
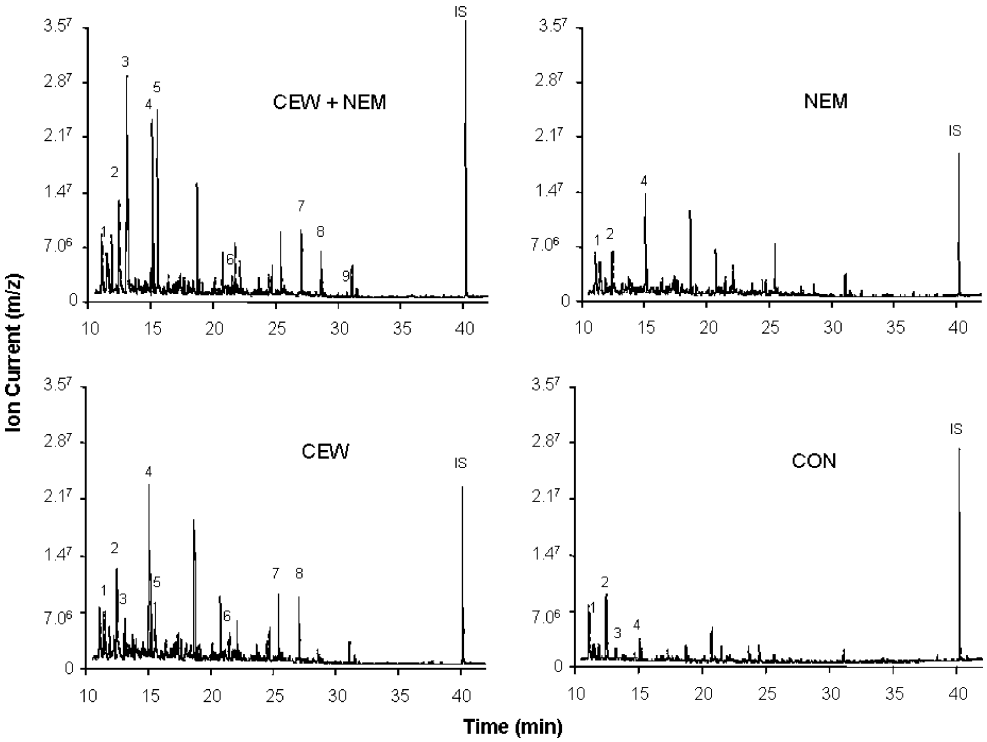

Fig. 3 Total ion current chromatograms of induced volatiles from the upper 30 cm of a cotton (*Gossypium hirsutum*) plant damaged by corn earworm (*Heliocoverpa zea*=CEW), root-knot nematode (*Meloidogyne incognita*=NEM), their combination (= CEW + NEM) and from control (undamaged = CON) plants collected from 12 p.m. to 3 p.m. Compounds: 1) (*Z*)-3-hexenyl acetate 2) ocimene 1, 3) ocimene 2, 4) linalool, 5) (*E*)-4, 8-dimethyl-1,2,7-nonatriene, 6) indole 7) (*β*)-farnesene, 8) (*α*)-farnesene, and 9) (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene. Added internal standard was (IS) methyl palmitate. All unnumbered peaks represent unidentified compounds. *N*=4 plants per treatment

by the foliage feeder, *Spodoptera exigua* (Hübner), as well as in mature and immature leaves in response to the root feeder, *Agriotes lineatus* (L.). In contrast, we found no effect of foliage or root herbivory on induction of hemigossypolone and the heliocides 1–4 in the immature and mature leaves of cotton. Several studies have shown induction of these compounds in the immature leaves of cotton in response to foliage herbivory (McAuslane et al. 1997; McAuslane and Alborn 1998; Bezemer et al. 2004). In these studies, the cotton plants had been damaged by *Spodoptera* spp. for 48 hr, but terpenoid analyses were conducted 1–5 wk later. It is possible that the cotton plants in our study did not have sufficient time (analyses done after 72 hr) to induce the terpenoid aldehydes in the leaves and roots of leaf-damaged plants. There also may be differences in the expression of terpenoids among cotton varieties; one of the above studies did not report the cotton variety used, and the others used varieties different from the one we used. Alternatively, it is possible that damage by corn earworms, a predominately fruit-feeding species, does not have the same effect on levels of gossypol and gossypol-like compounds as feeding by *Spodoptera* spp., which are predominately leaf feeders. The lack of induction of these compounds in response to the nematodes is unlikely to be explained by insufficient induction time or limited infestation, as the plant roots had been exposed to the nematodes for 5 wk, and the level of nematode infestation was high.

Several studies have shown that concentrations of gossypol and gossypol-like compounds in the roots of cotton are enhanced following belowground feeding by root knot nematodes and wireworms, or infection by bacterial or fungal diseases (Mace et al. 1990; Khoshkoo et al. 1993; Zhang et al. 1993; Howell et al. 2000; Bezemer et al. 2003, 2004). Increased gossypol levels were detected in the roots of cotton following *M. incognita* damage that used supple-

Table 2 Mean ± SEM ion current (m/z^+) from volatile terpenes (ocimene 1, ocimene 2, linalool, (*E*)-4,8-dimethyl-1,3,7-nonatriene, (*β*)-farnesene, (*α*)-farnesene, and (*E,E*)-4,8,12-trimethyl-1,3,7,11-tridecatetraene), (*Z*)-3-hexenyl acetate, and indole collected from cotton plants damaged by corn earworms (CEW), nematodes (NEM), corn earworms and nematodes (CEW + NEM), and undamaged control plants (CON)

mental applications of bioregulators (Khoshkoo et al. 1993). In the absence of additional bioregulator applications in our study, cotton plants failed to respond to root-knot nematode damage.

Cotton plants damaged at their roots by *M. incognita*, but not at the foliage aboveground, do not emit systemically induced volatiles that are attractive to *M. croceipes*. Plant responses to root-feeding nematodes are more variable and may depend on the type of root-feeding behavior (Matteille 1994; van Dam et al. 2005). As far as we are aware, there are no studies that have looked at comparisons of aboveground plant responses between sedentary gall-forming, migratory nematodes species, and other root herbivores.

Agronomic factors such as plant nutrient availability may also have an effect on both direct and indirect plant resistance mechanisms in cotton plants. Cotton plants with zero or 2 g N applied do not attract the parasitoid species *M. croceipes* as well as those plants with 1 g N, the latter representing the recommended amount of nitrogen (Olson et al., unpublished data). Although *M. incognita* root damage is known to increase nitrogen in the roots of some plants (Hunter 1958; Shafiee and Jenkins 1963; Burgeson 1966), presumably at a cost to the nitrogen levels in shoots, our nitrogen analyses of leaves and petioles indicated that nitrogen in shoots was not affected. Therefore, it is unlikely that the nitrogen was a factor affecting shoot volatile levels.

Microplitis croceipes clearly preferred corn earworm damaged plants over those plants that were undamaged or had been damaged by *M. incognita* alone. They also had a tendency to prefer plants damaged by CEW plus nematodes over those that had been damaged only by CEW. The volatile analyses indicate that *H. zea* feeding on cotton leaf tissue induces release of compounds known to be attractants for parasitoid species, and that adding nematodes to these plants increases the level of these emissions. This suggests that cotton fields that harbor both types of herbivores would not have a detrimental effect on host foraging by this parasitoid species.

Often, loss of either above- or belowground tissue alters the commitment of the plant to the other. Loss of leaf material from herbivores aboveground results in reduced root mass, while root grazing by a variety of nematodes and insect larvae leads to lower leaf mass aboveground (Geiger and Servaites 1991; Mooney et al. 1991). In addition to the quantitative impact on plant biomass, herbivory in one plant compartment usually changes overall plant quality in terms of primary and secondary metabolites, thus affecting herbivore load in the other plant compartment (Seastedt 1985; Seastedt et al. 1988). The magnitude of the response between roots and shoots depends on the plant species, the compounds produced, and the inducing agent (van Dam et al. 2005). The results from this study are unusual as they show no evidence of an interaction between a plant's direct defenses induced by a fruit-feeding aboveground species and a sedentary, gall-forming belowground species. More studies are needed to determine if these results can be generalized for these types of feeding paradigms.

impact of plant sectoriality on induced metabolic responses to herbivory has only recently been described (Jones et al. 1993; Mutikainen et al. 1996; Orians et al. 2000; Schittko and Baldwin 2003; Viswanathan and Thaler 2004). In these cases, leaves that share the strongest vascular connections (i.e., orthostichous pairs) also tend to transmit the strongest induced responses (Orians 2005; but see Frost et al. 2007 for within-plant volatile signaling).

The consequences of plant vascular architecture for induction have, thus far, only been emphasized in responses that are both elicited and expressed in foliar tissues. In fact, recent studies demonstrate that induced responses span the aboveground and belowground systems (van Dam et al. 2003; Bezemer and van Dam 2005, 2006; Kaplan and Denno 2007). Thus, root herbivory can induce changes in leaf secondary chemistry (Bezemer et al. 2004; Soler et al. 2005; van Dam et al. 2005; van Dam and Raaijmakers 2006; Kaplan et al. 2008), and leaf herbivory can similarly induce changes in root chemistry (Soler et al. 2007). Because resource sharing between leaves and roots is known to be sectored in certain plants (Orians et al. 2004; Bledsoe and Orians 2006; Zanne et al. 2006), vascular architecture may influence aboveground–belowground induction patterns in a manner analogous to orthostichous leaves. Yet, to our knowledge, this possibility has never been tested.

If leaf–root induction is indeed sectored, as is often the case with leaves, this has important ecological implications for understanding the causes of heterogeneity in plant defense traits and their extended effects on consumers. Importantly, leaf and root herbivores are known to be patchily distributed in the aboveground and belowground environments, and thus herbivory on only part of the plant is likely to be ubiquitous under natural growing conditions (Denno and McClure 1983; Ettema and Wardle 2002). When root feeders, for example, predominantly damage one sector of a root system (likely given the poor dispersal capabilities of most belowground consumers), then potential indirect effects on foliar herbivores may be restricted to the same sector of plant aboveground. Similarly, foliar herbivores that damage one or a few leaves may be more likely to affect resource quality for belowground consumers that occur on adjacent root tissue, potentially contributing to the inherent patchiness of soil communities (Ettema and Wardle 2002).

We experimentally manipulated foliar and root herbivory on tobacco (*Nicotiana tabacum*) by using a split-root design and quantified the effects of plant vascular architecture on aboveground–belowground-induced chemical responses.

Methods and Materials

Tobacco plants (var. MD 609) were propagated from seed in a greenhouse (seeds were cultivated in a standard potting mix described below and maintained in a mist room). After 9 week of growth, seedlings were transplanted to pots containing a sterilized growing medium [50% sand, 50% potting mix (SunGro LC1 and professional blend; sphagnum peat moss, bark, perlite, vermiculite, and clay)]. Plants were supplemented with nutrients weekly by applying a soluble fertilizer (20:10:20 NPK) and were maintained at 23–27°C under natural light conditions. A split-root technique was used whereby the roots of all seedlings were divided, and each of the two halves was transplanted into separate, but adjacent, 2-gal pots. Thus, each plant possessed a single root system divided equally between two independent growth environments. Plants were acclimated to these growing conditions for an additional 3 week until use in experiments. At such time, plants remained in the rosette stage of growth and possessed four to five fully expanded leaves and at least five additional developing sink leaves.

