachates of *S. virgata* on *A. thaliana* growth was similar to that observed by using commercial catechin. Treated plants showed a reduction in root biomass (Fig. 2b) when compared to control plants. This was most likely due to the characteristic effect of the bioflavonoid catechin in inhibiting the development of lateral roots of seedlings of *A. thaliana*. The phytotoxicity of catechin on root cell tissues of *A. thaliana* has been previously described as caused by condensation of the cytoplasm generated by the rapid induction of reactive oxygen species, followed by a subsequent increase of $Ca^{2+}$and acidification of the cyto-

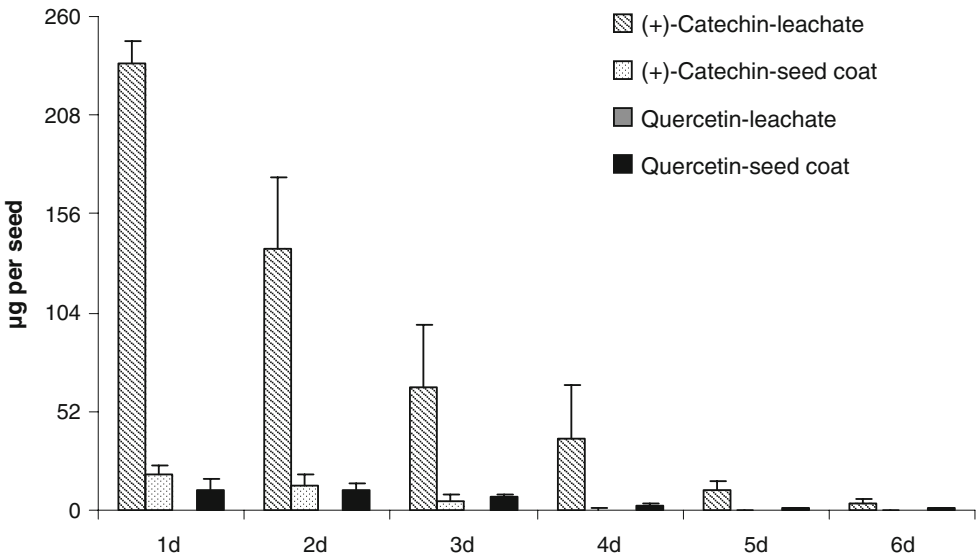

Fig. 4 Quantification of quercetin and catechin present in the seed coat and in the seed leachates of *S. virgata* during the beginning of imbibition (1 day—first day) to the ending of the germination process (6 days—sixth day). Analyses were performed by HPLC-MS, and compounds were quantified and detected by using a commercial standard. *Bars* represents the SD of the means (N=3)

plasm, which induces cell death (Bais et al. 2003). We also found phytotoxic effects of seed leachate catechin on rice seedlings (Fig. 3).

S. virgata is considered an invasive species in flood and damp soils, especially inundated rice plantations (Kissmann and Groth 1999). Therefore, the presence of this toxin in seed leachates may indicate an allelopathic strategy during germination and may contribute to the protection of *S. virgata* seeds against the attack of potential pathogens.

S. virgata is a pioneer species that produces many long-term viable seeds within indehiscent legume fruits. These fall on the ground and are further dispersed by water and/or wind, as reported for other *Sesbania* species (Pott and Pott 1994; Ceballos et al. 1998). The species thus forms a transitory seedbank, and its allelochemicals are released during seed imbibition. As described by Ceballos et al. (1998), the anatomical organization of *Sesbania* seeds is finely adapted to facilitate the rapid deployment of chemicals present in the seed coat, contributing to the rapid mobilization of these compounds toward the zone around the imbibed seed. Although these chemicals can be altered by reactions with other substances in the soil, microbial breakdown, and compound stability, the presence of active substances in the seed coat and their early release in high amounts at the beginning of imbibition suggest that they may play an ecological role. An early pulse of high catechin concentrations could contribute to enabling the species to rapidly and temporarily control the growth of nearby plants under specific environmental conditions. Early allelopathic effects may be advantageous to the competitive outcome; and resource depletion depends on the size of competing plants (Laterra and Bazzalo 1999). Moreover, antimicrobial activity of (+)-catechin could provide a hostile environment to potential microbial invaders.

Root-secreted (±)-catechin may contribute to the invasive behavior of the noxious weed *Centaurea maculosa*, which shows a devastating effect on species native to the Northeast of USA (Bais et al. 2002). Despite recent findings that indicate that the amounts of catechin found in soils around *C. maculosa* are lower than those previously reported to be phytotoxic (Blair et al. 2005, 2006), probably due to the low stability of the catechin in the soil, a short-term pulse of high amounts could be sufficient to confer some advantage at critical periods of development. This has been observed recently in the field for root exudates of *C. maculosa* (Perry et al. 2007). It is also important to note that the dynamics of root exudation is different from the release of substances from seed coats. As reported by Phillips et al. (2006), plants are able to recover part of their root-exuded compounds, sometimes with an influx rate that exceeds their efflux. *S. virgata* produces seeds with the ability to control water imbibition in early stages of germination, and as reported for other species of *Sesbania*, the anatomical structure of the seed coat plays a role in the establishment of an allelochemical-rich zone during imbibition (Ceballos et al. 1998). Additionally, seed coats remain in the environment, possibly increasing the amounts of soil catechin. The compound continues to be released up to 6 days after the beginning of imbibition as shown in Fig. 4.

The detection of other phytotoxic fractions derived from the *S. virgata* seed leachates that do not contain (+)-catechin in their molecular composition (Fig. 1) suggests that this seed can likely release other prospective phytotoxins that may relate to the invasive character and to adaptive mechanisms. Our data indicate that the seed coat of *S. virgata* contains the bioflavonoids (+)-catechin and quercetin, but that only (+)-catechin seems to operate as an allelochemical. Additional experiments are needed to

determine the presence of other active compounds and also the possibility of co-interactions that could potentiate phytotoxic effects.

Allelopathic Enhancement and Differential Gene Expression in Rice under Low Nitrogen Treatment

Biqing Song · Jun Xiong · Changxun Fang · Long Qiu · Riyu Lin · Yiyuan Liang · Wenxiong Lin

Received: 29 April 2007 / Revised: 30 December 2007 / Accepted: 27 February 2008 / Published online: 8 April 2008

Abstract The allelopathy-competition separation (ACS) based approach was used to explore the biointerference relationship between rice accessions and barnyardgrass exposed to different nitrogen (N) supplies in hydroponics. Rice accession PI312777 exhibited high allelopathic potential to suppress the growth of accompanying weeds, especially when the culture solution had low N content. The non-allelopathic rice Lemont showed an opposite result. Additionally, subtractive hybridization suppression (SSH) was used to construct a forward SSH-cDNA library of PI312777 to investigate gene expression profiles under low N treatment. A total of 35 positive clones from the SSH-cDNA library were sequenced and annotated. According to the function category, 24 genes were classified into five groups related to primary metabolism, phenolic allelochemical synthesis, plant growth/cell cycle regulation, stress response/signal transduction, and protein synthesis/degradation. Among them, two up-regulated genes that encode PAL and cytochrome P450 were selected. Their transcript abundance at low N level was compared further between the allelopathic rice and its counterpart by utilizing real-time quantitative polymerase chain reaction (qRT-PCR). The transcription levels of the two genes increased in both rice accessions when exposed to low N supply, but PI312777 at a higher magnitude than Lemont. At 1, 3, and 7 days of the treatments, the corresponding relative expression levels of *PAL* were 11.38, 4.83, and 3.57 fold higher in PI312777 root, but there were 1.15, 2.74, and 2.94 fold increases for Lemont, compared with the control plants fed with regular nutrient. The same trend was found for *cytochrome P450*. These findings suggest that the stronger ability of PI312777 to suppress target weeds, especially in low N nutrient conditions, might be attributed to the stronger activation of the genes that function in *de novo* synthesis of allelochemicals.

Introduction

Rice monocultural practices along with the heavy use of chemicals that include herbicides are characteristic of modern agriculture and are inducing herbicide tolerant and/or resistant weed biotypes, such as barnyardgrass (*Echinochloa crus-galli* L.), a major pest plant in rice production. Allelopathy has attracted increasing attention as a feasible option for controlling field weeds with an increasing awareness of environmental protection and human health. The relevant studies on rice allelopathy began about 20 years ago in the United States. Since then, progress has occurred in understanding the genetics, chemistry, and physiology of allelopathy (Olofsdotter et al. 2002; Bi et al. 2007).

Previous studies showed that allelopathic potential in the suppression of target weeds could be enhanced in response

to external biotic and abiotic factors such as pest attack, weak solar radiation, higher temperature shock, and nutrient starvation (Einhellig 1999; Wu et al. 1999; Belz 2007). Kim et al. (2000) first reported that the allelopathic ability in rice (*Oryza sativa* L.) was induced by higher densities of accompanying weeds. Besides biotic factors, several abiotic factors have been proposed to regulate the expression of crop allelopathy. These include agricultural production input factors and environmental conditions (He et al. 2004; Xiong et al. 2005; Belz 2007). Liu et al. (2006) found that production of allelochemicals was stimulated in *Alexandrium tamarense* after exposure to N- and P-limited conditions. The target plant *Prorocentrum donghaiense* was killed by the donor plant *A. tamarense* after co-culture for 4 days under nutrient-limited conditions but survived under nutrient-sufficient conditions. Shen and Lin (2007) also observed the inducible phenomenon in rice allelopathy, i.e., stronger inhibition of the target weed *E. crus-galli*, as P nutrient level dropped to below the optimum in hydroponic mixtures of rice/weed. Although the associated mechanism is not clear, these studies suggest that stress factors may elicit allelochemical biosynthesis in competing crops, which is similar to plant defensive responses when attacked by insects or pathogens. Thus, the triggering of differential induction of biosynthetic pathways by using specific stress factors can be applied to elicit the production of allelopathic compounds. Furthermore, such an approach may assist in the design of strategies for practical application of crop allelopathy (An et al. 2003; Xu et al. 2004; Friebe et al. 2006; Belz 2007).

This study evaluated the effect of allelopathic function of different rice accessions by using the allelopathy-competition separation approach (ACS) (Xiong et al. 2005). Additionally, a combined analysis of subtractive hybridization suppression (SSH) and real-time quantitative polymerase chain reaction (qRT-PCR) was performed to investigate differential gene expression patterns in allelopathic and non-allelopathic rice accessions treated with low N nutrient conditions in rice/weed mixtures.

Methods and Materials

Plant Materials Rice (*O. sativa*) accession PI312777 (high allelopathic potential) and Lemont (low allelopathic potential) introduced from the USA were selected as donor plants. Barnyardgrass (*E. crus-galli* L.) was used as the receiver plant.

Experiment 1: Allelopathic Performance in Response to N Treatments Treatments followed Xiong et al. (2005) with minor modification. Seeds of the two rice accessions and barnyardgrass were germinated on seedling trays. When the seedlings reached the 3-leaf (rice) and 2-leaf (barnyardgrass) stages, respectively, forty uniform seedlings of each were selected, transplanted into a Styrofoam plate (holes spaced at 5×6 cm^2), and the seedlings stabilized with a cotton plug inserted into each. The Styrofoam plate was floated on a pot ($45\times35\times15$ cm^3) filled with 10l Hoagland nutrient solution (normal nutrient condition) (Fajer et al. 1992; Belz and Hurle 2004; Kim et al. 2005; Xiong et al. 2005). PI312777 and Lemont seedlings were grown under the same condition. After 7 d of recovery in the Hoagland nutrient solution, 30 rice seedlings and 10 weed seedlings were transplanted into a Styrofoam plate to form a hydroponic rice-weed mixture with the barnyardgrass seedlings in the center surrounded by the rice seedlings. This setting can induce rice allelopathy (Belz and Hurle 2004; Kim et al. 2005; Xiong et al. 2005). Three N treatments in Hoagland's solution were prepared and consisted of normal N (20 mg•l^{-1}, denoted as 1N), half normal N (10 mg•l^{-1}, 1/2N), and quarter normal N (5 mg•l^{-1}, 1/4N). pH values of the treatment solutions were all maintained at 5.5 throughout the experiment by using 1M NaOH or 0.5M H_2SO_4 (Kim et al. 2005; Shen and Lin 2007). A monoculture of barnyardgrass under the same condition was used as control (ck) for each treatment.

Barnyardgrass, the target plant, including control plants, were sampled 7 d after the start of co-culture. Harvested tissues were snap-killed in an oven at 105°C for 20 min, and then dried at 70°C until constant weight. Dry weight (DW) was used to determine inhibition rates (IR) above controls and to evaluate the biointerference (BI) that consisted of the allelopathic effect (AE) and resource competition (RC) (Olofsdotter 1998; Xiong et al. 2005). IR was calculated as: IR = (ck - treatment)/ck × 100%, which indicates inhibition when IR> 0 and promotion when IR< 0.

After barnyardgrass seedlings were harvested, the used nutrient solutions from the three treatments were collected and their nitrogen (N), phosphorus (P), and potassium (K) concentrations were all reconstituted to full Hoagland levels. These treated solutions, denoted as A, B, and C corresponding to the treatments 1/4 N, 1/2 N, and 1N, respectively, were then used for hydroponic barnyardgrass monoculture to determine whether its growth response was mediated by the root exudate residuals from the two rice accessions. Nine barnyardgrass seedlings at the 3-leaf stage were transplanted into each pot. Seedlings grown in fresh Hoagland solution were used as control (ck). The pH of the culture solution and residual levels of N, P, and K were measured and balanced weekly. Barnyardgrass in all treatments was sampled on d 14. The DW of barnyardgrass from each treatment was recorded. IR differences were used to evaluate allelopathic effects of the two rice accessions on barnyardgrass. BI was separated into AE and RC using the equation: BI = AE + RC.

Table 1 Comparison of biointerference (BI) of barnyardgrass by two rice accessions under different nitrogen treatments

Hydroponic N level (mg•l^{-1})	BI of barnyardgrass by PI312777 (%)	BI of barnyardgrass by Lemont (%)
5	72.65±6.45Aa	67.12±4.76Aa
10	73.70±4.02Aa	19.15±0.51Bb
20	64.86±3.91Aa	12.66±0.14Bb

BI = (1-(DW of target weed in the mixture)/ DW of the target weed in monoculture) × 100%. Values in the table are means ± SD of three replicates. The small letters represent significant differences at the 5% level; capital letters represent significant differences at 1% level. The same convention was used for all the tables unless stated otherwise.

Experiments were conducted in triplicate in a greenhouse of the Agroecological Institute, Fujian Agriculture and Forestry University, Fuzhou, China between 2004 and 2006. All data were subjected to statistical analysis using Least Significant Difference Test.

Experiment 2 - Differential Expression of Allelopathy-Associated Genes To detect the differential expression of genes associated with biointerference in the rice/weed interaction, a combination of SSH and qRT-PCR was used. Seedling preparation and subsequent treatment conditions were the same as the above mixtures, except that culture solutions had two N levels – 5 mg•l^{-1}N (the lower N treatment; 1/4 strength Hoagland, denoted as 1/4 N) and 20 mg•l^{-1} N (normal N; 1N as full strength Hoagland). Roots of the two rice accessions were sampled on d 1, 3, and 7 after N treatment, respectively. Roots were frozen in liquid N_2, and stored at –80°C until analysis.

Construction of Subtractive Library SSH was used to construct a subtractive library (Diatchenko et al. 1996). Total RNA was extracted with Trizol Reagent (Invitrogen), and genomic DNA was removed with *DNaseI* (TaKaRa). Tester and driver RNA samples were prepared by pooling equal amounts of RNA from rice roots grown in 1/4N and 1N solutions. cDNA was synthesized according to the method of SMART PCR cDNA Synthesis. LD-PCR products were purified and digested with 15 unit *RsaI* at 37°C for 4 hr. SSH was carried out by using the PCR-Select cDNA Subtraction Kit (Clontech) based on the manufacturer's instructions. After two hybridizations, a nested PCR was performed to selectively amplify the differentially expressed fragments. Products of PCR were purified by E.Z.N.A. Cycle-Pure Kit (OMEGA), ligated into pMD18-T Vector (TaKaRa), and then transformed into *E. Coli* DH5α cells by $CaCl_2$. The bacteria were plated onto ampicillin-containing Luria-Bertani (LB) agar plates, which were overlaid with X-Gal and isopropyl-beta-D-thiogalactopyranoside (IPTG). After incubation (overnight at 37°C), white colonies (putative positive clones) were picked and cultured in 1.5 ml microfuge tubes with 500 μl LB liquid medium (AMP^+).

Screening and Identification of Positive Clones Rice clones were amplified by PCR by using primer 1 and primer 2R in the Clontech PCR-select cDNA subtraction Kit. PCR products were blotted onto Hybond-N + nylon membranes (Amersham), which were dried for 2 hr at 80°C under vacuum. Tester cDNA and driver cDNA were used as forward and reverse probes, respectively; both were hybridized with the selected clones. Colonies that showed strong hybridization signal with the forward SSH probe, but not with the reverse probe were positive clones. Reverse northern blots were performed according to the manufacturer's instructions of DIG-High Prime DNA Labeling and Detection Starter Kit® (Roche). The hybridization membranes were scanned by ArtixScan 1010 (Microtek).

Sequence Analysis Thirty-five clones were selected and sequenced at Shanghai Sangon Biological Engineering Technology and Service Co., Ltd. The identity of these genes was searched by blastn and blastx in the National Center for Biotechnology Information, USA (NCBI) database.

Confirmation of Up-Regulated Gene Expression qRT-PCR was used to validate the results from SSH analysis. First strand cDNA was synthesized from the same DNA-free-total RNA extracts used for SSH with ExScript RT reagent Kit (TaKaRa). After dilution (1:10, v/v), cDNA samples were amplified with gene-specific primers (5′-CTCGCCGTTCCA CTCCTTG-3′ and 5′-GCTCGGCTGCGTATTCCT-3′ for *PAL*; 5′-TGCTGTATCATGGGAAACTAAA-3′ and 5′-AGT CATAGATAGCCAAGAGGGT-3′ for *cytochrome P450*). RT-PCR was performed according to the method of SYBR Green Iwith the *SYBR Premix Ex* Taq (TaKaRa). *Actin* was

Table 2 Effects of the used solutions for culturing two rice accessions (PI312777 and Lemont) on the inhibition rate (IR) of barnyardgrass in monoculture

Treatment solution	IR of barnyardgrass over control mediated by PI312777 (%)	IR of barnyardgrass over control mediated by Lemont (%)
A	54.16±2.97Aa	3.65±0.66Aa
B	44.58±3.16Aab	13.81±7.58Aa
C	38.54±0.00Ab	9.45±0.06Ba

Treatment solution A, B, C in this monoculture refer to the used solutions collected from the mixture trial and were all reconstituted to the same N, P, and K levels as full Hoagland solution, but putatively contained different levels of allelochemicals released from allelopathic rice accession and its counterpart in the mixture under different nitrogen treatments (5, 10, and 20 mg•l^{-1} denoted as 1/4 N, 1/2 N, and 1N) as described in experiment 1

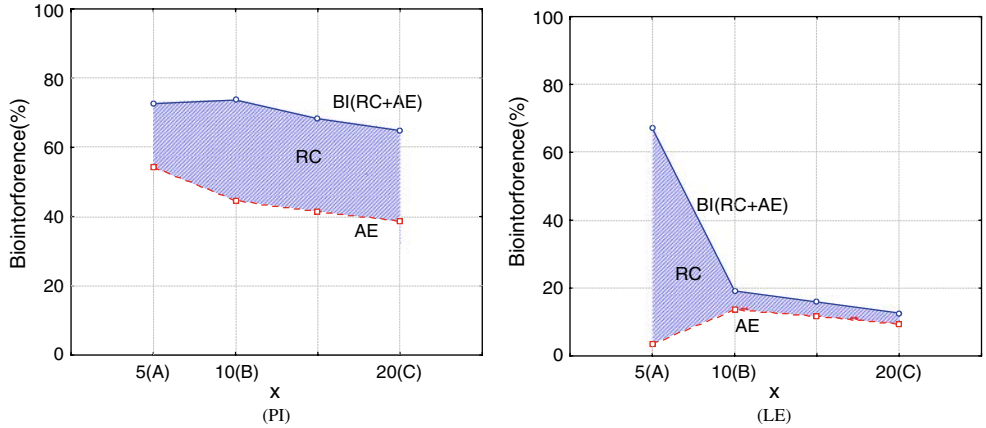

Fig. 1 The biointerference of allelopathic rice PI312777 (*PI*) and its counterpart Lemont (*LE*) with the accompanying barnyardgrass exposed to different nitrogen levels. Note: biointerference (*BI*) = allelopathic effect (*AE*) + resource competition (*RC*). *A*, *B*, *C* in this monoculture refer to the used solutions collected from the mixture trial and were all reconstituted to the same N, P, and K levels as full Hoagland solution, but putatively contained different levels of allelochemicals released from allelopathic rice accession and its counterpart in the mixture under different nitrogen treatments (5, 10, and 20 mg•l^{-1} denoted as 1/4 N, 1/2 N, and 1N) as described in experiment 1

used as the reference gene detected with primers 5′-TGTAAGCAACTGGGATGA-3′ and 5′-CCTTCGTAGATTGGGACT-3′. The amplification procedure was: an initial denaturation at 95°C for 10 sec followed by 41 cycles of 95°C for 5 sec and 60°C for 20 sec. The specificity of the amplification was verified by the melting curve at the end of the PCR cycle. Fluorescence was read at every temperature increment of 0.2°C with a hold time of 2 sec. The relative quantification (ratio) of a target gene was calculated with the following formula: ratio = $2^{-\Delta\Delta Ct}$ (Pfaffl 2001) and was analyzed using software SPSS 11.5.

Results

Allelopathy and Resource Competition Biointerference (BI) of allelopathic rice PI312777 was much greater with barnyardgrass under the normal N hydroponic solution compared with the non-allelopathic rice Lemont (Table 1). As N decreased, biointerference of barnyardgrass by both rice accessions appeared to increase, but the increase by PI312777 was not statistically significant. In contrast, the biointerference of barnyardgrass by Lemont was dramatic (Table 1). When N levels were reduced to 5 mg•l^{-1} (i.e., the low N level), the BI of neither rice accession was significant). Barnyardgrass in the different treated solutions in subsequent monoculture experiment were all inhibited to some extent compared with control plants growing in fresh nutrient solutions (Table 2). Treated solutions derived from PI312777 strongly suppressed target plants and accounted for ca. 60-71% of the total biointerference; the allelopathic effect increased from C to A treatment (Table 2). This suggests that the allelopathic effect of PI312777 could be enhanced under limited N conditions. Treated solutions derived from Lemont only slightly inhibited target plants (Table 2). Instead, Lemont showed high resource competition under N-limited conditions,

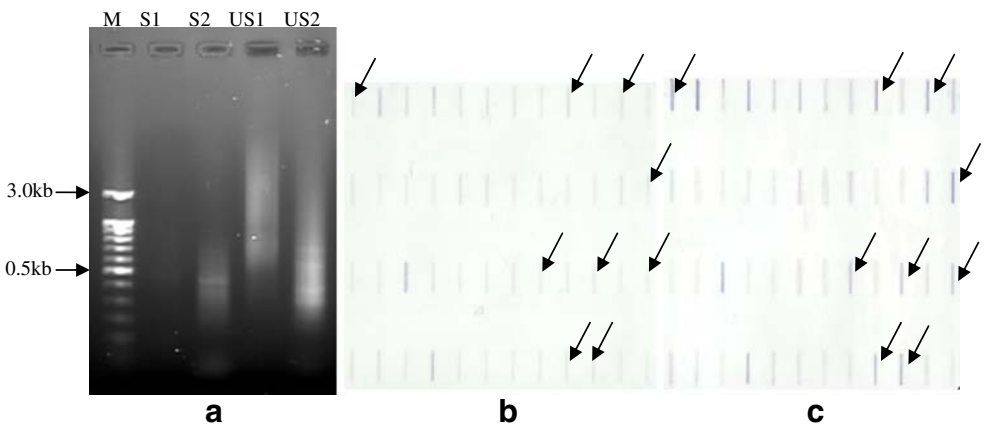

Fig. 2 The results of SSH (**a**) and the screening of positive clones by reverse northern blot (**b** and **c**). **a** *M*, marker; *S1*, first PCR product of subtracted tester cDNA; US1, first PCR product of unsubtracted tester cDNA; S2, second PCR product of subtracted tester cDNA; *US2*, second PCR product of unsubtracted tester cDNA. **b** Reverse hybridization. **c** Forward hybridization. *Arrows* pointed out positive clones

explaining approx. 95% of total biointerference (Table 1, Table 2, and Fig. 1).

Induced Gene Expression in Allelopathic Rice The forward subtracted cDNA library was constructed by SSH to detect the molecular response of PI312777 to low N (1/4 N) treatment (see Fig. 2a). A total of 994 clones were obtained from the forward subtractive library; 188 of them were selected for reverse northern blots after PCR (see Fig. 2b and c). Gene expression in 35 PI312777 clones were positive for up-regulation. These clones were sequenced, and the cDNA sequences were searched against standard databases (www.ncbi.nlm.nih.gov). According to nucleic acid homologies and encoded protein sequences, 32 out of the 35 clones were successfully assigned. The putative functions of the assigned expressed sequence tags (ESTs) are given in Table 3. Clones 312, 403, and 891 encode for the same putative triosephosphate isomerase, and clone 323 showed the highest homology to putative glycine hydroxymethyltransferase from rice (*O. sativa*), all of which are involved in plant primary metabolism. Clones 278, 547, and 663 had homology to phenylalanine ammonia-lyase

(PAL), putative o-methyltransferase from *O. sativa* and cytochrome P450 from *Plutella xylostella,* respectively. These enzymes were associated with *de novo* synthesis of phenolic-based allelochemicals. Clones 34, 84, 257, 642, 935, 489, and 272 showed the highest homologies to putative SCARECROW gene regulator-like, no apical meristem (NAM) protein, subitilisin-chymotrypsin inhibitor, DNA binding protein S1FA family protein, S1/P1 nuclease, BolA-like protein, and putative CLB1 protein (calcium-dependent lipid binding), respectively from *O. sativa,* which participate in plant growth and cell cycle regulation. Clones 803, 943, and 243 had the greatest homologies to putative protein kinase interactor 1, catalase 2 (CAT-2), and myosin-like protein. In contrast, clones 201, 120, 715, and 917 had homologies to the same metallothionein-like protein type 1, and an expressed protein from *O. sativa* that plays a critical role in stress resistance and signal transduction. Clones 188, 341, 640, 177, and 657 encode for the same putative 60S ribosomal protein L22–2 and 40S ribosomal protein S13, respectively, but clones 486, 399, 349, 622, and 743 showed the highest homologies to putative 40S ribosomal protein S9, putative 60S ribosomal protein L5, putative chaperonin 10, putative apoptosis-related protein, and HSP20-like chaperone, respectively, from *O. sativa*. Those enzymes function in protein synthesis and degradation. The four assigned sequences encoded for by clones 298, 308, 645 and 700 have no known function (Table 3).

Differential Expression of Two Genes by qRT-PCR Gene expression of both *PAL* and *P450*, which are involved in *de novo* allelochemical synthesis, increased in PI312777 and Lemont when exposed to nutrient conditions with limited N availability. The relative expression levels of the two genes in PI312777, however, were higher than those in Lemont, showing that the relative transcript abundance of *PAL* in root of PI312777 increased by 11.38, 4.83, and 3.57 times, while in Lemont they increased by 1.15, 2.74 and 2.94 times on day 1, 3, and 7 after treatment with low N, respectively. The same was true in the expression of *P450* gene for the two rice accessions as shown in Fig. 3. This finding further confirms the findings of SSH analysis (Table 3).

Discussion

The present study shows that rice PI312777 has higher allelopathic potential in the suppression of target weed growth under all N treatments, accounting for 59.57-78.83% of the total biointerference. The reverse was true for rice Lemont that had a lower allelopathic effect (4–14% in terms of barnyardgrass inhibition) in all N treatments, but dramatically increased resource competition (by up to 64% when N was reduced to 5 $mg \bullet l^{-1}$) and explained nearly 95% of the total biointerference (Fig. 1). It is suggested that the allelopathic potential of PI312777 is enhanced under N-limited conditions. The change in allelopathic potential seems to result from differential gene expression mediated by different N conditions, since N deprivation and other stress factors can induce gene expression associated with secondary metabolism in many crops (Sheveleva et al. 1997; Scheible et al. 2004). Up-regulation of the putative genes that encode for PAL, O-methyltransferase, triosephosphate isomerase, and cytochrome P450, which are involved in *de novo* synthesis of phenolic allelochemicals and detoxification of toxic substances, was detected in PI312777 by SSH at low N. PAL is the first key enzyme in phenylpropanoid metabolism that can be regulated by various biotic and abiotic factors to different extents depending on different plant species (Dixon and Paiva 1995; Dixon et al. 2002). P450 is directly involved in the formation of *p*-coumaric acid (Anterola et al. 2002), an intermediate for methylated polyphenolic synthesis, and detoxification of plant autotoxic substances (Li et al. 1997). Triosephosphate isomerase is vital in the glycolytic pathway, and provides substrate for phenylpropanoid metabolism (Xu and Hall 1993). It is suggested that allelopathic potential can be enhanced under N-limited conditions,

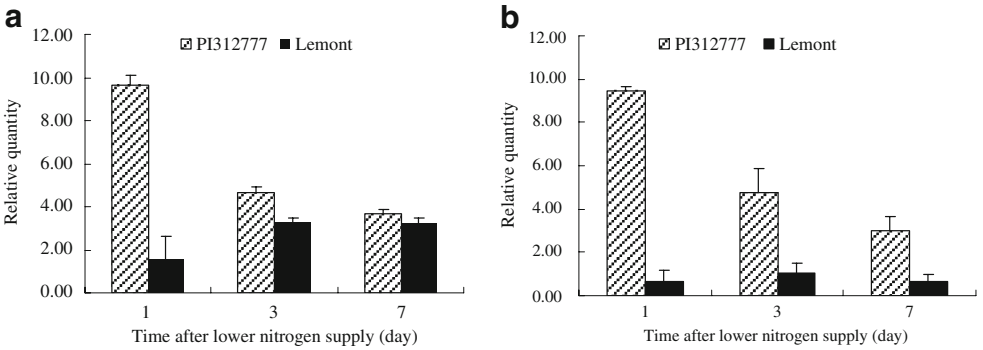

Fig. 3 Relative expression levels of the genes encoding PAL (**a**) and Cytochrome P450 (**b**) in allelopathic rice accession PI312777and its counterpart Lemont under low nitrogen treatment by using qRT-PCR analysis

which may result in the activation of genes that encode for PAL and P450. In turn, this may lead to increased phenolic allelochemicals that can suppress the growth of accompanying weeds under limited N conditions in hydroponic solution.

Phenolic allelochemicals are derived mainly from L-phenylalanine via *t*-cinnamate (Razal et al. 1996; Scheible et al. 2004). Stimulation of phenylpropanoid metabolism can be triggered by changes in N levels and mediated by the induction of enzymes in the early steps of phenylpropanoid biosynthesis (Chishake and Horiguchi 1997; Fritz et al. 2006; Kovacik et al. 2007). Under decreased N availability, phenolic content and PAL activity in plants may increase because of decreased demand for proteins required for growth. In this process, ammonium ions released by PAL can be assimilated to increase N cycling, for example, via the GS/GOGAT system (Razal et al. 1996). The resulting N-free carbon skeletons of *t*-cinnamate can be shunted into phenylpropanoid metabolism (Bryant et al. 1987; Reichardt et al. 1991). This hypothesis seems to explain why the allelopathic potential increases in response to low N stress by phenolic compounds that have low turnover rates, but not by terpenoids that have higher turnover rates (Reichardt et al. 1991; Mihaliak et al. 1991).

In addition, the present work shows that molecular changes in plant growth and the cell cycle are also involved in the enhancement of rice allelopathic potential under limited N conditions. For example, the putative SCARE CROW (SCR) gene regulator-like is involved in cell division (Wysocka-Diller et al. 2000). Subitilisin-chymotrypsin inhibitor in rice is one of bifunctional α-amylase/subtilisin inhibitors, which functions in the regulation of seed development and root growth of rice seedlings (Yamagata et al. 1998). The genes that encode for putative CLB1 protein and BolA-like protein appear to be involved in the modulation of the cell cycle (Luo et al. 1994; Kasai et al. 2004). The up-regulation of these genes detected by SSH in the present study suggests that root growth of allelopathic rice was facilitated in low N conditions, which, in turn, led to the increased root/shoot ratio as auto adaptation to the limiting nutrient conditions (data not shown here).

The present study also indicates that other genes were upregulated in PI312777 when exposed to low N. For instance, the genes that encode for putative protein kinase interactor 1, metallothionein-like protein type 1, catalase 2 (CAT-2), ribosomal proteins, and S1/P1 nuclease were detected simultaneously in PI312777 (Table 3). These genes are involved in signal transduction, stress resistance and detoxification, protein synthesis, and programmed cell death-associated endonuclease (Elias et al. 2002; Bauwe and Kolukisaoglu 2003). Therefore, the transcriptional activation of various biosynthetic pathway genes can be an important step for regulating the accumulation of phenylpropanoids during a plant's response to nutrient deficiency. Extensive molecular work is still needed to understand the network of signal transduction and the associated control for increasing chemical defense and growth adaptation to the limiting nutrient conditions in rice/weed mixtures (Dixon and Paiva 1995; Dixon et al. 2002).

In summary, rice allelopathy has been confirmed as an inducible genetic trait (Bi et al. 2007) that is associated with molecular regulation of secondary metabolic pathways. It may be feasible to trigger allelopathic potential through alteration of agricultural practice or manipulation of environmental conditions. Further study needs to be directed to this end to elucidate the molecular genetics and enzymology of associated biosynthetic pathways, and to establish a series of specific management strategies that can be applied to crop production to avoid down-regulation of the relevant genes associated with allelopathic activity (Belz 2007; Macias et al. 2007).

Relationships Between Sex and Stress Hormone Levels in Feces and Marking Behavior in a Wild Population of Iberian Wolves (*Canis lupus signatus*)

Isabel Barja · Gema Silván · Juan Carlos Illera

Received: 4 May 2007 / Revised: 6 March 2008 / Accepted: 6 March 2008 / Published online: 5 April 2008

Abstract Feces deposited by the breeding alpha pair on exposed substrates and/or zones may act as visual and olfactory marks associated with social dominance in wolves. The aim of this study was to determine if there was a correlation between marking behavior, sex hormone levels, and physiological stress in a wild population of Iberian wolves in Northwest Spain. The glucocorticoid and sex hormone levels were measured in feces collected as a function of exposure (conspicuous/inconspicuous), height (above ground level/at ground level), and strategic location in the habitat (at crossroads/off crossroads), as well as the frequency of re-marking. The feces, believed to serve as marking cues, had higher glucocorticoid levels (cortisol) and sex hormones (testosterone, progesterone, and estradiol). The results suggest that in Iberian wolves, the alpha pair is subject to higher social stress than subordinate individuals, and that the reproductive suppression of subordinates is not mediated by chronic glucocorticoid elevation.

Introduction

Vertebrates may use chemical signs in different contexts and under different environmental conditions, and these can be of particular importance in situations (at night, underground, or in dense vegetation) when visual and auditory signs are difficult to detect (Gorman and Trowbridge 1989). A number of the features of these chemical signals, such as spatial range, localizability, temporal parameters, intensity, detectability, and information content, may be adjusted for particular social functions (Alberts 1992).

In carnivores, marking behavior may serve many functions, which include the identification of individuals, their reproductive state, and/or social status, as well as information with respect to territoriality (Gorman and Trowbridge 1989). An association between marking and dominance has been reported for a large number of species (Ralls 1971; Gorman and Trowbridge 1989), and in some cases only high-ranking individuals (alpha pair) exhibit marking behavior (Peters and Mech 1975; Rothman and Mech 1979) through which they continually announce their status to subordinates (Gorman and Trowbridge 1989).

Although many species use urine and feces as visual and scent marks (Macdonald 1980; Gorman 1990), it is often difficult to distinguish between normal excretion and their use in communication. However, one feature is that those used as signals are usually produced in small quantities and are often left in prominent sites (Kleiman 1966; Macdonald 1985; Gorman and Trowbridge 1989; Barja and De Miguel 2004; Barja et al. 2004, 2005), such as junctions on frequently used tracks, where they may be detected by animals traveling in different directions (Peters and Mech 1975; Vilà et al. 1994; Zub et al. 2003; Barja et al. 2004).

In social species, agonistic and aggressive interactions between individuals may be a source of stress (Creel 2001; Sands and Creel 2004; Creel 2005), initiating a cascade of physiological responses that results in glucocorticoid secretion (cortisol/corticosterone) by the adrenal cortex (Axelrod and Reisine 1984; Stewart 2003). Short-term glucocorticoid secretions have been related to adaptive responses of animals to stressors, and are considered beneficial for the organism. However, long-term glucocorticoid secretion may lead to pathologies (e.g. reproductive and/or endocrine disruption, suppression of the immune system, and gastrointestinal ulcerations) (Stewart 2003) that could significantly reduce overall fitness, by affecting survival and reproductive success (Sapolsky 1992; Möstl and Palme 2002). Consequently, glucocorticoids have been used as physiological indicators of stress in several species (Möstl and Palme 2002; Stewart 2003), and it has been suggested that such assays may provide a noninvasive method for evaluating adrenal and gonadal functions (Wasser et al. 2000; Young et al. 2004).

Wolves are social animals, and packs can be characterized as dominance hierarchies that consist of a dominant male and female (the alpha pair), with the remainder of the pack usually made up of their offspring from several litters (Mech and Boitani 2003). Only a small proportion of all wolf scats found in the habitat are in "exposed" sites, and if they serve as cues left by the alpha pair (the only individuals that reproduce in the group), then one would predict that levels of sex hormones in the putative marking scats would be significantly higher than in those found in unexposed sites. Furthermore, one would predict that glucocorticoid levels would also differ, reflecting different stress levels between dominant and subordinate members of the pack. The present study was designed to test these hypotheses.

Methods and Materials

Study Site The research was conducted between June 2004 and August 2005 in the Macizo Central Ourensano in Galicia (NW Spain), a 120-km^2 mountainous area, 850–1,707 m above sea level with a continental (hot summers and cold winters) climate. The area was occupied by a pack of Iberian wolves, with an alpha pair that reared pups in both years.

Fecal Sample Analysis and Collection Fecal samples were collected once each month along roads and trails frequently used by the wolves, but away from human habitation to minimize the chances of collecting domestic dog feces. Wolf feces were identified by their size and shape, and in cases that there was any doubt as to the origin of specific scats (<5% of the total found), they were not collected for the subsequent analyses. In each monthly sampling period, transects were visited twice, at dusk and the following morning, to ensure that only fresh scats (< 12 hr), characterized by a layer of mucus, a strong smell, and no signs of dehydration, were sampled. Approximately 10 g were collected from each scat and held at −20°C until assayed. The fact that wolves are nocturnal ensured that the scats collected each morning had only been exposed to low night time temperatures, thereby reducing potential losses of glucocorticoids, as the concentrations detected may be influenced by prevailing temperature conditions (Möstl et al. 2002; Möstl and Palme 2002).

The spatial characteristics of the deposition site for each scat found was recorded, using substrate type, height, and positions of fecal markings, as well as the incidence of re-marking. Substrates were classified as inconspicuous or conspicuous, the latter being those that, for a human observer, stood out from the surroundings including rocks, plants, and mounds of soil. All others were regarded as inconspicuous (Barja et al. 2005; Barja and List 2006). Feces were considered as true marking cues if they occurred on an exposed substrate >4 cm above ground level (Barja et al. 2005; Barja and List 2006), at an intersection where two or more trails crossed (Barja et al. 2004) and/or they occurred on previous fecal marks, usually those that were on conspicuous substrates.

The fecal samples were analyzed to quantify the metabolite levels of cortisol, testosterone, progesterone, and estradiol. Hormones were extracted by using previously established methods (Brown et al. 1994; Young et al. 2004; Barja et al. 2008), and the efficiency of extraction was tested by the addition of radiolabeled hormones (3H-cortisol, 3H-testosterone, 3H-progesterone, and 3H-estradiol, 4,000–8,000 dpm, ICN, CA, USA) to a parallel set of fecal samples. Hormone levels were determined by using an enzyme immunoassay developed by us and validated for

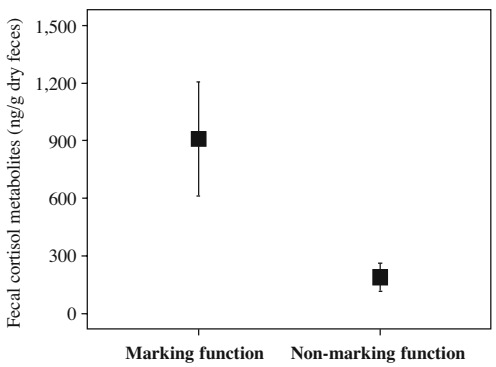

Fig. 1 Comparison of fecal glucocorticoid levels in Iberian wolf scats with (N=21), and without (N=39), a presumed marking function. The fecal samples were collected from June 2004 to August 2005 in Montes do Invernadeiro Natural Park (NW Spain). Mean ± SE is shown for both groups

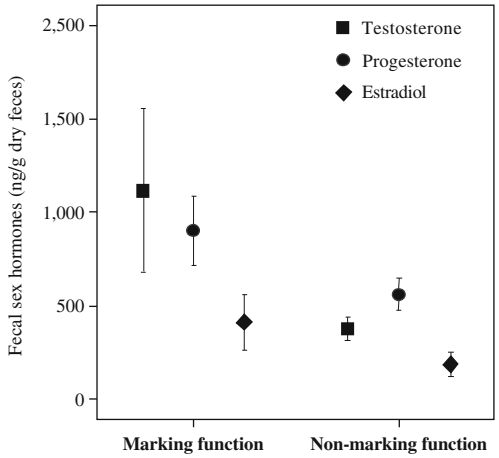

Fig. 2 Comparison of fecal sex hormone concentrations (androgens, progestins, and estrogens) for fecal samples with and without a presumed marking function. Data are presented as mean ± SE

this study system (Barja et al. 2008). Standard dose–response curves were constructed by plotting the binding percentage (B/Bo×100) against the standard hormone concentrations added. Fecal hormone metabolite concentrations are presented as nanogram per gram of dry fecal matter.

Statistical Analyses Kolmogorov–Smirnov–Lilliefors and Levene tests were used to determine the normality of data and homogeneity of variances, respectively. All hormone metabolite concentrations were log-transformed to normalize the data and to decrease heterogeneity of variances. Samples were divided into two groups, depending on whether they were considered to have a marking function or not. *t* tests were used to test for significant differences between two groups. Pearson correlation coefficients were computed to assess the relationship between cortisol metabolite concentrations and sex steroid hormone levels. The data are given as means ± SE and the level of significance for statistical tests was $P<0.05$. The statistical analyses were conducted with the software SPSS 15.0.

Results

Scats presumed to have a marking role had significantly higher levels of glucocorticoids (Fig. 1) and sex hormones (Fig. 2) than those that did not. Furthermore, these significant differences were evident regardless of the criteria used to identify those scats assumed to play a marking role, except for testosterone and progesterone in feces from re-marked and non-re-marked sites (Table 1). Both male and female hormone levels rise at the beginning of the reproductive period, and these changes are associated with the expression of reproductive behavior (Seal et al. 1979; Asa and Valdespino 1998; Mech and Boitani 2003). Consequently, it is of interest to note that in the scats assumed to play a marking role, the mean concentrations of testosterone (1,636.6±819.5 vs. 1,028.4±462.9 ng/g of dry feces; $N=21$, $t=9.7$, $P<0.001$) and estradiol: 441.5±387.6 vs. 409.9±158.5 ng/g of dry feces; $N=21$, $t=7.2$, $P<0.001$) were higher during the breeding than in the non-breeding season. However, the mean levels of progesterone were higher during the non-breeding period (772.1±641.1 vs. 919.0±225.1 ng/g of dry feces, $N=21$, $t=15.4$, $P<0.001$).

Significant positive correlations were found between cortisol metabolite levels, an indicator of stress, and the three sex hormones examined: testosterone ($r=0.249$, $P=0.055$, $N=60$), progesterone ($r=0.594$, $P<0.001$, $N=60$) and estradiol ($r=0.623$, $P<0.001$, $N=60$).

Discussion

The higher levels of sex hormones in the scats in exposed sites, presumed to play a marking role, would support the hypothesis that these were deposited by the breeding alpha pair, as it has been well documented that, in wolves, they are usually the only individuals that reproduce within group (Mech 1999; Mech and Boitani 2003).

Table 1 Mean levels (± SE) of steroid hormones found in wolf scats at Montes do Invernadeiro Natural Park (NW Spain) In relation to physical characterization deposition site

Substrate/Position	Cortisol	Testosterone	Progesterone	Estradiol	No. Samples ($N=60$)
Conspicuous	786.1±340.9*	1,737.6±795.9*	1,380.4±367.0*	467.4±173.7*	10
Inconspicuous	372.1±115.8	412.8±78.4	540.0±73.0	225.9±64.6	50
> 4 cm above ground	936.7±412.0*	2,113.2±956.9*	1,277.6±327.3*	550.8±207.5*	8
< 4 cm above ground	364.9±111.5	406.0±75.7	588.1±90.5	222.3±62.2	52

Fecal hormone metabolite concentrations are presented as ng/g of dry fecal matter
* Indicates a significant difference ($P<0.001$) between the two samples.

Early research with mice (Louch and Higginbotham 1967) and squirrel monkeys (Manogue 1975) in captivity suggested that subordinate individuals were subjected to higher stress. Also, in captive timber wolves, urinary cortisol levels were similar in dominant and subordinate individuals (McLeod et al. 1996). In wolves, it is known that losing fights can increase glucocorticoid secretion (Creel 2005), and it has been argued that chronic stress might underlie reproductive suppression of social subordinates in cooperative breeders (Reyer et al. 1986).

However, the elevated glucocorticoid concentrations that we found, together with the higher levels of sex hormones, in marking scats of the Iberian wolf do not support the psychological castration hypothesis. Instead, our findings, including the positive correlations between the concentrations of cortisol metabolites and the sex hormones, support the notion that maintaining dominance, which yields significant benefits from access to food and mates that result in increased reproductive success, comes at a cost (Creel 2001; Sands and Creel 2004). This is similar to the results of other studies on wild populations of dwarf mongoose (Creel et al. 1992, 1996), African wild dogs (Creel et al. 1996, 1997), and the gray wolf (Sands and Creel 2004; Creel 2005) that showed that dominant individuals suffer higher levels of stress than subordinates. The apparent disparity between the results that use captive and wild populations may be explained by the fact that in captivity subordinate individuals are forced to remain close to dominants, whereas in the wild, moving away is a common means of terminating an attack when behavioral appeasement does not work (Creel 2001).

We believe that a noninvasive method of quantifying glucocorticoid and reproductive steroid levels in fecal samples will be a useful tool for future field studies. This will allow us to obtain both ecological and physiological data, and the combined information will provide the basis for elaboration of more effective and successful conservation programs (Wikelski and Cooke 2006).

Acknowledgments We express our thanks to the Xunta de Galicia and Nature Conservation Service of Ourense for allowing us to perform the study in the Natural Park Montes do Invernadeiro. We thank Stefano Rosellini and Ana Piñeiro for their help in the field, and appreciate the invaluable help of the gamekeepers Tomás Pérez, Ricardo Prieto, and Paco Barja during the data collection in the field. We are grateful to Jeremy N. McNeil and three anonymous reviewers for their helpful comments. This study has been partially supported by the Projects: USEK, no. 7-2004-05, Universidad SEK de Segovia and CAM-UCM no. 920694.

Distance Communication of Sexual Status in the Crayfish *Orconectes quinebaugensis*: Female Sexual History Mediates Male and Female Behavior

William S. Durgin · Kelly E. Martin · Heather R. Watkins · Lauren M. Mathews

Received: 1 June 2007 / Revised: 21 April 2008 / Accepted: 24 April 2008 / Published online: 28 May 2008

Abstract Chemical communication plays an important role in mediating social interactions of many taxa, particularly arthropods. Many individuals communicate information about their reproductive status to potential mates through distance and/or contact pheromones, an ability that may be advantageous to both signalers and receivers. In this paper, we describe tests of two hypotheses on the role of distance communication in the reproductive behaviors of crayfish (*Orconectes quinebaugensis*). First, we hypothesized that male crayfish would show stronger attraction towards virgin females (females with no viable sperm) than towards non-virgin females because of the fitness costs (to males) associated with sperm competition. Second, we hypothesized that female crayfish should show differential responses to mature male signals depending on their own sexual history: virgin females should be more strongly attracted to male signals than should non-virgin females because they must mate at least once to be able to fertilize eggs in the spring. Data from two Y-maze experiments yielded support for both hypotheses: males were attracted to signals from virgin females, but not to signals from non-virgins. Likewise, virgin females were attracted to signals from males, but non-virgin females were not. We discuss our data in the context of the potential costs and benefits of mate searching and suggest that distance chemical communication of sexual status may be particularly advantageous when the costs of mate searching are high.

Introduction

In many species, interactions among individuals are governed by signals that are normally undetectable by humans, including visual (Papke et al. 2007), acoustic (Conner 1999; Fenton 2003), and chemical (Wyatt 2003) signals. In particular, chemical signals are a primary mode of communication in both aquatic and terrestrial arthropods (Greenfield 2002). Although chemical cues may function in many behavioral interactions, their roles in mediating reproductive interactions are of particular interest. Sex pheromones may function in gender recognition during physical contact between conspecifics and/or at a distance and, in some taxa, affect sexual receptivity of one or both sexes (Schiestl and Ayasse 2000; Stebbing et al. 2003; Houck et al. 2007) and to play a role in mate choice by one or both sexes (Widemo and Johansson 2006; Costanzo and Monteiro 2007).

If individuals can accurately send or receive information about sexual status at a distance, this could reduce the risk of costly mate-searching decisions. Males of some taxa can distinguish low- from high-value (e.g., virgin from mated) females by physical contact (Kelly et al. 1998; Uhía and Cordero Rivera 2005; Friberg 2006). However, distance communication of mating history has not been widely reported. In aquatic habitats, distance chemical signals may be subject to complex dispersion patterns (Atema 1995). Nevertheless, much research indicates that waterborne signals play important roles in mediating social interactions of aquatic animals, particularly arthropods (Greenfield 2002). In crayfish, chemical signals carried in the urine

function in dominance interactions among conspecifics (Bergman et al. 2005; Bergman and Moore 2005). However, their roles in reproductive interactions are unclear, although Acquistapace et al. (2002) found that female chemical cues alone were insufficient to elicit responses in males of *Austropotamobius pallipes*, while Stebbing et al. (2003) reported evidence for a sex pheromone released by adult females of the crayfish *Pacifastacus leniusculus*. A number of other crayfish species use pheromones to communicate gender or sexual status (Bechler 1995).

In this study, we explore the role of distance chemical signaling in the reproductive behavior of the crayfish *Orconectes quinebaugensis* (Mathews and Warren 2008), a taxon that may be subject to high mate-search costs (e.g., an increased risk of predation: Garvey et al. 1994; Hill and Lodge 1999). We were interested in determining how chemical signaling and behavioral responses to chemical signals change in response to the sexual histories of females. In this species, mating is temporally decoupled from fertilization, and females store ejaculates in their spermathecae between the autumn mating and spring egg-laying seasons (Hamr 2002). We first hypothesized that sexually mature males would prefer waterborne signals of virgin females (females carrying no viable sperm) over the signals of non-virgin females because of the potential costs of sperm competition. Second, we hypothesized that virgin females would be more attracted to signals from sexually mature males than would non-virgin females because females must mate with at least one male to produce any fertile eggs and should be under selection to associate with sexually mature males. We tested these hypotheses by using a Y-maze apparatus.

Methods and Materials

Collection and Care of Crayfish Crayfish were collected by hand or by seine from the Quinebaug River in Sturbridge, MA, USA. We considered females to be "virgins" at the time they were collected (August) because we have not observed mating behavior before late September either in the field or in the laboratory and have never obtained fertile eggs from isolated females collected in late summer (personal observation). Females were held in two tanks, one with no males and one with a ~1:1 sex ratio. All were ≥25 mm carapace length and sexually mature. Our assumptions that all "virgin" females were unmated (at the time of collection) and that all "non-virgin" females were mated (while in the holding tanks) may not be correct. However, false assignment of the sexual status of females would bias our data in support of our null hypothesis. Experimental males were collected between August and November. All males were in form I (sexually mature; Hamr 2002) and were housed in two tanks with no access to females. All holding tanks were ~190-l and were maintained at light/dark cycles that mimicked external conditions and at ambient temperatures. Clay pots were provided as shelter for the crayfish, and the animals were fed a diet of Wardley shrimp pellets daily.

Design and Testing of Y-Maze Apparatus We designed and constructed a Y-maze apparatus to allow experimental subjects to choose between two water sources (Fig. 1a). The apparatus comprised a pair of Y-mazes constructed of black ABS piping cut in half longitudinally and connected with ABS cement. A wire gate was placed ~15 cm from the end of each stem to contain the crayfish during an acclimation period before the start of each trial. The two Y-mazes were each connected to two water sources (Fig. 1a,b). The sources comprised two components (Fig. 1b): the lower reservoir container (57 l) and the upper secondary container (7.6 l). The secondary containers each had a hole in the bottom, plugged with a 10-cm diameter polyvinyl chloride standpipe elevated 4 cm above the bottom of the secondary container. A 150-W submerged electric pump moved water from the reservoir to the secondary container where the standpipe regulated water depth and, therefore, the rate of flow of water through a valve and into rubber tubing connecting to the Y-mazes.

Experimental Procedure In experiment 1, there were three treatments. In two, experimental males were presented with a choice between control (unconditioned) water and water conditioned by either virgin females or non-virgin females. In the third, males were given a choice between water conditioned by virgin females and water conditioned by non-virgin females. In experiment 2, there were two treatments. In one, virgin females were presented with a choice between control water and water conditioned by mature males, and in the other, non-virgin females were presented with a choice between control water and water conditioned by mature males. In both experiments, crayfish were distributed among treatments haphazardly with respect to carapace length.

Treated water was conditioned for 24 h before use. In the field, crayfish live in environments with some water exchange (particularly in streams), and therefore, a small volume of water conditioned for 24 h may result in an unnaturally high concentration of chemical signals, though such signals may also be volatile and undergo degradation over a 24-h period. We chose a 24-h conditioning period in part for logistic reasons (it simplified coordination among multiple testers), to increase the chance that chemical cues were present in the conditioned water and to reduce the risk of contamination by alarm signals, which have been shown

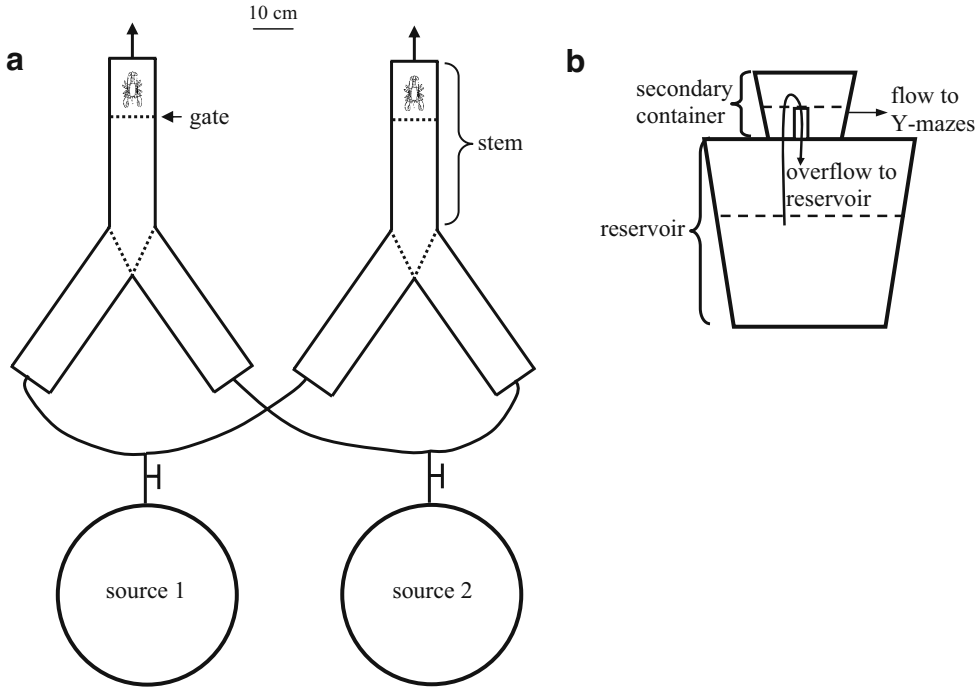

Fig. 1 Diagram of Y-maze apparatus. The apparatus comprised a pair of Y-mazes connected to two water sources. **a** Water flow from each source container was controlled by a stopcock and was split and delivered to one arm of each of two Y-mazes where it flowed down the arm, mixed with water from the other arm in the stem, and finally exited through the rear of the stem. **b** Detailed diagram of a single source container. Each source container comprised a larger reservoir and a smaller secondary container. Water was pumped from the reservoir to the secondary container where it flowed out through tubing to the two Y-mazes. Water depth in the secondary container was controlled by a 4-cm standpipe, which allowed water to flow back into the reservoir when it reached a depth of 4 cm

to affect behavior in the sister species *O. virilis* for >15 min (Hazlett 1990). Other investigators using Y-maze designs to study responses to chemical cues in crayfish have used variable exposure times to treat water sources, ranging at least from 3 h (Zulandt Schneider et al. 1999) to 48 h (Tierney and Dunham 1982).

A 38-l aquarium was filled with 4 l of tap water. Four crayfish of the appropriate treatment group were selected haphazardly from their holding tank and were placed in the conditioning tank with four clay pots. Control water was treated identically, except that no crayfish were added. After 24 h, 2 l of water was removed by siphoning, and water was used in trials within 20 min. Before adding the conditioned waters, the entire apparatus was flushed with tap water. Next, in each reservoir, 2 l of treated or control water was mixed with 57 l of tap water to yield a large enough volume of water for 7 min of data collection. One experimental crayfish was placed behind the wire gates in the neutral zone of each Y-maze (Fig. 1); after a 5-min acclimation period, the outflow valves were opened and the gates removed. All movements were recorded by a video camera above the Y-mazes.

Data Analysis For each treatment, we quantified the total time the experimental crayfish spent in each arm of the Y-maze for the first 7 min of each trial. A crayfish was considered to have entered or exited an arm when the tip of its rostrum passed over the seam that joined the arms in the Y-maze (Fig. 1a). For each trial, we subtracted the time spent in one arm from the time spent in the other. For most treatments, this was the time in the experimental arm minus the time spent in the control arm, but for one treatment in experiment 1, this was the time in the virgin female arm minus the time in the non-virgin female arm. We compared these values with the expected values of zero (no difference in time spent in the two arms of the maze) with Wilcoxon signed-ranks tests in SPSS 14.0, with $\alpha = 0.05$.

The Y-maze apparatus was designed (because of logistical constraints) such that two Y-mazes, each with a focal crayfish, received water from the same control and experimental sources. To investigate the impact of this pseudo-replication on our data set, statistical analyses were run in two ways: first, with each focal crayfish considered to be independent and second, with half the data (one from each set of paired replicates) randomly eliminated for each treatment. In all treatments, random elimination of one sample from each pair of replicates resulted in qualitatively similar inferences (i.e., the same statistical inference was reached with the partial data set as with the entire data set). Therefore, we report means and Z and P values based on the entire data set for each treatment.

Results

In both experiments, all focal crayfish were responsive, spending at least some of the time in one or each of the arms of the Y-maze. In experiment 1, males spent significantly more time in the arm containing water treated by virgin females than in the arm containing control water, but appeared to behave randomly with respect to water conditioned by non-virgin females and control water (Fig. 2). In addition, when presented simultaneously with signals from both virgin and non-virgin females, males spent significantly more time in water conditioned by virgin females than in water conditioned by non-virgin females (Fig. 2).

In experiment 2, virgin and non-virgin females behaved differently towards signals from sexually mature males (Fig. 3). In one treatment, virgin females spent significantly more time in water conditioned by males than in control water, while in the other, females spent more time in control than in water conditioned by males, though this difference was not statistically significant.

Discussion

Our data indicate that both male and female behavior in *O. quinebaugensis* is mediated by the previous mating histories of females. Males showed a significant preference for water treated by virgin females, while they showed no preference for water treated by non-virgins. This suggests that unmated females may represent a more valuable resource to males; mated females may either have low reproductive value to males, or they may not produce chemical signals that advertise their locations to males. There are a number of possible factors that could decrease a female's perceived

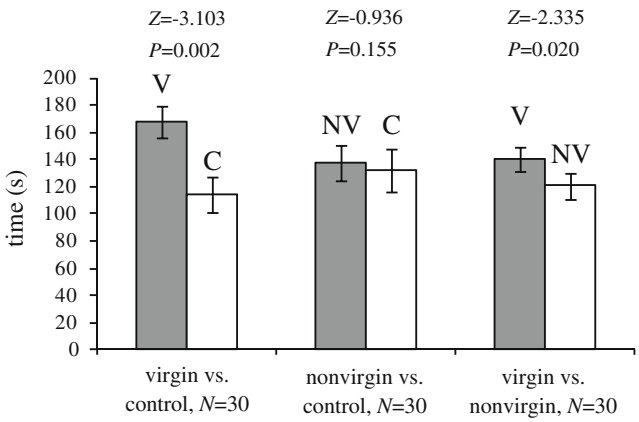

Fig. 2 Mean times spent in each of two arms of Y-maze by males in three treatments. *V* virgin female water, *NV* non-virgin female water, *C* control water. *Z* and *P* values from Wilcoxon signed-ranks tests are shown *above the bars*; sample sizes are listed *below bars*. *Error bars* show standard error of the mean

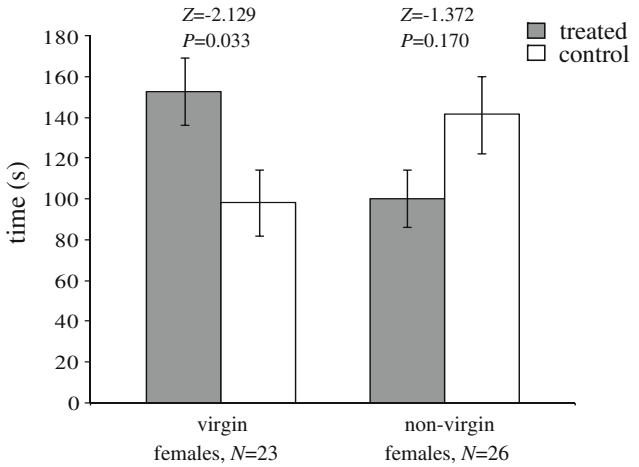

Fig. 3 Mean times spent in each of two arms of Y-maze by virgin or non-virgin females. In each treatment, females were presented with a choice between water treated by exposure to a mature male and control water. *Z* and *P* values from Wilcoxon signed-ranks tests are shown *above the bars*; sample sizes are listed *below bars*. *Error bars* show standard error of the mean

value to males once she has mated. If the first male to mate with a female has an advantage in sperm competition, then males that selectively mate with virgin females would have higher fitnesses. First male sperm precedence has been demonstrated in a number of arthropods, including both spiders (Elgar 1998) and insects (Simmons and Siva-Jothy 1998), but in decapod crustaceans, most investigations have indicated that last-male precedence is most common (Koga et al. 1993; Urbani et al. 1998; Murai et al. 2002). Alternatively, mating males may deposit sperm plugs, making it energetically costly (because of the need to remove the sperm plug) or impossible for other males to mate with the same female. Sperm plugs have been described in other crustaceans (Jivoff 1997; Aiken et al. 2004; Oh and Hankin 2004) and may occur in other orconectid crayfish (Berrill and Arsenault 1984). Finally, already-mated females may be less likely to mate than virgin females, particularly if the costs of polyandry outweigh the potential benefits. If mated females cannot often or easily be coerced into mating again, then males may be less inclined to invest in searching for and courting them.

In addition, our data show that virgin and non-virgin females responded differently when exposed to the signals of mature males. Virgin females spent significantly more time in water conditioned by males than in control water, while non-virgins showed no significant difference in the time they spent in control or treated water, indicating that virgin and non-virgin females may differ in the extent to which they actively seek potential mates. Once mated, females are already assured of having a supply of sperm with which to fertilize their eggs in the spring and may be less willing to engage in costly mate searching, although they may accept matings from some courting males, e.g.,

for potential genetic benefits or as bet-hedging against male infertility.

The importance of chemical signals in communicating detailed information with conspecifics has probably long been underestimated by behavioral ecologists because such signals are so difficult to observe directly. Here, we have provided indirect evidence for distance communication of recent mating history through chemical signals. Although males of many arthropods are known to assess female reproductive status through physical contact, the importance of distance pheromones for assessment of conspecifics is less well known. In addition, distance chemical signaling has been considered to be problematic in aquatic taxa because the direction of water flow is often unpredictable, and therefore, the sources of signals may not be located with great accuracy (Breithaupt 1999; Kozlowski et al. 2003). However, in some other decapod crustaceans in which mating is tied to the female's molt, males show an ability to detect distance signals from pre-molt females (Gleeson 1991; Mathews 2003), and therefore, males may exploit part of a normal endocrine process as a signal of a female's value as a mate. In addition, female lobsters may use signals in the urine of males to make mate-choice decisions based on male dominance status (Bushman and Atema 2000). Similarly, female rock shrimp (*Rhynchocinetes typus*) may use chemical cues to locate dominant males (Diaz and Thiel 2004).

In general, individuals of many taxa may exchange a great deal of information about one another without any contact that is perceptible to humans. Distance chemical communication may be of particular importance whenever movement through space is especially energetically costly or risky, as is likely to be the case for individuals of *O. quinebaugensis*. Under such circumstances, there should be a strong selective advantage in being able to identify at a distance those individuals with which physical contact would be most beneficial. Future research, for example, into the complexity of personal information that can be transmitted in broadcast signals, will reveal insight into the importance of distance chemical signaling in many taxa.

Acknowledgments We are grateful to L. Adams, M. Basile, M. Buckholt, and J. Caron for assistance in the field and laboratory, and D. Gibson for laboratory support. We also thank H. Johari and W. Durgin (Sr.) for assistance in the design and construction of our apparatus. We also thank two anonymous reviewers for helpful comments on the manuscript. Finally, we wish to thank the United States Army Corps of Engineers for granting a Special Use Permit (to LM) to collect crayfish at the East Brimfield Dam in Sturbridge, MA.

Identification of the Airborne Aggregation Pheromone of the Common Bed Bug, *Cimex lectularius*

Eric Siljander · Regine Gries · Grigori Khaskin · Gerhard Gries

Received: 20 June 2007 / Revised: 4 January 2008 / Accepted: 21 January 2008 / Published online: 10 May 2008

Abstract Adults and juveniles of the common bed bug, *Cimex lectularius* L. (Hemiptera: Cimicidae), return to and aggregate in harborages after foraging for hosts. We tested the hypothesis that the aggregation is mediated, in part, by an airborne aggregation pheromone. Volatiles from experimental *C. lectularius* harborages were captured on Porapak Q, fractionated by liquid chromatography, and bioassayed in dual-choice, still-air olfactometer experiments. Of 14 compounds with >100 pg abundance in gas chromatography–mass spectrometry analyses of two bioactive fractions, 10 compounds [nonanal, decanal, (*E*)-2-hexenal, (*E*)-2-octenal, (2*E*,4*E*)-octadienal, benzaldehyde, (+)- and (−)-limonene, sulcatone, benzyl alcohol] proved to be essential components of the *C. lectularius* airborne aggregation pheromone.

Keywords *Cimex lectularius* · Cimicidae · Bed bug · Aggregation pheromone · Octanal · Nonanal · Decanal · (*E*)-2-Hexenal · (*E*)-2-Octenal · (2*E*,4*E*)-Octadienal · (2*E*,4*Z*)-Octadienal · Benzaldehyde · Benzyl acetate · Benzyl alcohol · Limonene · Sulcatone · Geranylacetone

Introduction

The common bed bug, *Cimex lectularius* L. (Hemiptera: Cimicidae), has been an ectoparasitic pest of humans throughout recorded history (Usinger 1966; Panagiotakopulu and Buckland 1999; Reinhardt and Siva-Jothy 2007). Recently, it has experienced a global resurgence (Krueger 2000; Boase 2001) with large economic impact due to costly control efforts, lost business, and litigation (Doggett et al. 2004). Considering that all stages of *C. lectularius* bloodfeed, an investigation of their pheromonal communication was warranted (Reinhardt and Siva-Jothy 2007) to determine whether synthetic pheromones could be exploited for detection or management of infestations.

Previous studies demonstrated that *C. lectularius* produce an alarm pheromone [(*E*)-2-hexenal and (*E*)-2-octenal] and an adult 'assembling scent' (Marx 1955; Levinson and Bar Ilan 1971; Levinson et al. 1974a,b). More recent research has shown that the 'assembling scent' is perceived only by contact chemoreception (Siljander et al. 2007) and thus is an arrestant rather than an attractant.

Cimex lectularius aggregates within refugia and returns to these harborages after each blood meal (Kemper 1936). This behavior has been attributed to a specific 'nest odor' (Marx 1955). However, there is no experimental evidence in support of an airborne aggregation pheromone. In the kissing bug, *Triatoma infestans*, both airborne attractant and chemotactile arrestant pheromones mediate aggregation behavior (Schofield and Patterson 1977; Lorenzo Figueiras et al. 1994; Lorenzo and Lazzari 1996; Lorenzo Figueiras and Lazzari 1998). We postulated that *C. lectularius* also might utilize both contact and airborne aggregation pheromones.

In this study, we show that *C. lectularius* uses an airborne aggregation pheromone and report the identification of components of the pheromone.

Methods and Materials

Experimental Insects Cimex lectularius were supplied by, or collected from, three sources: (1) Harold Harlan,

E. Siljander · R. Gries · G. Khaskin · G. Gries (✉)
Department of Biological Sciences, Simon Fraser University,
8888 University Drive,
Burnaby, British Columbia V5A 1S6, Canada
e-mail: gries@sfu.ca

Crownsville, MD, USA; (2) George Keeney, Ohio State University, Columbus, OH, USA; and (3) natural populations in human dwellings, Vancouver, BC, Canada. Insects from all three sources were combined and kept in wide-mouth glass jars (=colony jars; 9×9.5 cm) containing strips of cardboard folded accordion-style to provide a surface on which they could walk and oviposit. Insects were reared at 21–28°C, 25–50% RH, and a 16L/8D photoperiod. They were blood-fed through an artificial membrane (Montes et al. 2002) or on human volunteers. The membrane system used heparinated chicken blood as a food source. For feeding on humans, groups of insects were placed into jars (3.5×5.5 cm) topped with nylon mesh and allowed to feed to repletion through the mesh. Third- to fifth-instar juveniles were randomly selected and fed at least 2 wk before use in experiments, thus allowing them time to digest partially their blood meal and molt to the subsequent instar or adult stage. Mating status of adults used in experiments was not known, unless specified.

Collection of Volatiles To collect airborne semiochemicals for bioassays and chemical analyses, colony jars containing 500–700 *C. lectularius* of mixed stage, age, and gender, exuviae, eggs, and cardboard strips were placed in a cylindrical Pyrex glass chamber (15.5×26 cm). A pump drew charcoal-filtered air at ~2 l/min through each chamber and through a glass column (14×1.3 cm OD) containing 0.5 g of Porapak Q (50–80 mesh; Waters Associates, Inc., Milford, MA, USA). After 72 hr, volatiles were eluted from the Porapak Q trap with 2 ml of pentane. Jar aeration extracts (JAEs) contained ~43,200 bug hour equivalents (1 BHE=volatiles released by one *C. lectularius* during 1 hr) and were stored under darkness at −15°C.

To determine the stage and gender of *C. lectularius* that emitted volatiles, groups of 100 adult males, 100 adult females, or 100 juveniles 1- to 3-wk post-molt were placed on folded filter paper (Whatman no. 1; 9 cm diameter) in separate cylindrical Pyrex glass chambers (10×18 cm) and aerated for 6 d. Each Porapak Q trap was eluted with 2 ml pentane, which was concentrated under a nitrogen stream to a volume of 100 µl for subsequent chemical analysis.

To determine the enantiomer(s) of limonene produced by *C. lectularius*, 50 adult males aged 1–6 wk were placed on folded filter paper (Whatman no. 1; 9 cm diameter) in a cylindrical Pyrex glass chamber (10×5 cm) and aerated for 6 d. Males were chosen because they appeared to release the largest quantity of limonene in previous volatile collections. The Porapak Q trap was eluted with 2 ml pentane, and extract was stored in the dark at −15°C. Porapak Q extracts from four aerations were obtained and fractionated on silica gel. Fractions containing limonene were pooled and concentrated to a volume of 10 µl for subsequent analysis.

Collection of Contact Pheromone Twenty-five juvenile (fourth- or fifth-instar) *C. lectularius* were placed into a glass jar (5×8 cm) containing a folded Whatman no. 1 filter paper disc (5.5 cm diameter). Five such jars were kept for 14 d at room temperature under a 16L/8D photoperiod, allowing insects to walk, rest, defecate, and/or deposit juvenile contact pheromone (Siljander et al. 2007). Each disc received 8,400 contact pheromone hour equivalents (1 CPHE=contact pheromone deposited by one *C. lectularius* during 1 hr). To extract the pheromone, each exposed paper disc was submerged in methanol (HPLC-grade) for 1 hr at room temperature. The supernatant was withdrawn with a pipette, and the five samples were pooled and stored at room temperature until needed.

Analytical Methods Aliquots of JAE or adult male aeration extracts were concentrated under a nitrogen stream and fractionated on silica gel (0.5 g) in a glass column (14×0.5 cm ID). After pre-rinsing the silica gel with pentane, aeration extract aliquots were applied and then eluted with 2 ml each of pentane/ether (100:0, 90:10, 75:25, 50:50, and 0:100) generating five fractions that contained analytes of increasing polarity.

Aliquots of JAEs, bioactive fractions (see olfactometer experiments), and insect aerations were analyzed by coupled gas chromatography–mass spectrometry (GC-MS) in full-scan electron impact mode by using a Varian Saturn 2000 Ion Trap GC-MS fitted with a DB-5 column (30 m×0.25 mm ID, J&W Scientific, Folsom, CA, USA). The temperature program started at 50°C for 2 min, then increased at 10°C per min to 280°C. All volatile constituents of >100 pg abundance in two bioactive fractions were considered candidate pheromone components. They were identified by comparing their retention indices (Van den Dool and Kratz 1963) and mass spectra with those reported in the literature [(*E*)-2-hexenal, benzaldehyde, 6-methyl-5-hepten-2-one (sulcatone), octanal, limonene, benzyl alcohol, nonanal, benzyl acetate, decanal, and geranylacetone: Adams 1989; (*E*)-2-octenal: Marques et al. 2000; Staples et al. 2002; (2*E*,4*E*)- and (2*E*,4*Z*)-octadienal: Aldrich et al. 1999; Adolph et al. 2003] and with those of authentic standards.

To determine the enantiomeric composition of limonene emitted by adult male *C. lectularius*, the GC-MS was fitted with a Cyclodex-B™ column (30 m×0.25 mm ID, J&W Scientific), and aliquots of extracts were chromatographed isothermally at 80°C for 15 min. The presence of each enantiomer was determined by comparing retention times and intensity ratios of selected ions (*m*/*z* 93, 121, 136) in the analyte with those of authentic (+)- and (−)-limonene.

Authentic Standards Octanal, nonanal, decanal, 6-methyl-5-hepten-2-one (sulcatone), geranylacetone, benzyl alcohol, benzyl acetate, (+)- and (−)-limonene were purchased from

Sigma-Aldrich (Oakville, ON, Canada). (*E*)-2-Hexenal, (*E*)-2-octenal, and (2*E*,4*E*)-octadienal were purchased from Bedoukian Research (Danbury, CT, USA), and benzaldehyde was purchased from Fisher Scientific (Ottawa, ON, Canada). All commercial compounds were >95% pure.

(2*E*,4*Z*)-Octadienal was synthesized (Fig. 1). 2,3-Dihydropyran (11.45 g) and trifluoroacetic acid (50 µl) were added to *cis*-2-butene-1,4-diol (Aldrich; Fig. 1, compound **1**, 10.00 g, 113.6 mmol). After stirring for 3 hr, ether **2** (7.7 g, 79%) was separated on silica gel (100 g SiO_2, 20–70% ether in hexane as eluent) from unreacted diol **1** and the di-THP derivative. Alcohol **2** (3.0 g, 17.4 mmol) was oxidized to aldehyde **3** by stirring 1 hr in 40 ml of dichloromethane with 5.8 g (26.4 mmol) of pyridinium chlorochromate (PCC) and 3.6 g (26 mmol) of potassium carbonate. Aldehyde **3** was separated from the reaction mixture on silica gel with ether/hexane (1:9) as eluent. Immediately after separation, the *E*- and *Z*-isomers were present in a ratio of 91:9 based on GC. After standing 24 hr in 50 ml dry tetrahydrofuran (THF), only the *E*-isomer of aldehyde **3** (1.7 g, 10.0 mmol, 57.5% yield, >98% pure) was detectable by GC. A solution of aldehyde **3** (0.75 g, 4.40 mmol) in 22 ml THF was then added at −70°C to a stirred suspension (in 100 ml THF) of the ylid generated from butyltriphenylphosphonium bromide (4.0 g, 10.0 mmol) and 10.0 mmol sodium bis-(trimethylsilyl) amide (Aldrich) in 10 ml THF at −30°C to −10°C. The reaction mixture was allowed to warm to 0°C, quenched with water, and the products were extracted with ether/hexane (1:1). The organic layer was washed [water/methanol (3:1), brine], dried, and evaporated. Purification by flash chromatography (10 g silica gel, 30% ether in hexane as eluent) afforded 0.40 g of 1-*O*-tetrahydropyranyl-(2*E*,4*Z*)-octadienol (**4**) (90% pure, GC) to which methanol (100 ml) and trifluoroacetic acid (20 µl) were added. The resulting (2*E*,4*Z*)-octadienol was partially purified by flash chromatography (10 g silica gel, 25–50% ether in hexane as eluent) (0.23 g, 1.82 mmol, >95% by GC) and oxidized in dichloromethane with PCC (2.74 mmol) in the presence of K_2CO_3 (1.37 mmol) to yield 0.15 g of 85% pure (2*E*,4*Z*)-octadienal (**5**). Purification by flash chromatography (10 g silica gel, 5% ether/hexane) afforded 0.12 g of known aldehyde **5** (22% yield based on aldehyde **3**; overall yield, 10%; Adolph et al. 2003; Khrimian 2005). Aldehyde **5** was purified by high performance liquid chromatography (HPLC) using a Waters LC 626 HPLC equipped with a Waters 486 variable-wavelength UV/visible detector set to 210 nm, HP Chemstation software (Rev. A.07.01), and a reversed-phase Nova-Pak® C18 column (60 Å, 4 µm, 3.9× 300 mm, Waters Corporation), eluting with 0.75 ml/min of acetonitrile/water (1:1). Purified aldehyde **5** (>95%) contained only the *E*,*E*-isomer as an impurity.

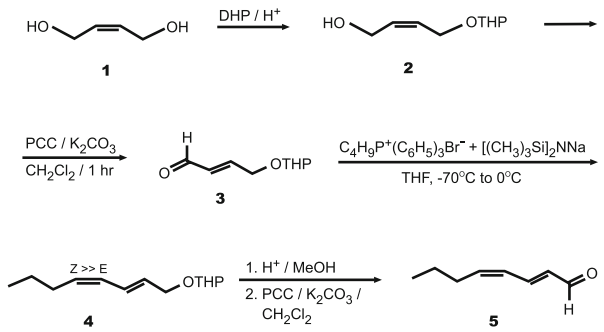

Fig. 1 Scheme for the synthesis of (2*E*,4*Z*)-octadienal

Olfactometer Experiments Responses of *C. lectularius* to test stimuli were bioassayed in still-air olfactometers because *C. lectularius* inhabits enclosed microhabitats with little or no air movement and avoid moving air (Kemper 1936; Johnson 1941; Usinger 1966; E.S., personal observation). The olfactometers consisted of three glass chambers (each 3.5×10 cm ID) linearly interconnected by glass tubes (each 2.5×1 cm ID; Takács and Gries 2001). Test stimuli were randomly assigned to one of the two lateral chambers, each containing a paper towel disc (9 cm diameter; folded eight times for corrugation) with a tab (2.5×0.7 cm) extending through to the central chamber to facilitate inter-chamber movement of bioassay insects. Stimuli were pipetted onto the discs, with treatment and control discs receiving the same amount of solvent. For each of the 23–50 replicates in each of experiments 1–44 (Table 1), one randomly selected 1- to 3-wk post-molt *C. lectularius* was released in the central chamber of the olfactometer 3 hr before the end of scotophase, when *C. lectularius* are most active (Mellanby 1939b). An insect was classed as a responder when it was found 16–18 hr later during photophase on a paper disc or within a lateral glass tube in a state of akinesis. To rigorously compare the effectiveness of test stimuli, experiments were often run in parallel to minimize the effect of any confounding variables, such as weather or time since last feeding. All experiments were conducted at 22–24°C, 25–40% RH, under an 18-hr photoperiod of 3D/15L. After each replicate, olfactometers were washed thoroughly with hot water and Sparklene™ detergent and oven-dried at 125°C for 3 hr.

To determine whether the JAE elicited behavioral responses, experiments 1–3 tested the responses of adult males, adult females, and juveniles (fourth- or fifth-instar) to 10 JAE (~2,000 BHE). Experiment 4 tested the effect of a lower dose (100 BHE) on the response of juveniles. In experiment 5, olfactometers were stacked (3 rows×3 columns) inside yellow plastic bins (38×31×11 cm; Columbia Plastics Ltd.®, Vancouver, BC, CA) covered with dark plastic trays (45×35×2 cm) to determine whether the absence of moving air and directional light improved the response of juveniles to the test stimulus (~200 BHE).

Table 1 Details on experimental insects and stimuli tested in three-chambered olfactometer and cage bioassays (experiments grouped by brackets were run in parallel)

46	SB *plus* Juvenile contact pheromone (720 CPHE[g])	Solvent *plus* Juvenile contact pheromone (720 CPHE)	10 Juveniles	10

[a] Olfactometers not placed in plastic bins for duration of bioassay.
[b] BHE=bug hour equivalents; 1 BHE=volatiles released by one *C. lectularius* during 1 hr.
[c] In all experiments, treatment and control stimuli received the same amount and composition of solvent(s).
[d] Solvent consisted of a 6:4 (*v*/*v*) mixture of pentane and ether.
[e] SB=synthetic blend of 14 components (200 BHE): see Table 2.
[f] NSB=new synthetic blend=SB *minus* octanal.
[g] CPHE=contact pheromone hour equivalents; 1 CPHE=contact pheromone deposited by one *C. lectularius* during 1 hr.

All subsequent still-air olfactometer experiments were conducted according to this protocol. Moreover, juveniles were chosen as bioassay insects because they showed the strongest response to JAE or synthetic blends, and their response was not affected by mating status, as was the case with mated adult females.

To determine candidate pheromone components (see Byers 1992), parallel-run experiments 6–11 tested the five recombined silica gel fractions of JAE vs. blends lacking single fractions. Taking the results of experiments 6–11 and those of GC-MS analyses into account, experiments 12–15 tested a synthetic blend (SB) of 14 candidate pheromone components [octanal, nonanal, decanal, (*E*)-2-hexenal, (*E*)-2-octenal, (2*E*,4*E*)-octadienal, (2*E*,4*Z*)-octadienal, benzaldehyde, benzyl alcohol, benzyl acetate, (+)-limonene, (−)-limonene, sulcatone, and geranylacetone], combined in ratios resembling JAE at 200 BHE (Table 2), for ability to elicit behavioral responses from juveniles, males, mated females, and virgin females.

To identify essential components in the SB, parallel-run experiments 16–22 tested SB vs. blends that lacked groups of organic chemicals, such as monoterpenes (experiment 17), benzyl derivatives (experiment 18), ketones (experiment 19), saturated aldehydes (experiment 20), monoene aldehydes (experiment 21), or diene aldehydes (experiment 22). Similarly, parallel-run experiments 23–36 tested SB vs. blends lacking a single component. (2*E*,4*E*)-Octadienal could not be removed as a single component because it kept forming as a rearrangement product of (2*E*,4*Z*)-octadienal and could not be separated by HPLC. Considering the results of experiments 23–36, parallel-run experiments 37–44 tested a new synthetic blend (NSB; SB *minus* octanal) vs. NSB blends that lacked one, two, or all of the three components (2*E*,4*Z*)-octadienal, benzyl acetate, and geranylacetone.