Experiment 1—Leaf–Root Vascular Connectivity Vertically aligned leaves and roots are predicted to be more strongly connected via the vascular system than leaves and roots on opposing sides of the plant. To test this hypothesis, we employed a dye tracer technique that used the above described split-root plants (Orians et al. 2000; Viswanathan and Thaler 2004). The first fully expanded leaf on each plant (N=18) was excised with a razor blade, and an Eppendorf tube filled with a 0.025% *w/v* solution of rhodamine-B dye (Sigma, St. Louis, MO, USA) was inserted onto the petiole. After 48 h, the main tap root was dissected by cutting a cross section, and the location of the dye was visually assessed relative to the excised leaf. The intensity of dye staining in the vascular tissue was compared between the root half that occurred closest to the labeled leaf and the remaining half of the root that was opposite from the labeled leaf. We then recorded whether the intensity of vascular dye was greater in the orthostichous root segment, the nonorthostichous root segment, or that there was no difference between the two root segments.

Experiment 2—Aboveground Herbivory Foliar herbivory was manipulated by applying beet armyworm caterpillars, *Spodoptera exigua*, to selected leaves. Beet armyworms are a polyphagous species that are known to feed and induce responses on tobacco (Voelckel and Baldwin 2004). Caterpillars were obtained from a biological supply company (Benzon Research, Inc., Carlisle, PA, USA) and reared on artificial diet until they reached the third instar. Fine-mesh sleeve cages were placed over leaves and fastened to the petiole with a twist tie to ensure that caterpillars only damaged the leaf assigned to the foliar herbivory treatment.

Thirty split-root plants were used; half of these were randomly assigned to caterpillar defoliation (N=15), while

the other half served as undamaged controls. Damage regimes were initiated 21 day after seedlings were transplanted into pots and thus in the rosette stage of growth. The first fully expanded leaf that was orthostichous (i.e., vertically aligned) with one of the two root sections (i.e., pots) was assigned to caterpillar damage. Three third-instar *S. exigua* were placed in sleeve cages and remained for 72 h, during which time they removed 20–50% of the leaf area. Control plants also received sleeve cages, but no caterpillars were added. After 48 h (5 day after the initiation of damage regimes) leaves and roots were harvested for analysis of secondary metabolites. This temporal scale is known to coincide with peak concentrations of nicotine and other induced tobacco secondary compounds following caterpillar herbivory (Keinänen et al. 2001).

Two recently expanded sink leaves (i.e., within 1 week of emergence) were collected from each plant—one leaf that was orthostichous with the caterpillar-damaged leaf and a second leaf that was opposite from the damaged leaf. Rosette-stage tobacco plants follow a 3/8 phyllotaxis whereby each new leaf emerges at a 135° angle from the previous leaf (Allard 1942; Jones et al. 1959; Schittko and Baldwin 2003). Therefore, the leaf that is eight positions higher on the plant from the damaged leaf is vertically aligned. Additionally, root tissue (only fine roots) was harvested from both pots in each plant for chemical analysis.

Tissue samples were frozen immediately in liquid N_2. Secondary chemicals with known antiherbivore properties were extracted and analyzed by high-performance liquid chromatography (HPLC; see Keinänen et al. 2001) on a reverse-phase C18 column (Gemini C18, 150×4.6 mm; Phenomenex). Concentrations of identified alkaloids (nicotine) and phenolics (chlorogenic acid and rutin) were quantified by using calibration curves prepared from commercially available standards. Caffeoyl putrescine is not commercially available and was quantified as chlorogenic acid equivalents as described by Keinänen et al. (2001). A further phenolic compound was putatively identified as 7-methyl esculin by comparison with published retention time and mass spectral data (Vereecke et al. 1997). HPLC–mass spectrometry (MS) was performed under identical HPLC conditions as described above, with the exception of trifluoroacetic acid replacing the phosphoric acid in the mobile phase. MS was performed on a Varian 1200 triple quadrupole instrument (Varian, Palo Alto, CA, USA). Under positive electrospray ionization conditions (needle voltage 4.8 kV; capillary voltage 35 V; drying gas 18.5 psi per 200°C, nebulizer gas 51 psi), the compound produced a $[M+H]^+$ at *m/z* 355. Collision-induced dissociation at a 10-V collision energy yielded a dominant fragment ion at *m/z* 193 corresponding to the 7-methyl esculin fragment or a loss of a hexose (Vereecke et al. 1997). Concentrations of nonnicotine alkaloids and 7-methyl esculin were calculated from peak areas at 254 nm (for alkaloids) and 320 nm (for 7-methyl esculin).

Experiment 3—Belowground Herbivory Root herbivory was manipulated by inoculating tobacco roots with the nematode *Meloidogyne incognita*. This polyphagous species is a sedentary endoparasite that induces a gall at feeding sites (Trudgill and Block 2001). Nematode cultures originated from local agricultural fields and were reared on tobacco prior to use in experiments. Nematode eggs were harvested from the roots of heavily infested plants by using a modified version of the Hussey and Barker (1973) extraction procedure. Galled roots were cut into 2-cm-long segments, placed into a 250-ml flask containing 100 ml of a 0.6% NaOCl dilution, and subsequently poured through nested sieves (250-μm-pore sieve on top of a 25-μm-pore sieve). The resulting eggs were counted and applied to the roots of experimentally inoculated seedlings at transplant. Each seedling assigned to the root herbivory treatment received ~100,000 *M. incognita* eggs. This density falls well within the range documented for *M. incognita*-infested tobacco fields (Barker and Lucas 1984) and also corresponds with inoculum levels used in prior studies on *M. incognita*–tobacco interactions (Hanounik and Osbourne 1975, 1977; Barker and Weeks 1991; Wheeler et al. 1991; Vovlas et al. 2004).

Thirty split-root plants were used—half were assigned to the nematode root herbivory treatment ($N=15$), while the other half acted as control plants. On nematode-treated plants, roots from only one of the two pots were inoculated with nematodes. Thus, in the root herbivory treatment, only half of the root system was galled by nematodes—the other half was not. Twenty-one days after nematode addition, plant leaves and roots were harvested for secondary chemical analysis. This time scale was used because *M. incognita* requires at least 3 week to complete gall development, and this also coincides with prior experimental work on nematode-induced responses in tobacco (Kaplan et al. 2008). Two recently expanded sink leaves were harvested from each plant (nematode root herbivory is known to induce secondary chemical changes in tobacco sink leaves; see Kaplan et al. 2008), one leaf that was orthostichous (i.e., vertically aligned) with the pot containing nematode-inoculated roots and a second leaf that was opposite from the inoculated root section. On control plants, the two leaves were chosen to align with each of the two pots as in the nematode treatment. Secondary plant chemicals were quantified in leaf and root tissue samples as described above (see Exp. 2). Roots in each pot were visually inspected to assess the efficacy of treatment and confirmed that nematode-induced galls only occurred on roots that were inoculated (i.e., there was no migration of juveniles between neighboring pots). Moreover, nematode-inoculated roots were heavily galled

and displayed no evidence of strong resource competition. Roots from each pot were dried (at 60°C for 72 h) and weighed to assess the impact of nematode herbivory on belowground biomass.

Statistical Analyses A *G* test was used to determine whether orthostichy affected patterns of dye accumulation in roots (Sokal and Rohlf 1994). To assess the impact of plant vascular architecture on induced responses to foliar and root herbivory,

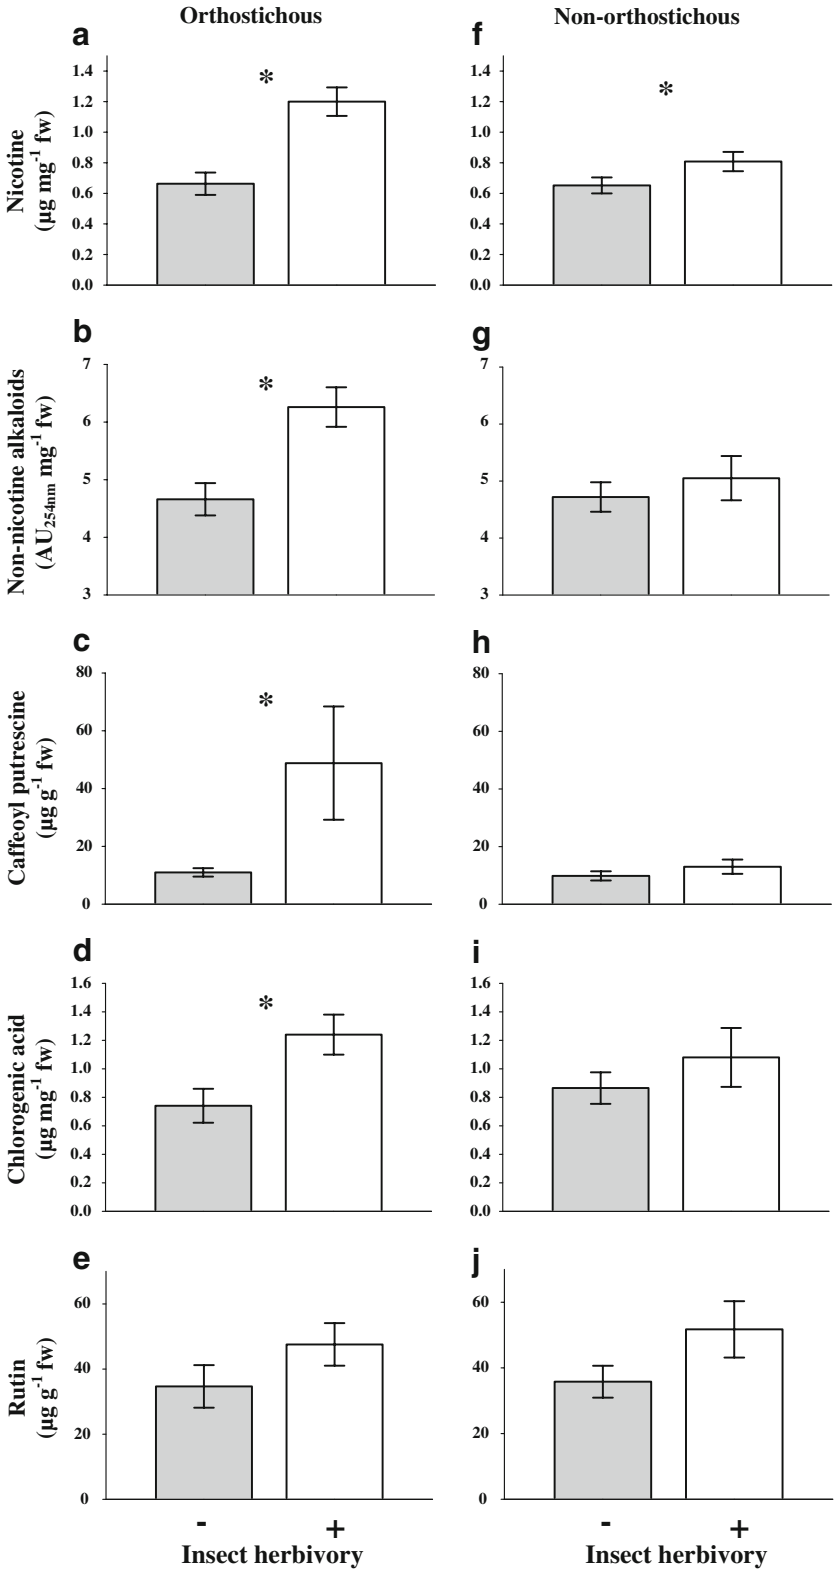

Fig. 1 Effects of aboveground caterpillar herbivory on the expression of secondary plant chemicals in orthostichous (*A–E*) and nonorthostichous (*F–J*) tobacco leaves, including nicotine, nonnicotine alkaloids, caffeoyl putrescine, chlorogenic acid, and rutin (means±SE). *Asterisks* denote significant differences between means ($P<0.05$)

we used multivariate analysis of variance (MANOVA; Proc glm; statistical analyses were performed using SAS, version 9.1; SAS Institute, Inc. 2001), followed by univariate analyses of variance for each secondary chemical measured (Proc mixed). Separate analyses were performed to quantify the impact of aboveground caterpillar herbivory on orthostichous and nonorthostichous leaves and roots, as well as the effect of belowground nematode herbivory on orthostichous and nonorthostichous leaves and roots. Blocks (i.e., spatial groupings of control and herbivory plants) were considered as a random effect in the model. Because the position of the caterpillar-damaged leaf in Experiment 2 varied along the stem (i.e., we were restricted to using the leaf that was growing directly above one of the two pots), we used regression analyses (Proc glm) with leaf number as the predictor variable and root chemistry as the response variable to test for potential relationships between leaf position and belowground induction. *T* tests were used to compare root dry mass on plants with and without nematodes. Data were transformed (square root and log transformations) as needed to meet assumptions of normality and homogeneity of variances.

To compare directly the overall magnitude of secondary chemical induction in orthostichous vs. nonorthostichous plant tissues, effect sizes were calculated (Hedges' *d*) for the impact of caterpillar herbivory on leaf and root chemistry, and the effect of nematode herbivory on leaf chemistry (Rosenberg et al. 2000). Mixed-effects categorical models were then used to compare effect sizes in orthostichous and nonorthostichous plant tissues. For each group, a mean effect size was calculated and reported with 95% bootstrap confidence intervals. Effect sizes greater than zero indicate that herbivory elicited an overall increase in the concentration of secondary plant chemicals. Between-group heterogeneity (Q_B) was tested against a χ^2 distribution to determine whether plant vascular architecture affected the magnitude of aboveground and belowground induction.

Results

The appearance of dye in tobacco roots was affected strongly by leaf position (G=24.95, df=1, P<0.001). In all cases (N=18), greater dye accumulation was found in roots that were vertically aligned with the labeled leaf than in roots that were opposite.

Foliar herbivory elevated the secondary chemistry of tobacco leaves that were both orthostichous (Figs. 1 A–E) and nonorthostichous (Figs. 1 F–J) with the caterpillar-damaged leaf (Table 1). However, the impact of induction was more apparent in leaves sharing strong vascular connections. Four of the five secondary chemicals measured (nicotine, nonnicotine alkaloids, caffeoyl putrescine, and chlorogenic acid) were induced to higher levels in orthostichous leaves (Figs. 1 A–D), compared with only one of five (nicotine) in nonorthostichous leaves (Fig. 1 F).

Similar results were found when comparing the effects of aboveground herbivory on root chemistry in vertically

Significant effects (P<0.05) are bolded for emphasis

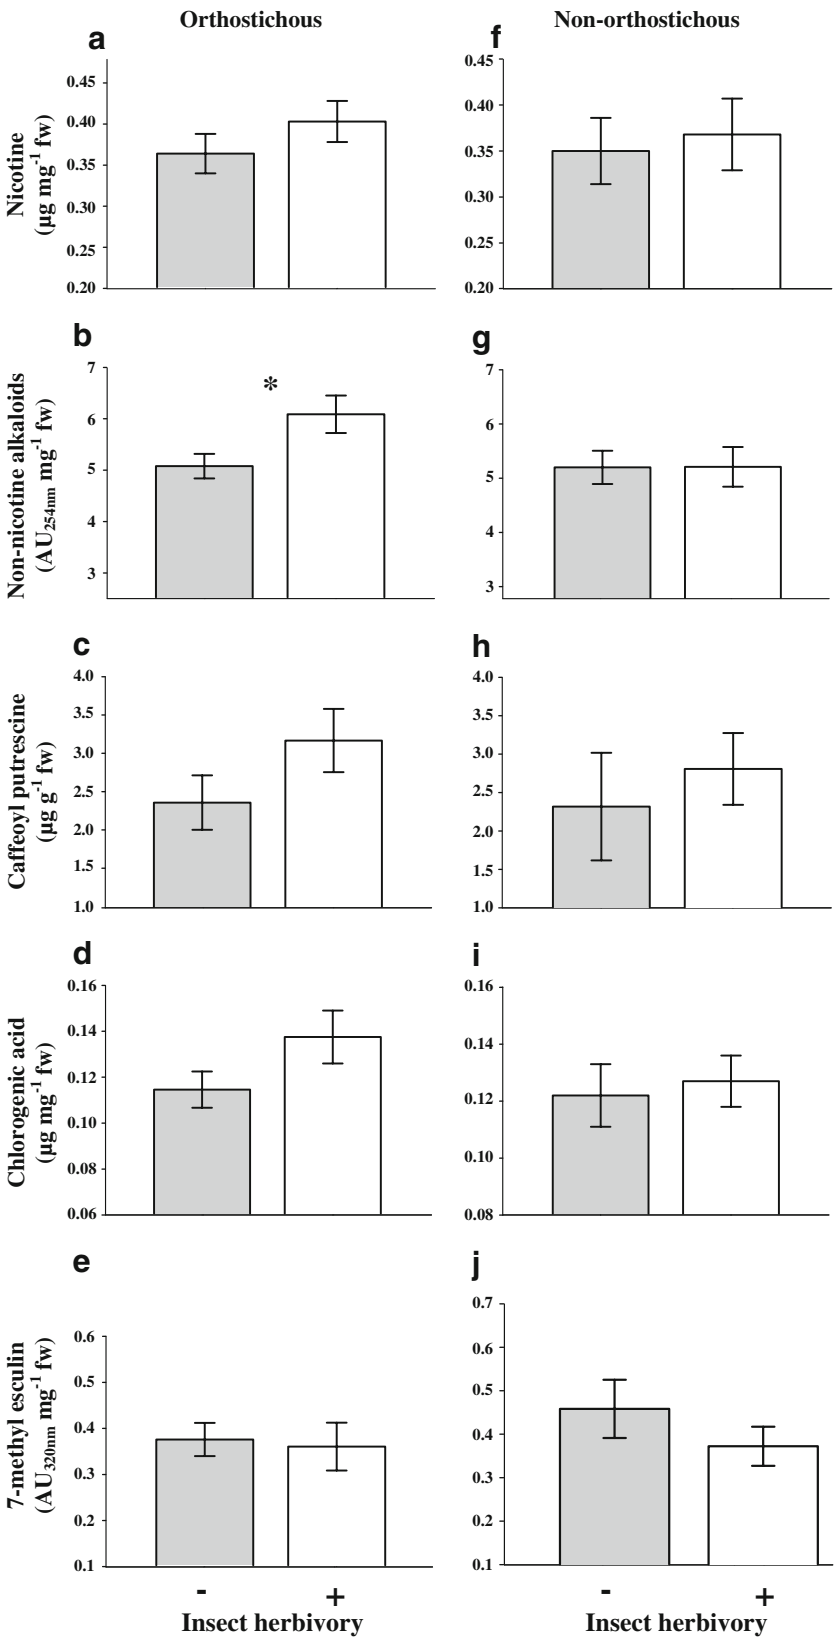

Fig. 2 Effects of aboveground caterpillar herbivory on the expression of secondary plant chemicals in orthostichous (*A–E*) and nonorthostichous (*F–J*) tobacco roots, including nicotine, nonnicotine alkaloids, caffeoyl putrescine, chlorogenic acid, and 7-methyl esculin (means±SE). *Asterisk* denotes significant differences between means ($P<0.05$)

aligned (Figs. 2 A–E) vs. opposing (Figs. 2 F–J) root sections (Table 1). Caterpillar feeding elevated the belowground concentration of certain compounds (e.g., nonnicotine alkaloids; Fig. 2 B), and there was a trend for herbivory to affect overall secondary chemical expression in orthostichous roots (MANOVA: P=0.075). In contrast, aboveground induction did not affect the chemistry of roots that were opposite from the insect-defoliated leaf (Figs. 2

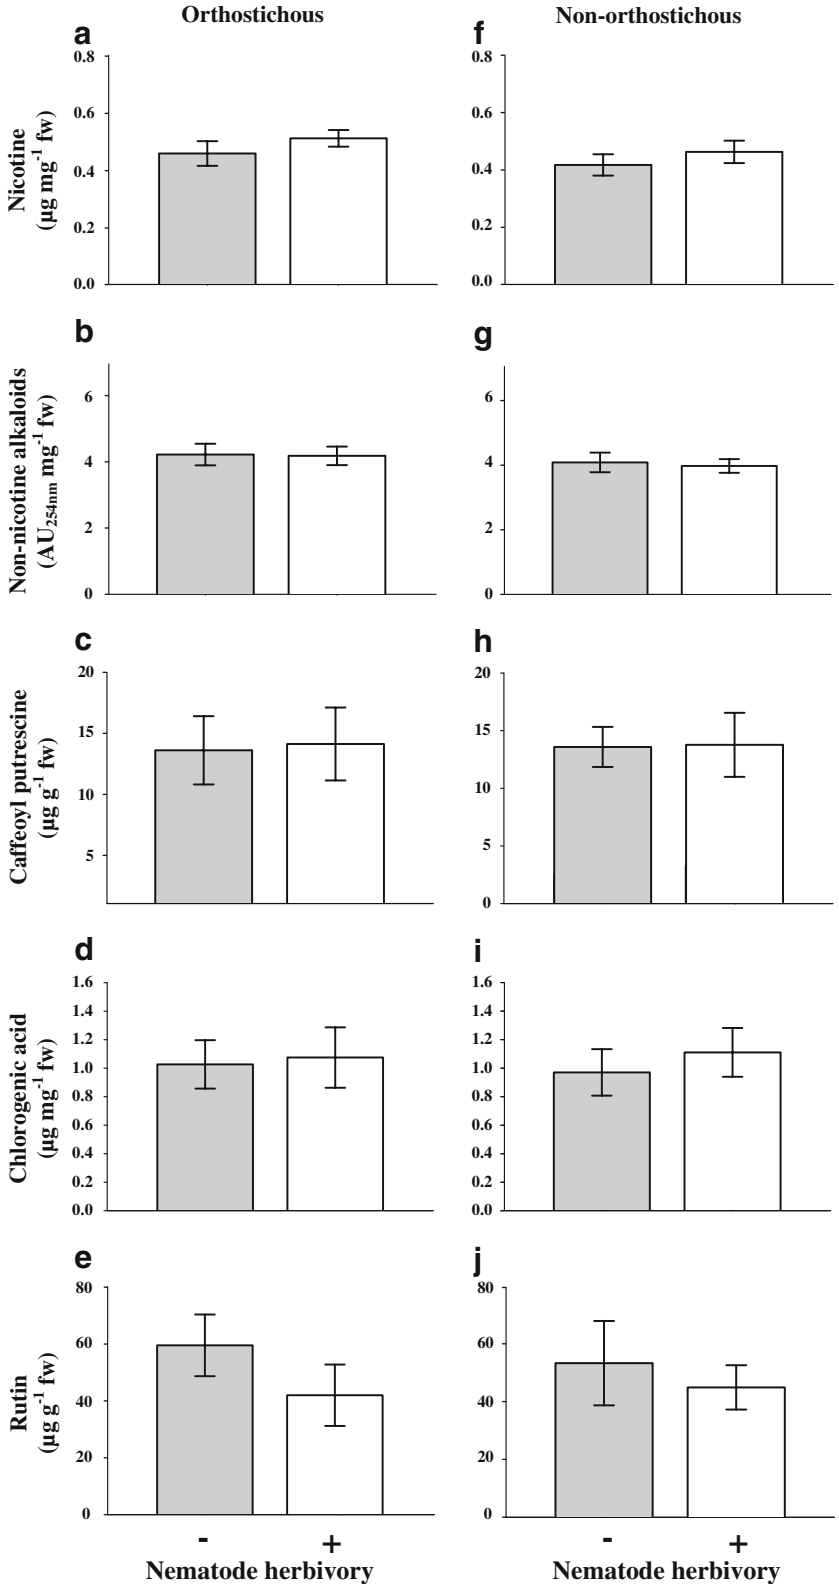

Fig. 3 Effects of belowground nematode herbivory on the expression of secondary plant chemicals in orthostichous (*A–E*) and nonorthostichous (*F–J*) tobacco leaves, including nicotine, nonnicotine alkaloids, caffeoyl putrescine, chlorogenic acid, and rutin (means±SE)