Table 2 Percentage (mean±SE, n=3) of components in *Cimex lectularius* colony jar aeration extracts relative to the most abundant compound, (*E*)-2-octenal, and quantities present in synthetic blend (SB)

Compound	Relative Ratio[a] (±SE) JAE[c]	Quantity Present in SB[b] (ng) 200 BHE[d]
(*E*)-2-Octenal	100	32.1
(*E*)-2-Hexenal	64.7±5.8	18.4
Benzaldehyde	3.1±1.3	0.7
Sulcatone	2.1±0.6	0.4
Octanal	2.1±0.4	0.6
Limonene	6.5±2.2	1.8[e]
Benzyl alcohol	0.7±0.1	0.6
(2*E*,4*Z*)-Octadienal	0.8±0.2	0.3
Nonanal	6.6±0.2	3.6
(2*E*,4*E*)-Octadienal	1.1±0.4	0.4
Benzyl acetate	0.9±0.1	0.4
Decanal	3.8±0.2	2.0
Geranylacetone	6.6±0.3	2.4

[a] Peak areas were calculated based on the ion current in GC-MS analyses.
[b] Ion current was corrected for instrument response to each standard.
[c] JAE=*C. lectularius* colony jar aeration extract.
[d] BHE=bug hour equivalents; 1 BHE=volatiles released by one *C. lectularius* during 1 hr.
[e] Total quantity of racemic mixture: 0.9 ng of (+)-limonene *plus* 0.9 ng of (−)-limonene.

In experiment 45, the ability of the 14-component SB to attract or arrest juvenile *C. lectularius* was tested in Plexiglas cage (30×30×42 cm) olfactometers, with four mesh-covered holes (18 cm diameter) for ventilation and a sliding door (21×25 cm) for access. Cages were topped with a dark plastic tray (45×35×2 cm) and covered with sheer white silk fabric to diffuse the overhead lighting. The rough (sandpaper-treated) cage floor allowed the insects to walk easily to either of two paper disc shelters (6 cm diameter; folded six times for corrugation) in opposing corners of the cage. The treatment (2,000 BHE) and solvent control stimuli were randomly assigned and pipetted onto these discs, with treatment and control discs receiving the same amount of solvent (pentane). For each of 10 replicates in experiments 45–46 (Table 1), 10 randomly selected 1- to 3-wk post-molt juvenile *C. lectularius* were released in the center of the cage 3 hr before the end of scotophase, and the number of juveniles on each disc was recorded 16–18 hr later during photophase. Insects were classed as responders when they were found on a paper disc in a state of akinesis. All experiments were conducted at 22–24°C, 25–40% RH, under an 18-hr photoperiod of 3D/15L. After each replicate, the cages were sequentially washed with 70% ethanol and hexane and then dried for 5 hr. Follow-up experiment 46 tested whether the response of insects to airborne pheromone in experiment 45 could be enhanced by adding juvenile contact pheromone at 720 CPHE to both treatment and control discs.

Statistical Analyses Numbers of *C. lectularius* responding to treatment and control stimuli in three-chamber olfactometer experiments 1–44 were analyzed with the χ^2 goodness-of-fit test, using Yates correction for continuity (α=0.05; Zar 1999). The mean proportion of juvenile *C. lectularius* that responded to treatment and control stimuli in cage olfactometer experiments 45–46 was analyzed with the Wilcoxon paired-sample test (α=0.05; Zar 1999). Nonresponders were not included in statistical analyses.

Results

Porapak Q extracts of colony jar aerations (JAEs; Fig. 2) tested at 2,000 BHE attracted/arrested females and juveniles (Fig. 3, experiments 2–3) but failed to elicit a significant response from males (Fig. 3, experiment 1). The lower dose of 100 BHE was still significantly effective for juveniles

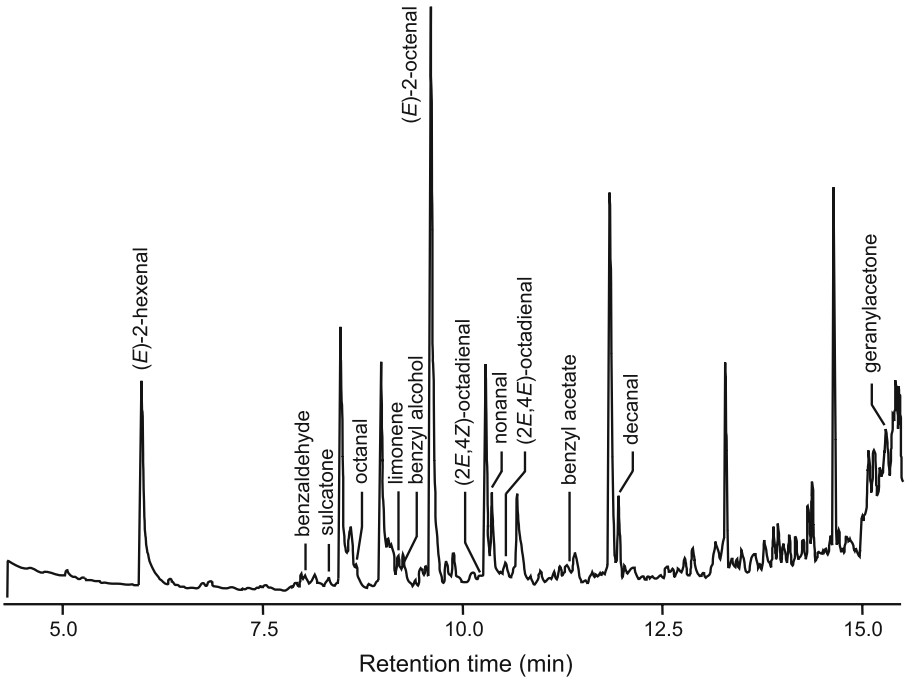

Fig. 2 Representative gas chromatogram of Porapak Q *Cimex lectularius* jar aeration extract. Chromatography: Varian Saturn 2000 Ion Trap GC-MS fitted with a DB-5 column (30 m×0.25 mm ID). Temperature program: 50°C (2 min), 10°C per min to 280°C

(Fig. 3, experiment 4). When bioassay conditions were modified so that olfactometers were housed within plastic bins, juveniles strongly responded to 200 BHE (Fig. 4, experiment 5).

The recombination of all five liquid chromatography fractions of JAE elicited significant responses from juveniles, as did blends lacking fractions 1, 3, or 5 (Fig. 4, experiments 6, 7, 9, and 11). JAE blends lacking either fraction 2 or 4 were not attractive (Fig. 4, experiments 8 and 10), indicating that fractions 2 and 4 contained the bioactive components. The components in fractions 2 and 4 were identified by comparing their GC-retention times and mass spectra with those of authentic standards. The 14 components identified included octanal, nonanal, decanal, (*E*)-2-hexenal, (*E*)-2-octenal, (2*E*,4*E*)-octadienal, (2*E*,4*Z*)-octadienal, benzaldehyde, benzyl alcohol, benzyl acetate, (+)-limonene, (−)-limonene, sulcatone, and geranylacetone (Table 2). A SB of these 14 candidate pheromone components tested at 200 BHE (Table 2) elicited significant responses from juveniles, males, and virgin females (Fig. 5, experiments 12, 13, and 15) but not from mated females (Figure 5, experiment 14). Synthetic blends that lacked monoterpenes, benzyl derivatives, ketones, saturated aldehydes, monoene aldehydes, or diene aldehydes were not attractive (Fig. 6, experiments 16–22). Synthetic blends that lacked either octanal, (2*E*,4*Z*)-octadienal, benzyl acetate, or geranylacetone were still attractive (Fig. 7, experiments 27, 32, 34, and 36), whereas SBs lacking either (*E*)-2-hexenal, benzaldehyde, sulcatone, (+)-limonene, (−)-limonene, benzyl alcohol, (*E*)-2-octenal, nonanal, or decanal were not attractive (Fig. 7, experiments 24–26, 28–31, 33, and 35). A NSB (SB *minus* octanal) unexpectedly failed to attract juveniles (Fig. 8, experiment 37), and NSB blends that lacked (2*E*,4*Z*)-octadienal, benzyl acetate, or both were not active (Fig. 8, experiments 38, 39, and 41). However, all blends that lacked geranylacetone, including the NSB without the four

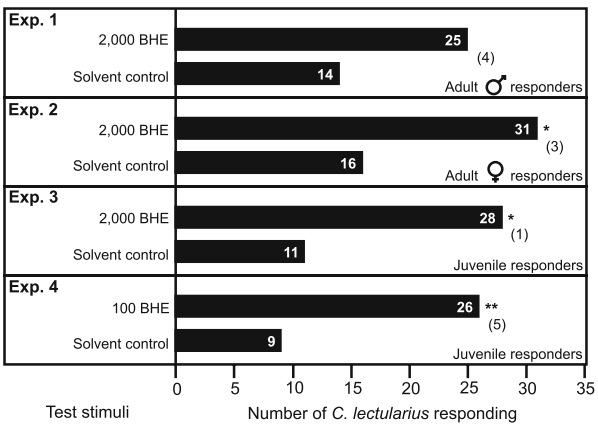

Fig. 3 Response of male (experiment 1), female (experiment 2), and juvenile (experiments 3 and 4) *Cimex lectularius* in three-chambered olfactometers to aliquots [100 or 2,000 bug hour equivalents (BHE)] of Porapak Q colony jar aeration extracts. 1 BHE=volatiles released by one *C. lectularius* during 1 hr. Number of insects responding to each stimulus is given *within bars*; number of insects not responding in each experiment is given *in parentheses*. For each experiment, an *asterisk* indicates a significant response to the treatment stimulus; χ^2 test with Yates correction for continuity; *P<0.05; **P<0.01. The same amount of pentane (7.5 µl) was applied to treatment and control stimuli

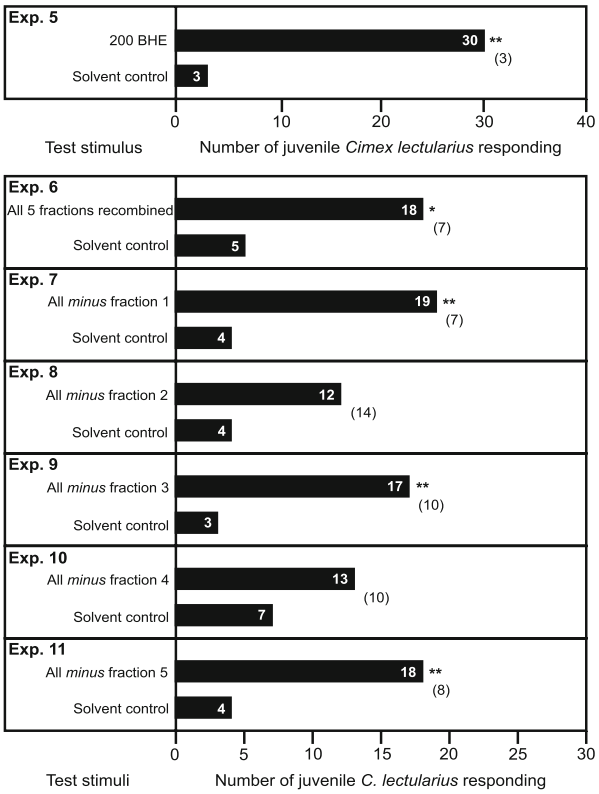

Fig. 4 Response of juvenile *Cimex lectularius* in three-chambered olfactometers to aliquots (200 BHE; see Fig. 2) of Porapak Q colony jar aeration extracts (experiment 5) or to silica gel fractions (200 BHE) of the same extract (experiments 6–11). Number of insects responding to each stimulus is given *within bars*; number of insects not responding in each experiment is given *in parentheses*. For each experiment, an *asterisk* indicates a significant response to the treatment stimulus; χ^2 test with Yates correction for continuity; *$P<0.05$; **$P<0.01$. Experiments 6–11 were run in parallel; the same amount of pentane (10 µl, experiment 5; 50 µl, experiments 6–11) was applied to treatment and control stimuli

components octanal, (2*E*,4*Z*)-octadienal, benzyl acetate, and geranylacetone, elicited significant responses from juveniles (Fig. 8, experiments 40, 42–44).

In cage experiment 45, the proportions of juveniles that responded to SB at 2,000 BHE or to solvent control were not significantly different (Fig. 9). However, when juvenile contact pheromone at 720 CPHE was added to both treatment and control discs (experiment 46), SB at 2,000 BHE attracted/arrested a greater proportion of bioassay insects than did the solvent control (Fig. 9).

Of the 14 components tested in SB, all except benzyl alcohol and benzyl acetate were detected in Porapak Q extracts of adult males and females (Table 3). Adult males appear to release the largest quantity of volatiles (Table 3).

In GC-MS analyses of the limonene enantiomer(s) emitted by adult males, the combined ion (*m/z* 93, 121, and 136) current for (+)- and (−)-limonene revealed a 1:1.3 ratio of the two enantiomers.

Discussion

Our data provide evidence that adult male, virgin adult female, and juvenile *C. lectularius* respond to an airborne aggregation pheromone. With 10 essential components, the pheromone is unusually complex. Such a complex aggregation pheromone has been reported only for cocoon-spinning *Cydia pomonella* larvae (Jumean et al. 2005). Similarly complex sex pheromones occur in 14 species of the Lepidoptera, each deploying pheromone blends of six or more components (Byers 2006). The essential components were identified from juveniles, but we predict that adult males and virgin adult females will respond to the same components because all insects responded similarly to the SB (Fig. 5).

The origin of each of the ten essential pheromone components remains unknown, but (*E*)-2-hexenal, (*E*)-2-octenal, (2*E*,4*E*)-octadienal, benzaldehyde, nonanal, decanal, and sulcatone were all prevalent in headspace volatiles from adult male and adult female *C. lectularius* (Table 3). The trace component benzyl alcohol co-eluted with limonene in GC-MS analyses, rendering its detection and quantification difficult. (+)- and (−)-Limonene were present in above-background quantities in aerations only of adult males (Table 3), suggesting that males are the primary or sole emitters of limonene enantiomers.

The bioassay protocol took into account that *C. lectularius* are active during the scotophase and most active during the last few hours before photophase (Mellanby 1939b). Therefore, bioassays commenced 3 hr before

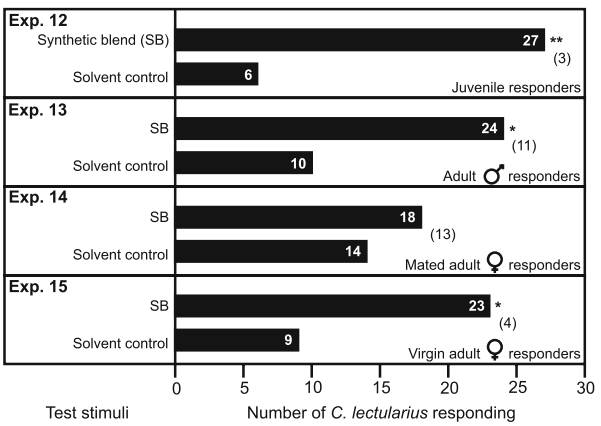

Fig. 5 Response of juvenile (experiment 12), male (experiment 13), mated female (experiment 14), and virgin female (experiment 15) *Cimex lectularius* in three-chambered olfactometers to a synthetic blend (*SB*) of 14 candidate pheromone components at 200 BHE. Number of insects responding to each stimulus is given *within bars*; number of insects not responding in each experiment is given *in parentheses*. For each experiment, an *asterisk* indicates a significant response to the treatment stimulus; χ^2 test with Yates correction for continuity; *$P<0.05$; **$P<0.01$. Composition of SB is listed in Table 2. The same amount of pentane (10–15 µl) was applied to treatment and control stimuli

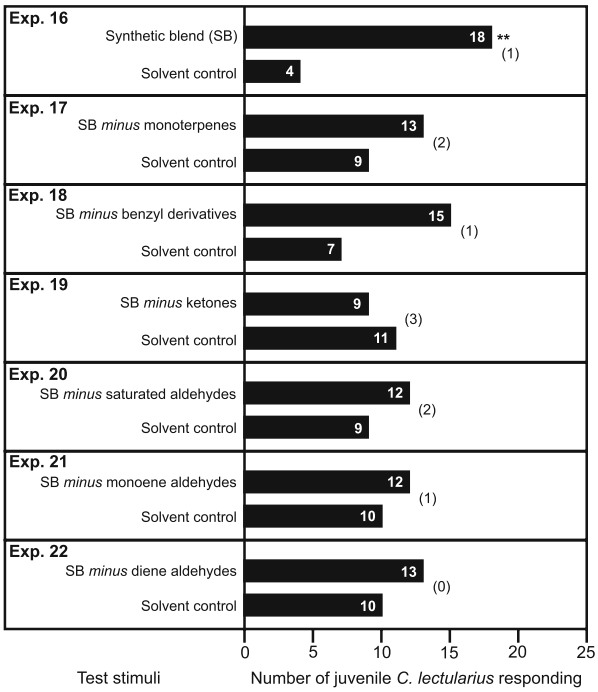

Fig. 6 Response of juvenile *Cimex lectularius* in three-chambered olfactometer experiments 16–22 to synthetic blends (*SB*) at 200 BHE (see Table 2), lacking groups of candidate pheromone components. Number of insects responding to each stimulus is given *within bars*; number of insects not responding in each experiment is given *in parentheses*. For each experiment, an *asterisk* indicates a significant response to the treatment stimulus; χ^2 test with Yates correction for continuity; $*P<0.05$; $**P<0.01$. All experiments were run in parallel; the same amount of pentane (15 µl) was applied to treatment and control stimuli

photophase, when *C. lectularius* typically seek hosts and then return to their shelters. Levinson and Bar Ilan (1971) observed that *C. lectularius* sought shelter during the first 4 hr after release and then remained relatively still for the next 16 hr. In preliminary overnight experiments with three-chambered still-air olfactometers, we observed that bioassay insects did not change chambers after they became inactive, usually within the first hour of the photophase. They would remain for the duration of the bioassay in the chamber that they selected as a resting or aggregation site.

The concern that the ratio of synthetic pheromone components released from paper towel discs may differ from that of natural pheromone components released by insects was addressed by comparative analyses of headspace volatiles from both sources. These analyses revealed no significant difference in the blend composition of natural and synthetic pheromone.

The sensitivity of *C. lectularius* to their aggregation pheromone cannot be determined from this study. However, response of juveniles to JAEs with a 20-fold difference in applied dose (Fig. 3, experiments 3 and 4) and response of adults to JAE (Fig. 3, experiments 1–2) or SB (Fig. 5, experiments 13 and 15) that differed 10-fold in dose suggest that the airborne aggregation pheromone is effective over a concentration range of at least one order of magnitude.

The two most abundant aggregation pheromone components in *C. lectularius*, (*E*)-2-hexenal and (*E*)-2-octenal, have previously been reported as alarm pheromone (Levinson and Bar Ilan 1971; Levinson et al. 1974a,b). Their threshold for eliciting alarm behavior [1.3–2.3 µg/ml air for (*E*)-2-hexenal; 0.25–0.29 µg/ml air for (*E*)-2-octenal; measured at time of alarm reaction] greatly exceeds the physiological detection threshold, which for (*E*)-2-hexenal was estimated by receptor potential response to dose range to be 2×10^{10} molecules/ml air [3.25×10^{-6} µg/ml air] (Levinson et al. 1974b). The detection threshold for (*E*)-2-octenal would be similar because it elicited receptor potentials at the same dose as (*E*)-2-hexenal (Levinson et al. 1974b). In our study, assuming that all applied pheromone components evaporated and were contained within a single olfactometer chamber, the levels tested could not have exceeded 9.50×10^{-4} µg/ml air of (*E*)-2-hexenal or 1.56×10^{-3} µg/ml air of (*E*)-2-octenal. These levels are significantly lower than the alarm response threshold but higher than the proposed physiological detection threshold. These data and calculations suggest that (*E*)-2-hexenal and (*E*)-2-octenal serve as multifunctional pheromone components that are attractive/arrestant at

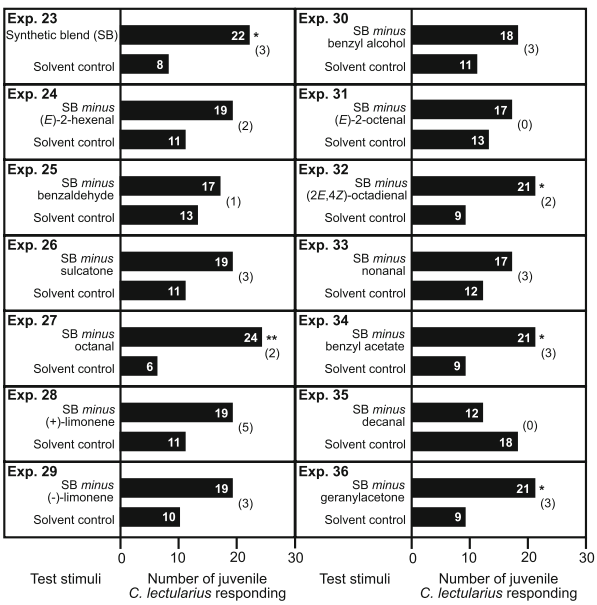

Fig. 7 Response of juvenile *Cimex lectularius* in three-chambered olfactometer experiments 23–36 to synthetic blends (*SB*) at 200 BHE (see Table 2), lacking single candidate pheromone components. Number of insects responding to each stimulus is given *within bars*; number of insects not responding in each experiment is given *in parentheses*. For each experiment, an *asterisk* indicates a significant response to the treatment stimulus; χ^2 test with Yates correction for continuity; $*P<0.05$; $**P<0.01$. All experiments were run in parallel; the same amount of pentane (15 µl) was applied to treatment and control stimuli

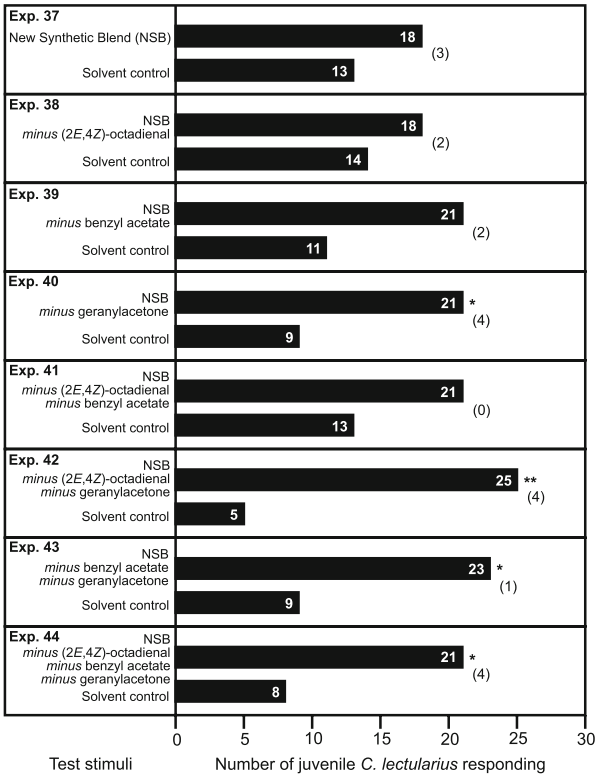

Fig. 8 Response of juvenile *Cimex lectularius* in three-chambered olfactometer experiments 37–44 to a new synthetic blend (*NSB*; blend as listed in Table 2 but without octanal) at 200 BHE, lacking one or more candidate pheromone components. Number of insects responding to each stimulus is given *within bars*; number of insects not responding in each experiment is given *in parentheses*. For each experiment, an *asterisk* indicates a significant response to the treatment stimulus; χ^2 test with Yates correction for continuity; $^*P<0.05$; $^{**}P<0.01$. All experiments were run in parallel; the same amount of pentane (10 µl) was applied to treatment and control stimuli

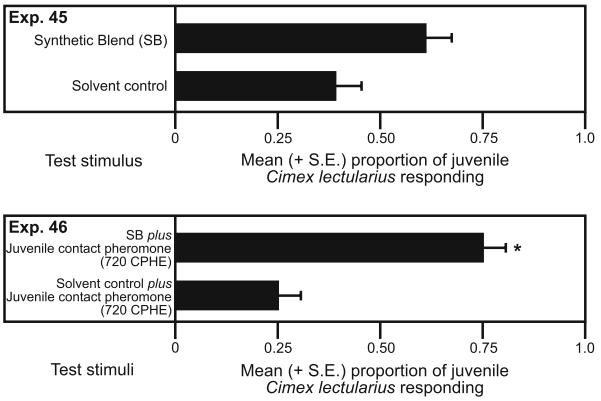

Fig. 9 Mean (+SE) proportion of 10 juvenile *Cimex lectularius* per replicate (10 replicates) responding in cage olfactometer experiments 45 and 46 to a synthetic blend (SB; see Table 2) at 2,000 BHE (experiment 45) or SB in combination with *C. lectularius* juvenile contact pheromone at 720 contact pheromone hour equivalents (CPHE; experiment 46). 1 CPHE=contact pheromone deposited by one *C. lectularius* during 1 hr. For each experiment, an *asterisk* indicates a significant response to the treatment stimulus; Wilcoxon paired-sample test; $^*P<0.05$. The same amount of pentane (50 µl) for SB application or methanol (100 µl) for CPHE application was applied to treatment and control stimuli

low concentrations but repellent at high concentrations (Borden 1985; Blum 1996). Multifunctional pheromones have also been reported in other Hemiptera, such as *Eurydema rugosa* (Ishiwatari 1974, 1976) and *Nezara viridula* (Lockwood and Story 1985).

Pheromones that mediate aggregation behavior may attract and/or arrest conspecifics. Our three-chambered and cage olfactometer experiments did not allow us to discern between attraction and arrestment responses. Anemotactic response to pheromone would demonstrate unambiguously long-range attractiveness, but such responses would be difficult to obtain because *C. lectularius* avoid moving air (Kemper 1936; Johnson 1941; Usinger 1966). However, results of cage experiments (Fig. 9) imply that the airborne aggregation pheromone may function mainly as an attractant. In the relatively large bioassay cage where treatment and control paper discs were not confined and sheltered, as they were in the small three-chambered olfactometers (experiments 1–44), SB alone appeared insufficient to attract and arrest a significant proportion of juveniles (experiment 45). However, when the juvenile contact pheromone (Siljander et al. 2007) was added to both treatment and control discs, SB was preferred significantly over the solvent control (experiment 46). If the juvenile contact pheromone were to arrest juveniles at the site of their first choice, then the airborne aggregation pheromone must have functioned as an attractant. In natural settings, the airborne aggregation pheromone may direct refuge-seeking *C. lectularius* toward established harborages,

Table 3 Percentage of components in aerations of adult male, adult female, and juvenile *Cimex lectularius*, relative to the most abundant compound, (*E*)-2-octenal, emitted by males

Compound	Relative Ratios[a]		
	Male	Female	Juvenile
(*E*)-2-Octenal	100	21.4	1.6
(*E*)-2-Hexenal	9.9	2.3	–[b]
Benzaldehyde	0.1	Trace	–
Sulcatone	0.5	0.2	Trace
Octanal	0.9	0.2	0.1
Limonene	0.2	Trace	Trace
Benzyl alcohol	–	–	–
(2*E*,4*Z*)-Octadienal	0.2	0.1	Trace
Nonanal	9.3	1.1	0.7
(2*E*,4*E*)-Octadienal	0.4	0.1	0.0
Benzyl acetate	–	–	–
Decanal	1.7	1.1	0.4
Geranylacetone	1.2	0.7	Trace

[a] Peak areas were calculated based on ion current in GC-MS analyses.
[b] A dash (–) indicates that the component was not detected in GC-MS analyses.

whereas the stage-specific contact pheromones arrest them at the source.

Aggregation pheromones likely have evolved due to the Allee effect, which is a positive relationship between any component of individual fitness and either numbers or density of conspecifics (Stephens et al. 1999; Wertheim et al. 2005). The use of pheromones by *C. lectularius* to locate aggregations of conspecifics within refugia may benefit individuals by marking harborages with suitable microclimates, potential mates, or protection from predators. Aggregated *C. lectularius* are less sensitive to desiccation (Benoit et al. 2007), and aggregated juveniles may also benefit from a higher rate of development at lower temperatures, a phenomenon observed in nymphs of *N. viridula* (Lockwood and Story 1986). Moreover, aggregation may facilitate mate-finding for adults, which do not appear to possess a sex pheromone that mediates mate attraction, and adults in aggregations may benefit from communal calling that increases the active space of pheromone (Wertheim et al. 2005). Finally, individual *C. lectularius* in aggregations may benefit from increased vigilance for natural enemies, which would help explain the use of both aggregation and alarm pheromones (Wertheim et al. 2005).

The pheromone elicited behavioral responses from juveniles, males, and virgin females (Fig. 5; experiments 12, 13, and 15), but not mated females. The fact that mated females did not respond to pheromone (Fig. 5; experiment 14) might be attributed to the injurious nature of mating in *C. lectularius*. During traumatic insemination, the male pierces the abdomen of the female with a needle-like intromittent organ, the paramere, and releases sperm into her body cavity (Carayon 1966). Females have a specialized structure (spermalege) that receives sperm and contributes to wound-healing and defense against infection, but frequent rematings reduce longevity and reproductive success (Mellanby 1939a; Stutt and Siva-Jothy 2001; Morrow and Arnqvist 2003; Reinhardt et al. 2003). Considering that females may have little or no control over remating frequency (Stutt and Siva-Jothy 2001), gravid females may avoid repeated traumatic insemination by seeking new refugia devoid of conspecifics. Dispersal of gravid females would explain observations that most nonaggregated individuals in natural populations are females (E.S., unpublished; R. Cooper, personal communication). It would also explain the spread of populations. Wingless *C. lectularius* are reliant on host transportation from place to place on clothing, luggage, and furniture (Usinger 1966; Doggett et al. 2004; Reinhardt and Siva-Jothy 2007). The likelihood of transportation on any of these objects depends upon *C. lectularius* actively seeking new refugia, as opposed to returning to an old one. Therefore, mated females not returning to established harborages and exploiting new refugia may be passively dispersed more often than males or juveniles. This hypothesis is supported by findings that most dispersing bat and bird bugs detected on the bodies of host bats or birds are females (Loye 1985; Heise 1988; Brown and Brown 2005; Reinhardt and Siva-Jothy 2007). Whether this concept applies to *C. lectularius* is unknown and would require interception data (Doggett et al. 2004) including stage, gender, and mating status of passively transported specimens.

The increased numbers of juvenile *C. lectularius* recorded as positive responders to a combination of airborne plus contact aggregation pheromone than to airborne aggregation pheromone alone in our bioassays (Fig. 9) can be attributed to the contact pheromone, which arrested responding insects and reduced further movement between shelters. We are currently investigating whether a suitable harborage in lieu of contact pheromone would be equally effective in eliciting aggregation responses in *C. lectularius*. If so, field testing could determine whether traps baited with airborne aggregation pheromone can detect the presence of *C. lectularius* in human dwellings with greater sensitivity than current methods.

Acknowledgements We thank Harold Harlan for supplying *Cimex lectularius* and advice on their rearing, Cory Campbell, Thomas Cowan, Christine De Pape, Zaid Jumean, Charlene Wood, and Nathan Woodbury for helping feed the bed bug colony, Zaid Jumean and Eberhard Kiehlmann for reviewing the manuscript, Richard Cooper for observations of wild *C. lectularius*, all laboratory colleagues for advice throughout the project, and Jocelyn Millar and two anonymous reviewers for constructive comments. The research was supported by a Thelma Finlayson Graduate Entrance Scholarship, a Master of Pest Management Graduate Entrance Scholarship, and a Simon Fraser University Graduate Fellowship to E.S., and by a Natural Sciences and Engineering Research Council of Canada—Industrial Research Chair to G.G. with SC Johnson Canada, Pherotech International Inc. and Global Forest Science (GF-18-2007-226; GF-18-2007-227) as the industrial sponsors.

Sex Pheromone of the Plant Bug, *Phytocoris calli* Knight

Qing-He Zhang · Jeffrey R. Aldrich

Received: 28 December 2007 / Revised: 14 March 2008 / Accepted: 10 April 2008 / Published online: 9 May 2008

Abstract Female *Phytocoris calli* Knight produce a sex pheromone from metathoracic scent glands. The pheromone consists of hexyl acetate (HA; present in both sexes), with the female-specific compounds (*E*)-2-hexenyl acetate (E2HA), octyl acetate (OA), and (*E*)-2-octenyl acetate (E2OA). HA and E2OA are key components of the pheromone, since deletion of either ester from the blend resulted in a total suppression of conspecific male trap catches. However, the binary blend of HA and E2OA was only slightly attractive to males, and was significantly less active than the four-component blend. The two ternary blends, HA/OA/E2OA and HA/E2HA/E2OA, were each as attractive as the full four-component blend. Evidence from previous research on the pheromones of *Phytocoris* species suggests that the apparent chemical redundancy in the pheromone of *P. calli* may actually be involved in maintaining reproductive isolation from other sympatric species. The patterns observed for pheromones of the five *Phytocoris* species whose pheromones have been directly (*P. californicus*, *P. relativus*, *P. difficilis*, and *P. calli*) or indirectly (*P. breviusculus*) studied are discussed vis-à-vis the pheromone intractable species of *Lygus* and *Lygocoris* plant bugs.

Introduction

Plant bugs (Miridae) are the most speciose heteropteran family that includes some 10,000 described members. The mirid genus *Phytocoris* is among the largest of the plant bug genera, containing about 650 species (Schuh and Slater 1995), 200 of which occur in western North America (Stonedahl 1988). Many *Phytocoris* are predacious, with mottled color patterns that render them cryptic on the bark of trees they inhabit. Some species, however, are serious pests of fruit and nuts (Wheeler 2001). Despite the abundance and agricultural importance of plant bugs, only 10 or so sex pheromones of mirids have been identified (Millar 2005). Millar (2005), somewhat casually, noted that mirid pheromones fall into two groups: "The first (e.g., *Campylomma verbasci* and *Phytocoris* spp.) is characterized by pheromones that were straightforward to identify, whereas pheromones of the second group, including *Lygus* and *Lygocoris* spp., have proven to be remarkably intractable despite decades of effort by numerous research groups." Since Millar's review, Innocenzi et al. (2005) reported that females of the European tarnished plant bug, *Lygus rugulipennis* Poppius, attract males with a blend of *(E)*-4-oxo-2-hexenal and hexyl butyrate, with the key to synthetic pheromone activity being the slow release of the active compounds; at higher release rates, the *(E)*-4-oxo-2-hexenal/ hexyl butyrate blend did not attract bugs (Innocenzi et al. 2004). For rice leaf bug, *Trigonotylus caelestialium* (Kirkaldy) (Miridae), high pheromone concentrations were also inhibitory (Kakizaki and Sugie 2001).

The first sex pheromone identifications of *Phytocoris* spp. were for two western US species, *P. californicus* (Millar and Rice 1998) and *P. relativus* (Millar et al. 1997). Our elucidation (Zhang and Aldrich 2003a) of the pheromone of the eastern US species, *Phytocoris difficilis*, and

concomitant inferences to the pheromone composition of the sympatric species, *P. breviusculus*, by default make the sex pheromones of *Phytocoris* spp. the best known of all 1400 mirid genera (Schuh and Slater 1995).

The present pheromone investigation of a fifth member of the genus *Phytocoris* was undertaken after the fortuitous discovery of this species by one of us (Q-HZ) in residential Spokane, WA, USA. Although *P. calli* is apparently not an economically significant pest or predator, we undertook the study to expand our understanding of the pheromone systems of these insects, and perhaps, to obtain new information that may suggest fruitful approaches to deciphering the pheromones of species in the group of "intractable" mirids.

Methods and Materials

Adult Insects and Preparation of Extracts *Phytocoris calli* adults were collected from residential porch lights around 9:30 P.M.—midnight during the summer of 2007 in Spokane, WA, USA. All bugs were dissected within 10–20 hr of capture for extraction of the metathoracic scent glands (MSG) and subsequent electrophysiological and chemical analyses. MSGs from male and female *P. calli* were excised from CO_2-anesthetized bugs submerged in tap water, and the glands were extracted individually in 50 µl of methyl-*tert*-butyl ether. Extracts were kept at −20 °C until analysis.

Gas Chromatography-Electroantennogram Detector (GC-EAD) and GC-Mass Spectrometry (GC-MS) Analyses Mirid extracts were analyzed in the splitless mode with a Varian CP-3800 GC equipped with a polar column (HP-INNOWax; 30 m×0.53 mm×1.0 µm; Agilent Technologies), and a 1:1 effluent splitter that allowed simultaneous flame ionization and electroantennogram detection of separated compounds. Helium was used as the carrier gas, and the injector temperature was 220 °C. The column temperature was 50 °C for 1 min, rising to 240 °C at 10 °C min^{-1}, and then held for 10 min. The outlet for the electroantennogram detector (EAD) was held in a humidified air-stream flowing at 0.5 m sec^{-1} over the antennal preparation. A glass capillary indifferent electrode was filled with Beadle-Ephrussi Ringer solution (Zhang et al. 2000), grounded via a silver wire, and inserted into the open side of an excised mirid head. A similar recording electrode, connected to a high-impedance DC amplifier with automatic baseline drift compensation, was inserted over an antenna (the tip of the antenna was excised). Antennal signals were stored and analyzed on a computer equipped with a serial IDAC interface box and the program EAD ver. 2.5 (Syntech, Hilversum, The Netherlands). The MSG extracts were analyzed by GC-MS on an HP 6890 GC series coupled with an HP 5973 Mass Selective Detector by using the same type of GC column and conditions as described above. Compounds were identified by comparison of retention times and mass spectra with those of standards.

Chemical Standards The following authentic standards were obtained from commercial sources or were synthesized: 1-hexanol, (*E*)-2-hexenol, (*E*)-2-octenol, nonanal, hexyl acetate (HA), hexyl propanoate, octyl acetate (OA), and octyl butyrate (Aldrich Chemical Co., Milwaukee, WI, USA); (*E*)-2-octenyl acetate (E2OA), hexyl butyrate, (*E*)-2-hexenyl butyrate, (Bedoukian Research Inc., Danbury, CT, USA); heptyl acetate (Eastman Organics); and (*Z*)-3-octenyl acetate (J. G. Millar, Univ. California, Riverside). (*E*)-2-Hexenyl acetate (E2HA) was synthesized as described previously (Aldrich et al. 1997, 1999).

Field Trapping Two field-trapping experiments were carried out from August to September 2007 in a residential backyard with several apple, cherry, and other angiosperm trees that are common in residential Spokane, WA. Pherocon VI traps (Trécé Inc., Adair, OK, USA) with removable sticky inserts and baited with 10–80 µl of individual or mixed neat test compounds loaded onto gray rubber septa (5 mm sleeve-type, The West Co., Lititz, PA, USA) were used in the trials. Rubber septa were replaced every week. Traps were hung 1.5 m above the ground on a fence, ca. 5 m apart within each trap line. For each trapping experiment, one set of traps was deployed with their initial trap positions being random. The trap positions were systematically rotated after each visit, based on a procedure of Latin-square design (Byers 1991), so that traps appeared at least once per location. To minimize positional effects, mirid collections and trap rotations were carried out when ≥ 2 mirids were caught in a trap. Each replicate lasted several days to 1 wk, depending on mirid flight activity. Sticky inserts were taken to the laboratory for recording of species, gender, and number of bugs. Experiment 1 (August 7 to September 11, 2007) tested six treatments: a mixture of the EAD-active female MSG volatiles (4-compound "full blend"), subtraction of each EAD-active component from the full blend, and a blank. Experiment 2 (August 25 to September 24, 2007) was conducted to determine the potential activity of the two key EAD-active compounds, hexyl acetate, (*E*)-2-octenyl acetate, and their binary blend in comparison with the four-compound "full blend".

Statistical Analysis Trap catch data were transformed by log $(x+1)$ to fit the assumption of homogeneity of variance for analysis of variance (ANOVA). Means were compared by ANOVA followed by the Ryan–Einot–Gabriel–Welsh (REGW) multiple Q test (SPSS 8.0 for Windows) at $\alpha = 0.05$ (Day and Quinn 1989).

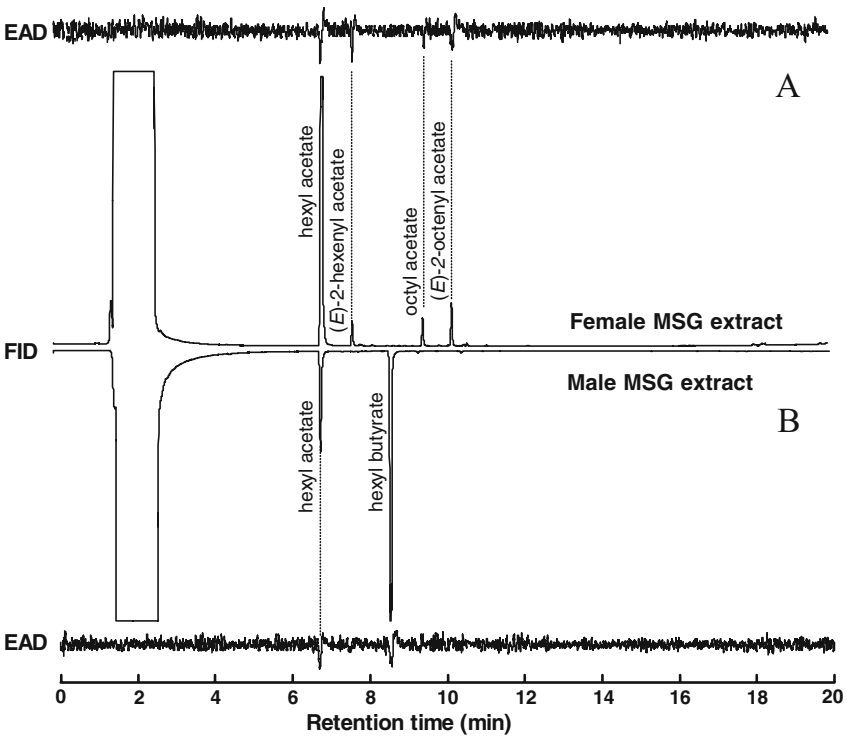

Fig. 1 Coupled flame ionization (FID) and electroantennogram (EAD) detection of *Phytocoris calli* male antennae to metathoracic scent gland (MSG) extracts of conspecific females (A) and males (B)

Results

GC-EAD and Chemical Identifications Antennae of *P. calli* males responded strongly to one major and three minor components from female MSG extracts. These compounds were identified by GC-MS as HA, E2HA, OA, and E2OA (in a ratio of ca. 20:1:1:1), respectively (Fig. 1A and Table 1). In male MSG extracts, there were only two major volatile components, HA and hexyl butyrate, each of which elicited strong responses from male antennae (Fig. 1B, Table 1). In addition to the EAD-active compounds, several other minor or trace amounts of chemicals also were

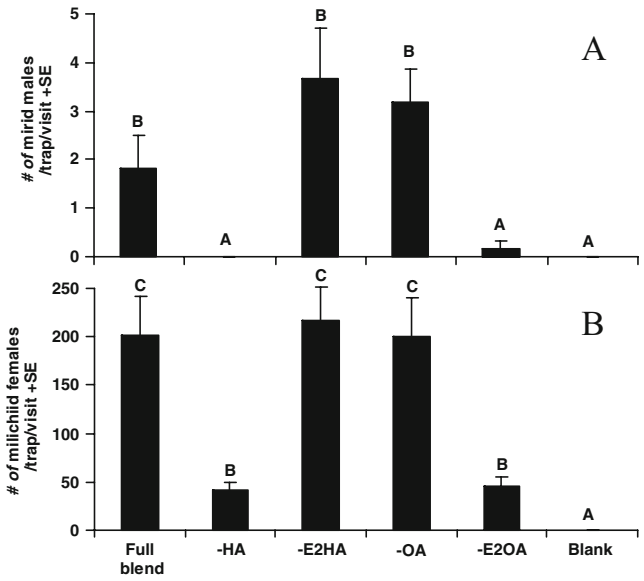

Fig. 2 Captures of *Phytocoris calli* males (A) and *Leptometopa latipes* females (B) in traps baited with full blend [HA (50 µl)/E2HA (10 µl)/OA (10 µl)/E2OA (10 µl)] or ternary blends of the four EAD-active female MSG volatiles (*HA* hexyl acetate, *E2HA* (*E*)-2-hexenyl acetate, *OA* octyl acetate, *E2OA* (*E*)-2-octenyl acetate). Means (N=6) followed by the same letter are not significantly different (P>0.05), ANOVA on log (x+1), followed by the Ryan–Einot–Gabriel–Welsh (REGW) multiple Q test

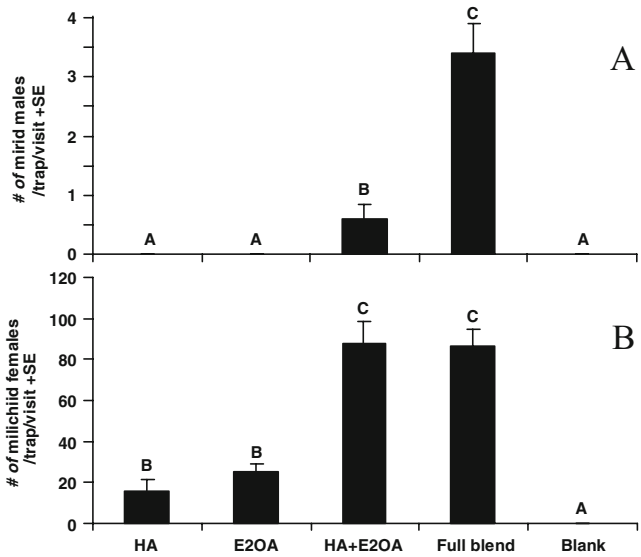

Fig. 3 Captures of *Phytocoris calli* males (A) and *Leptometopa latipes* females (B) in traps baited with hexyl acetate (50 µl), (*E*)-2-octenyl acetate (10 µl), and their binary blend (50 µl+10 µl) in comparison with the four-compound "full blend" (HA [50 µl]/E2HA [10 µl]/OA [10 µl]/E2OA [10 µl]). Means (N=5) followed by the same letter are not significantly different (P>0.05), ANOVA on log (x+1), followed by the Ryan–Einot–Gabriel–Welsh (REGW) multiple Q test

identified by GC-MS, including 1-hexanol and heptyl acetate from both sexes, (*E*)-2-hexenol, (*E*)-2-octenol, and (*Z*)-3-octenyl acetate from females, and hexyl propanoate, nonanal, (*E*)-2-hexenyl butyrate, and octyl butyrate from males (Table 1).

Field Experiments In experiment 1, traps baited with the blend of the four EAD-active components ("full blend") of female MSG volatiles (HA/E2HA/OA/E2OA) caught significant numbers of *P. calli* males (P<0.05, Fig. 2A). Subtraction of E2HA or OA from the four-component "full blend" had no effect on trap catches. However, deletion of HA or E2OA from the blend entirely eliminated catches of *P. calli* males (Fig. 2A), indicating that these two compounds may be key components of the pheromone. In experiment 2, traps baited with HA or E2OA alone caught a non-significant number of bugs, while traps baited with the binary blend caught some *P. calli* males, but significantly (>4 times) less in than traps baited with the four-component "full-blend" (Fig. 3A).

In addition to male bugs, large numbers of female milichiid flies (*Leptometopa latipes* Meigen) were captured in most traps. As for catches of mirid males, traps baited with the "full-blend" caught large numbers of *L. latipes* females, and deletion of E2HA or OA from the four-component "full blend" had no effect on the catches of flies. However, removal of HA or E2OA from the blend dramatically reduced trap catches of the milichiid females (Fig. 2B). Traps baited with HA or E2OA alone caught low numbers of milichiid females; however, the binary blend of these two compounds elicited much greater trap catch than did either compound individually (Fig. 3B). There was no difference in catches of milichiid females between traps baited with the binary blend or the four-compound "full-blend.".

Most mirids (males from traps or lights or females from lights) were collected or trapped during the first half of the scotophase (after sunset to midnight), whereas milichiids were captured exclusively during the daytime.

Discussion

Phytocoris sex pheromones, including that of *P. calli*, consist of HA, which is produced by both sexes, plus related female-specific esters (Millar 2005) (Table 2). Pheromone compounds are produced by adult females in the MSG (Zhang and Aldrich 2003a). Redundant pheromone esters in sympatric *Phytocoris* species (Millar et al. 1997; Millar and Rice 1998) and *P. calli* may help maintain reproductive isolation, although more research is needed to verify whether this possibility is correct or not.

Traps baited with HA and E2OA also were strongly attractive to the scavenging milichiid fly, *Leptometopa latipes* (Fig. 3B). Similar synergistic attraction between hexyl butyrate and *(E)*-2-hexenyl butyrate to *L. latipes* also was reported in a previous study of the tarnished plant bug, *Lygus lineolaris* (Zhang and Aldrich 2004). These results

suggest that milichiid females may use pheromonal compounds from plant bugs as kairomones to find freshly injured or dead bugs on which to feed.

The major volatiles from males, whether from aeration or MSG dissection, are almost identical among the five *Phytocoris* species studied, with hexyl butyrate being the dominant component (Millar et al. 1997; Millar and Rice 1998; Zhang and Aldrich 2003a, b) (Table 1). Hexyl butyrate elicited strong EAD responses from antennae of male *P. calli* (this paper), *P. difficilis*, and *P. breviusculus* (Zhang and Aldrich 2003a, b). For *P. difficilis*, we demonstrated that hexyl butyrate totally stopped attraction of males to the female-produced sex pheromone. We consider this signal to be a natural anti-sex pheromone, perhaps that repels other males from further mating attempts, or for precluding a male from remating with a female. A similar inhibitory effect of hexyl butyrate also has been reported in two other mirids, *Lygocoris pabulinus* (Groot et al. 2001) and *Lygus lineolaris* (Zhang et al. 2007). It remains to be determined whether hexyl butyrate is an anti-sex pheromone for *P. calli*. The phenomenon of a male-to-male inhibitory pheromone was reported long ago as one likely mode of action for hair pencil secretions of male Lepidoptera (Hirai et al. 1978).

Intractable and easily identified mirid pheromones are all female-produced, and apparently based on compounds (especially esters) biosynthesized in the MSG (Millar 2005). The MSG is characteristic of "true bugs" (Heteroptera) and is usually considered to be a defensive gland (Aldrich 1988). However, males or females of various seed bugs (Lygaeidae) (Aldrich et al. 1997, 1999; Marques et al. 2000) and broad-headed bugs (Alydidae) (Leal et al. 1995, 1996; Aldrich et al. 2000) release attractant pheromones from the MSG, while retaining the ability to release chemical irritants from the MSG when attacked by predators. In most bugs, the MSG consists of a pair of lateral accessory glands and a median reservoir in which the principal irritants (aldehydes and acids) are enzymatically derived from esters produced in the accessory glands (Aldrich et al. 1978). The sexual role of the MSG is evidently associated with compartmentalization of the MSG, such that the insects are able to release pheromone directly from the lateral accessory glands or accumulate defensive compounds in the median reservoir until needed for defense.

In mirids, species of *Phytocoris* and *Campylomma* seem to express the sexual manifestations of the MSG primarily, with little capacity to produce aldehydic or acidic allomones. At the other extreme is the aposematic mirid, *Lopidea robiniae* (Uhler), with a MSG secretion dominated by *(E)*-2-hexenal (Staples et al. 2002). Judging by the coexistence of *(E)*-4-*oxo*-2-hexenal with hexyl and *(E)*-2-hexenyl butyrates in the MSG of *Lygus* bugs (Aldrich et al. 1988; Innocenzi et al. 2004), the defensive and sexual roles of the MSG seem more entwined for *Lygus* bugs than is the case for *Phytocoris* spp., thus complicating the task of deciphering the sex pheromones.

Acknowledgments We thank T. J. Henry (Miridae) and Allen L. Norrbom (Milichiidae), Systematic Entomology Laboratory (SEL), USDA-ARS, Beltsville, Maryland, for identification of mirid and milichiid species, respectively. We are also grateful to J. G. Millar, Department of Entomology, University of California at Riverside, for the gift of chemical standards.

Interspecific Pheromone Plume Interference Among Sympatric Heliothine Moths: A Wind Tunnel Test Using Live, Calling Females

Jonathan P. Lelito · Andrew J. Myrick · Thomas C. Baker

Received: 3 October 2007 / Revised: 2 February 2008 / Accepted: 9 April 2008 / Published online: 7 May 2008

Abstract Three species of North American heliothine moths were used to determine the level at which interspecific female interference of male attraction to conspecific females occurs. We used live calling females of *Heliothis virescens*, *H. subflexa*, and *Helicoverpa zea*, as lures for conspecific males in a wind tunnel, and then placed heterospecific females on either side of the original species such that the plumes of the three females overlapped downwind. In nearly all combinations, in the presence of heterospecific females, fewer males flew upwind and contacted or courted the source than when only conspecific females were used in the same spatial arrangement. Males did not initiate upwind flight to solely heterospecific female arrangements. Our results show that the naturally emitted pheromone plumes from heterospecific females of these three species can interfere with the ability of females to attract conspecific males when multiple females are in close proximity. However, the fact that some males still located their calling, conspecific females attests to the ability of these male moths to discriminate point source odors by processing the conflicting information from interleaved strands of attractive and antagonistic odor filaments on a split-second basis.

Introduction

The heliothine moths are a well-studied group of crop pests in North America. The two most economically important species are the tobacco budworm, *Heliothis virescens* Fabricius (Lepidoptera: Noctuidae), and the corn earworm, *Helicoverpa zea* Boddie. A third species, which is a pest of tomatillo in Mexico, is *Heliothis subflexa* Guenée. All three of these moths share the same major pheromone blend component, (*Z*)-11-hexadecenal (*Z*11-16:Ald), but differ in the other components of their respective blends. In *H. virescens*, the secondary component is (*Z*)-9-tetradecenal (*Z*9-14:Ald; Roelofs et al. 1974; Tumlinson et al. 1975; Klun et al. 1980b; Pope et al. 1982; Vetter and Baker 1983; Teal et al. 1986), while for *H. zea*, the secondary component is (*Z*)-9-hexadecenal (*Z*9-16:Ald; Klun et al. 1979, 1980a; Vetter and Baker 1984; Pope et al. 1984). Finally, in *H. subflexa*, secondary components include *Z*9-16:Ald, (*Z*)-11-hexadecen-1-ol (*Z*11-16:OH), and (*Z*)-11-hexadecenyl acetate (Z11-16:Ac; Teal et al. 1981; Klun et al. 1982; Heath et al. 1990, 1991; Vickers 2002; Groot et al. 2006).

The secondary components of one species of moth can act as behavioral antagonists if they are added to the sex pheromone blend of another species (Cardé et al. 1977; Löfstedt 1990, 1993; Löfstedt et al. 1991; Gries et al. 1996; Potting et al. 1999; Quero and Baker 1999), often most strongly where the species in question are sympatric and synchronic (Cardé et al. 1977; Guerin et al. 1984; Gemeno et al. 2000; McElfresh and Millar 1999, 2001; Gries et al. 2001; El-Sayed et al. 2003; Groot et al. 2007). This is expected as a result of selection against mating mistakes by males in areas where the species co-occur.

These antagonistic effects are well known in wind tunnel studies for the heliothine moths, mainly from adding the

heterospecific secondary components onto the same point source as the synthetic conspecific pheromone blend (Vickers et al. 1991; Vickers and Baker 1997; Fadamiro and Baker 1997; Fadamiro et al. 1999). Both Z11-16:OH and Z11-16:Ac from the *H. subflexa* blend antagonize the attraction of male *H. virescens* (Vetter and Baker 1983, 1984; Vickers and Baker 1997) and *H. zea* (Teal et al. 1984; Quero and Baker 1999; Quero et al. 2001). However, the antagonistic effects caused by the coemission of a heterospecific compound from the same point source does not necessarily mean that a confluent plume from a nearby heterospecific female would interfere with the attraction of a male to a conspecific female whose plume was being overlapped. Plumes are comprised of individual strands of odor interspersed with pockets of clean air, the strands having been sheared off at the source and later shredded into finer substrands by microturbulence (Murlis 1986).

Moths have an exceptionally good ability to fly upwind to and locate sources of their pheromone, even when sources of behaviorally antagonistic compounds are placed 10 cm away to create confluent plumes (Witzgall and Priesner 1985; Liu and Haynes 1994; Baker et al. 1998; Fadamiro et al. 1999). For instance, *H. virescens* males were able to discriminate strands of their two-component pheromone from strands of the antagonist Z11-16:Ac when the strands were experimentally generated to be separated by only 1 mm (Baker et al. 1998; Fadamiro et al. 1999). When the antagonist was coemitted in every strand along with the pheromone, however, attraction was negligible, and the suppression of attraction was apparent on a strand-by-strand basis in the behavior of flying males in both *H. virescens* (Vickers and Baker 1997) and *H. zea* (Quero et al. 2001).

Our goal in the current study was to examine the behavior of males in a wind tunnel in response to live, calling conspecific females in the close presence of live, calling heterospecific females. The experiments examine the effects of heterospecific blends that arrived downwind on flying males' antennae in naturally mixed or staggered strands. Using each of the six species pairs possible, we tested the hypothesis that the sex pheromone plumes from heterospecific live heliothine moths may interfere with the attraction of males to their conspecific females when the time-averaged plumes are known to overlap. However, when sufficient proportions of heterospecific strands might arrive asynchronously on the antenna with conspecific strands, we hypothesized that low levels of attraction to conspecific females should still occur.

Methods and Materials

Insects Moths of the three species used in this experiment were maintained over many generations on a modified pinto bean diet (*H. zea* and *H. virescens*; Shorey and Hale 1965) and a corn–soy diet (*H. subflexa*; Vickers 2002). Single larvae were placed into individual diet-filled cups, removed at pupation, and sexed under a dissecting scope. Sexed pupae of each species were placed into screen cages lined with paper toweling and provided with a 10% sucrose solution for adults to feed on upon eclosion. Each day, any live, properly formed adults of either sex were removed and placed into a separate cage, sorted by species. Male and female moths of the three species were kept in separate Percival environmental chambers (Percival Scientific, Boone, IA, USA) at 29–30°C and 50% or higher relative humidity, under a reversed light cycle, 16:8-h light/dark, with the scotophase starting at 9:30 A.M. Dead and malformed moths were discarded daily, and the sucrose–water dispenser was refilled. The entire screen cage was sprayed twice daily (just before lights-off and just after lights-on) with distilled water. All male moths were between 3 and 6 d of age, and all female moths were between 2 and 6 d of age when utilized for these experiments.

Behavioral Assays The wind tunnel, with a width of 1.2 m, a length of 2.8 m, and a height of 1 m at its peak (a bowed shape based on Miller and Roelofs 1978), was set to a wind speed of 60 cm s^{-1}, the room darkened to 2.96 lx (2.20 lx of red light and 0.76 lx of white light) emanating from eight overhead incandescent light sources (four red, four white) connected to a variable transformer. Just before the onset of the scotophase, 15 male moths of each of the three species, in individual 6 by 6-cm metal screen cages, were placed into the wind tunnel itself. At the same time, at least 10 female moths of each species were placed into individual metal screen cages, in an adjacent fume hood in the darkened wind tunnel room to prevent the males from being exposed to pheromone prior to flight. All flights were conducted in the last 4 hr of the scotophase, giving the moths several hours to adjust to the conditions in the wind tunnel room.

Control flights were performed each day to judge the response level of males of each species to conspecific females under our wind tunnel conditions. Three calling females of the same species were placed in individual metal screen cylinders (4 cm diameter×6 cm height) on a metal screen pedestal 35 cm above the wind tunnel floor in a triangular arrangement with the apex of the three-female triangle facing upwind (Fig. 1). The separation between the two downwind cages was only 2–3 cm, and thus the maximum distance that plumes from the calling females (depending on where they were situated when calling) would be separated by was 4 cm. Females were placed into the wind stream and allowed to acclimate for up to 10 min, by which time they had resumed calling. Once all three

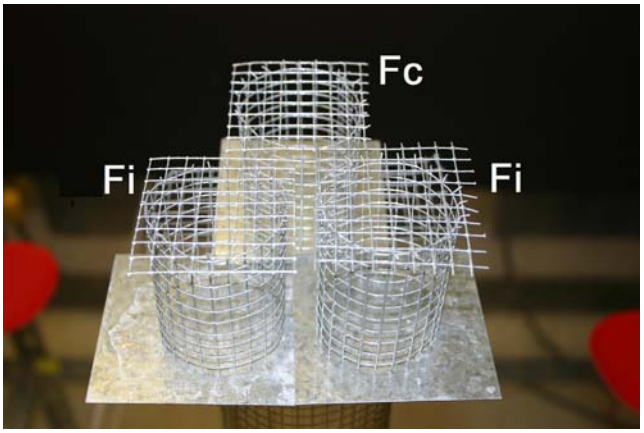

Fig. 1 Arrangement of female cages in the control and experimental wind tunnel experiments conditions. *Fc* indicates the conspecific female position. *Fi* indicates the interference female positions for the experimental treatments; during control flights for each species, all three positions are occupied by conspecific females. The direction of air movement in the wind tunnel is from *top* to *bottom* in the image

females were visibly calling, males were released in the center of the wind tunnel by hanging their cage, open end upwind, on a pedestal 35 cm high, 1 m directly downwind from the females. Each male was given up to 2 min to respond, after which nonresponders' cages were removed, while responding males were captured and removed with a net. Between each male test, the females were observed, and in the few instances when they were no longer visibly calling, they were replaced with another individual from the fume hood; the new females were given time to resume calling if the move from the hood to the wind tunnel had disturbed them. Males of a given species were also tested against three females of each of the other two species. Each individual male was exposed only to one of these treatments and then discarded.

For each male, we scored his progress toward completion of the entire flight sequence: "no flight," "wing fanning," "flight," "casting," "locked on plume," "half the distance to source," "10 cm from source," "contact source," and "hair pencils and courtship." The temperature at the beginning and end of the flight period was averaged to yield the temperature recorded for that day.

After the control flights were complete, experimental flights were performed. These were conducted in a manner similar to the control flights, except that the apical female in the triangular arrangement was a conspecific of the male being tested, and the other two cages held individual heterospecific females of the same species (Fig. 1). The same protocol of observing the females in a calling posture and replacement of noncalling ones was used. Males again were given 2 min to respond. Experimental flights were conducted such that individual females of both "interfering" species were assessed; that is, male *H. subflexa* were tested to *H. subflexa* females under interference from two *H. virescens* and subsequently from two *H. zea* females. As before, an individual male of a given species only was exposed to one experimental treatment and not used again.

For simplicity, treatments will hereafter be referred to by three-letter combinations. For example, the array of three *H. subflexa* females would be abbreviated as "SSS," while an array comprised of one *H. subflexa* female in the presence of two *H. zea* females would be abbreviated "ZSZ," because this annotation most closely reflects the spatial arrangement of the species of females on the platform.

Plume Strand Analyses The degree to which plume strands of females were or were not coincident in their arrival downwind was measured by using cages of calling females placed in the positions on the platform as described above. We used calling females of *Trichoplusia ni* and *H. virescens* and the Quadroprobe four-antenna biosensor (Park et al. 2002) on which two *T. ni* male antennae and two *H. virescens* antennae were placed on the four-channel simultaneous electroantennogram (EAG) probe. The probe was situated in the wind tunnel 1 m downwind of the calling females where males had been released earlier in the behavioral experiments. The system for odor classification, using a computer algorithm (Myrick et al. 2005; Hetling et al. 2006), was first trained to classify the plume strands from calling *T. ni* and *H. virescens* females, as well as a synthetic mixture of 10 μg of each of the two major components of both species emitted from a filter paper with greater than 95% accuracy for all training odors. *T. ni* and *H. virescens* females were used due to the need to discriminate the major pheromone components of females so closely placed together in upwind cages. Threshold for detection "events" (EAGs) from plume strands was set at 50 μV. Readings from the Quadroprobe were then taken in the confluent plumes from calling *T. ni* and *H. virescens* females from 1 m downwind using the caged female configurations described above (Fig. 1). EAGs from the calling females of the three heliothine moth species used in behavioral experiments could not be placed in different classes due to the predominant EAG responses resulting from the major component of all three species, Z11-16:Ald. A total of 83s (195 strands), 33s (85 strands), and 33s (135 strands) was used for the Quadroprobe algorithm training sessions in the plumes from *H. virescens* females, *T. ni* females, and the synthetic mixture, respectively.

Statistical Analyses A Fisher's exact test was used to compare each category of male response among female treatments within each species of male assessed (Fisher 1922). Chi-square contingency tests (χ^2) were used to examine the difference in response rates between contacting

the source and extending hair pencils for each species of male, under each treatment (Steel and Torrie 1960).

Results

Males of all three species exhibited a significant reduction in at least one of their upwind flight attraction behaviors when two heterospecific females were positioned next to their own female, compared to when three conspecific females were present (Figs. 2, 3, 4, 5, 6, and 7). No males of any species responded with attraction-related behaviors to an array of three heterospecific females; it is important to note that none even "locked on" to the plumes of heterospecific females (Figs. 2, 3, 4, 5, 6, and 7).

The presence of either *H. subflexa* or *H. zea* females on either side of a *H. virescens* female significantly reduced the upwind flight behavior of the *H. virescens* males, starting with the "locking on" stage (Figs. 2 and 3). At subsequent stages of upwind flight, reductions caused by the heterospecific females were not as severe, and several of the *H. virescens* males were able to land at the cage of the centrally located, conspecific female (Figs. 2 and 3).

It is interesting to note that the effects of heterospecific females seemed to carry over to the courtship stage after males had landed, even though the pheromone components they were exposed to near the cage were more likely to be only conspecific. Seventy-one percent of *H. virescens* males that contacted the conspecific female array also exhibited the hair pencil courtship display, whereas in the ZVZ and SVS treatments, the courtship responses were significantly lower, 44.4% and 37.5%, respectively ($p<0.05$; Chi-square 2×2 test of independence).

Similarly, the presence of either *H. virescens* or *H. zea* females significantly reduced the upwind flight behavior of *H. subflexa* males to a conspecific, starting downwind at the "locking on" to the plume stage (Figs. 4 and 5). Several of the *H. subflexa* males were able to land at the cage of the centrally located conspecific female (Figs. 4 and 5).

The effects of heterospecific females around *H. subflexa* females seemed to carry over to the courtship stage. For *H. subflexa* males flying to the SSS treatment, 41.2% of those that contacted the source also exhibited the hair pencil courtship display. However, in response to the VSV and ZSZ treatments, the percentages of males that had contacted the source that also exhibited courtship was significantly lower, 0% and 20%, respectively ($p<0.05$; Chi-square 2×2 test of independence).

H. zea males did not respond as well to conspecific females as did *H. virescens* and *H. subflexa*, but their responses to either of the heterospecific female controls (SSS and ZZZ) were significantly lower (Figs. 6 and 7). The presence of heterospecific females on either side of a *H. zea* female significantly reduced the upwind flight behavior of the *H. zea* males, with the interference from *H. subflexa* females (Fig. 6) being greater than that of *H. virescens* females (Fig. 7), in that, in the latter case, only "locking on" to the plume stage was affected. *H. subflexa* females interfered with male *H. zea* attraction to *H. zea* females at every stage. For *H. zea*, such a low percentage of males landed on their conspecific female cages that no analysis of the subsequent hair pencil displays of these landed males would be meaningful.

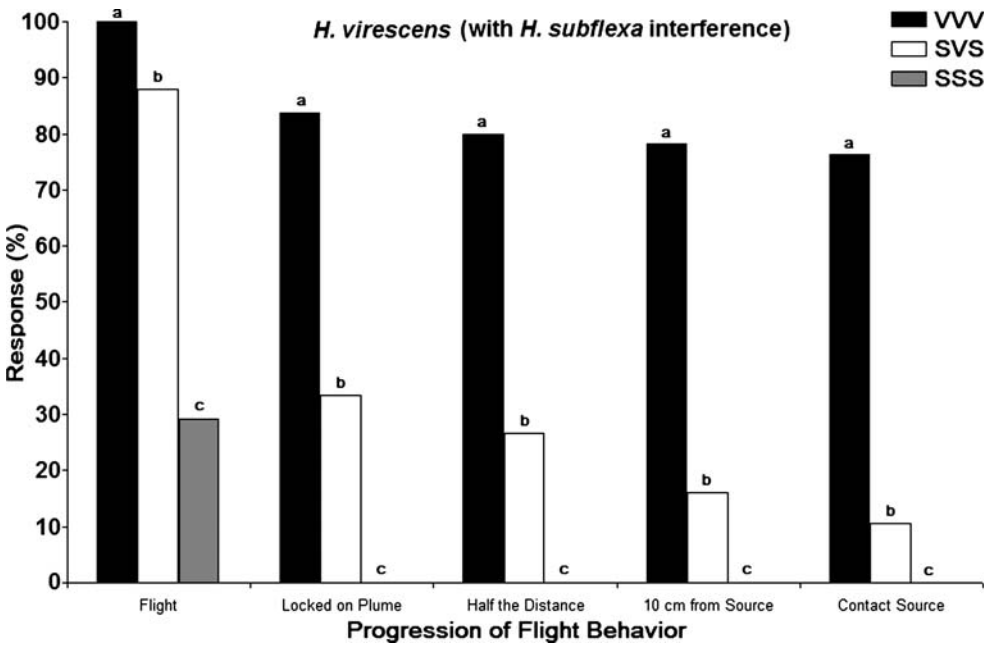

Fig. 2 Responses of male *H. virescens* to conspecific (*VVV*) and heterospecific (*VSV* and *SSS*) treatments involving *H. subflexa* females. Within each behavioral category, *bars having no letters* in common are significantly different from each other

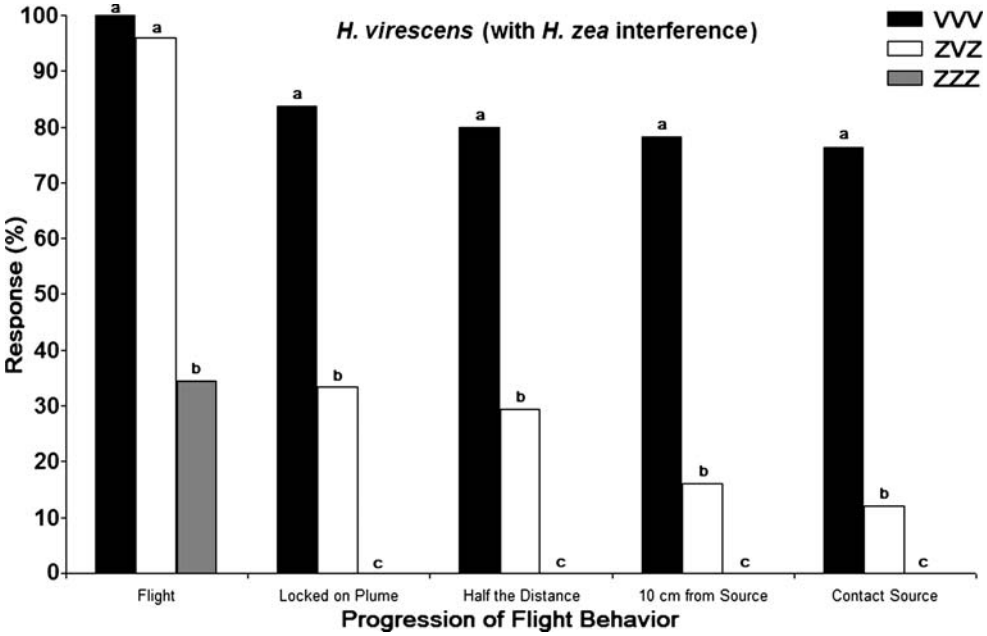

Fig. 3 Responses of male *H. virescens* to conspecific (*VVV*) and heterospecific (*VZV* and *ZZZ*) treatments involving *H. zea* females. Within each behavioral category, *bars having no letters* in common are significantly different from each other

The degree of coincident arrival of plume strands, as measured by the Quadroprobe four-antenna system using two heterospecific, calling females, was substantial. The fact that females of the two species were placed so closely together in their cages on the platform perhaps makes this not so surprising. Strands classified as "mixture" comprised 670 out of the 1,525 strands arriving on the probe (43.9%) for the VTV (*H. virescens*/*T. ni*/*H. virescens*) placement. Strands classified as *T. ni* comprised 600 out of 1,525 strands (39.3%), and those identified as *H. virescens* were 255 out of 1,525 (16.7%). For the TVT arrangement, 285 out of 625 strands (45.6%) were classified as "mixture," 270 (43.2%) were classified as *T. ni*, and 70 (11.2%) were classified by the algorithm as *H. virescens*.

Discussion

Despite years of studies on the behavioral antagonism caused by the addition of synthetic heterospecific heliothine pheromone components to the synthetic sex pheromone blends of other heliothine species, there has been a relative lack of information about the degree of antagonism caused by actual overlapping plumes emitted by heterospecific

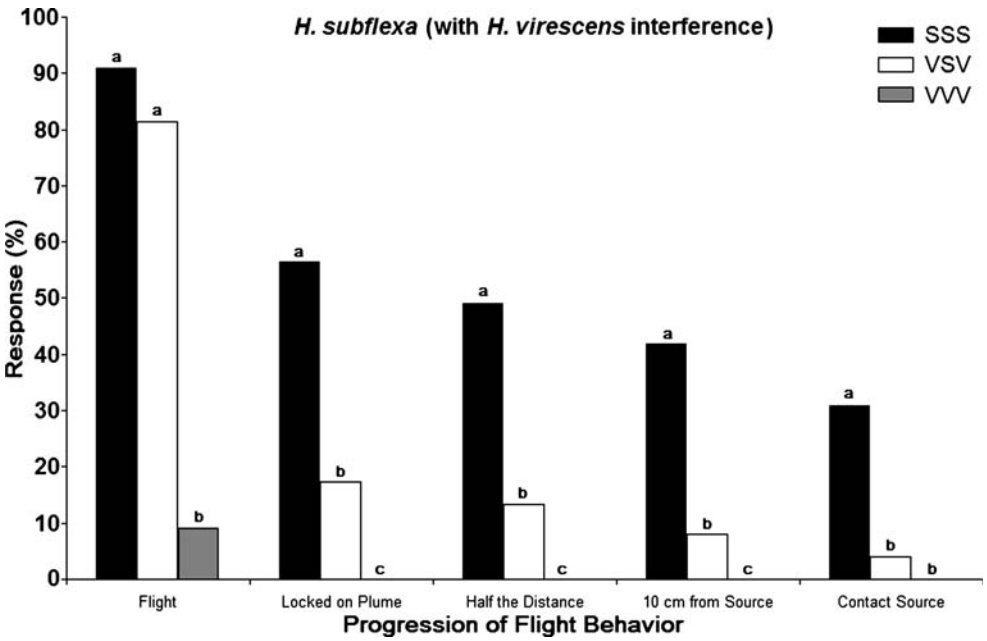

Fig. 4 Responses of male *H. subflexa* to conspecific (*SSS*) and heterospecific (*VSV* and *VVV*) treatments involving *H. virescens* females. Within each behavioral category, *bars having no letters* in common are significantly different from each other

heliothine females. The question of naturally emitted female–female sex pheromone plume interactions relates directly to the possible selection pressures that may have occurred over evolutionary time. Practical issues of sex pheromone monitoring trap specificity, not the evolutionary forces that determine species-specific communication channels, were the initial driving force behind the identification of these field-trapping heliothine blends.

Our results using live, calling females of these three heliothine species show that there is no cross-attraction whatsoever between males of one species and females of the other two species. This is in agreement with field-trapping studies that used synthetic blends, as well as those that used live females, as lures in field-trapping tests (Haile et al. 1973; Sparks et al. 1979a, b; Klun et al. 1979, 1982; Carpenter et al. 1984; Lopez and Witz 1988). The interfering effects of a confluence of plumes in previous field-trapping tests using cages of calling females could not be verified due to the uncertainties produced by the ever-shifting wind fields under these conditions. In the current experiments, these uncertainties were eliminated.

It had been inferred from studies that used synthetic lures that male *H. subflexa* will not fly upwind to females of either *H. virescens* or *H. zea* because *H. virescens*

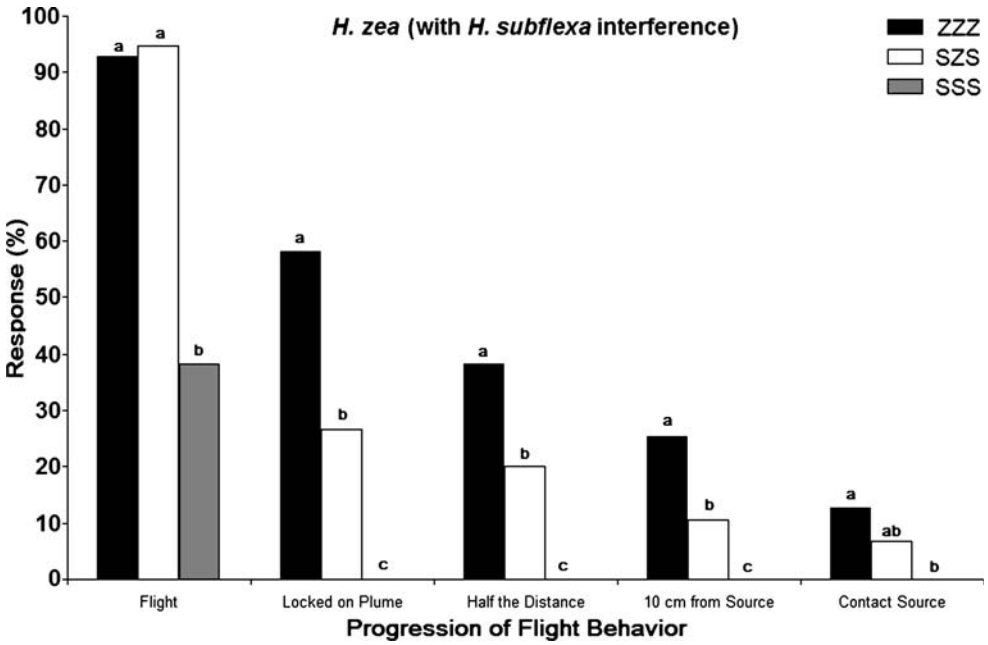

Fig. 6 Responses of male *H. zea* to conspecific (*ZZZ*) and heterospecific (*SZS* and *SSS*) treatments involving *H. subflexa* females. Within each behavioral category, *bars having no letters* in common are significantly different from each other

females emit trace amounts, at best, of Z9-16:Ald and Z11-16:OH, and *H. zea* females do not emit Z11-16:OH (Klun et al. 1979; Pope et al. 1984; Heath et al. 1990; Vickers et al. 1991). Our results support these suppositions, showing no cross-attraction of *H. subflexa* males to females of the other two species.

It had been assumed that neither *H. virescens* nor *H. zea* males will fly upwind to *H. subflexa* females because they emit Z11-16:OH, which is antagonistic to males of both these species (Klun et al. 1982; Teal et al. 1984; Vickers and Baker 1997; Quero and Baker 1999). It had also been assumed that *H. virescens* males would not be attracted to *H. zea* females because they do not emit the essential component Z9-14:Ald, and *H. zea* males would not be attracted to *H. virescens* females because the amount of Z9-14:Ald they emit relative to Z11-16:Ald acts as a behavioral antagonist. Field-trapping tests that used live, calling females (Haile et al. 1973; Sparks et al. 1979a, b) had supported these ideas, and our results confirm them.

We have further shown that the plume strands from heterospecific heliothine females contain sufficient amounts of the above-mentioned antagonistic compounds to interfere with upwind flight and source location of conspecific females by males when the plume strands are intertwined. This had been conjectured in past studies (Vickers et al. 1991; Vickers 2002), based on the potential antagonism imposed by the known heterospecific antagonist compounds applied to single sources, but it had not been rigorously tested before by using live, calling females.

To determine the precise effects when heterospecific females are in close proximity, we measured the percentages of plume strands that might be registered on heliothine male antennae downwind from the release point as "mixture" (coincident strands from two females) or else as the "pure" blend of either species. We found that nearly 50% of the strands in two configurations, VTV and TVT, were classified as "mixture" from the plumes of calling females placed in such close proximity. We suggest that this tendency toward "mixture" strands is responsible for the interspecific interference in male attraction we document here. This, in combination with the presence of antagonists in the noncoincident odor strands, reduces attraction of a given species of male moth to conspecifics. Nevertheless, sufficient numbers of strands of pure pheromone reach the males' olfactory systems to allow a significant percentage to locate their conspecific females in this closely spaced array.

Two unexpected instances of interference occurred, and they were unexpected because there are no known antagonists involved that can explain the reduced levels of upwind flight. First, *H. virescens* male attraction was reduced by the presence of *H. zea* plumes, the only explanation based on known behavior-modifying compounds for these species being that the ratio of Z9-14:Ald to Z11-16:Ald would be diluted due to the lack of emission of Z9-14:Ald by *H. zea* females. Second, the reduction in upwind flight by *H. subflexa* males in the presence of either *H. virescens* or *H. zea* females was also unexpected due to the lack of any known antagonism in *H. subflexa* males to any compounds emitted by the females of these two species. Barring the possibility of antagonism from other coemitted compounds from the females of either of these species, the only other explanation for reduced attraction of *H. subflexa* males would be that a ratio shift caused by overemission of some compounds by the other species would register suboptimally in the *H. subflexa* central

nervous system (Vickers et al. 1991; Vickers 2002), as suggested previously by Klun et al. (1982).

Acknowledgments The authors thank B. Banks, S. Benson, J. Benson, and M. Ewing for their assistance in rearing the moths needed for this study. B. Banks was also instrumental in the construction of the wind tunnel. Funding was provided by USDA/NRI Grant no. 2003-01471 to T.C.B.

Adults and Nymphs Do Not Smell the Same: The Different Defensive Compounds of the Giant Mesquite Bug (*Thasus neocalifornicus*: Coreidae)

Kathleen L. Prudic · Koji Noge · Judith X. Becerra

Received: 26 November 2007 / Revised: 6 March 2008 / Accepted: 6 April 2008 / Published online: 22 May 2008

Abstract Heteropteran insects often protect themselves from predators with noxious or toxic compounds, especially when these insects occur in aggregations. The predators of heteropteran insects change from small insect predators to large avian predators over time. Thus, a chemical that is deterrent to one type of predator at one point in time may not be deterrent to another type of predator at another point in time. Additionally, these predator deterrent compounds may be used for other functions such as alarm signaling to other conspecifics. Defensive secretion compounds from the adult and the nymph giant mesquite bug (*Thasus neocalifornicus*: Coreidae) were isolated and identified by gas chromatography–mass spectrometry and NMR. The predominant compounds isolated from the nymph mesquite bugs during a simulated predator encounter were (*E*)-2-hexenal and 4-oxo-(*E*)-2-hexenal. In adults, the major compounds released during a simulated predator encounter were hexyl acetate, hexanal, and hexanol. Results from predator bioassays suggest the nymph compounds are more effective at deterring an insect predator than the adult compounds. By using behavioral bioassays, we determined the role of each individual compound in signaling to other mesquite bugs. The presence of the nymph secretion near a usually compact nymph aggregation caused nymph mesquite bugs to disperse but did not affect adults. Conversely, the presence of the adult secretion caused the usually loose adult aggregation to disperse, but it did not affect nymph aggregation. The compounds that elicited nymph behavioral responses were (*E*)-2-hexenal and 4-oxo-(*E*)-2-hexenal, while those that elicited adult behavioral responses were hexyl acetate and hexanal. The differences between the chemical composition of nymph and adult defensive secretions and alarm behavior are possibly due to differences in predator guilds.

Introduction

Many species of warning colored insects have evolved chemical defenses that deter predatory attack and increase insect survival (Blum 1981; Eisner et al. 2007). However, the identification of which chemical is important in conferring functional benefits is difficult since insects often contain many compounds, and chemical mixtures may change in both space and time. The predators' behavioral response also varies with the identity of the predator (Eisner 1970; Eisner et al. 2007). Complications arise when compounds have multiple functions such as deterring predators and alerting conspecifics to predator attack (Eisner 1970; Eisner et al. 2007). Despite these complications and difficulties, however, an understanding of how these compounds function and to whom they are signaling is imperative in understanding adaptive significance and evolutionary history.