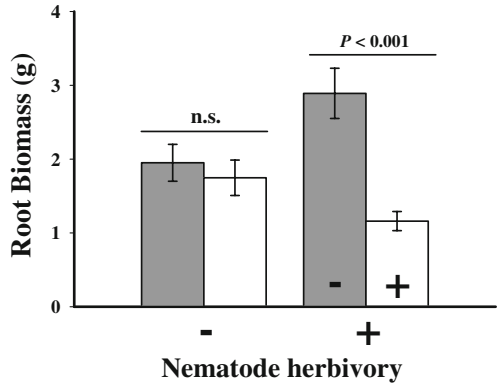

Fig. 4 The impact of nematode root herbivory on belowground plant biomass. The *bars* on the *right* denote plants that were experimentally inoculated with nematodes, whereas the group of *bars* to the *left* represent plants that were not exposed to nematode herbivory. A *positive sign* indicates which of the two split-root sections received nematodes. *n.s.* = nonsignificant

F–J). Moreover, there was no relationship for either root type between the position (age) of the caterpillar-damaged leaf and root chemistry ($P>0.1$ for all secondary metabolites measured).

Nematode root herbivory had no impact on leaf chemistry in either of the two leaf tissue types (Table 1), with nonsignificant effects of nematodes on secondary compounds in both orthostichous (Figs. 3 A–E) and nonorthostichous (Figs. 3 F–J) leaves. However, nematodes induced local changes (i.e., those measured in the roots of pots inoculated with nematodes) in the secondary chemistry of tobacco roots (MANOVA: $F_{5,\ 18}=9.24$, $P<0.001$), including nicotine ($F_{1,\ 22}=19.54$, $P<0.001$), nonnicotine alkaloids ($F_{1,\ 22}=30.93$, $P<0.001$), caffeoyl putrescine ($F_{1,\ 22}=37.14$, $P<0.001$), chlorogenic acid ($F_{1,\ 22}=25.56$, $P<0.001$), and 7-methyl esculin ($F_{1,\ 22}=37.20$, $P<0.001$). In all cases, the concentrations of secondary chemicals were higher in the roots of nematode-damaged plants.

Although nematodes did not affect total root biomass (i.e., pooled belowground dry weights from both split-root sections; $F_{1,\ 28}=0.49$, $P=0.489$), the effects of nematode herbivory on roots were apparent within each split-root pot (Fig. 4). The mass of the two root sections in control pots were not different from one another ($t=0.60$, $P=0.555$), but root mass in nematode-inoculated pots was >50% less than in the opposite pot of the same plant ($t=4.69$, $P<0.001$). This effect was driven partly by nematodes reducing root biomass relative to control plants (average control pot= 1.85±0.18 g, nematode-inoculated pot=1.16±0.13; $F_{1,\ 28}=10.00$, $P=0.004$) and also by plants compensating for nematode herbivory by increasing root biomass in the nematode-free pot of plants assigned to root herbivory (average control pot=1.85±0.18 g, nematode-free pot of root herbivory plants=2.89±0.34 g; $F_{1,\ 28}=7.36$, $P=0.011$).

The overall magnitude of phytochemical induction differed between orthostichous and nonorthostichous plant tissues for one of the three comparisons, i.e., the impact of caterpillar herbivory on leaf chemistry ($Q_B=4.90$, $df=1$, $P=0.027$). In this case, the effect size for responses in the orthostichous leaf was >2× as large as in the nonorthostichous leaf (Fig. 5 A). The difference in root responses to foliar herbivory was nearly significant ($Q_B=2.90$, $df=1$, $P=0.089$), with moderately strong responses in vertically aligned roots (effect size=0.45) and virtually no response in opposing root sections (effect size=0.02; Fig. 5 B). However, aboveground responses to root herbivory were equally weak in both leaf tissue types ($Q_B=0.03$, $df=1$, $P=0.864$; Fig. 5 C).

Discussion

Vascular architecture mediates herbivore-induced plant responses that are both elicited and expressed in leaves, but whether vascular connections similarly shape patterns of induction linking leaves with roots is unknown. In agreement with previously published accounts (Orians et al. 2000; Schittko and Baldwin 2003; Viswanathan and Thaler

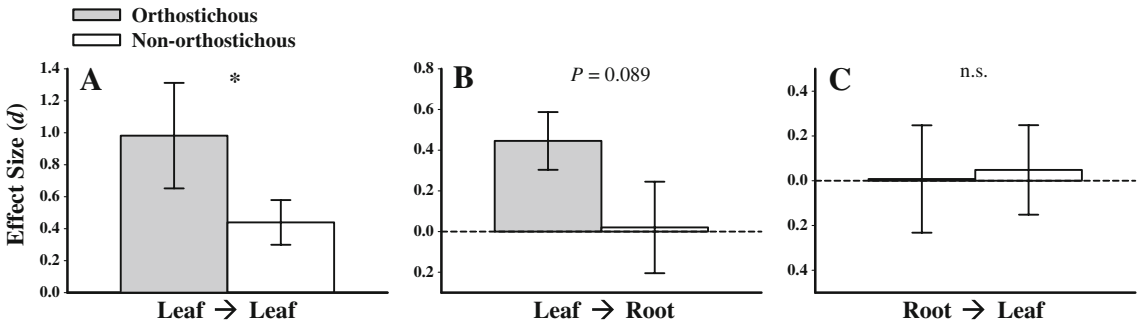

Fig. 5 The magnitude of herbivore-induced responses in orthostichous vs. nonorthostichous plant tissues, including (*A*) leaf responses to foliar herbivory, (*B*) root responses to foliar herbivory, and (*C*) leaf responses to root herbivory (means±95% bootstrap confidence intervals). Effect sizes (Hedges' *d*) were calculated to summarize the cumulative secondary chemical response to herbivory in leaves and roots. *Asterisk* denotes significant differences between means ($P<0.05$). *n.s.* = nonsignificant

2004), we found that the magnitude of phytochemical induction by foliar herbivory was most pronounced in leaves that share strong vascular connections with the caterpillar-damaged leaf (Figs. 1 and 5 A). However, we also document the novel finding that vascular architecture can similarly mediate the effects of foliar herbivory on certain root chemicals (e.g., nonnicotine alkaloids), with stronger induction in roots that are vertically aligned with insect-defoliated leaves (Figs. 2 and 5 B).

Because studies that measure the impact of leaf herbivory on root chemistry do not account for vascular architecture, whereas studies on aboveground induced responses often do, the magnitude of root responses to foliar induction may be underestimated in the literature. For example, in a recently published meta-analysis that merged data from multiple independent studies, evidence was found that foliar induction elicits a relatively weak response in root tissue (Kaplan et al. 2008). This outcome may in part be driven by the lack of control over leaf–root connectivity in previous studies. For this reason, we urge investigators in future studies of aboveground–belowground induction to consider plant sectoriality in the design of experiments. However, leaf responses to foliar herbivory were nevertheless stronger than root responses in the present study, despite controlling for vascular architecture in both cases (leaf–leaf effect size=+0.982, leaf–root effect size=+0.446). Also, the ontogenetic stage of belowground tissues (e.g., fine vs. tap roots) is likely to affect whether or not induced responses are detected in roots (Van Dam and Raaijmakers 2006).

Despite the fact that our experiments support the hypothesis that leaf–root induction follows the vascular architecture of plants, our results also indicate that this phenomenon is more apparent and potentially more important aboveground. Caterpillar damage induced higher concentrations of four of five secondary chemicals measured in orthostichous leaves (compared with only one of five in nonorthostichous leaves), whereas one of five chemicals were induced to higher levels in orthostichous roots (compared with zero of five in nonorthostichous roots). As a result, the overall magnitude of sectorial induction was significant among leaves (P=0.027) but nonsignificant for roots (P=0.089).

Surprisingly, root herbivory did not alter the subset of secondary chemicals that we measured in tobacco leaves (Fig. 3), making it difficult to evaluate the consequences of vascular architecture (Fig. 5C). This outcome was unexpected because in prior experiments strong foliar responses to nematode (*M. incognita*) root herbivory were documented with the same tobacco system and under similar environmental and ecological conditions (Kaplan et al. 2008). More specifically, we previously found that nematodes induced a 40% reduction in leaf nicotine and elevated foliar concentrations of phenolics and diterpene glycosides (two to four times) above control levels. Thus, nematode herbivory in only half of the root system appears to elicit very different aboveground responses when compared with plants experiencing widespread herbivory distributed throughout the entire root system. The quantity of tissue damaged affects the strength of herbivore-induced responses in leaves (see Table 4.5 in Karban and Baldwin 1997). Therefore, lower levels of root herbivory may lead to lower levels of aboveground induction. Because nematodes damage alkaloid biosynthetic sites and interfere with foliar expression (Hanounik and Osborne 1977; Barker and Weeks 1991; Kaplan et al. 2008), another potential explanation is that plants compensate for root damage on one side of the plant by increasing alkaloid production on the other undamaged side (Fig. 4). Moreover, compensatory root growth may come at the expense of foliar chemical responses if plants are limited in their allocation of resources towards growth and defense.

Foliar and root herbivores are often patchily distributed on plant leaves and roots (Denno and McClure 1983; Ettema and Wardle 2002). As a result, their systemic effects on plant defense traits are likely to be heterogeneous. Given the recent emphasis on linkages between aboveground and belowground biota (Wardle et al. 2004; Wardle 2002), our findings provide new mechanistic insight into the ecological circumstances in which foliar and root herbivores affect both plant chemistry and potentially other co-occurring herbivores. Additional studies are needed to assess the relative importance of sectorial induction between leaves and other plant tissues.

Acknowledgements Brian Crawford assisted with harvesting plants for secondary metabolite analyses. We thank Jen Thaler for the use of growth chamber space and rhodamine-B in the dye tracer experiment. The chemical characterization was supported by National Science Foundation grant DBI-0500550.

leading to drought stress symptoms that influence aboveground herbivores (Masters et al. 1993; Poveda et al. 2005). Plant-mediated interactions between root and shoot herbivores likely depend on the plant and herbivore species, as well as on abiotic factors (Wurst and Van der Putten 2007). However, it is unknown if genetic variation in plant defense traits influences belowground-aboveground interactions.

Plants display genetic variation in traits that influence the performance of herbivores. These resistance traits may respond to abiotic and biotic environmental factors that lead to variable defensive phenotypes (Agrawal and Karban 1999). So far, it is largely unknown whether the plant genotype affects the outcome of plant-mediated interactions between root and shoot herbivores. Moran and Whitham (1990) documented that plant resistance to leaf galling abolishes the negative impact of a leaf galling aphid on a root-feeding aphid on *Chenopodium album*. However, it remained unclear whether this effect was mediated by a difference in plant response or by the smaller number of leaf galling aphids on the resistant plants. In general, the way in which a plant responds to herbivores is expected to differ among genotypes and can be considered a trait that is subject to selection. Since root-associated soil organisms may interact with the plant before shoots emerge, root-induced plant responses might have a strong impact on aboveground plant–herbivore interactions and even on higher trophic levels such as predators and parasitoids (Bezemer and Van Dam 2005).