Heteropteran insects are known for their chemical defenses and gregarious behavior (Aldrich 1988; Millar 2005). Typically, the defensive secretions are mixtures of aliphatic compounds, most with carbon chains of C_4, C_6,

and C_8 (Aldrich and Yonke 1975; Aldrich 1988; Millar 2005). These compounds are thought to be more effective at deterring arthropod predators than birds or mammals (Eisner 1970). They may function not only as toxins and repellents to predators, but also as alarm pheromones to conspecifics, thereby alerting and dispersing threatened aggregations (Calam and Youdeowei 1968, Aldrich and Blum 1978; Blum 1981; Leal et al. 1994). However, it is often unclear which chemicals are defensive against predators, which elicit a dispersal behavior among conspecifics, and whether those chemical identities change through different life stages of insects.

The genus *Thasus* consists of neotropical and neosubtropical coreid bugs that range from the American southwest to northern South America. This genus contains some of the largest species of Heteroptera with some reaching over 50 mm in length (Brailovsky et al. 1994). Giant mesquite bugs (*Thasus neocalifornicus*: Coreidae) are among the largest heteropterans of the desert southwest USA. These insects appear to have different visual defensive strategies between the nymph and adult life stage. Adults are large (~40 mm), cryptic, and occur in small, loose aggregations, while nymphs are smaller (~5–30 mm), highly conspicuous, and occur in larger, compact aggregations (Olsen 2004). Both adults and nymphs occur simultaneously on the same host, and both life stages emit a visible secretion when disturbed. They are specialists on mesquite tress (*Prosopis* spp.: Fabaceae), and are frequently seen in southeastern Arizona, especially around Tucson (Forbes and Schaefer 2003). Nymphs are seen more often because of their conspicuous feeding aggregations on the young petioles or seed pods of mesquite (Olsen 2004). They are vividly colored red and white (Fig. 1). Adult giant mesquite bugs are colored dark olive with dark red and black legs (Fig. 1). Their size probably protects them from many insect predators, but they are attacked by lizards and birds (Olsen 2004). Both nymphs and adults emit a foul-smelling odor when disturbed, and they appear to disperse as observed in other closely related species (Aldrich and Blum 1978). Because of their different visual defensive strategies and potential predators, we investigated whether nymph and adult giant mesquite bugs contained different defensive compounds and whether those compounds elicited different behavioral responses in nymphs and adults.

By using gas chromatography–mass spectrometry (GC–MS) and ^{1}H and ^{13}C NMR, we investigated whether nymph and adult giant mesquite bugs emit different chemical compounds when disturbed. Once we identified the compounds, we used behavioral assays to determine: (1) if nymph chemicals were better at deterring insect predators than adult chemicals; and (2) if nymph and adult chemicals elicited similar or different escape behaviors in nymphs and adults.

Methods and Materials

Insect Collection Adults and third instar nymphs were collected off host plant, Arizona mesquite trees (*Prosopis*

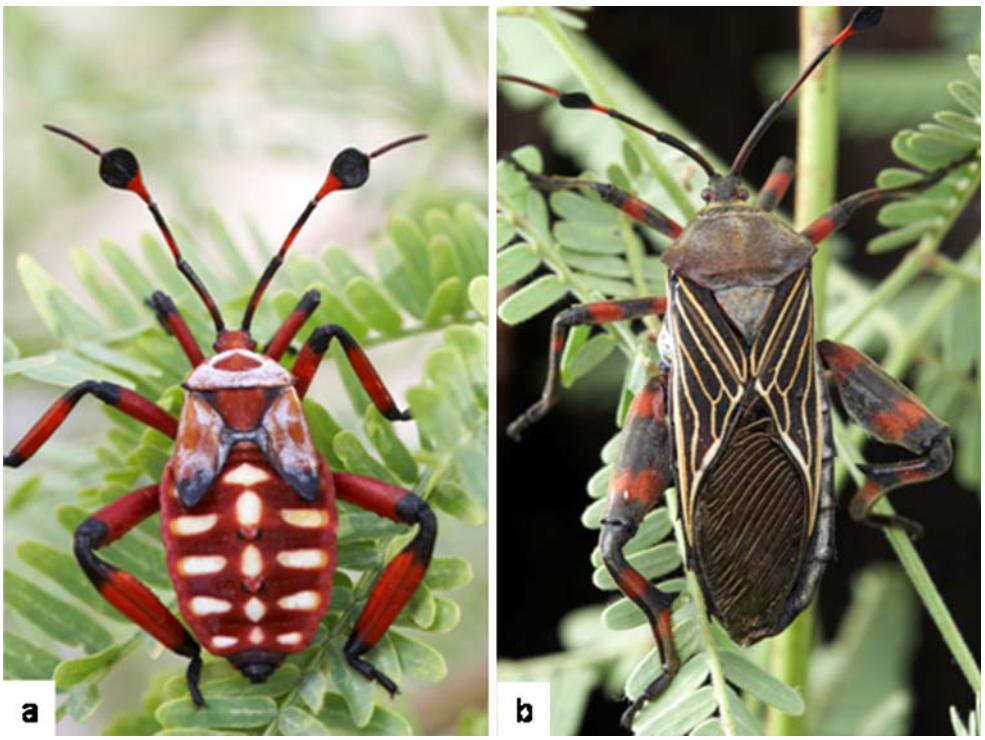

Fig. 1 Photo of **a** nymph and **b** adult giant mesquite bug, *Thasus neocalifornicus*, courtesy of Alex Wild

veluntina: Fabaceae) on June 30th, 2007 from two locations in Tucson, Pima County, AZ, USA: The University of Arizona campus (32.23°N, 110.95°W) and the Tucson Botanical Gardens (32.24°N, 110.91°W). Giant mesquite bugs were kept in the lab and fed Arizona mesquite leaves and pods for the period of experimentation.

Preparation of Extracts To collect the secretion emitted during a predation event, we pinned either an adult or a nymph (instar 3 or 4) onto a glass plate with forceps and collected the secretion from the abdomen on filter paper. The filter paper was extracted in 1 ml hexane for 5 min, and the extract was analyzed by GC and GC–MS.

To confirm our results, we also extracted whole insects. Nymphs (instar 4 or 5) were dipped into hexane (5 ml) for 3–5 min, and the extract was analyzed by GC and GC–MS. Adults were extracted with 10 ml hexane and analyzed in the same way. For identification of 4-oxo-(*E*)-2-hexenal, eight nymphs were extracted with hexane for 3 h. The extract was concentrated and then applied onto a SiO_2 column (300 mg), and successively eluted with 3 ml each of hexane, 3, 4, 10, and 50% ethyl acetate in hexane. 4-Oxo-(*E*)-2-hexenal (2.4 mg) was eluted purely in the 10% ethyl acetate fraction.

Chemical Analyses and Identification Gas chromatography (GC) analysis was performed with an Agilent 6890N GC with a flame ionization detector, by using an HP-5MS capillary column (Agilent Technologies, 30 m×0.25 mm i.d., 0.25 μm film thickness) with helium carrier gas at 2.0 ml/min in splitless mode. The oven temperature was programmed to change from 50°C (3-min holding) to 300°C at 10°C/min and then held for 5 min. The injector temperature was maintained at 200°C, and the detector temperature at 300°C. The relative percentages of each component were calculated based on the peak area by flame ionization detector (FID).

GC–Mass Spectrometry (GC–MS) analysis was performed with the Agilent 6890 N GC linked to an Agilent 5975B operated at 70 eV with an HP-5MS capillary column (Agilent Technologies, 30 m×0.32 mm i.d., 0.25 μm in film thickness) under the same analytical conditions described above, except the velocity of helium carrier gas was 1.2 ml/min.

All compounds except for 4-oxo-(*E*)-2-hexenal were identified by comparing their GC retention times and mass spectra with those of authentic standards. (*E*)-2-Hexenal, hexyl acetate, hexanol, and hexanal standards were purchased from Sigma Chemical Co. (USA). 4-Oxo-(*E*)-2-hexenal was synthesized by a one-step reaction described in Moreira and Millar (2005) and verified by GC–MS. The structure of the 4-oxo-(*E*)-2-hexenal was confirmed by ^{1}H and ^{13}C NMR spectra by using the purified natural compound. ^{1}H and ^{13}C NMR spectra were acquired on a Bruker DRX-500 spectrometer (^{1}H at 500 MHz and ^{13}C at 125 MHz) with a Bruker Dual ($^{13}C/^{1}H$) 5-mm probe at a sample temperature of 25°C in a $CDCl_3$ solution with tetramethylsilane (TMS) as an internal standard.

Mesquite Bug Behavioral Assays Mesquite bugs were organized into groups of five individuals and placed into separate arenas measuring 25 by 35 cm. Each group was composed of either third instar nymphs or adults (in total: three groups per life stage). Within each group, individuals were labeled one through five. During each trial, a single focal individual was observed for behavioral changes. The identity of the focal individual rotated among replicates. Volatiles were introduced into the arena via a piece of cotton with 3 μl of compound. The treatment compounds were distilled water (control treatment), nymph secretion collected from the abdomen, adult secretion collected from the abdomen, 4-oxo-(*E*)-2-hexenal, (*E*)-2-hexenal, hexyl acetate, hexanol, hexanal, 4-oxo-(*E*)-2-hexenal+(*E*)-2-hexenal, and hexyl acetate+hexanol+hexanal (N=15 observations/treatment). We measured the change in distance (cm) to the volatile source, change in number of neighbors in 5-cm radius, and change in distance to the nearest bug neighbor (0–43 cm) before and 2 min after the volatile(s) was introduced into the arena. All data were evaluated for normality and homoscedasticity. Count data were square root transformed to normalize. Data were analyzed with one way ANOVA by comparing control response to treatment response with JMP-In 5.0 (SAS Institute 2002). Bonferroni alpha level corrections were made to reduce type I errors.

Insect Predator Behavioral Assays California mantids, (*Stagmomantis californica*: Mantidae), were hand reared from oothecae collected on the University of Arizona campus. They were tested during their 4th instar and averaged 40 mm in length. A mantid was fed a maintenance diet of two crickets per day. In addition, for the first experiment, each mantid was fed a cricket the 1st day and a giant mesquite bug nymph the next (N=5). Cricket and nymph were paired based on weight. We recorded whether the mantid oriented, attacked, and ate each prey type. For the second experiment, crickets were treated with 2 μl of either distilled water (control treatment), or nymph secretion, adult secretion, 4-oxo-(*E*)-2-hexenal, (*E*)-2-hexenal, hexyl acetate, hexanol, or hexanal. These crickets were fed to another set of 4th instar mantids. We recorded whether the mantid oriented, attacked, and ate each prey type. Each mantid experienced one water treatment and one other treatment (N=5 per treatment, N=35 across all treatments). All data were evaluated for normality and homoscedasticity. Data were analyzed with a log-linear model by using JMP-In 5.0 (SAS Institute, 2002).

Results

Mesquite Bug Chemical Profiles Giant mesquite bug nymphs emitted (*E*)-2-hexenal and 4-oxo-(*E*)-2-hexenal, while adults emitted hexyl acetate, hexanal, and hexanol when disturbed. The two life stages had no compounds in common. The same pattern of compounds was also observed in the whole body extraction. Female and male adults differed slightly in the relative amounts of each compound, but these differences were not significant.

The mass and NMR spectra of purified 4-oxo-(*E*)-2-hexenal are summarized as follows: MS *m*/*z* (%): 112 (M+, 15), 84 (14), 83 (100), 57 (13), 55 (49); ^{1}H NMR ($CDCl_3$): δ 9.77 (1H, d, J=7.2 Hz), 6.86 (1H, d, J=16.3 Hz), 6.77 (1H, dd, J=16.3, 7.2 Hz), 2.72 (2H, q, J=7.2 Hz), 1.15 (3H, t, J=7.2 Hz); and ^{13}C NMR ($CDCl_3$): δ 200.31, 193.34, 144.69, 137.29, 34.52, 7.54. The total amount of 4-oxo-(*E*)-2-hexenal was 2.4 mg from eight nymphs for NMR analysis. The NMR spectra of the purified compounds were consistent with published spectra (Moreira and Millar 2005).

Mesquite Bug Behavioral Responses There was no effect of arena on mesquite bug behavior ($F_{1,5}$=1.22, P=0.23). Therefore, data were pooled across arena groups within a life stage. As compared to distilled water, nymph giant mesquite bugs disperse more in the presence of their own defensive compounds. Response by nymphs to adult secretion or any of the individual adult compounds did not differ from their response to water (Fig. 2; P>0.05). The presence of nymph secretion caused nymphs to travel farther away from the chemical source ($F_{1,14}$=5.33, P=0.012), to have fewer nymphs in a 5 cm radius ($F_{1,14}$=6.52, P<0.01), and to be farther away from the nearest giant mesquite bug ($F_{1,14}$=9.74, P<0.01). (*E*)-2-hexenal and 4-oxo-(*E*)-2-hexenal alone elicited bugs to travel away from the source ($F_{1,14}$=3.73, P=0.012 and $F_{1,14}$=12.34, P<0.01, respectively), but a mixture of these two compounds was

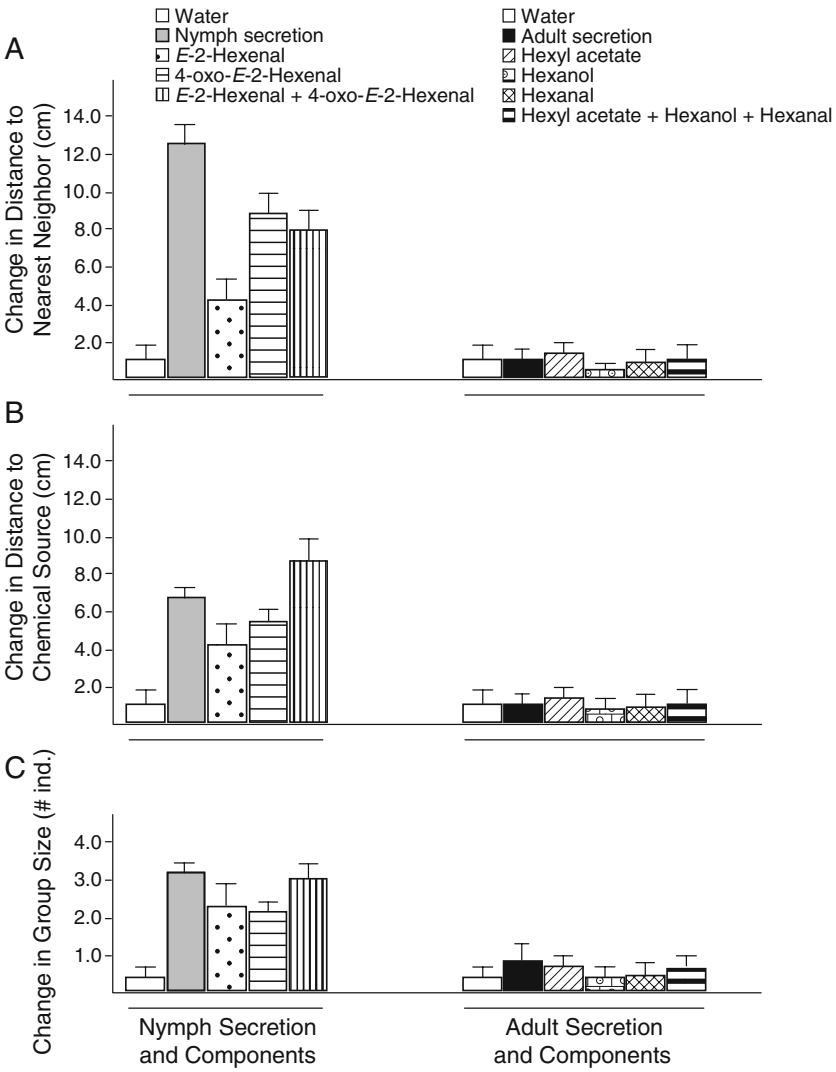

Fig. 2 Nymph behavioral responses to water (the control treatment), nymph secretion, adult secretion, and various authentic compounds from each secretion. We measured several variables: **a** change in distance to nearest neighbor, **b** change in distance to chemical source, and **c** change in aggregation group size after the treatment compound had been in the arena for 2 min. Means+SE shown (N=15 bugs per treatment)

almost as effective as the actual nymph secretion ($F_{1,14}$= 8.63, P<0.01). The same pattern was found also in both change in distance to nearest neighbor ($F_{1,14}$=7.90, P< 0.01) and change in group size ($F_{1,14}$=8.84, P<0.01).

Compared to distilled water, adult giant mesquite bugs also dispersed more in the presence of their own defensive compounds (Fig. 3). The presence of the adult secretion resulted in fewer adults nymphs in a 5 cm radius ($F_{1,14}$= 5.60, P=0.01) and farther away from the nearest adult bug ($F_{1,14}$=4.22, P=0.03). Adults also tended on average to travel farther away from the adult secretion source, but the difference was not significant after the Bonferroni correction ($F_{1,14}$=2.03, P>0.05). Hexyl acetate and hexanal alone elicited dispersal behavioral responses (P<0.02 for all comparisons), but hexanol did not (P>0.05 for all comparisons). A mixture of all three compounds was almost as effective as the actual adult secretion in changing the distance to source ($F_{1,14}$=3.04, P=0.05) and a change in group size ($F_{1,14}$=6.29, P=0.01). None of the behavioral responses by adults to nymph secretion or to any of the individual nymph compounds differed from the response to distilled water, the control treatment (P>0.05 for all comparisons).

Insect Predator Responses Compared to crickets, nymph mesquite bugs were not as palatable to mantids (Fig. 4). Untreated crickets were always oriented on, attacked, and eaten by mantids, while giant mesquite bug nymphs were oriented and attacked by mantids, but often released before consumption ($F_{1,9}$=8.46, P=0.004). Crickets treated with nymph secretions were more unpalatable to mantid predators than crickets treated with adult secretions ($F_{1,9}$=12.47, P=0.003). This effect was best explained by the presence of 4-oxo-(*E*)-2-hexenal ($F_{1,9}$=13.86, P=0.002). This compound caused four of the five mantids to die after attacking those crickets even though the crickets were not consumed.

Crickets painted with adult bug secretion and all other compounds not listed above were always consumed by the mantids (P>0.05 for all comparisons; Fig. 4).

Discussion

Our chemical analyses revealed that giant mesquite bugs (*T. neocalifornicus*) nymphs and adults emit different compounds when disturbed. Nymphs emit (*E*)-2-hexenal and 4-oxo-(*E*)-2-hexenal, while adults emit hexyl acetate, hexanal, and hexanol. These results were confirmed with whole-body extracts of both nymphs and adults. All compounds are found in other heteropteran and even coreid species, and are produced in the metathoracic gland from fatty acids acquired from the host plant (Blum 1981; Aldrich 1988; Leal et al. 1994; Millar 2005). Chemical differences between life stages have been shown in other coreid species (Prestwich 1976; Aldrich 1988; Leal et al. 1994), but this is the first time it has been documented in the genus *Thasus*.

Our predator behavioral experiments demonstrated that nymphs were chemically protected from insect predators while adults were not (Fig. 4). California mantids failed to consume nymphs and crickets treated with nymph secretion, but did consume crickets treated with adult secretion. We attempted to test the mantids' responses to adult giant mesquite bugs, but mantids failed to orient or attack adults. Mantids did not seem to perceive adult mesquite bugs as potential prey, perhaps because of their size. However, further behavioral experiments are needed to test this interpretation. Of all compounds, 4-oxo-(*E*)-2-hexenal was particularly deterrent and toxic to mantids. Mantids often died after exposure to nymph secretion and to 4-oxo-(*E*)-2-hexenal even without consuming prey. Tarantulas (*Eurypelma* sp.) have also been shown to die after exposure to the vapors of the giant mesquite bug nymph secretion (De La Torre-Bueno and Ambrose 1936). 4-Oxo-(*E*)-2-hexenal is known for its mutagenic and cytotoxic qualities by reacting with deoxyguanosine (Kasai et al. 2005); however, this is, we believe, the first time it has been evaluated as a source of chemical defense against predators. Relative to 4-oxo-(*E*)-2-hexenal, the other

compounds did not deter mantid prey consumption. The lack of response by adult mesquite bugs to nymph alarm pheromones fits with the cryptic defensive strategy of adults. Differences in both chemical composition and behavior between life stages of giant mesquite bugs and the predator responses to these bugs and their compounds support the idea that the nymph compounds are particularly effective at deterring arthropod predators (Eisner 1970). Further research will explore the adaptive significance of this pattern and how concentration differences may affect predator response. The compounds may no longer be relevant defensive compounds in an adult giant mesquite bug because the predator species have changed.

Our mesquite bug behavioral experiments indicated that the secretions can be also used as an alarm signal to other conspecifics in the same life stage (Figs. 2 and 3). Nymphs dispersed from their aggregation when nymph secretions, (*E*)-2-hexenal or 4-oxo-(*E*)-2-hexenal, were placed in the arena. However, nymphs failed to disperse when they were exposed to adult secretion or any of the individual compounds found in the adult secretion. Adults followed a similar pattern of dispersing after experiencing adult secretion, hexyl acetate, or hexanal. Hexanol did not elicit a behavioral response by either nymphs or adults. Future research, however, should address the question whether behavioral responses change when concentrations of secretion compounds change. These compounds are known alarm pheromones in other heteropteran species (Aldrich 1988; Millar 2005). It is not unusual that the two life stages respond differently to the signals (Aldrich 1988), although there are examples of nymphs and adults responding to each other's alarm pheromones (e.g., *Leptoglossus zonatus*, Leal et al. 1994).

The described alarm pheromones also may be particularly important in the evolution of warning coloration and gregariousness in nymphs of the giant mesquite bug. Warning coloration is thought to facilitate evolution of gregariousness (Sillen-Tullberg 1988, 1993; Tullberg and Hunter 1995). Yet, there is still a high individual cost of being attacked after a group is discovered by a predator, especially when the group is small (Gamberale and Tullberg 1998). One way to mitigate this cost is for the individuals under attack to disperse after a predator encounter and reform another group at a different location. Future research should focus on the question if the alarm pheromone compounds found in the nymphs of giant mesquite bugs function in this way.

The giant mesquite bug is a predominant insect in the southeastern Arizona, yet little is currently known about its ecology and evolution. Here, we have described some aspects of its chemical ecology and behavioral responses. We have shown that a single compound, 4-oxo-(*E*)-2-hexenal, functions both as a deterrent to predators and an alarm pheromone to conspecifics. Because of these multiple functions it may be a particularly interesting compound to study other members of the genus *Thasus*. We have also shown that the alarm pheromones in giant mesquite bugs are composed of multiple components and are different between nymphs and adults. The threat of predation is not communicated from one life stage to another. The adaptive reason explaining the need for multiple components in an alarm signal remains unexplored in this group.

Acknowledgments We thank Gabriela and Larry Venable for insect-collecting assistance, Carl Olson for insect-identification assistance, Neil Jacobsen for acquiring the NMR spectra, and Alex Wild for mesquite bug photos. An Unexpected Mixture of Substances in the Defensive Secretions of the Tubuliferan Thrips, *Callococcithrips fuscipennis* (Moulton)

Gunther Tschuch · Peter Lindemann · Gerald Moritz

Received: 7 December 2007 / Revised: 3 April 2008 / Accepted: 8 April 2008 / Published online: 28 May 2008

Abstract Adults and larvae of the thrips *Callococcithrips fuscipennis* (Moulton) (Thysanoptera: Tubulifera: Phlaeothripidae) live in the sticky wax masses of adult females of the felt scale insect *Callococcus acaciae* (Maskell) (Sternorrhyncha: Coccoidea: Eriococcidae). The scale is sessile and feeds on *Kunzea* shrubs (Myrtales: Myrtaceae). If stressed, the thrips produce droplets of secretions. The mixture contains pentadecane, tridecane, two monoterpenoids, hexadecyl butanoate, and smaller amounts of 15 other esters of long-chain unbranched alcohols identified as acetates, butanoates, hexanoates, and octanoates. The monoterpenoids are dolichodial, an iridoid, and an unknown substance with a mass spectrum very similar to that of anisomorphal and peruphasmal, diastereomers of dolichodial, but with a different retention time. Iridoids, butanoates, hexanoates, and octanoates have not been previously identified in Thysanoptera.

Keywords *Callococcus acaciae* · Dolichodial · Hexadecyl butanoate · Thysanoptera · Phlaeothripidae · Eriococcidae · Coccoidea · Alkanes · Iridoids · Acetates · Butanoates · Hexanoates · Octanoates

Introduction

During the last three decades, there have been more than 30 papers dealing with secretions of thrips, especially of the family Phlaeothripidae (Moritz 2006). Several thrips species, when they are disturbed, raise and lower their abdomen with a drop of fluid on the abdominal tip (Lewis 1973). The secretory reservoir seems to be the hindgut, but the gland cells have not yet been found (Howard et al. 1983, 1987). Some of the complete secretions, as well as single components, have been found to be ant repellents (Howard et al. 1983; Blum 1991; Blum et al. 1992; Tschuch et al. 2005).

The present paper deals with *Callococcithrips fuscipennis* (Thysanoptera: Phlaeothripinae), originally described as *Rhynchothrips* by Moulton (1968, pp. 97–98). The species subsequentially was associated with the genus *Teuchothrips* (Mound and Houston 1987), but this assignment was controversial[1] and changed recently to *Callococcithrips* (Mound and Wells 2007). *C. fuscipennis* are frequently found near Canberra (Australia) inside the wax masses of the adult female felt scale insects *Callococcus acaciae* (Maskell) (Coccoidea: Eriococcidae)[2], which are sessile on *Kunzea ericoides* (Myrtaceae) shrubs. Because of limited knowledge of *C. fuscipennis* biology, it remains unclear whether they are predators of *C. acaciae*, or feed on other items such as plant, scale secretions, scale feces, or other insects living in the wax. Predation by phlaeothripid thrips on scale insects is not unlikely, especially on larvae and eggs, and is well known on some species of armored (Diaspididae, Palmer and Mound 1990) and soft scales (Coccidae, Pfeiffer 1997).

[1] Moulton (1968) described another *Teuchothrips fuscipennis* in the same 1968 paper on pp. 100–101. This species was found to be a synonym for *Heligmothrips erinaceus* (Karny) (Mound 1970).

[2] Originally, the species was described by Maskell (1893) as *Sphaerococcus acaciae* and was subsequently combined with the genus *Callococcus* by Morrison and Morrison (1927). *Callococcus* was first placed into the family Asterolecaniidae, but is now a genus of the family Eriococcidae (Miller et al. 1998).

C. acaciae was originally named according to the host-plant "*Acacia* spec." by Maskell (1893), but this is likely to be a mistake. The host plants are species of the genera *Kunzea* (Myrtaceae) (personal communication, Penelope J. Gullan, University of California, Davis). Banks et al. (1976) collected *C. acaciae* from *Kunzea* and from *Leptospermum* (Myrtaceae). The wax masses of *C. acaciae* are unique, measuring around 10 mm in diameter and containing a sticky tangle of filaments. The stickiness of the wax is caused by a special surface coating and is the topic of a recent investigation (Tschuch et al. 2006)[3]. There are strong indications that *C. acaciae*, together with *C. pulchellus* (Maskell), arose from a gall-inducing Myrtaceae-feeding ancestor and re-evolved its protective cover (Cook and Gullan 2004). Other closely related species are still gall-formers on myrtaceans. In contrast to the wax of other scale insects, ants avoid contact with *C. acaciae* wax (Mound and Wells 2007). Therefore, it is likely that *C. fuscipennis* may have little need for a defensive secretion against predators, even though one seems to be produced. This suggests that these secretions may have additional biological functions. The objective of this study was to determine the composition of *C. fuscipennis* secretion.

Methods and Materials

Sample Collection Small branches and twigs of *K. ericoides* with wax masses of *C. acaciae* were collected in Canberra (Australia) early in March 2006. The samples were stored and transported at room temperature. After 2 weeks, the wax masses were dissected with caution to get undisturbed adult *C. fuscipennis* with a high amount of secretion. The adult thrips were placed on a glass slide and stimulated mechanically to produce droplets, which were collected with a fine glass capillary tube (Minicaps 5 µl, Hirschmann Laborgeräte). The tube was then rinsed with distilled methanol (Aldrich, 49,429-1). For chemical analysis, droplets were collected from ten thrips and investigated within 2 h.

Chemical Analysis Through coupled gas chromatography/mass spectrometry analyses, samples were dissolved in a small amount (50–100 µl) of methanol, and 5 µl was injected into an HP 5890GC linked to a 5972MSD (Hewlett-Packard) that was operated in electron impact mode at 70 eV. Separations were carried out with an HP5-MS column (30 m×0.25 mm ID; stationary phase: 0.25 µm). The carrier gas was helium (1 ml/min), the injector temperature was set to 300°C, and the detector temperature to 280°C. Column temperature was maintained at 100°C following the injection, and then linearly increased to 300°C at a rate of 7°C/min. The NIST database, literature data, and the software AMDIS (NIST, version 2.63) and NIST MS Search were used to analyze mass spectra and to compare retention times. For comparison with authentic compounds, the following substances and mixtures were used: tridecane (Aldrich, T57401), pentadecane (Aldrich, P3406), hexadecyl acetate (Sigma, P0260), octadecyl acetate (Sigma, S5003), purified secretions from stick insects *Anisomorpha buprestoides* (Stoll) (Pseudophasmidae; Dossey et al. 2006; Zhang et al. 2007; obtained from Aaron T. Dossey, Gainsville, FL, USA, one sample with only anisomorphal and another containing anisomorphal, peruphasmal, and trace dolichodial, dissolved in $CDCl_3$ and verified by NMR), and crude methanol extracts (1 h at 25°C) from chopped leaves of "cat thyme" germander *Teucrium marum* (Lamiaceae) (plant obtained from M. Hoffmann, Halle, and bought from a local florist), containing mainly dolichodial and teucrein.

In addition, hexadecyl and octadecyl butanoate, synthesized from authentic alcohols (Aldrich W25,540-8 and 258768) were used as standards. For comparison of the retention indices of iridoids, tetradecane (Fluka, 87140) was used as a standard.

Results

Most of the components of the defensive secretions were saturated alkanes (Fig. 1, *1* and *4*), monoterpenoids (*2* and *3*), and esters of saturated long-chain alcohols and short-chain acids (*5* to *20*; the chromatogram shows tailing, but the small number of animals available and small sample amount made it impossible to purify the sample, to use another solvent, or to repeat the investigation). The two monoterpenoids showed mass spectra characteristic of iridoids with base peaks at *m*/*z* 81 and further diagnostic ions at *m*/*z* 67, 95, and 109. The main component (*4*) was identified as pentadecane, and the first eluting component (*1*) as tridecane by comparison with authentic compounds.

Substance *2* produced a mass spectrum very similar to that of dolichodial (2-formyl-3-methyl-α-methylidenecyclopentaneacetaldehyde) in the NIST 98 database. Retention time and mass spectral comparisons with authentic dolichodial from *T. marum* and in a secretion from *A. buprestoides* confirmed the identification. It was not possible to determine the enantiomeric composition of dolichodial.

The mass spectrum of *3* was very similar to that of anisomorphal from *A. buprestoides* (the C2-epimer of

[3] In that paper the coccid species was incorrectly named as *Callococcus banksiae* instead of *C. acaciae*.

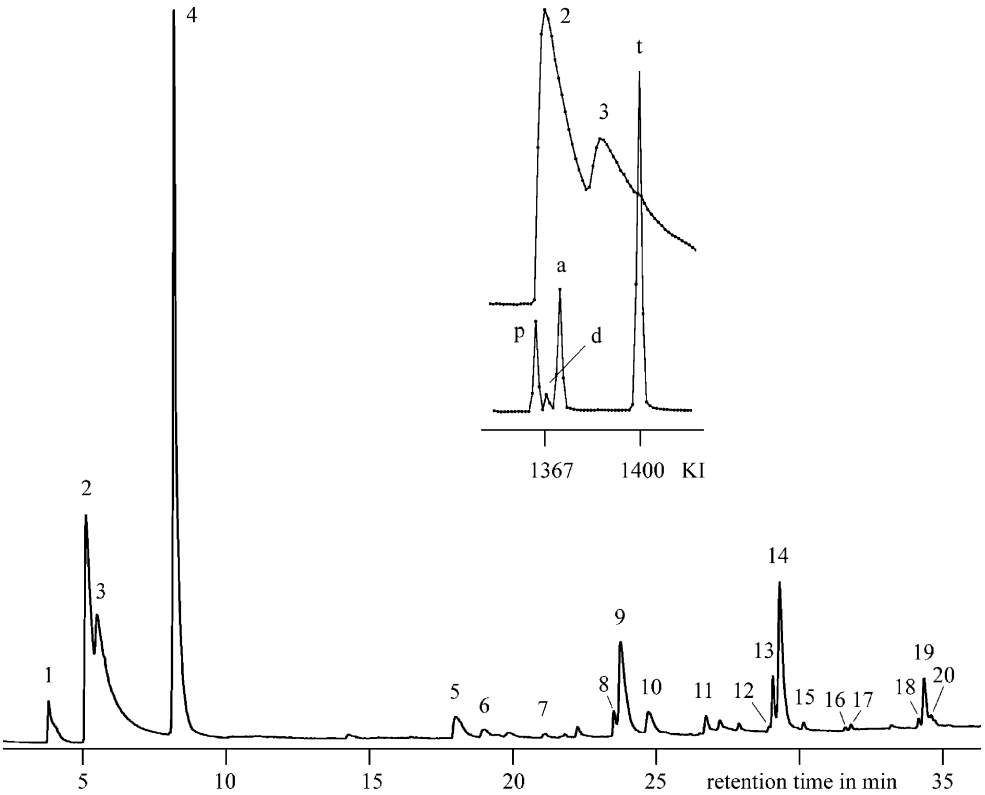

Fig. 1 Total ion gas chromatogram of the secretions of ten adult *Callococcithrips. fuscipennis* (*1* tridecane, *2* dolichodial, *3* unknown, *4* pentadecane, *5* to *20* esters, see Table 1; *X*-axis—retention time). *Insertion* Detail of the chromatogram (*upper graph*) in comparison to the chromatogram of a mixture (*lower graph*) containing peruphasmal (*p*), dolichodial (*d*), anisomorphal (*a*), and tetradecane (*t*); *X*-axis—Kovat's index

dolichodial) and peruphasmal from *P. schultei* (another diastereomer of dolichodial; see Dossey et al. 2006 and supporting information therein). As compared to dolichodial, the mass spectra of all three substances show the same small differences, including the lack of the molecular ion (M^+ 166) but the presence of $(M\text{-}1)^+$ (165, 3%), and differences in the relative intensities of the signals at *m/z* 133 and 137 compared with *m/z* 138 (Fig. 2). The retention index of *3* was distinctly different from those of the known stereoisomers of dolichodial (Fig. 1, insertion). Compared with dolichodial (KI=1367), the Kovat's index (KI) on a DB-5 column was lower for peruphasmal (KI=1,361: Δ KI=−6), higher for anisomorphal (KI=1,373: Δ KI=+6), and highest for 3 (KI=1,386: Δ KI=+19).

The mass spectra of many of the substances that eluted after pentadecane (Fig. 1, *5* to *20*) are not included in common databases. They show a relatively high abundance of diagnostic fragments with *m/z* values of 61, 89, 117, and 145, characteristic of esters of long-chain aliphatic alcohols with short fatty acids. A McLafferty-type rearrangement of

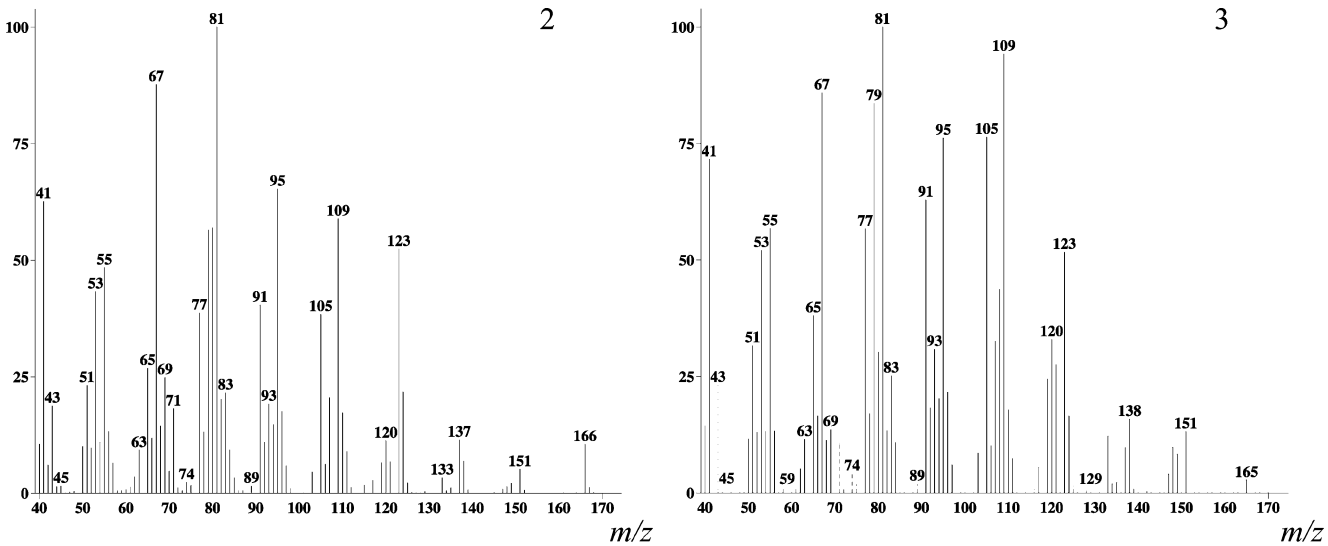

Fig. 2 Mass spectra of substances *2* and *3*. Spectrum of *2* is identical to the mass spectrum of dolichodial, while spectrum *3* is more similar to those of anisomorphal (*a*) and peruphasmal (*p*; see Fig. 1)

such esters, taking place at the alcohol side produces the respective acid and an alkene corresponding to the alcohol (Francke et al. 2000). Whereas the acid gives rise to a signal representing the protonated form (Table 1, $(A+1)^+$), the alkene fragment and a corresponding signal, produced by loss of the ethylene from the alkene are clearly visible ($(M-A)^+$ and $(M-A-C_2H_4)^+$). Another diagnostic fragment of esters of long-chain alcohols with short fatty acids is produced upon α-cleavage at the acid side, i.e., loss of the alkyl chain of the acid $(M-(A-COOH))^+$.

Apart from the most abundant ester, hexadecyl butanoate (Fig. 1, 14), almost all possible combinations of C12 … C16 and C18 alcohols with acetic, butyric, hexanoic, and octanoic acids in the mass range from 256 to 340 were found (*M* in Table 1). The esters with odd-numbered alcohols had low abundances. From that group, only traces of tridecyl butanoate (7), pentadecyl butanoate (11), and pentadecyl hexanoate (17) could be identified clearly.

The acetates, butanoates, and the hexanoates had no branch points in either the acid or alcohol parts. Besides the fragments mentioned above, the only signals between *A* and *M* were from the consistent low-mass ion series 69, 83, 97, …, indicating that there were no branch points in the alcohol portion. Branches in the acid portion of hexanoate isomers would cause cleavages before and behind the branch point, generating noticeable peaks of >1% abundance if the loss is greater than a methyl group (McLafferty and Tureček 1993). For instance, 3-methylpentanoates have diagnostic peaks at *M*-28 (loss of an ethyl group) and at *M*-57 (loss of a butyl group). In all possible branched isomers of hexanoates, there would be at least one loss causing a fragment ion other than the diagnostic ion mentioned above. However, with these considerations it is not possible to distinguish between the unbranched butanoates and the branched 2-methylpropanoates, because the abundance for the loss of a methyl group is too low, and the loss of a propyl group is observable as well in the unbranched butanoates. Here, the characteristic ions at *m/z* 60 and 61 are helpful. They appear in all butanoates and longer acid esters (other than methyl esters) if the acid's α-carbon is not substituted (McLafferty and Tureček 1993), as a result of a consecutive rearrangement of two hydrogen atoms. Peaks at *m/z* 60 and 61 with abundances of 5–12% both occur in all butanoates listed in Table 1 (*5*, *7*, *9*, *11*, *14*, and *20*). Thus, the butanoates also are not branched. Two acetates (*10* and *15*) and two butanoates (*14* and *20*) were compared with authentic substances and yielded matching retention times and mass spectra. Unfortunately, the abundances of the octanoates (*12*, *16*, and *18*) are too low to exclude all possible branch points for these substances.

Because wax particles were sometimes found to be stuck on the thrips cuticle, these could have contaminated the collected secretions. However, neither compounds known from the *C. acaciae* wax (Tschuch et al. 2006) nor any from the scale host-plant *K. ericoides* (Christoph 2001) were detected in the thrips extracts.

Table 1 Esters found in the defensive secretion of *Callococcithrips fuscipennis* and (in brackets) relative abundances of their diagnostic fragment ions $(A+1)^+$, $(M-A-C_2H_4)^+$, $(M-A)^+$, and $(M-(A-COOH))^+$

The ester with the highest abundance is hexadecyl butanoate (italics). The substances marked by an asterisk were confirmed by comparison with authentic substances. The identifications of the three octanoates (in brackets) are likely, but, because of the low abundances, it is not possible to exclude the existence of branch points completely (see text).

Discussion

Iridoid monoterpenes have never been reported before from Thysanoptera. However, dolichodial and its stereoisomers are well known from some species of ants (Dolichoderinae: Cavill and Hinterberger 1960; Cavill et al. 1976), from two species of stick insects (Pseudophasmatidae: Meinwald et al. 1962; Dossey et al. 2006), from larvae of several saw flies (Tenthredinidae: Boeve et al. 1984, 1992), from rove beetles (Staphylinidae: Huth and Dettner 1990), and from the plant *T. marum* (Pagnoni et al. 1976). Compound 3 very likely is a third stereoisomer of dolichodial, but not anisomorphal and peruphasmal. This is supported by the fact that the mass spectra of other known dolichodial isomers, like chrysomelidial and plagiodial, show big mass spectral and/or retention time differences between each other, and the spectra are different from the well-known stereoisomers mentioned above, as well as from substance 3 (Meinwald et al. 1977; Meinwald and Jones 1978; Sugawara et al. 1979).

In previously reported bioassays, dolichodial repelled insects, such as ants, flies, cockroaches (Eisner et al. 2000), and termites (Cornelius et al. 1995). Observations on *A. buprestoides* showed that iridoids also may repel vertebrates such as birds (Eisner 1965). In *T. marum*, dolichodial also was suggested to be an insect repellent because no insects are known to feed on the plant (Eisner et al. 2000). Other iridoid dialdehydes such as chrysomelidial and plagiodial, found in the secretions of larvae of leaf beetles (Chrysomelidae), also act as defensive substances (Meinwald et al. 1977; Sugawara et al. 1979; Pasteels et al. 1982). Thus, the two iridoid dialdehydes found in *C. fuscipennis*, dolichodial and the unknown compound 3, may have a defensive function.

The function of the esters in *C. fuscipennis* secretion is uncertain. Hexadecyl butanoate has been found in arthropods only in Dufour's gland secretions or cephalic extracts of a bumblebee (Tengö et al. 1991) and some other bee species from the families Melittidae (Tengö and Bergström 1976) and Apidae (Batra and Hefetz 1979; Francke et al. 2000). In *C. fuscipennis* secretion, hexadecyl butanoate possibly acts in a manner analogous to that of the acetates found in many other thrips species (Suzuki et al. 2004). For example, in *Gynaikothrips ficorum*, the secretions contain mainly hexadecyl acetate dissolved in pentadecane (Howard et al. 1987). Both substances are repellents against ants, and they work better as a mixture. Acetates may help to spread secretions and to wet sensory organs of predators with long-lasting coatings (see discussion in Tschuch et al. 2005). The use of butanoates instead of acetates may be advantageous because of the lower polarity, thus causing a better interaction with the cuticular lipids of the aggressor. This is a topic of further investigations.

The iridoids in the secretion of *C. fuscipennis* could serve a defensive function once the thrips are outside of the wax masses of scale insects, or against insects entering or living inside the wax masses as predators or parasitoids. Additionally, the larval defensive secretion in *Frankliniella occidentalis* (Thripidae), the most studied of all the thrips secretions (Teerling et al. 1993; MacDonald et al. 2002), has several other functions besides defense. Hence, the secretion in *C. fuscipennis* could also have other functions, which might at least partly explain why the species produces such a secretion despite an apparent lack of need for one due to its protective wax mass habitat. The protective nature of these insects' habitat, along with the chemical complexity of the secretions, suggests that these secretions may indeed have functions besides defense.

Acknowledgments We gratefully acknowledge Aaron T. Dossey, McKnight Brain Institute of the University of Florida (Gainsville, FL, USA) for the gift of NMR-confirmed samples containing dolichodial, anisomorphal, and peruphasmal; Matthias H. Hoffmann, Botanical Gardens of Martin-Luther-University, Halle for the gift of *T. marum*; and Willi Rettig, Institute of Pharmacy of the Martin-Luther-University Halle-Wittenberg for the syntheses of the butanoates used as standards. Oxidation of Ingested Phenolics in the Tree-Feeding Caterpillar *Orgyia leucostigma* Depends on Foliar Chemical Composition

Raymond Barbehenn · Quentin Weir · Juha-Pekka Salminen

Received: 4 December 2007 / Revised: 4 April 2008 / Accepted: 8 April 2008 / Published online: 13 May 2008

Abstract Tannins are believed to function as antiherbivore defenses, in part, by acting as prooxidants. However, at the high pH found in the midguts of caterpillars, the oxidative activities of different types of tannins vary tremendously: ellagitannins >> galloyl glucoses > condensed tannins. Ingested ascorbate is utilized by caterpillars to minimize phenolic oxidation in the midgut. Thus, leaves that contain higher levels of reactive tannins and lower levels of ascorbate were hypothesized to produce higher levels of phenolic oxidation in caterpillars. We tested this hypothesis with eight species of deciduous trees by measuring their foliar phenolic and ascorbate compositions and measuring the semiquinone radical (oxidized phenolic) levels formed in caterpillars that ingested each species. When the generalist caterpillars of *Orgyia leucostigma* (Lymantriidae) fed on the leaves of tree species in which condensed tannins were predominant (i.e., *Populus tremuloides*, *P. deltoides*, and *Ostrya virginiana*), semiquinone radical levels were low or entirely absent from the midgut contents. In contrast, species that contained higher levels of ellagitannins (or galloyl rhamnoses; i.e., *Quercus alba*, *Acer rubrum*, and *A. saccharum*) produced the highest levels of semiquinone radicals in *O. leucostigma*. Low molecular weight phenolics contributed relatively little to the overall oxidative activities of tree leaves compared with reactive tannins. Ascorbate levels were lowest in the species that also contained the highest levels of oxidatively active tannins, potentially exacerbating phenolic oxidation in the gut lumen. We conclude that the tannin compositions of tree leaves largely determine the effectiveness of foliar phenolics as oxidative defenses against caterpillars such as *O. leucostigma*.

Introduction

Phenolics are ubiquitous chemical defenses in leaves, playing protective roles against a wide variety of biotic agents and abiotic stresses. Tannins are the predominant phenolics produced in tree leaves, often reaching levels of 5–20% dry weight (DW) in temperate deciduous species. Whereas tannins were long believed to act as protein-binding agents that reduced the digestive efficiencies of insect herbivores, protein binding *in vivo* is now known to be precluded by high pH and/or surfactants generated from lipid digestion (Martin et al. 1987). Instead, as defenses against caterpillars, tannins can act as anti-feedants or have toxic or anti-nutritive effects. Because tannins are not absorbed, their post-ingestive effects are thought to result from their oxidation in the midgut lumen (Barbehenn 2001; Barbehenn et al. 2005). The oxidation of phenolics produces semiquinone radicals and other reactive oxygen species. If levels of these products overwhelm the antioxidant defenses in the midgut lumen or tissues, oxidative stress ensues. The oxidative damage to a wide variety of biological molecules (including nutrients, cell membrane

components, and DNA) that occurs from oxidative stress is believed to contribute to reduced fitness in insect herbivores (Summers and Felton 1994; Bi and Felton 1995; Bi et al. 1997).

Ascorbate is the main low molecular weight (MW) antioxidant found in the gut fluids and tissues of leaf-feeding insects (Felton and Duffey 1992; Barbehenn et al. 2001, 2003a). However, antioxidant defense systems that utilize ascorbate can be overwhelmed when insects feed on leaves that contain either large amounts or highly reactive types of tannins (Barbehenn et al. 2005). The most reactive types of tannins in the high pH conditions found in caterpillar midguts are ellagitannins, followed by galloyl glycosides (or "gallotannins") and, distantly, by condensed tannins (Barbehenn et al. 2006b; Moilanen and Salminen 2008). Whether this pattern of tannin structure and reactivity also occurs in the complex chemical mixtures found in the midgut fluids of leaf-feeding herbivores has been examined with only one pair of tree species. *Acer saccharum* (containing relatively high levels of ellagitannins) produced high levels of semiquinone radicals in the midgut contents of caterpillars, while *Quercus rubra* (primarily containing condensed tannins) produced low levels of semiquinone radicals in caterpillars (Barbehenn et al. 2005, 2006a). In this study, the association between foliar chemical composition and phenolic oxidation was examined in a diverse group of tree species when eaten by the generalist caterpillar *Orgyia leucostigma* (Lymantriidae). The caterpillars of *O. leucostigma* are highly polyphagous and include the wide variety of tree species in this study in their diet (Baker 1972; Wagner 2005). Phenolics and ascorbate were quantified in the leaves of eight North American deciduous trees: *Populus tremuloides* (quaking aspen), *P. deltoides* (cottonwood), *Ostrya virginiana* (ironwood), *Carya glabra* (bitternut hickory), *Q. rubra* (red oak), *Q. alba* (white oak), *A. rubrum* (red maple), and *A. saccharum* (sugar maple). Phenolic oxidation in the midgut fluids of *O. leucostigma* was compared between tree species by measuring levels of semiquinone radicals with electron paramagnetic resonance (EPR) spectrometry. EPR spectrometry permits the sensitive and specific detection of free radicals in the complex chemical environment of biological samples (Rosen et al. 1999; Barbehenn et al. 2005). This study tested the hypothesis that the proportion of oxidatively active tannins to ascorbate in tree leaves is positively associated with levels of phenolic oxidation in caterpillars.

Methods and Materials

Tree Leaf Chemistry Six trees of each species were tagged at ten sites, primarily in parks and woodlands in Ann Arbor, MI, USA. Trees of each species were sampled from at least three different sites. A mixture of wild and planted trees of *Q. rubra* and the *Acer* species were used. All other trees were growing wild. Trunk diameters at breast height were measured to estimate the following tree sizes (mean [centimeters] ± SE): *P. tremuloides*, 14.5±2.0; *P. deltoides*, 39.6±4.5; *O. virginiana*, 13.6±2.6; *C. glabra*, 59.5±24.0; *Q. rubra*, 32.6±4.6; *Q. alba*, 39.6±11.0; *A. rubrum*, 19.4±4.5; and *A. saccharum*, 27.7±7.7. Branch tips were cut from the sunny sides of trees at a height of 2–4 m and immediately placed in flasks of water. Leaves from the same collection used for feeding *O. leucostigma* were kept intact on twigs in containers of water overnight in an incubator to control for potential changes in foliar chemistry during the feeding period. Leaf midribs were removed with a razor blade, and the remaining leaf lamina were weighed. To measure ascorbic acid, leaves were ground in liquid nitrogen, extracted in 5% metaphosphoric acid (containing 1 mM ethylenediaminetetraacetic acid), and stored at −80°C until analyzed with high-performance liquid chromatography (HPLC; Barbehenn 2003). To measure phenolics, leaves were frozen (−80°C), lyophilized, and ground. Phenolic analyses were performed in Turku, Finland with HPLC coupled with a diode array detector and mass spectrometer, as described previously (Salminen et al. 1999; Barbehenn et al. 2006a). Hydrolyzable tannins were quantified in pentagalloyl glucose equivalents (280 nm), flavonoids in quercetin equivalents (349 nm), chlorogenic acids in chlorogenic acid equivalents (315 nm), coumaroylquinic acids in coumaric acid equivalents (315 nm), and the remaining phenolics (other than condensed tannins) as gallic acid equivalents (280 nm). In addition, total condensed tannins were estimated with the acid–butanol assay (Ossipova et al. 2001), with purified birch leaf condensed tannins as a standard. The chemical compositions of the leaves fed to larvae during a second experiment with multiple tree species were also analyzed as described above.

Free Radicals in Caterpillars Eggs of *O. leucostigma* were obtained from the Canadian Forest Pest Management Institute (Sault Ste. Marie, Ontario). Larvae were reared until the final instar in an incubator (23°C, 16:8 h, light/dark) on an artificial diet, as described previously (Barbehenn et al. 2005). Larvae were randomly assigned to feed on the leaves of one of two tree species examined at one of four dates: *Acer* species on July 4, 2006, *Quercus* species on July 7, *Populus* species on July 11, and *O. virginiana* and *C. glabra* on July 14. In the first experiments, a single tree from each species was used, providing seven to nine insect replicates on each foliar chemical profile. To demonstrate that results for each species tested were not limited by the use of a single tree per species, tree leaves from five of the tree species were fed to separate groups of *O. leucostigma*

on the same day (July 15), using trees from each species different from those used in the first set of experiments. Confirmatory EPR measurements were made on two to three larvae per tree species. *Q. rubra* and *A. saccharum* showed similar results in the first set of experiments as were found previously (Barbehenn et al. 2005; unpublished data), and these species were not reexamined. Leaves were surface sterilized in a dilute bleach solution (2.5 ml/l; 10 min) and rinsed in water (10 min). Twigs containing clusters of leaves were kept in tubes of water to maintain leaf turgor. Groups of final-instars were placed on the leaves of each species in separate ventilated plastic boxes (30×20×10 cm) and placed in an incubator (23°C, 16:8 h, light/dark). Leaves of each species were readily eaten, although a lower amount of feeding damage was observed on *Q. alba*. Fresh leaves were provided on two consecutive days, using the same tree from each species. A collection of leaves from each tree was made on its second day for chemical analysis, as described above. On the third day of feeding, larvae were individually chilled (−20°C, 6 min), and their midguts were dissected. Midgut fluids were extracted in 300 µl of low-oxygen pH 10 carbonate buffer (70 mM, containing 10% dimethyl sulfoxide; Barbehenn et al. 2005).

Semiquinone and ascorbyl radicals were quantified with EPR spectrometry, as described previously (Barbehenn et al. 2006b). Standard solutions of the stable free radical, 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO; Aldrich Chemical Co.) were run to confirm that the method was consistent through time and to provide a free radical standard for converting double integrals of spectra to a concentration basis (nanomolar). Radical concentrations are expressed as TEMPO radical equivalents. Radical concentrations in midgut fluid volumes were calculated by using a value of 90% water in the midgut contents (Barbehenn et al. 2003a). In some cases, EPR spectra were either too weak to integrate accurately (e.g., negative double integral values) or produced double integral values that were overestimated because the baseline regions surrounding the signal contributed (incorrectly) to the overall double integral values. In these cases, WinEPR software (Bruker Instruments, Billerica, MA, USA) was used to correct each spectrum as follows. The first derivative spectrum was baseline corrected by using the baseline area on either side of the signal region. The corrected first derivative spectrum was then integrated. The resulting absorption spectrum was again baseline corrected by using the baseline areas on either side of the signal region. This produced a signal region flanked by flat baseline regions abutting a *Y*-axis value of zero. The corrected double integral value was then determined. For spectra that contained signals from both semiquinone and ascorbyl radicals, an additional calculation was made to separate the two component signals. The ascorbyl radical double integral value was determined from a regression of the peak heights of ascorbyl radical absorption spectra (downfield peaks) vs. the double integral values of these spectra. The semiquinone portion of the mixed spectrum was then calculated as the difference between the total radical and the ascorbyl radical double integral values.

To test the possibility that the unusual EPR spectra from caterpillars on *C. glabra* might have been caused by the reduction of quinones by ascorbate, EPR was used to examine juglone (Sigma Chemical Co.), a common quinone from species of Juglandaceae. Juglone (0.9 mM final concentration) was run alone and in mixtures with ascorbic acid (0.4–0.8 mM final concentration). The same parameters and experimental conditions for EPR were used as described above.

The relative contributions of low MW phenolics to the semiquinone levels measured in the midgut fluid *O. leucostigma* was estimated by using representative compounds from each of the groups of phenolic compounds measured: gallic acid, *p*-coumaric acid, chlorogenic acid, catechin, rutin, and its aglycone quercetin (Sigma Chemical Co.). In addition, salicortin, a "phenolic glycoside" purified from *P. tremuloides*, was examined (Lindroth et al. 1987). All compounds were solubilized in 70% ethanol, prepared from nitrogen-purged solvents, with the exception of rutin, which was solubilized in 90% methanol. Semiquinone concentrations formed from each phenolic were measured at three phenolic concentrations (ranging between 22–648 µg/ml; N=3 independent preparations/phenolic). The slopes of the regressions of semiquinone concentration on phenolic concentration normalize semiquinone radical concentrations for the effect of phenolic concentration (Barbehenn et al. 2006b). Two scans of each sample were run by using parameters and other experimental conditions identical to those described for examining gut fluid extracts.

Statistical Analysis Foliar tannins, low MW phenolics and ascorbic acid were compared among tree species with one-way analysis of variance (Wilkinson 2000). Post hoc comparisons among means were made with a Bonferroni adjustment of α for unplanned comparisons. EPR spectra from *O. leucostigma* were not significantly different among trees (experiments) within species in terms of semiquinone concentration (P>0.414; see Fig. 3a) or in line shape. Therefore, EPR data were pooled within tree species, providing results from two trees for most species and sample sizes of 9–12 replicate larvae per tree species. Larvae were fed leaves from only one tree from *C. glabra*, thus limiting generalization from these results because of pseudoreplication. No replication of *A. saccharum* and *Q. rubrum* trees was done after obtaining results that confirmed previous results from these species (Barbehenn et al. 2005; unpub-

lished data). Free radical levels in *O. leucostigma* (replicates) were compared among tree species with Mann–Whitney *U* tests, with a Bonferroni adjustment for unplanned comparisons (Wilkinson 2000). This experimental design was intended to examine the main hypothesis that caterpillar gut biochemistry varies among trees with specific foliar phenolic profiles. Associations between foliar chemistry in individual trees fed to *O. leucostigma* and semiquinone radical levels in the midgut fluids of each larva were examined with Pearson correlations (SAS 2003).

Results

Tannins comprised the bulk of the phenolic compounds in most of the tree species (Table 1, Fig. 1). *P. tremuloides*, *P. deltoides*, *O. virginiana*, and *Q. rubra* contained little or no ellagitannins or galloyl glycosides. By contrast, *Q. alba*, *A. saccharum*, and *C. glabra* contained substantial amounts of ellagitannins. *A. rubrum* and *A. saccharum* were the only species that contained galloyl glycosides; *A. rubrum* contained large amounts of digalloyl rhamnose and lower levels of tri-, tetra- and pentagalloyl rhamnose (unpublished data), whereas *A. saccharum* primarily contained small amounts of pentagalloyl glucose. Condensed tannins represented a major fraction (30–70%) of the phenolics in five of the species (*P. tremuloides*, *P. deltoides*, *O. virginiana*, *C. glabra*, and *Q. rubra*). By comparison, in three of the most oxidatively active species (*Q. alba*, *A. rubrum*, and *A. saccharum*), condensed tannin was a minor fraction (4–16%) of the phenolics (Fig. 1).

Low MW phenolics were present in similar, small amounts (0.5–2.6% DW) in most species (Table 2), comprising between 6% and 41% of the total phenolics (Fig. 1; excluding ascorbic acid). However, in *P. deltoides*, low MW phenolics were both at higher absolute levels (3.6% DW) and comprised a major fraction of the total phenolics (69%). Chlorogenic acid (and its derivatives) and flavonoid glycosides were the main types of low MW phenolics in each species (Table 2). While chlorogenic acid had relatively high oxidative activity, the oxidative activity of rutin (a representative flavonoid glycoside) was low (Table 3). The aglycone of rutin, quercetin, had substan-

tially higher activity than the glycoside, but aglycones were below detectable levels in the tree leaves. The oxidative activities of catechin, rutin, and *p*-coumaric acid appeared to be negligible. Although gallic acid was highly active, it was present only in small amounts in *A. rubrum*. Salicortin produced no EPR spectrum. Based on these representative examples and the low foliar concentrations of low MW phenolics, their contributions to the semiquinone radical levels observed in the midgut contents of caterpillars appeared to be small.

Ascorbate levels varied widely between tree species: *C. glabra* and *P. tremuloides* ≫ *P. deltoides* and *O. virginiana* > *Q. rubra* and *Q. alba* > *A. rubrum* and *A. saccharum* (Table 1). For comparison with results provided on a fresh weight basis, ascorbate levels ranged from 6.0 μmol/g in *A. rubrum* to 25.6 μmol/g in *C. glabra*.

In the midgut contents of *O. leucostigma* that fed on tree species containing low levels of oxidatively active phenolics (i.e., *P. tremuloides*, *P. deltoides*, and *O. virginiana*), semiquinone radicals were absent or at low levels (Fig. 2; Table 4). In larvae on *P. tremuloides* and *P. deltoides*, only ascorbyl radicals (benign) were present. In larvae on *Q. rubra* and *O. virginiana*, EPR spectra were consistent with the line shapes of condensed tannin radicals. By contrast, species with substantial levels of ellagitannins, or galloyl glycosides, and low levels of ascorbic acid (i.e., *Q. alba*, *A. saccharum*, and *A. rubrum*) produced high levels of semiquinone radicals (Figs. 1 and 2). These EPR spectra were

similar to those of hydrolyzable tannins (Barbehenn et al. 2006b). EPR spectra from larvae on *C. glabra* were unique, showing substantial levels of both ascorbyl and semiquinone radicals (Fig. 2, Table 4). Similar "hybrid" EPR spectra were produced in pH 10 reaction mixtures that contained juglone and ascorbic acid (data not shown).

To quantify the association between foliar chemistry and levels of semiquinone radicals in *O. leucostigma*, correlations between these measures were plotted. The resulting correlations provided some support for the hypothesis that the proportion of oxidatively active tannins to ascorbate is positively associated with semiquinone radical levels. The correlation between total phenolics/ascorbate and semiquinone radical levels was relatively weak, in part, because species that contained high proportions of condensed tannins produced little or no measurable semiquinone radicals ($r=0.61$, $P<0.001$; Fig. 3a). The correlation between oxidatively active tannins/ascorbate and semiquinone radical levels appears to improve the correlation because weakly active species are positioned near the origin ($r=0.68$, $P<0.001$; Fig. 3b). However, *Q. alba* remained an exception to the pattern presented by the other species. The correlation between the percentage of oxidatively active tannins and semiquinone radical levels fits *Q. alba* and most other species closely ($r=0.78$, $P<0.001$; Fig. 3c). It is noteworthy that negative correlations were observed between ascorbate and semiquinone radical levels ($r=-0.62$; $P<0.001$) and between condensed tannins and semiquinone radical levels ($r=-0.53$; $P<0.001$).

Discussion

A major goal of this study was to examine the association between foliar chemistry (phenolics and ascorbic acid) and phenolic oxidation in the midgut contents of caterpillars. The percentage of the total phenolics composed of oxidatively active tannins (ellagitannins and galloyl glycosides) was strongly correlated with oxidative stress in *O. leucostigma*. A broad range of oxidative activities in tree species could be distinguished based on the levels of semiquinone radicals they produced in *O. leucostigma*: (1) species that produced a large percentage of oxidatively active tannins (*Q. alba*, *A. rubrum*, and *A. saccharum*), (2) intermediate species (*C. glabra* and *Q. rubra*), and (3) species that produced a small percentage of oxidatively active tannins (*P. tremuloides*, *P. deltoides*, and *O. virginiana*). Although only one insect species was examined, *O. leucostigma* is relatively phenolic tolerant (Barbehenn et al. 2005), and higher levels of oxidative stress would be expected in many less tannin-tolerant species.

As expected, ascorbate levels were negatively associated with phenolic oxidation in *O. leucostigma*: Low ascorbate levels were generally present in oxidatively active species, and high ascorbate levels were commonly present in species with low oxidative activities. Together with the analyses of foliar phenolics, these results generally support the hypothesis that the proportion of oxidatively active phenolics to ascorbate is associated with phenolic oxidation in caterpillars. However, *Q. alba* was an exception to this pattern. *Q. alba* produced higher levels of semiquinone radicals than expected, given its ellagitannin and ascorbate levels. One potential reason for this exception is the presence of highly reactive types of ellagitannins in *Q. alba*, including vescalagin, castalagin, cocciferin D_2, and castavaloninic acid (Moilanen and Salminen 2008). These ellagitannins are based on an acyclic glucose, whereas the main ellagitannins of the other species in this study (i.e., *Q. rubra*, *A. saccharum*, and *C. glabra*) have glucopyranose backbones (Salminen, unpublished data). Secondly, *Q. alba* contained low levels of condensed tannins, both in absolute terms and relative to the levels of the oxidatively active phenolics present (Table 1; Fig. 1). Because condensed tannins can decrease the rate of oxidation of more reactive tannins (Barbehenn et al. 2006a), a low percentage of condensed tannins means that the more reactive tannins can

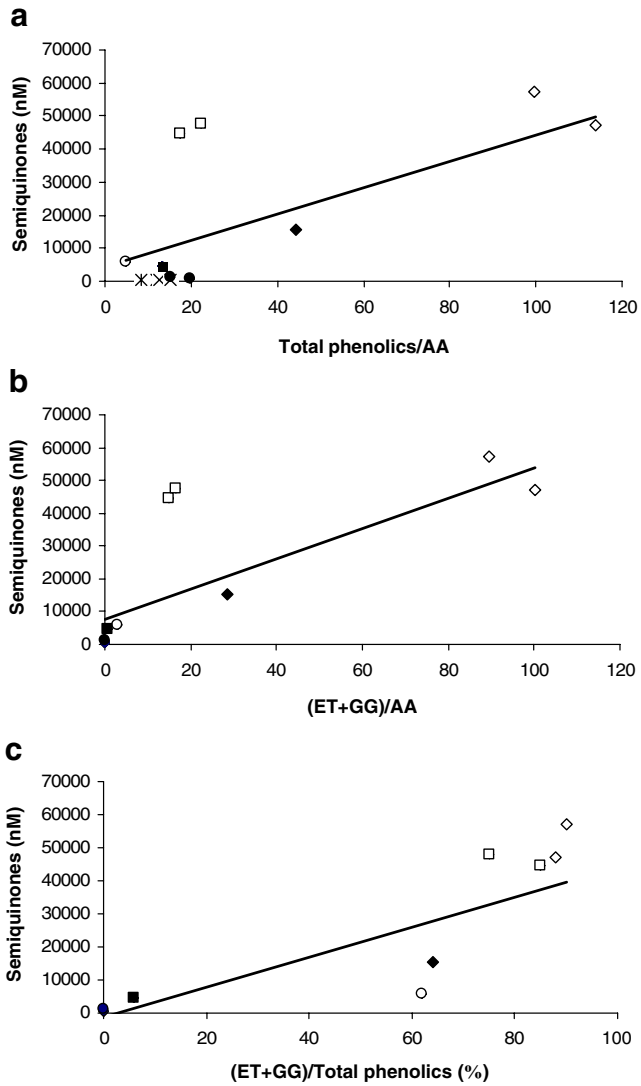

Fig. 3 Correlations between the foliar chemistry of ingested tree leaves and semiquinone radical levels in the midgut contents of final-instar *O. leucostigma*. Where not visible, data points are overlapping

oxidize near their maximum rates. This may explain the improved correlation between the percentage of oxidatively active phenolics and semiquinone radicals in *O. leucostigma* (Fig. 3c). The correlation in Fig. 3c is also a useful improvement over previous work, in which oxidative stress was associated with the proportion of total phenolics to ascorbic acid (Barbehenn et al. 2003b, 2005).

Tannins, especially ellagitannins and galloyl glycosides, were the primary sources of oxidative stress in the midgut contents of caterpillars in this study. This was due both to their intrinsic reactivity and to the high levels of tannins produced in oxidatively active leaves. Low MW phenolics were present in much lower levels than tannins in oxidatively active tree species, and many of these compounds have relatively low oxidative activities in the low-oxygen, high pH conditions of caterpillar midguts. Even in *P. deltoides*, which contained the highest levels of chlorogenic acid (1.5% DW), no measurable levels of semiquinone radicals were produced in the midguts of *O. leucostigma*. Although only one representative flavonoid and flavonoid glycoside was examined in this study, the low rates of browning of a wide range of these phenolics compared with ellagitannins support the generality of the EPR results on quercetin and rutin (Salminen, unpublished data). At sufficiently high levels, low MW phenolics could play other roles as chemical defenses in tree leaves. Unlike tannins, these phenolics can be absorbed from the midgut contents (Summers and Felton 1994; Barbehenn 2001). Therefore, low MW phenolics, and the quinones that they form, might produce oxidative stress and/or toxicity in insect tissues (Gant et al. 1988; Summers and Felton 1994; but see Johnson and Felton 2001). Other potential toxins in the trees in this study include alkaloids in species of Aceraceae, quinones in the Juglandaceae (e.g., *C. glabra*), and salicylates in the Salicaceae (Barbosa and Krischik 1987; Lindroth and Peterson 1988; Hemming and Lindroth 1995; Thiboldeaux et al. 1998).

Salicylates have often been called phenolic glycosides, and it has been suggested that products of their metabolism act as prooxidants in the midgut lumen (Clausen et al. 1989; Ruuhola et al. 2001). We were unable to detect the formation of measurable levels of semiquinone radicals in *O. leucostigma* that consumed the leaves of two salicylate-producing species, *P. tremuloides* and *P. deltoides*. In addition, salicortin produced no measurable semiquinone radicals and had a negligible rate of browning at pH 10 (Barbehenn, unpublished data). Previous work has noted the difficulty of detecting the oxidation of phenolics from *P. tremuloides* leaf tissues (Haruta et al. 2001), and work on the chemical fate of ingested salicylates from *Salix* species found little, if any, catechol (an oxidizable salicylate metabolite) in the frass of *Operophtera brumata* (Ruuhola et al. 2001). Together, these observations suggest that the chemical defenses of trees in the Salicaceae function most effectively as antifeedants and toxins in caterpillars.

We suspected that quinones in *C. glabra*, in combination with high levels of ascorbate, produced the unique EPR spectra observed in *O. leucostigma*. These spectra indicated the presence of both high levels of semiquinone and ascorbyl radicals (Table 4; Fig. 2). Mixtures of juglone and ascorbic acid produced EPR line shapes that were similar to those in *O. leucostigma* on *C. glabra*, suggesting that the chemical reduction of quinones by ascorbate could produce large concentrations of semiquinone and ascorbyl

radicals simultaneously. Only a single tree of *C. glabra* was examined, greatly limiting the extent to which results on this species can be interpreted. It is noteworthy, therefore, that similar "hybrid" EPR spectra were also observed when *O. leucostigma* larvae fed on another species of hickory (*C. ovata*) (Barbehenn, unpublished data). Foliar quinone levels were not measured in this study, and further work is needed to determine their potential impact on oxidative stress in caterpillars via redox cycling in the gut contents or tissues.

The phenolic composition of *A. rubrum* was unusual among the trees examined, containing large amounts of rhamnose-based galloyl glycosides (primarily digalloyl rhamnose). Previous work on *A. rubrum* foliar chemistry identified the presence of 1-*O*-galloyl-α-L-rhamnose (Abou-Zaid and Nozzolillo 1999), but found that the major phenolic component was ethyl *m*-digallate (Abou-Zaid et al. 2001). The complete absence of the latter compound in our analyses, and the presence of much higher levels of galloyl rhamnosides, lead us to question whether ethyl *m*-digallate could have been produced during the 2-day extraction period in ethanol that was used in previous studies. For example, methanol is known to cleave the *m*-depside bonds of digalloyl groups, producing methyl gallate (Hofmann and Gross 1990).

The results of this study suggest that trees such as *O. virginiana*, *Populus* species, and possibly *Q. rubra* might be superior host plants for generalist caterpillars. These tree species contain low levels of oxidatively active phenolics and produced little phenolic oxidation in the midgut lumen when ingested by *O. leucostigma*. Some field observations are consistent with this expectation: *Q. rubra* and *O. virginiana* are among the top host plant species for *Lymantria dispar* (Lymantriidae) (Liebhold et al. 1995), and *Populus* species are excellent host plants for *Malacosoma disstria* (Lasiocampidae) in its northern range (Parry and Goyer 2004). By comparison, *A. saccharum* and *A. rubrum* are relatively poor host plants for *L. dispar* and *M. disstria* (Liebhold et al. 1995; Parry and Goyer 2004). Given the high levels of oxidative stress in *O. leucostigma* on *Q. alba* in this study, it is surprising that *Q. alba* is considered a favored host for the closely related larvae of *L. dispar*. There is a large amount of geographical variation in the tannin compositions of oak species, including *Q. alba* (Salminen, unpublished data), suggesting that the suitability of species such as *Q. alba* as host plants could vary geographically.

We conclude that the tannin compositions of tree leaves largely determine the effectiveness of foliar phenolics as oxidative defenses against *O. leucostigma*. The basis for this conclusion includes the following main findings: (1) Oxidatively active tree leaves contained high proportions of ellagitannins or galloyl rhamnoses among their foliar phenolics; (2) low MW phenolics contributed relatively little to the overall oxidative activities of tree leaves compared with oxidatively active tannins; (3) ascorbic acid levels were lowest in the species that also contained the highest levels of oxidatively active tannins, potentially exacerbating phenolic oxidation in the gut lumen; and (4) even a "tannin-tolerant" caterpillar such as *O. leucostigma* was unable to control the oxidation of ingested phenolics when trees such as *A. rubrum*, *A. saccharum*, or *Q. alba* were eaten.

Colored and White Sectors From Star-Patterned Petunia Flowers Display Differential Resistance to Corn Earworm and Cabbage Looper Larvae

Eric T. Johnson · Mark A. Berhow · Patrick F. Dowd

Received: 30 November 2007 / Accepted: 8 February 2008 / Published online: 17 May 2008

Abstract Anthocyanins are likely a visual aid that attract pollinators. However, there is also the possibility that anthocyanins are present in some flowers as defensive molecules that protect them from excess light, pathogens, or herbivores. In this study, resistance due to anthocyanins from commercial petunia flowers (*Petunia hybrida*) was examined for insecticide/antifeedant activity against corn earworm (CEW, *Helicoverpa zea*) and cabbage looper (CL, *Trichoplusia ni*). The petunia flowers studied contained a star pattern, with colored and white sectors. CEW larvae ate significantly less colored sectors than white sectors in no-choice bioassays in most cases. All CEW larvae feeding on blue sectors weighed significantly less after 2 days than larvae feeding on white sectors, which was negatively correlated with total anthocyanin levels. CL larvae ate less of blue sectors than white sectors, and blue sectors from one petunia cultivar caused significantly higher CL mortality than white sectors. Partially purified anthocyanin mixtures isolated from petunia flowers, when added to insect diet discs at approximately natural concentrations, reduced both CEW and CL larva weights compared to the controls. These studies demonstrate that the colored sectors of these petunia cultivars slow the development of these lepidopteran larvae and indicate that anthocyanins play some part in flower defense in petunia.

Introduction

Insect herbivores cause crop losses by physically damaging tissue but can also contribute to the colonization of crops by fungi, some of which synthesize toxins (e.g., mycotoxins) that can harm livestock and humans (Dowd 1998). Strengthening plant resistance to herbivore damage is an important strategy of crop management (Dowd et al. 2005). Plants are capable of synthesizing a large variety of biochemicals that serve as defensive molecules (Sadasivam and Thayumanavan 2003), mediate biotic and abiotic stresses (Arasimowicz and Floryszak-Wieczorek 2007; Dixon and Paiva 1995; Horváth et al. 2007; Korkina 2007; Wasternack 2007), and potentially contribute to human health (Sampson et al. 2002). One class of plant secondary biochemicals, the flavonoids, exhibit a wide range of functions that include protection against UV-light and pathogens, signaling during nodulation, male fertility, and auxin transport (Koes et al. 2005). Humans consume substantial quantities of flavonoids (estimated to be several hundred milligrams daily) in diets rich in fruits and vegetables (Hollman and Katan 1999). Blue and red flavonoids in flowers, fruits, and vegetables, called anthocyanins, are free-radical scavengers and antioxidants (Wang et al. 1997; Tsuda et al. 2000) that may have a role in preventing carcinogenesis and heart disease (Omenn 1995). Anthocyanins are thought to function primarily in nature as pollinator attractors

(Koes et al. 2005). Anthocyanins possibly protect leaves from excess light, water stress, or herbivores (Manetas 2006; Schaefer and Rolshausen 2006). Studies on two different types of tree species suggest that leaf anthocyanins play a role in herbivore protection (Karageorgou and Manetas 2006; Schlindwein et al. 2006). Some anthocyanins from cotton flowers can inhibit the development of insect larvae (Hedin et al. 1983; Jenkins et al. 1983).

Petunia can synthesize more than three dozen steroidal compounds that are involved in resistance to lepidopteran larvae; however, these compounds appear to be made in the leaves but not in flowers (Elliger and Waiss 1991). Petunia has served as a model species for identifying many of the regulator genes and enzymes of anthocyanin biosynthesis (Koes et al. 2005). Many anthocyanin structures from garden and wild petunias have been determined (Wiering and De Vlaming 1984; Ando et al. 1999). Blue or violet petunia flowers generally contain delphinidin-type anthocyanins, which have three hydroxyl groups on the B ring of the anthocyanin, due to the presence of flavonoid 3′,5′-hydroxylase (Holton et al. 1993). Methylation of the 3′ hydroxyl group of delphinidin results in petunidin derivatives, while an additional methylation on the 5′ hydroxyl group of petunidin results in malvidin derivatives. A large percentage of commercial petunias available contain petunidin or malvidin derivatives (Ando et al. 2004).

Preliminary experiments indicated that a variety of lepidopteran larvae can eat most but not all commercial petunia flowers (Johnson and Dowd 2003). In addition, some purified anthocyanins reduce the growth of lepidopteran larvae (Johnson and Dowd 2003, 2004). Thus, a search for petunia material that displayed differential anthocyanin production in the flowers was initiated. Extensive breeding of *Petunia hybrida* has generated a number of unique flower phenotypes that include star patterns, which exhibit alternating colored and white sectors. Since the colored and white sectors of star-patterned flowers should be genetically identical, studies that compare the feeding activities of corn earworm (CEW) larvae (*Helicoverpa zea*) and cabbage looper larvae (*Trichoplusia ni*) on these floral sectors were investigated. These insect species can feed on members of the Solanaceae family, such as potato (CL), tomato (CL and CEW), and tobacco (CEW; Metcalf et al. 1951). While these insect larvae are not natural pests of *P. hybrida*, the potential effectiveness of *P. hybrida* anthocyanins as resistance molecules against these larvae that damage important crops may ultimately improve crop protection. For example, genetic regulation of anthocyanins in maize has been well studied (Koes et al. 2005), and it may be possible to induce production of petunia-like anthocyanins in certain maize tissues for insect resistance. On the other hand, the potential insect resistance of *P. hybrida* anthocyanins may be evidence of a molecular mechanism whereby petunia flowers both attract pollinators and defend the tissue from a wide range of potential herbivores.

Methods and Materials

Plant Material Seeds were purchased from the following commercial vendors: W. Atlee Burpee & Co., Warminster, PA, USA (Razzle Dazzle Mixed); Harris® Seeds, Rochester, NY, USA (F1 Ultra Blue Star, UBS); Ball Seed Co., West Chicago, IL, USA (Carpet Blue Star). Seeds were sown in moistened Metro Mix 350 (Scotts-Sierra Horticultural Products Company, Marysville, OH, USA) and germinated under a 14:10 L/D photoperiod at 25°C. Plantlets were transferred to larger pots and placed in a walk-in plant growth facility that contained 1,000 W sodium and halide lighting. Plants were kept at 24°C±2°C day and 18°C±2°C night temperatures and 50%±10% relative humidity. Plants were fertilized weekly with Peters Professional 20–20–20 general purpose fertilizer (Scotts Company, Marysville, OH, USA) at a concentration of 1 g/l or by the placement of indoor plant food spikes (Scotts Miracle-Gro Products, Marysville, OH, USA) into the soil every 30 days.

Insects Corn earworms (*H. zea*) were reared at 27°C±1°C, 40%±10% relative humidity, 14:10 L/D photoperiod as described previously (Dowd et al. 2003). CL larvae obtained from Dr. Robert Behle (USDA-Peoria) were reared under similar conditions (Behle et al. 2003). First instars were used in bioassays. The CEW and CL colonies have been propagated for approximately 180 and 120 generations, respectively.

No-Choice Bioassays Using Flower Sectors Bioassays with CEW larvae were begun soon after initial flowering of each petunia cultivar. Bioassays with CL larvae were begun 6–31 months after initial flowering. Petunia corollas of the same developmental stage (limb as flat as possible) were sectioned by color and placed separately into 5-cm diameter Petri plates with tight fitting lids (Falcon 351006, Becton Dickinson Labware, Franklin Lakes, NJ, USA). Each plate contained two (for large flowers) or four (for small flowers) sectors. Punches (7 mm) were removed from the remaining colored and white sectors and were frozen for subsequent chemical analysis. Several flowers of each cultivar were tested. Ten first instar *H. zea* or *T. ni* were added to each dish and placed in the dark at 27°C±1°C and 40%±10% relative humidity for 48 h. Corolla sectors were rated for feeding on day 2 by counting 1-mm^2 holes (or equivalent areas) with a dissecting scope as described previously (Dowd et al. 2003). Surviving larvae were frozen to weigh

later with an analytical balance (Mettler-Toledo AE163 or AX105DR, Columbus, OH, USA). Multiple bioassays were performed for each petunia cultivar and are indicated on the tables.

Quantification of Anthocyanins Anthocyanins were extracted from one or two punches overnight at 4°C in the dark with 500 μl of methanol + 0.1 M HCl (hereafter, solvent). The next day, the liquid extract was removed and the volume reduced by vacuum with an Eppendorf® Vacufuge™ Concentrator 5301 (Brinkmann Instruments, Inc. Westbury, NY, USA) at room temperature. The dried extract was suspended in 100 μl of solvent. Five hundred microliters of solvent were added to the flower punch(s), and they were ground with small plastic pestles. After another overnight extraction at 4°C in the dark, the first- and second-day extracts were combined, and volume was reduced in the Eppendorf® Vacufuge™. The residue was suspended in 200 μl of solvent and passed through a 0.45-μm syringe filter (4-mm diameter, Alltech Associates Inc. Deerfield, IL, USA). The final volume was measured with a gastight 250-μl syringe. Fifteen microliters of each sample were injected onto an Inertsil 5-μm ODS-3 column (250× 4.6 mm, Metachem Technologies Inc., Torrance, CA, USA) housed in an Agilent (Santa Clara, CA, USA) 1100 high-performance liquid chromatography (HPLC) with a diode array detector set to detect compounds at 520 nm. The mobile phases were A, 1% formic acid and B, acetonitrile and programmed to go from 0% to 39% B after 35 min, with a flow rate of 1 ml/min. The calculation for total anthocyanins consisted of all the peaks (excluding peaks that eluted within the first 5 min of the run) that had an integrated area that exceeded the lowest integrated peak area of the standard regression with malvin chloride (Fluka, Germany). The anthocyanin calculation was normalized to account for the final punch extract volume and was expressed as equivalents of malvin chloride per two flower disks.

Identification of Anthocyanins Flowers were collected approximately 3 months (UBS), 6 months (Razzle Dazzle blue), 7 months (Carpet Blue), and 23 months (Razzle Dazzle red and pink) after initial flowering and freeze dried at least overnight. Fractions were ground into a fine powder with a mortar and pestle. Typically, 100–200 g of dried flower material were needed to produce 5–25 mg of purified anthocyanins. For anthocyanin analysis, the samples were extracted with 0.12 M HCl in methanol. Fractions were sonicated for 15 min then allowed to stand overnight at room temperature. This was repeated at least twice more for each sample. Extracts from a sample were pooled, and an aliquot was removed from the vial and filtered through a 0.45-μM nylon 66 filter for liquid chromatography–electrospray ionization–mass spectrometry (LC–ESI–MS) analysis. For preparative work, the extracts were allowed to dry in a hood, then resuspended in a lesser volume of 0.12 M HCl in water. Samples were run on a ThermoFinnigan LCQ DECA XP Plus LC–MS system with a surveyor HPLC system (autoinjector, pump, degasser, and PDA detector) and a nitrogen generator, all running under the Xcaliber 1.3 software system. The MS was run with the ESI probe in the positive mode. The source inlet temperature was set at 220°C, the sheath gas rate was set at 88 arbitrary units, and the sweep (auxiliary) gas rate was set at 12 arbitrary units. The MS was optimized for the detection of the anthocyanins by using the autotune feature of the software, while infusing a solution of malvin with the effluent of the column and tuning on an atomic mass unit of 655 $[M]^+$ for malvin. The column used was an Inertsil ODS-3 reverse phase C-18 column (3 μm, 150×3 mm, with a Metaguard column, from Varian). For anthocyanin LC–MS analysis, the initial HPLC conditions were 2% acetonitrile and 0.25% acetic acid in water, at a flow rate of 0.3 ml per min. The effluent was monitored at 520 nm on the PDA.

Isolation of Anthocyanin Composites From UBS Flowers Flowers were collected over several weeks from two UBS plants that had been flowering for approximately 5 months and placed in a −20°C freezer. Once enough material was collected, the flowers were freeze dried and extracted as above. A Buchi (Newcastle, DE, USA) Sepacore flash chromatography system with dual C-605 pump modules, C-615 pump manager, C-660 fraction collector, C-635 UV photometer, with SepacoreRecord chromatography software was used. A Buchi C-670 Cartridger system was used to load 40×150 mm flash columns with approximately 90 g of preparative C18 reverse phase bulk packing material (125 Å, 55–105 μm, Waters Corp., Milford, MA, USA). The columns were installed in the flash chromatography system and equilibrated with 5% methanol and 0.5% acetic acid in water for 5 min at a flow rate of 30 ml per min. After samples (10–15 ml) were injected, the column was developed with a binary gradient to 100% methanol over 30 min. The effluent was monitored at 520 nm, and all fractions were collected in the fraction collector by the software program. Fractions were concentrated by evaporation in the hood at room temperature.

A Shimadzu (Columbia, MD, USA) preparative HPLC system was used with dual 8A pumps, SIL 10vp autoinjector, SPD M10Avp photodiode array detector, SCL 10Avp system controller, all operating under the Shimadzu Class VP operating system. Ten milliliters of sample aliquots in methanol were injected on a Phenominex (Torrance, CA, USA) Luna C18 (2) semi-preparative reverse-phase column (10 μm, 100 Å, 250×50 cm). The column was pre-equilibrated with 1% acetic acid, 2% acetonitrile, and 97% water at a flow rate of 50 ml per min, and the effluent was

monitored at 520 nm. The column was developed to 50% acetonitrile over 45 min. UV absorbing peaks were collected by hand. The procedure was repeated to obtain sufficient purified material. Pooled material was allowed to evaporate to remove organic solvent and then freeze-dried to recover the purified anthocyanins.

Bioassays with UBS Anthocyanin Composites Dried anthocyanin composites were dissolved in distilled water and absorbed onto small discs of pinto bean diet as previously described (Dowd et al. 2007) and kept at 4°C for several hours to overnight for full absorption. Ten first instar CEW or CL were added to the dishes and, after resealing, were kept in the rearing incubator in the dark. Mortality was recorded on each day, and the larvae were frozen on the second or third day (depending on the quantity of diet remaining in controls) and subsequently weighed with an analytical balance (Mettler-Toledo AE163 or AX105DR, Columbus OH, USA).

Statistical Analyses Statistical differences in feeding and mortality rates were determined by the paired means test (proc means), while larvae survivor weights were compared by analysis of variance (ANOVA; proc glm) using SAS version 9.1 (Cary, NC, USA). Correlation analyses were completed by using "proc reg corr" with the same SAS software.

Results

Flower Sector Studies Colored and white sectors from three different petunia star cultivars were tested for corn earworm resistance. CEW mortality was low (<10%) for all of the sectors tested, and none of the cultivars displayed significantly different CEW mortality rates between the two sector types (data not shown). The Razzle Dazzle cultivar contained star-patterned flowers with different types of anthocyanins. For Razzle Dazzle red/white flowers, the feeding ratings were significantly lower on the red compared to the white sectors, but there was no significant difference in the weights of larvae feeding on the two types (Table 1). One of the Razzle Dazzle pink/white flowered plants displayed significantly lower feeding on the colored sectors, and the weights of surviving larvae feeding on the colored sectors were lower than the weights of larvae feeding on the white sectors, but the other two Razzle Dazzle pink/white flowered plants did not display the same pattern of insect resistance (Table 1). One Razzle Dazzle blue/white flowered plant showed differential feeding on the colored and white sectors, and the weights of the larvae feeding on the colored sectors were lower than the weights of larvae feeding on the white sectors, but no additional blue/white flowering plants germinated from the Razzle Dazzle seed packets obtained. Thus, more blue/white star petunia flower cultivars from other vendors were purchased, including Carpet Blue Star and Ultra Blue Star. Both cultivars showed lower feeding rates on the colored sectors and lower larvae weights on the colored sectors, which indicated that the constituents of the blue sectors consistently inhibited CEW larvae growth.

Sectors of the blue/white flowers were also fed to CL larvae. No significant differences in feeding ratings or survivor weights (data not shown) were found in Razzle Dazzle blue/white flowers (Table 2). The mortality rate of larvae feeding on the Razzle Dazzle blue sectors was higher than that of larvae feeding on the white sectors but not significantly (P=0.11). No significant differences in the

feeding ratings, mortality rates, and survivor weights (data not shown) were found on Carpet Blue flowers (Table 2). Colored sectors from Ultra Blue Star (UBS) flowers (11 different plants were tested) were effective against CL larvae both in feeding ratings and mortality rates (Table 2). Correlations between feeding ratings and mortality ratings were significant for CB1 colored sectors and UBS colored and white sectors (Table 2).

Qualification of Anthocyanins All petunia white flower sectors contained low to no detectable anthocyanins (Table 3). The blue sectored cultivars, which displayed good resistance to CEW larvae feeding (Table 1), generally contained more malvin equivalents than the other colored cultivars. This was not true, however, for the Razzle Dazzle plant with blue-white sectored flowers, which had less malvin equivalents than Razzle Dazzle red sectors but was more resistant to CEW larvae feeding. The level of malvin equivalents in all the blue-sectored cultivars were negatively correlated to CEW larva weight. Malvin equivalent levels of both of the Razzle Dazzle pink sectored plants were seemingly negatively correlated to CEW larva weights, but in only one plant (Pink1) was this correlation significant. Neither of the Razzle Dazzle red-white sectored plants displayed a significant correlation between malvin equivalent levels and larva weights.

Identification of Anthocyanins The pigments from the blue sectored flowers were analyzed by LC–ESI–MS and contained primarily malvidin and petunidin derivatives (Table 4 and Fig. 1). The major pigments in red sectors were derivatives of cyanidin and delphinidin, while the pink sectors contained a peonidin derivative (Table 4). Structural identities were assigned only for those anthocyanins in which the experimental molecular weight matched with previously identified anthocyanins in petunia (Ando et al. 1999). The instruments used in the current study were not able to discriminate between *cis*- and *trans*-isomers, and thus, some presumed molecules were listed as either the *cis*- or *trans*- form (e.g., anthocyanin **5**). Most of the wild petunia anthocyanins with only a single sugar molecule are attached at the 3 position (Ando et al. 1999), and thus, anthocyanins **14** and **15**, which were not detected in wild petunias (Ando et al. 1999), were assumed to have their sugar attached at the 3 position. Peonidin-type anthocyanins are not present in wild petunias (Ando et al. 1999) but are present in a number of commercial *P. hybrida* lines (Ando et al. 2004). For the compounds detected in Razzle Dazzle pink sectors, it was assumed that the sugars would be attached to the peonidin base as it would be to malvidin or petunidin base for anthocyanins **10** and **13**. Because the Razzle Dazzle pink sectors are capable of producing petunidin- or peonidin-type anthocyanins, it was not possible to tell if the 933 mass from these flowers is anthocyanin **5** or **12**.

Bioassays with UBS Anthocyanin Composites Anthocyanins were partially purified from UBS flowers by using preparative chromatography. Seven different anthocyanin

composites added separately or in combination to insect diet significantly inhibited CL larvae growth (Table 5). While the combination of anthocyanin composites inhibited CEW larvae growth, only composites 1, 4A, 5A, and 5B were significantly inhibitory (Table 5). ANOVA between the following CEW means (Table 5) were not significant at $P<0.05$: 1 vs. 2, 1 vs. 3, and 5A vs. 3. No CEW or CL larvae died while feeding on the anthocyanin combinations (data not shown).

Discussion

CEW larvae generally fed less on colored than white sectors of all the petunia cultivars, which resulted in significantly lower weights in many cases (Table 1). The blue-sectored cultivars displayed superior CEW resistance compared to the red- and pink-sectored cultivars, with one exception (Razzle Dazzle Pink1). Statistically significant inverse correlations of mean CEW larva weight to mean anthocyanin levels (i.e., malvin equivalents) were found in all of the blue-sectored flower cultivars (Table 3). It may be argued that the effective CEW resistance of the blue-sectored flowers is due to a higher concentration of pigment. However, Razzle Dazzle Blu1 sectors and Razzle Dazzle Red1 sectors had statistically similar levels of malvin equivalents ($P=0.50$ by ANOVA), but the Razzle Dazzle blue sectors were more resistant to CEW feeding and caused lower CEW larva weights. Razzle Dazzle Pink1 sectors displayed good CEW resistance, while Pink2 and Pink3 colored sectors did not, perhaps due to the presence of unique allelochemicals specific to each plant. CL larvae were more sensitive to the constituents of the blue sectors because they displayed higher mortality rates than CEW larvae (compare Tables 1 and 2). While most correlations between CL mortality rates and feeding rates on Blu1 and the Carpet Blue flowers were seemingly negative (Table 2), only one was significant (CB1 on colored sectors), perhaps indicating that significant correlations would result only from more bioassays (as for UBS flowers). Correlations of CL feeding rates to mortality rates of Table 2 were −0.68 and −0.60 in UBS colored and white sectors, respectively. This suggests that anthocyanins in UBS colored sectors improves CL resistance present in the UBS white sectors but shows that other unknown defensive molecules in UBS colored and white sectors contribute to CL mortality.

Based on LC–ESI–MS analysis (not shown), the predominant anthocyanins of Razzle Dazzle blue/white and UBS flowers were anthocyanins **1** and **2**. While anthocyanin **2** was present in Carpet Blue Star flowers, the major anthocyanin was anthocyanin **1**. *P. hybrida* or garden petunias are likely the result of crosses of *P. axillaris* subsp. *axillaris* or subsp. *parodii* and *P. integrifolia* subsp. *integrifolia* or *P. inflata* (Chen et al. 2007). Anthocyanins **1** and **2** predominant in the blue star *P. hybrida* lines of this study do not occur in *P. integrifolia*, *P. inflata*, or the white flowers of *P. axillaris* subsp. *axillaris*

and subsp. *parodii* (Ando et al. 1999). The major anthocyanin in *P. inflata* and *P. integrifolia* subsp. *integrifolia* is malvidin 3-*trans*-*p*-coumaroylrutinoside-5-glucoside (Ando et al. 1999). At some point in the breeding history of the *P. hybrida* blue star lines used in this study, an enzyme that places glucose on the coumaric acid group of the anthocyanins became more active.

Interestingly, the flowers with the most CEW resistance in their colored sectors (blue stars) are more similar in their anthocyanin profiles to their presumed parents (*P. axillaris* and *P. integrifolia*) than those with lower CEW resistance in their colored sectors (red and pink stars). Anthocyanin **3**, detected in Razzle Dazzle red sectors, is the predominate anthocyanin in only one wild petunia species, *P. exserta* (Ando et al. 1999). However, anthocyanin **14**, also detected abundantly in Razzle Dazzle red sectors, is not present in any wild petunias, but cyanindin 3-rutinoside is present in *P. exserta* (Ando et al. 1999). The major anthocyanin found in Razzle Dazzle pink sectors was anthocyanin **10**, which is not found in any wild petunia lines (Ando et al. 1999). The limited distribution of anthocyanin **3** and absence of anthocyanins **10** and **14** in wild petunia taxa (Ando et al. 1999) suggest that these anthocyanins are not involved in pollinator attraction and/or floral defense.

When all seven of the anthocyanin composites from UBS flowers were added to insect diet at approximately natural concentrations, they significantly reduced both CL and CEW weights compared to the controls (bottom of Table 5). This may be due to antibiosis or feeding deterrence. The reduction of CEW weights observed in the UBS colored sectors (Table 1) can be attributed partially to anthocyanins from UBS flowers (bottom of Table 5). However, CL larvae feeding on UBS colored sectors exhibited significant mortality (Table 2), while no CL mortality was observed with the combination of anthocyanin composites in insect diet (data not shown). As mentioned above, this indicates that unknown compounds beside anthocyanins contribute to CL mortality. Each of the seven individual UBS anthocyanin composites resulted in significantly reduced CL weights compared to the control (Table 5). This suggests that each of the UBS anthocyanin composites causes CL antiobiosis or feeding deterrence. However, not all of the anthocyanin composites reduced CEW weights compared to the control, which suggest that the mixture of compounds in composites 2, 3, and 4B were not as inhibitory or deterrent as the others.

Optimal defense theory predicts that flower tissue should be protected from damage to ensure fitness and that secondary

chemicals should be present constitutively rather than induced upon attack (McKey 1979). Petunia petals synthesize high levels of anthocyanins: based on Table 3, anthocyanin levels in some flower tissues (e.g., Carpet Blue) are ~6% fresh weight (punches weigh ~2.9 mg). If anthocyanin production is metabolically costly, it would be advantageous for petunia to produce petal compounds that both attract pollinators and defend the flower against herbivores. The data of this study indicate that petunia anthocyanins do inhibit growth or deter feeding of both CEW and CL larvae. This suggests that the petunia anthocyanins inhibit or deter a broad range of herbivores, but CEW and CL are likely not natural enemies of petunia. More studies that use pure wild petunia anthocyanins, wild petunia lines, and a number of their indigenous pests are needed to test fully the possible dual function of anthocyanins.

Antifeedant and Phytotoxic Activity of the Sesquiterpene *p*-Benzoquinone Perezone and Some of its Derivatives

Eleuterio Burgueño-Tapia · Lucia Castillo · Azucena González-Coloma · Pedro Joseph-Nathan

Received: 30 January 2008 / Revised: 15 April 2008 / Accepted: 2 May 2008 / Published online: 5 June 2008

Abstract The sesquiterpene *p*-benzoquinone perezone (**1**), isolated from *Perezia adnata* var. *alamani* (Asteraceae), and its non-natural derivatives isoperezone (**2**), dihydroperezone (**3**), dihydroisoperezone (**4**), and anilidoperezone (**5**) were tested as antifeedants against the herbivorous insects *Spodoptera littoralis*, *Leptinotarsa decemlineata*, and *Myzus persicae*. Compounds **1**–**5** exhibited strong antifeedant activity against *L. decemlineata* and *M. persicae*, and elicited a low response by *S. littoralis*. Antifeedant activity on *L. decemlineata* and *M. persicae* increased when the hydroxyl group at C-3 in perezone (**1**) was changed to C-6 to give isoperezone (**2**). The same effect was found with hydrogenation of the double bond of the alkyl chain of **(1)** to yield dihydroperezone (**3**). In contrast, hydrogenation of this double bond in isoperezone (**2**) to give dihydroisoperezone (**4**) led to a reduction in antifeedant activity. Determination of the phytotoxic activity of **1**–**5** revealed that **3** had a significant inhibition effect on *Lactuca sativa* radicle length growth.

Introduction

Natural quinones and some derivatives have attracted attention as insecticidal (Xu et al. 2003), antifeedant (Marimoto et al. 2002; Wellsow et al. 2006), and phytotoxic compounds (Hejl et al. 1993; Barbosa et al. 2001; Lima et al. 2003;, Hejl and Koster 2004). To date, however, only a small group of sesquiterpenoid quinones has been tested with respect to these biological activities (Motti et al. 2007; Burgueño-Tapia et al. 2008). Perezone (**1**), a sesquiterpenoid *p*-benzoquinone described by Río de la Loza (1852), was the earliest natural product isolated in crystalline form discovered in the New World (Fig. 1). It originally was isolated from roots of *Perezia adnata* var. *alamani* (Asteraceae), popularly known as 'raiz del pipitzahuac'. Its structure was characterized (Archer and Thomson 1965; Bates et al. 1965; Wagner et al. 1965; Walls et al. 1965b) 113 years after its discovery, as a direct consequence of the structural elucidation of α- and β-pipitzol (Walls et al. 1965a), obtained by heating **1**. Ever since its original isolation more than 155 years ago, perezone has been the subject of extensive chemical studies (Joseph-Nathan and Santillan 1989; Roura-Pérez et al. 2007), including its rearrangement to isoperezone (**2**) (Rodríguez-Hernández et al. 1994; Burgueño-Tapia and Joseph-Nathan 1997).

Some pharmacological effects have been reported for perezone: hypoglycemic action (Alarcón-Aguilar et al. 1997), induction of a biphasic dose-dependent contractile response in calcium-free intestinal smooth muscle preparation (García et al. 1995), an increase in intestinal motility (Enríquez et al. 1980), lack of sensitizing capacity (Hausen

and Soriano-García 1987), electron donor-acceptor characteristics (Carabez and Sandoval 1988), impairment of Ca^{2+} homeostasis in adrenal cortex mitochondria (Cuéllar et al. 1987), protection from the deleterious effects of experimental ischemia and reperfusion (Téllez et al. 1999), and inhibition of ADP-, epinephrine-, and collagen-induced platelet aggregation (de la Peña et al. 2001). Furthermore, plant defense-related properties (insect antifeedant effects and phytotoxicity) of structurally similar quinones have been recently reported (Burgueño-Tapia et al. 2008).

In continuation of our studies on the chemical and plant defense-related properties of natural products and their derivatives (González-Coloma et al. 2005; Reina et al. 2006 Burgueño-Tapia, et al. 2007, 2008), we investigated the antifeedant activity and toxic effects of perezone isolated from *Perezia adnata* var. *alamani* (Asteraceae), and its derivatives **2**–**5** (Fig. 1) on the polyphagous lepidopteran species *Spodoptera littoralis*, the Colorado potato beetle *Leptinotarsa decemlineata*, and the aphid *Myzus persicae*. Moreover, we studied the phytotoxic activity of these compounds on *Lactuca sativa*.

Methods and Materials

General Silica gel 60 Merck (230–400 mesh ASTM) was used for column chromatography. Optical rotations were measured in $CHCl_3$ on a Perkin-Elmer 341 polarimeter. High-resolution mass spectrometry (HRMS) measurements were conducted on an Agilent LCTOF high-resolution mass spectrometer at the UCR Mass Spectrometry Facility, University of California, Riverside, CA. Nuclear magnetic resonance (NMR) measurements were carried out by using 5-mm probes at 22°C from $CDCl_3$ solutions with tetramethylsilane (TMS) as the internal standard. 1D ^1H and ^{13}C spectra were acquired under standard conditions on Varian Mercury spectrometers operated at 300 and 75 MHz, respectively. The 2D hydrogen-detected heteronuclear shift correlation spectra were obtained by using the gHMQC and gHMBC pulse sequences with 512 time increments, 64 transients having been collected for each time increment with a relaxation delay of 1.0 sec

Compounds Perezone (**1**) and its derivatives **2**, **3**, and **5** were available from previous studies (Burgueño-Tapia et al. 1997; Burgueño-Tapia and Joseph-Nathan 2000).

Dihydroisoperezone (**4**): A sample of 10 mg of 5% Pd/C was added to a solution of isoperezone (50 mg, 0.2 mmol) in AcOEt (5 ml). The air in the flask was replaced by H_2, and the solution was vigorously stirred at room temperature for 12 hr. The mixture was filtered through filter paper, and the filtrate was stirred at room temperature for an additional 12 hr to yield 47.9 mg (95% yield) of **4** as orange plates. mp: 121–122°C (mp 122–123°C, Rodríguez-Hernández et al. 1994). $[\alpha]_{589}$ +20.8, $[\alpha]_{578}$ 23.6, $[\alpha]_{546}$ 45.3 (c 1.06, $CHCl_3$). HRESIMS *m/z* $[M + Na]^+$ 273.1474 (calcd 273.1466). ^1H NMR: δ 6.98 (1H, brs, interchangeable with D_2O, OH), 6.44 (1H, d, *J*=1.2 Hz, H-3), 2.89 (1H, m, H-8), 1.94 (3H, s, H-7), 1.50 (1H, m, H-13), 1.45 (2H, m, H-10), 1.24 (2H, m, H-11), 1.14 (2H, m, H-12), 1.12 (3H, d, *J*=7.0 Hz, H-9), 0.85 (6H, d, *J*=6.6 Hz, H-14 and H-15). ^{13}C NMR: δ 188.2 (C-4), 183.3 (C-1), 151.3 (C-6), 149.7 (C-2), 133.0 (C-3), 116.7 (C-5), 38.8 (C-12), 35.8 (C-10), 31.3 (C-8), 27.8 (C-13), 25.0 (C-11), 22.6 (C-14), 22.5 (C-15), 19.3 (C-9), 7.8 (C-7).

Insect Bioassays Colonies of *Spodoptera littoralis* and *Leptinotarsa decemlineata* were reared on artificial diet and potato foliage (*Solanum tuberosum*), respectively (Poitout and Bues 1974). *Myzus persicae* was reared on bell pepper (*Capsicum annuum*) plants. All insects were maintained at 24±1°C, 60–70% r.h. with a 16:8 hr (L:D) photoperiod in a growth chamber. The environmental conditions for the assays described below were the same as those used for rearing. In both the feeding and settling bioassays, compounds **1** – **5** were tested. In addition, the model antifeedants ryanodine, which is a diterpene alkaloid (González-Coloma et al. 1999), silphinene, which is a tricyclic sesquiterpene (González-Coloma et al. 2002b), and polygodial, which is a sesquiterpene dialdehyde (Moreno-Osorio et al. 2008), were included as positive controls for *S. littoralis* and the aphids, respectively.

Feeding Assays These were conducted with newly molted *S. littoralis* 6th-instar larvae and adults of *L. decemlineata*. Leaf disks of *C. anuum* or *S. tuberosum* (1.0 cm^2) were treated on the upper surface with 10 µl of the test substance (5 µg/µl acetone). Three *S. littoralis* larvae or three adults of *L. decemlineata* were placed in a Petri dish with four 1-cm^2 leaf disks (two treated with test substance and two controls

with solvent only) (five to 10 Petri dishes in total per compound tested). Each compound was tested three times. Each assay was terminated after consumption of about 50–75% of the control disks. Feeding inhibition was calculated as % FI = [1 − (T/C) × 100], where T and C are the consumed leaf areas of treated and control leaf disks, respectively. These feeding bioassays were statistically evaluated by the Wilcoxon signed rank test.

Settling Assays Ten *M. persicae* adults were placed in an agar-coated box with one leaf disk cut in two pieces (each 1 cm^2), one for control and one treated with the test substance on the upper surface with 10 µl of the test substance (5 µg/µl acetone). In total, 20 boxes were used per compound tested. Each compound was tested three times. The bioassays were terminated after 24 hr (Gutiérrez et al. 1997; Reina et al. 2001). Settling bioassay data based on the number of aphids settled on the treated and control disks were statistically evaluated by the Wilcoxon signed rank test.

Forced Feeding To study the toxic effects of ingestion of compounds **1**–**5**, we forced pre-weighed newly molted *S. littoralis* 6th-instars to feed. A 6th instar was orally injected with 40 µg of the test compound in 4 µl of DMSO (treatment) or solvent alone (control) with a Rheodyne Hamilton syringe (50 µl) attached to a Hamilton micro-dispenser, as described by Reina et al. (2001). The syringe tip was inserted into the mouth of the larvae (maximum of 5 mm), and then larvae were forced to feed until no regurgitation was observed. In total, 20 larvae were "fed" this way per compound tested. At the end of the experiments (72 hr), food consumption and growth were calculated on a dry weight basis. A covariance analysis (ANCOVA1) of food consumption (ΔI) and biomass gains (ΔB) with initial larval weight (BI) as covariate (covariate $P>0.05$) was performed to test for significant effects of the compounds on these variables. An additional ANOVA analysis and covariate adjustment on ΔB with ΔI as covariate (ANCOVA2) were performed on those compounds that significantly reduced ΔB to understand their postingestive mode of action (antifeedant and/or toxic) (Reina et al. 2001). Rotenone, an insecticidal isoflavone, was included as a positive control (González-Coloma et al. 2002a).

Phytotoxic Evaluation These experiments were conducted with lettuce, *Latuca sativa* var. Carrascoy (Asteraceae) seeds as described by Moiteiro et al. (2006). Germination was monitored daily. Radicle length was measured at the end of the experiment after 7 d (20 digitalized radicles randomly selected for each experiment) with the application Image J Version 1.37r, 2006 (http://rsb.info.nih.gov./ij/). An analysis of variance (ANOVA) was performed on germination and radicle length data. Juglone was included as a positive control (Burgueño-Tapia et al. 2007).

Results and Discussion

The preparation of dihydroisoperezone (**4**) from isoperezone (**2**) has been previously described (Rodríguez-Hernández et al. 1994), although ^1H and ^{13}C NMR data were not reported. Compound **4** was obtained as orange plates, mp 121–122°C, after 5% Pd/C catalyzed hydrogenation of isoperezone (**2**) to give the respective hydroquinone, which was air-oxidized to quinone **4** in an EtOAc solution. Complete oxidation of the hydroquinone was monitored by TLC and ^1H NMR. The complete ^1H and ^{13}C NMR data assignment was made by comparison with data of isoperezone (**2**) (Burgueño-Tapia and Joseph-Nathan 1997) and by using one- and two-dimensional NMR experiments, including COSY, DEPT, gHSQC, and gHMBC.

Table 1 shows the antifeedant effects of (**1**–**5**). These *p*-benzoquinones were effective antifeedants to adult *L. decemlineata*, but not to larvae of *S. littoralis* as previously shown for hydroxyperezone and its derivatives (Burgueño-Tapia et al. 2008). The most active compounds against *L. decemlineata* were isoperezone (**2**) and anilidoperezone (**5**),

Table 1 Antifeedant effects of **1**–**5*** against *Spodoptera littoralis* larvae; *Leptinotarsa decemlineata*, and *Myzus persicae* adults. percent settling of *M persicae* adults on control (%C) and treated (%T) leaf disks

[g] From Moreno-Osorio et al. 2008
1=Perezone; **2**=Isoperezone; **3**=Dihydroperezone; **4**=Dihydroisoperezone; **5**=Anilidoperezone

followed by dihydroperezone (**3**), with activity levels within the range of the positive control silphinene, the major component of *Senecio palmensis* (Asteraceae) (González-Coloma et al. 2002b), for **2** and **5**. Hydrogenation of the alkyl double bond in perezone (**1**) to give dihydroperezone (**3**) increased this activity. The same effect was observed when the hydroxyl group at C-3 in **1** was changed to C-6 in **2**. The introduction of an anilido group at C-6 in **1** to afford **5** also increased this antifeedant effect.

Compounds **1**–**4** showed strong inhibition of settling by *M. persicae* (% settling on treated disks <30%), **2** being the most active (% setting on treated disks 10%) with activity levels similar to the positive control polygodial (Moreno-Osorio et al. 2008), followed by **3**, **1**, and **4** (Table 1). Similar to the structure-activity pattern observed for the antifeedant effects on *L. decemlineata*, the hydrogenation of the alkyl double bond in **1** to give **3** increased activity, while reduction of this alkyl double bond in isoperezone (**2**) to give dihydroisoperezone (**4**) reduced this effect.

Table 2 shows the nutritional effects of **1**–**5** on *S. littoralis* larvae. A covariance analysis (ANCOVA1) of food consumption (ΔI) and biomass gains (ΔB) with initial larval weight as covariate (covariate $p>0.05$) was performed to test for significant effects of the test compounds on these variables. An additional ANOVA analysis and covariate adjustment on ΔB with ΔI as covariate (ANCOVA2) were performed for those compounds that significantly reduced ΔB in order to gain insight into their post-ingestive mode of action (antifeedant and/or toxic) (Raubenheimer and Simpson 1992; Horton and Redak 1993; Reina et al. 2001). Compounds **1**–**3** and **5** had a similar negative effect on biomass gain (ΔB) and consumption (ΔI) within the range of activity of the positive control rotenone (González-Coloma et al. 2002a). Treatment effects on ΔB disappeared with covariance adjustment, indicating that these compounds are post-ingestive growth inhibitors. Perezone (**1**) inhibits mitochondrial electron transport through a process that differs from that of rotenone (Carabez and Sandoval 1988), and this could explain the post-ingestive effects of **1** and its derivatives on *S. littoralis*.

Table 2 Biomass gain (ΔB) and consumption (ΔI) effects (% control) **1**–**5*** (40μg/larvae) on *Spodoptera littoralis* larvae [†]

*Compounds as in Table 1

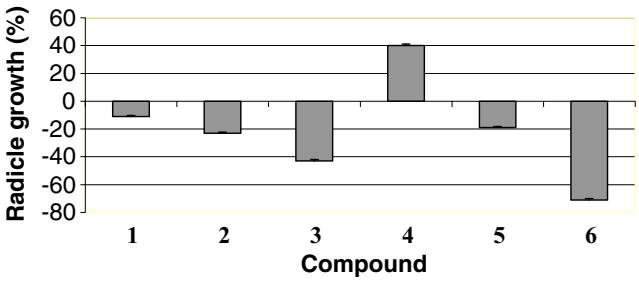

Fig. 2 Activity of the test compounds (50 μg/cm^2) on *Lactuca sativa* radicle length growth (mean ± SE, N=20). $P<0.05$, LSD test for all compounds except **1**. Compounds **1**–**5** as in Fig.1. Compound **6** is the positive control juglone (Burgueño-Tapia et al. 2008)

The test compounds did not affect germination of *L. sativa* seeds (% germination after 24 hr >99), but showed variable effects on radicle length growth (Fig. 2). Compounds **3, 2**, and **5** significantly reduced growth of radicle length (43%, 23%, and 19% growth inhibition, respectively, $P<0.05$, LSD test). Similar to the structure–activity pattern observed for the antifeedant effects, the alkyl double bond hydrogenation of **1** to yield dihydroperezone (**3**) and the change of the C-3 hydroxyl group of **1** to C-6 (**2**) increased this activity. In addition, hydrogenation of the side chain double bond in isoperezone (**2**) to give dihydroisoperezone (**4**) resulted in stimulation of radicle growth (40% growth increase, $P<0.05$, LSD test). On the other hand, the related compound hydroxyperezone with a second hydroxyl group at the 6 position reduced *L. sativa* germination after 24 hr (21–76% germination) and inhibited radicle growth (67–50% inhibition) more effectively (Burgueño-Tapia et al. 2008). Furthermore, sterification of its hydroxyl groups reduced post-ingestive effects on *S. littoralis*, while reduction of the alkyl double bond in leucohydroxyperezone tetraacetate increased it (Burgueño-Tapia et al. 2008). In this study, we have demonstrated that the position of the hydroxyl substituent along with the unsaturation/saturation of the alkyl chain can modulate strongly the antifeedant, post-ingestive, and phytotoxic effects of the perezone molecule.

Perezone is an electron-donor and electron-acceptor compound that behaves similarly to naphthoquinones (Carabez and Sandoval 1988). A recent study showed the importance of weak interactions of the olefin quinone type in the reduction process of quinones (Roura-Pérez et al. 2007). Chain size and flexibility is important for perezone's redox properties since it allows the approach of the

donating isopropenyl group to the quinone ring. These interactions can protect the quinone in biological media and even modify electrochemical potentials. In addition, it is possible that quinones with different side chains interact with different redox enzyme systems altogether (Roura-Pérez et al. 2007). These intra- and intermolecular interactions may likely explain the structure-dependent variation in the biological effects described here for perezone (**1**) and its derivatives.

Variation of Insect Attracting Odor in Endophytic *Epichloë* Fungi: Phylogenetic Constrains *Versus* Host Influence

Fabrizio Steinebrunner · Florian P. Schiestl · Adrian Leuchtmann

Received: 15 January 2008 / Revised: 26 March 2008 / Accepted: 3 April 2008 / Published online: 8 May 2008

Abstract Odor is a key trait for pollinator attraction in flowering plants, and many studies have investigated odor evolution in the light of pollinator selection by emphasizing the importance of the plant phylogenetic history. By contrast, little is known on the evolution of odors in fungus–insect interactions. In this study, profiles of three volatile compounds that are emitted by grass-inhabiting *Epichloë* fungi (Clavicipitaceae, Ascomycota) and that have a confirmed or likely role in the attraction of gamete-transferring *Botanophila* flies were investigated. We collected headspace samples from stromata of six European *Epichloë* species (including various host races) that originated from different locations in Switzerland, France, Poland, and UK for conducting gas chromatography analyses. Odor profiles exhibited considerable variation, but profiles of most species overlapped and did not discriminate at the species level. The exception was *Epichloë festucae*, which had a profile dominated by methyl (*Z*)-3-methyldodec-2-enoate. Based on an *Epichloë* phylogeny, there was some hierarchical structuring regarding levels of chokol K, another confirmed *Botanophila* attractant. However, patterns of odor profiles appeared to be largely dependant on particular *Epichloë*–host associations. The observed variation may be the result of complex selective pressures imposed by *Botanophila* gametic vectors, local environment, and mycoparasites.

Introduction

Odor is a key component of many sessile organisms in communicating with other organisms in an ecosystem. It may be important, alone or in concert with visual stimuli, for the attraction of insects that are involved in pollination or dispersal by eliciting searching, alighting, and feeding (Knudsen 2002; Plepys et al. 2002). Even though pollinator attraction is viewed as the primary function of odor, other functions that include plant defense or protection against abiotic stresses have been documented (Pellmyr and Thien 1986; Dudareva et al. 2006). While odor has received much attention in angiosperms, only a few studies have focused on odors of fungi and even fewer on the role of odor in fungal–insect interactions (Hedlund et al. 1995; Raguso and Roy 1998; Guevara et al. 2000). Recently, the biological function of volatiles for sexual reproduction of *Epichloë* fungi has been unraveled (Schiestl et al. 2006; Steinebrunner et al. 2008a).

Epichloë fungi (Clavicipitaceae, Ascomycota) are endophytes of pooid grasses with which they form constitutive, life-long symbioses. Infections are symptomless during vegetative growth of the host. Only at the flowering stage does the fungus produce external fruiting structures (stromata) on grass inflorescences. *Epichloë* is self-incompatible and has to be fertilized by gametes of the opposite mating type for sexual reproduction. Gametes (spermatia) are transferred by specialized flies of the genus *Botanophila* that feed and develop on fungal stromata (Bultman et al. 1995). Immediately after oviposition, the flies actively

fertilize the stroma, which involves spreading of viable spermatia containing feces over the stroma surface (Bultman et al. 1998). Thus, fly activity is indispensable for the formation of sexual ascospores that are wind dispersed and may infect new host grasses. Conversely, *Botanophila* larvae develop on the stroma and rely on the growing fungal tissue as a food source. In general, the *Epichloë–Botanophila* association is a balanced mutualism for which overexploitation by *Botanophila* larvae does not occur (Bultman et al. 2000). However, if the conditions are conducive, the mutualism may be disrupted to form an interaction of simple foraging by fly larvae (Rao and Baumann 2004).

The phylogeny of genus *Epichloë* based on multiple gene sequences is well established (Schardl et al. 1997; Craven et al. 2001). *Epichloë* comprises ten species, which have been circumscribed as distinct mating populations with one exception (Schardl et al. 1997). The species differ in host range and are restricted to either Eurasia or North America, following the native distribution of the host grasses (Leuchtmann 2003). A recent study of *Epichloë*-associated *Botanophila* revealed that at least six distinct fly taxa are involved in gamete transfer in Europe and North America (Leuchtmann 2007). While phylogenetic analyses indicated that seven *Epichloë* species coevolved by common descent with grass hosts (Schardl et al. 1997), comparison of molecular phylogenetic relationships of *Botanophila* with the associated *Epichloë* hosts did not suggest co-evolution of fungus and fly (Leuchtmann 2007).

Odor communication between *Epichloë* and the *Botanophila* flies is based on a relatively simple mechanism that involves two system specific volatiles, namely, chokol K and methyl (*Z*)-3-methyldodec-2-enoate (MME; Schiestl et al. 2006; Steinebrunner et al. 2008a). These compounds (and perhaps others) are assumed to be key traits responsible for *Botanophila* attraction and are likely adaptive for *Epichloë* and possibly *Botanophila* flies. In addition, chokol K is fungitoxic (Koshino et al. 1989) and has been shown to reduce spore germination of *Epichloë* mycoparasitic fungi (Steinebrunner et al. 2008b). Thus, the production of chokol K and MME in *Epichloë* may be the result of complex selection pressures.

In plant–insect interactions, odor profiles are often species specific (Levin et al. 2001; Grison-Pige et al. 2002; Knudsen et al. 2006), which potentially enables pollinators to recognize a particular plant species. Likewise, in the *Epichloë* system, species-specific odor profiles may allow for specific *Botanophila* attraction and, thus, could maximize successful cross-fertilization. Among three *Epichloë* species, differences in the production of chokol K and MME have been reported (Steinebrunner et al. 2008a). However, regarding *Botanophila* flies, there is little empirical evidence for host fidelity. With one exception, larval catches from *Epichloë* stromata indicate that *Botanophila* species are typically associated with several *Epichloë* species (Leuchtmann 2007). Similarly, a common *Botanophila* species did not differentiate between synthetic odor blends that imitate different *Epichloë* species offered in traps but visited all traps at equal rates (Steinebrunner et al. 2008a). On the other hand, an earlier study that examined gamete mixtures in the fly feces suggested that flies predominantly visited one host while visiting others less frequently (Bultman and Leuchtmann 2003). Therefore, *Botanophila* flies may display "flower" constancy, a tendency to visit stromata of one species repeatedly while ignoring suitable stromata of another *Epichloë* species.

A given odor profile may not only be viewed as result of selective biotic forces acting on its producer but may simply be a by-product of metabolic processes, or have remained, although the adaptive context has changed (Levin et al. 2003; Raguso et al. 2003). Therefore, interpretation of odor profiles should be made in a phylogenetic context. A further complication in studying odor in endophytic *Epichloë* is that its production may be modulated by the host grass, the *Epichloë* genotype, and/or the interaction of the two.

In the present study, we examined *Epichloë* odor production at species and at host race levels. We relied on the analysis of stromata emitted, previously described compounds (or its variants) by using headspace sampling. The following questions were asked: (1) How variable are odor profiles among *Epichloë* species? Are the profiles species specific? Is there evidence for fluctuations among years? (2) Are odor data phylogenetically informative so that they could be used to reconstruct phylogenetic relationships?

Our study is the first describing variation of insect attracting odor in *Epichloë* fungi and offering insight into phylogenetic patterns of odor production on a genus-wide scale.

Methods and Materials

Study Taxa and Sampling Plants infected by *Epichloë* fungi originated from various locations in Switzerland, France, Poland, UK, and USA and had been maintained for up to 14 yr in pots at an experimental garden in Zürich, Switzerland. In total, 14 different host plant–endophyte associations represented by 1–24 genetically distinct accessions were included in the study (Table 1). Before and during the experiment, plants were watered regularly and received liquid fertilizer once a week. To induce stromata formation for odor collection, potted plants were vernalized outside during winter. The following spring when stromata emerged (which usually coincides with host flowering), plants were moved into the laboratory, and volatiles emitted

Table 1 List of *Epichloë* associations used in the present study with number of accessions (genotypes) and geographic origin

Fungal species	Host species	Abbreviation	No. of accessions	Geographic origin[a]	Country
E. baconii	*Agrostis tenuis*	Eba–At	4	ZH	Switzerland
E. baconii	*Calamagrostis villosa*	Eba–Cv	3	GR	Switzerland
E. bromicola	*Bromus erectus*	Eb–Be	17	SH, AG, LU, Vesancy	Switzerland, France
E. clarkii	*Holcus lanatus*	Ec–Hl	8	VD	Switzerland
E. festucae	*Festuca rubra*	Ef–Fr	6	VD, VS, Vesancy, Lexington	Switzerland, France, USA
E. sylvatica	*Brachypodium sylvaticum*	Es–Bs	8	ZH	Switzerland
E. typhina	*Anthoxanthum odoratum*	Et–Ao	3	VD, TI	Switzerland
E. typhina	*Dactylis glomerata*	Et–Dg	24	VD, ZH, SH, Vesancy	Switzerland, France
E. typhina	*Brachypodium pinnatum*	Et–Bp	7	VD, ZH	Switzerland
E. typhina	*Phleum pratense*	Et–Php	1	Cardiff	UK
E. typhina	*Poa nemoralis*	Et–Pn	5	VD, ZH	Switzerland
E. typhina	*Poa pratensis*	Et–Pp	3	ZH, VS	Switzerland
E. typhina	*Poa trivialis*	Et–Pt	2	ZH	Switzerland
E. typhina	*Puccinellia distans*	Et–Pd	2	Gniebnia, Janikowo	Poland

[a] Swiss canton (*AG* Aargau, *GR* Grison, *LU* Luzern, *SH* Schaffhausen, *TI* Ticino, *VD* Vaud, *VS* Valais, *ZH* Zürich) or town if outside Switzerland

from the stromata were sampled with headspace sorption within the first 3 d after emergence. Sequential measurements on stromata from *Epichloë typhina* infecting *Phleum pratense* at days 1, 3, 6, 10, 13, 15, 20, and 23 after stroma emergence demonstrated that volatile production did not decrease considerably until day 3 (Fig. 1) suggesting that our sampling provided an accurate measure for maximum odor production. To estimate consistency of odor emission among years, odor was sampled from a representative subset of plants that included 15 accessions and 7 host grasses in 2 consecutive years (2005 and 2006).

Collection of Fungal Volatiles To collect volatiles, stromata-bearing tillers were covered individually with polyethylene terephtalate bags (Nalo®, Kalle GmbH, Germany) and the air pulled out by a vacuum pump (SCK Inc.) at a rate of approximately 100 ml/min. Volatiles were trapped on custom-made micropipette filters containing 5 mg of Porapak Q (Mesh size 80/100, Alltech Associates Inc., USA; Salzmann et al. 2006). If available, two to four stromata per plant were sampled individually, except for some plants where only one stroma-bearing tiller emerged. Before sampling, the Porapak Q adsorbent was cleaned with 100 µl of dichlormethane and 100 µl of hexane (Merck, Uvasol). Blank air samples were collected to check for background contaminants. After a sampling period of 24 hr (including day and night at room temperature), adsorbed volatiles were eluted from Porapak Q with 50 µl of a mixture of hexane/acetone (9:1; Merck), sealed in glass vials, and stored at −20°C. Headspace sorption is the method of choice for collecting compounds of medium to high volatility that are produced *de novo* and emitted immediately, as those from *Epichloë* stromata examined here, and relatively long sampling periods were necessary to collect sufficiently concentrated samples. Interval sampling of the key volatiles chokol K and MME did not show differences in emission between day and night (Steinebrunner, unpublished data), thus suggesting continuous odor production. Nevertheless, flies are active only during day, preferably at warm and sunny conditions between 10 A.M. and 4 P.M.

In vitro production of volatiles was examined in isolates of *Epichloë* grown on potato dextrose agar (Difco) in Petri dishes (Steinebrunner et al. 2008b). For collecting volatiles, Petri dishes with 2-wk-old colonies were placed in polyethylene terephtalate bags (Nalo®, Kalle GmbH), then

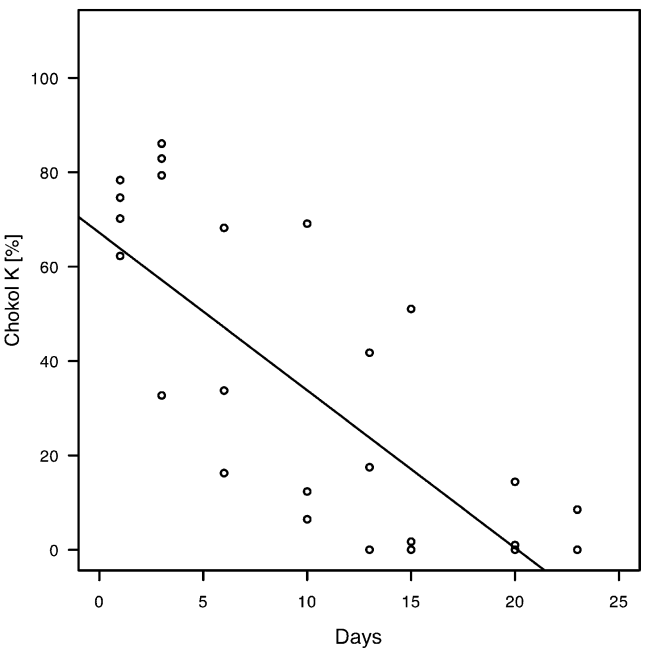

Fig. 1 Scatterplot of repeated headspace measurements from *Epichloë typhina* stromata on *Phleum pratense* (*Et–Php*) at days 1, 3, 6, 10, 13, 15, 20, and 23 after stromata emergence

the cover was lifted, and the air above the growing *Epichloë* cultures inside the bag was sampled as described above.

Quantitative GC Analyses and GC-Mass Spectrometry For quantitative analysis, 100 ng of *n*-octadecane were added to samples as an internal standard. One microliter of each sample was injected splitless into a gas chromatograph (GC; Agilent 6890N) equipped with an HP5 column (5%-phenyl-metylpolysiloxane, 30 m×0.32 mm diameter×0.25 μm film thickness) and a flame ionization detector. The column was temperature-programmed at 50°C for 1 min, followed by a temperature increase to 300°C at a rate of 10°C min^{-1}, with a final hold of 10 min at 300°C. The carrier gas was hydrogen (Carbagas, local distributor), and the GC was operated at constant flow (2 ml min^{-1}). Data acquisition and data analysis were done by using the Agilent Chemstation software package (Agilent Technologies, Palo Alto, CA, USA).

Previously known compounds (chokol K and MME) were identified by retention time comparison with authentic standards (Schiestl et al. 2006; Steinebrunner et al. 2008a). Identification of unknown compounds was done by using GC/mass spectrometry (MS) (HP G 1800 A, Hewlett Packard Inc., Palo Alto, CA, USA) with the operating conditions as described above, following tentative identification of the mass spectra on the basis of the NIST database information. To calculate absolute amounts, the internal standard method proposed by Schomburg (1990) was used.

Phylogenetic Analysis To establish a possible link between phylogeny of *Epichloë* taxa and the observed odor profiles, a maximum likelihood (ML) tree based on variations of intron sequences of β-tubulin (*tub2*) of representative strains of European *Epichloë* species plus the American outgroup taxon *E. brachyelytri* was constructed. The sequences used have been published in Craven et al. (2001) and were retrieved from GenBank (National Center for Biotechnology Information, Bethesda, MD, USA; http://www.ncbi.nlm.nih.gov/) with one exception. *E. typhina* from *Puccinellia distans* (*Et–Pd*) was newly sequenced in the course of this study, following the methods described in Craven et al. (2001), and submitted to GenBank (accession number EU375739). Aligned sequences were analyzed with PAUP *4.0b10 (Swofford 2003) employing ML and maximum parsimony analyses. ModelTest v.3.7 (Posada and Crandall 1998) was used to select the best fitting model (K80+G) for general time reversible ML analysis by using the tree bisection and reconnection branch swapping algorithm. Odor profiles from *in vitro* and *in vivo* results, including three compounds [chokol K, MME, and methyl 2,4,8-trimethylundecanoate (MTE)], plus a group of unknown diterpenes were then mapped into the ML phylogenetic tree. Phylogenetic reconstruction was done separately with odor data, but as expected, the resulting tree was poorly resolved due to the relatively small data set.

Statistical Analyses All comparisons of odor compounds from different *Epichloë* species and host races are based on relative amounts. We use relative values for technical reasons to provide a more reliable measure for comparison. Absolute values from samples that are not simultaneously processed are difficult to compare due to variations in absorption and elution of filters. Relative values of single compounds were calculated by dividing the amount of each compound by the sum of all other compounds in the headspace (excluding the solvent peak). Homogeneity of variances of data was tested with Levene's test. If no adequate transformation were found, data were analyzed by using the nonparametric Kruskal–Wallis test. Principal component analysis based on the three investigated compounds (chokol K, MME, and MTE) was used to illustrate the relationship among species. Sequential odor emission measurements in *E. typhina* from *Phleum pratense* (*Et–Php*) were analyzed with one-way analysis of variance based on log-transformed values. For comparisons of odor emission among years of selected genotypes, the 95% confidence interval (95% CI), based on the differences of the means of the 2 yr, was calculated. If zero was included in the CI, the emission was not regarded as significantly different. The CI calculations were done by using the bootstrapping method "boot" from the R library (boot) and are based on 10,000 replicates. All statistical analyses were done with the software R (R Development Core Team 2005).

Results

Epichloë Volatiles Analyses of headspace samples focused on three volatile compounds, chokol K, MME, and a trimethylester tentatively identified as MTE. The identification of MTE was done with MS-spectrum comparison from the NIST database and resulted in an 85.3% match of spectra (Fig. 2). Production of these volatiles are confined to the stroma tissue and could not be detected in samples taken from plant leaves or stems (data not shown). Chokol K and MME have been shown previously to attract *Botanophila* flies (Steinebrunner et al. 2008a). The third compound, MTE, is reported from *Epichloë* for the first time. MTE has not yet been shown to play a role in odor communication; however, due to its similar structure to MME and high abundance in some *Epichloë* associations, such a function seems likely. The rest of the headspace was made up of various other compounds for which no activity was indicated, and no attempts were made to identify them.

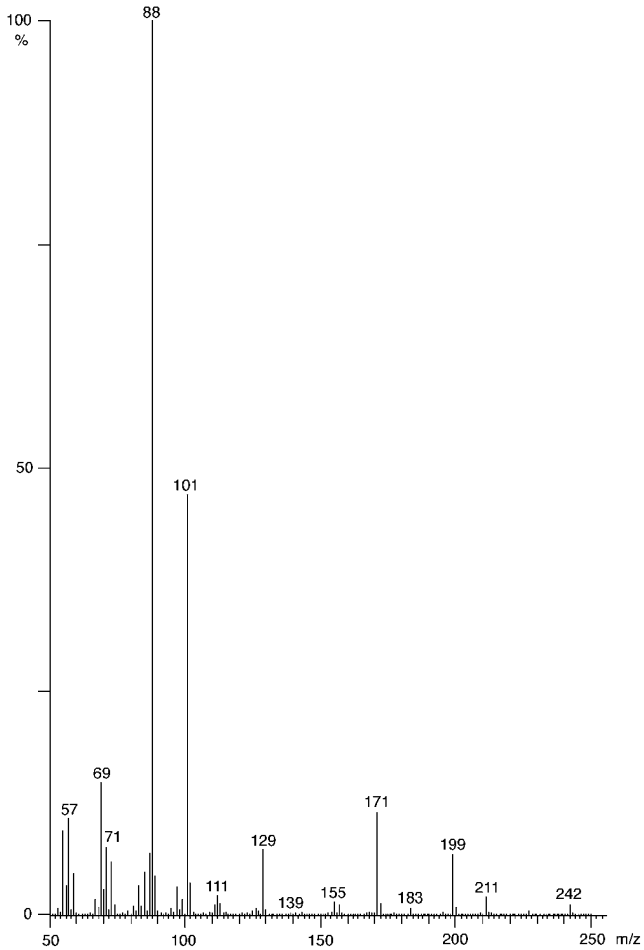

Fig. 2 Mass spectrum of the volatile compound from *Epichloë typhina* on *Puccinellia distans* identified as methyl 2,4,8-trimethylundecanoate (*MTE*) using the NIST database

Relative amounts of chokol K, as determined in headspace samples from fungal stromata, differed among the *Epichloë* species tested (Kruskal–Wallis test, χ=40.86, *df*=5, *P*< 0.001). Proportion of this compound was highest in *Epichloë sylvatica* (*Es*) comprising more than 56% on average of the total amount in headspace samples (Table 2). In other species, average amounts of chokol K were lower with 23% in *Epichloë clarkii* (*Ec*) and 10% in *E. typhina* (*Et*), while only trace amounts (<2%) were found in *Epichloë baconii* (*Eba*) and *Epichloë bromicola*. No chokol K at all was detected in samples from *Epichloë festucae* (*Ef*).

Chokol K production differed among the eight host races of *E. typhina* (Kruskal–Wallis test, χ=15.29, *df*=7, *P*= 0.018). Average emissions were relatively high from *E. typhina* stromata on *Anthoxanthum odoratum* (*Et–Ao*), *Brachypodium pinnatum* (*Et–Bp*), *Phleum pratense* (*Et–Php*), and *Poa trivialis* (*Et–Pt*) with proportions between 29% and 52% (Table 2). Lower emissions (<2%) were measured from stromata of *E. typhina* on *Dactylis glomerata* (*Et–Dg*), *Puccinellia distans* (*Et–Pd*), *Poa nemoralis* (*Et–Pn*), and *Poa pratensis* (*Et–Pp*). Exceptionally large genotypic differences were observed among accessions of the *Et–Bp* association with regard to the chokol K production: Five accessions were strong chokol producers (49.74%±9.27 SEM, *N*=5), while the other two produced only trace amounts (0.041%±0.01, *N*=2).

Proportions of the second volatile MME in headspace samples were also different among *Epichloë* species (Kruskal–Wallis test, χ=24.68, *df*=5, *P*<0.001). Only in samples from *E. festucae*, however, was the average amount high (39%), whereas in all other associations, no or little MME was found (Table 2). Interestingly, the other two volatiles were not detected in the *E. festucae* association.

The third volatile MTE showed a similar pattern of uneven distribution among *Epichloë* species (Kruskal–Wallis test, χ=11.35, *df*=5, *P*=0.045). With more than 57% on average, MTE was the main compound found in samples from *E. typhina* on *Puccinellia distans* (*Et–Pd*), where it appears to have replaced the other methyl ester MME. In all other associations, MTE did not exceed 3% of the total headspace (Table 2).

Principal component analysis (PCA) based on patterns of the three volatile compounds did not discriminate among *Epichloë* species, except for *E. festucae* (Fig. 3). *E. festucae* (*4*) was separated clearly from the other species owing to its unique pattern with the single dominating volatile MME. The correlation vectors show that a stronger correlation existed between chokol K and each of the methyl esters than between MME and MTE themselves. The greater length of the chokol K vector compared to the other vectors indicates that this compound is the best represented variable in the PCA.

Odor profiles of 14 *Epichloë* accessions representing seven host grasses were evaluated in 2 consecutive years. Mean year differences of volatile emissions were not significantly different from zero at 95% CI for all three compounds (chokol K, −4.8% to 13.53%; MME, 4.5% to 5.40%; MTE, −0.1% to 0.22%) suggesting that volatile production by a genotype is consistent and not affected by seasonal variations.

Headspace samples collected from axenic *Epichloë* cultures *in vitro* were screened for the three volatile compounds. Of these compounds, only chokol K was detected, but in small amounts and not in all isolates (Table 2). Chokol K was found in cultures of *E. sylvatica* (two isolates), *E. clarkii* (two isolates), and in most *E. typhina* associations (one to two isolates), but not in cultures of *E. bromicola* (two isolates), *E. baconii* (two isolates), and *E. festucae* (two isolates). Generally, genotypes that produced high levels of chokol K *in vivo* also produced chokol K *in vitro*. In addition, many isolates that

[a] For host abbreviations, see Table 1.

were found to produce no or only little chokol K under *in vitro* conditions produced a range of diterpenes that were not detected in headspace samples from stromata *in vivo*, notably, *E. baconii* from *Calamagrostis villosa* and *E. typhina* from *D. glomerata* (Table 2). Others produced neither chokol K nor diterpenes. These diterpenes are yet unidentified and are referred to in this study as unknown diterpenes (W. Boland, Jena, personal communication).

Phylogenetic Analysis The ML tree attempts to link the phylogeny of *Epichloë* species with observed odor profiles (Fig. 4). Following Craven et al. (2001), *Epichloë* species are grouped into two major clades: the "main group of *Epichloë* species" including *E. bromicola*, *E. baconii*, and *E. festucae* (at the base of the phylogram) and the "*E. typhina* complex" including *E. typhina* (with its host races), *E. clarkii*, and *E. sylvatica*. Here, we designate the well-supported, less basal subclade (88% bootstrap support) within the *E. typhina* complex as "*E. typhina* top clade" excluding the more basal *Et–Pn* and *Et–Pp* associations.

High levels of chokol K with a proportion of more than 10% in the headspace (levels 3 and 4) were found only in *Epichloë* accessions that were placed in the *E. typhina* top clade (Fig. 4). An exception was the accessions of *E. typhina* infecting *Puccinellia distans* from Poland (*Et–Pd*), whose profiles were dominated by MTE. All other accessions included in the more basal clades produced low amounts or no chokol K (levels 0 and 1). Regarding

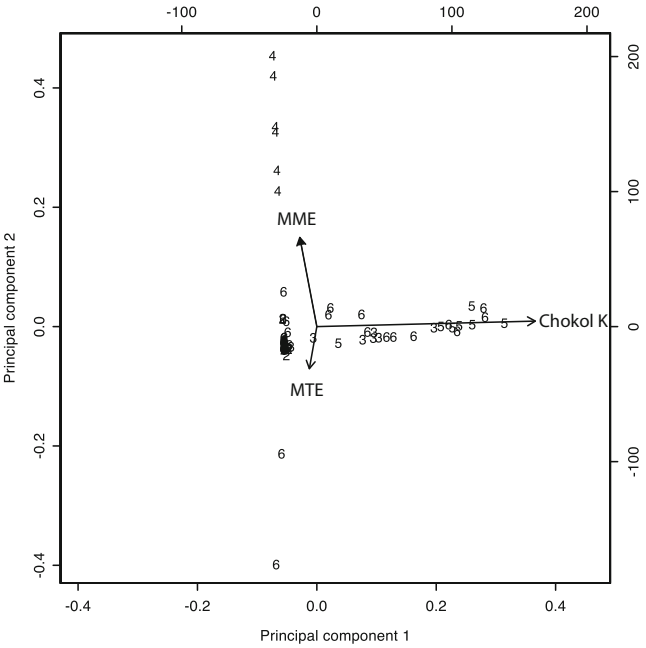

Fig. 3 Principal component analysis of odor compounds chokol K, methyl (*Z*)-3-methyldodec-2-enoate (*MME*), and methyl 2,4,8-trimethylundecanoate (*MTE*) found in headspace samples from stromata of different *Epichloë* species (1 *E. baconii*; 2 *E. bromicola*; 3 *E. clarkii*; *4 E. festucae*; *5 E. sylvatica*; *6 E. typhina*). The first two principal component analysis (*PCA*) factor loadings of the 93 analyzed accessions (genotypes) explain 73% of the total variance. *Correlation arrows* give the direction in which the relative amounts of odor compounds from particular genotypes increase. The *angles between the arrows* correspond to the correlation of the odor variables among each other, while the *arrow lengths* indicate how well a particular compound is represented in the dataset

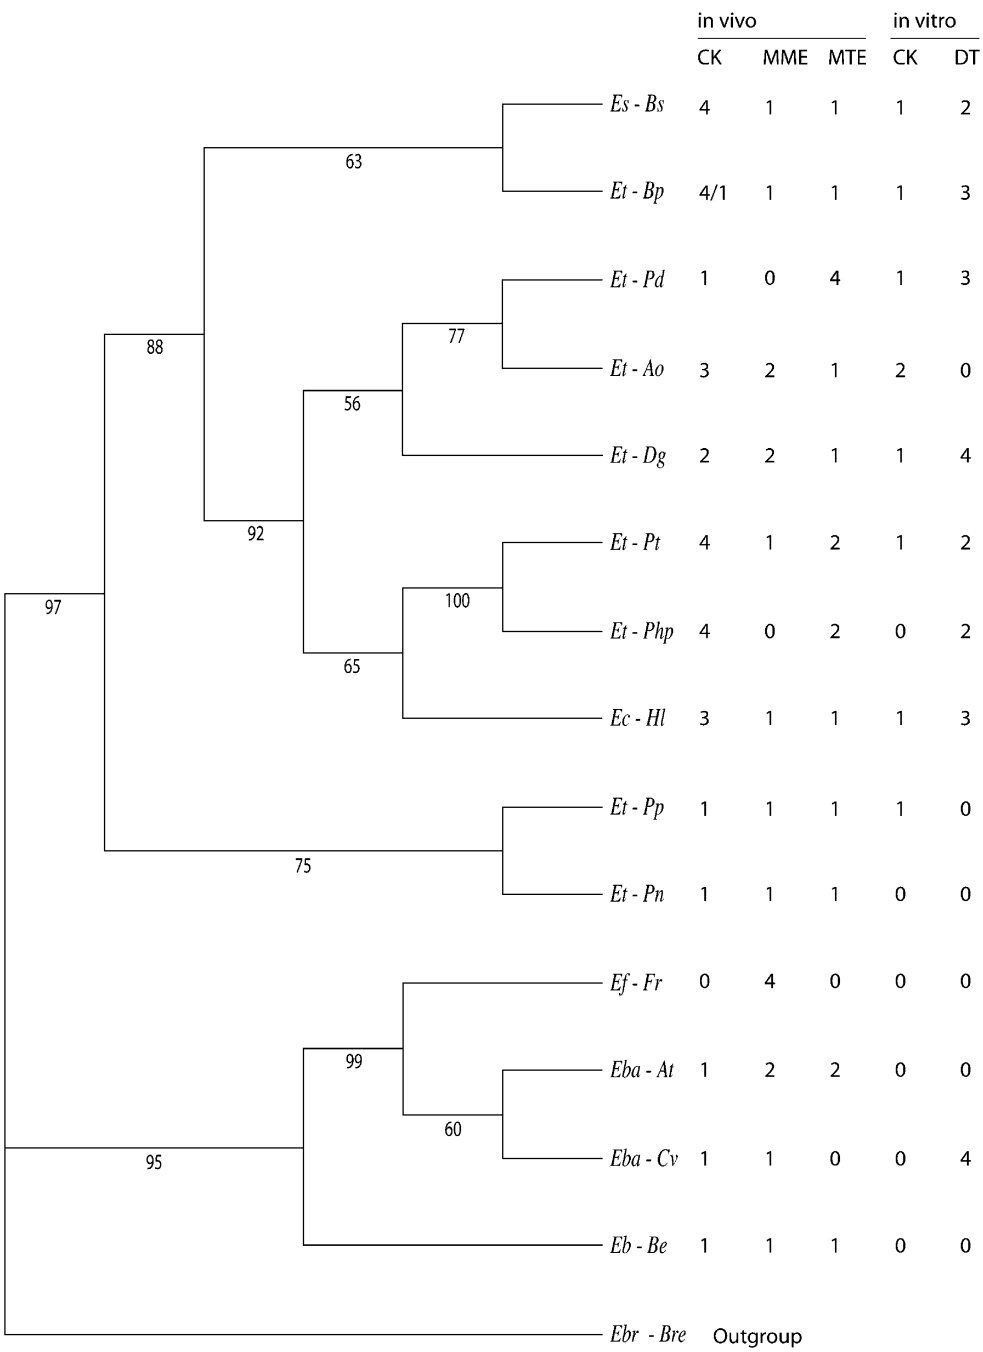

Fig. 4 Maximum likelihood tree (-ln 1600.19) based on fungal *tub2* sequences generated by PAUP*4.0b10 and using the K80+G model of evolution. *Numbers below the branches* are posterior probabilities (based on 1,000 bootstrap replications). Tabular figures at terminal positions indicate the relative abundance (*0* absent; *1* <1%; *2* 1–10%; *3* 10–30%; *4* 30–70%; *5* >70%) of odor compounds [*CK* chokol K; *MME* methyl (*Z*)-3-methyldodec-2-enoate; *MTE* methyl 2,4,8-trimethylundecanoate; *DT* unknown diterpenes] from *in vivo* and *in vitro* measurements. The tree is rooted with the outgroup taxon *E. brachyelytri* from *Brachyelytrum erectum* (*Ebr–Bre*). Other species and grass host abbreviations are as in Table 1

MME, low and moderate levels (0–2) were found in species of all major clades with one exception. The odor profile of *E. festucae* of the *Epichloë* main group was characterized by a high level of MME (level 4) as the dominant volatile. Similarly, the third volatile MTE was present in all major clades at low to moderate levels (0–2) with the exception of association *Et–Pd* mentioned above. The unknown diterpenes (DT) produced *in vitro* were present only in species of the top clade, again with one exception (*Eba–Cv* of the main group) and thus mostly occurred in parallel with high levels of chokol K *in vivo*.

Discussion

Evolution of odor profiles in *Epichloë* fungi may be complex, since host grass and fungal genotypes, the gamete transferring *Botanophila* flies, and even *Epichloë* mycoparasites may influence odor evolution. *Epichloë* species and host races examined in this study exhibited considerable variation in profiles of three volatile compounds, chokol K, MME, and MTE, that have a confirmed or likely role in odor communication. However, profiles overlapped among species, and only few associations exhibited distinct

profiles. Moreover, there was substantial variation within species, particularly in *E. typhina*, that naturally infects a range of different host species.

What is the Basis of Odor Variation? The plant material used in our study was from vegetatively propagated accessions, each representing an individual genotypic combination of a host and its systemic endophyte. Among naturally occurring associations, there is a high degree of host specificity, with many *Epichloë* species apparently forming host races or cryptic species on different hosts (Schardl et al. 2007; Zabalgogeazcoa et al. 2008). Observed variations in odor profiles among and within species may, therefore, be attributed to these more or less stable associations. However, with the sampling scheme used in this study, it is not possible to differentiate between host and fungus contributions to odor variation in *Epichloë* species that infect multiple hosts, such as *E. typhina*. To answer this question, a particular endophyte genotype would have to be introduced into different host species experimentally. In closely related *Neotyphodium* endophytes, investigations on the genetic control of toxic alkaloid secondary metabolites have been made by using experimental infections or reciprocal crosses between infected host plants. These investigations suggested that the ability to produce alkaloids is a property of the fungal genotype, but that the levels of fungal alkaloids may be modified to some extent by plant genotype (Hill et al. 1991; Roylance et al. 1994; Easton et al. 2002), while the influence of environmental factors is usually small (Agee and Hill 1994). In another study that compared endophyte haplotypes in different host genotypes, the host grass significantly influenced alkaloid production (Faeth et al. 2002). In our study, levels of chokol K and MME collected from the same host–fungus associations in different years remained almost constant between years, suggesting that there is a genetic basis for the observed odor variation and that environmental factors may play a minor role.

In vitro studies may be useful to dissect fungus and plant influences on production of odor compounds. In the present study, only chokol K, but not MME and MTE, were produced under *in vitro* conditions (Table 2). These findings confirm results from a previous study, which suggested that chokol K production was genetically encoded in *Epichloë*, but that for the methylester MME precursory substances of plant origin may be needed (Steinebrunner et al. 2008b). Alternatively, plant-specific signaling may be required for expression of genes involved in the biosynthetic pathway of MME and MTE, as has been shown for the endophyte produced secondary metabolite peramine that protects host plants from insect herbivory (Tanaka et al. 2005) and for an indole-diterpene mycotoxin of *Neotyphodium lolii* (Young et al. 2006). Moreover, in pure culture when host influences are eliminated, chokol K was detected only in species of the *E. typhina* complex but was not produced by other *Epichloë* species of the main clade, suggesting that species depend differently upon plant signaling.

Phylogenetic Analysis Mapping of odor compounds into the corresponding phylogenetic tree of *Epichloë* taxa did not show a strong phylogenetic signal of odor profiles. However, there was a tendency for *Epichloë*–grass associations in the *E. typhina* top clade to produce high levels of chokol K (Fig. 4), suggesting that chokol K production was favored early in the speciation of *E. typhina*. However, weak and strong chokol K producing genotypes of *E. typhina* were sometimes found within the same association, notably *E. typhina* on *B. pinnatum*, while for association *Et–Pd*, only low levels of chokol K were observed. A phylogeny based on odor alone showed a different tree topology, although it was poorly resolved (data not shown). Incongruence between odor phenotypes and the genetic relationship of the producer have been reported for various plants (Williams and Whitten 1999; Barkman 2001; Levin et al. 2003). It has been argued that environmental variation, adaptation to pollinators, and biosynthetic interrelation of compounds would make it difficult to use odor as a character for phylogenetic inference (Levin et al. 2003). Our study did not put the emphasis on validating odor characters for phylogenetic tree reconstruction but on combining DNA sequence and odor information to locate possible evolutionary key events in the phylogeny of *Epichloë*. Such an event may have been the ability to produce high amounts of chokol K, which occurred at the base of the *E. typhina* top clade after branching from the more basal *E. typhina* host races (*Et–Pp*, *Et–Pn*). Chokol K appears to play a role in the attraction of gamete transferring *Botanophila* flies (Schiestl et al. 2006; Steinebrunner et al. 2008a), and its increased production by *E. typhina* may have favored host range expansion and evolution of new host races.

Variability of Odor Profiles within and among Species Although there was some structuring with regard to compound levels, odor profiles based on chokol K, MME, and MTE mostly overlapped among species (Fig. 3). Exceptions were the profile of *E. festucae* that was characterized by the dominance of methyl ester MME and the profile of the *Et–Pd* association that showed a high level of MTE instead of MME. Thus, *Epichloë* taxa appear to be little differentiated at the species level with respect to odor profiles, but high variability was observed among genotypes, particularly in associations with *E. typhina*. Several studies have assessed variability of flower odors among plant species and investigated the use of odor profiles for

drawing species boundaries (Azuma et al. 1997; Williams and Whitten 1999; Levin et al. 2003; Raguso et al. 2003; Huber et al. 2005). While some of these studies found that each species had its own unique profile (Levin et al. 2003; Huber et al. 2005), others reported a high degree of homoplasy (Williams and Whitten 1999).

Odor emission by *Epichloë* stromata is thought to be important for the attraction of gamete-transferring *Botanophila* flies, and thus, patterns or levels of compounds may be selectively adaptive. In a trapping study that used synthetic versions of chokol K and MME, attraction of *Botanophila* flies was increased with increasing amounts of these compounds (Steinebrunner et al. 2008a), suggesting that high-odor emission would be advantageous. However, different, taxonomically closely related *Botanophila* species showed no preference for specific blends that represented different *Epichloë* taxa, notably *E. clarkii* with high levels of chokol K and *E. festucae* with high levels of MME.

The variability in odor profiles observed among genotypes of *E. typhina* from different accessions may be viewed in the light of Thompson's geographical mosaic theory. This theory predicts that geographic differences in interactions among local selection pressures, genetic drift, and migration create a range of possible outcomes (Thompson 1999). For example, the distinct MTE dominated odor profile in the *Et–Pd* association from Poland may be the result of different selection pressures imposed by the local environment, the *Botanophila* gametic vectors, or the host plant. *Puccinellia distans* is a halophyte naturally occurring on marine and inland salines, but infected plants examined in this study originated from highly disturbed anthropogenic habitats in the vicinity of an industrial plant (Lembicz 1998; Olejniczak and Lembicz 2007). Thus, migration of an *Et–Pd* association into this unusual environment and the interaction with the locally occurring *Botanophila* flies may have resulted in the distinct profile observed for these genotypes. Unfortunately, this hypothesis could not be confirmed because stroma-forming plants of *Puccinellia* are rare outside the industrial sites and were not available. However, local adaptation of the asexual *Neotyphodium* stage in terms of alkaloid production or herbivore defense has been documented in *Achnatherum robustum* (Faeth et al. 2006) and in a subarctic fescue (Koh and Hik 2007), suggesting that local adaptation may be a common occurrence in endophyte/grass symbiota.

Chokol K is not only involved in odor communication with *Botanophila* flies but, based on its antifungal properties, may also play a role in protecting *Epichloë* stromata from mycoparasites (Schiestl et al. 2006; Steinebrunner et al. 2008b). High levels of chokol K typically found in associations of the *E. typhina* top clade may have also been selectively favored under circumstances of intensive mycoparasite pressure. However, it is not known whether *E. typhina* associations are exposed to such pressure more often compared to the other species and whether mycoparasite resistance is adaptive.

Finally, differences at the *Epichloë* population level may leave a signature on odor profiles. Depending on whether populations are large or small, selection pressures on volatile production may be enhanced or relaxed. Thus, in small disjunctive populations, *Botanophila* flies will have to be attracted over a wider distance to guarantee outcrossing, which may select for increased odor production. Moreover, population size differences among species and locations could facilitate genetic drift.

In summary, profiles of three odor compounds produced by *Epichloë* stromata were often distinctive for particular grass–*Epichloë* associations but did not discriminate at the species level, except for *E. festucae*. Although there was some hierarchical structuring regarding levels of chokol K emission based on the *Epichloë* phylogeny, odor profiles appeared to be largely dependent on particular *Epichloë*–host associations. The observed profiles may be the result of complex selective pressures imposed by *Botanophila* gametic vectors, local environment, and mycoparasites. Future studies should focus on dissecting genetic and environmental factors responsible for the production of odor compounds and on testing host and *Epichloë* genotype contributions with experimentally manipulated associations by using cross-infections.

Tritrophic Effects of Xanthotoxin on the Polyembryonic Parasitoid *Copidosoma sosares* (Hymenoptera: Encyrtidae)

Evan C. Lampert · Arthur R. Zangerl · May R. Berenbaum · Paul J. Ode

Received: 23 August 2007 / Revised: 29 January 2008 / Accepted: 6 April 2008 / Published online: 4 June 2008

Abstract Plant chemistry can have deleterious effects on insect parasitoids, which include the reduction in body size, increased development time, and increased mortality. We examined the effects of xanthotoxin, a linear furanocoumarin, on the polyembryonic encyrtid wasp *Copidosoma sosares*, a specialist parasitoid that attacks the parsnip webworm, *Depressaria pastinacella*, itself a specialist on furanocoumarin-producing plants. Furanocoumarins, allelochemicals abundant in the Apiaceae and Rutaceae, are toxic to a wide range of herbivores. In this study, we reared parasitized webworms on artificial diets containing no xanthotoxin (control) or low or high concentrations of xanthotoxin. Clutch sizes of both male and female *C. sosares* broods were more than 20% smaller when they developed in hosts fed the diet containing high concentrations of xanthotoxin. Xanthotoxin concentration in the artificial diet had no effect on the development time of *C. sosares*, nor did it have an effect on the body size (length of hind tibia) of individual adult male and female *C. sosares* in single-sex broods. Webworms fed artificial diets containing low or high concentrations of xanthotoxin were not significantly smaller, and their development time was similar to that of webworms fed a xanthotoxin-free diet. Mortality of webworms was not affected by xanthotoxin in their artificial diet. Therefore, dietary xanthotoxin did not appear to affect *C. sosares* via impairment of host health. However, unmetabolized xanthotoxin was found in *D. pastinacella* hemolymph where *C. sosares* embryos develop. Hemolymph concentrations were fourfold greater in webworms fed the high-xanthotoxin-containing diet than in webworms fed the low-xanthotoxin-containing diet. We failed to detect any xanthotoxin metabolism by either *C. sosares* embryos or precocious larvae. Therefore, the observed tritrophic effects of xanthotoxin are likely to be due to the effects of xanthotoxin after direct contact in the hemolymph rather than to the effects of compromised host quality.

Introduction

The development of insect parasitoids is often influenced by the diet of their hosts. When hosts are herbivorous insects, plant defensive chemistry can adversely affect the fitness of third and sometimes higher (e.g., Harvey et al. 2003) trophic levels (Ode 2006). The diet of the host insect may affect developing parasitoids indirectly by altering host suitability or directly by exposing the parasitoid to unmetabolized defensive chemicals.

Numerous studies suggest negative associations between plant chemistry and/or plant species identity and parasitoid fitness measures in the field (reviewed in Ode 2006).

Whereas correlative studies are relatively numerous, few studies have explicitly demonstrated that plant chemistry is responsible for the oft-observed negative correlations between levels of plant defensive chemistry and parasitoid fitness proxies (Ode 2006). A handful of investigators have used artificial diets, to which known quantities of specific plant allelochemicals were added, to establish a cause-and-effect relationship between plant chemistry and parasitoid fitness. For instance, the ichneumonid *Hyposoter exigua* Viereck suffered morphological deformities, increased mortality and development time, and decreased body size and longevity when reared from the noctuid *Helicoverpa zea* (Boddie) larvae feeding on diets containing high concentrations of the alkaloid α-tomatine (Campbell and Duffey 1979, 1981). Another series of studies documented the negative effects of dietary nicotine supplements on the generalist parasitoid *Hyposoter annulipes* (Cresson) and the specialist braconid parasitoid *Cotesia congregata* (Say) (Thurston and Fox 1972; Barbosa et al. 1986, 1991; El-Heneidy et al. 1988).

In this study, we used artificial diets to explore the tritrophic effects of the furanocoumarin xanthotoxin on several fitness correlates of the polyembryonic wasp, *Copidosoma sosares* (Walker) (Hymenoptera: Encyrtidae). Like all copidosomatine encyrtids (Strand et al. 1991), *C. sosares* is a polyembryonic egg-larval parasitoid (Hardy 1996; Ode et al. 2004; Guerrieri and Noyes 2005). *C. sosares* produces three types of broods: all male, all female, and mixed sex. All-male and all-female broods result from a single unfertilized or fertilized egg, respectively; mixed-sex broods develop from one egg of each sex (Hardy 1996; Ode et al. 2004). As the host continues its larval development, *C. sosares* eggs proliferate clonally, resulting in 100 to 400 genetically identical offspring (Ode et al. 2004). The vast majority of embryos undergo morphogenesis during the host's last instar, completely consuming the host except for the exoskeleton, thus forming a "mummy" (Hardy 1996). As the mummy is formed, the *C. sosares* larvae begin to pupate. Typically, adult wasps emerge 10–12 d later. One or two embryos develop early (during the earlier host instars) into "precocious" or "soldier" larvae (Hardy 1996). In the well-studied congener *C. floridanum* (Ashmead), soldier larvae are implicated in defending reproductive individuals against multiparasitoids (Harvey et al. 2000) and superparasitoids (Giron et al. 2004) as well as in mediating conflicts over sex ratio in mixed-sex broods (Grbić et al. 1992).

C. sosares is a specialist parasitoid of the parsnip webworm, *Depressaria pastinacella* (Duponchel) (Lepidoptera: Elachistidae). The parsnip webworm is a specialist herbivore that feeds on reproductive structures of plants in the genera *Pastinaca* and *Heracleum* (Apiaceae), both of which are rich in furanocoumarins (Berenbaum and Zangerl 2006). Field studies conducted in western Europe, where this system is native, showed that two furanocoumarins are negatively associated with fitness correlates of *C. sosares* (Ode et al. 2004). Webworms feeding on host plants containing higher levels of isopimpinellin were less likely to be successfully parasitized by *C. sosares*; survivorship as well as clutch size of *C. sosares* broods were reduced when developing in webworms that fed on plants containing higher xanthotoxin levels.

Furanocoumarins are toxic to a wide range of herbivores (Berenbaum 1990; Berenbaum and Zangerl 1996). In addition to tritrophic effects observed in the field (Ode et al. 2004), laboratory studies that use artificial diets demonstrate tritrophic effects on two other insect parasitoids. Survivorship of *C. floridanum* decreased when their generalist hosts *Trichoplusia ni* (Hübner) (Lepidoptera: Noctuidae) fed on an artificial diet with high concentrations of a mixture of three furanocoumarins: bergapten, psoralen, and xanthotoxin (Reitz and Trumble 1996). Similarly, *Archytas marmoratus* (Townsend) (Diptera: Tachinidae) experienced reduced survivorship when its host, *Spodoptera exigua* (Hübner) (Lepidoptera: Noctuidae), was reared on an artificial diet with the same high-concentration mixture (Reitz and Trumble 1997).

The observed tritrophic effects of furanocoumarins on *C. sosares* may be the result of compromised webworm quality if the costs of detoxification or excretion are sufficient to reduce the nutritional quality or size of the webworm. Alternatively or in addition, some furanocoumarins may pass, unmetabolized, into the hemolymph of the webworm where developing *C. sosares* embryos would directly encounter these potentially toxic compounds. Webworms fed an artificial diet containing 0.3% fresh weight xanthotoxin had trace amounts of xanthotoxin in their hemolymph, and webworms feeding on *P. sativa* fruit had trace amounts of six furanocoumarins in their hemolymph. These findings suggest that immature *C. sosares* do encounter these compounds (McGovern et al. 2006). Moreover, metabolism assays failed to show any ability of *C. sosares* larva to metabolize xanthotoxin (McGovern et al. 2006).

We manipulated the amount of xanthotoxin present in artificial diets fed to parasitized webworms to establish the effects of xanthotoxin on *C. sosares*. Given the negative correlations between xanthotoxin and *C. sosares* fitness proxies observed in the field, we also measured the amount of unmetabolized xanthotoxin present in the webworm hemolymph. Although *C. sosares* larvae apparently are incapable of metabolizing xanthotoxin (McGovern et al. 2006), they spend a majority of their developmental time as polygerms (embryos) or precocious larvae. Host larvae continue to feed as the *C. sosares* polygerm proliferates, potentially exposing developing *C. sosares* directly to chemicals from the host's diet. Precocious larvae could

also potentially detoxify furanocoumarins that their reproductively destined clone mates would otherwise encounter. Therefore, we examined the ability of *C. sosares* embryos and precocious larvae to metabolize xanthotoxin.

Methods and Materials

Effect of Xanthotoxin on C. sosares Approximately 200 adult female and male *C. sosares* were collected as they emerged from 100 field-collected mummies from 45 cow-parsnip (*Heracleum lanatum* Michx.) plants in July 2005 from two sites (N 44°05′, W 103°38′ and N 44°25′, W 103° 53′) 44.3 km apart in the in the Black Hills National Forest. Males and females were allowed to mate and placed at 5°C and a 8:16-hr light/dark photoperiod for 4 mo to break the reproductive diapause. After this period, *C. sosares* females were placed individually into 100-mm-diameter plastic Petri dishes for 24 hr and allowed to oviposit in freshly laid webworm eggs on parsnip leaves. Neonate parasitized webworms hatched 6–7 d later. Approximately 100 additional mated adult females were collected with a handheld aspirator from the same sites in the Black Hills National Forest on 18 June 2006. Females were transported back to the laboratory where they were allowed to oviposit in freshly laid webworm eggs as described above. Webworms collected from *H. lanatum* in the Black Hills National Forest were the source of the host eggs used in both years. Once webworm eggs hatched, a trimmed paintbrush was used to place individual neonate larvae randomly into 44-ml diet cups (Solo®). Diet cups contained ~15 ml of semidefined artificial either with no xanthotoxin (control), a low (0.313 ng/μg fresh weight diet), or a high concentration of xanthotoxin (4.71 ng/μg fresh weight). These concentrations reflect the range of xanthotoxin concentrations observed in our field collections of *H. lanatum* seed material throughout the western USA (unpublished data). Furanocoumarins were dissolved in 50–150 ml acetone. α-Cellulose was placed in the furanocoumarin–acetone mixture and left in a fume hood 1–2 d to dry completely before incorporation into the artificial diet (Nitao and Berenbaum 1988). Parasitized webworms were allowed to develop in a growth chamber set to 27°C and a 16:8-hr light/dark photoperiod.

Cups containing parasitized webworms were checked daily, and the dates at which mummies were formed were recorded. Mummies were placed individually into 18× 180-mm glass tubes stopped with cloth plugs and returned to the growth chamber. They were checked daily until adult wasps emerged, whereupon the date was recorded, and the wasps were frozen at −20°C until clutch size and body size could be measured. The number of emerged adult wasps of each sex was counted, as were the numbers of unemerged adults, pupae, and larvae inside mummies. Clutch size was calculated as the total number of individual *C. sosares* per host (i.e., the primary clutch size (sensu Ode and Strand 1995)): emerged plus unemerged adults (secondary clutch size), pupae, and larvae. Within-brood mortality was calculated as the total number of dead pupae and larvae divided by the primary clutch size. Mummies that failed to produce any emerged adults by 30 d postmummy formation were dissected, and body size and sex of any unemerged adults were recorded along with primary clutch size and within-brood mortality. Both metatibiae were removed from 10 randomly selected wasps of each sex from each mummy and measured with an ocular micrometer at ×50 magnification. Lengths of both tibiae were averaged for each wasp, and the measurements from 10 wasps were averaged for each mummy. Tibial length was chosen as a measure of body size, as tibial length correlates strongly with egg load and male mating ability in the congener *C. floridanum* (Ode and Strand 1995).

The effects of diet composition and sexual composition (all male, all female, and mixed sex) on primary clutch size and development time were analyzed separately with two-way analyses of variance (ANOVAs; PROC GLM; SAS Institute 2003). The effect of diet composition on within-brood mortality was analyzed with a logistic model that treated the response, mortality, as a binomial count (PROC LOGISTIC; SAS Institute 2003). The effect of diet composition on body size was analyzed with an analysis of covariance, with clutch size as a covariate. Tukey's honestly significant difference (HSD) multiple comparisons tests were performed when the overall test was significant (PROC GLM; SAS Institute 2003).