In this study, we investigated the effects of coleopteran root herbivores (*Agriotes* sp. larvae, Elateridae) on secondary plant chemistry of two full-sib families of *Plantago lanceolata* (Plantaginaceae) from lines that were selected for low and high levels of defensive compounds (iridoid glycosides [IG]). IG are known to deter generalist insect herbivores (Bowers and Puttick 1988) and pathogens (Marak et al. 2002a). However, they are used as feeding and oviposition stimulants by specialist herbivores (Bowers 1983). Production of IG can be induced both by herbivores (Darrow and Bowers 1999) and pathogens (Marak et al. 2002b).

Additionally, we investigated whether the production of aboveground volatiles differed between the plant lines and between root herbivore-induced and noninduced plants. While IG may serve as direct defense compounds against herbivores, leaf volatiles may attract carnivorous enemies of herbivores as an indirect defense mechanism (Dicke 1999). Recently, insect root herbivores were shown to change the release of leaf volatiles, which affects aboveground parasitoid behavior (Soler et al. 2007). In a field assay, we monitored leaf damage of root herbivore-induced and noninduced plants of the two lines. The results indicate that plant responses to root herbivory differ between plant lines leading to different defensive phenotypes that aboveground herbivores have to deal with.

Methods and Materials

Experiments were performed with seeds of two full-sib families of *Plantago lanceolata* L. from lines artificially selected for low and high levels of IG (Marak et al. 2000). After four generations, leaf IG concentrations of the "low-IG line" were in average twofold to fourfold lower than of the "high-IG," depending on environmental conditions (Marak et al. 2000, 2003; Biere et al. 2004). The "low-IG" and "high-IG" full-sib families used in the current experiments were the offspring of crosses between two (self-incompatible) parents from the "low-IG line" and between two parents from the "high-IG line", respectively.

On 19 May 2006, seeds of the two *Plantago* lines were surface-sterilized with potassium hypochlorite solution (1%) and sown on wet paper in Petri dishes in the greenhouse (16 h light, 20°C/25°C night/day temperature). Twelve days after sowing, germinated plants were transplanted into seedling trays filled with gamma-sterilized (25 kGy) experimental soil. The experimental soil was a loamy, sandy mineral soil (N=0.13%, C=2.1%, C/N=16.7) that had been sieved through a 0.5-cm mesh.

Experimental Set-Up A total of 48 pots (11.5 cm height, 13 cm diameter) filled with 1,300 g nonsterile experimental soil were placed in a greenhouse with 16 h light and 20°C/25°C night/day temperature. *P. lanceolata* plants with two to three leaves (except the cotyledons) were planted from the seedling trays into the pots on 13 June (day 1 of the experiment). Half the pots were planted with one plant from the "low-IG line," the other half with one plant from the "high-IG line." Two weeks later, two *Agriotes* larvae (fresh biomass added: mean=45.14 mg, SE=1.62) were added to half of the pots of each IG line. *Agriotes* larvae (wireworms) are abundant root herbivores in grasslands, feed on a wide range of plant species, and have a long life cycle with the larval stage taking 4–5 years (Staley et al. 2007). The set-up resulted in a full factorial experimental design with six replicates per treatment and harvest time (two harvests).

The pots were watered with 50 mL demineralized H_2O every second day and redistributed randomly within the greenhouse every second week. In week 8 of the experiment, the stalks were cut and frozen at −80°C to prevent a possible influence of inflorescence odor on the subsequent leaf volatile measurements.

In week 9, the volatile organic compounds (VOC) of 40 experimental plants were measured (ten replicates per

treatment; replicates of harvest 1 and 2 were combined). Plants were placed under 17 L bell-shaped glass cylinders (30 cm height, 24.5 cm diameter) in a controlled climate cabinet (21°C, 72% relative humidity). The glass cylinders were supplied constantly with 300 mL pressurized air (Hoekloos, NL) from the top. The air was cleaned by a Zero Air generator to remove hydrocarbons (Parker Hannifin, Tewksbury, MA, USA). Plant VOC were collected from a potted plant by using a steel trap filled with 150 mg Tenax TA and 150 mg Carbopack B. The trap was connected to a vacuum pump (flow rates 200 mL/min). Traps were removed after 1 h from the pump and kept for approximately 1 week at 5°C until analysis. For control, we measured background VOC profiles from empty glass cylinders (N=2) and VOC profiles from a pot with soil but without a plant inside the cylinder (N=2).

In week 10, half of the plants (N=24) were harvested. Wireworms were collected and weighed during root washing. Since wireworms might have affected colonization of roots by arbuscular mycorrhizal fungi (AMF) with subsequent effects on leaf chemistry and herbivore damage (Gange et al. 1994; Gange 2001; Gange and West 1994), random subsamples of approximately 1.5 g fresh roots were taken, stored in ethanol (50%), stained, and assessed for mycorrhizal fungi colonization (for details see Wurst et al. 2004). Shoots and roots were frozen at −80°C, freeze-dried, weighed, and subsamples were ground for analyses of N and C, glucose, and IG.

The other half of the pots (N=24) was placed in a randomized block design outside on a meadow to expose them to natural herbivory from June until November (field experiment). Fourteen weeks later, these plants were harvested. The leaves of these plants were counted, and their size and extent of herbivore damage (area of holes eaten from the leaf area) were recorded with WinFOLIA (Regent Instruments, Sainte-Foy, Canada). The leaves and roots were frozen at −80°C, freeze-dried, and weighed.

Chemical Analyses Volatiles (VOC) were desorbed from the steel traps by using an automated thermodesorption unit (model Unity, Markes, Pontyclun, UK) at 200°C for 10 min (He flow 30 mL/min) and focused on a cold trap (−10°C). After 1 min of dry purging, trapped volatiles were introduced into the gas chromatograph–mass spectrometer (model Trace, ThermoFinnigan, Austin, TX, USA) by heating the cold trap for 3 min to 270°C. Split rate was set to 1:4, and the column used was a 30-m×0.32-mm ID RTX-5 Silms, film thickness 0.33 μm. Temperature raised from 40°C to 95°C at 3°C/min, then to 165°C at 2°C/min, and finally to 250°C at 15°C/min. The VOC were detected by the mass spectrometer operating at 70 eV in EI mode. Mass spectra were acquired in full scan mode (33–300 AMU, three scans per second). Compounds were identified (a) by their mass spectra by using deconvolution software (AMDIS) and comparison with mass spectra from NIST 98 and Wiley 7th edition spectral libraries, (b) by their linear retention indices and comparison with values reported in the literature (C.A. Hordijk, personal database), and (c) by analyzing reference substances commonly reported to be detected in plant volatile profiles (octanal, nonanal, decanal, limonene, benzylcyanide, *cis*-3-hexenyl acetate, *cis*-3-hexen-1-ol, dimethyl trisulfide [Sigma-Aldrich, St Louis, MO, USA], methyl salicylate [Merck, Darmstadt, Germany], *cis*-3-hexenyl isobutyrate [Oxford Chemicals, Harlow, Essex, UK], and 4,8-dimethyl 1,3,7-nonatriene [kindly provided by Dr. TA Van Beek, Wageningen University, The Netherlands]) and comparing their mass spectra with those of the compounds detected. Peak areas of identified compounds were integrated by the Xcalibur software (Version 1.3, Finnigan). To exclude potential interference by coeluting compounds, specific quantifier ions were carefully selected for each individual compound of interest. In general, these quantifier ions were similar to the most intense model ions extracted from the raw mass spectrum by AMDIS. The integrated absolute signal of the quantifier ion(s) were used for comparison between the treatments. Peak areas in each sample were divided by the total volume in milliliters (calculated as total volume= $(\text{flow}_{\text{begin}}+\text{flow}_{\text{end}})/2\times$sampling time in minutes) that was sampled over the trap. This procedure corrects for differences in flow rates over individual traps that arose during the sampling procedure and minor difference in sampling times between replicate sets.

IG and glucose from 25 mg freeze-dried and ground root samples were extracted overnight with 70% methanol. The concentrations of the IG aucubin and catalpol were analyzed using a Dionex (Sunnyvale, CA, USA) BioLC equipped with a GP50 gradient pump, a Carbopac PA1 anion-exchange guard (2×50 mm) and analytical column (2×250 mm), and an ED50 electrochemical detector for pulsed amperometric detection. Compounds were eluted with NaOH (1 M) and ultrapure water (10%:90%). Retention times were 3.5 and 5.0 min for aucubin and catalpol, respectively. Concentrations were analyzed with Chromeleon Software Release 6.60 (Dionex). Contents of total N and C in leaves and roots were measured by using a C/N analyzer (Flashea Series1112, Interscience, Breda, NL, USA).

Statistical Analyses Data were analyzed by factorial analyses of variance (ANOVA) in a general linear model (GLM, Statistica 6.0, Statsoft) with the class factors "*Plantago* line" and "wireworms." The data were tested for normality (Kolmogorov–Smirnov one-sample test) and homogeneity of variances (Levene test) and log-transformed or arcsine transformed (for percentage data) if necessary. Volatiles

were analyzed by a redundancy analysis (RDA) followed by a Monte Carlo 999 permutation test in CANOCO for Windows 4.5. The linear method RDA was justified by the length of the gradients being shorter than 3.0 in a detrended canonical correspondence analysis (Lepš and Šmilauer 2003). Only volatiles that were not detected in the background controls (i.e., empty glass cylinders) and were detected in at least 70% of the ten replicates of one treatment were used for statistical analysis (Table 1).

Results

Harvest 1 (Greenhouse Experiment) Leaf biomass was greater in plants from the "high-IG line" ($F_{(1,\ 20)}$=21.74, P<0.001) (Fig. 1), while plants from the "low-IG line" produced more inflorescences ("low-IG line": mean=2.50, SE=0.26; "high-IG line": mean=1.00, SE=0.17; $F_{(1,\ 44)}$= 23.53, P<0.001) and higher reproductive biomass ("low-IG line": mean=0.41 g dry weight, SE=0.03; "high-IG line": mean=0.15 g dry weight, SE=0.02; $F_{(1,\ 37)}$=33.74, P< 0.001). Note, however, that the inflorescences were cut in week 8 (prior to VOC analyses), while the leaves and roots were harvested in week 10 (after VOC analyses). Overall, the total aboveground biomass did not differ between the lines. Plants from the "high-IG line" had a greater root biomass ($F_{(1,\ 20)}$=8.00, P<0.05), resulting in a greater total biomass than plants from the "low-IG line" ($F_{(1,\ 20)}$=7.18, P<0.05). Wireworms did not affect the biomass of roots and inflorescences, but enhanced the leaf biomass ($F_{(1,\ 20)}$= 7.46, P<0.05) and the total shoot biomass ($F_{(1,\ 20)}$=6.64, P<0.05) (Fig. 1). The effects of wireworm feeding on plant biomasses did not depend on the *Plantago* line.

Carbon concentration (percent dry weight) in leaves was slightly but significantly higher in plants from the "high-IG line" (mean=41.62, SE=0.23) than in plants from the "low-IG line" (mean=40.73, SE=0.34; $F_{(1,\ 20)}$=4.79, P<0.05). Nitrogen concentrations in leaves (mean=1.15, SE=0.11) and roots (mean=0.89, SE=0.16) and carbon concentrations in roots (mean=37.65, SE=0.98) were not affected by the plant line or by wireworms. Glucose concentration in shoots (mean=0.55%, SE=0.07) was unaffected by the treatments, while glucose concentration in roots increased when wireworms fed upon the "high-IG line," but decreased in the "low-IG line" (interaction between *Plantago* line and wireworms: $F_{(1,\ 20)}$=6.86, P<0.05; Fig. 2).