Xanthotoxin Effects on Host Quality Effects of xanthotoxin on *C. sosares* may be the result of compromised host quality. To examine this possibility, we randomly assigned unparasitized neonate parsnip webworms individually to one of the three artificial diets as described. Cups with unparasitized webworms were examined each morning for the formation of pupae. The sex of pupae was determined by the location of the bursal scar (Nitao and Berenbaum 1988); the scar is on the ninth abdominal tergite in males and eighth abdominal tergite of females. Pupae whose sex could not be determined were removed from the analyses. Pupal mass was recorded to the nearest 0.0001 g with an analytical balance. After measurements, pupae were placed individually into empty diet cups in the growth chamber until moths emerged, and the total number of days from the time that neonates were placed on diet until emergence of adult moths was recorded. The effects of diet and gender on *D. pastinacella* pupal mass and development time were analyzed with separate two-way ANOVAs (PROC GLM;

SAS Institute 2003). Pupae that failed to emerge after 30 d were dissected to determine whether death occurred before or after an adult developed inside. The mortality of *D. pastinacella* was calculated as the proportion of neonates that failed to develop into adult moths; mortality was compared across the three artificial diets with a likelihood ratio chi-square test (PROC FREQ; SAS Institute 2003).

Webworm Hemolymph Analysis To quantify unmetabolized xanthotoxin encountered by developing *C. sosares* embryos and precocious larvae, we removed parasitized fourth-instar webworms (*C. sosares* individuals are either embryos or precocious larvae at this point) from each diet treatment (26 total=nine from low-xanthotoxin diets, 17 from high-xanthotoxin diets). Webworms were anesthetized with CO_2, and prolegs were snipped with fine spring scissors. Hemolymph drained from these wounds was drawn with a pipette and transferred into 0.5-ml centrifuge tubes.

Webworms from which hemolymph was collected were dissected lengthwise in physiological saline, and any *C. sosares* precocious larvae and polygerms were removed and placed separately into 1.5-ml sample tubes. Precocious larvae (three samples from low-xanthotoxin diet and four from high-xanthotoxin diet) and polygerm (five samples from low-xanthotoxin diet and five from high-xanthotoxin diet) were frozen at −80°C until metabolic assays could be run (see below). Hemolymph samples plus the tubes in which they were contained were weighed to the nearest milligram and dried in a lyophilizer, and the residues were extracted with 30 μl methanol. The tubes from which the samples were drawn were washed, dried, and reweighed to quantify the fresh mass of hemolymph analyzed. Ten microliters of the extract was analyzed by high-pressure liquid chromatography (HPLC; Waters, Milford, MA, USA, gradient HPLC, with diode-array detector and autosampler). Solvent A was 1% formic acid in water, and solvent B was acetonitrile (linear gradient from 85% A to 100% B over 30 min, followed by 5 min at 100% B, flow rate 1 ml min^{-1}). Furanocoumarins were separated with a C-18 column (Shiseido, Capcell, 4.5×250 mm, 5-μm particles). Differences in hemolymph titers of xanthotoxin (ng mg^{-1} fresh weight of hemolymph) among webworms reared on the different diets were analyzed with an ANOVA (PROC GLM; SAS Institute 2003).

Metabolism of Xanthotoxin by C. sosares Embryos and Precocious Larvae Despite encountering furanocoumarins in host hemolymph, *C. sosares* larvae do not exhibit detectable metabolic detoxification of xanthotoxin (McGovern et al. 2006). To examine the possibility that embryos and/or precocious larvae are able to detoxify xanthotoxin, collected embryos and precocious larvae (see above) were analyzed according to McGovern et al. (2006). In brief, samples were homogenized and incubated for 30 min at 30°C in a reaction mixture that contained 500 ng xanthotoxin and an NADPH-regenerating system. The reactions were halted by adding 0.1 N HCl. Ten microliters of each reaction mixture was removed for protein quantification by using a dye assay (BioRad, Hercules, CA, USA) before HPLC analysis of unmetabolized furanocoumarins (extracted with 300 μl of ethyl acetate).

Results

Effect of Xanthotoxin on C. sosares Experiments that examined the effects of xanthotoxin on *C. sosares* clutch size, survivorship, and body size were repeated in 2005 and 2006. In none of the analyses was the year in which the experiment was conducted significant ($P>0.2$ in all tests). Therefore, we pooled data across 2005 and 2006 in the analyses presented below. A total of 269 *C. sosares* broods developed on the three diets: 28 all male, 27 all female, and three mixed sex on the control diet; 56 all male, 36 all female, and six mixed sex on low xanthotoxin; and 74 all male, 31 all female, and eight mixed sex on high-xanthotoxin diets.

C. sosares that developed in webworms fed with the artificial diet with a high concentration of xanthotoxin produced smaller primary clutch sizes than those that developed in webworms fed with diets with low xanthotoxin concentrations or no xanthotoxin (Fig. 1; $F_{2,\ 260}=$

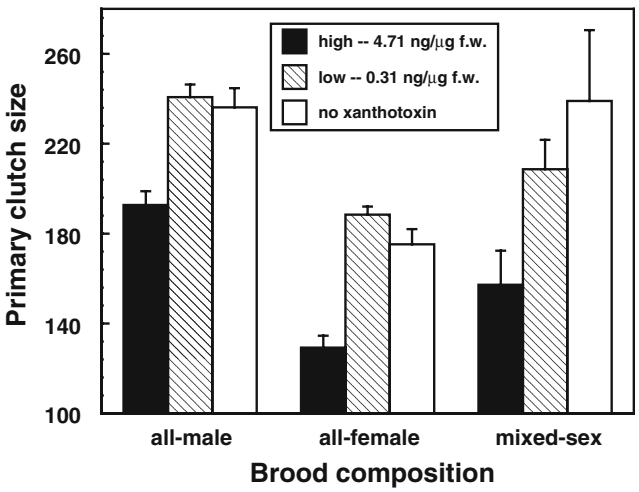

Fig. 1 Effects of dietary xanthotoxin on the mean (±SEM) primary clutch sizes (see text for explanation) of all-male, all-female, and mixed-sex broods of *Copidosoma sosares*. Clutch sizes from webworms fed a high-xanthotoxin diet were significantly smaller than clutch sizes from either the low-xanthotoxin or xanthotoxin-free diets; clutch sizes from the low-xanthotoxin and xanthotoxin-free diets did not differ (Tukey's HSD multiple comparisons test)

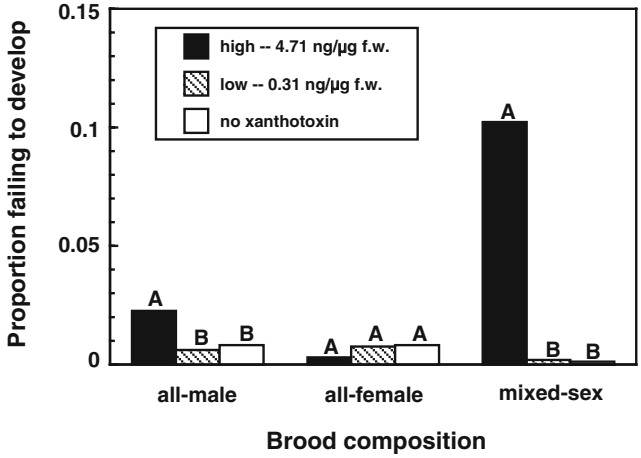

Fig. 2 Effects of dietary xanthotoxin on the proportion of the primary clutch that failed to develop into adults of all-male, all-female, and mixed-sex broods of *Copidosoma sosares*. Within each brood type (all-male, all-female, and mixed-sex), bars with different letters indicate significantly different odds of larval mortality as a function of diet type. Data were analyzed with logistic regression models (see text)

24.60, $P<0.001$). All-male and mixed-sex clutch sizes were larger than all-female clutch sizes irrespective of diet on which they were reared ($F_{2,\ 260}=54.60$, $P<0.001$). Xanthotoxin concentration in the artificial diet had a similar effect on all-male, all-female, and mixed-sex broods (diet×sex interaction $F_{4,\ 260}=0.70$, $P=0.594$).

Within-brood mortality was affected by the concentration of xanthotoxin in the diet (diet term: Wald $\chi^2=45.58$, $P<0.001$), and this effect differed among the three types of *C. sosares* broods (diet×sex interaction term: Wald $\chi^2=71.85$, $P<0.001$; Fig. 2). Whereas the odds of an individual female surviving to adulthood in an all-female brood were not influenced by diet composition (Wald $\chi^2=4.02$, $P=0.134$), this was not the case for individuals in all-male or mixed-sex broods. The odds of an individual male failing to complete development to adulthood in a host on a high-xanthotoxin diet were 3.3 times greater than the odds for developing in a host fed a xanthotoxin-free diet (Wald $\chi^2=69.37$, $P<0.001$) but did not differ between low-xanthotoxin and xanthotoxin-free diets (Wald $\chi^2=3.10$, $P=0.078$). Likewise, the odds of an individual in a mixed-sex brood failing to complete development in a webworm fed a high-xanthotoxin diet was nearly 58 times greater than the odds of failing to complete development on a xanthotoxin-free diet (Wald $\chi^2=16.25$, $P<0.001$); the odds of larval mortality did not differ between the low-xanthotoxin and xanthotoxin-free diets (Wald $\chi^2=0.0123$, $P=0.912$). Larval survivorship to adulthood was 89% or above in all cases (Fig. 2).

After accounting for the effects of clutch size and diet, individual females were larger than males (male tibial length=0.54±0.01 mm; female=0.48±0.01 mm; $F_{1,\ 241}=233.72$, $P<0.001$). Neither artificial diet type nor the interaction with sex affected body size (diet: $F_{2,\ 241}=1.37$, $P=0.256$; diet×sex: $F_{2,\ 241}=0.72$, $P=0.486$).

Although individuals in all-female and mixed-sex broods developed more quickly than individuals in all-male broods (male=40.6±3.4 d; female=37.7±3.4 d; mixed=34.0±3.2 d; $F_{2,\ 257}=13.87$, $P<0.001$), xanthotoxin concentration had no effect on the amount of time parasitized webworms fed on diet (diet: $F_{2,\ 261}=2.32$, $P=0.101$; diet×sex: $F_{4,\ 261}=2.05$, $P=0.088$).

Xanthotoxin Effects on Host Quality A total of 241 *D. pastinacella* successfully pupated on the experimental diets: 23 male and 21 female moths on the xanthotoxin-free diet, 41 male and 58 female moths on the low-xanthotoxin diet, and 46 male and 52 female moths on the high-xanthotoxin diet.

The amount of xanthotoxin added to the artificial diet had no effect on the mass of *D. pastinacella* pupae ($F_{2,\ 234}=2.15$, $P=0.520$). Likewise, after adjusting for the effects of xanthotoxin, males and females did not differ in pupal mass nor in how mass responded to dietary xanthotoxin (sex: $F_{1,\ 234}=0.11$, $P=0.743$; sex×diet: $F_{2,\ 234}=0.66$, $P=0.520$). The number of days from when neonates were placed on the diet until moth emergence was not influenced by xanthotoxin in the diet ($F_{2,\ 154}=0.25$, $P=0.779$). Development time from neonates until adulthood did not differ between males and females ($F_{1,\ 154}=1.05$, $P=0.306$). Development time of males and females did not differentially respond to diet composition ($F_{2,\ 154}=0.70$, $P=0.497$). Finally, mortality rates of *D. pastinacella* were similar across the control, low-xanthotoxin, and high-xanthotoxin diets (likelihood ratio $\chi^2=3.47$, 2 *df*, $P=0.177$).

Webworm Hemolymph Analysis Hemolymph from webworms fed with the artificial diet high in xanthotoxin (4.71 ng/µg fresh weight) had almost four times the unmetabolized xanthotoxin concentration as hemolymph from webworms fed with the artificial diet low in xanthotoxin (0.313 ng/µg fresh weight; Fig. 3; $F_{1,\ 15}=7.11$, $P=0.018$).

Metabolism of Xanthotoxin by C. sosares Embryos and Precocious Larvae Neither *C. sosares* embryos nor precocious larvae showed any detectable levels of metabolic detoxification of xanthotoxin. Of 34 reactions, only 17 showed detectable levels of protein ranging from 34 to 4,700 mg. The amount of unmetabolized xanthotoxin remaining after the metabolic assays of both *C. sosares* embryos and precocious larvae was no different from the mean of the four time-zero controls (*t* test, $t=0.013$, $P=0.99$). Comparison of the eight reactions with more than 1 mg of protein to time-zero controls gave a similar result ($t=0.252$, $P=0.807$).

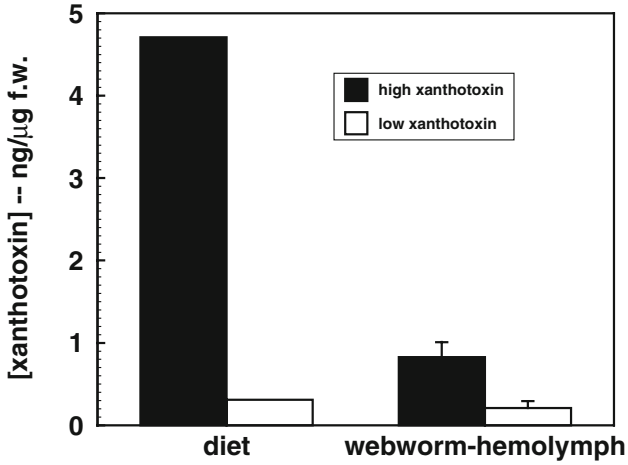

Fig. 3 Unmetabolized xanthotoxin (ng/μg fresh weight hemolymph) in *Depressaria pastinacella* hemolymph fed with a high-xanthotoxin (4.71 ng/μg fresh weight) artificial diet or a low-xanthotoxin (0.313 ng/μg fresh weight) artificial diet

Discussion

A previous field study that examined the correlation between the concentration of seven furanocoumarins in the host plants, *Pastinaca sativa* and *Heracleum sphondylium* (a common host plant in Europe), and the fitness measures of *C. sosares* showed that one furanocoumarin, xanthotoxin, was negatively correlated with clutch size as well as within-brood survivorship (Ode et al. 2004). In this study, we demonstrate that xanthotoxin added to an artificial diet consumed by webworms is responsible for both of these tritrophic correlations observed in the field. Clutch sizes from webworms reared on an artificial diet with a high level of xanthotoxin were 20–30% smaller than those reared on diets containing 15-fold less xanthotoxin or on a xanthotoxin-free diet. Further corroborating observed correlations in the field (Ode et al. 2004), our results demonstrate that within-brood survivorship of all-male and mixed-sex broods but not of all-female broods was reduced by high levels of xanthotoxin in diets compared to low levels or xanthotoxin-free diets. However, while the effects of xanthotoxin are statistically significant, within-brood larval mortality was low across all brood type and diet combinations relative to observed survivorship of field-collected broods (cf. Ode et al. 2004), suggesting that factors other than xanthotoxin have an impact on larval mortality of *C. sosares*.

Specialist parasitoids are less strongly affected by plant defensive chemistry than generalist parasitoids (Gunasena et al. 1990; Barbosa et al. 1991; Harvey et al. 2003, 2005; Sznajder and Harvey 2003). However, despite being a highly specialized parasitoid of a specialist herbivore, *C. sosares* exhibited significant variation in clutch size and survivorship in response to variation in the concentration of xanthotoxin in the host diet. Similarly, Barbosa et al. (1991) found that nicotine resulted in increased mortality in the specialist parasitoid *C. congregata*, whereas its sphingid host, *Manduca sexta* L., was not as strongly affected. Such studies suggest that specialist parasitoids are not necessarily immune to the negative effects of plant chemistry.

Whereas xanthotoxin has demonstrable effects on *C. sosares* fitness proxies, we were unable to detect any negative effects on host quality in terms of reduced webworm mass, increased development time, or increased mortality. It does not appear that the observed effects of xanthotoxin on *C. sosares* are the result of compromised host quality in response to dietary xanthotoxin. However, it is possible that other furanocoumarins or synergistic combinations, not considered in this study, could reduce host quality. For instance, the angular furanocoumarin sphondin is negatively correlated with the proportion of the linear furanocoumarin bergapten in seeds, and both are associated with resistance to webworms (Berenbaum et al. 1986). The concurrent presence of bergapten and xanthotoxin may compromise the ability of *D. pastinacella* to metabolize xanthotoxin. Diets high in such furanocoumarins conceivably could reduce host quality to the point that *C. sosares* fitness is also reduced. On the other hand, previous field correlative studies (Ode et al. 2004) indicate that xanthotoxin alone, out of seven analyzed furanocoumarins, was negatively correlated with *C. sosares* fitness.

Xanthotoxin likely affects *C. sosares* fitness by directly acting as a toxin. Although webworms are remarkable for their efficiency in metabolizing xanthotoxin (Zangerl and Berenbaum 1993), our results, in addition to those of McGovern et al. (2006), show that developing *C. sosares* do encounter unmetabolized xanthotoxin in the hemolymph of their webworm hosts. Furthermore, hemolymph titers of xanthotoxin increased fourfold in webworms fed with a diet that contained high levels of xanthotoxin compared to webworms consuming a diet low in xanthotoxin, indicating that changes in webworm diet, be they artificial or natural, correspond directly to the amount of xanthotoxin encountered by developing *C. sosares*.

Despite the presence of potentially toxic levels of xanthotoxin during development, we found no evidence that either *C. sosares* embryos or precocious larvae are able to metabolize it. Successful development of *C. sosares* embryos and larvae (see McGovern et al. 2006) likely depends in part on the ability of the webworm to detoxify furanocoumarins as well as the furanocoumarin content of the host plant tissues consumed by the webworms. Webworms from different geographical regions vary in their metabolic capacities (Berenbaum and Zangerl 1998; Zangerl and Berenbaum 2003; Berenbaum and Zangerl 2006). Similarly, plant populations vary considerably in

terms of the furanocoumarin profiles produced, both within a species (Berenbaum and Zangerl 1998; Zangerl and Berenbaum 2003) and among species (Zangerl and Berenbaum 2003; Ode et al. 2004). In western Europe, where this tritrophic interaction is native, *C. sosares* clutch size and survivorship are greater on *H. sphondylium* (a host plant that contains relatively low levels of xanthotoxin) than it is on *P. sativa* (which typically contains 10 times the levels of xanthotoxin as *H. sphondylium*). Together, variation among webworm populations in terms of detoxification abilities and among host plant populations/species in terms of furanocoumarin profiles may have a strong influence on the establishment success of *C. sosares*.

The establishment success of *C. sosares* may be influenced ultimately by the trophic complexity in which the selective interactions between wild parsnip and parsnip webworm are embedded. The interaction intensity between parsnip and webworm determines the variation in wild parsnip furanocoumarin profiles and parsnip webworm detoxification abilities (Berenbaum and Zangerl 2006). The level of trophic complexity involving parsnips and webworms in The Netherlands is, by and large, greater than in midwestern North America. Higher trophic complexity in The Netherlands populations is indicated by the presence of alternative host plants and attacks by parasitic wasps, both of which are largely absent in midwestern North American parsnip populations. As a possible consequence of decreased trophic complexity, xanthotoxin concentrations in midwestern North American populations of parsnip are generally higher than in populations in The Netherlands (Ode et al. 2004; Berenbaum and Zangerl 2006). If *C. sosares* was introduced to midwestern North America (whether intentionally, accidentally, or naturally), it may experience, to its detriment, significantly elevated levels of xanthotoxin in its webworm hosts. Alternatively, such effects of xanthotoxin may be negated by the elevated detoxification abilities of midwestern North American webworms. An understanding of the effects of reduced trophic complexity on the selective intensity between plant and herbivore is important not only for interpreting the evolution of trophic relationships but also for predicting and understanding the outcome of biological control introductions.

Predatory Mite Attraction to Herbivore-induced Plant Odors is not a Consequence of Attraction to Individual Herbivore-induced Plant Volatiles

Received: 7 January 2008 / Revised: 16 April 2008 / Accepted: 28 April 2008 / Published online: 3 June 2008

Abstract Predatory mites locate herbivorous mites, their prey, by the aid of herbivore-induced plant volatiles (HIPV). These HIPV differ with plant and/or herbivore species, and it is not well understood how predators cope with this variation. We hypothesized that predators are attracted to specific compounds in HIPV, and that they can identify these compounds in odor mixtures not previously experienced. To test this, we assessed the olfactory response of *Phytoseiulus persimilis,* a predatory mite that preys on the highly polyphagous herbivore *Tetranychus urticae.* The responses of the predatory mite to a dilution series of each of 30 structurally different compounds were tested. They mites responded to most of these compounds, but usually in an aversive way. Individual HIPV were no more attractive (or less repellent) than out-group compounds, i.e., volatiles not induced in plants fed upon by spider-mites. Only three samples were significantly attractive to the mites: octan-1-ol, not involved in indirect defense, and *cis*-3-hexen-1-ol and methyl salicylate, which are both induced by herbivory, but not specific for the herbivore that infests the plant. Attraction to individual compounds was low compared to the full HIPV blend from Lima bean. These results indicate that individual HIPV have no *a priori* meaning to the mites. Hence, there is no reason why they could profit from an ability to identify individual compounds in odor mixtures. Subsequent experiments confirmed that naive predatory mites do not prefer tomato HIPV, which included the attractive compound methyl salicylate, over the odor of an uninfested bean. However, upon associating each of these odors with food over a period of 15 min, both are preferred. The memory to this association wanes within 24 hr. We conclude that *P. persimilis* possesses a limited ability to identify individual spider mite-induced plant volatiles in odor mixtures. We suggest that predatory mites instead learn to respond to prey-associated mixtures of volatiles and, thus, to odor blends as a whole.

Introduction

Natural plant odors are usually blends of many molecules. Upon infestation by herbivores, plants change the composition of the odors they emit (Arimura et al. 2005). This information is used by the third trophic level to locate and prey on the herbivores that feed on the plant (Sabelis et al. 2006). The induced odor thus constitutes a signal to predatory arthropods, but exactly which features of this induced odor are perceived as the signal? Predators may either respond to one or a few of the induced compounds that they recognize individually in the mixture. Alternatively, predators could respond to the new odor mixture as a whole. If herbivore species induce the same volatile compounds in the plants they feed on, and if predators possess the ability to identify specific compounds in odor mixtures, the population of predators could evolve a set genetically fixed olfactory responses to these specific compounds. Predators with such innate responses to specific prey-related odors can minimize the exploration of plants that are not infested with their prey by limiting their olfactory acuity to a subset, of specific, ecologically

relevant compounds (Bernays 2001; Egan and Funk 2006). Alternatively, predators could maximize their olfactory acuity for a wide variety of odors and perceive the plant odor mixture as a whole, i.e., distinct from its components. Consequently, individual compounds have no *a priori* meaning to such predators. Although this forces the predators to cope with much more information, it will facilitate the ability to differentiate among odors with chemically overlapping compositions. This may, for example, help them learn the difference between the odors that emanate from plants harboring suitable prey and plants harboring unsuitable prey. Here, we ask, if we can find a preference for individual herbivore-induced plant compounds in a population of the predatory mite *Phytoseiulus persimilis*.

Phytoseiulus persimilis preferably preys on the two-spotted spider mite *Tetranychus urticae* Koch. The predatory mites are blind and rely on odors to locate distant prey patches (Sabelis and Van der Baan 1983; Sabelis et al. 1984a, b). By using olfactory cues that emanate from spider mite-infested plants, the predatory mites are able to discern plants with prey from plants without (Sabelis and Van der Baan 1983; Dicke and Sabelis 1988; Dicke et al. 1990a, 1998; Dicke 1994; Sabelis et al. 1999). The prey, *T. urticae*, is highly polyphagous and has been reported to feed on more than 900 species of plants in 124 genera (Bolland et al. 1998). Infestation by spider mites induces different host plant species to emit different blends (Van Den Boom et al. 2004).

Under natural conditions, the quantitative and qualitative odor emission from plants is not only affected by herbivory of a predator's prey, but also by several other independent biotic and abiotic factors. Different herbivore species induce different blends of herbivore-induced plant volatiles (HIPV) in the same plant species (De Moraes et al. 1998; De Boer et al. 2004, 2005). The same herbivore induces different HIPV in different plant species (Van Den Boom et al. 2004). The HIPV composition changes with leaf age (Takabayashi et al. 1994) and during the onset of infestation (Kant et al. 2008). Genetic variation within herbivore and plant species also affects HIPV production (Degen et al. 2004; Kant et al. 2008). Biotic factors such as herbivore-vectored viruses (Eigenbrode et al. 2002; Jimenez-Martinez et al. 2004) and abiotic factors such as fertility of the soil, light, and temperature, all qualitatively and quantitatively, affect the odor composition of a plant (Gouinguene and Turlings 2002; Vallat et al. 2005). Under natural conditions, these factors together generate a wealth of olfactory cues that vary in time, space, and possibly also information (Sabelis et al. 2006).

Phytoseiulus persimilis is able to adjust its olfactory response based on experience. Rearing the predatory mites from egg to adulthood on different species of spide mite-infested plants induces a preference for these plant odors (Takabayashi and Dicke 1992; Krips et al. 1999). Prolonged feeding (24 hr or more) of adults in the presence of HIPV blends also induced an acquired olfactory preference for these HIPV (Krips et al. 1999; Drukker et al. 2000; de Boer and Dicke 2004a; De Boer et al. 2005). This ability to learn from experience may help dispersing predatory mites detect spider mite-infested plants that they are already familiar with. The polyphagous nature of the prey, however, makes it worthwhile to explore not previously experienced odors as well. How can the dispersing predatory mites determine which odor sources are worthwhile exploring and which are not? Predatory mites could generalize their preference from odors that have been previously experienced in association with their prey to similar odors not previously experienced. On the other hand, predatory mites could possess an innate preference for specific spider mite-induced compounds that they identify in odor mixtures not previously experienced. The literature offers evidence for and against both possibilities. Drukker et al. (2000) found that *P. persimilis* females reared in the absence of plant odors did not innately prefer the odor of spider mite-infested plants over that of uninfested plants. Results obtained by de Boer and Dicke (2004a) suggested that *P. persimilis* preferred methyl salicylate only if the mites had experience with a methyl salicylate containing odor-blend. Hence, an innate preference for methyl salicylate seems to be absent. This acquired attraction to methyl salicylate could indicate that *P. persimilis* generalizes the acquired preference from the mixture *to* the individual compound. This generalization could be facilitated by the fact that the few (about 20) olfactory receptor cells that *P. persimilis* possesses may perceive only a fraction of an odor mixture (Jackson 1974; Jagers op Akkerhuis et al. 1985; van Wijk et al. 2006). On the other hand, the acquired preference for methyl salicylate reported by de Boer and Dicke (2004a) could also indicate that *P. persimilis* possess the ability to identify the presence of this particular compound in a mixture, which would suggest that olfaction in *P. persimilis* is elemental. More evidence in support of elemental odor perception can be found in the reported attractiveness of several typical spider mite-induced plant compounds (Dicke et al. 1990b; de Boer and Dicke 2004a, b; Kappers et al. 2005). An innate preference for specific compounds in combination with the ability to identify these compounds in unfamiliar mixtures could explain how *P. persimilis* has been able to prefer, without prior experience, the odor of spider mite-infested plants over that of uninfested conspecifics for several plant species (van den Boom et al. 2002). Thus, some experiments with *P. persimilis* do not provide evidence for an innate preference for HIPV, whereas others indicate that individual compounds could represent attractants by themselves and as part of odor mixtures.

In this paper, we aim to elucidate whether individual compounds can represent a signal that is recognized as a distinct element of the odor mixture that spider mite-infested plants emit. Acceptance of this hypothesis requires two prerequisites: first, individual spider mite-induced compounds should be attractive, and second, the mites should be able to identify the attractive components in mixtures. To test the first prerequisite, we investigated if individual compounds that are typically induced by spider mites elicit a specific behavioral response that differs from the response elicited by compounds that—to the best of our knowledge—are not involved in indirect plant defense. We used the information about the olfactory preference for individual compounds gained in the first experiment to test the second prerequisite. In this experiment, we assessed whether the mites can utilize their preference for specific spider mite-induced plant compounds to select without prior experience the odor that emanates from a spider mite-infested plant, which emits attractive HIPV, over the odor of an uninfested plant. We further assessed whether the presence of HIPV affects the ability to learn about odors, and we asked how long the mites maintain this memory.

Methods and Materials

Plants and Mites Lima bean plants (*Phaseolus lunatus*) were reared in a climate room (22°C, 60% RH, 16:8 LD) from seeds until they were 2 wk old. Next, they were infested with two-spotted spider mites, *T. urticae*. The predatory mites (*P. persimilis*) were reared in a climate room (25°C, 80% RH, 16:8 LD) on detached spider mite-infested Lima bean leaves. Every day (except on the weekend), the predatory mites received fresh spider-mite-infested Lima bean leaves, and the culture was harvested. The frequent harvesting of the mites ensured that the females used were one to a few days old since their final molt. The predatory mites were originally obtained in 2001 from field samples at various sites near the coast of Sicily, Italy. The predatory mites were collected from spider mite-infested plants, and the plants were from different genera in three different plant families (*Convolvulaceae*, *Asteraceae*, *Euphorbiaceae*). Before testing the olfactory response, all mites were brought in a hungry state, which mimics the conditions before and after dispersal (Sabelis and Afman 1994). To this end, adult female predatory mites were kept in Eppendorf tubes, deprived of water and food for 16–22 hr (24°C.).

Odors The response to a panel of 30 odors was tested. Most were obtained from Fluka with the exception 2,3-dimethyl-pyrazine, which was obtained from Sigma-Aldrich. Octan-1-ol and butan-1-ol were obtained from Sigma, *cis*-3-hexenyl acetate, dodecyl-acetate, nerolidol, proionic acid were obtained from Aldrich, methyl salicylate from Sigma-Aldrich, and β-ocimene (70% E- and 30% *Z*- isomers) from R. C. Treatt & Co. (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, (TMTT) were provided by Dr. W. Boland of the Max Planck Institute for Chemical Ecology, Jena, Germany.

Olfactory Response Tests The response to each compound in the odor panel was tested by using a "choice arena". The basic arena consisted of an upside-down Petri dish (diam 9 cm) (Fig. 1a). An opening at the bottom of the arena was connected to a vacuum pump (flow 0.42 l/min). Prior to the experiment, groups of about 20 female predatory mites were placed in a cartridge that could be fitted between the vacuum pump and the choice arena. For each replicate experiment, freshly made odor sources and a new cartridge with a new group of predatory mites were provided. Insect glue barriers divided the arena in two sides while leaving an opening at the center of the bottom of the arena (Fig. 1a). One side of the arena contained a filter paper (diam 1 cm) with the 0.5-µl odor (dissolved in hexane), while the alternative side contained a control filter paper treated with the solvent only (0.5 µl hexane). The odor sources were prepared in a fume, and the solvent was allowed to evaporate for exactly 1 min before the odor source was placed in the set-up. Mites were released from the cartridge, and after 3 min, the mites at each side of the arena were counted. Each odor was tested in five concentrations, covering a concentration range that spans five orders of magnitude (pure and diluted with a factor 10, 10^2, 10^3, and 10^4). The response to each concentration of each odor was tested in six replicate experiments, and each contained 20 predatory mites. Fresh arenas were used for each odor, and the choice arena was rotated between replicate experiments to correct for any unforeseen directional bias. To avoid contamination of the air that entered the choice arena, it was placed in a flow cabinet that was continuously supplied with clean air. Assuming individual mites make independent choices, the preference of the mites for either side of the arena was evaluated with a replicated *G*-test (Sokal and Rohlf 1995). In short, significant values of G_t indicate an overall deviation from a 50:50 distribution. This statistic is broken down into two components that characterize/evaluate different aspects of the deviation; G_h and G_p. Significance of G_h indicates heterogeneity among replicate experiments, while significance of G_p indicates a deviation from an even distribution in the overall pooled result.

To aid graphical display of the data, we calculated the following preference index to each odor-sample: [(mites at odor side—mites at control side)/total amount of mites) × 100]. In this way, repellent odors were assigned a negative

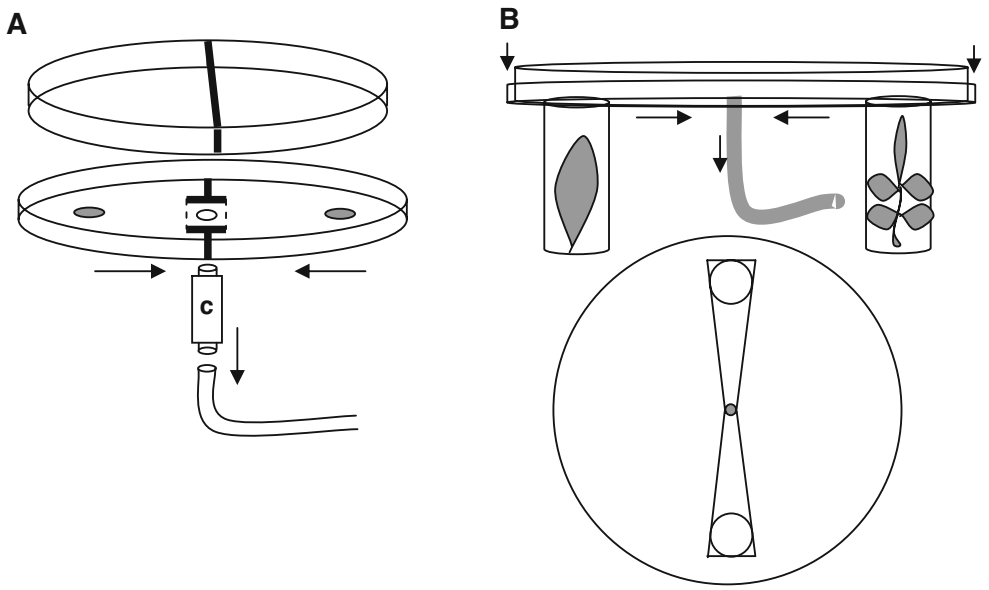

Fig. 1 1A: The "choice arena" consists of an upside down Petri dish. At the center, the arena connects to a cartridge (c) that holds the predatory mites. The cartridge is connected to the vacuum pump. Arrows indicate the direction of the radial airflow in the arena. Odors are applied on filter paper (gray circles).The choice arena is divided in the two sides by a thin layer of insect glue (thick black lines). 1B: Modified version of 1 A that can be fitted with two veils that hold a tomato or a bean leaf placed on moist cotton wool. Gauze covered holes connect the veils to the choice arena. A single mite is released into the center and from 30 min the time it spends in each of the odor fields (triangles in the lower panel) is measured

preference index (−100 to 0), and attractive odors a positive preference index (0 to 100).

Natural Odors In this set of experiments, individual mites were placed into an experimental arena. This consisted of an upside-down Petri dish (diam 14 cm) with two vials mounted just below an opening in the bottom (Fig. 1b). The vials held either an uninfested bean leaf (*Phaseolus vulgaris*) or an infested tomato leaf (*Lycopersicon esculentum*). Tomato plants were infested with *T. urticae* more than 1 wk before the onset of the experiment. Spider mite-infested tomato was selected because *P. persimilis* that originated from the same laboratory population are attracted to its odor when reared on spider mite-infested tomato leaves (Kant et al. 2004). To establish a radial airflow, a vacuum pump was connected to an opening in the center of the arena. Odor fields were defined as the triangular area that had a base just wide enough to encompass the opening above the vial that contained the odor source, while the tip encompassed the opening where the setup was mounted to the vacuum pump (Fig. 1b). The mites could freely move over the bottom of the arena, and the time spent in each odor field was continuously measured for 30 min. The mites were allowed to associate odors with the presence of food in an arena. To this end, washed spider mite eggs were placed on gauze that covered an odor source. To make sure that the odor sources were the only cues that the mites used during the behavioral observation in the *post*-experience phase, the mites were always observed in an identical, but different arena. The mites' ability to learn about the absence of food in a particular odor field was assessed in two ways: first, by restricting the mites to one of the odor sources in the absence of food, and second by offering the same unrewarded odor at both sides, while the mites were not restricted to one of the odor sources and could leave the odor field.

Results

Validation of the Choice Arena Several tests were conducted to validate the experimental setup. First, the airflow in the choice arena was visualized with smoke derived from droplets of chloric acid and ammonia. This revealed a steady radial airflow along the bottom of the choice arena. When the fumes were applied to one side of the arena, they never entered the other side, while gauze that covered the bottom of the cartridge in the vacuum entrance was progressively covered with NH_4Cl salt starting from one side only. This indicated that the separation of the odor plumes extended to the bottom of the cartridge.

Unforeseen bias in the setup was investigated with a choice test in the absence of odor sources (Fig. 2). This resulted in an even distribution among both sides of the choice arena. The average preference index was −0.25. None of the six replicate experiments had a significant bias

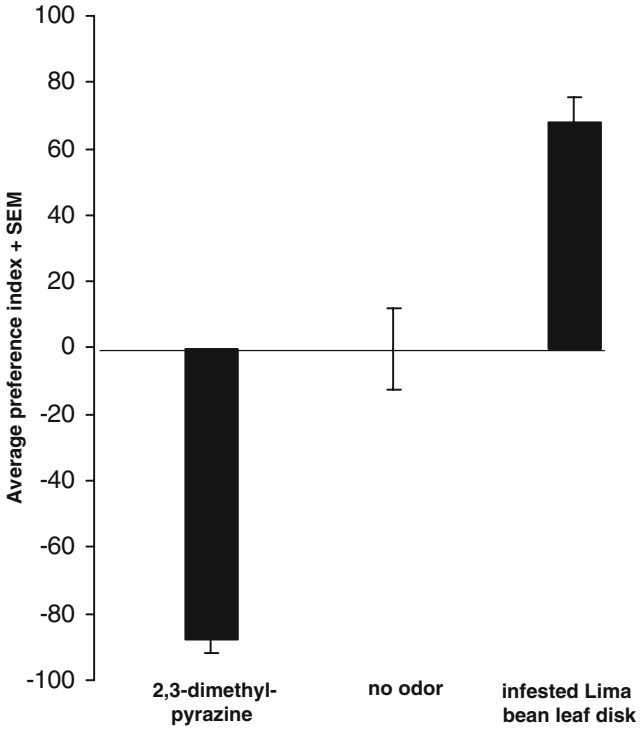

Fig. 2 Control experiments: 0.5 μl 2,3-dimethyl pyrazine is highly repellent and the mites easily avoid the side of the choice arena that contains this odor. In the absence of odors, the mites are evenly distributed along both sides of the choice arena. A small leaf disks excised from spider mite-infested lima bean leaf is attractive to the mites

to either side, and the data were not anymore heterogeneous than expected (G_p^{ns}, G_h^{ns}, G_t^{ns}). Subsequently, two positive control experiments were conducted. In the first, an excised, spider mite-infested, lima bean leaf-disc (diam 1.5 cm) was placed on moist filter paper at one side, whereas only moist filter paper was placed at the other side. This resulted for each of the six replicate experiments in a significant attraction of starved *P. persimilis*, and the overall attraction was also significant (G_p^*, G_h^{ns}, G_t^*). The average preference index was 67.8. Finally, an odor that was *a priori* known to be highly repellent to the mites, 2,3-dimethyl pyrazine (0.5 μl), was offered at one side, while a control paper was placed at the other. This resulted for each of the six replicate experiments in a significant avoidance of the odor with an overall significant aversion (G_p^*, G_h^{ns}, G_t^*). The average preference index was −87.5.

Response to the Odor-Panel The overall response to odors changed as a function of the concentration (Fig. 3). High concentrations elicited on average the most aversive response. Also, the strength of the response increased with increasing concentration. This correlation between the (log) odor concentration and the strength of the response (R^2= 0.77) was, however, present only for odor samples that were significantly repellent (G_t*, G_p*, and G_h^{ns}) (Table 1). For the nine moderately attractive samples (G_p* and G_h^{ns}), such a correlation was absent (R^2=0.00002).

Thus, the predatory mites perceived most odors in the panel. Out of 30 odors, 24 elicited a response (e.g., (P ($G_{p,\ df=1}$) < 0.05)) at one or more of the tested concentrations (Table 1). The six that did not elicit a response were acetone, α-humulene, α-pinene, linalool, propan-1-ol, and *trans*-caryophylene. Overall, 27 out of 150 choice tests were more heterogeneous than expected under the null hypothesis (P ($G_{h,\ df=5}$) < 0.05) (Table 1). These heterogeneous results were more prevalent at the higher concentration range (pure to 100× diluted odor samples) than in the lower concentration range (1,000 and 10,000× diluted samples). Based on a significance of G_p, 20 out of 30 odors at the highest concentration elicited a response, of which 19 were

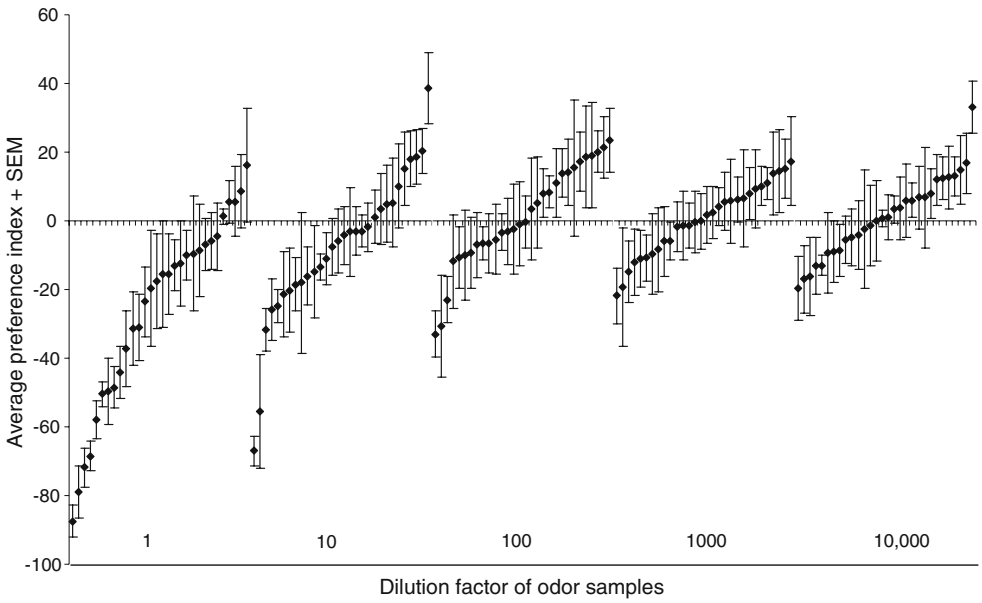

Fig. 3 The response that odors elicit from *P. persimilis* as a function of the odor concentration. Along the *x*-axis, the odors are sorted from repellent to attractive for each tested concentration in decreasing order. The strength of the response decreases with decreasing odor concentration. The number of repellent samples is correlated strongly with increasing odor concentration, whereas this correlation is absent for the occurrence of attractive odor samples. At the lowest concentration, most odors do not elicit a significant response

Table 1 The table contains the response of the mites to all 30 tested compounds at each of the five concentrations

Each sample was tested with six replicate experiments that each contained about 20 starved mites. Negative average preference indices correspond to cases where the majority of the mites avoided the odor side, whereas positive preference indices correspond to cases where the majority of the mites moved toward the odor source. Average preference indices marked by gray cells correspond to nine moderately attractive samples (G_p* and G_h^{ns}). Just 3 of these nine odors additionally include significance of the total *G* statistic (G_t^*), octan-1-ol, methyl salicylate, and *cis*-3-hexen-1-ol. SIPV indicates that the compound has been reported as a spider-mite-induced plant volatile in de references in the adjacent column.

repellent and only one was attractive. The 10 and 100× diluted samples each contained 10 odors that elicited a response, but here, at the10× dilution, six were attractive whereas only four were repellent. At the 100× dilution, seven odors were repellent and only three were attractive. At the lowest concentrations, the 1,000x dilution yielded only two repellent and one attractive odor, whereas the 10.000× dilution only yielded two repellent and two attractive odors.

Out of 150 samples tested, 18% were significantly more heterogeneous than expected, and sometimes the same set of six replicate experiments revealed statistically significant heterogeneity, whereas the pooled results deviated significantly from an even distribution. In such cases, the pooled significance may depend on one or two extreme replicate experiments. A better indication of the olfactory preference of the population of predatory mites is, thus, found by using more stringent statistical criteria of the replicated *G* test for goodness of fit (Sokal and Rohlf, 1995). By using significance of G_t and G_p and non-significance of G_h as the criteria for choice, 13 repellent compounds at the highest concentration remain; these are 1-*trans*-2-hexenol, 2,3-dimethyl-pyrazine, 2-benzyl-ethanol, acetic acid, α-terpinene, butan-1-ol, *cis*-3-hexenyl acetate, farnesol, hexan-1-ol, methyl salicylate, propionic acid, (*S*)-(-)-

limonene, and β-ocimene. At the 10× diluted samples, only five repellent compounds remain; these are 1-*trans*-2-hexenol, *cis*-3-hexenyl acetate, farnesol, methyl salicylate, and *trans*-β-ocimene. The lowest concentration (10,000×) no longer contains repellent compounds under these statistical criteria, whereas the 100× and 1,000× diluted samples contain only one repellent compound each; these are methyl salicylate and nerolidol. In total, just three samples are attractive based on significance of G_t and G_p and non-significance of G_h, and each at just one of the five tested concentrations. Octan-1-ol was attractive at dilution 10×, *cis*-3-hexen-1-ol at dilution 100×, and methyl salicylate at a dilution of 10,000×.

We also investigated whether typical spider mite-induced compounds are more attractive than other compounds. The set of attractive odor samples, whose preference index does not exceed 39, is only weakly to moderately attractive compared to the repellent samples that often have a preference index smaller than −50, and to the control experiment with a spider mite-infested leaf disc that has a preference index of 68 (Fig. 2). If the statistical criteria for a choice are reduced to the significance of G_p, non-significance of G_h and no restrictions on the significance of G_t are applied, nine out of 150 (30 odors at five concentrations) samples were attractive (indicated by marked preference index in Table 1). This set contains eight out of 30 odors tested (propionic acid was present twice at 10× and 100x dilution). These represent a variety of structurally very different molecules. At the same time, the other set of "non-attractive" odors contains molecules that are structurally similar to some attractive odors. For example, propionic acid was attractive, whereas acetic acid was not; octan-1ol was attractive, whereas 3-octanone was not; *cis*-3-hexen-1-ol was attractive, whereas hexen-1-ol and *cis*-3-hexenyl acetate were not; and octan-1-ol and decan-1-ol were attractive, whereas hexan-1-ol was not. Finally, the attractiveness was highly concentration-dependent. Only propionic acid was attractive at two concentrations and all others at only one. Only three out of these eight attractive odors have been implicated in HIPV produced after spider mite infestation, i.e., methyl salicylate, *cis*-3-hexen-1-ol, and β-farnesene. The other five compounds (propionic acid, octan-1-ol, benzyl benzoate, decan-1-ol, and dodecyl-acetate) have, to the best of our knowledge, never been reported as part of a spider mite-induced odor blend. Thus, starved females of *P. persimilis* are not specifically more attracted by individual spider mite-induced plant volatiles than by volatiles that are not associated with their prey.

Natural Odor Sources If *P. persimilis* does not specifically respond to typical spider mite-induced plant compounds, one may wonder if the mites are able to detect individual HIPV in complex mixtures for which they have no prior experience. This was investigated by using natural plant odors. In this experiment, we were interested not only in the initial choice of the predatory mites, but also in the time spent in the exploration of odor sources that could be associated with prey. To this end, the time that an individual mite spend in each of two odor fields that contained the odor of spider mite-infested tomato (*Lycopersicon esculentum*) (HIPV) or the odor of uninfested bean (*Phaseolus vulgaris*) (no HIPV), was continuously measured for 30 min.

In the absence of experience, the mites invested an equal amount of time in exploring both odor sources (Fig. 4). Subsequently, we experimentally mimicked conditions in which predatory mites explore an uninfested plant for a prolonged time. To this end, the mites were not starved in

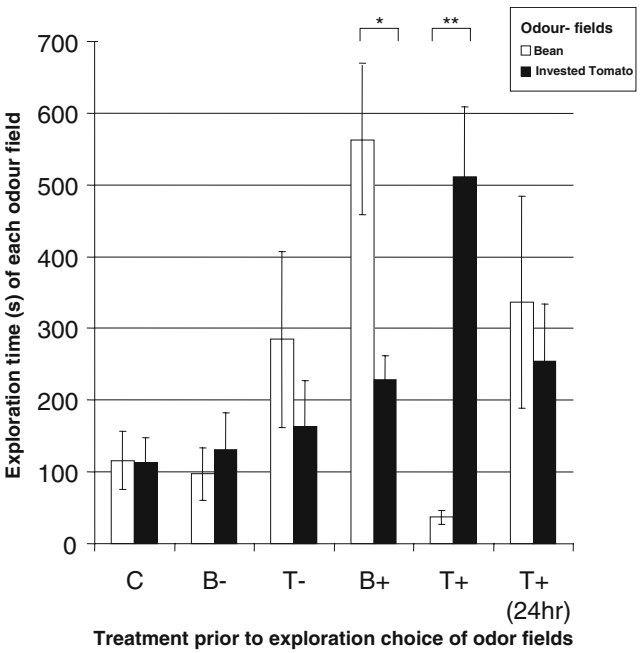

Fig. 4 Innate and acquired preference for spider mite-infested- and uninfested plant odors for which mites have no prior experience. Bars represent the time mites spent in each odor field (during 30 min). Black represents spider mite-infested tomato (HIPV source), white represents uninfested bean (no HIPV source). Significance was tested with a paired sample *t*-test ($^{*}P<0.05$, $^{**}P<0.001$). *C*: without prior experience, predatory mites do not invest more time in the exploration of the HIPV source than in the alternative ($N=11$). *B*−: mites were starved in the arena for 24 hr, while both sides contained bean leaves. There was no evidence of an acquired aversion ($N=10$). *T*−: Starved mites were restrained for 15 min above the infested tomato field without food ($N=8$). There is no evidence of a non-associative acquired response as a result of this treatment. *B* + and *T* + : Starved mites were allowed to feed for 15 min in the presence of either odor, the mites associate the odor with the reward ($N=15$ and $N=16$). T + (24 hr): Mites were first starved, subsequently allowed to forage in the arena, while the tomato patch contained food and the bean patch was unrewarded. Subsequently, the mites were starved for 24 hr until tested ($N=12$). The result suggests that the memory was lost within 24 hr

an Eppendorf tube outside the setup, but instead the starvation took place inside the setup with two odor sources that each contained an uninfested bean leaf. Twenty-four hours later, the mites were transferred to a fresh, identical arena that contained an uninfested bean leaf in one vial, and an infested tomato leaf in the alternative vial. As in the first experiment with naïve individuals, these mites did not spend more time in one of the two fields (Fig. 4). To assess whether the mites were able to associate the odors with food, washed spider mite eggs were offered above one of the odor sources. However, because feeding in the presence of an odor also results in the arrestment of predatory mites in the presence of the odor, we first conducted a control experiment to assess the role of this potential confounding effect. In this control experiment, starved individuals were forced to stay for 15 min in the area above the infested tomato odor (Fig. 4). This treatment did not significantly affect the subsequent olfactory response of the mites, and they still did not prefer one odor over the other. Next, the predatory mites were allowed to feed for 15 min on washed spider mite eggs while experiencing the infested tomato leaf odor or the uninfested bean leaf odor (Fig. 4). This short period of feeding and contact with their food induced a strong behavioral change. After placing the predatory mites in an identical arena without food, they now spent much more time in the odor fields of the odors that were associated with a reward. The mites were able to learn both odors, but they seemed to have slightly more trouble ignoring the infested tomato odor field than the uninfested bean odor field as is evident from the difference in the time spent in both unrewarded odor fields (*t* test: $P<0.05$) (Fig. 4). To analyze the role of memory, we used this acquired response to assess if a prolonged experience with a reward-associated and a non-reward-associated odor would influence the olfactory response of the mites 24 hr after this experience. To this end, the predatory mites were first starved 24 hr, subsequently allowed to forage in the arena for 24 hr where food was available above the infested tomato leaf, and the area above the uninfested bean leaf yielded no food. After this experience, the predatory mites were again starved for 24 hr and subsequently, the time spent in each odor field was measured. After this experience, the mites again spent an equal amount of time in both odor fields (Fig. 4). Hence, we conclude that the type of learning involved in our setup induces only a short-term memory.

Discussion

Several authors have reported on the olfactory responses of *P. persimilis* to individual spider mite-induced plant volatiles (Dicke et al. 1990b; De Boer and Dicke 2004b; De Boer et al. 2004; Kappers et al. 2005). Dicke et al. (1990b) reported on responses elicited by linalool, methyl salicylate, (*E*,*E*)- and (*Z*,*E*) TMTT, *cis*-3-hexen-1-ol, *cis*-3 hexen-1-yl acetate, octan-3-ol, and both (*Z*)- and (*E*)-β-ocimene. In contrast to the experiments presented here, the predatory mites in the experiments by Dicke at al. (1990b) were satiated and thus in a physiological condition that is different from that during long-distance dispersal. Dicke et al. (1990b) reported that, as in our study, methyl salicylate was attractive, but in contrast to our results these authors also reported that (*E*,*E*)-TMTT, linalool, and (*E*)-β-ocimene were attractive. They also assessed the effect of mixing (*E*)- and (*Z*)-β-ocimene, and found only (*E*)-β-ocimene to be attractive, whereas the chemotactic response attenuated when (*Z*)-β-ocimene was added to (*E*)-β-ocimene. We used a racemic mixture of 70% (*E*)-β-ocimene and 30% (*Z*)-β-ocimene, and as in Dicke et al. (1990b) this blend was not attractive. De Boer and Dicke (2004a, 2004b) also reported on the attractiveness of methyl salicylate and additionally showed that it is attractive to both starved and satiated mites. In a second study, de Boer and Dicke (2004b) reported on the attractiveness of 2-butanone, a compound not tested by us. In addition, they found that (*E*,*E*)-TMTT and (*E*)-DMNT did not elicit a significant response from starved *P. persimilis*, although as in Dicke et al. (1990), (*E*)-DMNT was attractive to satiated mites while (*E*,*E*)-TMTT bordered significance. Similarly, these two compounds did not elicit a significant response (G_p^*, G_h^{ns}, G_t^*) from the starved predatory mites in our study, whereas the attractiveness bordered significance at some concentrations. Finally, Kappers et al. (2005) reported on the attractiveness of (*E*)-nerolidol to starved (24 hr) *P. persimilis*, whereas we observed no attraction to this compound.

Behavioral studies are sometimes difficult to compare because starvation times (Dicke et al. 1998; Shimoda and Dicke 2000), wind speeds, the genetic background of the population (Margolies et al. 1997), rearing condition, and previous experience (Takabayashi and Dicke 1992; Krips et al. 1999; Drukker et al. 2000; de Boer and Dicke 2004a, 2005; De Boer et al. 2005) might all vary among experiments from different authors. In this study, we report a comprehensive study on the olfactory responses to a range of individual spider mite-induced plant volatiles in starved *P. persimilis* females. To avoid reporting on the particular preference of a particular strain of *P. persimilis*, a large laboratory population was founded with mites that were collected at various locations along the coast of Sicily (Italy). The results should, thus, be interpreted as responses at the population level. The olfactory response among individual mites could differ as a result of genetic factors (Margolies et al. 1997), and might explain some of the heterogeneity observed among replicate experiments.

The predatory mites responded to a wide range of structurally different molecules. There also was no clearly observable pattern of chemical motifs that elicited a specific response from the mites. It appears that the olfactory system of the mites is not specifically sensitive to a few ecologically relevant compounds. The olfactory system is rather more likely to identify a wide range of chemical motifs. This is not self-evident, especially if we do not take the simplicity of the olfactory system into account (Jagers op Akkerhuis et al. 1985; van Wijk et al. 2006). These results are, however, consistent with observations in insects and vertebrates where olfactory receptor cells possess a broader molecular receptive range, and respond to several, similar odors, particularly at higher concentrations (de Bruyne et al. 2001; Abaffy et al. 2006; Pelz et al. 2006). Moreover, the strength of the response, which odors elicit in predatory mites, increases with increasing concentration. Close examination of the data, however, revealed that this only applies to significantly repellent (G_t^*, G_p^*, and G_h^{ns}) samples. For the nine attractive samples (G_p^* and G_h^{ns}), such a correlation does not exist. Repellence of individual compounds is, thus, largely explained by odor quantity, whereas attraction appears to depend on unique combinations of odor quality and quantity.

The most remarkable result is the low number of significantly attractive compounds among spider mite-induced plant volatiles. Under the most stringent statistical criteria (G_t*, G_p*, and G_h^{ns}) just three samples were attractive, i.e., octan-1-ol, *cis*-3-hexen-1-ol, and methyl salicylate. These odors are only moderately attractive compared to the control experiment that involved spider mite-infested Lima bean (Fig. 1), and the results indicate that individual compounds hardly induce a chemotactic response. Octan-1-ol is—to the best of our knowledge—not involved in indirect plant defense. *Cis*-3-hexen-1-ol is known as a green leaf volatile, and is induced in many plants upon spider mite infestation (Van Den Boom et al. 2004), but also in direct response to wounding of plant tissue (Arimura et al. 2001). Like *cis*-3-hexen-1-ol, methyl salicylate is often induced by spider-mite feeding (e.g., Ament et al. 2004; De Boer et al. 2004; Kant et al. 2004; Van Den Boom et al. 2004). Methyl salicylate is, however, already induced in plants when only aspects of the mechanical damage caused by chewing insects are simulated (Mithofer et al. 2005). Thus, it is by no means a spider mite-specific signal.

The absence of a strong chemotactic response to individual typical HIPV indicates that these stimuli have no *a priori* meaning to predatory mites. This suggests that the ability to perceive the individual compounds in mixtures will be of little survival value. Consequently, mites are unlikely to possess the ability to discriminate between odors from herbivore-infested and clean plants on the basis of one or a few attractive compounds when they have never experienced these odors before. The results indicate that naïve mites are not able to discern infested tomato odor from uninfested bean odor (Fig. 4). The infested tomato is known to produce several typical spider mite-induced volatiles, among which is methyl salicylate (Ament et al. 2004; Kant et al. 2004), a compound that is attractive to the mites. With experience, the predatory mites were capable of differentiating between these odors. These data are, thus, not consistent with the hypothesis that mites possess an elemental odor perception that enables them to respond to the presence of specific HIPV that they identify in mixtures. The results also suggest that mites do not possess an innate preference for a combination of HIPV that could help them to select without prior experience the infested tomato leaf. Similar results were reported by Drukker et al. (2000) who found that *P. persimilis* reared in the absence of plant odors did not prefer the odors of infested plants over those of uninfested plants. These predatory mites only acquired a preference after prolonged (24 hr) feeding in the presence of either the uninfested- or infested plant odor. In a similar way, the mites in our experiment were able to associate both odors, irrespective of the HIPV contents of the blend, with the presence of food (Fig. 4).

The predatory mites require only a short learning period of less than 15 min to acquire a preference for an odor, a period much shorter than previously reported for the mites. Prolonged experience with odors that were not associated with food (24 hr) did not induce avoidance, in contrast to the results reported by Drukker et al. (2000). This result, however, is similar to those reported by de Boer et al. (2004), who also found no evidence of an acquired aversion as a result of starvation in the presence of odors. With respect to learning and memory, we conclude that the mites were able to associate odors with the presence of prey after a brief learning experience of less than 15 min, but the same learning experience of 24 hrs was insufficient to induce a long-term memory.

In summary, the mites responded to a wide range of structurally different molecules, suggesting that their small olfactory system is not sensitive to a few specific ecologically relevant compounds. This is further supported by the fact that the mites were not more attracted to spider mite-induced plant volatiles than to volatiles that are not associated with spider mites. This indicates that these individual spider mite-induced plant volatiles have no *a priori* meaning and that the ability to identify these compounds in mixtures is of little use to the mites. As a consequence, mites are not expected to use the presence of these compounds in odor mixtures, to select a spider mite-infested plant, for which they have no prior experience. Results of our study confirm that the predatory mites were not able to innately identify a spider mite-infested plant

odor, even though it emits methyl salicylate, a compound that was attractive to *P. persimilis*. We, thus, conclude that *P. persimilis* females possess a limited ability to identify individual spider mite-induced plant volatiles in odor mixtures. Instead, the mites learn to respond to prey-associated odor mixtures.

Acknowledgments We thank Dr. W. Boland of the Max Planck Institute for Chemical Ecology, Jena, Germany for providing us with (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT) and (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene, (TMTT).

Protein Expression Changes in Maize Roots in Response to Humic Substances

Received: 4 December 2007 / Revised: 28 March 2008 / Accepted: 4 April 2008 / Published online: 3 June 2008

Abstract Humic substances are known to affect plant metabolism at different levels. We characterized humic substances extracted from earthworm feces by diffuse reflectance infrared Fourier transform (DRIFT) spectroscopy and used them to treat corn, *Zea mays* L., seedlings to investigate changes in patterns of root protein expression. After root plasma membrane extraction and purification, proteins were separated by two-dimensional gel electrophoresis, and differential spot intensities were evaluated by image analysis. Finally, 42 differentially expressed proteins were identified by liquid chromatography-tandem mass spectrometry (LC-MS/MS). The majority of them were downregulated by the treatment with humic substances. The proteins identified included malate dehydrogenase, ATPases, cytoskeleton proteins, and different enzymes belonging to the glycolytic/gluconeogenic pathways and sucrose metabolism. The identification of factors involved in plant responses to humic substances may improve our understanding of plant–soil cross-talk, and enable a better management of soil resources.

Introduction

Humic substances (HS) consist of a mixture of different organic compounds resulting from the decomposition of plant and animal residues (MacCarthy 2001). They are found in all terrestrial and aquatic environments and constitute one of the most abundant forms of organic matter on the surface of the Earth (MacCarthy 2001). HS interact with the organic component of soil and the root apparatus of plants in the soil matrix, where HS can have a fundamental influence not only on overall soil fertility and conservation, but also on plant physiology (Nardi et al. 2002). Under laboratory and field conditions, HS enhance plant growth, as measured in terms of an increase in length or in the fresh and dry weights of shoots and roots. HS also result in the production of higher leaf chlorophyll concentrations, more lateral root initials, an improved micro- and macronutrient uptake, and many other biological effects (Nardi et al. 2002). These effects have been attributed partly to the complexing properties of HS, which increase the availability of micronutrients from scarcely soluble hydroxides, and particularly to the maintenance of sufficient levels of Fe and Zn in solution (Cesco et al. 2000).

Other targets of HS on plant roots are the enzymes associated with the plasma membrane (PM) (Canellas et al. 2002). At the molecular level, the effects of HS have been demonstrated on the expression of specific genes, such as the two H^+-ATPase isoforms *Mha1* and *Mha2* (Quaggiotti et al. 2004). Muscolo et al. (2007b) showed that HS, and particularly those with a low molecular mass, are taken up by plant cells and are able to affect plant metabolism. In this sense, a hormone-like activity has been suggested for several humic fractions (Zandonadi et al. 2007) whose biological action appears to mimic the responses induced by gibberellic and indole-3-acetic acid (IAA). The metabolic

pathways involved in these responses have been only partially described, and the whole mechanism implicated is far from being elucidated.

The PM represents the site for the exchange of information and substances between the cell and its environment. Proteins associated with root cell PMs can thus be reasonably assumed to be a target for HS, and changes in their expression may be seen as the primary reactions leading to the biological responses reported so far. Since protein analysis is the most direct approach for studying the dynamics of plant cell metabolism, valuable information on plant cell and HS interactions can be obtained from a proteomic assay.

We extracted HS from earthworm feces, and used the extract to treat 11-d-old seedlings of corn, *Zea mays*. Next, we used a proteomics approach to assess changes in protein expression in PM-enriched root extracts in response to HS treatment. The biochemical reaction of *Z. mays* to HS at the level of root proteins is shown here for the first time. The main aim of this study was to establish which proteins are differentially regulated after exposure to HS, and to provide new insight on the molecular basis of the response of *Z. mays* PM to these compounds.

Methods and Materials

Preparation of Humic Extract The feces of *Nicodrilus* [=*Allolobophora* (Eisen)=*Aporrectodea* (Oerley)] *caliginosus* (Savigny) and *Allolobophora rosea* (Savigny) (Minelli et al. 1995) were collected from the Ah horizon of an uncultivated couchgrass, *Agropyron repens* L., growing in soils classified as Calcaric Cambisol (CMc-F.A.O. classification) (FAO-UNESCO 1990). Earthworm culture conditions, HS extraction, and extract purification were conducted as reported in Quaggiotti et al. (2004). HS extraction and purification were performed with 0.1 N KOH. The extract was desalted by using 14 kDa cut-off dialysis Visking (Medicell, London, UK) tubing against distilled water. Subsequently, the extract was desalted on ion exchange Amberlite IR-120 (H^+ form), assessed for organic carbon content, and lyophilized before conducting the following analyses.

Diffuse Reflectance Infrared Fourier Transform Spectroscopy DRIFT spectroscopy was performed with a Nicolet Impact 400 FT-IR Spectrophotometer (Nicolet Instruments, Madison, WI, USA) fitted with an apparatus for diffuse reflectance (Spectra-Tech. Inc., Stamford, CT, USA). SiC disks (320-grid-Carb paper obtained from Spectra-Tech) were used to collect 5 mg of lyophilized sample. Spectra were obtained by combining at least 200 scans at a resolution of 4 cm^{-1}. The background was obtained on the abrasive SiC disk. Spectral data were analyzed with Grams 386 spectral software (Galactic Industries, Salem, NH, USA).

Plant Material and Growth Conditions Maize (*Zea mays* L. cv. DKc 5783, Dekalb, Monsanto Agricoltura SpA, Lodi, Italy) seeds were soaked for one night in running water and germinated in the dark at 27°C on filter paper wetted with 1 mM $CaSO_4$ for 96 hr (Nardi et al. 2000b). Seedlings were grown in pools containing 40 l of Hoagland solution for 11 d as follows: 16 hr of light at 25°C and 60% relative humidity, 8 hr of dark at 18°C and 80% relative humidity. For the treatment, a batch of plants was moved for 16 hr to a nutrient solution with HS added at a concentration of 1 mg/l carbon (C), while controls were moved in fresh medium without HS. The HS concentration was chosen according to Nardi et al. (2000b) and in light of preliminary experiments (data not published). At the end of the treatment time, about 120 g of plant roots were collected, snap frozen in liquid nitrogen, and immediately treated for extraction.

Protein Extraction from Root Tissues and Two-Dimensional Polyacrylamide Gel Electrophoresis A total of eight independent samples, i.e., biological replicates (four control and four HS-treated), were extracted. Plasma membrane enriched fractions were obtained by two-phase partitioning (Sandelius and Morrè 1990; Ephritikhine et al. 2004). The sensitivity of the H-ATPase (Mg-dependent) activity to vanadate was used as a marker of PM purity. The activity that was sensitive to vanadate amounted to 83.3% (N=8) of the total ATPase activity, which was similar to the purity reported in other studies (Santoni et al. 1998). PM-enriched samples were submitted to phenol extraction followed by methanolic ammonium acetate precipitation, according to the method of Hurkman and Tanaka (1986). Proteins were then solubilized in 7 M urea, 2 M thiourea, 2% CHAPS, 2% DTT, and a protease inhibitor cocktail. The amount of protein in the PM fraction was assayed with the Biorad (Hercules, CA, USA) protein quantitation kit following the manufacturer's instructions.

After solubilization, isoelectric focusing (IEF) was performed with IPG strips (11 cm, pH range 3–10) by using IPGphor instrumentation following the manufacturer's instructions (GE Healthcare Bio-Science AB, Uppsala, Sweden). IPG strips were loaded with 100 μg protein, 2% ampholytes (pH range 3–10, GE Healthcare), 60 mM DTT, and bromophenol 121 blue (as a tracer) in 210 μl final volume. Rehydration was done overnight. Next day, a pre-focalization program was run at low voltage (300 V) for 2 hr to enable salt removal, then focalization was performed according to the manufacturer's instructions (GE Healthcare), followed by reduction and alkylation with

iodoacetoamide and equilibration in a solution containing 2% SDS, 15 mM DTT, 62 mM TRIS–HCl pH 6.8, and 10% glycerol. Strips were then placed on top of precast gels and sealed with agarose. Separation on the second dimension was done on polyacrylamide gradient precast gels (8–16%, Biorad) in electrophoretic chambers accommodating up to 12 gels at once (Criterion DodecaCel, Biorad). Running conditions: buffer 25 mM Tris-Base, 192 mM glycine, and 0.1% SDS; 20 mA per gel. Proteins were fixed at least 30 min in 10% methanol + 7% acetic acid. The fixing solution was changed at least twice to wash the gel. Gels were then incubated in undiluted Sypro Ruby (Biorad) stain overnight and rinsed with water. Each of the eight biological replicates was analyzed through three separate gels (technical replicates) for a total of 24 gels. Gel images were acquired with the Chemidoc system (Biorad).

Image and Data Analysis Gel images were analyzed with the Imagemaster 2D Platinum 6.0 software (GE Healthcare Amersham Biosciences AB, Uppsala, Sweden,) To select only high-quality protein spots for expression profiling, the following threshold criteria were applied: Each protein spot had to be present in at least three biological replicate gels per class (treated or untreated) and detected in at least six gels per class. Only spots with over 1.5-fold changes in volume after normalization between the two classes were defined as altered and further validated with the nonparametric Wilcoxon–Mann–Whitney test (Imagemaster 2D Platinum 6.0 software with either $P<0.05$ or $P<0.01$) as recommended in Wilkins et al. (2006). Spots appearing in only one class on visual inspection were also defined as newly induced or suppressed by the treatment.

In-Gel Digestion, Protein Identification and Database Search Excised from the gel spots were washed with 50% *v/v* acetonitrile (ACN) in 0.1 M NH_4HCO_3, and vacuum-dried. The gel fragments were reduced for 45 min at 55°C in 10 mM DTT in 0.1 M NH_4HCO_3. After cooling, the DTT solution was immediately replaced with 55 mM iodoacetamide in 0.1 M NH_4HCO_3. After washing with 50% ACN in 0.1 M NH_4HCO_3, the dried gel pieces were swollen in a minimum volume of 10 µl digestion buffer containing 25 mM NH_4HCO_3 and 12.5 ng/l trypsin (Promega, Madison, WI, USA) and incubated overnight at 37°C. Tryptic-digested peptides were extracted according to the protocol described by Kim et al. (2004).

Liquid chromatography-tandem mass spectrometry (LC-MS/MS) analyses were performed on a Micromass CapLC unit (Waters, Milford, MA, USA) interfaced with a Micromass Q-TOF Micro mass spectrometer (Waters) equipped with a nanospray source. For each 2D gel spot, 6.4 µl of tryptic digest were injected at a flow rate of 20 µl/min into an Atlantis dC18 Trap Column. After valve switching, the sample was separated in an Atlantis dC18 NanoEase column (Waters, 0.075×150 mm, 3-µm particle size) at a flow rate 200 nl/min with a gradient from 10% B to 55% B in 35 min (solvent A: 95% H_2O, 5% ACN, 0.1% formic acid; solvent B: 5% H_2O, 95% ACN, 0.1% formic acid). Instrument control, data acquisition, and processing were performed with MassLynx V4.0 software (Waters, Milford, MA, USA). Database searching was done with the on-line version of the Mascot program (www.matrixscience.com) by using the following parameters: one missed cleavage; 0.8 and 0.6 Da mass accuracy allowed for parent and fragment ions, respectively; carbamidomethyl as fixed modification; oxidized methionine as variable modification; 100 hits allowed. Proteins identified with at least two peptides, both showing a molecular weight search (MOWSE) score (Perkins et al. 1999) higher than 40, were considered as matched. For proteins identified by only one peptide with a MOWSE score higher than 40, the peptide sequence was routinely checked manually. All database searches were performed in both the National Center for Biotechnology Information (NCBI) complete database with no species specified, and in the NCBI Viridiplantae-specified database.

Results and Discussion

DRIFT Spectroscopy The DRIFT spectrum of the HS considered in this study (Fig. 1) shows an intense and broad band centered at 3,282 cm^{-1} attributed to water bridging of OH stretching of the phenolic hydroxyl groups or to stretching of the hydrogen-bonded OH and NH groups (Niemeyer et al. 1992); the shoulder at 3,089 cm^{-1} might be attributable to aromatic CH stretching, whose weak relative intensity may be due to the extensive substitution of aromatic rings in HS macromolecules and/or to masking from the broad band of the OH stretching. The peak at 2,930 cm^{-1} and the weaker shoulder at 2,850 cm^{-1} are attributable to CH asymmetric and symmetric stretching in aliphatic groups, respectively (Montecchio et al. 2006). The broad band at 2,626 cm^{-1} was attributed to the formation of intermolecular hydrogen bonding between OH groups in oxygenated compounds (Niemeyer et al. 1992). The sharp, strong band at 1,717 cm^{-1} is caused by C=O stretching vibration, mainly of COOH. This band assigned to C—O stretching and OH deformation and the band at 1,231 cm^{-1} are the most clearly distinct bands of the COOH group vibrations (Ding et al. 2002). In addition, the band at 1,231 cm^{-1} might also be due to C—OH stretching of the phenolic groups (Francioso et al. 2002). The strong band at 1,655 cm^{-1} might denote the presence of C=O stretching in quinonic and ketone (Gressel et al. 1995) or amide groups (Niemeyer et al. 1992). The peak at 1,542 cm^{-1} is due to secondary amide deformation (Gressel et al. 1995) and to

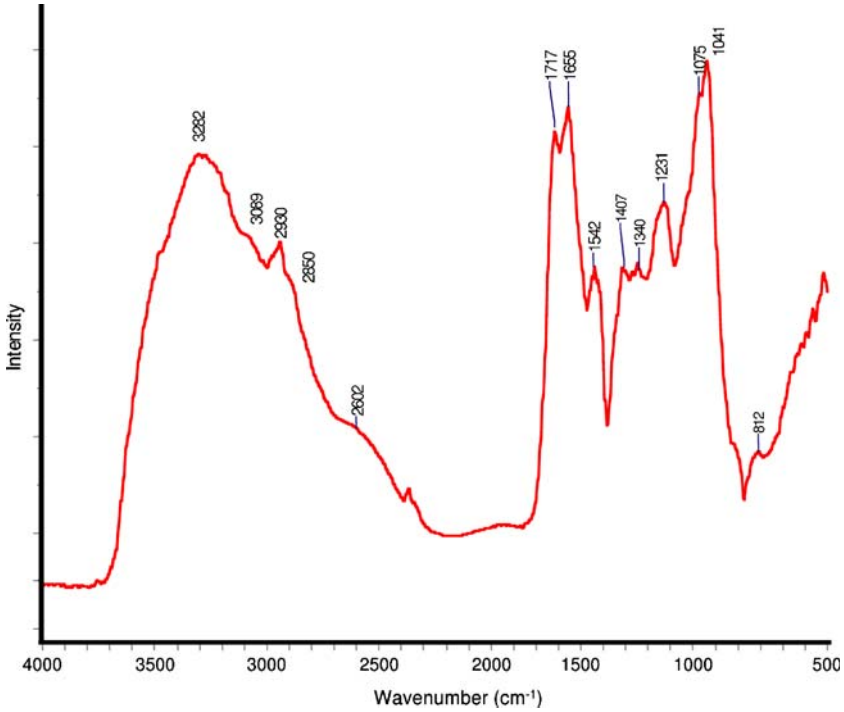

Fig. 1 Diffuse reflectance infrared Fourier Transform (DRIFT) spectroscopy spectrum for Humic Subtances (HS) extracted from earthworm feces

C=C stretching vibrations of aromatic moieties. The region between 1,400–1,300 cm^{-1} is assigned to CH_2 and CH_3 bending, C—OH deformation of COOH, and COO- symmetric stretching (Ding et al. 2002). The intense peak at around 1,040 cm^{-1} is attributed to C—O stretching of polysaccharide-like components. Taken together, these findings show that this humic fraction is endowed with the characteristic structural network described for most HS isolated from different sources of organic matter (Clapp and Hayes 1999).

Proteomic Analysis In many cases, plant gene expression modifications are induced by changes in nutrient availability. In particular, Ca^{++} affects the activity of many actin-binding proteins, and HS are able to chelate cations. In our case study, the Ca^{++} was provided in the nutrient solution as 0.2 mmol/L of $Ca(NO_3)_2$. Both treated and untreated plants were grown in the same medium and HS ash content was very low (<1%). Thus, the reported effects in the proteome could be regarded neither as Ca-dependent nor as related to improved nutrient contents following HS addition.

Image analysis of the 24 sypro-stained gels enabled the detection of approximately 480–550 spots on each gel. By using the threshold criteria (see Methods and Materials), a total of 325 protein spot groups were matched, manually validated, and quantified. Sixty-three spots were found affected by HS treatment, representing more then 10% of the total proteins detected on each gel. Twenty-two spots were upregulated by the HS treatment, whereas 38 were downregulated (Fig. 2). The most upregulated spot (ID 370) represented a 2.92-fold enhancement, whereas the most downregulated protein (ID 1272) resulted in a 2.53-fold diminishment (Table 1). Moreover, two spots appeared to be suppressed by HS treatment, whereas one spot was detected only in gels from treated plants. These 63 spots (Fig. 3) were excised from the gels, digested with trypsin, and the peptides were analyzed by LC-MS-MS, thus enabling the identification of 42 protein species (some of which are illustrated in Fig. 4). In most cases, the database search revealed that the experimental p*I* and M_r values of the identified proteins matched their theoretical values (Table 1). In a few cases, a discrepancy was observed, but this happens frequently in proteomic analyses and is probably a consequence of posttranslational modification, proteolytic cleavage, or matching proteins from different species. In this expression study, proteins were isolated from plasma membrane-enriched fractions. Although the purity was good and in line with other studies (Santoni et al. 1998), some contamination from other cell components certainly occurred. Even if some of the identified protein species have been previously described from other subcellular compartments, the reproducibility and statistical analysis of the expression data indicate that the differences depended on HS treatment.

According to the FunCat functional classification (Ruepp et al. 2004), the proteins identified were grouped into the following categories: energy and metabolism; cellular transport, transport facilitation and transport routes;

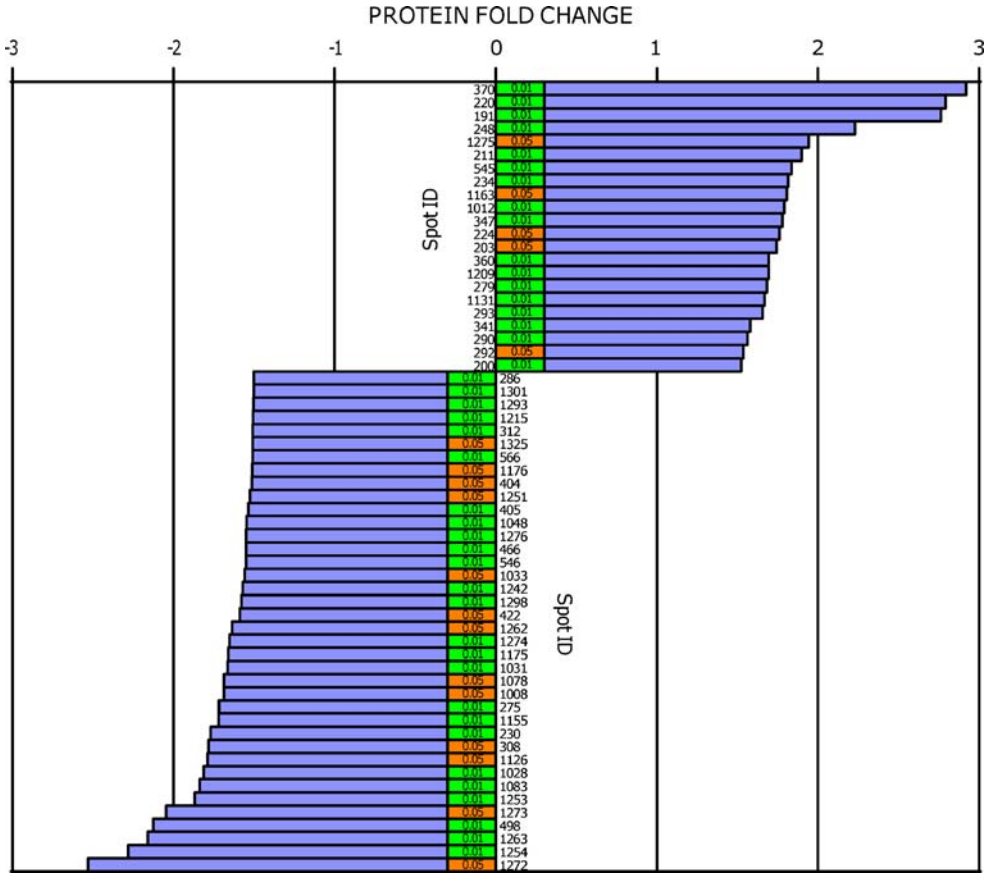

Fig. 2 Relative intensities, spot ID, and *P* values (Wilcoxon–Mann–Whitney test) for the 60 differentially expressed protein spots

interaction with the environment, signaling, defense, cell rescue; and unclassified proteins (Table 1). Below, we briefly discuss the possible significance of these protein groups and the interpretation of changes in abundance of the protein species.

Energy and Metabolism Glycolytic enzymes have long been considered to exist as soluble proteins in the cytosolic compartment, but in recent years it has been suggested that the cytoskeleton and/or membranes contribute to this compartmentalization (Holtgrawe et al. 2005). Protein–protein interactions exist between actin or tubulin and a number of glycolytic enzymes and enzymes of sucrose metabolism (Holtgrawe et al. 2005) that have also been found to co-localize (Anderson and Carol 2005), so it is hardly surprising to find these enzymes in PM-enriched fractions (Santoni et al. 1998, 1999b). In the present study, the enzymes identified were triosophosphate isomerase (TIM; EC 5.3.1.1), glyceraldehyde-3-P dehydrogenase (GAPD; EC 1.2.1.12), phosphoglycerate mutase (PGAM; EC 5.4.2.1), fructose biphosphate aldolase (FBA; EC 4.1.2.13), 2-phosphoglycerate dehydratase (enolase, ENO; EC 4.2.1.11), phosphoglucomutase (PGM; EC 5.4.2.2), and 3-phosphoglycerate kinase (PGK; EC 2.7.2.3). In our experimental conditions, all of the above-mentioned enzymes appear to be downregulated after HS treatment except for TIM, which showed a 69% increase, and GAPD, which maintained the same level of expression in treated and untreated samples. An effect of HS on enzymes involved in the glycolytic/gluconeogenic pathways has already been reported (Muscolo et al. 2007a), and it was thought to impair these pathways. This impairment may affect starch and sucrose metabolism. Three spots (IDs 1251; 1253; 1254) match with sucrose synthase (SUS; EC 2.4.1.13). Spot 546 has been identified as fructokinase-1 (FRK; EC 2.7.1.4) and spot 1298 as PGM, representing the link between glycolysis and starch synthesis pathways. These two proteins were downregulated by HS treatment. SUS can associate with actin, the cytoskeleton, and the plasma membrane, where it is thought to funnel uridine diphosphoglucose (UDP-glucose) to cellulose synthase to produce cellulose (Amor et al. 1995). Merlo et al. (1991) reported that SUS activity appeared to be lower in HS-treated maize leaves. The depletion of these enzymes after HS treatment in our experimental conditions may indicate a slackening of the energy machinery.

Malate has a central role in the energetics of the plant cell, and malate dehydrogenase (MDH; EC 1.1.1.37) is one of the key enzymes in malate metabolism. Sukalovic et al. (1999) found that purified PMs isolated from maize roots contain a

[a] Increased or decreased (±) compared to the control.
[b] NCBI accession number.
[c] Proteins have been identified in *Zea mays* L. protein database when no species is reported.
[d] Sequence coverage. Peptides with individual ion MOWSE scores lower then the threshold indicating identity or extensive homology ($P<0.05$) have not been reported, but have been considered in sequence coverage calculation.
[e] Number of peptide matches.
[f] Underscored methionine in sequences reported indicate oxidation.
[g] Newly induced.
[h] Suppressed by the treatment.
[i] In instances where proteins were identified based on a single peptide, precursor mass, charge, and mass error observed are provided.

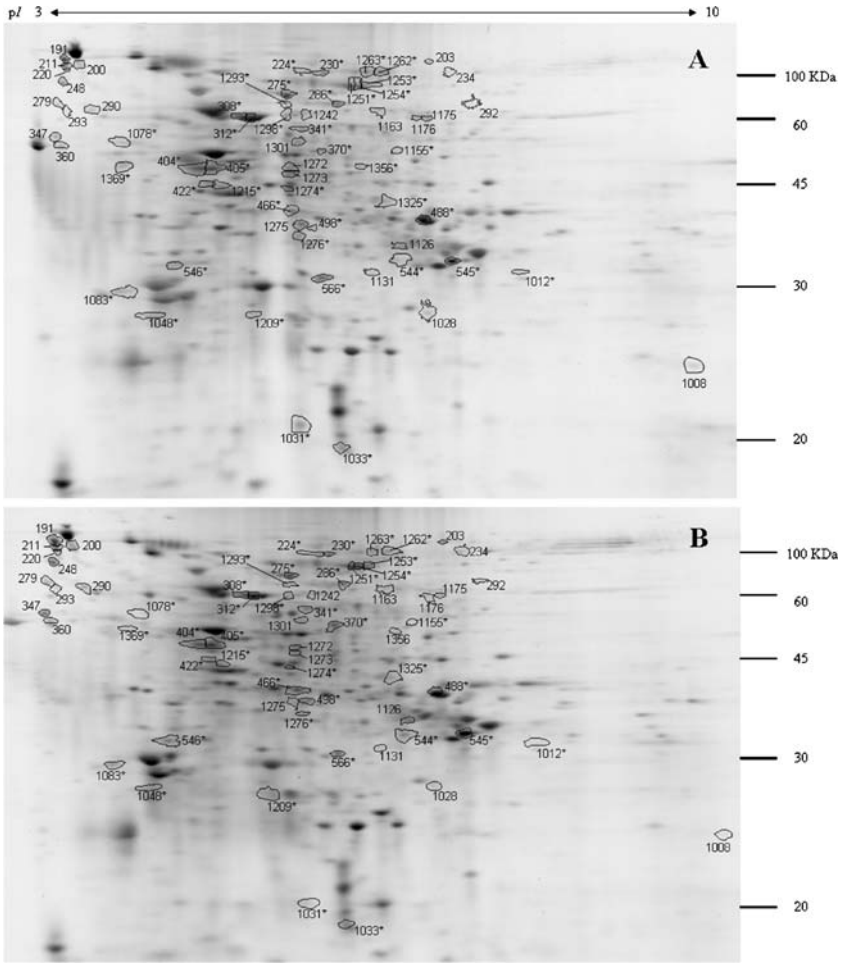

Fig. 3 Two-dimensional polyacrylamide gel electrophoresis (2-DE) analysis of maize, *Zea mays*, root plasma membrane proteins after HS-treatment. One hundred micrograms of protein were extracted and separated by 2-DE, as described in "Methods and Materials" and visualized by Sypro-Ruby staining. A and B show 2-DE gel patterns of protein samples prepared from control and HS-treated roots, respectively. Numbers indicate differentially expressed proteins subjected to LC-MS-MS analysis. Numbers marked with asterisk indicate identified proteins

closely associated, deeply buried, NAD^+-dependent MDH, and this enzyme was also identified in *Arabidopsis* PM-enriched fractions (Santoni et al. 1998). This enzyme is involved in the plasma membrane redox system (Berczi and Moller 2000). Spots 498 and 1276 identified as MDH, showed downregulation after HS treatment in both cases. An *in vitro* inhibition of this enzyme has already been reported after treatment with HS (Pflug and Ziechmann 1981), whereas activity was reportedly stimulated in carrot cell cultures and, more recently, in maize leaves (Nardi et al. 2007).

Aconitase (ACO; EC 4.2.1.3) catalyzes the reversible isomerization of citrate to isocitrate via the intermediate product *cis*-aconitate. There are two isoforms of ACO; the mitochondrial isoform is a component of the citric acid cycle, whereas the cytosolic isoform participates in the glyoxylate cycle (Moeder et al. 2007). We identified two adjacent protein spots as cytosolic ACO from *Cucurbita maxima*, one showing downregulation (spot 230, −77%) and the other upregulation (spot 224, +79%). This result is suggestive of a posttranslational modification of this enzyme. Citric acid is a component of root exudates and plays an important role in disaggregating HS (Nardi et al. 2000a). ACO expression may induce changes in root excretion participating in the rhizospheric cross-talk between plant and soil. Methionine synthase (MS, EC 2.1.1.14) was found as a downregulated protein: the function of this enzyme is the *de novo* synthesis of methionine on one hand and, on the other, the regeneration of the methyl group of *S*-adenosyl methionine from *S*-adenosyl homocysteine after methylation reactions (Hesse et al. 2004). Although cytosolic and plastid isoforms have been reported, this enzyme has also been identified in PM extracts (Santoni et al. 1999b). Muscolo and Nardi (1997) found that HS-treated plants showed no change in methionine concentrations.

Cellular Transport, Transport Facilitation and Transport Routes Annexin, actin and tubulin isoforms were identified in our samples. These proteins have been reported already in studies on the *Arabidopsis* plasma membrane proteome (Santoni et al. 1999a, 2000; Marmagne et al. 2004). Actin and tubulin are major components of the cytoskeleton, forming microfilaments and microtubules, respectively. The cytoskeleton coordinates all aspects of growth in plant cells, including exocytosis of the membrane and wall components

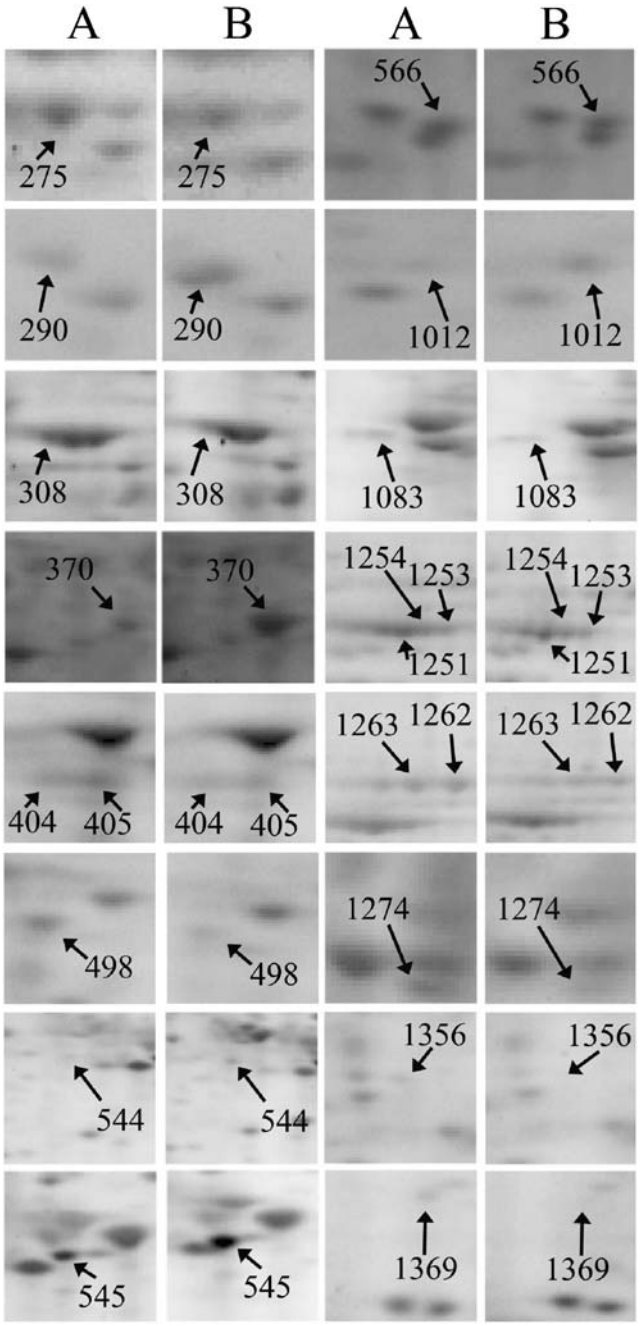

Fig. 4 Magnified views of some differentially expressed proteins in maize roots plasma membrane in response to HS treatment. Plants were controls (column A) or treated with HS for 16 hr (column B) (see "Methods and Materials")

during cell expansion. Both proteins are reported to be associated with plasma membranes and also an interaction between the two proteins has been demonstrated by Wasteneys and Galway (2003). It is generally assumed that annexins are implicated in several processes related to membranes, including the regulation of membrane organization, membrane trafficking, interactions with the cytoskeleton, and secretion (Konopka-Postupolska 2007), but the primary physiological function of annexins has yet to be elucidated. Certain proteins from this family were identified as actin binding, making them ideal mediators in cell membrane and cytoskeleton interactions (Konopka-Postupolska 2007). In this study, the protein spots 545 and 1012, identified as annexin, were upregulated by about 80%. Spot 544, also identified as annexin, was detectable in 10 of the 12 gels generated from treated roots and in none of the gels obtained from control samples. The fact that multiple spots in the same gel area are recognized as annexin may be due to posttranslational modifications, e.g., phosphorylation has been reported for maize annexin (Delmer and Potikha 1997). Due to the role of annexins in cell exocytosis and cell expansion, their upregulation may be correlated with modifications in plant metabolism leading to humic substances-induced stimulation of plant growth (Canellas et al. 2002). Spot 1369, identified as actin, was detectable in seven of the gels obtained from control samples and in none of the HS-treated ones: this indicates that PM-associated actin is low in untreated plants and drops to below the detection limits in treated plants. Spots identified as tubulin showed a depletion of about 53% in the gels obtained from treated plants. Alpha tubulin expression was reported to be modulated by cell sugar content (Datta and Chourey 2001), so this result may correlate with the previously shown modifications in the enzymes of the sucrose pathway. These effects point to an involvement of the cytoskeleton proteins in the response to HS. The responsiveness of the cytoskeleton to environmental cues has been widely documented (for a review, see Wasteneys and Galway 2003).

ATPases are membrane-bound ion transporters that couple ion movement through a membrane with the synthesis or hydrolysis of ATP. Different forms of membrane-associated ATPases have evolved over time to meet specific cell demands. V-ATPases hydrolyze ATP to drive a proton pump but cannot work in reverse to synthesize ATP. They are involved in a variety of vital intra- and intercellular processes such as receptor-mediated endocytosis, protein trafficking, and active transportation of metabolites. The F-ATPases ($F_{(0)}F_{(1)}$-ATPases) can synthesize ATP by using a H^+ gradient, and they work in reverse to create a H^+ gradient by using the energy gained from the hydrolysis of ATP. Subunits belonging to either the V_1 vacuolar sector or the F_1 mitochondrial complex of ATPase were found among the differentially expressed proteins in this research: these proteins are classically thought to reside in the tonoplast (Nelson and Harvey 1999) and in the mitochondrial membrane, respectively, although they were found in the PM in other organisms (Nelson and Harvey 1999). The presence of these two proteins either reveals a true contamination caused by technical problems or it reflects

functional interactions between the PM and these particular structures (Marmagne et al. 2004). Moreover, V-ATPase subunits have been identified already in highly purified plasma membrane extracts (Santoni et al. 1998; Marmagne et al. 2004). In the case of the regulatory alpha subunit of mitochondrial ATP synthase that shows an almost three-fold relative increase in the treated samples, this effect may be caused by an enhanced metabolic energy demand in response to HS. In the case of vacuolar ATPase, the result is apparently contradictory, given the presence of two down-regulated spots (308 and 312, −78% and −51%, respectively) and one upregulated spot (341, +58%). This variation may result from posttranslational modifications of the protein that could not be resolved in this work. In most of the previous cases, the results were attributed to the plasma membrane E_1-E_2-type ATPase, but changes in vacuolar (Pinton et al. 1992) and mitochondrial (Visser 1987) ATPases have also been found.

Others A number of the differentially expressed proteins are involved in the plant's interaction with the environment, while the functions of others have yet to be clarified. The interpretation of the changes in their abundance after the HS treatment is more challenging because of the complex network of signaling pathways. In some cases, the changes observed might reflect interesting aspects of plant metabolism that deserve further study. For example, beta-glucosidase-aggregating factor (BGAF) (spot 566, lowered by the treatment) interacts with beta-glucosidases (Kittur et al. 2007), which may release IAA from its glycosidic form, thus influencing IAA availability and possibly inducing a hormonal effect (Pizzeghello et al. 2001). Phenylalanine ammonia-lyase (PAL) expression was also affected by HS. As it links the primary metabolism of aromatic amino acids with the secondary metabolism of the phenylpropanoid pathway, its downregulation can be interpreted as forcing carbon skeletons toward energy metabolism.

To the best of our knowledge, this is the first proteomic analysis of changes induced in maize root plasma membranes after exposure to HS. A total of 42 differentially expressed proteins were identified. We focused on the proteins that relate to energy and metabolism, and cellular transport, transport facilitation, and transport routes. The majority of the proteins identified were downregulated. HS appeared to affect sucrose metabolism, malate dehydrogenase, ATPases, and cytoskeletal proteins. In some cases, our data better illustrate effects already reported in more simple models (i.e., *Nicotiana tabacum* callus), whereas in other cases, they enable a more detailed description of previous findings, or help to explain earlier results reported on the level of enzyme activity.

HS concentration and time of incubation are major parameters in unraveling plant responses to HS. Given the theoretical and practical limitations of proteomics, future investigations should consider these issues. Moreover, to investigate completely the HS/maize system, changes on the m-RNA level in HS-treated plants should also be considered in future research.

The proteins analyzed in this study are only a small part of the maize proteome; many other HS target proteins remain to be identified. However, the HS-responsive proteins in the root PM of *Z. mays* reported in this work can serve as a platform for future work investigating plant reactions to HS.

Acknowledgments The authors thank Dr. Ornella Francioso of the Dipartimento di Scienze e Tecnologie Agroambientali, Università degli Studi di Bologna, for the DRIFT characterization of humic substances. The authors are also grateful to Prof. Angelo Fontana (CRIBI) for fruitful discussions.

Letter from the Editor-in-Chief

Published online: 25 June 2008

This is the fifth Special Issue of the Journal of Chemical Ecology since 2000. Previous topics were: Allelopathy—September 2000; Aquatic Chemical Ecology—October 2002; Molecular Chemical Ecology—December 2004; and Mammalian Chemical Ecology—June 2006. This issue on "Olfactory Ecology" is largely the result of efforts by John Hildebrand and Jeffrey Riffell both in the Division of Neurobiology at the University of Arizona. It resulted from discussions at the International Society of Chemical Ecology meeting in 2006.

As well as contributing as authors, Hildebrand and Riffell established a conceptual framework for this issue, solicited review papers, had each paper peer reviewed, and contributed to the editing. As stated in their following preface, they have bridged the field of chemical ecology, olfactory neurobiology, and animal behavior. The focus on both vertebrates and invertebrates is this regard is unique. I suspect that these papers will both enlighten many workers in diverse research areas and assist others in focusing future work.

The issue includes three other major contributions: two modeling papers by Gould et al. (with a separate introductory Preface by Marcel Dicke) and a review article by Thomas Baker based on his Silverstein/Simeone Award Lecture at an International Society for Chemical Ecology meeting in Hamburg. While not directly linked to the "olfactory ecology" symposium effort, these papers seem to be well placed here.

I express particular thanks to John Hildebrand for the original idea and the intellectual stimulation and to Jeffrey Riffell for hours and hours of drudge work, diplomacy, and collaborative goodwill; to Marcel Dicke for graciously helping us place some perspective on the modeling work; and especially to the authors of these stimulating and important contributions.

Preface

Received: 12 May 2008 / Revised: 15 May 2008 / Accepted: 20 May 2008 / Published online: 26 June 2008

This special issue of the *Journal of Chemical Ecology* focuses on the olfactory ecology of insects and other vertebrate and invertebrate taxa. The impetus for this project arose in part from discussions at the Annual Meeting of the International Society of Chemical Ecology in Barcelona in 2006 and in connection with a symposium on sensory ecology at the FENS Forum in Vienna in the same year. Eight invited review papers, two contributed papers, and an invited paper by a Silverstein/Simeone honoree explore important aspects of the physical nature of behaviorally relevant olfactory stimuli in the natural environment and the adaptedness of the olfactory system to detect and process them in mediating behavioral responses.

Our goal was to bridge the fields of chemical ecology, olfactory neurobiology, and animal behavior, and to highlight synergies. Much is known about olfaction in vertebrates and invertebrates, and the field has been vigorous and productive in the last two decades. Chemical ecologists have clarified the chemistry of natural mediators of interactions among organisms and associated behavioral responses to those stimuli for many taxa. Most studies of olfaction, however, emphasize the neurobiology of the olfactory system but pay relatively less attention to natural chemical stimuli and their role in the natural environment—that is, the stimuli for which the olfactory system is adapted. We believe that there is a need for chemical ecology to inform olfactory research and *vice versa*, and that the emerging field of sensory ecology offers a fruitful context for such bridge-building.

We have focused on "olfactory ecology" as a specific case of sensory ecology. In our view, research on insects has been in the vanguard in making the connections we hope to foster, while other taxa often provide interesting contrasts and comparisons with what has been learned from insects. Thus, this issue offers four articles on insects as exemplars, each paired with a companion article that focuses on other, vertebrate or invertebrate, taxa.

Explanation of olfaction-mediated search strategies requires understanding of the spatial and temporal properties of natural chemical stimuli. Indeed, olfaction-mediated navigation is exquisitely governed by physical–environmental processes and their effects on natural chemical stimuli. In the introductory paper, Zimmer and Zimmer discuss the need for accurate simulation of both chemical and physical processes for accurate determination of how air- and waterborne chemical signals mediate ecological interactions. The following paper, by Riffell, Abrell, and Hildebrand, suggests techniques for measurement of the physical properties of chemical stimuli in the environment for studies of odor-modulated behavior of insects. The articles by Cardé and Willis and by DeBose and Nevitt review the behavioral mechanisms by which insects, birds, and fish navigate in turbulent odor plumes. The similarity of behavioral strategies employed by both aquatic and terrestrial animals—vertebrates and invertebrates alike—suggests that the challenges associated with olfaction-mediated searching for sources of chemical stimuli are universal and may be reflected in similar neural mechanisms in diverse taxa.

Olfactory-receptor responses and olfactory coding in peripheral sensory organs provide examples of ways in which olfactory systems track rapidly varying, natural stimuli and encode specific cues while sampling the complex chemical landscape that guides innate and adaptive behaviors. With the recent sequencing of insect genomes, a wealth of information has emerged about molecular and neural mechanisms of receptor-cell responses to chemical stimuli. The paper by de Bruyne and Baker provides insight into the ecological importance of natural chemical cues while enabling phylogenetic comparisons among insect

species. In their companion paper, Derby and Sorenson address the complexity of the olfactory systems of aquatic animals and of the chemical stimuli they must analyze, relative to the situation for terrestrial insects. Together, these two papers highlight exciting research opportunities that combine genetic and molecular with behavioral and analytical approaches. Moreover, the articles demonstrate that while chemical stimuli that mediate interactions among aquatic animals and terrestrial animals differ, olfactory receptor cells in fish, crustaceans, and insects can sample the chemical environment rapidly while encoding diverse and complex stimuli.

An understanding of how sensory information about natural chemical stimuli is processed by the olfactory system is essential for unraveling mechanisms by which complex odors evoke innate and adaptive behaviors. In their paper, Lei and Vickers examine some of the mechanisms by which the primary and higher-order processing centers of the olfactory system in insects may encode information about odor mixtures. In a review of olfactory processing in vertebrates, Gelperin examines the computational means by which the higher-order olfactory system encodes complex stimuli. For both insects and vertebrates, single odorants predominantly have been used to examine how the olfactory system encodes odor information. In nature, however, olfactory stimuli typically are mixtures. The mechanisms by which such complex olfactory stimuli are discriminated, recognized, and elicit behavior currently are under investigation, but recent evidence suggests that behaviorally important mixtures may be encoded by the olfactory system as a singular object, whereas odors of lesser significance may be represented by the dominant constituents.

Finally, as the eight review articles in this special issue provide an overview of the processes that underlie olfaction-mediated behaviors and ecological interactions, we hope that this collection will stimulate chemical ecologists, investigators of animal behavior, and olfactory neurobiologists to cooperate and collaborate in future research.

REVIEW ARTICLE

Dynamic Scaling in Chemical Ecology

Richard K. Zimmer · Cheryl Ann Zimmer

Received: 27 March 2008 / Revised: 24 April 2008 / Accepted: 28 April 2008 / Published online: 3 June 2008

Abstract Natural rates of chemical production, release, and transport of fluid-borne molecules drive fundamental biological responses to these stimuli. The scaling of the field signaling environment to laboratory conditions recreates essential features of the dynamics and establishes ecological relevance. If appropriately scaled, laboratory simulations of physical regimes, coupled with natural rates of chemical cue/signal emission, facilitate interpretation of field results. From a meta-analysis of papers published in 11 journals over the last 22 years (1984–1986, 1994–1996, 2004–2006), complete dynamic scaling was rare in both field and laboratory studies. Studies in terrestrial systems often involved chemical determinations, but rarely simulated natural aerodynamics in laboratory wind tunnels. Research in aquatic (marine and freshwater) systems seldom scaled either the chemical or physical environments. Moreover, nearly all research, in all environments, focused on organism-level processes without incorporating the effects of individual-based behavior on populations, communities, and ecosystems. As a result, relationships between chemosensory-mediated behavior and ecological function largely remain unexplored. Outstanding exceptions serve as useful examples for guiding future research. Advanced conceptual frameworks and refined techniques offer exciting opportunities for identifying the ecological significance of chemical cues/signals in behavioral interactions and for incorporating individual effects at higher levels of biological organization.

Introduction

The nature of chemical cues and signals varies considerably over time and in space. Behavioral activation is a unique property of specific stimulus conditions that characterizes each microhabitat. Responses of chemosensory receptors, cells, organs, and hence, whole, integrated organisms are scaled according to the number of molecular contacts per unit time (Hildebrand 1995; Mead 2002). Larger values usually reflect higher rates of contact. The intensity of a given reaction to an ecologically relevant chemical cue, therefore, determines whether or not a behavior is effective. Appropriate scaling of the field signaling environment to the laboratory simulates the essential characteristics of the dynamics (Nowell and Jumars 1987; Zimmer and Butman 2000). Such scaling enables analysis of constraints imposed by natural physicochemical phenomena on biological responses at individual, population, and community levels.

Whereas many studies have contributed significantly to current knowledge of dynamic scaling, two watershed contributions, published in 1984, are particularly seminal. Elkinton et al. (1984) presented the first experiments to test predictions of the Gaussian plume model within a complex natural habitat. They provided unequivocal evidence that

time-averaged, Gaussian descriptions of airborne attractants could not account for observed behavioral responses. Nowell and Jumars (1984) offered a fresh, new conceptual framework, along with compelling examples, of hydrodynamic effects on organisms living in boundary-layer flow environments. Together, these studies showed that (1) tracking scents depends on fine details of near-bed, turbulent fluid motions, and (2) mean and fluctuating terms of velocity (i.e., Reynolds stresses) determine the outcomes of basic ecological processes, including courtship and mating, habitat colonization, and predator–prey interactions.

In the present synthesis, research on contact and fluid-borne chemical cues/signals is assessed relative to the basic principles of dynamic scaling. There are two, complementary, components to the paper. The first section is a discussion of conceptual issues, and the second evaluates, quantitatively, recent history and current research trends in the literature (Tables 1 and 2). By using a meta-analysis of papers published in 11 journals, this critique evaluates the pervasiveness of dynamic scaling in studies of chemical cues and signals. The contribution of a research field cannot be determined solely by the number of papers published in specific subdisciplines. Nevertheless, this assessment of status and trends is a valuable starting point, and suggests fruitful avenues for future research.

Table 1 Meta-analysis[a]: For 11 journals, papers were included in the analysis if published as research articles, notes, or communications over three, 3-yr blocks (1984–1986, 1994–1996, and 2004–2006)

Subject area	Periodical name (abbreviation)
Chemical ecology	Journal of Chemical Ecology (JCE)
	Chemoecology (C)
General ecology	Ecology (E)[b]
	Ecological Monographs (EM)[b]
	Ecology Letters (EL)
	Oecologia (O)
Marine biology/ ecology	The Biological Bulletin (BB)
	Marine Ecology Progress Series (MEPS)
	Marine Biology (MB)
	Journal of Experimental Marine Biology and Ecology (JEMBE)
	Limnology and Oceanography (LO)

[a] While not exhaustive, this select list was a reasonable representation of each field. Chosen journals were ranked highly by impact factor (ISI 2006). The present analysis did not take into account general biological and scientific journals (e.g., Science, Nature, PNAS, and PLoS Biology), because they devoted <3% of all published manuscripts to overall topics in ecology, as indicated by a more limited survey (1986, 1996, 2006). Far fewer papers were dedicated to chemical cues/signals.

[b] Manuscripts appearing in Ecology and Ecological Monographs were pooled prior to analysis, because they are essentially the same journal, published by the Ecological Society of America.

Dynamic Scaling: Conceptual Issues

Chemical, physical, and biological variables are rarely static in nature. Experiments, thus, require 'dynamic scaling'—the simulation of essential chemical and physical features of a changing native signaling environment—to establish ecological relevance. Moreover, in chemical ecology, the dynamics of individual-based performance must be scaled up to understand basic population, community, and system structure and function.

Field studies are designed to capture the innate spatiotemporal properties of cue/signal distributions and experimentally evaluate cause and effect. Complementary field measurements also can set boundary conditions for dynamically scaled laboratory experiments. In the lab, separate effects of biological, chemical, or physical factors often can be analyzed more clearly in experiments with individual organisms, small populations, or even multiple species at different trophic levels. Whereas laboratory studies may offer insights about processes that influence community-wide and system-level mechanisms, they lack the complexity of native field environments. Studies of how ecological relationships are mediated by chemical cues/signals may profit from an approach that combines natural field studies with dynamically scaled laboratory experiments.

Scaling the Chemistry The physical and chemical properties of habitats can determine the nature and success of ecological interactions. In terrestrial environments, for example, compounds with high vapor pressures facilitate chemical transport in air. Many signal molecules thus are low molecular weight (less than 20 carbon atoms) and hydrophobic (alcohols, aldehydes, or ester acetates; Roelofs 1995; Ando et al. 2004). In contrast, aqueous solubility imparted mainly by electronic charge or hydrophilicity, rather than gaseous volatility, may constrain the types of substances that act principally as waterborne chemical agents (Carr 1988). Peptides, free amino acids, carbohydrates, organic nitrogen bases, nucleotides and nucleosides, and fatty acids are all putative, chemical cues/signals that mediate ecological processes in aquatic environments (Howe and Sheikh 1975; Pawlik 1992; Painter et al. 1998; Krug and Manzi 1999; Hardege et al. 2004; Cummins et al. 2005; Kicklighter et al. 2007). Even compounds with low solubilities, being small and hydrophobic, or large proteins, can provide effective signals in water when suspended and transported by fluid motion.

Chemical identities are essential for studies that link behavior, chemosensory physiology, and receptor function. Structural elucidations are required to distinguish unique natural products from more common metabolites that serve a variety of functions. The courtship and mating attractants

Table 2 Meta-analysis: major goals, rationales and qualifications

Goal	Rationale and qualification
1. Establish, for each journal, the relative percentage of all papers published on topics pertaining to chemical cues and chemical signals (Fig. 1)	A. Manuscripts on marine and freshwater systems were analyzed separately within categories of 'chemical ecology' and 'general ecology' B. Studies pertaining to the use of chemical defense compounds and allelopathics were not included with cues and signals, unless direct evidence was presented for chemosensory-mediated processes. Antifeedants, toxins, and related molecules often target physiological processes unrelated directly to behavior.
2. Of those papers published on chemical cues/signals, establish the percentage associated with a given habitat type (terrestrial insects, other terrestrial, and aquatic [freshwater + marine] organisms; Fig. 2)	A. The terrestrial habitat group was broken into two sub-groups, because of a preponderance of studies on insects in some journals.
3. Establish the percentage of papers that focused on a particular behavior and/or ecological relationship (habitat [or host] selection, trophic relations, courtship and mating, other social interactions, and miscellaneous; Fig. 3)	A. Categorization, according to infochemical terminology (e.g., pheromone, allomone, synomone, kairomone; Dicke and Sabelis 1988), was avoided because these names relate only costs and benefits to cue/signal producing and receiving organisms without specifying the type of ecological interaction.
4. Establish the percentage of papers that reported results using either partially-, fully-, or un-identified chemical cue/signal molecules (Figs. 4, 5, and 6)	A. The 'fully identified' cue/signal group was broken into two sub-groups: (a1) substances identified via bioassay-guided fractionations of natural materials, and (a2) compounds taken directly off-the-shelf without reference to a native source.
5. Establish the percentage of papers that reported results using either partially-, fully-, or un-characterized flow environments (Fig. 7)	A. Field and lab investigations, with measurements of mean and fluctuating components of velocity, were classified as 'fully'. In contrast, studies having any type of determination, such as mean flow speed, were labeled as 'partially'.
6. Establish the percentage of papers having as a principal focus individual organisms, populations, communities, or ecosystems (Fig. 8)	A. The 'individual organism' group was divided into three subgroups of 'molecular biology/biochemistry', 'physiology', and 'behavior and/or ecology'.

of lepidopteran insects are especially useful examples. They present a wide range of novel compounds and mixture blends that confer species-specific recognition. The molecular basis for attractant biosynthesis has revealed much about the evolution of chemical communication systems and the explosive radiation of lepidopteran species (e.g., Mayer and McLaughlin 1991; Roelofs 1995; Roelofs and Rooney 2003). Notably, a single point mutation can cause activation of a nonfunctional desaturase gene transcript, alter attractant structure, and lead to insipient speciation within a single generation (Roelofs et al. 2002). Ordinary molecules also have extraordinary effects. Histamine, for instance, initiates local immune responses (Jutel et al. 2006; Sugata et al. 2007), regulates receptor-mediated physiological processes in the gut (Filippova and Nozdrachev 2007), acts as a neurotransmitter (Jones 2005; Stuart et al. 2007), and stimulates habitat colonization by organisms of highly divergent species (Swanson et al. 2004, 2006). Such assorted communication functions arise from convergent evolution. Studies on the comparative biology of signaling systems across taxa, therefore, can lead to improved appreciation for mechanisms that create and maintain biodiversity.

Laboratory experiments dynamically scaled to field environments simulate natural patterns of contact between signal molecules and biological sensors. The type and magnitude of behavioral responses depend on rates of signal production and release, and hence, on stimulus encounter frequencies. Chemical identification is the first step towards achieving dynamic scaling, and enables matching of natural concentrations and fluxes among study environments. As an example, the relative effects of chemical composition (of an attractant mixture), concentration, mean volume flow rate (of chemical input), and flux (concentration × volume flow rate) were evaluated for search behavior of marine snails (Zimmer et al. 1999). In separate field tests, only flux was significantly correlated with the number of animals attracted to the site of chemical emission. Behavioral responses were more tightly coupled to chemical release and transport dynamics than to specific properties of any single attractant molecule.

Scaling the Physics For organisms living in air or water, fluid motion is a characteristic property of the environment. Even in the absence of noticeable wind or water flow (such as in small ponds), differential heating causes convection

and induces movement. Fluid velocity is characterized by mean and random, fluctuating terms. Whereas the mean flow moves fluid along one principal axis (such as downwind or down current), velocity fluctuations generate shear forces that potentially distribute momentum in three spatial dimensions (Nowell and Jumars 1984; Denny 1988; Weissburg 2000). The rate at which fluid disperses dissolved chemicals away from a principal axis, as a consequence of random velocity fluctuations, is called turbulent (or eddy) diffusion. Just as a biologist measures the mean and variation of a morphological, physiological, or behavioral trait, a chemical ecologist needs to quantify the mean and variation of chemical transport due to fluid flow. Scaling between native field environments and laboratory regimes (i.e., in wind tunnels and flumes) involves matching key dimensionless parameters that embody the essential physics of the research system (Miller et al. 1984; Nowell and Jumars 1987; Peterson and Hastings 2001). The creation of dynamic similarity is usually straight forward and facilitates the extrapolation of laboratory results to the field.

For macroscopic organisms, distributions of chemical cues are patchy, both temporally and spatially, as a consequence of turbulent diffusion (Murlis and Jones 1981; Zimmer-Faust et al. 1988; Murlis et al. 1992, 2000; Mylne et al. 1996; Finelli et al. 1999). The magnitude of signal variation ultimately depends, however, on the relative strength of mean versus fluctuating terms of fluid motion. These two quantities reflect the unique properties of inertial forces that put fluid into motion, of structural features that distinguish natural habitats (e.g., heights and densities of plants or trees, topographies of seafloor or stream bottom sedimentary environments), and of morphological features that characterize respondent organisms. In combination, such features establish complex sets of spatiotemporal dynamics in the chemical cues/signals affecting behavior of different organisms in various ways.

Effects of turbulence can be experienced by organisms of all sizes. At the smallest scales (bacteria, sperm, many protozoa), adjacent layers of fluid slide past each other without being mixed (called "laminar flow"; Karp-Boss et al. 1996). Much like a pot of honey stirred by a spoon, the fluid moves along lines of constant velocity and quickly stops when the force ceases. Within the smallest turbulent structures (called "eddies"), speed increases from the center towards the perimeter, characterizing the laminar shear flow within. Whether suspended in a moving fluid or attached to a wall (e.g., blood vessel), at any fluid–surface interface, single cells experience shear stresses on their membrane surfaces.

Behavior is an important process that mediates recruitment of sperm to conspecific eggs (Miller 1985; Ward et al. 1985; Riffell et al. 2002; Yoshida et al. 2002; Kaupp et al. 2006). Relative to high shears, cells swim significantly faster and orient more directly towards eggs at low shears and in still water. In fact, even though male gametes swim at the same speed in low shears and still water, sperm navigation is significantly enhanced at low shears (Riffell and Zimmer 2007). Accordingly, fertilization success peaks in these slow flows. Low shear/slow flow creates fluid-dynamic conditions that are highly conducive for broadcasting chemical signals. Egg attractant is released and transported by flow with minimal dilution. The result is a behaviorally active attractant plume. Plume length and active volume peak at the lowest shears tested, and then decay rapidly thereafter, reflecting precisely the patterns described for sperm recruitment and fertilization success (Riffell and Zimmer, unpublished data). As for macroscopic organisms, dynamic scaling of flow relative to nature is required to understand the ecological and evolutionary consequences of chemosensory-mediated behavior of single cells.

Scaling up from Individuals Services rendered by an ecosystem reflect the composite attributes of its inhabitants. System-level processes, such as total primary productivity, efficiency of nutrient use, disease dynamics, invasions by exotic species, and stability in the face of natural climate forcing and human perturbations have profound global implications (Tilman 1999; Loreau et al. 2001; Duffy and Stachowicz 2006). These properties are, in turn, highly dependent on networks of interactions among individuals both within and between species. Relying on sensory information to shape decisions, individuals exploit beneficial and avoid detrimental interactions. In fact, stimulus-response dynamics potentially influence every other level of organization, from population to ecosystem.

Because cellular mechanisms of chemosensory reception are highly converged across taxa (Ache 1994; Hildebrand 1995; Hildebrand and Shepherd 1997), the same bioactive compounds can be informative for phylogenetically diverse species. One, or only a few, "infochemicals" potentially have system-level consequences. A well-documented case of scaling up chemosensory-mediated interactions is found in the open ocean. Here, single-celled plants ("phytoplankton") create dense blooms at convergent zones where high nutrient levels occur in surface ocean waters. These cells have extremely high concentrations of dimethylsulfoniopropionate (DMSP) that equalize osmotic pressure between the cytoplasm and external ocean environment (Dacey et al. 1987; Matrai and Keller 1994). When phytoplankton cells burst open during herbivore ("zooplankton") grazing, DMSP is released into seawater and enzymatically cleaved to dimethylsulfide (DMS), acrylic acid, and a proton (Dacey and Wakeham 1986). In seawater, acrylic acid acts as a chemical deterrent against protozoan grazers (Wolfe et

al. 1997; Wolfe 2000). Alternatively, DMSP serves as a chemoattractant to biodegradatory bacteria (Zimmer-Faust et al. 1996). Whereas dissolved DMS stimulates zooplankton foraging (Steinke et al. 2006), atmospheric DMS guides seabirds over kilometers to rich zooplankton feeding grounds (Nevitt et al. 1995; Nevitt 2000). Thus, a combination of three closely related compounds (DMS, DMSP, and acrylic acid) produces effects that cascade down four trophic levels, thus connecting microbial loop dynamics (protozoans, bacteria) with apex predation (seabirds).

Dynamic Scaling: Recent History and Current Trends

The evaluation of recent history and current trends of dynamic scaling in studies of chemical cues/signals provides a judicious retrospective of ecological context. Papers published in 11 journals over the last 22 years were classified according to various attributes (Tables 1 and 2). Having identified the percentage of studies on chemical cues/signals, research was further broken down by habitat type, ecological interaction, chemical identification, flow characterization, and level of ecological organization. Specific goals and details of the meta-analysis procedure are provided in Table 2. Where appropriate, differences in literature trends were tested for significance by using Students *t* tests, or analysis of variance (ANOVAs) and post hoc Scheffé tests, with percentages arc-sine transformed before analyses. When data were pooled across 3-year intervals (1984–1986, 1994–1996, and 2004–2006), we applied *G* tests in determining significance levels among proportions of published articles between specified categories.

Meta-Analysis: Chemical Cues/Signals For chemical ecology journals, mean percentages of published papers on chemical cues/signals decreased over time [Fig. 1A and one-way ANOVA $F_{2,6}=31.32$, $P<0.001$ for Journal of Chemical Ecology (JCE)]. During the last 22 years, JCE devoted ~50–75% of all articles per year to this topic. Similar percentages, although based on much lower numbers, were published by Chemoecology (C), since its inception in 1990. Still, overall, total number of articles printed on cues/signals varied considerably from 240–310/year in JCE to 16–24/year in C. Both periodicals dedicated a majority of these papers to work highlighting terrestrial insects, and thus, were relatively limited in scope (Fig. 2, and two-way ANOVA followed by Scheffé tests: $P<0.001$ for JCE).

Likely, more articles were published on chemical cues/signaling concerning insects simply because more work was done on this topic. Increased access to model organisms and habitats for experimental manipulations, availability of funding, and the focus of entire academic departments and research labs on entomology, per se, all could have contributed to proportionally more research articles on insects relative to other taxa. By using JCE as a case study, no significant difference was found in the ratio of manuscripts submitted to those accepted for publication on insects relative to other taxa (J. Romeo, personal communication). Thus, there is no inherent bias for, or against, any specific taxonomic group.

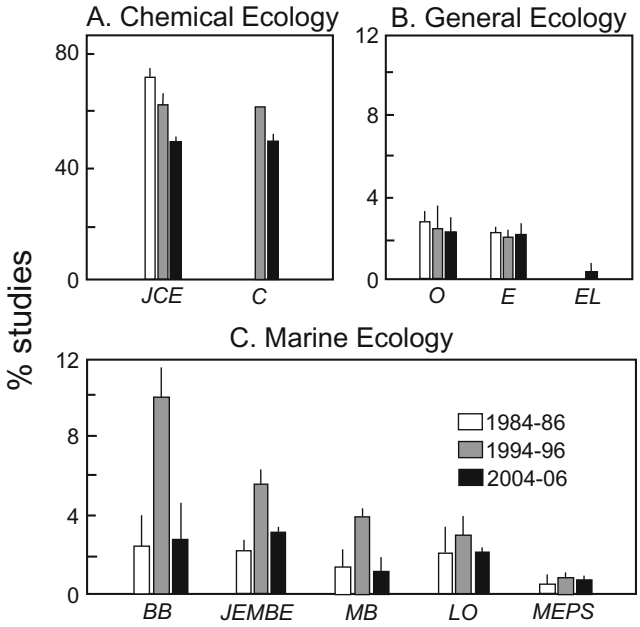

Fig. 1 Relative percentages (mean ± SEM) of all papers published on topics pertaining to chemical cues and chemical signals. Abbreviations: JCE (Journal of Chemical Ecology); C (Chemoecology); O (Oecologia); E (Ecology and Ecological Monographs, combined); EL (Ecology Letters); BB (Biological Bulletin); JEMBE (Journal of Experimental Marine Biology and Ecology); MB (Marine Biology); LO (Limnology and Oceanography); MEPS (Marine Ecology Progress Series)

A different trend was identified for general ecology journals (Fig. 1B). Mean percentages of papers on chemical cues/signals were nearly constant, but extremely low [2–3% per year for Ecology (E) and Oecologia (O)] over the survey period (one-way ANOVAs: $F_{2,6}\leq 0.61$, $P\geq 0.59$, both tests). A third journal, Ecology Letters (EL), appeared in 1998 and published only 0.25% of papers on cues/signals from 2004 to 2006. Over 1984–1986, rates of publication in E and O were nearly identical for chemical cue/signal research (2.3–3.0%) and for chemical defense/allelopathic research (2.6–3.1%) (Students *t* tests: $t_4\leq 0.37$, $P\geq 0.72$, for E and O). The values for defenses/allelopathics increased precipitously to 4.1–5.2% during 1994–1996, and remained steady through 2004–2006. By comparison, percentages of papers on chemical cues/signals decreased slightly (to 2.0–2.4%) from 1984–1986 to 2004–2006 (*t* tests: $t_4\geq 5.43$, $P\leq$

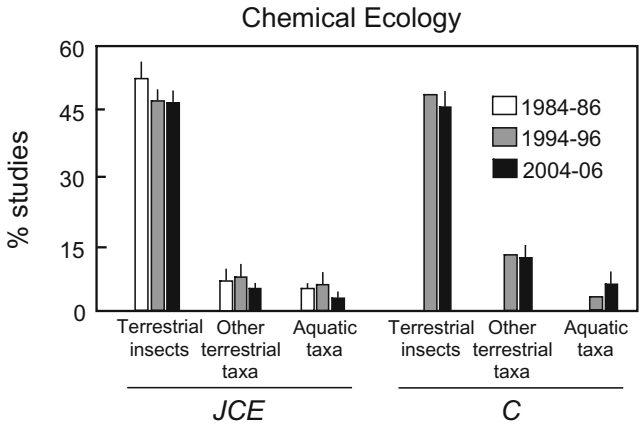

Fig. 2 Chemical ecology journals: Relative percentages (mean ± SEM) of all papers published on topics pertaining to chemical cues/signals for terrestrial insects, other terrestrial organisms, or aquatic (freshwater + marine) organisms. Abbreviations: JCE (Journal of Chemical Ecology) C (Chemoecology)

0.008, both tests, when comparing separately data for 2004–2006 in O and in E). These trends may reflect heightened interest in chemical defense/allelopathics relative to chemical cues/signals.

In fact, ecologists have championed community-wide impacts of defenses and allelopathics. Historically, these natural products were known as direct contributors to competition and predator–prey interactions, two biological processes that regulate strongly community dynamics (Muller et al. 1964; Feeny 1976; Atsatt and O'Dowd 1976; Hay and Fenical 1988; Hämback and Beckerman 2003; Agrawal et al. 2006). Research on cues and signals, in contrast, has focused almost entirely at the organism level, without much attention to higher levels of biological organization (see details in subsequent sections). There is, however, growing appreciation for chemical cues and signals in determining trait-mediated interactions of animals, plants, and microbes. Community-level consequences of such chemically mediated behavioral and morphological responses by organisms are a newly emerging topic of growing interest (Alborn et al. 1997; De Moraes et al. 1998; Peacor and Werner 2001; Trussell et al. 2002, 2006; Pohnert et al. 2007). The ratio of published articles on defense/allelopathy to cues/signaling, therefore, may tend more towards unity over the next 5 to 10 years.

For marine journals, a third publication pattern distinguishes it from other periodicals (Fig. 1C). Except for Marine Ecology Progress Series (MEPS) and Limnology and Oceanography (LO) all surveyed publications exhibited a major spike in percentages of papers on chemical cues/signals during 1994–1996 (two-way ANOVA, journal × time: $F_{4,30}=9.63$, $P<0.001$; Scheffé tests: $P<0.05$), although it was not sustained by The Biological Bulletin (BB), Journal of Experimental Marine Biology and Ecology (JEMBE), and Marine Biology (MB). Mean percentages showed a slight, but nonsignificant, increase from 1984–1986 to 2004–2006 (Scheffé tests: $P>0.20$).

Repeatedly, over these two decades, marine chemical ecology was declared an exciting, emergent field (Bakus et al. 1986; Hay 1996, 2002; McClintock and Baker 2001). Yet, this enthusiasm is not reflected in the percentage of research articles dedicated each year to marine chemical cues/signals. Many factors may contribute to the current paucity of research on marine species. First, chemical ecologists have had limited ability (or interest?) to scale-up findings from organism-based research to populations and communities. In particular, there have been relatively few successful efforts to isolate and identify the complete structures of marine natural products that act as dissolved chemical cues and signal molecules (see review of Zimmer and Butman 2000). Second, critical properties of fluid dynamic environments have been only rarely measured within natural habitats or applied appropriately in scaling laboratory experiments that investigate chemical-mediation of ecological interactions among plants and animals. These limitations in scaling chemistry and physics are detailed more fully in subsequent sections of this paper.

Either marine biologists are not talking with chemists and physicists, or their messages are not being heard. In the absence of adequate chemical and physical determinations, cues and signals from laboratory and field experiments cannot be interpreted within natural historical contexts. With recent, seminal advances in theory and technology, especially over the last 10–15 years, however, future research on marine organisms should progress more quickly and consistently towards natural-product identifications and hydrodynamics characterizations (see, for example: Painter et al. 1998; Crimaldi et al. 2002; Webster et al. 2003; Swanson et al. 2004; Dreanno et al. 2006; Jackson et al. 2007; Kicklighter et al. 2007).

Meta-Analysis: Ecological Interactions The breadth of publications in chemical ecological journals has increased over time (Fig. 3A, and G test: $G_8=16.11$, $P=0.05$). From 1984–1986, investigations focused primarily on structural elucidations of mating and courtship attractants. An exciting period, there was a major paradigm shift away from single attractant molecules towards novel blends of attractant mixtures that confer species specificity in communication between prospective mates. Later (1994–1996 and 2004–2006), percentages of publications were more evenly distributed among trophic relations, other social interactions, and mating and courtship. During these intervals, research emphasized, for example, feeding attractants of specialized insect herbivores, chemically mediated relations between predators (or parasitoids), herbivores and host plants, conspecific attraction and aggregation (such as

those in pine bark beetles), courtship and mating attraction, as well as intra- and interspecific communication among eusocial insects (e.g., Camacho et al. 1994; Agelopoulos et al. 1995; Loughrin et al. 1995; Hamilton et al. 2005; Gammans et al. 2006).

Historically, ecologists have emphasized predator–prey interactions as seminal factors that structure populations, communities, and ecosystems (Paine 1966; Murdoch 1969; Connell 1970). Trophic relations, thus, have dominated journal publications on chemical cues/signals in general ecology (G test: G_8=27.71, P<0.001, comparing among each topic category and each 3-year interval). There was, however, a compelling reorganization of research priorities over time (Fig. 3B). For E and O, 78% of cue/signal publications during 1984–1986 focused on prey selection by consumers (e.g., Inouye and Waller 1984; Marden 1984). This research largely involved tests of optimal foraging theory. In contrast, a significant percentage (68%) of more recent articles (during 2004–2006, and G test: G_1=8.12, P=0.004 for E and O combined) focused on the consequences of prey alarm and avoidance behavior, and on prey morphological responses to predator presence (e.g., Blaustein et al. 2004; Winder et al. 2004; Brodin et al. 2006). Thus, contributions of chemical cues/signals to trophic interactions were explored sequentially by general ecologists from both predator and prey perspectives.

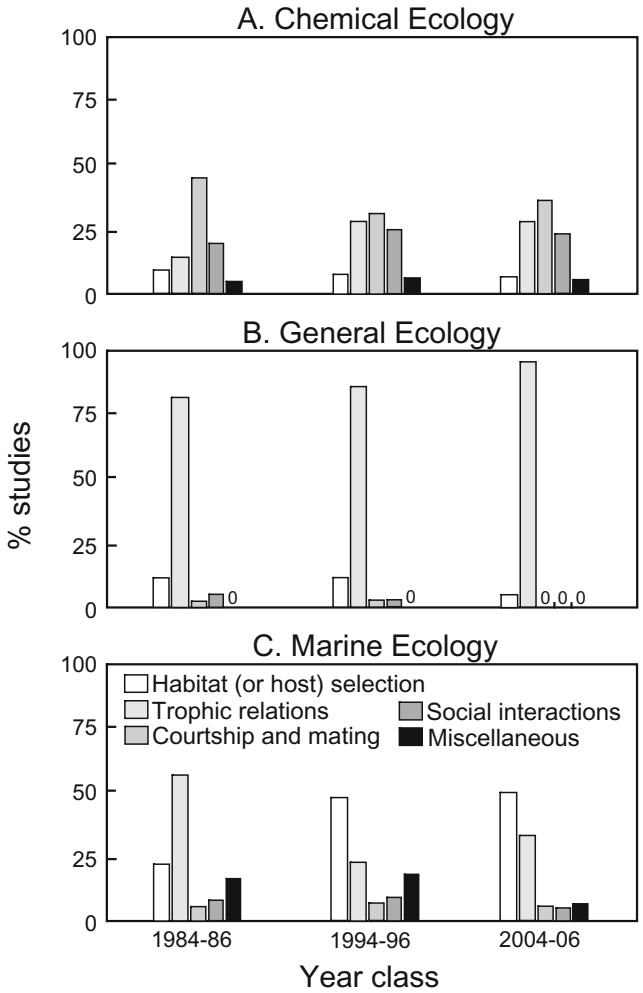

Fig. 3 Of those papers published on chemical cues/signals, the relative percentage that focused on a particular ecological interaction (see legend in **c**.). Data were pooled for chemical ecology (JCE and C), general ecology (O, E, and EL), and marine biology/ecology (BB, JEMBE, MB, LO, MEPS) journals over indicated time intervals

Research published by marine journals likewise evolved over the last 22 years (Fig. 3C). Investigations were dominated by trophic interactions from 1984–1986, with an emphasis on feeding attraction and stimulation (e.g., Trott and Robertson 1984; Johnson and Atema 1986; Sakata et al. 1986). This trend shifted in 1994–1996, when studies concentrated more on habitat colonization (G test: G_1=6.81, P=0.01). Considerable research has targeted effects of surface-adsorbed and waterborne chemical cues in mediating larval settlement behavior and metamorphosis (e.g., Gibson and Chia 1994; Boettcher and Targett 1996; Toonen and Pawlik 1996). Such cues are generally associated with hospitable habitats that provide valuable food resources for newly metamorphosed juveniles and adults, or that improve survivorship and/or mating. Responses, therefore, establish an irreversible commitment by larvae to colonize a given habitat, potentially driving rates of immigration to open marine populations, with profound consequences for demographics and community structure.

Over the last 10–15 years, there has been an explosive growth in the field of microbial chemical ecology (Crespi 2001; Fenchel 2002; Redfield 2002; Strack et al. 2003; Visser and Jackson 2004; Keller and Surette 2006; Hense et al. 2007). This work, however, has been published primarily in periodicals that target basic and applied microbiology. Positive interactions, and especially mutualisms, are gaining increased attention from general ecologists for their roles in mediating community and system dynamics (Bertness and Callaway 1994; Stachowicz 2001; Bruno et al. 2003). Many of these positive interactions are the products of relationships among microbes, or between microbes and eukaryotes. Corals, for example, can live in unproductive, oligotrophic waters because of their relationship with endosymbiotic single-celled algae. The algae produce organic carbon substrates through photosynthesis, and then pass on large proportions of these energy-rich molecules in response to chemical signals from their coral hosts (Gates et al. 1995, 1999). Similarly, sedimentary environments of terrestrial plant roots are characterized by diverse communities of microorganism species. These microbes are of singular importance in making essential nutrients bioavailable. Through quorum sensing and diffusion signaling pathways, chemical cues/signals ultimately regulate many microbial and symbiotic interactions, and

thus, have profound consequences in structuring both prokaryotic and eukaryotic communities (Perret et al. 2000; Hirsch et al. 2003; Jones et al. 2007). Future trends hopefully will see a stronger integration of research on microbial cues/signaling into leading chemical ecological, general ecological, and marine biological journals.

Meta-Analysis: Chemical Identifications Over the entire survey interval, investigations on terrestrial organisms in chemical–ecological journals have regularly included structural identities of cue/signal molecules (Fig. 4, and *G* test: $G_2=14.13$, $P<0.001$, showing a significant difference between bioassay-guided fractionations and all other cue/signal categories combined). Starting at 70–79% during 1984–1986, percentages of papers that identified molecules increased to 90–94% during 2004–2006 (*G* test: $G_1=12.36$, $P<001$, for data pooled among each 3-year interval). There has been a strong commitment to bioassay-guided fractionation, with direct tests of known bioactive compounds.

The general ecology journals demonstrated different patterns altogether (Fig. 5). Publications on terrestrial versus aquatic (marine + freshwater) systems also showed divergent temporal trends. Most terrestrial studies used unidentified chemical cues/signals during 1984–1986 and 1994–1996, whereas many cues were fully identified by 2004–2006. Percentages of cue/signal molecules, fully identified through bioassay-guided fractionation, increased from 18% to 74% over this 22-year interval (*G* test: $G_1=5.21$, $P=0.02$, comparing 1984–1986 to 2004–2006). In contrast, studies on aquatic systems rarely, partially, or fully, identified cues/signals over the entire meta-analysis period. Of all aquatic investigations evaluated, 86–98% used unidentified, while only 0–4% used fully identified cues/signals over the last 22 years (*G* test: $G_1=1.03$, $P=0.39$).

As potential sources of cues and signals, targeted aquatic organisms frequently were homogenized, and their filtered, crude extracts were bioassayed for effects on respondents.

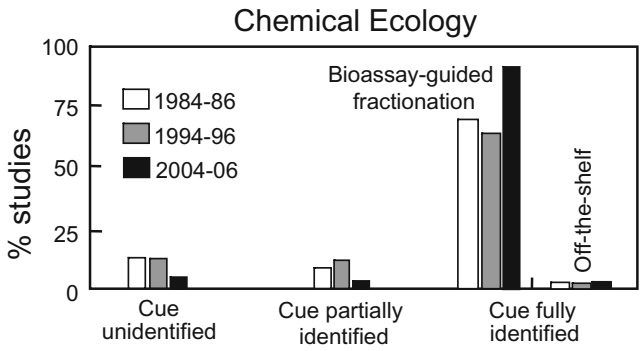

Fig. 4 Of those papers published on chemical cues/signals in chemical ecology journals (JCE and C), the relative percentage that reported results using either partially-, fully-, or unidentified compounds. Data were pooled over indicated time intervals

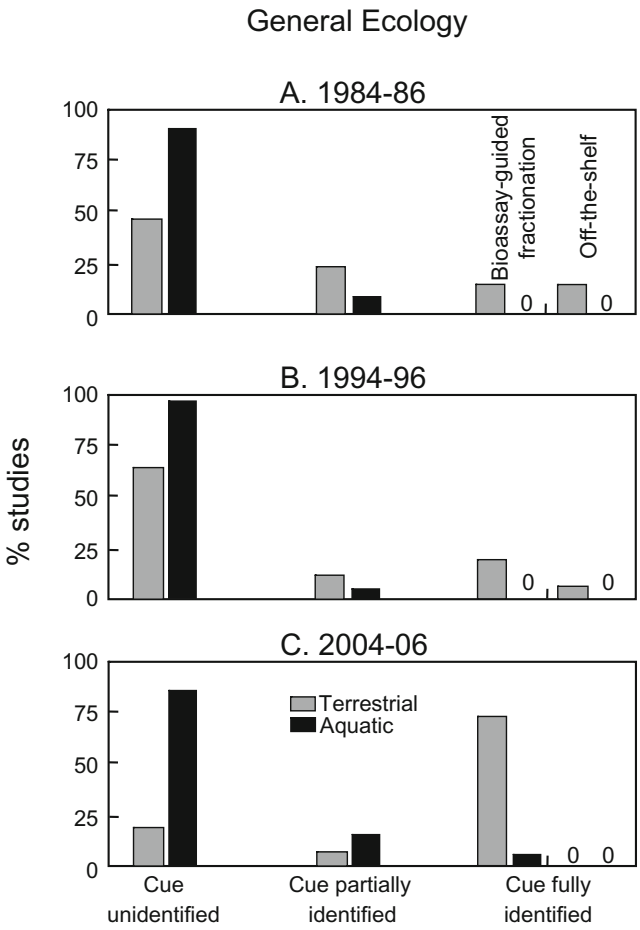

Fig. 5 Of those papers published on chemical cues/signals in general ecology journals (O, E, and EL), the relative percentage that reported results using either partially-, fully-, or unidentified compounds. Data were pooled over indicated time intervals

These procedures would be appropriate only in studies of phagostimulation. In other applications, such preparations are vulnerable to considerable artifacts (Velez et al. 2007; Nylund et al. 2007). Homogenate molecules, elaborated through invasive cell disruption, can differ substantially from those released naturally from live, intact organisms.

Alternatively, water-conditioned stimuli used in aquatic studies often were produced by bathing a targeted organism (i.e., for release of bioactive compounds). Although conditioned water is preferable over a homogenate, immersion periods often were unrealistically long (one to many [24–48] h), and in questionably small water volumes (milliliters to liter). Concentrations of combined secreta, excreta, and other effluents from targeted organisms may have been appreciably higher, or lower, than those encountered by respondents in nature. Moreover, placements of targeted organisms in running water would allow cues/signals to accumulate at natural levels only if densities and flow conditions (advection, turbulent mixing) matched actual field environments. Thus, ecological relevance is

equivocal without chemical identifications and known concentrations (and fluxes) of applied stimuli.

The probability of chemical cue/signal identification was smallest in studies published in marine journals (Fig. 6). In the early studies (1984–1986), for example, only 5% used fully identified cue/signal molecules (i.e., via bioassay-guided fractionation). In fact, cues typically were not identified: 62% (1984–1986) to 73% (2004–2006) of the investigations (*G* test: G_1=1.41, P=0.33). These results differ from those for terrestrial systems, where chemical structural elucidations have become the accepted norm.

Meta-Analysis: Physical Environments Across research environments, there have been several compelling studies that demonstrate chemical signaling effects as a function of flow. In air, the behavioral basis and neural control of odor plume navigation by flying and walking insects has superseded that for any other taxonomic group. Unprecedented knowledge of navigational mechanisms now extends from primary, olfactory receptor neurons to the brain (Vickers et al. 2001; Bau et al. 2005), and from brain to behavior (Mafra-Neto and Cardé 1994a, b; Vickers and Baker 1992, 1994). In the sea, essential properties of the field have been scaled in several laboratory flumes (Pawlik and Butman 1993; Weissburg and Zimmer-Faust 1994; Moore and Crimaldi 2004). As a consequence, fundamental relationships have been established between the mechanics of search behavior and dynamics of turbulent odor plumes (Weissburg and Zimmer-Faust 1993; Smee and Weissburg 2006). These principles were extended to field experiments (Zimmer-Faust et al. 1995; Finelli et al. 2000; Smee et al. 2008), enabling predictions of chemosensory-mediated behaviors to populations and communities.

Still, ecological significance is contingent on dynamic similarity between field and flume/wind tunnel environments (Nowell and Jumars 1987). If not, results are generic, at best, and may or may not have direct relevance to the field. As an overall group, studies in air and water showed little tendency to dynamically scale physical environments between field and laboratory (wind tunnel or flume). Mean wind speeds usually were reported in chemical ecology journals, but no investigation (over 1984–1986, 1994–1996, or 2004–2006) described the structure of turbulent flow within an apparatus or scaling to the field. Moreover, in general ecology journals, all but one investigation (Smee and Weissburg 2006) did not characterize mean and fluctuating components of natural flow environments. Over the last 22 years, marine papers exhibited growing awareness of physical controls/constraints on ecological processes (Nowell and Jumars 1984; Butman 1987; Denny 1988). A few studies, thus, involved fully characterized flows (8% in 2004–2006; Fig. 7). Still, far more of these papers (78% over 2004–2006) included no flow determinations at all (*G* test: G_1=24.11, $P<0.001$, comparing "no flow" to all other flow categories combined).

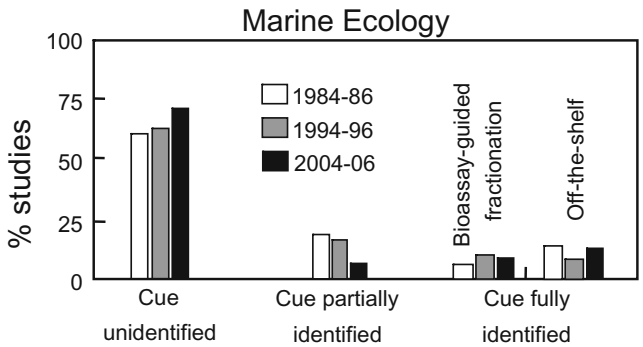

Fig. 6 Of those papers published on chemical cues/signals in marine biology/ecology journals (BB, JEMBE, MB, LO, and MEPS), the relative percentage that reported results using either partially, fully, or un-identified compounds. Data were pooled over indicated time intervals

Meta-Analysis: Scaling up from Individuals There is strong convergence among journals in publication patterns at the four levels of biological organization (individual, population, community, ecosystem). Each of the 11 surveyed periodicals on chemical ecology, general ecology, and marine biology printed, almost exclusively (≥97%, over 1984–1986, 1994–1996, and 2004–2006), articles that summarized interactions among individual organisms only. For chemical ecology journals, this trend revealed an emphasis on molecular and physiological mechanisms of chemosensory-mediated behavior, on the evolutionary basis for chemical communication and on chemical determinants of immediate trophic relations (Fig. 8, and *G* test: $G_2 \geq 7.71$, $P \leq 0.02$, showing a significant difference between molecular/biochemistry, physiology, and behavior categories among each of the 3-year intervals). Moreover, a majority of papers highlighted details of biosynthetic pathways, molecular receptive fields, and cue/signal structural elucidations. Consequently, behavior was mostly a bioassay tool, aiding the discovery of active chemical moieties. With a few notable exceptions across all journal categories (e.g., Philips et al. 2003; Kunert et al. 2005; Trussell et al. 2006, Torto et al. 2007), clear connections have yet to be established between individual-based behavior and ecological interactions at other levels. Outstanding opportunities await.

Synthesis and Conclusions

Chemical cues/signals present an extraordinary opportunity for broadening knowledge of ecological processes. The extent to which future research advances the field depends, in part, on appreciation for conceptual and methodological

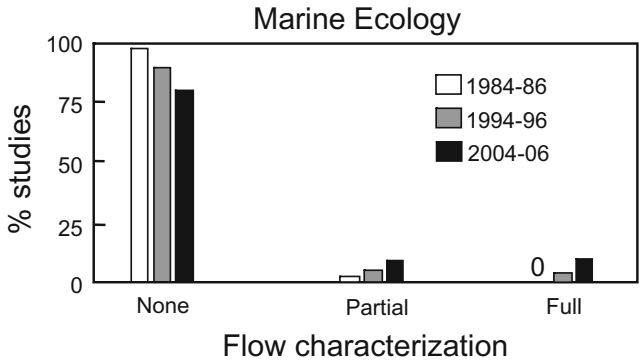

Fig. 7 Of those papers published on chemical cues/signals in marine biology/ecology journals (BB, JEMBE, MB, LO, and MEPS), the relative percentage that reported results using partially, fully, or uncharacterized flow environments. Data were pooled over indicated time intervals

issues of the past. Increased attention to combined chemical and physical determinations will improve the ecological significance of future investigations. Such advancements will be especially welcome in aquatic systems, where cue/signal molecules only rarely have been identified. Moreover, progress in ecology will proceed more rapidly from extending research beyond individual organisms to encompass populations, communities, and even ecosystems.

Current emphasis on individual-based studies is largely a research legacy. Historically, work on chemical cues/signals began in earnest through pioneering efforts of notable ethologists. Karl von Frisch (1941), for example, investigated behavioral reactions of European minnows to alarm substances from skin of damaged conspecifics. These compounds are emitted only after successful predatory attack and serve as an early warning to other, yet-unharmed, minnows. Such investigations ultimately inspired physiologists to understand the cellular basis of behavior. Today, research that links chemistry, physiology, and behavior flourishes, with a common goal of understanding the molecular basis and evolutionary ecology of chemical communication systems.

New, broad integrative approaches will be challenging, but can bear significant fruit. No longer is there a clear distinction between bioactive molecules acting either in communication or in defense. Many herbivorous animal species exhibit resistance, borrowing plant toxins for their own defense and using these same compounds in courtship and mate attraction (Shulz et al. 1993; Matsumura 1995; Zimmer and Ferrer 2007). Moreover, toxins act as feeding stimulants for consumer species that are resistant to their adverse effects (Camacho and Thacker 2006; Glendenning 2007). Similarly, plants use volatile chemical constituents for communicating with each other at a distance (Agrawal 2000; Baldwin et al. 2006; Izaguirre et al. 2006; Frost et al. 2007). Airborne substances in response to herbivore attack are carried downwind, reaching plants not yet in contact with the predator and activating inducible defenses in their tissues. Thus, lines are becoming blurred between experimental studies on animal and plant taxa, and between chemical communication and chemical defense.

Outstanding examples can guide future research. Historically, research has emphasized, for instance, the roles of chemical cues/signals in mediating behavioral interactions among single predator and single prey systems. Yet, some studies have failed to capture the more realistic ecological scenario in which prey must contend with multiple predators. Today, new investigations are increasingly incorporating three, or more, species that comprise simple food webs of top-, mid-, and bottom-level consumers with, or without, primary producers (Bernot and Turner 2001; Werner and Peacor 2003; Preisser et al. 2005). The complexity of trait-mediated (behavioral and morphological) interactions among, and between, individuals within small trophic networks can reveal the roles of chemical cues/signals under more realistic ecological conditions (Peacor and Werner 2001; Trussel et al. 2006).

Findings of diverse studies also can be assembled in creating a composite view on how chemical cues/signals influence species across multiple trophic levels, and hence, influence population-, community-, and system-wide dynamics. Pyrrolizidine alkaloids, for instance, function in plant chemical defense, mate attraction, and the stimulation of feeding among resistant insect and vertebrate consumers (Dussourd et al. 1989; Eisner and Eisner 1991; Trigo et al. 1996; Weller et al. 1999; Eisner et al. 2000; Bernays et al. 2002a,b). Thus, they fundamentally impact species at multiple trophic levels. The marine alkaloid, saxitoxin (STX), likewise, has varied, opposing physiological effects with strong, but contrasting, ecological consequences. Its presence in phytoplankton behaviorally cues habitat selec-

tion and prey choices of higher-order consumers, significantly structuring coastal ocean communities (Kvitek 1991; Kvitek and Bretz 2004, 2005). Combined behavioral and toxic effects mediated by STX also modify primary plant–herbivore relationships and regulate trophic cascades between benthic and pelagic environments (Carpenter et al. 1985; Myers and Worm 2003; Bruno and O'Connor 2005).

As exemplified by studies on pyrrolizidines, STX, and trait-mediated interactions among suites of species, the scaling up of research on individuals to higher levels of organization can paint an integrated picture of ecological processes. Chemical cues and signals do not operate in isolation. Discovering their full biological impacts will require interdisciplinary studies on multiple scales over time and in space. There now are vast opportunities for ascertaining how organisms react to chemical cues/signals under environmentally realistic conditions. The incorporation of these findings within a larger ecological framework should lead to improved understanding of natural physicochemical phenomena that establish communities and determine ecosystem dynamics.

Acknowledgments The authors thank Drs. John Hildebrand and Jeff Riffell for their invitation to write this review, and Dr. Ken Sebens, Director, Friday Harbor Laboratories for graciously offering facilities, services and hospitality in making the work possible. Dr. Arthur Whiteley and The Helen Whiteley Foundation provided an exceptional academic environment for putting ideas into written words. This contribution was supported by awards from the National Science Foundation (OCE 02-42321), California Sea Grant (R/F-197), and the UCLA Council on Research.

REVIEW ARTICLE

Physical Processes and Real-Time Chemical Measurement of the Insect Olfactory Environment

Jeffrey A. Riffell · Leif Abrell · John G. Hildebrand

Received: 31 October 2007 / Revised: 10 April 2008 / Accepted: 22 April 2008 / Published online: 12 June 2008

Abstract Odor-mediated insect navigation in airborne chemical plumes is vital to many ecological interactions, including mate finding, flower nectaring, and host locating (where disease transmission or herbivory may begin). After emission, volatile chemicals become rapidly mixed and diluted through physical processes that create a dynamic olfactory environment. This review examines those physical processes and some of the analytical technologies available to characterize those behavior-inducing chemical signals at temporal scales equivalent to the olfactory processing in insects. In particular, we focus on two areas of research that together may further our understanding of olfactory signal dynamics and its processing and perception by insects. First, measurement of physical atmospheric processes in the field can provide insight into the spatiotemporal dynamics of the odor signal available to insects. Field measurements in turn permit aspects of the physical environment to be simulated in the laboratory, thereby allowing careful investigation into the links between odor signal dynamics and insect behavior. Second, emerging analytical technologies with high recording frequencies and field-friendly inlet systems may offer new opportunities to characterize natural odors at spatiotemporal scales relevant to insect perception and behavior. Characterization of the chemical signal environment allows the determination of when and where olfactory-mediated behaviors may control ecological interactions. Finally, we argue that coupling of these two research areas will foster increased understanding of the physicochemical environment and enable researchers to determine how olfactory environments shape insect behaviors and sensory systems.

Keywords Odor plume · Insect behavior · Odor-plume tracking · PTRMS · Mass spectrometry · Gas chromatography · Odor landscape

Notation for Physical Processes and Analytical Technologies, respectively, is summarized in Appendices 1 and 2.

Introduction

Since animals crawled onto land approximately 400 mya, they have had to contend in a terrestrial, chemosensory environment where airborne signals are chemically different and fluctuate faster than under water. Airborne chemicals must have coevolved with multicellular organisms, especially with the large Angiosperm and insect diversification about 100 mya (Hildebrand 1995; Zimmer and Butman 2000; Bargmann 2006). In water or in air, the extraction of necessary chemical information from the environment has always depended upon discriminating signal from noise and resolving distance and orientation to the source.

In the last 25 years, efforts aimed at understanding how chemical signals are distributed in space and time have gained traction in a research discipline traditionally focused on identifying the behaviorally important chemical signals. A realization has occurred that the physical environment determines (a) whether or not and how much chemical signal is available to the animal and (b) the behavioral response and navigational strategies used by the recipient

organism (Weissburg and Zimmer-Faust 1993; Mafra-Neto and Carde 1994; Vickers and Baker 1994). A number of studies, pioneered by Murlis and Jones (1981), have documented that chemical signals are dynamic in both space and time (Murlis et al. 2000a; Justus et al. 2002b) due to physical processes of the fluid environment (Murlis and Jones 1981; Elkinton et al. 1984; Moore and Atema 1991; Murlis et al. 2000b; Webster and Weissburg 2001; Justus et al. 2002b). Seminal work by Baker and Cardé, in turn, has demonstrated that the physical environment dictates the navigational behavior employed by an organism through its effects on controlling the information provided by the chemical signal (Willis and Baker 1988; Mafra-Neto and Carde 1994; Vickers and Baker 1994; Kuenen and Carde 1994; Willis et al. 1994; Zimmer-Faust et al. 1995; Vickers and Baker 1996). The aerodynamic environment can dictate important ecological interactions and be a selective force on the evolution of olfactory systems, as it determines the chemical information available to an organism (Hildebrand 1995; Zimmer and Butman 2000).

The olfactory systems of terrestrial animals sample the environment and process chemical stimuli faster than once per second, but most chemical analysis methods for behaviorally relevant volatiles require extended time periods for sample collection, preparation, and separation (Tholl and Röse 2006). Thus, the temporal resolution of the olfactory information traditionally has been lost to scientists. New analytical technologies involving fast (<1 s or <1 min) sampling times and quantitative resolution are becoming available for chemical ecologists, thereby providing a means to sample the odor environment at time scales approaching that of the insect olfactory system.

In this review, we examine how the physical environment constrains olfactory-guided behavior by considering five main ideas. First, because the fluid environment controls the chemical information available to an organism, a review of some simple, but critical, physical processes that can provide linkages between the physical environment and odor-mediated behavior are considered. This information hopefully will provide researchers a set of tools to aid in characterizing the physical environment. Second, a qualitative description of the different characteristics of a turbulent odor plume is reviewed. Third, we consider the different physicochemical environments that insects navigate in. Fourth, we examine the effects of body size on the odor landscape experienced by a navigating insect. Whether an animal is <1 mm or >10 cm will potentially influence the physicochemical landscape in which it exists and the sensory strategies that it utilizes. Last, we examine the current analytical technologies available to chemical ecologists and behavioralists to examine spatial and temporal distribution of chemicals that control behavior. Taken together, the aim of these sections is to provide a broad understanding of the physical factors that control odor information and behavior and the rapidly evolving technologies that may increase our understanding of these processes.

Physics of the Odor Environment

Once odorant molecules evaporate from a source, they will instantly become subject to the physical forces of the environment and transported by ambient motions of the air. There are two physical processes that influence the transport of odor at different spatial scales: molecular diffusion and turbulence and advection. Molecular diffusion transports odorants by Brownian motion and occurs under small spatial scales (<1 mm) and long time periods (ca. 80 min for an odorant molecule to travel 1 m). In contrast, ambient motion by air can transport odorant molecules $>10^3$ times quicker than diffusion over equivalent distances and is thus the principal physical process that controls odor transport at distances >1 cm.

At these much larger spatial scales, the odor environment is dynamic, both spatially and temporally. There are two physical processes that cause this variability: advective and turbulent transport. Advection is the bulk transport of the odorants by the mean direction of the flow, whereas turbulent transport comprises the chaotic, three-dimensional mixing of odor with clean air. By using Gaussian distribution models for pollutant transport, researchers initially modeled chemical plumes as a diffusive, time-averaged process. However, the sensory systems of animals flying or walking in the terrestrial environment rarely, if at all, use such time-averaged odor information. Instead, animals use near-instantaneous concentrations of the odor plume to navigate to a source. It is, therefore, important to understand the near-instantaneous resolution of odor information to determine how animals can locate odor sources. To understand this process, it is necessary first to understand the physical forces that control odor information at these spatial and temporal scales. Excellent reviews of the instantaneous structure of plumes are found in Murlis et al. (1992), Weissburg (2000), and Koehl (2006). In this review, we examine physical processes and parameters useful to characterize the odor dynamical processes and the rapidly evolving analytical technology that may be used to characterize the terrestrial chemical environment.

Aerodynamic Parameters

Odor temporal dynamics and dispersion are governed by ambient air currents. An insect living in a calm, low wind environment will experience different chemical stimulus dynamics from one inhabiting a high-energy, windy environment. A measure of the fluid dynamic regime experienced by a navigating insect can be approximated by

the body Reynolds number (*Re*), which compares the inertial forces with viscous forces. Inertial forces represent the large momentum-containing scales that maintain the turbulent motion. In contrast, the viscous forces signify the "stickiness" of the fluid that dampens the momentum, thereby bringing it to a halt. The inertial term takes the form of ρu^2 [where ρ is the density of air (kg/m^3), and u is the wind velocity or translational velocity of the organism (m/s)], and the viscous term takes the form of $\mu u/S$ [where μ is the air viscosity (Ns/m^2), and S is the spatial scale of interest (m)]. The ratio of these two forces thus takes shape in the equation as

$$Re = \frac{\rho u^2}{\mu u/S} = \frac{\rho S u}{\mu}, \quad (1)$$

thereby producing a non-dimensional number that indicates the nature of the air flow. When $Re >> 1$, the air momentum will overwhelm viscous damping, and air motion will be turbulent. As *Re* increases, the air flow becomes more turbulent and causes the spatial scale of the turbulence to increase (e.g., the size of the turbulent eddies) and the time scales of the turbulent fluctuations to increase. As *Re* decreases and approaches unity, the spatiotemporal dynamics of the turbulent flow decrease until the flow becomes laminar (without three-dimensional structure).

The Reynolds number is useful for examining the fluid environment an organism might experience, but to accurately replicate the aerodynamic conditions of the field within the laboratory, it is necessary to go beyond the mean advective bulk flow and instead examine the fluctuations (turbulence) of air flow. Fluid (liquid or gas) near any surface will stick to the surface and not slide along that substrate. Due to this "no-slip" condition, the fluid in contact with the substrate will impose a frictional force on the fluid layers directly above it causing the fluid to shear or change in velocity with increasing distance from the substrate (Fig. 1A). Within this velocity gradient region—also called the "log layer" because of the logarithmic change in velocity with vertical distance from the substrate—momentum is transferred from the large turbulent structures (called 'eddies') to progressively smaller and smaller eddies until energy is dissipated into heat by the frictional force of viscosity near the surface (Fig. 1A). Thus, turbulence can be much greater near the surface than in the region of the free-stream velocity. The turbulence and momentum transfer to the surface can be described through shear stress (τ_R) (also called Reynolds shear stress) and is a the function of

$$\tau_R = -\rho\overline{u'w'}, \quad (2)$$

where the term $\overline{u'w'}$ is the mean of the cross-product of fluctuating velocities in the horizontal (u) and vertical (w) dimensions, and the negative term in front of the air density (ρ) denotes the downward flux of momentum. The

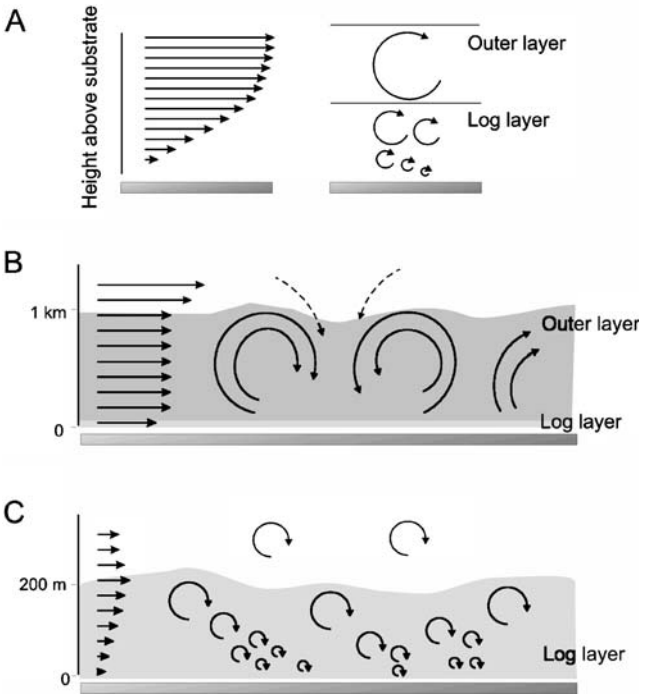

Fig. 1 The effect of flow velocity on the structure within a turbulent boundary layer and the change in diurnal conditions. **A** The boundary layer is defined by the region where the flow velocity reaches 95% of the free stream velocity (*left*). A schematic of the turbulent velocity fluctuations is shown on the right where turbulent kinetic energy is transferred from the large energy-containing eddies in the outer region of the boundary layer to progressively smaller and smaller eddies in the log layer. **B** A schematic of the daytime boundary layer conditions where surface-layer heating causes the large eddies in the outer layer to reach all the way to the substratum. **C** A schematic of the nighttime boundary layer conditions. Substrate cooling causes a stable boundary layer to develop and the kinetic turbulent energy levels to drop in comparison to daytime turbulent conditions

Reynolds shear stress provides a measure of the turbulence of a system. Another term for describing boundary layer turbulence is the friction velocity (m/s), u_*, and is related to the shear stress by $(\tau_R/\rho)^{-1/2}$. This term has the units of a velocity (m/s) but is more accurately described as the scalar of momentum in a boundary layer or the velocity at which momentum is transferred. As u_* increases, turbulent fluctuations in velocity also increase; therefore, u_* is an important scaling parameter in boundary layer and turbulent wind studies. The turbulent conditions of a boundary layer (e.g., a large grassy meadow or a desert plain) can be parameterized through the roughness Reynolds number (Re_*), which is analogous to the Reynolds number described above but provides a means to describe the turbulent conditions of a boundary layer. This term is described by the equation

$$Re_* = \frac{\rho u_* D}{\mu}, \quad (3)$$

where D is the size (m) of the elements on the substrate (e.g., the rocks and vegetation on the ground), and u_* is the friction velocity described above. For Re_* values of 3.5–6, turbulent

eddies begin to penetrate the upper region of the boundary layer, and if $Re_*>75$, then turbulence extends all the way to the substratum (Schlichting 1987; Stull 1988). An insect navigating to an odor source within a boundary layer of $Re_*>75$ will experience a dynamic, filamentous odor stimulus, whereas an insect navigating at $Re_*<6$ will experience a smooth continuous odor gradient near the substratum (where diffusional and inertial processes are near unity) and a filamentous odor stimulus farther from the substratum.

The roughness Reynolds number provides a useful parameter to describe certain environments (further detailed below), but caution must be used as it may not accurately describe the dominant physical processes for a given habitat. For instance, the velocity fluctuations of a meadow sat the foot of a 1,000-m-tall mountain will reflect the influence of the mountain on the atmospheric conditions rather than the grass and shrubs found within the meadow (D=1 m), thereby causing underestimation between realized and expected Reynolds roughness numbers. Therefore, the length scale, D, used in calculating Re_* should be chosen carefully. Nevertheless, measurement of τ_R and u_* provides valuable information regarding the level of turbulence in a given habitat and also allows these physical conditions to be simulated in the laboratory for dynamically scaled odor-plume tracking studies (Zimmer and Zimmer 2008).

In the field, an important function of the stability, or lack thereof, of the boundary layer is the atmospheric conditions (temperature and air turbulence). In the absence of energetic atmospheric events that mix the atmosphere, like frontal passages, daytime temperature-induced convection occurs from heating of the surface, causing large eddies to form and thoroughly mix the air from the surface to >1 km height (Figs. 1B and 2A,B; Kaimal and Finnigan 1994; Mole and Jones 1994). In contrast, at sunset, the temperature-driven convection weakens, and a stable boundary layer develops near the surface (0–200 m; Fig. 1C and 2A,B; Mylne 1992; Yee et al. 1993; Mole and Jones 1994). The stability of the boundary layer can be determined through the Richardson number (R_i), which is a dimensionless parameter that represents the relative importance between temperature- and wind-driven turbulence and has the form

$$R_i = \frac{\left(g/\overline{\theta}\right)\left(\partial\overline{\theta}/\partial z\right)}{\left(\partial\overline{u}/\partial z\right)^2}, \tag{4}$$

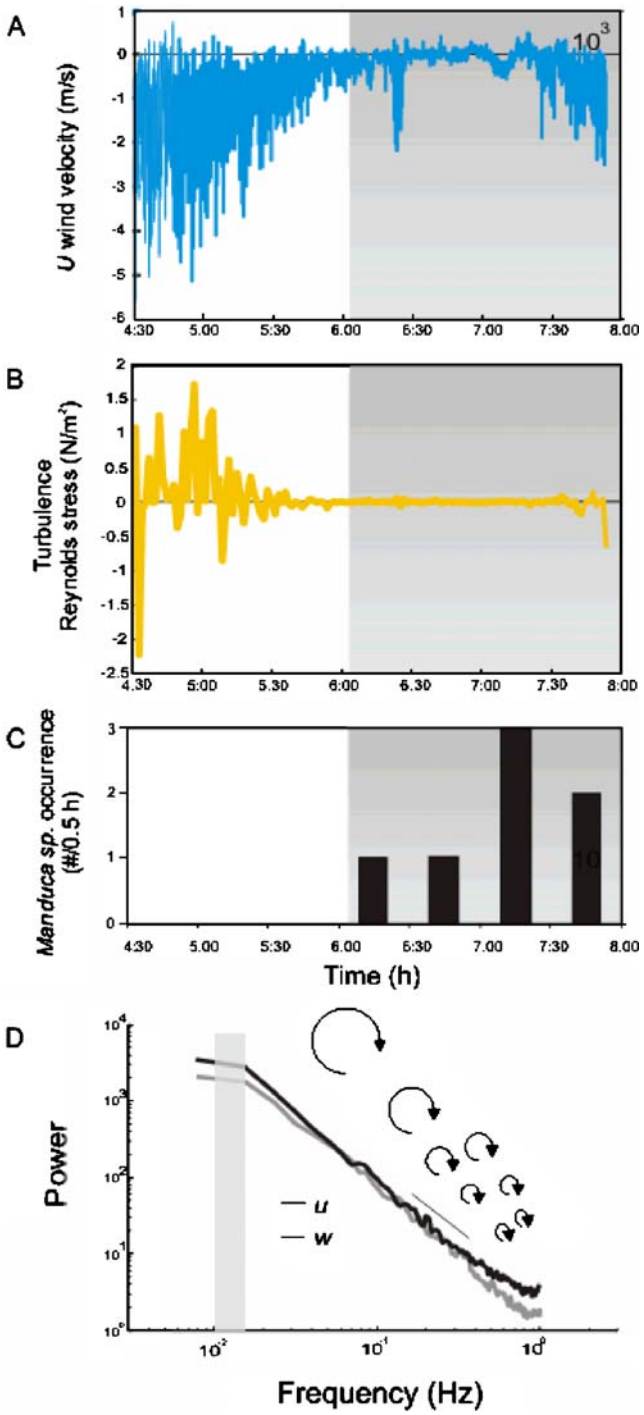
where g is the acceleration due to gravity (9.81 m/s^2), $\overline{\theta}$ is the mean temperatures, z is the height above the substrate, and $\overline{u}$ denotes the mean wind. When R_i is positive, the boundary layer is stable (Fig. 1C). R_i is negative for an unstable boundary layer (Fig. 1B) and zero for a neutral boundary layer. For example, Mole and Jones (1994) found that plume intermittency, filament concentration, and average concentration were higher for stable than for unstable conditions. Thus, when atmospheric conditions are relatively calm and uncloudy, the odor environment at night might be conducive for odor plume transport and the maintenance of plume structure and hence insect navigation (e.g., Fig. 2C).