Catalpol concentration (percent dry weight) in leaves was higher in the "high-IG line," but only in the absence of wireworms. When wireworms were present, plants from the "high-IG line" reduced leaf catalpol concentrations, while plants from the "low-IG line" showed enhanced concentration of this IG in leaves (interaction between *Plantago* line and wireworms: $F_{(1,\ 20)}$=9.21, P<0.01; Fig. 3). The same pattern was observed for the concentration of total IG (aucubin+catalpol) in leaves (interaction between *Plantago* line and wireworms: $F_{(1,\ 20)}$=6.36, P<0.05). The leaf aucubin concentration did not differ significantly between treatments (mean=2.86%, SE=0.34), but tended to show the same pattern (interaction between *Plantago* line and wireworms: $F_{(1,\ 20)}$=3.62, P=0.07). In roots of both lines, the catalpol concentration was enhanced in the presence of wireworms ($F_{(1,\ 20)}$=4.85, P<0.05; Fig. 3). The concentrations of aucubin (mean=2.52%, SE=0.18) and total IG (mean=2.89%, SE=0.19) in roots were not significantly affected by wireworms or plant line.

Colonization of roots by AMF (mean=41.17%, SE= 2.24) was not affected by plant line or wireworms. Recovery rates of wireworms at harvest 1 were as follows: 37.5% as larvae, 12.5% as pupae, and 12.5% as adult beetles. In 83.33% of the wireworm-treated pots, at least one *Agriotes* individual was recovered. Since the *Agriotes* specimens recovered were of different life stages, no potential effect of the plant line on wireworm weight could be measured.

Table 1 Volatiles of *Plantago lanceolata* that were detected in ≥70% of the ten replicates of at least one treatment and not present in the background controls

Terpenes (RI)	Green leaf volatiles (RI)	Others (RI)
cis-β-ocimene (1048)	*cis*-3-hexen-1-yl-acetate (1010)	2-Methyl furan (0604)
(3-*Trans*)-4,8-dimethyl-1,3, 7-nonatriene (1117)	1-Hexyl-acetate (1015)	Heptanoic acid (1081)
		2-Nonanone (1091)
β-elemene (1385)		Octanoic acid (1184)
cis-caryophyllene (1408)		Nonanoic acid (1274)
Trans-α-bergamotene (1429)		
Unknown sesquiterpene (1434)		
Unknown sesquiterpene (1439)		
Trans-β-farnesene (1454)		
(δ or γ)-Cadinene (1511)		
Germacrene A (1494)

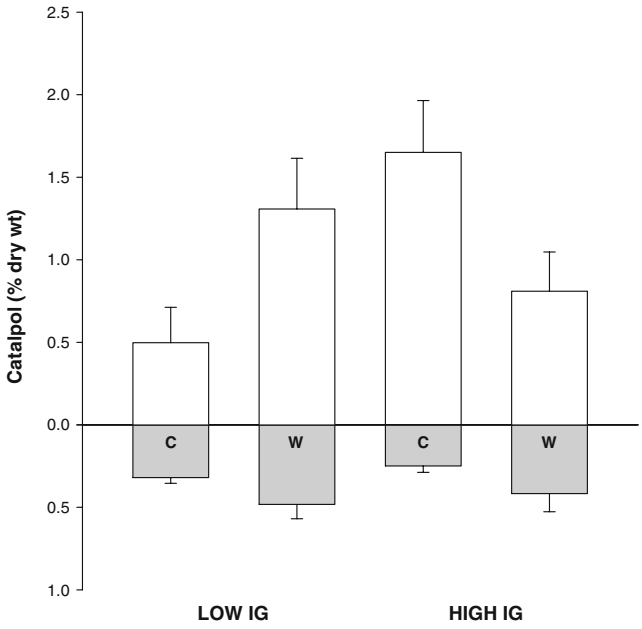

Fig. 3 Effects of plant line (low IG and high IG) and wireworms (*C* without wireworms, *W* with wireworms) on the concentration of catalpol (mean+SE) in shoots (*white*) and roots (*gray*) of *Plantago lanceolata*. For the significant main and interaction effects of ANOVA, see text

Volatiles The RDA showed that the environmental variable "*Plantago* line" explained 14.5% of the total variability in volatile emission (999 Monte Carlo permutations test: F= 6.42, P<0.01; Fig. 4). No effects of wireworms or an interaction between wireworms and *Plantago* line on the volatile blends were detected. Germacrene A and β-elemene were only detected in "high-IG" plants. Cadinene (either the gamma- or the delta-isomer), an unknown sesquiterpene with retention index 1434, and *cis*-3-hexen-1-yl-acetate were omitted in higher quantities from "high-IG" plants. When corrected for leaf biomass, the emission of *cis*-3-hexen-1-yl-acetate and cadinene did not differ between the plant lines, while the unknown sesquiterpene was still emitted in higher quantities from "high-IG" plants.

Harvest 2 (Field Experiment) After more than 3 months in the field, the "low-IG line" and the "high-IG line" did not differ in root (mean=2.12 g, SE=0.07), remaining leaf (mean=1.07 g, SE=0.05), and total biomass (mean=3.19 g, SE=0.10) and were no longer affected by the wireworms. While the number of leaves (mean=24.96, SE=2.03) did not differ between lines, the rosette and average leaf area of plants from the "high-IG line" were 32% and 40% larger than rosette and average leaf area of plants from the "low-IG line," respectively (rosette area: $F_{(1,\ 20)}$=4.44, P<0.05; leaf area: $F_{(1,\ 20)}$=7.38, P<0.05). Total leaf damage (measured as the hole area within the leaf area) of the plants was enhanced in wireworm-induced "low-IG" plants,

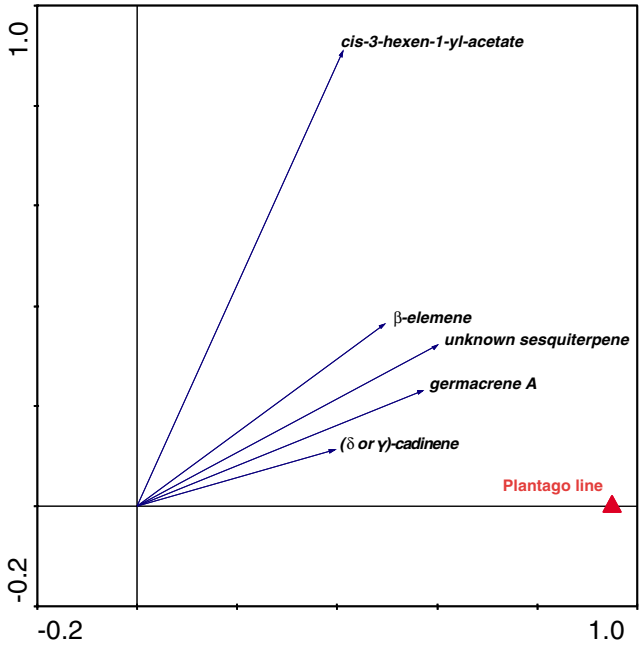

Fig. 4 Species–environment biplot from RDA summarizing differences in the leaf volatile compounds between the *Plantago* lines studied. The substrates shown are well-fitted by the sample scores on the first (*horizontal*) ordination axis, i.e., at least 14.5% of their variability is explained by the *Plantago* line. The second (*vertical*) ordination axis represents the residual variance

but tended to be reduced in "high-IG" plants affected by wireworms (interaction between *Plantago* line and wireworms: $F_{(1,\ 20)}=5.35$, $P<0.05$; Fig. 5). From the added wireworms, 12.5% were recovered as larvae and 4.2% as imagines.

Discussion

Both *Plantago* lines responded to wireworms by increasing the levels of catalpol in roots, thus indicating a defense response upon root herbivory. Induction of secondary metabolites in roots due to root feeding by insect larvae has been reported for a number of plant and herbivore combinations (Birch et al. 1992; Bezemer et al. 2003, 2004; Borowicz et al. 2003; Van Dam and Raaijmakers 2006) and might be a general plant response similar to aboveground induction due to shoot herbivores (Karban and Baldwin 1997). Irrespective of plant line, wireworms had no significant effect on root biomass, but led to an increase in leaf biomass, pointing to compensatory shoot growth (Wurst and Van der Putten 2007). However, the indirect effect of wireworms on leaf chemistry differed between plant lines. While the "low-IG line" showed an increase of catalpol concentration in leaves in response to wireworms, the "high-IG lines" responded with a reduction. By contrast, wireworm feeding led to a reduction of glucose concentration in roots of the "low-IG line," but to an increase of glucose concentration in the roots of the "high-IG line." Whether the contrasting patterns observed for catalpol and glucose are related to a trade-off response in the plants is unclear. The carbon and nitrogen concentrations and the AMF colonization of roots were not affected by wireworms. Consistently, another insect root herbivore (*Otiorhynchus sulcatus*—Coleoptera: Curculionidae) did not affect AMF colonization of roots (Gange et al. 1994; Gange 2001)

The leaf volatile profiles differed between the plant lines, but were not affected by the wireworms. In contrast, Soler et al. (2007) reported changes in leaf volatile profiles of *Brassica nigra* due to root herbivory by *Delia radicum*. The "high-IG line" emitted higher amounts of cadinene and higher amounts of an unknown terpene and the green leaf volatile *cis*-3-hexen-1-yl-actetate. Germacrene A and β-elemene were only detected in the volatile blend of plants from the "high-IG line." The higher emission of the green leaf volatile *cis*-3-hexen-1-yl-acetate and the terpene cadinene could be explained by the greater leaf biomass of the "high-IG line." The other terpenes were emitted only or to a greater extent by the "high-IG" plants, irrespective of the leaf biomass. This might be considered a characteristic trait of the "high-IG line," possibly leading to enhanced indirect defense by attraction of parasitoid or predators. Thus, we found no evidence for a trade-off between direct and indirect defenses in *P. lanceolata*.

Plants from the two lines differed in a number of traits. As expected, noninduced plants of the "high-IG line" contained twofold higher levels of total IG and threefold higher levels of catalpol in the leaves, but levels of these

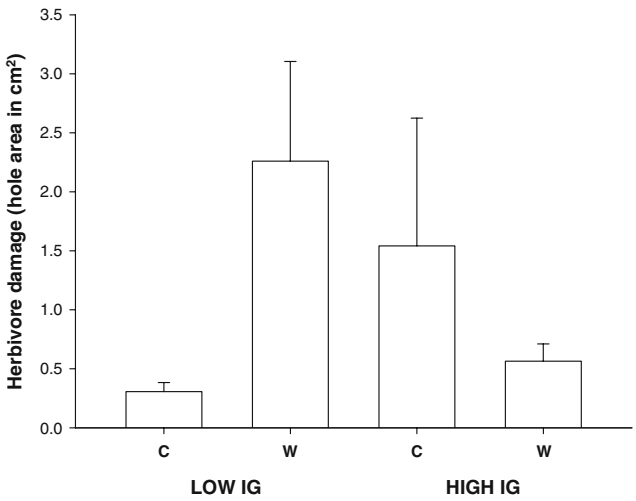

Fig. 5 Effects of plant line (low IG and high IG) and wireworms (*C* without wireworms, *W* with wireworms) on leaf damage by herbivores (mean+SE; measured as total hole area in square centimeter) of *Plantago lanceolata* in the field. Significant interaction between *Plantago* line and wireworms ($F_{(1,\ 20)}=5.35$, $P<0.05$), ANOVA

compounds in roots were similar between lines. Leaf carbon concentration was generally higher in the "high-IG line," while the carbon concentration in roots and the nitrogen concentration in roots and shoots were not affected by the plant line. As in previous studies (Marak et al. 2003), plants from the "high-IG line" produced fewer flower stalks, but produced more root and leaf biomass than plants from the "low-IG line." Former studies also did not detect costs in terms of vegetative biomass for plants producing high levels of IG (Bowers and Stamp 1992; Adler et al. 1995; Marak et al. 2003).