The Odor Landscape and Turbulent Odor Plumes

Examination of olfactory tracking behavior of insects, mammals, and birds (all inhabitants of turbulent flows) has demonstrated clearly that animals do not use time-averaged properties of the odor (Elkinton et al. 1984) and instead use near-instantaneous (< 1 s) information present in the plume (Mafra-Neto and Carde 1994; Vickers and Baker 1994).

Temporal Features of the Plume At time and spatial scales <1 s and >1 mm, respectively, turbulent odor plumes are patchy (Fig. 3B) and are composed of odor spikes or 'filaments' of intense concentration interspersed with periods and regions of low or undetectable concentrations. The dynamic occurrence of the chemical signal is termed its intermittency, which is a proportional value ranging from 0 (odor continuously present) to 1 (odor absent; Cardé and Willis 2008). The spatial and temporal scales in which the odor filaments occur are directly related to the temporal and spatial scales of the turbulence (Fig. 3B; Zimmer-Faust et al. 1988).

A number of different factors can influence plume intermittency. A higher wind speed or turbulence can cause the odor filaments to become thin (Yee et al. 1993) and increase in frequency (more filaments per unit time; Fackrell and Robins 1982). However, an increase in turbulence has a corresponding effect of lowering the odor-laden filament concentration (Finelli et al. 2000; Moore and Crimaldi 2004). Moreover, the size and position above the substrate of an odor source also affects the plume dynamics. Odor sources high off the substratum will be subject to higher advective flows than those nearer the ground (Fig. 1C). For instance, flowers of the agave, *Agave palmeri*, which produce strong night time odor emissions, are 4–6 m from the ground and are subject to high advective wind velocities (2.2–7.1 m/s). Whereas flowers from the jimsonweed plant, *Datura wrightii*, are close to the ground (~0.5 m) and experience lower wind velocities (0.1–2.3 m/s). Odor source size will also affect the plume structure close to the source. For example, plume intermittency is higher for larger sources than smaller, but if a small source is in close proximity to a large structure (e.g., a female moth calling from a tree), then the plume will behave as if coming from the large structure. A rough approximation of the effects on odor source size and air velocity on plume intermittency may be determined by the



◀ **Fig. 2** A time series of the turbulent conditions near a *Datura wrightii* flower patch measured with a 3D sonic anemometer (Young, USA) sampling at 32 Hz. Regions in gray represent the time from when the sun began to set. In the daytime, wind velocities (**A**) and turbulent shear stresses (**B**) are nearly two-orders of magnitude higher then those that occur in the evening (shown in *gray*). **C** The drop in turbulent intensities corresponds with the nighttime foraging activity by *Manduca sexta* hawkmoths which feed on nectar from *D. wrightii* flowers. The drop in turbulent intensities may enable hawkmoths to effectively navigate to the strong volatile emissions of *D. wrightii* flowers. **D** Daytime energy spectra of wind velocities in the vertical (w) and longitudinal (u) dimensions. The largest energy-bearing eddies (in *shaded region*) occur at a time period of 100 s (frequencies ~10^{-2} Hz), and corresponds to n, where n is the frequency of peak intensity of the power spectrum. The large eddies progressively cascade smaller and smaller eddies until the turbulent kinetic energy is dissipated at a frequency of 0.8 Hz. Spectra of the velocity fluctuations contain information on the temporal and spatial features of the turbulence and relate directly to dispersion and structure of the plume

Strouhal number (St), which relates to the frequency in which eddies are shed by structures in flow. For cylindrical objects, the eddies are shed with a predictable rate,

$$St = \frac{fD_{\text{object}}}{u}, \tag{5}$$

where f is the frequency of eddy shedding (per second), and D_{object} is the diameter of the object (m). Eddies shed by the object will entrain the odor and impose a dominant frequency on the olfactory information transmitted in the object's wake. For smooth cylinders in the Re range of 10^2–10^5, St is a constant of 0.2, thereby allowing rearrangement of the equation for the dominant eddy frequency (and hence, plume intermittency) to be $f=0.2u/D_{\text{object}}$. We caution use of St in the field, however, under conditions of strong, three-dimensional winds, which will change the projected diameter of the obstacles (D_{objects}) thereby affecting the plume filament frequencies. Another aspect that can influence the temporal features of the odor plume is "active" behavior by the animal (or source) releasing the odor. For instance, female moths can periodically pump pheromone into the air (Conner et al. 1980) and flowers in the wind oscillate back and forth (Sprayberry and Daniel 2007). The intermittent release and odor source movement will influence the temporal structure of the plume signal, thereby creating a biologically mediated intermittency coupled to that of the turbulent flow.

Spatial Structure of the Plume The plume structure will change as a function of the distance from the odor source (Fig. 3). Research by atmospheric scientists who study pollutant transport for the past 30 years have scoured the countryside searching for large (~1 km), flat (~10 cm vegetation height) sites in which to examine the effects of boundary layer turbulence on plume structure. Experiments on the fields in UK, Canada, and USA provide a framework for understanding the effects of turbulence on odor plume structure (Mylne and Mason 1991; Yee et al. 1993; Mole and Jones 1994). For plumes on a relatively flat surface, the plume increases in width and height and decreases in filament intensity and intermittency (the proportion of time odor is present) as distance from the source increases. For instance, Dinar et al. (1988) found that chemical signal concentration in a plume was high and present 75% of the time at a position <4 m downwind from the source, but

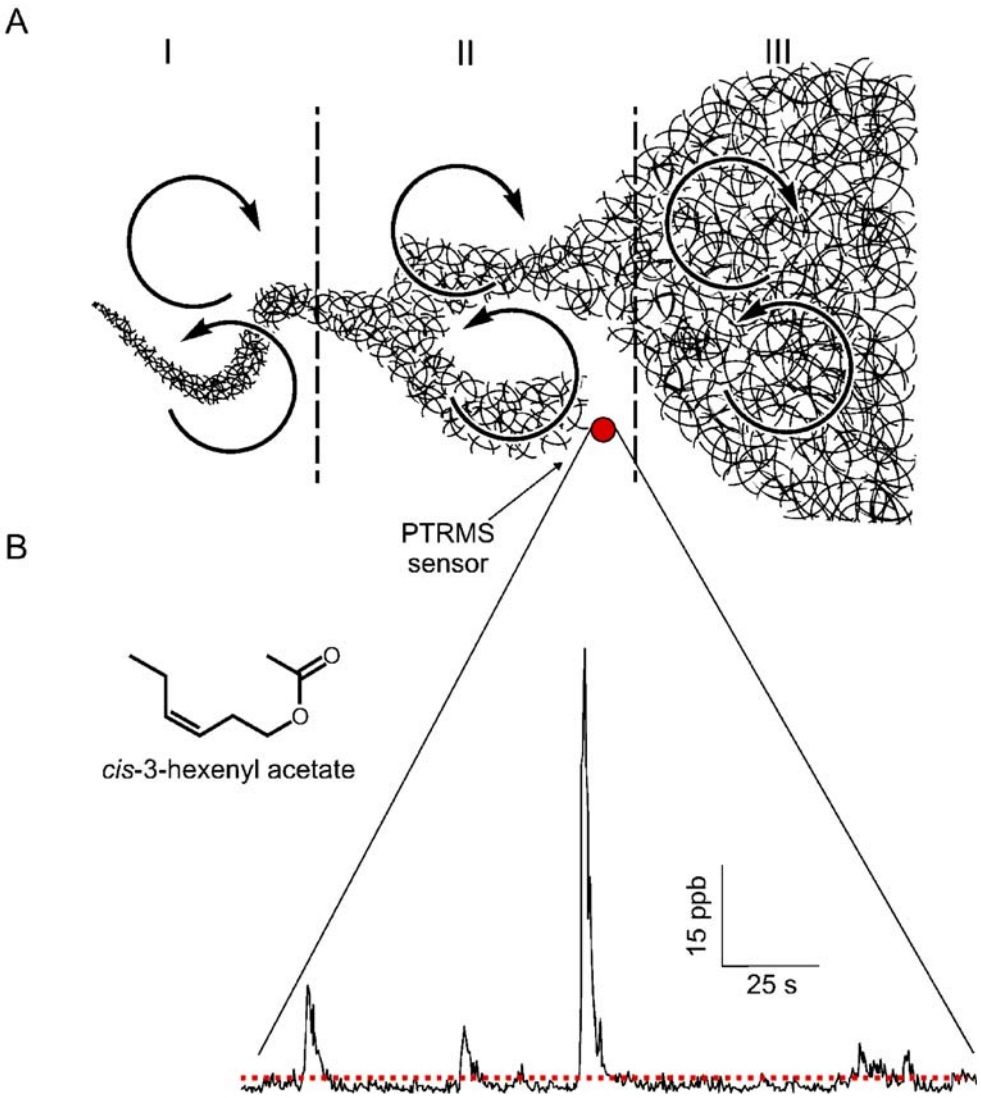


Fig. 3 Odor plumes are spatio-temporally dynamic. **A** A schematic of a conceptual model for plume dispersion modified from Mylne (1992). When the plume width is smaller than the dominant crosswind eddy size the plume will begin meandering. Once the plume width approaches the eddy size the plume becomes mixed with clean air. The plume will continue to develop and increase in size until its width exceeds the eddy scale (Environmental Effects on the Odor Landscape). The plume structure as a whole will depend upon the dominant eddy scale and the variation in concentration fluctuations of the plume. **B** A mass chromatogram of a *cis*-3-hexenyl acetate ($C_8H_{14}O_2$) plume as measured by proton transfer reaction mass spectrometry (*PTRMS*). Measurements occurred 4 m downwind from the source at an average wind velocity of 40 cm/s, dominant eddy size of 2.1 m and frequencies of 10 s. Based on conditional sampling of the plume measurements, odor bursts occurred every 11.1 s which approximately matched those predicted by Mylne (1992). The PTRMS sample rate was 4 Hz

concentrations dropped to 20% and occurred only 20% of the time at 40 m downwind (Dinar et al. 1988). Similarly, Murlis (1997) found that the chemical signal in a plume was present 40% of the time at a position 2.5 m downwind from the source but only present 10% of the time at 20 m downwind (Murlis 1997).

A conceptual model of the effects of turbulence on the large-scale plume structure can be based on the size of the turbulent eddies mixing the plume. For instance, Mylne (1992) described the formation of a plume based on its width relative to eddy size present in the turbulent flow. When the plume width is narrower than the dominant eddies, then the plume will meander (move side-to-side), thereby creating large patches of odor-laden air interspersed with odor-free air (Fig. 3A; Yee et al. 1993; Mylne et al. 1996; Finelli et al. 1999). As the plume width approaches or exceeds the dominant eddy length scale, vigorous mixing occurs with non-odor laden air transported into the interior of the plume (Fig. 3A). The distance that plumes meander can be estimated by u/n, where n is the frequency of the peak intensity of the velocity power spectrum (e.g., the dominant energy-containing eddies) and u is the wind velocity (Yee et al. 1993). Taking the range of velocities (0.2–2.0 m/s) and eddy frequencies (0.01–1.0/s) from Yee et al. (1993), Mylne and Mason (1991), and Murlis (1997), eddy lengths responsible for plume meandering range from 0.2 to >200 m. While this analysis may only approximate plume meandering under stable atmospheric conditions, it demonstrates the extreme odor patchiness that an insect must navigate toward.

While plume meandering will be critical for the large-scale structure of the plume, the edges and interior of the plume are dynamic and consist of fine-scale features important for navigating animals. For instance, the concentration of chemical signals in filamentous plumes is lower farther from the source in the along-wind direction; although some odor filaments of high concentration do

occur, they are encountered much less frequently (Murlis et al. 1992, 2000a; Murlis 1997). The intensity of concentration fluctuations also decreases with distance from the source (Murlis et al. 1992; Zollner et al. 2004). Moreover, with increasing distance from the center of the filamentous plume to the edges in the crosswind direction, odor intensity and intermittency also decrease (Mylne and Mason 1991; Yee et al. 1993; Murlis 1997). Although odor filaments occur less frequently on the edges of the plume than near the centerline, the concentration of the filaments can be as high as those in the middle.

The Dynamics of a Plume in a Laboratory Wind Tunnel Until now, we have focused on the dynamics of an odor plume in fairly idealized conditions: large area (~1 km), short vegetation (~10 cm), and steady turbulent wind conditions. Under these conditions, the plume will grow and meander. Can all of these conditions be replicated in the laboratory wind tunnel? Unfortunately, the size of a typical wind tunnel (~0.5–1 m^2 height and width and 2–5 m length; Visser 1976; Miller and Roelofs 1978) is much smaller than the dominant turbulent length scales in the field (1–200 m); therefore, a plume in a wind tunnel will not exhibit the same characteristics. However, physical turbulent conditions in the field, including turbulent fluctuations (root-mean-square velocity divided by the mean velocity) and Reynolds stresses, can be simulated in the laboratory to approximate those forces in the field (Cermak and Arya 1970; Fackrell and Robins 1982; Justus et al. 2002). Such scaling parameters are paramount, as they are necessary to replicate a natural aerodynamic regime and will dictate the plume spatiotemporal characteristics. Turbulent conditions in the field involve both the advective (mean velocity and direction) and turbulent (fluctuating velocities) components of the wind, as well as a number of other parameters that involve wind gusting (acceleration reaction) and change in direction. However, researchers that use wind tunnels have tended to simulate complex wind conditions by using single velocity measurements or, at best, single Reynolds numbers. Before beginning a behaviorally oriented, odor plume study, it is essential to determine the number and nature of the critical wind parameters (Fig. 2). Otherwise, reproducibility (i.e., dynamic similarity) is difficult to achieve (Zimmer and Zimmer 2008).

Environmental Effects on the Odor Landscape

Turbulent motion and molecular diffusion will spread a chemical plume in three dimensions to create what may be viewed as an odor landscape (Atema 1996; Murlis 1997; Zimmer and Butman 2000) in which an animal must navigate. The degree to which these motions dominate odor transport depend largely upon the physical environment. For habitats that are relatively flat (e.g., a large, grassy meadow, or a sandy plain), a useful rule of thumb for establishing the turbulence of the physical environment is by the roughness Reynolds number (Re_*). Re_* depends upon the shear velocity (u_*) and the roughness element (D) (Schlichting 1987). Therefore, the three-dimensional environment where odors are released will determine the odor intensity and spatiotemporal dynamics.

Odor Dynamics on a Desert Plain

A large, sandy plain, for example, near Maharès, Tunisia, provides an excellent example for effects of the roughness element on boundary layer turbulence. The degree to which turbulent eddies from the atmosphere come into contact with the substrate depends in large part on the size of the roughness element and wind velocity. For a shear velocity of 0.4 m/s (Wolf and Wehner 2000) and average sand grain size of 0.00025 m, the Reynolds roughness number is 6.5. At this number, turbulence begins to reach the outer regions of the boundary layer (Schlichting 1987), and the odor plume will be dominated by advection rather than large turbulent eddies thereby causing the odor plume to become a sheared continuous gradient (Weissburg 2000; Wolf and Wehner 2000). In contrast, if the sand size increases to 0.0025 m and the u_* remains 0.4 m/s, the Re_* is 65.8, which indicates that turbulent eddies are close to reaching all the way to the substrate, and hence, the boundary layer (and the odor plume) is fully turbulent. This raises an important point: The presence of roughness on the substratum decreases the velocity, which causes the boundary to become fully turbulent, and hence turbulence changes as a function of roughness element size. Observations of smoke used to simulate a plume for odor-tracking ants in this desert environment suggests that the Re_* values may be ca. 6, with the smoke remaining close to the substrate and becoming "smeared" by the low wind velocity.

Odor Dynamics in a Field

In more heterogeneous habitats, substrate differences and wind velocity begin to play a larger role in controlling the odor. For instance, by using the same shear velocity from the example above in the desert (0.4 m/s; Yee et al. 1993; Mole and Jones 1994) but using vegetation height as our roughness element (0.1–1.0 m), we find that the roughness Reynolds number ranges from 2,630 to 26,300. Because turbulence will fully dominate this habitat under a variety of spatial and temporal conditions, the odor landscape will also be dynamic reflecting the three-dimensional fluctuations in velocity. For instance, Yee et al. (1993) found that because of the large eddy sizes associated with the field

environment (u_*=0.25–7.0 m/s; D=0.5 m; Re_*=3,290–13,200), plume meandering only occurred close to the plume source, and at larger downwind distances (>100 m), the plume became well mixed, lacking a large-scale meandering structure but still being highly intermittent (Yee et al. 1993). Hence, a foraging insect far from a food odor source may experience a wide plume that has fine-scale structure and odor intermittency, but as it approaches the source—due to plume meandering and the plume width decreasing—the odor signal will become more spatiotemporally complex with longer periods of odorless air.

Odor Dynamics within a Forest

In contrast to the relatively flat surfaces of a grassy field or desert plain, the physical environment within a forest is dynamic and depends upon the vertical location between the canopy and the floor. Whereas Re_* provides a good rule of thumb for boundary layer turbulence in field and desert environments, forest habitats are so spatially complex that a developed boundary layer does not exist. This is because the upper canopy and large diameter tree trunks constrain large eddies from entering the understory regions of the forest, and thus, turbulence, radiation, thermal, physiological, and structural properties of a forest vary most in the vertical dimension (Rauner 1976; Hutchison and Baldocchi 1989), where turbulence levels are maximal near the upper canopy and decline rapidly in the understory toward the shrub layer and forest floor (Baldocchi 1989). Thus, in the understory, turbulence levels are low (u_*=0–0.2 m/s), the length of the turbulent eddies are small (1–3 m), and the bulk advective motion of the wind is minimized (0.1–1.0 m/s) relative to the turbulent eddies which cause the wind direction to shift chaotically (Kaimal and Finnigan 1994).

Studies that examine the transport of the tracer sulfur hexafluoride (SF_6) within a forest have shown that plume concentrations exhibit a logarithmic decrease in concentration with increasing distance from the source. For example, LeClerc et al. (2003) and Thistle et al. (2004) showed that mean tracer concentrations drop from 20% within 5 m of the source to 0.1% 60 m downwind. Moreover, individual filament concentrations can be tenfold higher than the average concentrations 10 m from the source, with the plume being intermittent and time between odor bursts long (40–300 s) in duration. An interesting phenomenon that affects plumes is the lack of a strong advective wind velocity, which causes the odor plume to swing back and forth extending in two directions 180° opposed (Leclerc et al. 2003; Thistle et al. 2004). Thus, a flying insect moving from a meadow into the forest will experience a totally different physical environment that may require different sensory strategies for navigation.

Effects of Scale

An important aspect that influences the odor environment experienced by animals is body size and translational speed —or wind velocity—of the animal itself. Returning to the Reynolds number, which indicates the ratio of inertial to viscous forces, and is the product of the size and speed, we can begin to examine the odor landscape experienced by insects of different sizes.

Small insects will experience a completely different physicochemical environment from larger, faster insects. The leaf-cutter ant, *Atta vollenweideri*, provides an interesting example of the effects of small size and the environment for the type of forces experienced by the ant. For instance, leaf-cutter ants are small (ca. 0.005 m) and, when in their nest, experience air flows of 0.005–0.02 m/s (Kleineidam and Roces 2000; Kleineidam et al. 2001) with corresponding Reynolds numbers of 1.6–6.5. Within this environment, ants experience a fluid dynamic regime where viscous forces nearly balance inertial forces. This will have an important effect on the odor landscape by smoothing out three-dimensional structures of the flow and hence causing the odor plumes to become sheared gradients. In contrast, when these ants leave their nest, they experience a grassy field environment with wind velocities of 1–6 m/s and the corresponding Re>300. In this environment, the odor will be fully turbulent and dynamic. For much larger or faster insects (S≥0.02 m, u≥0.5 m/s), for example, the flying hawkmoth *Manduca sexta*, Reynolds numbers are typically 1,000–10,000. These insects, then, exist in a fully turbulent environment where the odor will be intermittent and three dimensional.

Analytical Equipment

Role of Technology

In the previous sections, we detailed how atmospheric and landscape conditions may distribute chemical odors spatiotemporally. Valid measurements of something as amorphous as an odor plume may seem currently inaccessible. Nonetheless, to be able to measure chemical signals in real time as they are emitted and perceived by the organism is critical for determining how chemical signaling processes determine ecological and evolutionary interactions. Therefore, a continuous goal is the acquisition of improved technologies that will provide rapid and sensitive chemical data, which can then be merged with behavioral or electrophysiological observations and integrated into a mechanistic description of olfactory ecology.

A grand challenge to improve the sensitivity of our analytical measurements was unintentionally laid before us

nearly 40 years ago when Kaissling and Priesner (1970) discovered that, by using olfactory receptor cells on sensilla structures lining their antennae, male moths can detect a single pheromone molecule. Although fluorescence detection and other techniques have pushed limits of chemical detection into the zeptomole (10^{-21}) range, today, we still appreciate the animal nose (or insect antenna) as a type of ultimate detector.

Animal olfactory receptors remain supreme not only for their molecular sensitivity but also for their respectable sample collection speed. *M. sexta* moths, a favorite model organism, optimally collect odor samples in the range of one to five times per second (1–5 Hz; Heinbockel et al. 1999), but *Spodoptera exigua* and *Cadra cautella* moths have been shown to exhibit electroantennographic responses to stimulus intermittencies given at up to 33 Hz (Bau et al. 2002). Modern analytical techniques can also collect samples at this rate, and faster, but in most cases, these instruments are tuned to a single chemical identity. For the best information about chemical identification, gas chromatography mass spectrometry (GCMS) has remained the most reliable and popular technique for many years, but sample collection for this method is traditionally slow. Recently, GCMS sensitivity has become quite high (10^{-12} g; Song et al. 2006). Analytical equipment available to chemical and olfactory ecologists will be reviewed in the context of analyzing odor dynamics with maximal sensitivity, speed, and accurate chemical identification, where unfortunately one feature is often sacrificed for improvement of the others. Examples will range from commercially available devices to emerging technologies that tend to appear first as applications in atmospheric chemistry or in monitoring industrial environments.

Valuable reviews have addressed aspects of modern instrumentation and sampling methods useful for temporally analyzing biogenic volatile organic chemicals (BVOCs). Tholl et al. (2006) specifically address challenges and advances in monitoring environmentally dependent changes in plant volatile emissions by including in-depth descriptions of instruments, sampling techniques, and respective biases and limitations. D'Alessandro and Turlings (2006) pay special attention to above- and below-ground sampling techniques for herbivore-induced plant volatiles that mediate interactions among plants and insects. Ten emerging sensor technologies from the US Sandia National Laboratories for volatile organics monitoring are reviewed by Ho et al. (2007), and a recent review on electronic noses by Röck et al. (2008) discusses the integration of multiple sensor techniques. In this review, we focus on chemical detection technologies (and other supportive techniques) that feature low limits of detection, and rapid temporal measurement capability as a strength for maximum resolution of odor dynamics, and portability is emphasized.

Gas Chromatography

Terrestrial animal olfactory systems sample the environment and process chemical stimuli faster than once per second. In contrast, popular methodologies for analysis of behaviorally relevant volatiles involve significant time periods for collection, preparation (e.g., concentration or cryofocusing), and separation. The introduction of these samples into analytical instruments for structural characterization and quantification (e.g., by GCMS) usually results in significant loss of temporal resolution of the chemical signal. However, new, fast (ca. 200–400 s run times) GC systems are becoming available for chemical ecologists, thereby providing a means to sample the odor environment at time scales more relevant to moving, probing insects. Matisola and Dömötörová (2003) review multiple design strategies employable for streamlining GC analysis and provide tabulated examples of different approaches, including a shortlist of field-portable GC systems in use. Many of the these strategies were advanced in the laboratory of the late Richard Sacks, including at-column heating to enhance selectivity, use of atmospheric air as a carrier gas to facilitate portable GC, development of pre-concentrator systems, microelectro-mechanical system silicon columns (etched into a ca. 10 cm^2 chip), and alternative inlet devices and detectors needed to support miniaturization (Reidy et al. 2007; Sanchez and Sacks 2007).

Kunert et al. (2002) demonstrated rapid GC for improved temporal characterization of plant volatile emissions by employing the zNose™ miniature GC with a surface acoustic wave quartz microbalance detector (SAW; Electronic Sensor Technology, Newbury Park, CA, USA; or see Lu and Zellers 2002). They achieved a 3-min time resolution of lima bean volatile terpenoids in response to leaf wounding. By using standard charcoal pre-concentration, this rapid analysis is a drastic temporal improvement over classic GC runs that last 10–60 min. Even without the capability to define odor fluctuations that occur from second to second, this portable technology is useful in olfactory dynamics for making confident chemical identifications in the field just minutes after sample collection or for creating a temporal odor profile with ca. 3 min temporal resolution (e.g., if left to run continuously and automatically). Other fast GC systems with automated pre-concentration have been custom built for atmospheric monitoring from aircraft and employ helium ionization detection (HID) and electron capture detection (ECD) for selective detection down to parts per trillion level of non-methane hydrocarbons (C_2–C_5) every 5 min (Whalley et al. 2004).

Mass Spectrometry

Chemical Ionization Techniques Atmospheric pressure chemical ionization (APCI; soft ionization) mass spectrometry

techniques for environmental air analysis have attracted much interest (Charles et al. 2001). APCI mass spectrometers performing proton transfer reaction mass spectrometry (PTRMS) and selected ion flow tube mass spectrometry (SIFTMS) are both commercially available. PTRMS has been applied numerous times for measuring BVOCs (De Gouw and Warneke 2007) and has been adapted for measuring BVOC fluxes by using eddy covariance approaches (Karl et al. 2000).

PTRMS uses H_3O^+ as a reagent gas, so that H_3O^+ primary ions travel into a drift tube and collide with gaseous organic volatiles (*M*) by the proton transfer reaction

$$H_3O^+ + M \rightarrow MH^+ + H_2O$$

if energetically allowed (if *M* has a proton affinity exceeding that of water, 166.5 kcal/mol, a condition fulfilled for essentially all VOCs). Quadrupole unit mass detection limits of 5–30 ppt have been reached, and measurement times can be as low as 2 ms per observed ion, thus allowing real-time monitoring of ambient air in environmental situations that include aircraft flight missions and extended environmental sampling campaigns (Lindinger et al. 1998a, b). At 130 kg, the PTRMS is portable on wheels or can be lifted by several people for short distances. PTRMS is also available with high resolution time of flight (HRTOF) mass detection and has been adapted with a GC inlet and ion trap (IT) detection. SIFTMS also employs a quadrupole for detection limits of a few parts per billion and measurement times of a few seconds (Freeman and McEwan 2002). An additional upstream quadrupole filter is used to select reagent gas ions of H_3O^+, O_2^+, NO^+, or others. The instrument is similar in size and cost with quadrupole PTRMS. APCI inlets on benchtop liquid chromatography (LC)ITMS instruments have also been successfully modified to accept gas samples with rapid measurement times of 20–200 ms per observed ion (Jublot et al. 2005).

PTRMS has been used in a variety of different applications that involve emission of volatile compounds. Karl and others have used PTRMS for examining dynamics of green leaf volatiles, pollutants, and herbivory-induced changes in volatile emissions from plants (Karl et al. 2003; von Dahl et al. 2006; Filella et al. 2006). Recently, we have used PTRMS to measure synthetic floral odor plumes simultaneously with insect electroantennography measurements in wind tunnels. Raw and processed data both appear as a temporal evolution of mass intensities for a single, or multiple ions, over a particular time period (PTRMS measurement of a single odor species for a 190 s time period is shown in Fig. 3B).

Sample Desorption Techniques A desire to analyze samples under ambient conditions (outside of the vacuum area) has driven the development of ambient desorption techniques. Desorption ionization (DI) techniques can use a laser or charged particles (i.e., an electrospray) to dislodge and ionize ambient sample particles for introduction into a mass spectrometer (Cooks et al. 2006). The popular desorption electrospray ionization (DESI) method works well typically on solid samples. Numerous related techniques have evolved, some of which accommodate gaseous samples, like the direct analysis in real time (DART) method, which uses an excited gas (plasma) to drive the desorption process of solid, liquid, or gas samples (Cody et al. 2005; Haefliger and Jeckelmann 2007), or atmospheric pressure Penning ionization (APPeI; Iwana et al. 2006), which uses argon or helium (rare gases) activated by a negative-mode corona discharge to ionize a pulled gaseous sample before analysis by TOFMS. Laser photoionization of trace gas molecules has been developed mainly along two, parallel paths: resonance-enhanced multiphoton ionization time-of-flight mass spectrometry (REMPI-TOFMS) and single photon ionization (SPI) TOFMS (Zimmermann 2005). Real-time gas sample analyses (e.g., coffee roasting emissions at 10 Hz; Dorfner et al. 2004) have been achieved by using REMPI-TOFMS, a selective ionization method for aromatic and highly unsaturated compounds. SPI-TOFMS is a less selective ionization method that allows detection of aliphatics and aromatics. Although the DI techniques above have not yet been directly applied to volatiles from plants or insects, their high temporal resolution, direct gas sampling, and limits of detection present promising opportunities for olfactory ecology (e.g., Fig. 4). Neutral desorption of analytes by extractive electrospray ionization (EESI; Chen et al. 2007) has been used to analyze human breath and also appears to hold promise for applications in ecology.

Alternate Analytical Technologies

Ion Mobility Spectroscopy IMS is broadly applied today for detecting trace chemical substances, notably in screening air travelers' carry-on baggage for detection of chemical weapons. Eiceman et al. (1990) characterized methylsalicylate ($C_8H_8O_3$) and dimethylsulfoxide (C_2H_6OS) odor plumes in a continuous field setting with IMS in an early environmental application. IMS functions under atmospheric pressure wherein different ion species travel through a buffer gas in a small (ca. 3–15 cm length) chamber (a.k.a. drift tube; also used in PTRMS) along an electric field at different rates, depending on individual mobility, which is determined by mass, charge, and collision cross-section (Borsdorf and Eiceman 2006). IMS techniques based on this concept have evolved for over a century under different names like ion chromatography. The arrival times (i.e., time of flight (TOF); ca. 2–15 ms) of different ion species at the IMS Faraday type detector are used to distinguish them. Short ion travel times allow fast

instrument cycling and rapid sampling. Recent advances in IMS have achieved instrument miniaturization and incorporation of new ionization techniques like ESI and corona discharge. More traditional ionization techniques employ CI initiated by radioactive ^{63}Nickel, and photoionization.

Differential mobility spectroscopy (DMS) differs from IMS by the ion path in having two planar electrodes that produce an electric field that oscillates between high and low values (e.g., 500 to 1,500 V) and a sweeping compensation voltage. DMS promises excellent chemical separation for complex volatile organic mixtures in a miniature chip size. Lambertus et al. (2005) detected and separated a complex mixture of 45 organic volatiles ranging from C_2–C_9 at ca. 1–100 ppb by using a 3.0-m GC column on a microchip attached to a 15-mm microchip DMS. High-field asymmetric waveform ion mobility spectrometers (FAIMS) operate similarly to DMS (Borsdorf and Eiceman 2006).

Absorbance Spectroscopies Volatile organics strongly absorb energy at mid- to far-infrared (IR; ca. 3–1,000 μm) wavelengths, and this makes their detection possible at low concentrations. The near-IR (ca. 0.75–1.4 μm) range is also useful, but detection of VOCs based on overtones in this region is 10^2 less sensitive. Fourier transform infrared spectroscopy (FTIR) is widely used for analysis of many organic compounds, and open-path FTIR (OP-FTIR) is a direct extension of this method for open spaces (from meter to kilometer). Industrial, environmental, and remote sensing applications of OP-FTIR demonstrate its utility. Active OP-FTIR sensing (includes an instrument light source) is more sensitive than passive sensing (uses ambient light; Vogt 2006). With advanced chemometric techniques, the application of multiple or sweeping OP-FTIR spectrometers and reconstructed tomographic maps has allowed temporal visualization of some vapor plumes (Todd 2000). A direct comparison between OP-FTIR (measurement cycle time 1.2 Hz), PTRMS (ca. 100 Hz), and GC analysis of canister grab samples revealed good agreement with methods that measure parts per billion amounts of volatile organics (Christian et al. 2004).

Several portable laser absorption spectroscopic (LAS) techniques useful for trace gas detection reflect the recent

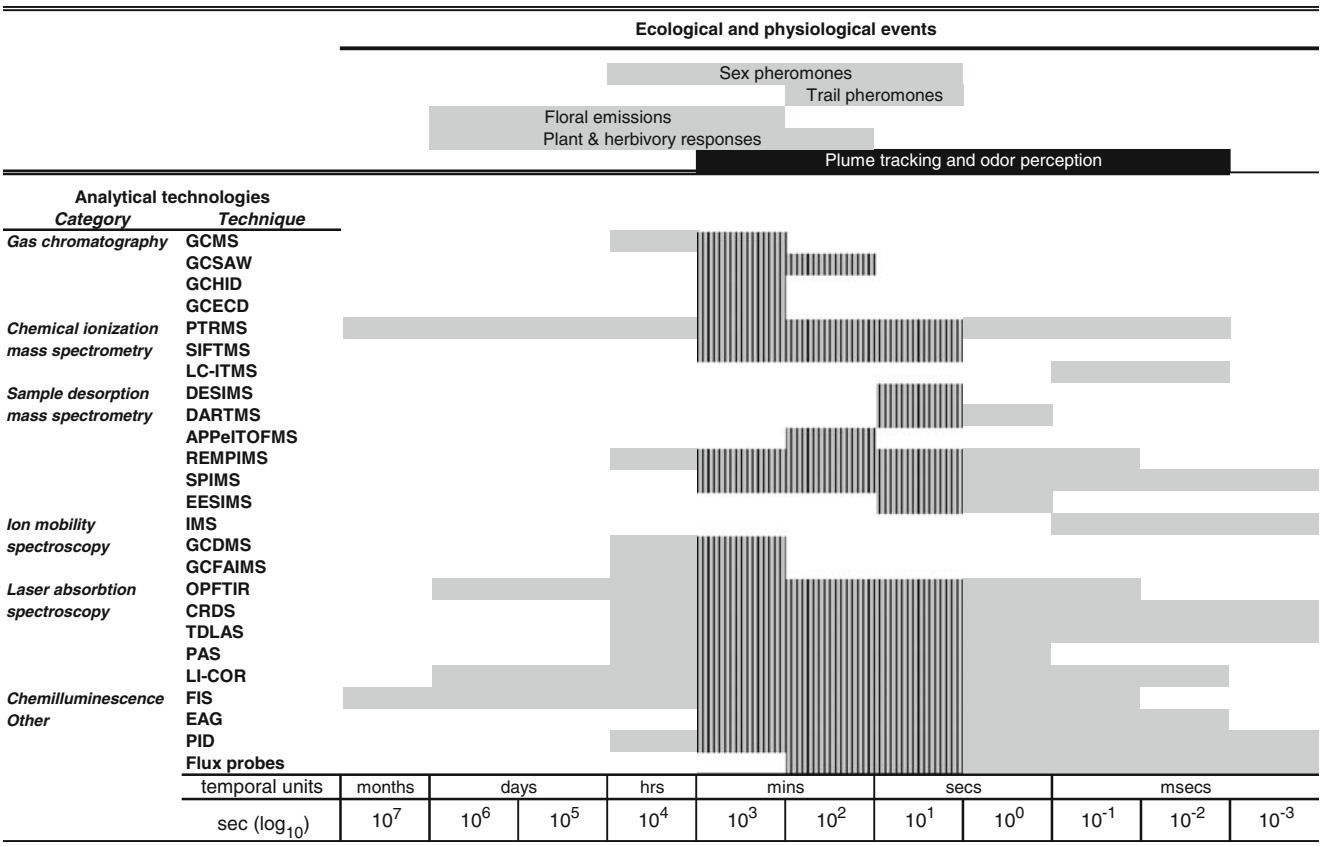

Fig. 4 Ecological and odor producing physiological activities (*upper five rows*) are compared with available analytical technologies having potential application in olfactory ecology. Ecological events are portrayed as two types: odor emissions (*gray*) lasting from seconds to hours, and odor tracking and perception (*black*) lasting from milliseconds to minutes. Temporal resolution ranges (in seconds; *lower rows*; log scale) obtainable from measurements with analytical technologies listed by category (acronyms defined in "Analytical Equipment", see also Appendix 2) are shown in *gray*. The temporal range where chemical signal emission and signal reception (olfaction) overlap is indicated by *hashed marks*

evolution of optical spectroscopy. Small and robust diode lasers with high optical intensity have mostly replaced lamp and filament light sources to provide greater sensitivity and portability for trace gas detections. However, small spectral coverage from these lasers has limited new diode laser dependant devices to the detection of a single gas species per laser. LAS applications in atmospheric science, environmental monitoring, semiconductor production, and breath analysis have demonstrated parts per million–parts per trillion detections of organics of phyto-relevance such as acetone (C_3H_6O), isoprene (C_5H_8), and methanol (CH_4O) among others (Khunemann et al. 2002; Cias et al. 2007; Ngai et al. 2007; Wang and Mbi 2007). Recently, broadly tunable diode lasers have become commercially available in the 1,528–1,608 nm (near-IR) range that are suitable for measuring gases like CO_2 and NH_3, but not appropriate for semiochemical-type VOCs (Kachanov et al. 2006). The lack of availability of lasers in the VOC-appropriate mid-infrared 1,610–1,710 nm range reflects industry needs rather than technological barriers, so commercially available mid-IR laser devices may become more common as the VOC sensor industry matures. Three primary approaches of LAS technology have led to instrumentation that is now available and in use for trace gas detection: cavity ringdown spectroscopy (CRDS), photo acoustic spectroscopy (PAS), and tunable diode laser absorption spectroscopy (TDLAS; Kachanov et al. 2006).

Infrared Gas Analyzer for CO_2 Measurement Many insects possess olfactory receptor cells that are specifically sensitive to ambient CO_2 levels. Detection of CO_2 concentration changes is important for many insect species (Stange 1996; Guerenstein and Hildebrand 2008). Expression of CO_2 sensory organs among invertebrates appears to be strongest in herbivorous Lepidoptera (Bogner 1990; Stange 1997; Guerenstein et al. 2004). Sexual dimorphism of the CO_2 sensory labial palp organs (LPOs) and sensilla therein is variable among insects. The LI-7500 non-dispersive infrared CO_2/H_2O gas analyzer (LI-COR Biosciences, Lincoln, NE, USA) is the standard tool used by ecophysiologists for measuring precise CO_2 fluctuations from ca. 0–3,000 ppm with response times from 5–20 Hz. The battery operated 0.75 kg instrument is 30×6.5 cm and mountable in any orientation. The LI-7500 has been used to measure dynamic plumes of artificially high CO_2 above host plants inside free air carbon dioxide enrichment (FACE) rings for evaluating the effects of fluctuating, elevated CO_2 on moth oviposition preference (Abrell et al. 2005).

Chemiluminescence For real-time (10 Hz measurement cycle time) detection (to 400 ppb) of isoprene, Hills and Zimmerman (1990) developed the fluorescent isoprene sensor (FIS) based on detection of chemiluminescence coming from decay of the excited formaldehyde intermediate in the reaction of isoprene (a terminal alkene) with ozone. Other existing chemiluminescence-based trace gas detectors are specific for non-semiochemical type gases.

Insect Antennae as Biosensors Use of the insect antenna for determination of biologically important volatiles has emerged as an important type of biosensor for specific VOCs, especially pheromones (Roelofs 1984; Park et al. 2002). First, electroantennography (EAG), and later, single-sensillar recording, have emerged as sensitive tools for elucidating behaviorally important volatiles (Schneider 1969; Mustaparta 1975; Guerenstein and Guerin 2001; Stranden et al. 2003). Single-sensillar recording, the electrophysiological recording of a receptor neuron located on the insect antennae, has been used only in the laboratory due to the delicate arrangement of electrophysiological recording equipment. In contrast, EAGs are robust and have been used in the field. While not as sensitive as single-sensillar responses, EAGs can provide a qualitative measure of volatile semiochemicals in the atmosphere. Established by Dietrich Schneider (1957) by using the *Bombyx mori* silkworm moth antenna, an EAG response is described as recording the sum of receptor potentials in many sensory neurons by chemical stimuli presented to the antenna (Schneider 1969). The electrical signal from the antenna is collected from electrodes placed at the base and tip of the antenna, amplified, and recorded. EAG response amplitude is dependent on the stimulus concentration and chemical structure. Both EAGs and single-sensillum recordings have been used in tandem with GCMS for determination of biologically relevant volatiles, and EAGs have been used in the field for detection of simulated and natural plumes (Murlis et al. 2000).

Chemical Tracers Unavailability of fast, sensitive, and affordable chemical detectors for volatile semiochemicals has led to the development of odor plume experiments that rely on surrogate molecules that, optimistically, behave like odor molecules in a plume. Initially, Murlis and Jones (1981) used an ion collector method downwind from an ion generator acting on air at a coastal field to generate a 15 m outdoor plume. Downwind detection of intermittent ion bursts revealed fine scale plume structure, but ion-ion repulsions may have affected plume structure. More recently, gypsy moth pheromone [(+)-disparlure, $C_{19}H_{38}O$] was released synchronously with generated ions upwind and measured by male moth antennae downwind by using EAG. This creative validation approach revealed that pheromone and ion arrival at vertical Langmuir flux probes (ca. 1.2 m^2) was concurrent but quantitatively uncorrelated (Murlis et al. 2000). A more modern surrogate

plume approach utilizes fast photoionization detection (PID; up to 330 Hz). Justus et al. (2002, 2005) controlled release of a surrogate propene gas in a 3-m wind tunnel and measured plume structure by using a miniPID from Aurora Scientific (Aurora Scientific Inc., Ontario, Canada). PID continues to offer high temporal resolution of plume structure, but the inherent shortcoming is a lack of discrimination for individual VOCs. Odor concentrations (50–3,000 ppm) measured by PID reflect the sum of all odor mixture components ionized by radiation (8.5-11.7 eV will ionize most organic volatiles $\leq C_{10}$ depending on their respective ionization potentials) from a UV lamp in a detection chamber (Palassis 1997). Development of improved odor stimuli delivery techniques requires high frequency odor detection, which PID can provide (French and Meisner 2007).When coupled with a sonic anemometer, PIDs provide a powerful means to characterize the physical odor environment.

For an insect, the behavioral (odor perception and subsequent navigation) response to an odor is generally immediate (millisecond to minute). The analytical technologies reviewed above and listed in Fig. 4 span a wide range of response times and conceptually fundamental detection methods. As GC is a separation process and not a detection process, GC speed is mainly limited by separation time rather than detection speed. In mass spectrometry, only ions are detected, so the ionization process is fundamental in determining molecule detection efficiency and sample inlet speed. Similar to GC, ion mobility spectroscopy is also a separation process, but ~10^3 times faster than GC (Fig. 4). Laser absorption spectroscopies show promise for trace gas detections in diverse environments, including remote sensing and tomographic applications. The fastest technology reviewed in this paper is photoionization detection (up to 330 Hz; Fig. 4) which Cardé and coworkers have already exploited for several years now (Justus et al. 2002). Other fast techniques shown in Fig. 4 include PTRMS, OPFTIR, LI-COR, EAG, and FIS. Among these, PTRMS, OPFTIR, and EAG have the widest ability to measure diverse chemicals in a single measurement cycle, and may be the most useful techniques going forward in olfactory ecology today.

Summary and Future Directions

The olfactory environment in which insects navigate is dynamic, with physical processes ultimately controlling the chemical signal available to the organism. In this review, we described features of the physical environment that control the dynamics of the chemical signal and a menu of technological innovations that may allow measurement of the fluctuating chemical signal. A multi-disciplinary research approach is thus necessary to effectively investigate and understand the olfactory environment that insects inhabit. Recent advances in analytical technologies allow unprecedented opportunities for chemical ecologists and behavioralists to characterize the physicochemical environment and determine when and where olfactory-mediated behaviors control ecological interactions.

Different physical environments, such as a forest or a desert plain, over land or in water, and the size of an animal body, will affect the chemical stimuli available and may operate as a selective pressure on the sensory system. It follows that different "odor landscapes" will set constraints on insect olfactory systems and odor-tracking navigational behavior. Small insects (<1 mm) inhabit a fluid regime with filamentous odors, but also smooth, sheared odor gradients will exist during periods of limited air movement (Zimmer and Zimmer 2008). In contrast, larger, faster insects inhabit a fluid regime with filamentous and three-dimensional odor. Do insects living at these different scales utilize different behavioral strategies to locate odor sources? Do animals that exist in different environments but inhabit dynamically similar fluid regimes (e.g., a moth and a salmon) use equivalent strategies (see DeBose and Nevitt 2008; Cardé and Willis 2008; Zimmer and Zimmer 2008)? Moreover, much of our understanding of odor plume dynamics comes from sampling at a fixed point. Navigating insects, on the other hand, will be translating in the same space as the filamentous plume and, thus, will be experiencing the plume from a moving reference frame (Lagrangian versus Eulerian frame). How does this influence the chemical signal variation and fine-scale features experienced by the insect? On an evolutionary scale, we might predict that the physicochemical environment has shaped the sensory system and behaviors of these organisms. A comparative, phylogenetic approach presents an exciting opportunity toward an examination of how the physical environment may have influenced organismal sensory systems, behaviors, and morphologies. The improvement of analytical technologies will foster increased understanding of the physicochemical environment and will enable researchers to determine how olfactory environments shape insect behaviors and sensory systems.

Acknowledgments We thank C. Reisenman, H. Lei, and C. M. Jones for comments during earlier versions of this manuscript. We especially thank H. Thistle, C. A. Zimmer, and R. K. Zimmer for discussions on odor plume dynamics and atmospheric processes. This work was supported by National Institute of Health grant DC-02751 (JGH), National Science Foundation grant CHE-0216226, and a seed grant from the University of Arizona's Center for Insect Science. J. A. R. was supported by a NIH postdoctoral training grant (2 K12 GM000708-06).

Appendix 1

Table 1 Notation for physical processes

Symbol	Definition	Units
D	Roughness element height (Eq. 3)	m
D_{object}	Diameter of object used in Strouhal number calculation (Eq. 5)	m
f	Eddy shedding frequency (Eq. 5)	1/s
G	Gravitational acceleration.	m/s^2
μ	Air viscosity (Eq. 1)	Ns/m^2
p	Air density (Eq. 1)	kg/m^3
N	Frequency of the peak intensity of velocity spectra	1/s
Re	Reynolds number (Eq. 1). The ratio between inertial and viscous forces, $Re = \frac{\rho S u}{\mu}$	dimensionless
Re_*	Reynolds roughness number (Eq. 3). Describes boundary layer, $Re_* = \frac{\rho u_* D}{\mu}$	Dimensionless
R_i	Richardson number (Eq. 4). Describes boundary layer stability, $R_i = \frac{(g/\overline{\theta})(\partial\overline{\theta}/\partial z)}{(\partial\overline{u}/\partial z)^2}$	Dimensionless
S	Insect spatial scale (Eq. 1)	M
S_t	Strouhal number (Eq. 5). Eddy shedding frequency by objects in wind. $St = \frac{fD_{\text{object}}}{u}$	Dimensionless
u	Velocity in the horizontal dimension (Eq. 1)	m/s
$\overline{u}$	Mean horizontal velocity (Eq. 1)	m/s
u'	Fluctuating horizontal velocity (Eq. 2)	m/s
u_*	Friction velocity (Eq. 3). Describes intensity of the turbulence	m/s
w	Velocity in the vertical dimension (Eq. 2)	m/s
w'	Fluctuating vertical velocity (Eq. 2)	m/s
τ_R	Reynolds shear stress (Eq. 2), $\tau_R = -\rho\overline{u'w'}$.	N/m^2
z	Height above the substrate (Eq. 4)	m
$\overline{\theta}$	Mean temperature (Eq. 4)	Kelvin

Appendix 2

Table 2 Notation for analytical technologies

Category	Technique abbreviation	Technique
Gas chromatography	GCMS	Gas chromatography mass spectrometry
	GCSAW	Gas chromatography surface acoustic wave quartz microbalance detection
	GCHID	Gas chromatography helium ionization detection
	GCECD	Gas chromatography electron capture detection
Chemical ionization mass spectrometry	PTRMS	Proton transfer reaction mass spectrometry
	SIFTMS	Selected ion flow tube mass spectrometry
	LCITMS	Liquid chromatography ion trap mass spectrometry
	DESIMS	Desorption electrospray ionization mass spectrometry
	DARTMS	Direct analysis in real time mass spectrometry
	APPeITOFMS	Atmospheric pressure Penning ionization time of flight mass spectrometry
	REMPIMS	Resonance-enhanced multiphoton ionization mass spectrometry
	SPIMS	Single photon ionization mass spectrometry
	EESIMS	Extractive electrospray ionization mass spectrometry
Ion mobility spectroscopy	IMS	Ion mobility spectroscopy
	GCDMS	Gas chromatography differential mobility spectroscopy
	GCFAIMS	Gas chromatography high-field asymmetric waveform ion mobility spectrometry

Table 2 (continued)

Category	Technique abbreviation	Technique
Absorption spectroscopy	OPFTIR	Open-path Fourier transform infrared spectroscopy
	CRDS	Cavity ringdown spectroscopy
	TDLAS	Tunable diode laser absorption spectroscopy
	PAS	Photo acoustic spectroscopy
	IRGA	Infrared gas analyzer
	LICOR	Refers to the LI-7500 non-dispersive infrared CO_2/H_2O gas analyzer from LI-COR Biosciences
Chemiluminescence	FIS	Fluorescent isoprene sensor
Other	EAG	Electroantennography
	PID	Photoionization detection

REVIEW ARTICLE

Navigational Strategies Used by Insects to Find Distant, Wind-Borne Sources of Odor

Ring T. Cardé · Mark A. Willis

Received: 2 January 2008 / Revised: 24 February 2008 / Accepted: 18 April 2008 / Published online: 26 June 2008

Abstract Insects locate many resources important to survival by tracking along wind-borne odor plumes to their source. It is well known that plumes are patchy distributions of high concentration packets of odor interspersed with clean air, not smooth Gaussian distributions of odor intensity. This realization has been crucial to our understanding of plume-tracking behavior, because insect locomotory movements and sensory processing typically take place in the range of tens to hundreds of milliseconds, permitting them to respond to the rapid changes in odor concentration they experience in plumes. Because odor plumes are not comprised of smooth concentration gradients, they cannot provide the directional information necessary to allow plume-tracking insects to steer toward the source. Many experiments have shown that, in the species examined, successful source location requires two sensory inputs: the presence of the attractive odor and the detection of the direction of the wind bearing that odor. All plume-tracking insects use the wind direction as the primary directional cue that enables them to steer their movements toward the odor source. Experimental manipulations of the presence and absence of the odor, and the presence, absence, or direction of the wind during plume tracking, have begun to resolve the relationship between these two sensory inputs and how they shape the maneuvers we observe. Experiments, especially those undertaken in the natural wind and odor environments of the organisms in question and those directed at understanding the neural processing that underlie plume tracking, promise to enhance our understanding of this remarkable behavior.

Introduction

Many kinds of organisms use odors to locate and identify a wide variety of resources, such as potential mates, conspecifics for aggregation, food, and sites for oviposition. Finding these sources involves a number of potential selective forces—such as economy of movement and the rapidity and likelihood of source location. In some cases, the time to location may be paramount, as in the case of a female moth that is emitting pheromone. She may be mated by the first male that reaches her, and consequently, there should be a considerable selective advantage accorded to males that have an efficient strategy for finding her pheromone plume and then navigating rapidly and accurately along the plume to its source. Greenfield (1981) categorized this competition as "a race to locate females." In other cases, such as finding a fruit suitable for oviposition, the resource may be available continuously, and, therefore, the importance of rapid navigation to the odor's source may be lessened.

This review focuses on examples selected to exemplify the diversity of navigational strategies that insects employ to find a distant, wind-borne odor source by navigating along its plume. An odor is typically a mixture of chemicals that evokes a specific behavioral reaction, upwind orientation in

the context of this review. Odors that are incomplete may not evoke "natural" orientation behavior, as in the case of a partial blend of pheromone components or a complete mixture presented at an unnatural ratio (see Vickers 2006). This review is confined to cases where the odor presented is assumed to be the single natural chemical or the naturally occurring mixture. Among the issues considered are: How the odor is distributed within the plume, strategies for finding an odor plume, mechanisms to detect wind flow, direction of wind flow as a directional guide to the odor's source, and the kinds of orientation maneuvers used in navigation.

Odor Dispersion

A thorough consideration of the dynamics of odor dispersion in wind is beyond the intent of this review. However, a brief description of this process is necessary to begin to understand how the spatial distribution of odor within the plume and the direction of wind flow modulate orientation maneuvers. In this paper, we define the plume as the volume wherein odor concentration is generally above behavioral threshold; because of turbulence, the odor is unevenly distributed in the plume, with odor-containing eddies interspersed with air that is odor-free or below behavioral threshold. Important reviews on the patterns of odor dispersion in air and water as they affect animal responses to semiochemicals include those of Elkinton and Cardé (1984), Murlis et al. (1992), Weissburg (2000), Conover (2007), Willis (2008), and Riffell et al. (this issue).

Early analyses of the dispersion of a pheromone plume in wind used a time-averaged (Gaussian) model developed by Sutton (1953) to depict concentration distributions downwind of the source (Bossert and Wilson 1963). The work of Fares et al. (1983) incorporated turbulent diffusion and accounted for atmospheric stability, i.e., the scale of turbulence, but these models also generated Gaussian distributions. All such approaches produce time-averaged distributions (e.g., the Sutton equation estimates a 3-min average of concentration), whereas, as first pointed out by Wright (1958), insects typically react to very brief exposures to odors (e.g., ≈10 ms in the case of the almond moth, *Cadra cautella*, to a single filament of its pheromone, Mafra-Neto and Cardé 1996). By using the wing-fanning reaction of the male gypsy moth, *Lymantria dispar*, to pheromone, Elkinton et al. (1984) found that time-averaged dispersion models substantially underestimated the instantaneous concentration of pheromone in a forest habitat. Aylor et al. (1976) and Miksad and Kittredge (1979) proposed plume models that calculate instantaneous concentration relative to the plume's centerline, but these did not account for the lateral movement of the plume (i.e., meander), and consequently, these models can not be used to predict concentration at a fixed point downwind (Elkinton and Cardé 1984).

Dispersion of odor in wind is dominated by the forces of turbulent diffusion that stretch and stir odor filaments as they are released from the odor source, simultaneously creating gaps of odor-free air within the plume as it expands and is transported downwind (Murlis et al. 1992). Molecular diffusion, on the other hand, is so slow that it is important only at very small distances. The diffusion coefficient for ethanol is only 1.32×10^{-5} m^2 s^{-1} and that for hexadecanol (similar in size to many moth pheromones) is 2.5×10^{-6} m^2 s^{-1} (Loudon 2003). The slow rates of molecular diffusion mean that the distribution of odor in the plume is due mainly to turbulence rather than molecular diffusion, and in cases where the odor is a mixture, the ratio of compounds throughout the plume will be close to the ratio emitted at the source. Relatively undiluted packets of odor ("bursts") can thus persist many meters downwind of the plume's origin (Murlis and Jones 1981).

Insects navigating along turbulent plumes thus encounter odor in bursts interspersed with patches of clean air (Fig. 1). In analyzing the temporal features of such intermittent signals, it is helpful to use only those portions of the record when the signal is present, the so-called conditional signal. This variable presence of a signal at a fixed sampling point downwind is termed its intermittency (a proportional value that ranges from a value of 1 when the signal is *not* present to zero when it is present continuously—see Fig. 1). Intermittency is caused by turbulent diffusion and plume

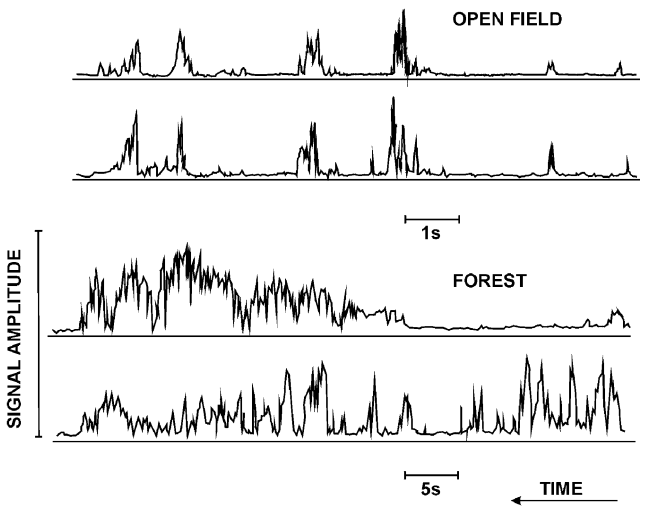

Fig. 1 Ion signals measured in daytime with a Langmuir probe in an open field and in a forest 2.5 m downwind of an ion source. The ions served as a surrogate for odor. Note the difference in the time scales for measurements in the two habitats. In the open field, there are many gaps of several seconds duration when no ions were detected, showing that the signal sampled at a fixed point in space is highly intermittent. When the signal is present (in "bursts"), it varies enormously in concentration. See Murlis et al. (2000) for details.

meander and undulation. As the plume is carried downwind, the conditional mean concentration of odor bursts within the plume and the conditional peak-to-mean ratio of odor intensity both decrease, while signal intermittency increases (Murlis et al. 2000). However, given the patchy distribution and highly variable concentration of odor filaments within the plume, the use of changes in odor concentration as a guide to the direction toward the source is not reliable unless the odor source is decimeters or so away (Murlis et al. 1992).

The effect of wind speed on small and large scale turbulence is complex. As wind velocity increases, generally the directional flow of the plume is more consistent (i.e., the plume is straighter) and thus the plume's outer envelope encompasses a reduced volume and increased concentration (Griffiths et al. 1995). Episodes of increased wind speed and consistency of directional flow seem to account for time periods when gypsy moths navigate successfully over tens of meters along pheromone plumes in a deciduous forest (Elkinton et al. 1987).

The initial size of odor sources that are important to insects varies enormously. Even moderately sized insects such as arctiid moths (e.g., 1–3 cm in length) can generate an initially small plume of pheromone, on the order of several square millimeters in cross-section, emanating from two small pores at the tip of their abdomen. Pheromone-emitting ("calling") arctiid females elevate their wings in a "V" posture, enabling air to flow freely around their body and, thereby, preserving plume size as the odor is carried away from the female (Conner and Best 1988). However, insects may more typically emit odor while perched within foliage or on tree trunks, thereby generating much larger plumes. For example, a gypsy moth (*L. dispar*) female typically calls while perched on a tree trunk. Eddies swirling in the trunk's downwind wake immediately expand her pheromone plume to approximately the tree's diameter (Charlton and Cardé 1990; see also Brady et al. 1989; Willis et al. 1991; Wyatt et al. 1993).

Whether odor emitting individuals choose calling sites specifically to enhance signal propagation is currently not well understood. In the case of the pink bollworm moth, *Pectinophora gossypiella*, Kaae and Shorey (1973) found that females select calling sites near the top of the cotton canopy when night winds are light and farther down in the canopy in windy conditions. Female-baited traps placed in both positions caught more males in the upper position on calm nights and more in the lower position on windy nights, suggesting that the male's orientation success is influenced by wind speed and position of the signal in the canopy. We do not, however, know how the interactions of position in the foliage and wind speed influence the plume's distribution or the male's ability to track it.

Odor plumes from the body of vertebrates generally would have an initial size roughly as large as the size of the body from which the odor emanates. Sizes range for example from a small bird to a large ungulate or even a herd of ungulates. The odor cues within such plumes, however, may be unevenly distributed, particularly close to the source. A female mosquito blood feeds preferentially, dependent on mosquito species, on different regions of the torso, legs, arms, and head of a seated human (de Jong and Knols 1996). Such partitioning of feeding sites may be mediated in part by odor profiles that differ by body region and may dictate orientation maneuvers. Odor from human breath, particularly CO_2, which itself is highly attractive to host-seeking female mosquitoes, forms a plume that is pulsed with each exhalation; initially, this plume would not overlap with the body odor plume except near the head. A fluctuating intensity of CO_2, due mainly to turbulent diffusion, has been suggested to be the principal odor cue used at a distance by female yellow fever mosquitoes, *Aedes aegypti*, to initiate plume following (Dekker et al. 2005).

Many other odor sources also have an initially large plume size. Mass attack of hundreds of bark (scolytid) beetles boring into a tree releases pheromone and phloem volatiles that generate a plume that initially is as wide as the tree trunk and that has a vertical expanse matching the trunk area that is infested. Volatiles released by leaves often serve as orientation cues, and the odor plume's initial size typically would be as large as the plant. These examples indicate that initial plume size varies enormously with the kind of odor source. Plumes issuing from small sources have reasonably defined borders that are readily crossed and detected by a flying insect within meters to centimeters of the source; such plume boundaries may facilitate orientation by collimating its flight path. Indeed, recent studies of male cockroaches, *Periplaneta americana*, that track plumes of different widths while walking have identified specific turns back into the plume that appear to be triggered by these animals nearing or crossing the lateral boundary of a wind-borne plume (Willis and Avondet 2005). Large plumes may have ragged or ill-defined edges, which, because of the plume's large size, are not routinely traversed or detected during orientation. Far from the source (e.g., tens of meters), plumes may be so wide that the expanded individual filaments of the plume may be treated like "plumes" by animals with the size and movement scales of a flying insect.

Structural features of the habitat also influence a plume's fine-scale distribution and meander. Landscape-level features such as trees and shrubs, when they contact the plume, can stir and dilute it (mechanical turbulence) or cause it to meander around the obstacle. Plume structure also varies with the daily patterns of wind velocity and levels of turbulence. Wind velocities on average peak from late morning to mid afternoon and then generally decline until reaching a daily low near dawn. Levels of turbulence can

be related either to atmospheric stability, which is governed by incoming solar radiation during daytime and the extent of nighttime cloud cover or to vertical temperature gradients (Fares et al. 1983). Directional variability (plume meander) is correlated inversely with wind speed (Brady et al. 1989) and, generally, is less over open ground than in woodlands (Brady et al. 1989; Murlis et al. 2000). Fares et al. (1983) have suggested that observed variation in the daily times that *Dendroctonus* bark beetles are attracted to their pine hosts is correlated with favorable periods for semiochemical dispersal—namely when stable atmospheric conditions tend to "trap" the plume under the canopy. Conover (2007) provides a thorough consideration of how structural features of the habitat such as trees and atmospheric conditions influence plume structure.

Given that weather can differ enormously from day to day and the habitat that a particular species occupies also typically varies in structure, there may be no single, optimal navigational strategy. Rather, the orientation maneuvers must be sufficiently flexible to operate across a range of wind speeds and turbulence conditions (Belanger and Willis 1996).

Wind Direction

Generally, heading upwind while in contact with the odor is the principal mechanism that flying and walking insects employ during orientation along a plume. However, shifting wind direction causes the plume to meander and, surprisingly, the instantaneous wind direction within the plume is not always aligned with the plume's long (downwind) axis. When the wind holds at a relatively steady speed but changes direction, upwind direction within such a meandering plume generally points toward the odor's source (David et al. 1982), but heading upwind also may lead the insect out of the plume (Fig. 2b). Surrogate odors (puffs of smoke) released over an open field typically travel in a straight line for at least 25 m. When the wind speed and direction both fluctuate as would be typical in nature, however, the upwind direction may lead out of the plume and be a poor directional guide to the odor's source. Such meandering can be accentuated by the presence of shrubs and trees around which plumes may flow (Elkinton et al. 1987; Brady et al. 1989). The consequences of variable directionality and wind velocity on plume following are that insects flying upwind along plumes would be expected routinely to exit the plume's boundaries. As we explain later, insects are well adapted to deal with this challenge.

The last consideration is the possible vertical undulation of the plume. A plume traveling through a forest into a patch of sunlight will be warmed and consequently will rise in thermal chimneys (e.g., Fares et al. 1983). At nighttime in the Costa Rican rain forest, pheromone plumes from cockroaches calling on tree trunks also flow upward because of a temperature gradient, and accordingly, males of a given species appear to position themselves on trunks higher than conspecific females (Schal 1982). In relatively still air, odor plumes that emanate from a warm source (e.g., odors from human skin) may have a significant vertical component because of convective flow until the plume cools to the ambient temperature. There is not a great deal of information on how much vertical distribution of plumes influences odor plumes at spatial scales relevant to insect orientation, but vertical undulations, when they do occur, must add to the navigational challenge.

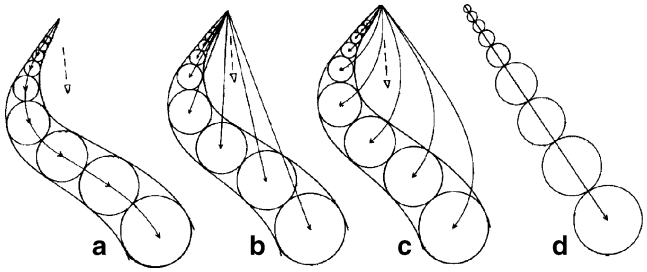

Fig. 2 Schematic of the possible effects of changing wind direction on the trajectory of meandering pheromone plumes as viewed from above. Pheromone is depicted as a series of puffs (circles), which expand with time. The trajectories of the puffs are shown by the lines leading from the source to the center of each puff with the arrow tips depicting the instantaneous wind direction within each puff. The dashed lines and arrow tips represent the mean direction of wind flow measured at the source over the time course of each plume's meandering. **a** Trajectory assumed by workers before the David et al. (1982) publication. The plume's centerline and the instantaneous wind direction at any point are assumed to be aligned. Therefore, heading upwind would lead to the odor source. **b** Conforms with the experiments of David et al. (1982) in an open field with a shifting wind direction but a relatively constant wind speed. Heading upwind in the downwind sector of the plume routinely leads the responder out of the plume. **c** Matches observations of Elkinton et al. (1987) beneath a forest canopy and Brady et al. (1989) in an open savannah; this effect is correlated with changes in wind direction and velocity measured at the source. **d** Shows a steady wind direction—during such "favorable" and typically brief alignments of wind direction and the plume's centerline, insects can make rapid progress toward the source. Reprinted with permission of Wiley–Blackwell from Elkinton et al. (1987), p. 400.

Finding an Odor Plume

Although this review emphasizes how the distribution of odors influences the navigation of insects to an odor's source, also of importance are the strategies employed to contact an odor plume. These have been termed "searching," "ranging," "questing," "wandering," and "appetitive" behaviors, but their key properties are a straightened-out locomotory path and a lowered threshold of responsiveness to resource-linked stimuli. The optimal strategies to locate a wind-borne odor plume often have been considered as a

separate theoretical issue (e.g., Sabelis and Schipper 1984; Dusenbery 1989, 1990). Generally, implicit in such models is an ability of the organism to estimate and average wind direction and its variability over some time interval, with the resultant optimal course for contacting a wind-borne plume being aimed on average crosswind, upwind, or downwind, depending on the model's assumptions. For example, if the wind is shifting direction more than 60°, it could be more advantageous to head either upwind or downwind than to head crosswind, because the crosswind expanse of the plume will exceed the distance of its downwind projection (Sabelis and Schipper 1984). There are, however, unstated assumptions implicit in this model. The distribution of odor across a plume that shifts more than 60° is patchy because of turbulence, and the probability of meeting odor may differ in traversing such a plume's via its downwind versus its crosswind axis (even if a plume is not continuous along its windline axis, the likelihood of contacting it while heading crosswind ought to be higher than approaching the plume from upwind or downwind directions). Other assumptions are that the searching organism must able to "calculate" the mean wind direction (Zanen et al. 1994), must be able to determine over the relevant time interval that the wind is shifting by more than 60°, and, most importantly, be able to assign these wind vectors to an absolute cardinal heading, such as fluctuating ≈60° around due north. This requires the organism to have a directional "map" of the immediate area and a memory of the wind's fluctuations.

Behavioral evidence to support any of these optimality models is scanty. Field observations of gypsy moths (*L. dispar*) have documented that female-seeking males flying within a meter or so of ground level take random courses with respect to the instantaneous wind direction (Elkinton and Cardé 1983). Although many gypsy moth females call from heights within 2 m of ground level, some call throughout the height of the tree canopy. Males observed in dense populations also search for calling females by flying vertically along tree trunks, apparently without reference to wind direction (Cardé and Hagaman 1984). Field observations of initial flight direction upon take-off of female onion flies, *Delia antiqua*, in absence of host plant odor appear random with respect to wind direction (Judd and Borden 1988, 1989). Wind-tunnel observations of the malaria mosquito, *Anopheles gambiae s.s.*, in an unscented air flow of steady direction determined that many females in the host-seeking stage generally flew upwind (Takken et al. 1997; Costantini et al. 2001). In field observations of orientation to human "baits" with netting barriers deployed in differing directions of wind flow, mosquitoes were documented to fly downwind before host encounter, in accord with a model of optimal energy expenditure to find a plume (Gillies and Wilkes 1974). However, in subsequent field work Gillies and Wilkes (1978) discounted their previous interpretation of a downwind host-seeking strategy, because they determined that screened fences had a negligible effect on mosquito movement. However, field observations of tsetse flies in absence of host odor or visual cues indicated that such "ranging" flights have a downwind bias (Gibson et al. 1991). Manipulations of hungry *Drosophila* fruit flies in a small wind tunnel in steady and shifting wind directions, however, suggest that they can shuttle between two strategies (Zanen et al. 1994). In a steady wind direction, they flew generally crosswind, in agreement with the predictions for an optimal path to encounter a plume, whereas in shifting winds they flew upwind in conformity with Dusenbery's (1990) analysis.

Provided the organism could use only currently or very recently sensed wind direction as a guide, a crosswind searching strategy would be optimal if the search organisms detected little variability in wind direction. Conversely, if the organism experienced continual changes in wind direction, then heading upwind or downwind by using the then-sensed wind direction would be optimal. These simple rules would not necessitate knowing the amount of wind variability (is it >60°?) nor its cardinal direction, but the general effects on searching success should be similar to using the implicit assumptions of the Sabelis and Schippers model. This suggests that strategies for finding the plume by assuming a particular heading with respect to *current* wind flow would be most effective: upwind or downwind when the wind direction varies, and crosswind when the wind direction holds steady. Additional issues that add to the complexity to calculating an optimal strategy are the relative speed of the wind versus the speed of the flying insect (see Dusenbery 1990).

An interesting "special case" has recently been discovered (Wolf and Wehner 2006). The desert ant *Cataglyphis* sp. uses visual cues from polarized light and inertial cues from the movement of its own body to steer a return course to its nest or good foraging sites (Wehner 1996). However, when returning to distant feeding sites, they apparently approach from downwind and intentionally steer off the wind line to intercept the plume of odor issuing from the food, and thus assure location of its source (Wolf and Wehner 2006). In this case, memory of the location of a good food source is combined with wind information to allow the ant to steer its walking course into a quadrant of the environment where it should encounter a reliable cue to locate important resources.

Finding a "Lost" Odor Plume

An insect flying upwind along the odor plume can lose contact with the plume in three ways: (1) Gaps within the plume caused by turbulence may be of sufficient size to

cause a cessation in upwind displacement; (2) insects may exit the plume's boundaries because the direction upwind may not always lead along the plume's path (Fig. 2b,c); and (3) the moth's own plume-tracking maneuvers may carry it outside the time-averaged plume boundaries. A strategy used by moths to re-contact a lost plume is called "casting," in which upwind displacement ceases and the moth flies to and fro in increasingly wider lateral zigzags across the windline (e.g., David et al. 1983; Kennedy 1983; Kuenen and Cardé 1994). The vertical component of flight also expands upon loss of the pheromone plume (von Keyserlingk 1984; Vickers and Baker 1996). Casting moths have been observed to hold station near the point of plume loss or drift downwind as the width of their tracks increases (Baker and Haynes 1987). This flight pattern may allow the moth to regain contact with the plume by reentering it or, if casting persists for a sufficient time, be in a location where the plume's meander itself causes re-contact. Casting moths continue to orient their flight with respect to the wind direction (David et al. 1983; Baker and Haynes 1987), and in some cases, this may enable them to re-contact the plume closer to the source then where it was lost (David et al. 1983). Another strategy for re-contacting the plume is to loop downwind, as observed in a parasitoid wasp (Kaiser et al. 1994) and the oriental fruit moth (Baker and Haynes 1996). A third option is simply station keeping until the plume swings back to the insect's location. Once the plume is re-contacted, upwind flight can resume. If contact is not re-established within a set time (a "giving-up time"), the insect should return to plume searching (Kuenen and Cardé 1994).

Odor-Induced Orientation to Wind

Important recent reviews of the mechanisms of insect flight to odor sources include those of Gibson and Torr (1999), Vickers (2000, 2006), and Hardie et al. (2001). Kennedy (1983) provided a comprehensive review and analysis of the early literature. Reviews of plume following in water are also of interest, as the issues of turbulent diffusion of an odor in water, information processing, and orientation are parallel to those when the plume is airborne (Atema 1996; Weissburg 2000).

Optomotor Anemotaxis The principal navigational mechanism used by a flying insect in location of an odor source is to head upwind while in contact with the odor. Detection of the direction upwind once an insect is airborne is accomplished by the optomotor response. An insect flying along the windline perceives an image flow viewed below as moving front to rear. When the insect's heading is not due upwind, the image flow has a transverse component because of wind-induced drift. This navigation system was first verified by Kennedy (1939) by using female *Aedes aegypti* mosquitoes stimulated to fly upwind by human breath introduced into a wind tunnel. Mosquitoes reacted to their apparent visual displacement which was provided by a pattern projected onto the tunnel's floor. Mosquitoes headed in the visually perceived upwind direction when the floor pattern was moved to simulate the effect of downwind displacement. This steering system is termed "optomotor anemotaxis."

Male Moth Orientation to Pheromone Much of what has been learned about odor-induced in-flight orientation has come from studies of male moth navigation along plumes of female-emitted pheromone. Most of these studies have used wind tunnels that permit a moderate degree of manipulation of the pheromone plume's structure, wind speed, and visual environment. The moth's maneuvers generally have been recorded in planar view, and so, the analyses of flight tracks have been two dimensional. A few studies have recorded flight tracks of moths flying freely in the field, often using a visual marker such as soap bubbles to indicate the path the odor plume has taken (Murlis et al. 1982; David et al. 1983; Willis et al. 1994; Vickers and Baker 1997).

Upwind flight of moths along a pheromone plume has typically been described as having a zigzag form, with regular left and right reversals across the windline. These turns in the gypsy moth are remarkably metronymic, occurring ≈3.5 to 4 reversals s^{-1} in a variety of conditions of plume concentration, plume structure, ambient temperature, and light level (Charlton et al. 1993; Cardé and Knols 2000), all of which change other flight parameters such as flight speed. A robustness of turning frequency during plume tracking is characteristic of all moth species in which it has been measured (Willis and Arbas 1991—*Manduca sexta*; Vickers and Baker 1992—*Heliothis virescens*; Willis and Baker 1987—*Grapholita molesta*). Often the only way to experimentally alter the turning frequency is to remove the odor plume altogether (Willis and Arbas 1991). Kennedy (1983) viewed zigzag turns in plume following and in casting as modulated by the same motor program and termed them "counterturns." The possibility that counterturns are caused by exiting the plume's boundary and then turning back toward where it was last sensed was once widely assumed (e.g., Farkas and Shorey 1972, 1974; Kennedy and Marsh 1974; Marsh et al. 1978; Cardé and Hagaman 1979) and had been described as "feeling for the edges." However, as turns can be executed well inside a plume (Kuenen and Baker 1982) or successively in clean air (i.e., casting flight; Kennedy and Marsh 1974), loss of odor contact is not the initiating stimulus for counterturning.

The establishment of the direct effects of a plume's internal structure and boundary position on orientation maneuvers has been at times contentious. Wright (1958)

proposed that flight along the plume was governed by encountering successive filaments of odor within the turbulent plume, with the pattern of contact shaping the form of the flight track. His analysis, however, assumed that the directional cues used in orientation were entirely chemical, in the plume's internal fenestration and outer boundaries, a view he later abandoned (Daykin et al. 1965). Simply detecting wind flow and then heading upwind while in contact with the odor was not considered a relevant navigational mechanism.

Farkas and Shorey (1972) proposed that moths sensed the overall shape of the pheromone plume while flying a zigzag path that carried them in and out of the plume's boundaries. The fact that they referred to this behavior as "aerial trail following" suggests that they imagined that plume-tracking male moths used chemo-orientation mechanisms similar to those used by walking ants to follow pheromone trails deposited on the ground (Hangartner 1967). Successive comparisons of the plume's position would enable flight along the plume's long axis toward the pheromone's source. In wind-tunnel experiments with the pink bollworm, *P. gossypiella*, a plume was first drawn out in wind, a male was then released into the plume, and the wind was immediately stopped (Farkas and Shorey 1972). The males' tracks were monitored after wind stop, during which time directional orientation could not be attributed to wind cues. According to Farkas and Shorey (1972), the only possible explanation for the successful plume tracking observed was longitudinal klinotactic chemo-orientation, that is, orientation directed by comparing concentration changes along the plume's length. Farkas and Shorey (1972) attempted to demonstrate an optomotor reaction that could support optomotor anemotaxis by moving a treadmill floor pattern beneath the tunnel, but no consistent response was observed. Therefore, they concluded that pink bollworm moth males did not use optomotor anemotaxis to direct their flight orientation in their wind tunnel, rather that moths steered by orienting directly to the odor concentrations in the plume.

This mechanism was challenged by Kennedy and Marsh (1974) who showed in their wind-tunnel trials that Indian meal moth, *Plodia interpunctella*, males steered their flight toward the source by reacting to changes in feedback from their visual flow field as predicted by optomotor anemotaxis. However, the principal observation of Farkas and Shorey (1972) that moths that have initiated flight along a plume in wind indeed can continue successful orientation along the plume in still air has been substantiated in two additional moths, *G. molesta* (Baker and Kuenen 1982; Kuenen and Baker 1982) and *L. dispar* (Willis and Cardé 1990). Given the variability of wind in nature, the ability to follow plumes in still air or wind velocities too low to resolve wind-induced drift by using optomotor feedback (Cardé and Knols 2000) should be a great advantage in mate finding. It has been demonstrated (Kennedy and Marsh 1974; Baker et al. 1984; Cardé 1984), and is now widely accepted, that plume-tracking moths use optomotor anemotaxis to direct their flight upwind toward the source. However, the mechanisms used to track plumes during lulls in wind are not well understood and are still open to study.

The first experiments to manipulate plume structure systematically sought to determine if signal intermittency was important to orientation. Kennedy et al. (1981) found with the summerfruit tortrix moth, *Adoxophyes orana*, that initial contact with pheromone initiated regular zigzag turning, but immediately, subsequent emersion in a homogeneous miasma of pheromone inhibited upwind flight; the males initiated casting flight as if they had lost contact with odor. Conversely, flight in a cloud of pheromone with a fluctuating intensity promoted upwind flight similar to that observed during plume tracking (Baker et al. 1985). Cessation of upwind movement in a homogeneous pheromone environment has been observed now in two other moth species, the oriental fruit moth, *G. molesta* (Willis and Baker 1984), and the pink bollworm, *P. gossypiella* (Justus and Cardé 2002). The almond moth, *C. cautella*, however, is capable of flying upwind in a homogeneous cloud of pheromone, at least over short distances, although the heading was aimed at an angle averaging ≈15° off of due upwind (Justus and Cardé 2002).

A precise role for contact with pheromone filaments in setting an upwind course was proposed by Baker (1990). According to this idea, two parallel control systems are activated upon contact with pheromone. The first generates the regular counterturning thought to underlie the zigzagging flight tracks we observe (either upwind or casting). The second suppresses this turning and steers the moth more directly upwind, resulting in an upwind surge toward the source. Subsequent experiments with *Heliothis virescens* showed that puffs of pheromone generated at the source at a rate of 4 Hz induced sustained upwind flight and source location and in some individuals, almost completely suppressed casting maneuvers, resulting in prolonged bouts of upwind flight with few detectable turns (Vickers and Baker 1992).

Working with the almond moth in a laminar flow wind tunnel, Mafra-Neto and Cardé (1994, 1995) monitored upwind surges after either interception of a filament of pheromone in a ribbon plume or a single puff of pheromone. A single encounter with a filament or puff induced an upwind surge within ≈200 ms, followed by initiation of crosswind casting. The duration of pheromone contact positively influenced the distance (and duration) of the surge, and, provided that contacts with filaments occurred at a sufficiently high rate, the surges could be linked into an essentially due-upwind heading. The rate of filament

generation at the pheromone source, ensuring a relatively due upwind course, appeared to be 10 Hz and above (Mafra-Neto and Cardé 1994, 1995; Justus et al. 2002b). Given the moth's airspeed, the in-flight rate of filament encounter would be higher than the rate of production at the source (Baker and Vickers 1994; Mafra-Neto and Cardé 1995).

Vickers and Baker (1994, 1996), working contemporaneously with *H. virescens*, reached the same conclusion: Contact with a sequence of pheromone filaments sets a relatively due-upwind course. The cast—filament contact—upwind surge model seems to explain both the zigzag flight track commonly noted in moth orientation to pheromone (and likely female orientation to host plant and flower volatiles, see Mechaber et al. 2002) and occasional segments of straight upwind flight. Recent studies of freely flying *D. melanogaster* fruit flies show that they behave in a manner similar to the almond moth (Budick and Dickinson 2006). When presented with a ribbon plume of banana odor, *D. melanogaster* individuals generate flight trajectories that are essentially indistinguishable from those of male moths tracking pheromone plumes (Fig. 5 in Budick and Dickinson 2006). Like freely flying moths, *D. melanogaster* responses vary, from tracks almost straight upwind, to moth-like zigzagging. However, unlike most moths studied so far, *D. melanogaster* flies straight upwind when presented with a homogeneous fog of attractive odor. This behavior is consistent with that observed from the almond moth (Justus and Cardé 2002) and with previous anecdotal reports of *D. melanogaster* flight behavior (Kellogg et al. 1962). The common house fly, *Musca domestica*, also generates moth-like flight trajectories when tracking plumes of attractive odors (Cossé and Baker 1996). No experimental manipulation of odor stimuli has been performed with this species, and we can only speculate that the mechanisms underlying its behavior are similar to those that govern the orientation of male moths to pheromone.

Mosquito orientation to host odors Many cues are implicated in the attraction of female mosquitoes to a vertebrate host for a blood meal, including expired CO_2, other body odors, heat, humidity, and visual features (reviewed by Clements 1999). Long-distance orientation (tens of meters downwind of the host and beyond visual range) could be governed by expired CO_2, body odors, or a combination of both. CO_2 is unusual among odors in that it is present as a constant "background" odor (≈0.04% ambient concentration), whereas it is expired by vertebrates at ≈4%. In the case of CO_2 released from a point source at the same rate as breathe from an ox into a riparian woodland in Africa, bursts of CO_2 above ambient were detected by using a high-resolution analyzer up to 64 m downwind (Zöllner et al. 2004). The importance of CO_2 relative to other host odors in mosquito attraction to a host is debated, and the value of this cue in inducing upwind flight may be in part contingent on the breadth of the host range of a given mosquito species (Gillies 1980; Takken and Knols 1999; Dekker et al. 2001), with generalist species being more likely to rely on CO_2 alone as a reliable indicator of a possible upwind host and with other body odors (along with humidity, heat, and visual cues) mediating orientation at close range.

Grant and O'Connell (1996) found that receptors on the maxillary palps of female mosquitoes are exquisitely sensitive to changes in concentration of CO_2, with fluctuations of as little as 40 ppm reflected by changes in receptor firing rates. Thus, well downwind of the host, the plume of CO_2 should be detectable by mosquitoes as a fluctuating concentration above ambient. Geier et al. (1998) demonstrated in a small wind tunnel that *A. aegypti* females readily flew upwind in turbulent and filamentous plumes of CO_2, but a homogeneous plume of CO_2 was far less likely to evoke upwind orientation. Conversely, plumes of human skin odor had the opposite effect, with homogeneous plumes being more apt to elicit upwind flights than turbulent and filamentous plumes. Dekker et al. (2001) found with the malaria mosquito, *A. gambiae s.s.*, that a turbulent flow of CO_2 improved orientation (measured in a large assay chamber with a choice between two entrance ports) when CO_2 was mixed with skin odor. A homogeneous flow of CO_2 mixed with skin odor, however, depressed the catch over skin odor alone. Although CO_2 alone presented as either a turbulent or homogeneous flow evoked less trap-entering behavior than clean air, CO_2 in either a turbulent or homogeneous flow improved orientation when flight nearby the port entrance was assayed via contact with an electric net. These comparisons establish that a turbulent flow of CO_2 is important to upwind orientation of malaria and yellow fever mosquitoes and suggest that the cast—filament encounter—upwind surge model that dictates moth flight to pheromone is applicable to mosquito response to CO_2 plumes.

Dekker et al. (2001) also assessed the responses of *A. aegypti* to the same combinations of CO_2 plumes and skin odor. In both species, homogeneous CO_2 plumes reduced trap entry compared to a clean air control, whereas homogeneous skin odor plumes increased trap entry over clean air. These studies suggest that processing of CO_2 and complex odor mixtures such as skin odor may have differing time requirements, with the latter requiring longer, continuous exposure.

Further wind tunnel studies with *A. aegypti* have shown that a single, transient encounter with a filament of CO_2 instantly lowers the threshold concentration evoking upwind flight to human skin odor (Dekker et al. 2005). This suggests that CO_2 alone in *A. aegypti* could be the long-

distance orientation cue, with body odors being utilized when the mosquito is close to a potential host. In highly anthropophilic species such as the yellow fever and malaria mosquitoes, females may enter or rest outside human dwellings before feeding. There they would be exposed to residual human odors. The encounter of a fluctuating concentration of CO_2, however, signifies the nearby presence of a potential host whose chemical signature can be verified by sensing the constituents of body odor.

Studies with two highly anthropophilic species point to a fluctuating concentration of CO_2 that induces upwind orientation (Geier et al. 1998; Dekker et al. 2001), with human body odor being most effective when its concentration remains relatively constant, as would be the case close to the host. In the yellow fever mosquito, a transient encounter with a filament of CO_2 induces a salience for skin odor, such that the concentration of skin odor needed to induce orientation is reduced (Dekker et al. 2005). Clearly, we need to know how the structure of odor plumes generally modulates host finding in additional species, especially non-anthropophilic species, with broad host ranges.

Aim-Then-Shoot Orientation of Diptera A second mechanism for orientation relies on mechanoreceptor sensing of wind direction before initiating flight and then heading that direction while in contact with the plume. This navigation system is termed "aim-then-shoot" (Kennedy 1986). Flight is presumably visually guided, as in optomotor anemotaxis, by maintaining a generally front-to-rear image flow of the ground pattern as long as contact with the odor plume is maintained. If the wind direction changes while the organism is in flight, then transverse image flow is generated, which if sensed would indicate an off windline heading. In-flight adjustments to course based on the detection of wind-induced drift are not assumed for the aim and shoot navigation. Orientation to hosts over a distance of many meters presumably consists of a series of short flights interspersed by landings when contact with host odor is lost, "as a series of steps" (Bursell 1987).

Evidence in support for an aim-then-shoot mechanism is, to date, limited to a few Diptera. Some tsetse flies (*Glossina*) upon detection of host odor take off heading directly upwind, quickly achieving an airspeed of ≈5 m s^{-1}, considered too fast to permit the flies to detect crosswind drift and, therefore, to use in-flight optomotor anemotaxis (Griffiths et al. 1995). By using released tsetse flies and monitoring their arrival at an upwind source of host odor, Griffiths et al. (1995) found that the "fast cohort" of released flies (about half of the flies) arrived at odor sources 30, 50, and 75 m upwind in less than 40 s! The rest of the flies took from 1 to >20 min, presumably by orienting in a series of short flights and landings. Wind-tunnel trials, however, also support the ability of tsetse flies to use conventional optomotor anemotaxis (e.g., Colvin et al. 1989), and so, it is possible that tsetse flies toggle between these two navigational mechanisms. The meteorological observations of Brady et al. (1989) in the tsetse's natural woodland habitat demonstrated that the direction of arrival of wind-borne host-odor would be a reliable guide to the actual direction toward a host 15 m away only about a third of the time; 20% of the time it would direct the fly at least 90° away from the host. How the tsetse fly uses information on wind direction, given its tenuous correlation with direction to the host, remains unclear. Finally, as the tsetse fly closely approaches a prospective host, visual cues presented by the host may become important for orientation. The final stage of orientation may be guided visually and, in fact, may be made from the upwind direction (Gibson and Torr 1999).

Cabbage root flies (Hawkes and Coaker 1979) and onion flies (Dindonis and Miller 1980) also seem to orient toward upwind host plant odors by the aim-then-shoot mechanism, but the use of this orientation strategy by other insect groups remains to be documented. As pointed out by Griffiths et al. (1995), the aim-then-shoot mechanism as used by tsetse seems relatively crude in comparison to the precision track of a male moth locating a female. However, it may serve in locating a large and mobile host by enabling sampling of a large area where the host is many meters away. When the host is in the range of tens of meters, it may be effective in rapid host finding. However, to date, the validity of the aim-then-shoot mechanism by tsetse remains largely an argument by exclusion—tsetse flight speed is too fast to permit in-flight processing of wind drift and, therefore, use optomotor navigation—rather than a mechanism supported by definitive experiments.

Future Work

One of the major impediments to understanding the precise relationship between in-flight orientation maneuvers and the pattern of encountering either odor filaments or more evenly dispersed odor patches is that we cannot readily establish how individual maneuvers correspond to the pattern of encountering patches of odor. We can measure the general, spatial features of odor plumes in wind tunnels (e.g., Justus et al. 2002a, with propylene as an odor) and in the field (Murlis and Jones 1981; Murlis et al. 2000, with negatively charged ions as a surrogate for odor), but it is difficult to establish how the patterns of odor contact in plumes with complex spatial structures modulate orientation, because we can only correlate the average patterns of odor distribution with behavioral output at the most general level of analysis, namely the overall flight track. In wind-

tunnel trials of moth flight along a pheromone plume, moths typically slow their rate of upwind progress and have a more narrow flight track as they approach the source (e.g., Justus et al. 2002b; Willis and Baker 1984; Willis and Arbas 1991). Which of the many features of plume structure (e.g., intermittency, peak concentration, peak-to-mean concentration, etc.) that change with distance to the source (Murlis et al. 1990; Justus et al. 2002a) and dictate these changes in flight track is unknown. By manipulating the rate of odor encounter and concentration, Vickers and Baker (1992) demonstrated that both of these variables affect the structure of *H. virescens* responses. Further studies are needed to determine to what extent other parameters of the odor plume affect the structure of plume-tracking behavior.

To record what a flying insect perceives as odor input while maneuvering along the plume would seem intractable. Vickers and Baker (1994), however, mounted a third antenna on the thorax of an *H. virescens* male and simultaneously recorded, via fine wires, its electroantennogram (EAG) responses to pheromone filaments encountered while it flew along the plume in a wind tunnel. Not surprisingly, bursts of pheromone were most often contacted near the plume's centerline; bursts confirmed the expected intermittency of the signal. The amplitude of flying EAGs, however, was unexpectedly higher than those recorded for a stationary EAG rig mounted at the same positions in the plume or one artificially moved upwind. Recent results from tethered flying *M. sexta* show that air flow, from head to tail, induced by the flapping wings should increase the speed of encounters with odor filaments by the antennae (Sane and Jacobson 2006). This is a possible explanation for the unexpectedly larger EAGs observed previously (Vickers et al. 2001). Unfortunately, no obvious relationship between EAG and moth behavior (other than pheromone present during plume tracking) was observed in this study, and no follow-up study has appeared. One important caveat for studies such as this is that the antenna recorded from was not providing the information that the moth was using to control its flight.

One useful technique for matching odor contact and behavioral reactions is the use of a long, thin ribbon plume in a laminar flow in a wind tunnel and to record the immediate reaction of an insect after it contacts the odor filament (e.g., Mafra-Neto and Cardé 1994; Dekker et al. 2005; Budick and Dickinson 2006). The plume's precise position relative to the insect can be determined by adding a visual tracer to the plume or by three-dimensional video recording. Such stretched-out, narrow plumes do not occur naturally, but an argument can be made that a single encounter with the ribbon plume corresponds to contact with a single odor filament in a turbulent plume. Another approach is to use tethered insects "flying" in a virtual world with movement simulated by flow of their visual surround (e.g., Gray et al. 2002). This system would enable presentation of precise patterns of odor impingement and measurement of resultant thrust and turning maneuvers. However, tethering may restrict maneuvering, and it has been interpreted to yield misleading conclusions about what inputs control counterturning (cf. Preiss and Kramer 1986; David and Kennedy 1987).

Simulation modeling with virtual insects in a virtual environment is another approach to understanding what kinds of sensory inputs from the plume can be extracted to navigate a course to its source. Models can specify the sensory inputs and navigational rules needed to create a zigzag track along a plume in a wind tunnel (Belanger and Arbas 1998), or the full spectrum of field behavior that include plume finding, plume following, maneuvers to re-contact a lost plume, and declaration that the source has been found (Li et al. 2001) in a simulated plume in a directionally fluctuating wind field (Farrell et al. 2002). These navigational strategies have been implemented and tested on an underwater robotic vehicle that has successfully searched for and located over a range of ≈1 km the source of a visual tracer that served as a surrogate for an odor (Li et al. 2006). Simulation models enable us to explore how varying sensory inputs and maneuvering rules modulate the effectiveness of the navigational strategy, but we should recognize that such simulations and robotic implementations can be successful without employing the same inputs and rules as the insects themselves utilize.

Field observations that meld meteorological measurements with flight track records offer insights into the distances over which odors are attractive and the kinds of flight tracks that occur under natural conditions. Such observations, so far, have been limited largely to day-active insects such as tsetse flies, gypsy moths, and oriental fruit moths that can be readily observed (however, see Vickers and Baker 1997), but they provide insights into the real-world capabilities of insects searching for distant odor sources that cannot be gleaned from wind tunnel studies.

Lastly, orientation to odor sources is a common reaction among many kinds of insects, but what we know of the mechanisms that govern this process is based on a handful of model systems. Such orientation is often simply termed "attraction," which as Kennedy (1978) pointed out, is a convenient but teleological term that fails to reveal the complexity of this process and the diversity of underlying mechanisms.

REVIEW ARTICLE

The use of Odors at Different Spatial Scales: Comparing Birds with Fish

Jennifer L. DeBose · Gabrielle A. Nevitt

Received: 18 April 2008 / Revised: 18 April 2008 / Accepted: 28 April 2008 / Published online: 20 June 2008

Abstract Salmon travel hundreds of kilometers of open ocean and meandering rivers to return to their natal stream to spawn; procellariiform seabirds soar over thousands of kilometers of the ocean's surface searching for foraging opportunities and accurately return to their nesting islands. These large-scale olfactory-guided behaviors are among the most dramatic examples of animal navigation ever described. At much closer ranges, the sense of smell can be used for behaviors as diverse as tracking prey, nest location, and mate selection. Both fish and birds face similar problems interpreting olfactory information in fluid mediums where odors are dispersed as filamentous patches. Similar to insects, which have served as model organisms for investigating olfactory related behaviors, the few fish and bird species that have been studied tend to use olfactory information in conjunction with other sensory modalities. Similar to insects, fish and birds also employ oscillatory or cross-stream movement as sampling mechanisms. This review compares and contrasts the use of odors by fish and birds over a range of spatial scales that span from thousands of kilometers to less than a meter. In so doing, we identify behavioral similarities and new questions that need to be addressed regarding the olfactory ecology of these diverse groups of organisms.

Introduction

Both fish and birds use olfactory information over a range of spatial scales. At large spatial scales on the order of hundreds of kilometers, olfactory-guided behaviors are among the most dramatic examples of animal navigation ever described. For instance, salmon require olfaction to relocate their natal streams, and pigeons released in unfamiliar territory are able to set a course for their home loft by using information derived from odors at the release site. At much closer ranges, the sense of smell can be used for behaviors as diverse as foraging and mate selection. Although one group swims and the other flies, both fish and birds face similar problems interpreting olfactory information in natural environments. Both groups have evolved to operate in three-dimensional space, in fluid mediums that share similar characteristics relevant to odor transport. Water and air both move in currents, and these currents distribute odors such that plumes have a filamentous, discontinuous structure (Zimmer-Faust et al. 1995; Finelli et al. 1999). As these odor filaments move away from a source, they can be widely dispersed depending on the turbulence of their environment (Zimmer-Faust et al. 1995; Moore et al. 2000); the higher the turbulence, the more irregular and patchier the distribution of odor filaments.

How organisms decipher reliable information from such discontinuity has consequently been a topic of much interest.

Not surprisingly, many advances in this field have been informed by previous work with insects, which have served as model organisms for investigating olfactory-related behaviors in freely flying organisms (see Willis 2005; Cardé and Willis 2008). As with insects, the few fish and bird species that have been studied tend to use olfactory information in conjunction with input from other sensory modalities. While insects combine odor cues with visual flow to direct upwind flight, a variety of environmental cues provide directional information to fish and birds, and these cues can vary, depending on the spatial scale of the problem. In many fish species, olfactory information is interpreted with respect to input from the lateral line system, whereas in birds (pigeons, for example), olfactory, visual, and geomagnetic information are likely used together in different ways, depending on whether the bird is homing from familiar territory near to its loft or from unfamiliar territory hundreds of kilometers away. Like insects, many species of fish and birds use up-current or up-wind movement coupled with zigzagging or casting movements to focus search activity to the source of a plume (Fig. 1), but given that most of these species cannot be studied easily in laboratory conditions, the dynamics of odor tracking are not as well characterized as they are in moths and other insects. Unlike insects, where tracking behavior can be induced by the controlled release of well-defined, species-specific pheromone blends, in most fish and bird species, potential odor cues tend to be poorly defined or characterized, and information about their distribution, production, and decay in the natural environment is typically lacking. This mini-review will compare and contrast the use of odors by fish and birds over a range of spatial scales, spanning from thousands of kilometers to less than a meter, to better define similarities in the use of scent and identify new questions that need to be addressed.

Olfactory-Mediated Behaviors in Fish

Fish use their sense of smell for behaviors that are performed over both large and small spatial scales, the dimensionality of which is relative to the species in question. For example, many species of salmon (*Oncorhynchus* spp.) use olfactory cues to home over hundreds of kilometers to a natal river (reviewed by Dittman and Quinn 1996), whereas black rockfish (*Sebastes inermis*) experimentally displaced as little as 4 km also require olfaction to return to their original,

familiar home range (Mitamura et al. 2005). How fish use olfactory information to locate a goal over such large distances is not yet well understood despite considerable research effort. By contrast, olfactory cues mediate other types of behaviors at much closer ranges. For example, single amino acids introduced into a flow tank almost instantaneously increase foraging-related activity (e.g., surfacing and jumping) in lake charr (*Salvelinus namaycush*; Hara 2006), whereas specific alarm pheromones elicit antipredator behaviors in fathead minnows (*Pimephalus promelas*) even in the absence of a visual cue (Hartman and Abrahams 2000). At close range, odors can also aid some species in identifying potential mates. For example, living in turbid environments where visibility is limited, Lake Malawi cichlids (*Pseudotropheus emmiltos*), depend on olfaction to identify conspecifics (Plenderleith et al. 2005).

Although considerable research effort has focused on investigating large-scale, olfactory-guided migrations, with particular attention paid to commercially important fish species, the most detailed investigations of olfactory tracking to date have been conducted in laboratory or flume settings. These studies have focused on behaviors that can be elicited by olfactory cues that operate at close range. The emphasis on flume studies is, in part, due to logistic considerations of tracking animals in the field, yet no fish species has been studied in as much detail as moths at any spatial scale (see Cardé and Willis 2008). A consideration of data across insect and fish species suggests that olfactory tracking is highly adapted to and constrained by characteristics of odor dispersal linked to flow (Belanger and Willis 1996; Vickers 2000). Not surprisingly, many fish species have well-developed peripheral olfactory systems (Caprio 1988), including elaborate sniffing apparatuses (Nevitt 1991), and olfactory detection thresholds can be quite low. For instance, sea lamprey (*Petromyzon marinus*) can detect larval bile acids at 10^{-10} M (Bjerselius et al. 2000), and sablefish (*Anoplopoma fimbria*) can detect dilute squid extract made up of free amino acid concentrations between 10^{-13} and 10^{-17} M (Davis et al. 2006). In the following sections, we review recent advances that have been made in our understanding of how fish use olfactory information under natural conditions over relatively large and small spatial scales.

Large Spatial Scales

Olfactory-guided behaviors that occur over large spatial scales (which we will define as on the order of tens to hundreds of kilometers for this discussion) have been studied primarily in the context of homing (Hasler et al. 1978; Dittman and Quinn 1996; Ueda et al. 1998; Døving and Stabell 2003; Mitamura et al. 2005; Nordeng and Bratland 2006; Keefer et al. 2006). In fisheries studies, homing typically refers to the directed movement of displaced fish back to an original location or home range. A number of these investigations have used tracking methods to study how fish move through the water as they home, and certain trends emerge. For example, when navigating over these large distances to locate a goal, various species have been shown to move vertically up and down in the water column (Fig. 1d; Døving et al. 1985; Døving and Stabell 2003). These behaviors have suggested to researchers that, in order to home, fish need to sample the water column for olfactory cues released from a particular habitat or odor source even when they are kilometers or even tens of kilometers from that source. Other studies have attempted to identify these 'habitat' cues and suggest that they are produced, in part, by conspecifics or by specific populations of fishes that reside within the given habitat. For example, sea lamprey (*Petromyzon marinus*) have been shown to home to specific rivers that carry scented compounds produced by larval sea lamprey (Bjerselius et al. 2000; Vrieze and Sorensen 2001; Sorensen et al. 2003).

Many fish species also navigate across the expanse of oceans, lakes, and rivers, at times without obvious visual reference points. The mechanisms by which fish determine direction in these often visually homogeneous environments are not yet well understood. While it commonly has been assumed that odors mediate rheotaxis, more integrative hypotheses have been proposed to explain how fish track odors up-current without a fixed point of reference. These questions have been studied in salmonids, freshwater eels, and sea lamprey, which we will review in more detail in the following sections.

Salmonids Salmon (e.g., *Salmo* spp., *Oncorhynchus* spp.) are anadromous fishes. They start and end their lives in freshwater but typically spend most of their sub-adult lives foraging at sea. During sensitive periods of development linked to surges in plasma thyroid hormone, juveniles imprint to the scent of their natal stream (e.g., Dittman et al. 1996; reviewed by Dittman and Quinn 1996; Lema and Nevitt 2004; Nevitt and Dittman 2004). After undergoing a physiological metamorphosis (parr–smolt transformation) that prepares them for life in seawater, juvenile fish outmigrate to the ocean. Toward the end of their life cycle, depending on the species, salmon navigate over hundreds of kilometers to return to spawn in their natal stream. It is not known how fish return to the appropriate river system; however, numerous studies have shown that olfaction is essential in the freshwater homing migration (Hasler et al. 1978; Dittman et al. 1996; Courtenay et al. 1997; Nordeng and Bratland 2006).

Westerberg (1982) and Døving's laboratory in Norway (Døving et al. 1985; Døving and Stabell 2003) have

provided some of the most intriguing results to date to suggest how salmon track odors at large spatial scales. In Norway, Atlantic salmon (*Salmo salar*) must navigate fjords before entering the river system on the homeward migration. The fjord portion of the migration, thus, provides an excellent opportunity to track salmon before they reach their home river, as fish can be followed more easily in the confines of fjords than in the open ocean. Moreover, in fjords, as in the ocean, there are micro-structured, horizontal layers in the water column, and these layers vary in temperature, thickness, and other parameters (Westerberg 1982). By using passive sonic tracking methods to follow individually tagged fish, Døving et al. (1985) have convincingly demonstrated that salmon oscillate vertically through these layers, which the authors speculate to have distinct origins (Westerberg 1982; Døving and Stabell 2003). According to this idea, as the fish moves up and down in the water column, it comes into contact with layers of water that originate from different sources.

Westerberg (1982) reasoned that these layers provide different chemical information to fish that is presented in conjunction with directional information via the thermal fluctuations that result from current shear. In support of this idea, Døving et al. (1985) found that unmanipulated (olfactory-intact) salmon limited their oscillatory swimming behavior to specific temperature layers of the water column, typically between the surface and 30 m in depth, whereas anosmic salmon did not restrict their swimming behavior and continued to oscillate between the surface and 80 m in depth. Furthermore, Døving and co-authors showed that olfactory-intact salmon made brief, vertical dives (Fig. 1d). They hypothesized that the purpose of these explorations was to sample the fine-structure of different water layers for both olfactory cues and directional cues provided by thermal shear or other input (i.e., infrasound; see Sand and Karlsen 2000).

In conjunction with these studies, Johnsen (1982) proposed a mechanism to explain how salmon locate their home streams within the river system. He suggested that familiar home-stream waters trigger positive rheotaxis and zigzag swimming behavior, whereas the absence of home-stream odor triggers either downstream drift or negative rheotaxis. In support of this hypothesis, Nordeng and Bratland (2006) found that juvenile salmonids displaced to neighboring river systems, which each emptied into the Salangen Fjord approximately 10 km apart, returned to their natal rivers with high precision. They reasoned that these fish homed by swimming up-current in response to odorants of their own population and down-current in the absence of population odors. Døving and Stabell (2003) have since postulated that salmon will exhibit positive or negative rheotaxis in response to a set of chemical signals, depending on the physiological state of the fish. According to this idea, fish use the same chemical cues for foraging as they do to find the direction of their natal river when in a migratory state.

Salmon homing can, thus, be explained as a two-step process. As salmon enter the fjords, they sample odors by swimming in a pattern of vertical oscillations through the water column. This behavior occurs in conjunction with a combination of positive and negative rheotaxis in response to specific odors. Olfactory-mediated rheotaxis then persists as individuals enter the river system and find their way home to spawn.

Freshwater Eels Freshwater eels (*Anguilla* spp.) have a catadromous life history in that they are spawned in saltwater, migrate as juveniles to freshwater, then out-migrate to spawn in the Sargasso Sea. Yellow-phase American eels (*Anguilla rostrata*) initially migrate into the river system. During most of this stage of their life history, they reside as brackish or freshwater bottom-dwellers, moving between estuaries and river systems where they stay until they sexually mature. Similar to salmon, American eels undergo a physiological metamorphosis before out-migration that prepares them for life in seawater. These silver-phase eels migrate from freshwater and estuary habitats back to the Sargasso Sea. Both yellow and silver-phase eels use selective tidal stream transport, or STST, to travel into and out of the estuary during the appropriate migratory phase of their life cycle (Barbin 1998; Barbin et al. 1998). By using STST, eels can travel horizontally over tens of kilometers (between 12 and 32 km in these studies) with energetic efficiency, so long as they are able to choose the appropriate tide. Barbin et al. (1998) found that this ability depended on the eel having an intact sense of smell, although other sensory modalities also contributed to this behavior. Similar to the situation in fjords, in estuaries, differences in temperature and salinity lead to layering of water masses with a defined density boundary, or pycnocline. The depth of the pycnocline varies depending on hydrographic conditions but, in this study, ranged from 0.7 to 10.7 meters, with the bottom depth ranging from approximately 5 to 18 m (Barbin 1998). Barbin (1998) showed that olfactory-intact yellow-phase eels ascended to the surface and descended to the pycnocline with equal frequency as they used STST; ascents and descents were defined as a change in depth of greater than 3 m (Barbin 1998). In contrast, anosmic eels moved sporadically throughout the water column, rarely reaching the depth of the pycnocline, and ascended to the surface more frequently than olfactory-intact eels.

The results of Barbin et al. (1998) showed that anosmic, silver-phase (out-migrating) eels were less able to use STST and failed to choose the correct tidal currents. Only two of the eight anosmic silver-phase eels migrated out of the estuary within 7 days of release, and the other six had not left after 9 days (Barbin et al. 1998). In contrast, olfactory-

intact silver-phase eels timed their vertical movements with the tidal cycle and were able to move out of the estuary (over 32 km) in 4 days, on average, which is only slightly longer than the time it takes for water to move through the estuary on ebb tides (three nights on average). Behavioral differences between anosmic and olfactory-intact eels were similar to what Døving et al. (1985) observed with Atlantic salmon in fjords.

Sea Lamprey Like salmon, sea lamprey (*Petromyzon marinus*) are anadromous fish that begin life in the river as suspension feeding larvae and then make their way to lakes and oceans as fish parasites. Years later, they use olfactory cues that guide them back to an appropriate river to spawn. In contrast to salmon, this river is not necessarily their natal river. Instead, adult sea lamprey use pheromones released by larval lamprey to find suitable spawning streams (Bjerselius et al. 2000; Sorensen et al. 2003). A major advance that facilitates working with this system is that the pheromone blends have been characterized (Vrieze and Sorenson 2001). Consequently, the dynamics of odor search can be explored with respect to a known cue that can be identified as present or absent in natural water systems.

With this goal in mind, Sorensen et al. (2003) have studied movement patterns of sea lamprey in the process of searching for appropriate spawning rivers. As part of this study, the researchers tracked both anosmic and sham-treated lamprey in the Great Lakes by using acoustic telemetry (see Vrieze and Sorensen 2001; Sorensen et al. 2003). Similar to what Døving et al. (1985) reported for salmon, they found that lamprey actively swam on constant bearings while vertically migrating or oscillating through the water column of the lake. Once a lamprey encountered a river plume, it would begin circling before swimming upstream into the river. Though movement patterns were not reported for anosmic lamprey, stream capture rates revealed that only 10% of anosmic lamprey located streams, whereas nearly half of the sham-treated lamprey succeeded (see Vrieze and Sorensen 2001). Laboratory trials that used two-choice mazes have also shown that lamprey prefer waters from rivers and streams where larval pheromones are present (see Bjerselius et al. 2000; Vrieze and Sorensen 2001; Sorensen et al. 2003). Taken together, results from both sea lamprey and eels provide more general support for Døving's and Westerberg's hypotheses originally proposed in salmon, suggesting that vertical oscillations aid fish in determining the direction of an odor source when navigating over distances of kilometers.

Small Spatial Scales

By far, the majority of investigations have been carried out at much smaller spatial scales (typically less than 10 m from the odor source). Most studies suggest that fish are capable of tracking odor plumes to the source within this more-limited range and that this behavior requires other sensory modalities, including the lateral line system. The use of olfaction in tandem with the lateral line system to direct movement up-current contrasts with insects that tend to use optical feedback to progress upwind to an odor source (Willis 2005). Our understanding of small-scale olfactory-mediated behavior comes from a combination of field manipulations and flume experiments, which we review below.

Field Experiments Relatively little work has been conducted under natural, field conditions. However, the research that has been done indicates that current olfactory information is needed for fish to locate odor sources. For example, Montgomery et al. (1999) examined olfactory search tracks in Antarctic fish (*Trematomus bernacchii*), which are adapted to forage in low light conditions under Antarctic ice sheets. Working in the field, they made video observations of benthic Antarctic fish tracking an experimental odor plume from 5 m to the source. The odor plume was created by passing a solution of minced fish through a hose. By using computer simulations, they determined what search strategies fish used to find the source of this odor plume. The matching of field observations to computer simulations suggested that fish could not locate the source unless a combination of chemosensory and current information was provided.

Elliott et al. (1995) conducted an elegant test of olfactory-guided host-selection in anemonefish (*Amphiprion* spp.). Anemonefish lay their eggs next to the trunk of their host anemone where the adults tend to them until they hatch into pelagic larvae. Most species of anemonefish are obligate symbionts to a species-specific host anemone. This means that the pelagic larvae must settle and re-locate a host anemone after their pelagic life-stage concludes. Elliott et al. (1995) found that when they released juvenile anemonefishes greater than 1 m down-current from a host anemone, they would swim in zigzag patterns or counterturns in the direction of the anemone, turning less frequently as they got closer. If the anemonefish were instead released within 1 m down-current of its anemone, it would swim in a straight path toward it. If an anemonefish were released either perpendicular or up-current with respect to the anemone, it frequently was unable to locate its host. Interestingly, in these situations, the fish swam either laterally or drifted until it was down-current of the anemone. It would then descend to the substrate and swim up-current until it reached its host. At distances of half a meter or more, anemonefish were not visually attracted to their host anemones and required down-current chemical cues to locate them. These experiments went on to illustrate how currents effectively increase the

range of detection by fishes. With no current, anemonefishes' ability to locate their host anemones was severely reduced. At current velocities greater than 2.5 cm s^{-1}, fish were attracted to host anemones from up to 8 m down-current. From these and other experiments, Elliott et al. (1995) suggested that anemonefish used "decision rules" to locate a host anemone (i.e., if downstream from a host, swim directly upstream staying within 1 to 5 cm from the substrate, or if the odor plume is lost, turn and swim laterally across and down-current in a zigzag fashion until the stimulus is encountered again).

Another elegant field system has been developed to study foraging behavior of cod (*Gadus morhua*). Løkkeborg and Fernö (1999) tagged cod with acoustic transmitters and tracked them while the fish searched for a baited line, again in the fjords of Norway. Their tracks ran for several hundred meters, with an average of 262 m between the baited line and tagged fish. Cod found the bait line through chemically mediated rheotaxis (Løkkeborg 1998). Cod increased their swimming speed when heading up-current, and these faster swimming fish also tended to succeed in locating the baited line. The faster the fish were swimming, the higher the probability that they would encounter the odor plume and head up-current to the source. As fish also found the bait much more quickly during the day, the authors concluded that visual cues were probably used in conjunction with olfaction and rheotaxis to mediate bait search.

Thus far, the picture presented from field studies is that fish use olfaction in combination with other cues, that include rheotactic and visual cues, to locate odor sources in close proximity. Next, we will review results from flume studies that have examined olfactory search mechanisms with greater precision.

Laboratory Flume Experiments Blind cave fish (*Astyanax fasciatus*) are an ideal system for studying problems related to multimodal search in the absence of vision. These fish evolved in dark environments where they have become adapted to forage by using information from water movements and chemical cues. Baker and Montgomery (1999) found that both odor and current stimuli are required for blind cave fish to locate an odor source (for similar results in nocturnal banded kokopu *Galaxias fasciatus*, see Baker et al. 2002). If an appropriate odor stimulus was presented, fish oriented or swam upstream when current velocities were as low as 0.4 cm s^{-1}. The rheotactic threshold increased to 3 cm s^{-1} if olfactory cues were absent. In no-current conditions, fish tended to position themselves randomly throughout the tank and showed little attraction to the odor source. Because they used an experimental tank with a water inflow that was physically separated from an odor injection site, they could also determine how current and odor worked together to trigger olfactory search. Interestingly, they found that, when an odor stimulus was paired with a unidirectional current, fish tended to cluster around the current inflow and not the odor injection site. This experiment showed that blind cave fish need a combination of olfactory and rheosensory input to locate an odor source.

Flume work with other species has provided evidence for horizontal casting behavior during olfactory search. For example, Carton and Montgomery (2003) looked at the behavioral reactions of freshwater eels (*Anguilla australis* and *Anguilla dieffenbachii*) in response to food odors in a semi-natural, turbulent flow raceway (5 m in length). They found evidence for both odor-mediated rheotaxis and cross-stream casting in response to experimental odor injections (Fig. 1b). At distances greater than 0.9 m from the odor source, eels swam up-current. Eels seemed to detect and track the edges of the odor plumes, as they initiated cross-stream, horizontal casting behaviors one second after moving beyond the lateral margins of the plume. These casting movements were slower than direct, up-current movements, and eels spent more time casting and searching closer to the odor source than farther away.

In summary, these flume experiments support field observations in suggesting that fish typically use a combination of olfaction and rheotaxis to locate the source of an odor plume. Although subtle differences appear in each of the studies described here, common themes are to use cross-stream casting behaviors to search for the odor source or to stay within the plume and to head up-current when the plume is detected. We now review how fish locate odor sources in no-flow and variable flow situations.

No-Flow or Variable-Flow Situations Although all of the studies we have discussed so far have concluded that currents are required for fishes to locate an odor source, species probably differ in their ability to locate odor sources depending on their specific adaptations. For example, working with brown bullhead catfish (*Ameiurus nebulosus*), Sherman and Moore (2001) showed that these fish were always successful in locating an odor source under no-flow conditions, whereas success rate diminished when current was present.

There also is evidence for area-restricted search (ARS) in response to odors in non-uniform flow situations. Bonnethead sharks (*Sphyrna tiburo*) showed behavioral responses to chemical stimuli in experimental circular tanks (1.8-m-diameter pools; Johnsen and Teeter 1985). When these fish were presented with blue crab homogenate in still water, they began turning in tight circles near the stimulus site, even in the absence of a distinct visual cue. Johnsen and Teeter (1985) speculated that this searching behavior functioned to keep the shark near its initial point of contact

with the stimulus. In contrast, when the same experiment was done with the addition of a current, sharks would reverse direction when they contacted the cue. Sharks would then swim in loops that extended progressively down-current, giving the impression that they were tracking the stimulus within the flow structure of the tank. How bonnethead sharks use odors to mediate ARS in natural situations requires further study.

Sniffing Fish are also able to sample odors through active sniffing—a behavior that resembles a cough in some species (Nevitt 1991). During a sniffing event, a spontaneous jaw protrusion increases water flow to accessory olfactory sacs. Nevitt (1991) recorded pressure fluctuations in the nasal sacs of flounders during spontaneous coughing and respiration. These experiments demonstrated that ventilation over the olfactory epithelium was mechanically linked to respiration. In controlled behavioral studies, coughing behavior was elicited as flounders sampled a defined odor plume within a flow tank. From these and other investigations, Nevitt concluded that coughing was analogous to "sniffing" in air-breathing organisms. Coughing in fishes has since been used as a measure of olfactory responsiveness in laboratory situations (e.g., Nevitt 1991; Murphy et al. 2001; Belanger et al. 2006). Ventilation rates in round gobies have been shown to correspond to voltage changes in electro-olfactograms recorded at the olfactory epithelium. Murphy et al. (2001) suggested that these changes were due to odor-induced ventilation. Further support for this connection between olfaction and ventilation rate was provided through olfactory deprivation studies in gobies (Belanger et al. 2006). They found that rendering fish anosmic, either through copper sulfate treatment or nasal occlusion with dental impression material, inhibited their reaction to pheromones as measured by gill ventilation rate. These results suggest that the increase in ventilation is another mechanism by which fish sample the aquatic environment for pertinent olfactory cues, especially in those species that are benthic or less active.

Olfactory-Mediated Behaviors in Birds

Questions related to the use of olfaction in birds have been hampered by the erroneous yet common assumption that most birds are anosmic. Consequently, compared to fish, little is known about how birds are able to track odors in natural situations (for review, see Roper 1999). Unlike insects that sense odors through olfactory receptor neurons housed on complex filamentous structures, the olfactory systems of birds are enclosed and, like fish, accessed typically through paired naral openings. In some groups such as the procellariiform seabirds, these naral openings are sometimes modified into a single, tube-like structure at the top of the bill. By contrast, in turkey vultures and ducks, naral openings laterally traverse the bill, thus allowing continuous airflow between them. From a comparative perspective, the sense of smell in birds continues to be relatively overlooked (for exceptions, see Bang 1960, 1971; Bang and Wenzel 1985; Wenzel 1987; reviewed by Roper 1999), but nearly every species that has been investigated behaviorally for olfactory abilities has been shown to have them, from highly specialized species such as ground dwelling Kiwis (Wenzel 1960) and Kokapo (Hagelin 2004) to even the most pedestrian—starlings, chickens, and ducks (reviewed by Roper 1999; Van Buskirk and Nevitt 2007). Birds may present the next advance in understanding how olfactory information is used across an enormous range of spatial scales. In this paper, we review three of the best-described systems: homing pigeons, procellariiforms, and turkey vultures.

Homing Pigeons

One of the most intensely studied problems in animal navigation is the homing ability of the domesticated rock pigeon (*Columba livia*), and nearly all olfactory work in birds has focused on this problem. Pigeons released hundreds of kilometers from their home loft will fly home in a goal-oriented way, even when released from completely unfamiliar territory (for reviews, see Papi 1990; Able 1991, 1995; Walcott 1996). This behavior requires multimodal integration of an array of environmental cues, conceptualized in the navigation literature as the 'compass' (an orientation mechanism) and 'map' (a spatial coordinate system) senses (Kramer 1952). With respect to the compass, it is now generally accepted that pigeons use redundant, more-or-less condition-dependent mechanisms for orientation. For example, displaced birds orient by using either a sun compass or earth-strength magnetic field depending on whether or not the sun is visible (for review, see Walcott 1996; Wiltschko and Wiltschko 1998). With respect to the map, the physical substrate continues to be hotly debated with researchers arguing for both magnetic and olfactory input (see Wallraff 2000; Wiltschko and Wiltschko 2000). This discussion focuses on the olfactory map, but we refer readers to numerous, more comprehensive treatments of the field (e.g., Able 1991, 1995; Roper 1999; Alerstam 2006; Papi 2006).

The idea behind the olfactory map is that pigeons learn to associate windborne olfactory information with compass direction before they leave the loft. Papi was the first to suggest that pigeons form what was later termed a 'mosaic' map of the olfactory environment that surrounds the loft, which is then extended during exploratory flights

(e.g., Papi et al. 1971; reviewed by Papi 1990). In an effort to explain the ability of pigeons to home from distant (greater than 100 km), unfamiliar sites, Wallraff further proposed that odors form large-scale, two-dimensional gradient maps (e.g., Wallraff 1989; reviewed by Wallraff 2004, 2005). According to this model, scented winds provide directional information that the bird learns before leaving the loft area. From this information, the bird can extrapolate relative positional information at an unfamiliar release site by comparing spatial variation in relative odor concentrations between the release site and the loft. In search of a physical substrate, the model assumes spatially explicit, monotonic gradients in odor profiles that run along a bi-coordinate axis surrounding the loft and extending to distant sites.

Elements of these two models are summarized as follows: (1) Pigeons are exposed to a radial spectrum of wind-borne odor blends at or in the vicinity of the loft; (2) they learn to associate the directions of the scented winds with general compass headings (either by using the sun compass or the magnetic compass); (3) upon release, pigeons sample the air and make a mental comparison of the ambient odor blend (or ratio, according to Wallraff) with the blend at the release site; and (4) they then use this information to set a course for home. According to Papi, this would be achieved by following a simple set of learned rules (i.e., in response to odor blend X at the release site, go in the opposite direction from which odor blend X was experienced at the loft). According to Wallraff, a pigeon would deduce a course home at the release site by comparing the ratio of odors at the release site with the memory of the ratio at the loft and extrapolating relative positional information to set a course for home.

In support of each of these theories, a variety of carefully conducted research documents that pigeons require an intact sense of smell to home and that homing does not involve simply tracking an odor or odor blend to its source (reviewed by Able 1995; Papi 1990; see also Gagliardo et al. 2001a). Similar to studies with salmon, rendering birds anosmic (either by olfactory nerve transection, chemical removal of cilia, or by application of a local anesthetic) interferes with homing (for example, see Bingman and Benvenuti 1996; Bingman et al. 1998). Homing ability is also impacted by changes in rearing environment in that pigeons must have access to windborne odors at or in the vicinity of the loft to later be able to home from unfamiliar areas (for example, see Gagliardo et al. 2001b). Among numerous studies, Papi has demonstrated that olfactory homing is seasonally and geographically variable, and limited to distances of 500 km in some locations, and that range can be extended if birds are allowed access to the odor environment during transport (reviewed by Papi 1990). As with salmon, a major stumbling block has been to identify and characterize the odor cues involved, which is, in the case of pigeons, the biogenic substrate for the putative map (for a more complete discussion on this topic, see Roper 1999).

To better define an odor map, Wallraff's model suggests a spatially explicit gridwork of odor gradients, which offers predictive value in estimating location relative to the loft. To pin this gridwork to a genuine, physical substrate, Wallraff and Andreae (2000) collected air samples over three consecutive years from 96 rural sites distributed within a 400-km-diameter circle around an experimental pigeon loft near Wurzburg, Germany. They then used gas-chromatography to measure a suite of largely anthropogenic hydrocarbons distributed over the landscape and analyzed their spatial distribution as a proxy for the spatial distribution of natural odor blends that pigeons might use to home. Their data show rising and falling profiles in the proportions of volatile hydrocarbons in the spatial domain that were fairly consistent from year to year and resilient to changing wind conditions (Fig. 2). They went on to document a systematic, directional relationship between wind direction at the loft and relative amounts of aromatics correlated to positional direction.

While this experiment was clearly monumental, potential limitations that the authors pointed out are that, with the exception of isoprene (Fig. 2), the study focused on aromatics that were not natural, biogenic compounds but rather long-lived, anthropogenic pollutants, and there was no demonstration that birds could smell these or other, more appropriate compounds at the concentrations measured. By necessity, air was collected along roads and much closer to

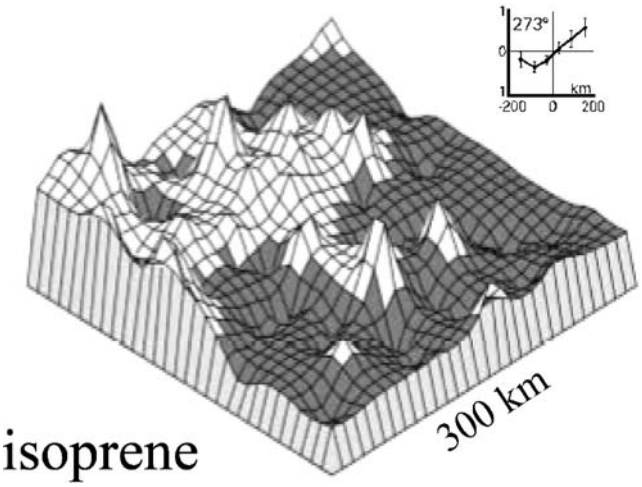

Fig. 2 Isoprene concentrations expressed as a proportion of six hydrocarbons (adapted from Wallraff and Andreae 2000). Data were collected from 96 rural locations in a 200-km radius around a pigeon loft in Wurzburg, Germany. Complete landscapes were computed by interpolation. Areas with above-average values have lighter shading, while areas with below-average values have darker shading (for further details, see Wallraff and Andreae 2000)

the substrate (4.5 m) than a pigeon normally flies. The physical association between point sources (potential emission sites such as roads, factories, or mining operations) and the ratios measured could not be considered in the analysis. Finally, samples were not taken synchronously, and sampling duration and volume (48 l of air over 2 h), as well as subsequent analysis, averaged out fine-scale structure (odor filaments), the unit the bird is likely to be sampling (Wallraff and Andreae 2000; reviewed by Wallraff 2005).

However, somewhat analogously to the work of Døving et al. (1985) with salmon, this approach is among the first to attempt a description of the spatial complexity in the odor landscape through which pigeons navigate. Further work is needed to determine flux rates of volatile substances produced by that landscape and to make clear-cut associations between what can be measured and what can be smelled. While the compounds analyzed were fairly stable, the properties of biogenic odorants are likely to vary with respect to lifetime and decay time. Thus, it will be critical to show that biogenic odor blends that are produced in a given area retain some spatial homogeneity and that pigeons can link that homogeneity to a compass direction back at the loft via experience with windborne delivery. In an alternative scenario, depending on the dynamics of fine-scale mixing and odor transport, a pigeon might get an occasional whiff of source concentration produced some distance away and still learn to associate those occurrences with compass direction. In this hypothetical example, intermittency of the pigeons' encounter rate with source concentration might also encode distance from the loft. The possibility that the fine-scale, filamentous nature of odor transport could add a different dimension to the problem ought to be considered.

The monotonic gradient model provides a starting point for humans who tend to lack an intuitive framework (and vocabulary) to describe and understand how olfactory features are related over large spatial scales on the order of hundreds of kilometers (we are reminded of the 'aroma of Tacoma', a paper mill city south of Seattle). However, this framework currently imposes unrealistic constraints on the spatial distribution of odors. Wallraff's relief maps showing standardized ratios of hydrocarbons reinforce this idea—they are as complex as mountain ranges, depending on which way an axis is drawn. However, this is not a shortcoming and only illustrates that the problem presents challenges comparable to those presented by other sensory features. For example, characteristics of visual landscapes that seem intuitively obvious to humans can be difficult to parameterize in the context of pigeon homing (e.g., Lau et al. 2006). Thus, a major strength of this study (Wallraff and Andreae 2000) is that it illustrates that identifiable, relatively stable features occur in the chemical realm, opening up new avenues for inquiry into an age-old problem.

Procellariiforms

Like pigeons, procellariiforms present an attractive model for investigating olfactory navigation over large distances. This Order, commonly referred to as the tube-nosed seabirds, is represented by the petrels, albatrosses, and shearwaters, which are in many ways like fishes of the air. These birds live highly pelagic lifestyles, coming to land only for a few months each year or every other year to breed and rear a single offspring (for comprehensive review of procellariiforms, see Warham 1990, 1996). These birds generally mate for life and routinely forage over hundreds and thousands of square kilometers of open ocean in search of patchily distributed prey. Not surprisingly, they have among the largest olfactory bulbs of any bird and, depending on the species, rely more or less upon their unusually highly developed sense of smell to find their prey. Procellariiforms use odors to forage over vast distances of open ocean, and much research has focused on understanding the mechanisms different species use to find prey (reviewed in Nevitt and Bonadonna 2005a). We have shown, for example, that procellariiforms can use olfactory cues at both large (hundreds to thousands of square kilometers in this case) and small (less than a hundred square kilometers) spatial scales for foraging. Our current understanding is that, at large spatial scales, birds use odors to identify productive areas for foraging, whereas at smaller spatial scales, they use odors in combination with other cues to track prey directly (reviewed by Nevitt 2000; Nevitt 2008).

Large Spatial Scales Results from extensive behavioral testing performed mostly at sea have led to classifications of olfactory responsiveness to prey-related odors among different species (reviewed by Nevitt 2008). These differences in behavior have provided us with a better understanding of the various ways different species use scent, both in terms of long-distance navigation and tracking prey. Toward this end, we have overcome a major stumbling block that confronts researchers working in the area of pigeon navigation by identifying a measurable, biogenic, scented compound that contributes to stable and predictable landscape features on the ocean surface. Dimethyl sulfide (DMS) is a breakdown product of dimethylsulfoniopropionate (DMSP), which is, in turn, a metabolite produced by various species of phytoplankton (most notably, *Phaeocystis* in the sub-Antarctic). Phytoplankton tend to aggregate where upwelling occurs, and, during senescence or consumption by phytoplankton grazers

(e.g., krill, fish, and squid), DMSP and DMS are released. DMS is not very soluble in seawater, and so it is quickly emitted into the atmosphere where it also can serve as a local, small-scale foraging cue for seabirds (Nevitt et al. 1995; see also Nevitt et al. 2004). Biogenic DMS has been shown to be a significant source of biogenic sulfur on a planetary scale and plays a key role in global climate regulation, so considerable research has been devoted to mapping regions noted for DMS production and flux (Kettle et al. 1999). The elucidation of such areas suggested to us that predictable odor features are superimposed upon the ocean, thus offering seabirds olfactory landmarks to identify useful foraging regions such as shelf breaks, sea mounts and upwelling zones (reviewed by Nevitt 1999; 2000). We coined the term "olfactory landscape" to describe this idea (Nevitt et al. 1995). We have since shown through physiological, behavioral, and observational tracking studies that procellariiforms respond to DMS at biogenic concentrations and will orient to it in non-foraging contexts (for example, Nevitt et al. 1995; Nevitt and Haberman 2003; Nevitt and Bonadonna 2005b).

With respect to olfactory navigation and foraging over large (hundreds and thousands of square kilometers) spatial scales, the current hypothesis driving our work is that birds build a map of their familiar surroundings through experience, first with odors in the nest, and then with odors associated with foraging experience at sea (Cunningham 2005). We have recently shown, for example, that Antarctic prion (*Pachyptila desolata*) chicks will orient to DMS and other prey-related odors at biogenic concentrations (10^{-12} M) even before fledging, and currently, we are testing the idea that this is a learned behavior through contact with parents in the nest (Bonadonna et al. 2006; Nevitt et al., unpublished). As chicks leave the nest to forage for the first time without parental assistance, we reason that knowledge of scents that are typically associated with prey prepares them to recognize productive foraging grounds (Cunningham 2005; Cunningham et al. 2006; Bonadonna et al. 2006). Once birds fledge, we hypothesize that they build up an association of potential foraging locations with scented compounds through experience, including interactions with con- and hetero-specifics (Silverman et al. 2004). Since birds routinely forage over expansive distances, this hypothesis suggests that, over time, the foraging landscape that may span thousands of square kilometers for some species becomes predictable through familiarity, despite it seeming so large from a human perspective. Because ocean features that are not strictly tied to the bathymetry (physical structure of the ocean floor) can be spatially more variable, we speculate that odor cues associated with productivity allow birds an effective means of recognizing ocean features that may vary spatially with season or weather conditions (for a more complete review, see Nevitt 2008).

Small Spatial Scales Many species of procellariiforms perform characteristic zigzag upwind search in response to odor cues. Researchers commonly have reported that procellariiforms are attracted to experimental deployments of prey-related scents from distances of several hundred meters to kilometers (for example, Grubb 1972; Hutchison and Wenzel 1980; Nevitt and Haberman 2003; Nevitt et al. 2008). Results from several studies suggest that olfactory tracking is more typical of burrow-nesting rather than surface-nesting species (Nevitt et al. 1995, 2004; Nevitt 1999) and that this behavior may be linked to differences in developmental environments in the nest (Van Buskirk and Nevitt 2008; reviewed by Nevitt 2008). However, surface-nesting procellariiforms also have large olfactory bulbs, and new evidence suggests that hunting by smell is a principal foraging strategy for at least one albatross species. This study involved examining the tracks of freely ranging wandering albatross (*Diomedea exulans*) for evidence of olfactory search (Nevitt et al. 2008). Tracks were analyzed from 19 birds equipped with miniature global positioning systems (GPS) and stomach temperature recorders (Weimerskrich et al. 2007). This combination of devices provided high-precision location data (GPS, 10-s sampling rate; Weimerskirch et al. 2002) in combination with data on the size and location of prey ingestion (Wilson et al. 1995).

On a typical foraging trip, wandering albatrosses fly in vast, looped paths, which often cover thousands of square kilometers of open ocean. Wandering albatrosses are known to forage primarily on squid, often in the form of carrion floating on the surface of the water (Croxall and Prince 1994). This suggested to us that scent might be an important cue for these birds to locate prey opportunistically. We predicted that if olfaction were used in prey capture, then wandering albatross should show a tendency to fly crosswind, since this would optimize the likelihood of encountering an odor plume and that we should see evidence for upwind, zigzag turning before prey capture (Dusenbery 1992). By contrast, if birds were using visual search, then we should see evidence of them bee-lining to prey items, irrespective of wind direction. To avoid bias, tracks were first analyzed blind with respect to wind direction in a radius of 10 km from the touchdown point. We calculated this distance to be beyond the visual range at which a bird was likely to be able to easily see a prey item or a conspecific on the water.

The analysis confirmed that wandering albatrosses tend to fly cross-wind, a behavior that had previously been shown and considered primarily as an adaptation for energetic efficiency (Weimerskirch et al. 2000; see discussion in Nevitt et al. 2008; Fig. 3). We found that initial

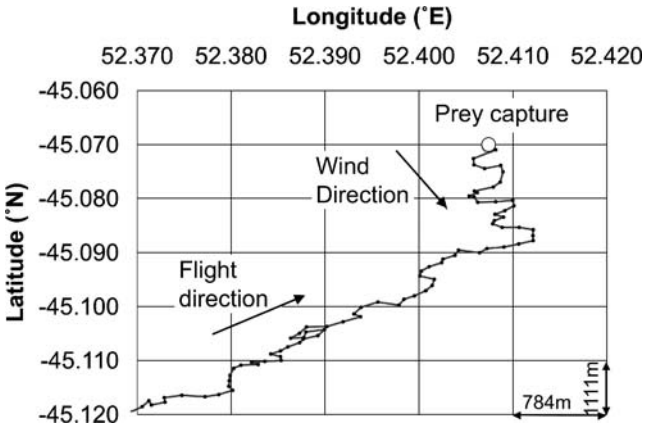

Fig. 3 GPS track of a wandering albatross equipped with a stomach temperature recorder to monitor feeding events. This track illustrates crosswind flight followed by zigzag upwind flight preceding a feeding event (*open circle*). *Arrows* refer to flight and wind direction as indicated. The horizontal and vertical distances represented by the *smallest grid rectangle* are shown in the *lower right corner*

olfactory detection was implicated in nearly half (46.8%) of all flown approaches that preceded prey capture events, thus accounting for 45.5% of the total prey mass captured by in-flight foraging. We further showed that zigzag approaches were initiated, on average, approximately 2.5 km (2,401±346 m) downwind of the prey capture site, with maximum detection distances observed at 5 km (5,002 m). This result suggested to us that, as a wandering albatross flies along a foraging transit, the area of ocean it surveys is extended, on average, approximately 2.5 km upwind via olfaction. However, when we examined tracks beyond the 10-km spatial limit of the original analysis, we occasionally observed upwind tracks that originated as far as 20 km from the point of prey capture, suggesting that prey detection may be possible from further distances. Finally, it should be noted that, while this discussion focuses on olfactory search in flight, wandering albatrosses also use sit-and-wait strategies to forage (e.g., Weimerskirch et al. 2007). Odors may be useful in this context for identifying productive areas where prey are likely to surface (see Nevitt 2000).

Apart from foraging, olfaction is used for a variety of other behaviors that operate at more localized (within 1 km) spatial scales. Within this range, several species of burrow-nesting petrels have been shown to require a sense of smell to relocate their nest, and individual-specific odors are likely to be involved in the context of nest-site recognition (reviewed by Nevitt and Bonadonna 2005b; see also Bonadonna and Nevitt 2004). When birds are displaced from their burrows at night, they typically sweep their heads from side to side in a manner consistent with olfactory search. This behavior can be elicited in chicks as well as in adults. For example, O'Dwyer et al. (2008) report that when Leach's storm petrel (*Oceanodroma leucorhoa*) chicks are presented with a choice between nest material from their own burrow and nest material from a neighboring burrow, they will sweep their heads in broad arcs around their body. This behavior is accompanied by rapid biting movements and coughing, with the bill placed close to the substrate (O'Dwyer et al. 2008; see also Cunningham et al. 2003). In simple wind tunnel experiments, we have shown in other species (thin-billed prions *Pachyptila belcheri* and blue petrels *Halobaena caerulea*) that chicks increase their turning rate in response to prey-related odors, suggesting that simple wind tunnels may provide a useful means for investigating olfactory tracking in more precocial species (e.g., Cunningham et al. 2006). We are clearly only scratching the surface of the questions that can be addressed in this fascinating order of birds.

Turkey Vultures

Turkey vultures (*Cathartes aura*) are one of the few terrestrial birds that are commonly accepted as having a remarkable sense of smell. Like procellariiforms, turkey vultures have among the largest olfactory bulbs of any bird (Bang 1960; Bang and Cobb 1968). These birds forage exclusively by scavenging for viscera and muscle tissues of dead animals, and humans have co-opted their abilities for practical purposes. In the late 1930s, for example, the Union Oil Company of California introduced ethyl mercaptan (CH_3CH_2SH), a sulfur-based compound associated with animal decay, into 40-mile gas lines so that they could use the presence of turkey vultures as an easy means to locate leaks in the lines in the remote backcountry (reviewed by Stager 1964). Similarly, black vulture (*Coragyps atratus*), a species noted for its visual rather than olfactory abilities, has been reported to use turkey vultures to find carcasses (Buckley 1997).

Although research exploring the use of olfaction by turkey vultures has been debated by scholars as notable as Audubon and Darwin, it was K. E. Stager who carried out the most comprehensive studies on this subject (Stager 1964). Working with vulture populations mainly in California and Mexico, he designed several different foraging challenges, which he carefully controlled for visual cues. These tests involved presenting birds with open containers of ethyl mercaptan or covered baits. He found that turkey vultures tended to be attracted to odor cues whether or not a visual stimulus was also present but not to visual cues (mounted specimens) in the absence of odor cues.

Pertinent to olfactory tracking, Stager (1964) also noted the flight patterns of turkey vultures in response to carcasses and ethyl mercaptan in the absence of visual cues. He reports that vultures approached odor sources from downwind and that they tended to circle the source at elevations estimated by eye to be within 100 m off the

ground. If a visual cue (in this case, an actual carcass) was also present, birds eventually tended to approach it and sometimes landed; in the absence of a visual cue, they typically circled for about 20 min and then left the area. To Stager, these observations suggested that turkey vultures located a potential prey item, first, by using olfaction, whereas visual cues allowed them to deduce its exact location.

In an effort to better understand the characteristics of the odor stimuli that are attractive to turkey vultures, other studies have suggested that the age of the carcass comes into play. Although humans often associate turkey vultures with rotting flesh, results from controlled studies suggests that they have a much more discriminating palate. For example, Owere and Northington (1961) showed that captive vultures consistently preferred freshly killed chicks over decaying food. In field studies, Houston (1986) confirmed that 1-day-old carcasses attracted more vultures than either fresh or 4-day-old carcasses, whereas putrid carcasses were ignored. Thus, for turkey vultures, olfaction may be important not only in locating potential prey but in assessing the age of the carcass.

Given the technical challenges involved, much less is known about the detailed behavioral mechanisms turkey vultures use to locate odor sources, in part because soaring altitudes typically exceed 50 m (see Estrella 1994). Unfortunately, one of the only published attempts to explain how they might accomplish this feat used a Gaussian plume model and concluded that turkey vultures should be unable to detect prey by smell above an altitude of 17 cm (Smith and Paselk 1986). The short-coming of this approach is that a Gaussian dispersion model estimates average concentration for a given distance (altitude in this case) and is thus not well suited to the biological problem. The actual situation is much more complex and requires different predictive tools (for example, large eddy simulation, or LES, Deardoff 1972). In the real atmosphere, odors from a carcass will be lifted as discrete patches that present pockets of high concentration that vultures should be able to detect. Moreover, turkey vultures typically soar on sequences of updrafts generated by thermals and ridges. Since these thermal updrafts also provide a means of vertical transport of odor patches, a more detailed examination of their use of thermals in relation to odor tracking coupled to a more rigorous treatment of atmospheric boundary layer modeling may be a starting point. We are currently exploring this problem.

Summary and Future Directions

Olfactory-mediated behaviors operate over a wide range of spatial dimensions for both fish and birds. By organizing our discussion into spatially explicit terms, specific themes emerge. In this paper, we summarize consistent findings among these seemingly disparate groups and suggest future directions to explore.

At large spatial scales, odor search reflects physical features of the fluid medium. As we have described, fish as diverse as salmon, eels, and lamprey all show patterns of vertical, oscillatory swimming as they travel through estuaries and fjords. In marine and brackish systems, water tends to be stratified by temperature or salinity gradients, and a number of studies suggest that fish actively sample different water masses as they swim through these layers. The situation is much less clear in birds, where researchers do not have as detailed an understanding of how odors might be distributed in the environment with respect to a physical substrate. Proposed mechanisms include the use of large-scale gradients for navigating distances of hundreds of kilometers. However, in some systems (procellariiforms), the physical evidence points to odors occurring as landscape features associated with sources of odor production. Following the example of Døving and others, future work with birds should be directed toward individual tracking with respect to such features.

Equally important to this problem will be developing more realistic models of atmospheric transport of odors at the spatial scales pertinent to olfactory sampling. Unlike fishes, the bird species that have been looked at do not generally fly in vertical oscillations (with the exception of the Kerguelen petrel *Lugensa brevirostris*), suggesting that birds do not need to sample air masses in the same way that fish are presumed to sample water layers (e.g., salmon and freshwater eels). This likely reflects the different stabilities of thermal or density layers in water as compared to air due to the greater degree of turbulent mixing in the atmospheric boundary layer. However, analogous to fish sampling water layers in fjords, birds that soar on thermal updrafts (e.g., vultures) may have the opportunity to sample thermals (i.e., vertical stratifications) for their odor content.

Another trend we see is that both fish and birds use olfaction in combination with other sensory cues, and attempts to study behaviors with respect to one cue in isolation are problematic. In fish, olfactory-mediated tracking has been shown convincingly to work in combination with both the lateral line and visual systems in a number of species (e.g., Baker and Montgomery 1999; Baker et al. 2002; Carton and Montgomery 2003), and recent evidence suggests involvement of the otolith system as well (Sand and Karlsen 2000; see Døving and Stabell 2003). In birds, olfaction may be used in combination with visual cues or geomagnetic information, depending on the species and the spatial scale of the behavior. The take-home message is that, in natural situations, olfaction works in combination with a range of other sensory modalities. An

understanding of how organisms interpret multimodal cues should take precedence over focusing on any one modality.

Finally, the distribution of natural cues and how these odorants disperse in turbulent environments remain largely unknown (see Zimmer-Faust et al. 1995; Moore and Crimaldi 2004), and yet the few systems where cues have been identified have led to significant advances in our understanding of how animals make sense of olfactory information in natural contexts (e.g., Nevitt et al. 1995; Carton and Montgomery 2003; Sorensen et al. 2003). Since the challenges will require understanding how cues are produced, released, and decay over time and space, progress will depend on researchers being able to think across disciplines and draw on expertise from various fields, including marine and atmospheric chemistry. Already, considerable information is available about the production and distribution of compounds not normally associated with olfaction. For example, DMSP, which is typically studied in the context of sulfur cycling in the ocean, recently has been identified as a potentially important foraging cue for fishes over coral reefs (DeBose and Nevitt 2007; DeBose et al. 2008). Gaining insight into how animals glean information from naturally occurring, biogenic odorants at appropriate biological concentrations remains a top priority for olfactory ecology.

Acknowledgment We thank Dr. J. Riffell and Dr. J. Hildebrand for inviting us to participate in this special issue. The manuscript was improved by the comments of Sandra Black, Ian Faloona, Sean Lema, Marcel Losekoot, Terrence O'Dwyer, and an anonymous review. Contribution number is 2413 to Bodega Marine Laboratory, University of California at Davis.

Odor Detection in Insects: Volatile Codes

M. de Bruyne · T. C. Baker

Received: 27 March 2008 / Revised: 23 April 2008 / Accepted: 28 April 2008 / Published online: 6 June 2008

Abstract Insect olfactory systems present models to study interactions between animal genomes and the environment. They have evolved for fast processing of specific odorant blends and for general chemical monitoring. Here, we review molecular and physiological mechanisms in the context of the ecology of chemical signals. Different classes of olfactory receptor neurons (ORNs) detect volatile chemicals with various degrees of specialization. Their sensitivities are determined by an insect-specific family of receptor genes along with other accessory proteins. Whereas moth pheromones are detected by highly specialized neurons, many insects share sensitivities to chemical signals from microbial processes and plant secondary metabolism. We promote a more integrated research approach that links molecular physiology of receptor neurons to the ecology of odorants.

Insect Olfaction: A Renewed Challenge

In their quest for locating important resources such as mates, nutrients, oviposition, and resting sites, insects rely on their chemical senses to a large extent. While gustatory neurons signal the quality of food or mates after contact, it is the information encoded by olfactory neurons that provides cues where to look in the first place. Equally important, and often overlooked, odors can indicate toxic or other life-threatening environments. Hence, olfactory receptor neurons (ORNs) play an important role in an insect's behavioral ecology.

The past 10 years has seen a tremendous increase in our understanding of insect olfaction. The discovery of odorant receptor (OR) genes in the vinegar fly *Drosophila melanogaster* (Clyne et al. 1999a; Vosshall et al. 1999) has affected profoundly the nature of our research and has made it an important model organism. However, the behavioral ecology of odor perception has been investigated largely in other species. In light of the recent sequencing of insect genomes, it is useful to review the wealth of information on insect olfactory ecology.

Insect species are numerous and can have very different life styles and feeding ecologies. They encounter a wide range of chemicals, as each species has its special interests. Though olfaction has been studied in many insect species, comprehensive data come mainly from a few groups. Cockroaches such as *Periplaneta americana* (Boeckh et al. 1987) are ground dwellers, predominantly feeding on decaying organic matter. Its sex pheromone is a unique sesquiterpene (periplanone B, Persoons et al. 1976). Several species of large moths (Hansson 1995) mainly from the Bombicoidea (*Bombyx mori*, *Manduca sexta*) and Noctuioidea (e.g., *Heliothis* spp.) traditionally have been investigated because of their powerful long-range sex pheromones. Many moths also deposit eggs on particular host plants with differing degrees of specialization. The vinegar fly, *D. melanogaster* (Vosshall and Stocker 2007), feeds and oviposits on a variety of decaying fruits. It does not have a close relation with a particular host-plant. The

honeybee *Apis mellifera* (Galizia and Menzel 2000) is a social insect with an intricate pheromonal communication system. Asexual females collect pollen and nectar from flowers, and they have the ability to discriminate many odorants. Mosquitoes (Takken and Knols 1999) such as *Anopheles gambiae* and *Aedes aegypti* feed on various nectar sources, but females need a blood-meal to mature their eggs. *A. aegypti* is more a generalist feeder, while *A. gambiae* prefers to bite humans.

To respond to the environment with appropriate behaviors, insect peripheral olfactory systems need to do two things: (1) Provide fast and reliable information about specific cues that induce innate behaviors, and (2) Sample salient features of the broad chemical landscape that can be learned and guide adaptive behaviors. What are the features of insect olfactory receptors that do this, and how does our newfound knowledge of molecular and neural mechanisms contribute to our understanding of the ecology of volatile signals?

Insect Noses: Organization of the Peripheral Olfactory System

Although it is the brain that transforms a set of chemical stimuli comprised of individual odorants (chemicals) into distinct odors (sensations) and associates them with a behavioral response, the ORNs are the sensors that limit what can be detected. The scope and accuracy with which odors can be identified is determined by how many different sensors there are and how they are tuned to different chemicals. Insect ORNs are bipolar neurons that develop from epithelial cells (Keil 1997). In early development, a pre-sensillum cluster of cells is formed (Ray and Rodrigues 1995; Endo et al. 2007). Some of these will move basally and become neurons, but three remain apical and form the accessory cells that will wrap themselves around the neurons. While it is the neurons that process odor information, accessory cells provide the extracellular milieu that supports their function (Park et al. 2002). These cells form sensilla, small cuticular structures where the neuronal dendrites are bathed in a lumen filled with mucus-like sensillum lymph (Zacharuk 1985). Pores in the cuticle allow odorants to pass and dissolve in the lymph (Steinbrecht 1997).

The majority of olfactory sensilla can be found on the antennae, but smaller sets are also located on other head appendages such as maxillary (de Bruyne et al. 1999) or labial palps (Stange 1992; Kwon et al. 2006). Irrespective of their location, all ORNs project to the antennal lobe of the brain. Olfactory sensilla fall into two ultrastructural categories, double walled (dw) and single walled (sw; Altner and Prillinger 1980). While the former are usually small and uniformly peg shaped, the latter can take on many different shapes (Zacharuk 1985; Steinbrecht 1997). In moths, sw sensilla can be up to 100 μm long thick-walled pointed hairs (trichoid sensilla), but in most insects (e.g., *Drosophila*), they are much smaller. Trichoid sensilla typically house neurons with unbranched dendrites (Zacharuk 1985; Shanbhag et al. 2000). Hymenoptera (e.g., honeybees) and certain Coleoptera have pored plates (placoid sensilla), some with large numbers of branched dendrites (Behrend 1971; Esslen and Kaissling 1976; Nikonov and Leal 2002). Most insects have thin-walled short (5–30 μm) blunt hairs (basiconic sensilla, Shanbhag et al. 2000). It remains unclear why insect ORNs are housed in sensilla of different shapes and sizes or how sensillum structure affects olfactory function.

In *Drosophila*, genetic experiments have shown that dw and sw sensilla develop differently, using different neurogenic genes (Gupta and Rodrigues 1997; Goulding et al. 2000). The *atonal* gene determines dw sensilla, while the *amos* gene regulates sw sensilla. The different structural subcategories of sw sensilla are regulated by patterning genes such as *lozenge* (Gupta and Rodrigues 1998; Goulding et al. 2000). In insect sensilla, usually two to four ORNs with distinct neuronal identities are combined within a single sensillum type. (Boeck et al. 1987; de Bruyne et al. 1999, 2001). The *notch* gene is involved in determining the fate of neurons within a single sensillum by being expressed in only one of them, creating *notch*-on and *notch*-off neurons (Endo et al. 2007). Neuronal identity is further determined by the *acj6* gene (Clyne et al. 1999b).

The spatial organization of ORNs in the antennal epithelium is lost upon entry of their axons into the brain. It is tempting to think of the antennal lobe as a map of olfactory information. Are ORN axon projections sorted to glomeruli according to some sort of chemical logic (a chemotopic map), transforming the intermingled distribution of ORNs in the epithelium into a functional spatial arrangement in the brain? In mosquitoes and flies, there is evidence that the antennal lobe is organized in zones for the different structural categories of sensilla and the different appendages (Anton and Rospars 2004; Couto et al. 2005; Endo et al. 2007). Within these zones, ORNs that co-inhabit a single sensillum tend to be separated based on *notch* expression with *notch*-on glomeruli clustered together on one side and *notch*-off on the other (Endo et al. 2007). It remains to be seen if the main organizing principle of the axonal projections is based on odor chemistry or the neuron's place in structures of the periphery. However, *Drosophila* ORNs that have their odor responsiveness removed by a mutation show normal projection patterns (Dobritsa et al. 2003). Hence, neural identity i.e., an ORN's place in the system, is determined independent from (and probably before) its chemical response profile. This means

that evolution of gene regulation through transcription factors can potentially reorganize odor sensitivities in the periphery, thus causing evolutionary shifts in behavioral responses.

Molecular Codes: Olfactory Genes in Neurons

In vertebrate ORNs, odor receptor (OR) genes (Buck and Axel 1991) with seven prominent transmembrane domains have been shown to be G-protein coupled receptors that mediate odor sensitivity (Firestein 2001). A large family of genes with expression in ORNs has been discovered in *Drosophila* (Clyne et al. 1999a; Vosshall et al. 1999). Although hydropathy analysis of these insect OR proteins strongly suggests they have seven transmembrane domains, they are very different from the vertebrate ORs, and indeed from any other G-protein coupled receptors. Insect ORs lack many of the characteristics of other G-protein coupled receptors (Wistrand et al. 2006), and recent evidence suggests they may insert the other way around in the membrane (Benton et al. 2006). There is also no direct evidence that they activate a G-protein-mediated transduction cascade as vertebrate ORs clearly do. Furthermore, insect ORs require the co-expression of *Or83b*, a special member of this family that is needed for correct OR transport and function in vivo (Larsson et al. 2004). The Or83b gene is the only member of this family that is highly conserved in several insect species (Krieger et al. 2003; Jones et al. 2005), indicative of its fundamental role across insects. The most recent evidence suggests that insect ORs form ligand-gated channels (Sato et al. 2008; Wicher et al. 2008), that bypass a G-protein-coupled signal transduction cascade. This would enable rapid odor processing and corroborate earlier physiological investigations (Kaissling 1987; de Bruyne et al. 1999) that highlight the fast responses of insect ORNs.

It is clear that this insect-specific family determines the response properties of most insect ORNs. OR proteins are localized to ORN dendrites (Elmore and Smith 2001). Expression of an OR transgene in *Drosophila* ORNs (Störtkuhl and Kettler 2001) or in an in vitro cell system (Wetzel et al. 2001) induces odor responses and mutations that remove OR gene expression from ORNs cause loss of odor activity (Clyne et al. 1999b; Dobritsa et al. 2003). Dobritsa et al. (2003) also demonstrated that a single OR mediates activity for the full range of odorants that excite an ORN by expressing a *Drosophila* OR transgene in a neuron from which the indigenous gene has been removed. Hallem and Carlson (2006) have shown that this applies to most *Drosophila* ORs. Interestingly, these experiments also showed that OR genes normally expressed in sensilla with a grooved peg (dw) or trichoid (sw) structure are also functional in a basiconic (sw) sensillum. Receptor-swapping is also possible among different insect species. A mosquito receptor for 2-methylphenol and a moth sex pheromone receptor detect their ligands when expressed in a *Drosophila* ORN (Hallem et al. 2004; Syed et al. 2006).

OR genes form one of the largest gene families in insects, and because they guide behavioral interactions of insects with other organisms, the analysis of their molecular evolution is of considerable interest. OR sequences show low conservation except for relatively conserved intron/exon boundaries, which suggest they arose from a common ancestor (Robertson et al. 2003). Complete sets of OR genes have been sequenced from the genomes of *Drosophila* (Robertson et al. 2003, Guo and Kim 2007), the honeybee (*A. mellifera*, Robertson and Wanner 2006), and two mosquitoes (*A. gambiae* Hill et al. 2002, and *A. aegypti*, Bohbot et al. 2007) ,and their numbers are featured in Table 1. Some OR genes have also been sequenced from the moths *B. mori* (Sakurai et al. 2004, Wanner et al. 2007) and *Heliothis virescens* (Krieger et al. 2002, 2004). If we exclude the *Or83b* gene and its homologues, *D. mela-*

Table 1 Estimates of olfactory coding units in different insects

Insect species	Order	ORs[a]	ORNs[b]	Glomeruli[c]
Drosophila melanogaster	Diptera	61	44	50±2
Anopheles gambiae	Diptera	78	>27	60±2
Aedes aegypti	Diptera	100	>10	50±2
Bombyx mori	Lepidoptera	>48	>5	60±2
Heliothis virescens	Lepidoptera	>20	>20	64±2
Apis mellifera	Hymenoptera	162	n.a.	165±2
Periplaneta americana	Blattaria	n.a.	>25	125±2

[a] Predicted from the genome, excluding pseudogenes, incomplete sequences and Or83b orthologs, including multiple splice forms
[b] Identified electrophysiologically or by gene expression (in situ)
[c] Variability is due to sexual dimorphisms and/or individual variability

nogaster has 59 OR genes that encode 61 proteins (Robertson et al. 2003). The *A. gambiae* genome reveals 78 OR genes (Hill et al. 2002), while *A. aegypti* has at least 100 (Bohbot et al. 2007). The honeybee genome has 162 of them (Robertson and Wanner 2006). This tells us that the full complement of coding units in most insect systems is likely to be ca. 10× lower than that found in most mammals. This may reflect selection pressure trade-offs between detection sensitivity and discrimination ability.

The comparison of OR genes within a species (paralogs) or between species (orthologs) shows that the OR gene family has undergone rapid evolution. Some OR genes in *Drosophila* occur in small clusters of two to three genes, and many of these clusters suggest recent gene duplications (Robertson et al. 2003; Guo and Kim 2007; Nozawa and Nei 2007). Interestingly, in the honeybee, most genes occur in large arrays with one of them encompassing 60 genes, indicating recent rapid expansion of a few subfamilies that may be bee-specific (Robertson and Wanner 2006). Comparisons between the two mosquitoes, *A. aegypti* and *A. gambiae*, separated by ca. 150 m years of evolution, confirms this species-specific expansion of subgroups but also shows orthologous subgroups that are relatively conserved (Bohbot et al. 2007). It is likely that rapid evolution of OR sequences is driven by changes in chemical ecology of these species even if the exact relation between OR sequence and ligand binding remains obscure. These comparative analyses also demonstrate the need to study the variety in insect olfactory systems.

While OR sequences are highly varied, comparative analysis of closely related *Drosophila* species shows that structural integrity of OR proteins is evolutionarily preserved (Tunstall et al. 2007). However, positive selection appears to be acting on some of these genes, at specific sites and along certain lineages. In 12 more distantly related *Drosophila* species, gene numbers are conserved (Guo and Kim 2007; Nozawa and Nei 2007). Although sequences are variable, each gene still has a clear ortholog, which suggests that over a comparable evolutionary period, insect ORs may evolve more slowly than vertebrate ones. An electrophysiological comparison of nine closely related *Drosophila* species also suggests that ORN response properties are relatively conserved (Stensmyr et al. 2003). Out of eight classes studied, only one showed changes in three species. Dekker et al. (2006) show for one of these species, *Drosophila sechellia*, that these shifts are correlated with changes in behavior. *D. sechellia*, which unlike *D. melanogaster* specializes on one particular fruit, appears to have lost OR genes and to have fixed point-mutations in the remaining genes at a higher rate than *Drosophila simulans*, which has a feeding ecology similar to *D. melanogaster* (McBride 2007). Like the higher number of OR genes in *A. aegypti* compared to *A. gambiae*, this indicates that niche specialization may lead to a loss of ORN classes. Stensmyr et al. (2003) also noted a loss of one sensillum type in *D. sechellia.*

While the loss of a sensillum type is most likely due to changes in developmental genes, changes in the regulation of OR expression can potentially reshuffle the array. Specific regulatory elements were discovered upstream of OR genes that determine whether an OR is expressed in the antenna or palp and in which neuron class (Ray et al. 2007). While most ORNs express a single OR gene, there are several cases of two or three genes per cell. In some of these cases, the two genes arise from a recent duplication, and one of them is not functional (Dobritsa et al. 2003), but in another case, both genes contribute to the response spectrum of the ORN (Goldman et al. 2005). Ray et al. (2007) showed these genes share common neuron-specific regulatory elements.

Modifying the Code: Olfactory Genes in Accessory Cells

The sensillum lymph forms the watery transition medium between volatiles and ORN dendrites, and is a mucus-like liquid packed with proteins secreted by the accessory cells. Before OR genes were identified, a group of proteins was isolated from moth olfactory sensillum lymph and dubbed pheromone-binding proteins (PBP, Vogt and Riddiford 1981) or odorant-binding proteins (OBP, Vogt et al. 1991). In moths, PBPs form a distinct subfamily of OBPs associated with the different pheromone-sensitive sensilla. In general, these proteins are differentially expressed in the different olfactory sensillum types (Vogt et al. 1991). Unlike the membrane-bound ORs, they are small, secreted hydrophilic proteins that can be extremely abundant in the lymph (Pelosi et al. 2006). Vertebrate OBPs belong to the larger family of lipocalins, but insect OBPs again define an insect-specific family of proteins. There are 51 OBP-like sequences in the *Drosophila* genome (Galindo and Smith 2001). OBPs are characterized by six cystein residues that are thought to form three disulfide bonds and a hydrophobic pocket inside (Sandler et al. 2000). A second family dubbed chemosensory proteins (CSPs) contains somewhat smaller proteins that have four disulfide bonds (Angeli et al. 1999). Neither OBPs nor CSPs are olfactory-specific genes. Many OBPs are expressed in gustatory sensilla, and several OBPs and particularly CSPs occur elsewhere in the body (Galindo and Smith 2001; Shanbhag et al. 2001; Pelosi et al. 2006).

It is thought that PBPs help solubilize hydrophobic moth pheromone molecules in the sensillum lymph, and specific binding of moth pheromone components has been demon-

strated (Du and Prestwich 1995; Leal et al. 2005). However, the presence of a specific OBP is not necessary for odor response per se. *Drosophila*, *Bombyx*, and *Anopheles* OR genes are functional in a *Drosophila* ORN where they are in an environment that does not have the OBPs that normally surround them (Hallem and Carlson 2006; Syed et al. 2006). In addition, specific responses to pheromones and other odors can be obtained in vitro from OR genes expressed in cultures of transfected cells (Wetzel et al. 2001; Nakagawa et al. 2005; Grosse-Wilde et al. 2006; Kiely et al. 2007). In vitro experiments with OR-expressing cells indicate that PBPs solubilize pheromones and can improve specificity of the receptor (Grosse-Wilde et al. 2006).

There are 51 OBP-like sequences in the *Drosophila* genome, none of which are closely related to moth PBPs. However, one of them, *obp76a*, plays a crucial role in the perception of cis-vaccenyl acetate (Z11-18:Ac), a compound quite similar in structure to moth pheromone components. The *lush* mutation removes all *obp76a* from a subset of trichoid sensilla, and its ORNs become insensitive, a defect that can be rescued by adding recombinant OBP76a protein to the preparation (Xu et al. 2005). In *Drosophila*, this compound is thought to be an aggregation pheromone produced by males, passed on to females and then to the oviposition substrate (Bartelt et al. 1985).

OBP sequence similarities across insect species are low (Vogt 2005), with only some subfamilies present across insect orders, and most with radiations within a single insect order or family. For example, the PBPs appear to have adapted specifically to a role in lepidopteran pheromone communication (Vogt 2005). This suggests that, like ORs, OBPs are under strong adaptive selection. Another line of evidence highlights this potentially important role of OBPs in insect chemical ecology, but also demonstrates their function outside the olfactory system. The feeding preference of *D. sechellia* for the toxic noni fruit (*Morinda citrifolia*) is linked to the expression pattern of *Obp57d/e* in taste sensilla on the tarsi (Matsuo et al. 2007).

Finally, in addition to OBPs, accessory cells also secrete a variety of enzymes that are likely to play a role in removing active odorants from the dendritic membranes (Vogt and Riddiford 1981; Maïbèche-Coisne et al. 2004; Ishida and Leal 2005). It is still unclear which role all these specific proteins in the sensillar lymph play in modifying ORN responses. Most likely, their roles are varied. While some PBPs appear to enhance only ORN functions, obp76a (*lush*) appears crucial. Expression of OBPs also can bridge ORN classes. *Drosophila* obp76a is also expressed in another class of sensilla that do not contain Z11-18Ac-sensitive neurons where the *lush* mutation has a much less dramatic effect (Shanbhag et al. 2001; Xu et al. 2005).

Odor Responses across ORN Populations: A Broad Olfactory Net

How many different coding units does an insect need to encode relevant odors in its environment? The number of different OR genes is a reasonable estimate, but there is no strict one-to-one OR/ORN ratio. Some ORNs express two or three genes (Couto et al. 2005; Ray et al. 2007). Some ORNs do not express any of the known OR genes. The identification of all ORN classes physiologically is informative but is tedious (Table 1). Only in *Drosophila* are we close to achieving characterization of all ORN classes (de Bruyne et al. 1999, 2001; Yao et al. 2005; van der Goes van Naters and Carlson 2007), and Table 2 shows an overview of the response properties of most of its ORNs. The number of glomeruli in the antennal lobe can be indicative because, with few exceptions, ORNs of a single class converge on a single glomerulus (Hansson and Christensen 1999; Vosshal et al. 1999). Unfortunately, glomerulus borders are difficult to visualize in some insect species, and numbers can vary slightly among individuals. Nevertheless, the estimates for all three parameters in Table 1 show that for these model species, 50–60 units appears sufficient. The ca. 160 units for honeybees (genes and glomeruli) possibly indicate the high end.

Odor stimuli contain three elements of information: odor identity, odor intensity, and a temporal component, i.e., how these two vary in time. If an odor is a mixture, its identity can change if the composition changes. Studies in which a large number of odorants are tested on many ORNs invariably show that they can be classified into response types. Most ORN classes respond to a small subset of odorants, and several odorants evoke responses from a few classes. The identity of many odors is, thus, encoded in the activity of different sets of ORN classes (Hildebrand and Shepherd 1997). However, this is dose-dependent. For instance, at relatively high doses, ethyl acetate excites three ORN classes in *Drosophila* (pb1A, ab1A, and ab2A in Table 2), but at different levels (de Bruyne et al. 1999, 2001). At lower doses, only ab1A will respond because the other two are less sensitive to this odorant but better tuned to related esters. Odor concentration in a single ORN class is usually encoded over a short range of concentrations. Dose–response curves typically show a sigmoid shape with the dynamic part covering two to three log steps (de Bruyne et al., 1999, 2001). Table 2 also outlines that each ORN class is tuned to a different odorant. What the table does not show is that there are some odorants that are promiscuous, exciting many ORNs, while others appear to be encoded by the activity of a single ORN class.

It is important to realize that the olfactory system's main function is to capture changes in an insect's odor environment and guide it toward resources or away from