After placing half of the experimental plants for more than 3 months in the field, the root and remaining leaf biomass of the plant lines did not differ and were not affected by the wireworm treatment anymore. However, the rosette area and average leaf area of plants from the "high-IG line" was still greater compared to the "low-IG line." Leaf damage by naturally occurring herbivores was enhanced in wireworm-induced plants from the "low-IG line." Interestingly, aboveground herbivore damage was reduced in wireworm-induced plants from the "high-IG line." During the field experiment, shoot herbivores such as flea beetles, caterpillars, cicadas, and snails were observed on the plants. Since the "low-IG line" increased leaf catalpol concentrations, while the "high-IG line" decreased them after root herbivory, one of the possible explanations for the observed pattern in leaf damage could be the attraction of specialist herbivores to plants containing higher levels of catalpol (Bowers 1983; Bowers and Puttick 1988). For example, flea beetles (*Longitarsus*) are specialist herbivores of plants containing IG (Willinger and Dobler 2001) and might use these compounds as feeding stimulants.

In summary, the two *Plantago* lines examined both showed compensatory leaf growth and enhanced catalpol concentrations in roots in response to wireworm feeding. However, other physiological plant responses to wireworms differed between the "low-IG line" and the "high-IG line." An interaction between *Plantago* line and root herbivory was found for the catalpol concentration in leaves and the glucose concentration in roots. The different responses of the plant lines to root herbivory led to different aboveground defensive phenotypes which herbivores had to deal with. In the field, greater leaf damage was observed on plants with higher leaf catalpol concentration, possibly caused by some specialist herbivores. The present study documents for the first time that intraspecific variation in plant defense can affect the outcome of plant-mediated interactions between root and shoot herbivores.

Acknowledgments We thank Wiecher Smant for analyzing plant N and C concentrations, Sander Van Beersum for determining the arbuscular mycorrhizal fungi colonization of the roots, and Kees Hordijk for the gas chromatography–mass spectrometry measurements. largely responsible for the characteristic flavors of crucifers. The glucosinolate-myrosinase system is regarded as an important defense strategy for the Brassicaceae as it may protect plants from some generalist pests and pathogens (Giamoustaris and Mithen 1995). However, glucosinolates and their breakdown products also act as stimulants and attractants for insects specialized on brassicaeous hosts (Roessingh et al. 1992; van Loon et al. 1992; Renwick et al. 2006). Many studies to date have concentrated solely on the effect of herbivory on glucosinolate induction in plants. An increase in total glucosinolates, especially those containing an indole-based side chain, has often been observed in plant tissues after herbivore damage (Koritsas et al. 1991; Bartlet et al. 1999; van Dam and Raaijmakers 2006).

In addition to the stress caused by herbivory, other factors also affect glucosinolate concentrations in plants including competition for light, nutrients, and water (Yosuf and Collins 1998; Radovich et al. 2005). While the effects of herbivory have received much attention, little work has been done to establish the effect of plant–plant interactions on the concentrations of secondary compounds in brassicaceous plants; even less effort has been made to investigate the combined effect of herbivory and plant competition. When subjected to herbivory, plants growing in competitive environments may not have access to, or allocate, the same amount of resources towards the synthesis of secondary compounds. Theory predicts that the biological costs of plant defense should increase in environments that expose plants to intense competition (Siemens et al. 2002). The growth-differentiation balance (GDB) hypothesis predicts how plants balance the processes that allocate resources between growth and differentiation depending on environmental conditions (Herms and Mattson 1992). One consequence of this may be that brassicaceous plants grown in highly competitive environments allocate a lower proportion of their resources to the production of defensive compounds, in this case, glucosinolates. Because of reduced attacks from pest insects (Risch 1983; Theunissen 1997) and infestations of specialized insects on brassicaceous plants (Theunissen et al. 1995; Finch and Kienegger 1997; Björkman et al. 2007), intercropping has received increased attention. The main mechanism for pest reduction in intercropped systems is thought to be a disruption of host-plant searching behavior of the herbivore (Finch and Collier 2000) and possibly an enhanced effect of natural enemies suppressing the negative effects of the pest insect (Root 1973). In addition, intercropping often creates an environment where crops have to compete with companion plants for mutual resources. The changes, brought about in the crop plants by the competitive environment, are also likely to affect herbivores in intercropping systems.

It is of interest to investigate how the glucosinolate content of plants is impacted by herbivory in a competitive environment, such as intercropping, due to the role of these chemicals in plant defense. The present study examined the combined effect of intercropping with red clover and larval feeding by the turnip root fly, *Delia floralis* Fall. (Diptera: Anthomyiidae), on the glucosinolate content of cabbage (*Brassica oleracea* var. *capitata*). The aims were to investigate how the concentration of total and individual glucosinolates in both above and below ground cabbage tissues were affected by (1) competition from different densities of clover, (2) the damage of different densities of *D. floralis*, and (3) whether the co-occurrence of simultaneous stress from clover competition and *D. floralis* herbivory had any additional affects on glucosinolate concentrations.

Methods and Materials

Plant Material Plant material was grown in a greenhouse, under natural light supplemented with 400-W sodium lamps to give an 18:6 h L/D regime. Cabbage (*B. oleracea* var. *capitata* genotype Castello) and red clover (*Trifolium pratense* genotype Betty) were planted in small pots (50×50×50 mm) containing potting soil (Hasselfors Garden AB, Hasselfors, Sweden). Seven-week-old clover plants and 5-week-old cabbage plants were transplanted into plastic boxes (L×W×D=360×255×215 mm) filled with 15 L of a sand-potting soil mixture (one third washed sand − grain size 0.5 to 5 mm and two thirds potting soil).

Insect Material A culture of the turnip root fly, *D. floralis* Fall. (Diptera: Anthomyiidae), was established at the Department of Ecology (Swedish University of Agricultural Sciences) from field-collected pupae [collected in 2002–2003 from an experimental site growing cabbage at Röbäcksdalen, Umeå (63°45′ N; 20°15′ E)]. Adult flies were kept at 20°C, 70% RH, 16:8 h L/D regime and fed with a standardized diet of milk, yeast-powder, and honey (based on Finch and Coaker 1969). A Petri dish containing a piece of fresh swede (*Brassica napus* ssp. *rapifera*) was placed on top of moist sand (grain size 1.0–1.6 mm) as an oviposition site. Eggs were floated from the sand with water and sieved through a black cloth. Eggs were taken from the cloth and inoculated onto the plants with a fine paintbrush.

Experimental Procedure Cabbage plants were transplanted into the boxes alone (M) or with one of the two clover densities (IC1 or IC2). Clover plants were transplanted into the boxes at either one row (IC1) of four plants on each side (10 cm from) of the cabbage, or two rows (IC2) of four plants (a total of eight plants) on each side of the cabbage. The boxes were left for 2 weeks in the greenhouse to allow cabbage and clover plants to establish.

The experiment consisted of ten blocks with one block set up each day for ten successive days. Within each block, there were four cabbage plants grown with each clover density (M, IC1, and IC2). Throughout the experiment, the greenhouse was kept at 17°C during the day and 12°C during the night. Light conditions were natural light, supplemented with 400-W sodium lamps when natural light was below 100 W/m^2, between 6 AM and 9 PM. After 2 weeks of plant establishment *D. floralis* eggs (<24-h old; either 0, 10, 20, or 40) were inoculated on each of the four cabbage plants within the three growing conditions, leading to a total of 12 different treatments within each block. As there were ten blocks, each treatment was replicated ten times. Eggs where inoculated onto the stem base of cabbage plants with a fine brush according to the methods of Birch et al. (1992). At the time of egg inoculation, cabbage plants were at the 6–7 true leaf stage.

Throughout the experiment, only pure water was added to the boxes to create a competitive environment in terms of space, light, and nutrients in the intercropped treatments. Plants were watered according to their requirements, i.e., boxes with clover were given more water so that drought did not influence survival of the turnip root fly larvae. Water was added in moderate doses two times a day. For the first week after egg inoculation, a spray bottle was used to keep the soil near the stem base moist to avoid dehydration of unhatched eggs and to avoid eggs from being washed away from the stem base by ordinary watering. There was no significant difference in the percentage pupation of *D. floralis* depending on the density of eggs applied or the density of clover (Björkman, unpublished data). Consequently, the number of eggs applied is equivalent to herbivore density.

Prior testing of *D. floralis* developmental time under similar conditions revealed that the development time was approximately 6 weeks. Therefore, 6 weeks after egg inoculation, the experiment was terminated at a rate of one block per day. Green cabbage parts were cut to ground level and the cabbage roots were freed from soil. A 6–6.4-g foliage sample and a 1.3–1.7-g root sample were cut from each individual plant and immediately frozen in liquid nitrogen, prior to being lyophilized and milled for glucosinolate analysis. Foliage samples were taken from the youngest leaves, while root samples were taken from the main root. Freeze-dried samples from blocks 1–5 and blocks 6–10 were bulked and analyzed together, with the consequence that each treatment was twice replicated in the chemical analyses.

Glucosinolate Identification Glucosinolate analysis was performed by hplc according to Nilsson et al. (2006). Glucosinolates were identified by their retention times (Rt) and comparison with authentic standards. A rapeseed (*B. napus*) standard with added sinigrin was used to validate the Rt for all glucosinolates except for glucoraphanin, for which a radish (*Raphanus sativus*) seed sample was used.

Statistical Analyses The overall analysis of glucosinolate content was performed with separate multivariate analyses of variance (MANOVAs) for foliage and root samples. Total glucosinolate concentration, amount of aliphatic or indole glucosinolates, and individual analyses of glucosinolates were carried out with general linear model (GLM). Intercrop and egg densities were used as variables in the model as well as the squared egg density. The latter density was to reveal nonlinear responses to an increase in damage or plant competition. Data for root gluconapin were analyzed by using a log-link to achieve a normal distribution. GLMs were simplified by removing variables that did not improve the explanatory power. This was done by comparing the simplified model with the original model by using an F test (Crawley 2003). Variables with a P values <0.1 were retained in the model (and are presented in the tables). Nonsignificant variables were excluded as long as they were not included in a significant interaction. Excluded variables are marked with a hatched line in tables, and nonsignificant variables that were retained in the model are marked with N.S. As the number of analyses per root and shoot sample was as many as nine for root and foliage glucosinolates, respectively, a Bonferroni correction would give a corrected P value of 0.006 for a 5% risk of making a Type I error. All analyses were made using S-PLUS statistical software (Insightful Corp. Seattle, USA. S-PLUS® 6.0).

Results

Five aliphatic and four indole glucosinolates were found in the plant samples—all nine were present in both foliage and roots. The aliphathic glucosinolates were sinigrin (2-propenyl), gluconapin (3-butenyl), glucoiberin (3-[methylsulphinyl] propyl), progoitrin (2[*R*]-2-hydroxy-3-butenyl), and glucoraphanin (4-[methylsulphinyl] butyl). The indole glucosinolates were glucobrassicin (indol-3-ylmethyl), neoglucobrassicin (1-methoxyindol-3-ylmethyl), 4-hydroxyglucobrassicin (4-hydroxyindol-3-ylmethyl), and 4-methoxyglucobrassicin (4-methoxyindol-3-ylmethyl).

Total glucosinolate concentration of in cabbage foliage did not changed in response to treatment, although there was a tendency toward a decrease in glucosinolate concentration both due to egg and clover densities (Table 1). Total root glucosinolate concentration was decreased by clover density, particularly at high egg densities (Table 2). In monocultured control plants, the concentration of foliage glucosinolates was 26±6 μmol g^{-1} freeze-dried matter (FDM) and in roots

Table 1 Changes in glucosinolate concentrations in cabbage foliage due to *D. floralis* egg density and clover density

Table presents *P* values, followed by (+) or (−) to describe the changes in concentrations. When nonlinearity was observed (Egg^2), + and – are used to describe the appearance of the curve. A *dashed line* represents variables excluded from the analysis when they did not improve the explanatory power of the GLM.

10±0.6 μmol g^{-1} FDM. The concentrations of individual glucosinolates were generally higher in foliage than in roots, although this was not the case for hydroxyglucobrassicin or for neoglucobrassicin at high egg densities. MANOVA showed that there was an effect of intercropping density on individual glucosinolates for both foliage (approximately F=2.70; $d.f.$=2; P=0.017) and roots (approximately F=4.60; $d.f.$=2; P<0.001). Root glucosinolates were also affected by egg density (approximately F=5.63; $d.f.$=1; P=0.008). GLM analyses suggested that individual glucosinolates responded variously to treatment, even within the aliphatic and indole groups.

Of the foliage glucosinolates, glucobrassicin and aliphatic sinigrin were the dominant compounds in the foliage of monocultured control plants with concentrations of 12±2 and 10±3 μmol g^{-1} FDM, respectively. Glucobrassicin levels decreased in response to intercropping but were not significantly altered by herbivory. The concentrations were almost identical for cabbage plants grown with high and low densities of clover and intercropping at the different egg densities and resulted in a decrease in glucobrassicin by nearly half. No statistically significant responses were found for sinigrin, although there was a tendency toward lower concentrations in infested plants. Of the remaining aliphatic glucosinolates, gluconapin concentration decreased sharply in intercropped plants (Table 1). This compound was found in small amounts in monocultured control plants (0.69± 0.15 μmol g^{-1} FDM) and had a mean reduction of 54% in intercropped plants for all egg densities (mean of IC1 and IC2). Progoitrin (2.1±0.35 μmol g^{-1} FDM in monocultured control plants) was the second most common aliphatic glucosinolate, and the only glucosinolate in the foliage that responded to both egg and clover density—in both cases with a reduction in concentration (Table 1). Glucoiberin and glucoraphanin were not changed by either turnip root fly damage or intercropping, as was the total concentration of

aliphatic glucosinolates (Table 1). The latter was probably influenced by the lack of response by the dominant sinigrin. The concentration of hydroxyglucobrassicin also decreased significantly in intercropped plants. Hydroxyglucobrassicin was a trace glucosinolate component (0.18±0.06 μmol g^{-1} FDM) in monocultured control plants, and decreased by a mean of 53% in intercropped plants at all egg densities (mean of IC1 and IC2). Neoglucobrassicin, the second most common indole glucosinolate (0.89±0.23 μmol g^{-1} FDM in monocultured control plants), decreased in concentration in response to increasing egg densities while the concentration of methoxyglucobrassicin remained unchanged (0.41± 0.15 μmol g^{-1} FDM in monocultured control plants). Similar to glucobrassicin, the dominant glucosinolate in foliage, the total concentration of foliage indole glucosinolates responded to treatment with a decrease with clover density (Table 1).

Root glucosinolates responded differently and in a more complex manner than foliar glucosinolates. Sinigrin was the dominant glucosinolate (6.8±0.3 μmol g^{-1} FDM in monocultured control plants) in roots. Both monocultured and intercropped plant roots contained similar sinigrin concentrations. However, the concentration of sinigrin decreased with egg density in intercropped plants. In monocultured roots, sinigrin concentration was similar to the levels in control plants at all egg densities except for the ten egg treatments where the concentration was somewhat lower. This mixed response caused both an interaction between eggs and clover and a tendency toward a nonlinear response (Table 2, Fig. 1). Progoitrin, another aliphatic glucosinolate, occurred in relatively large amounts in monocultured control plants (1.1±0.2 μmol g^{-1} FDM) and decreased in concentration with increasing clover density (Table 2, Fig. 1). Glucoiberin decreased in concentration in response to both egg and clover densities, while glucoraphanin tended to increase as a result of damage by *D. floralis* (Table 2, Fig. 1). Gluconapin showed a strong nonlinear response as it decreased rapidly with egg inoculation at low

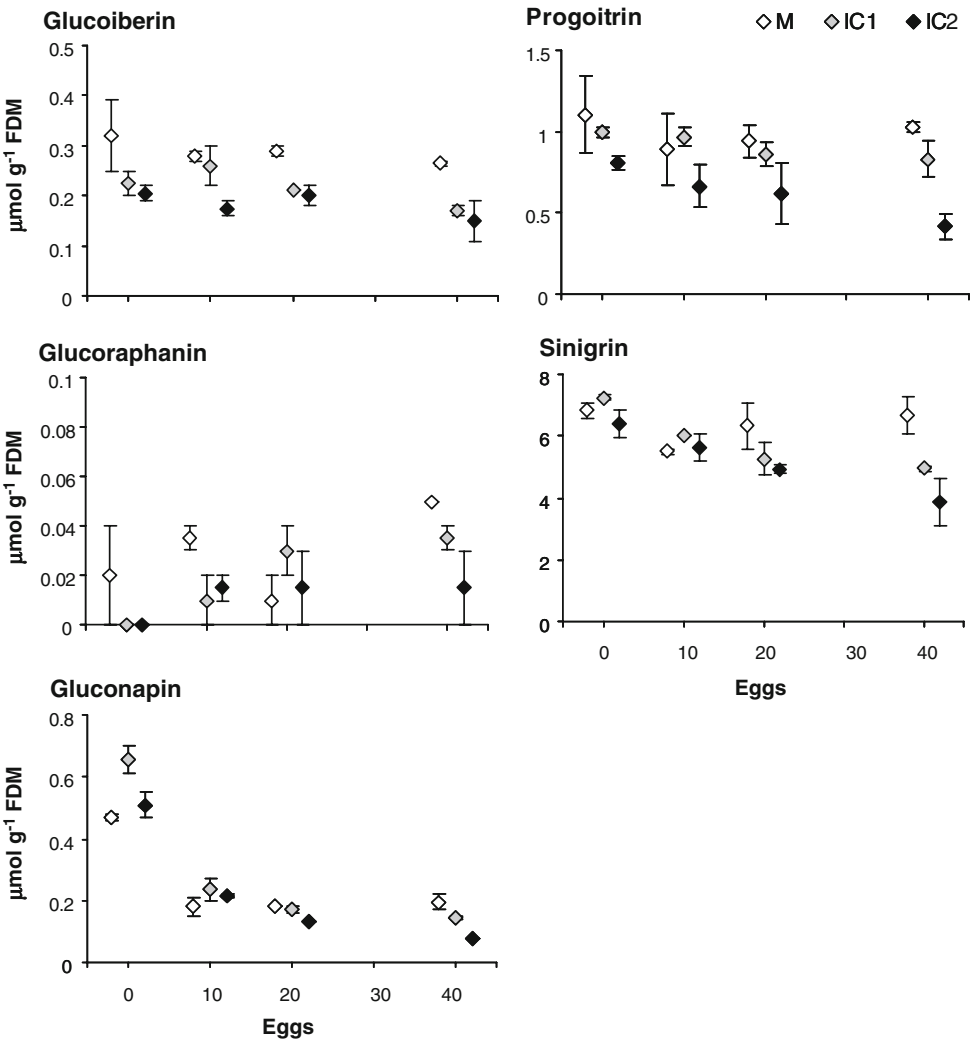

Fig. 1 Changes in concentration of individual aliphatic glucosinolates (μmol g^{-1} FDM) in cabbage roots caused by an increase in clover density (*IC1* and *IC2*) compared with monoculture (*M*), and increasing *D. floralis* egg density (0, 10, 20, and 40 eggs; *N*=2)

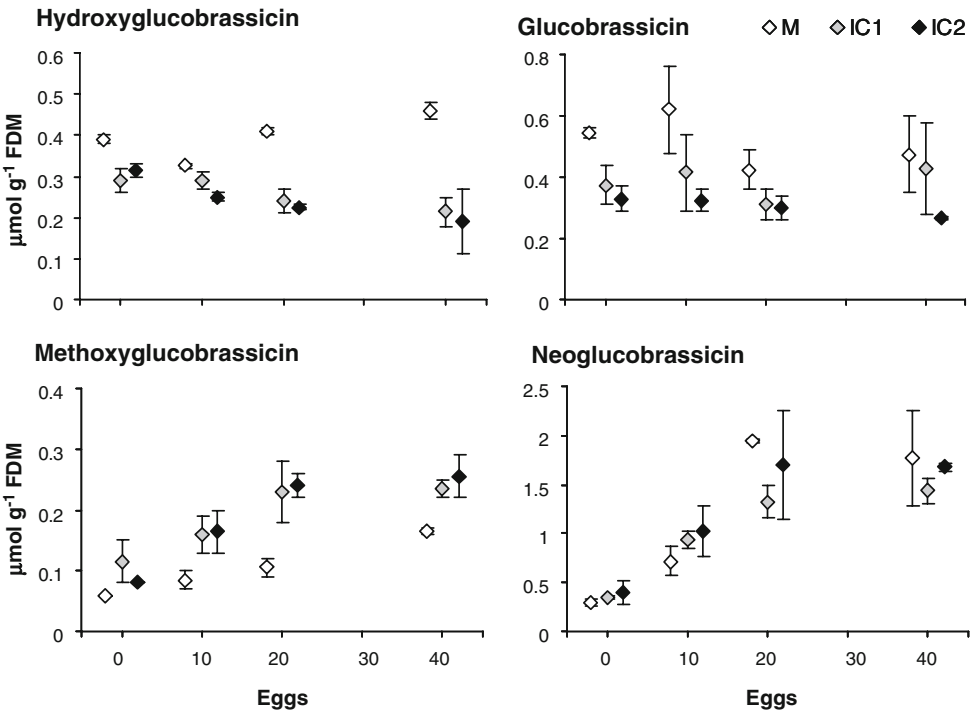

Fig. 2 Changes in concentration of individual indole glucosinolates (μmol g^{-1} FDM) in cabbage roots caused by an increase in clover density (*IC1* and *IC2*) compared with monoculture (*M*), and increasing *D. floralis* egg density (0, 10, 20, and 40 eggs; *N*=2)

egg densities, while additional eggs did not result in much further decreases (Table 2, Fig. 1). The higher concentrations in intercropped control plants and the lower concentrations in intercropped plants with higher egg densities caused an interaction effect between egg and clover (Table 2, Fig. 1). As the aliphatic glucosinolates were dominated by sinigrin, the response of the group as a whole was almost identical to that of sinigrin (Table 2, Figs. 1 and 3).

Of the indole glucosinolates found in roots, neoglucobrassicin responded strongly to egg density and concentrations increased from 0.39±0.01 μmol g^{-1} FDM in monocultured control plants to 1.95±0.03 μmol g^{-1} FDM in monocultured plants at a density of 20 eggs.

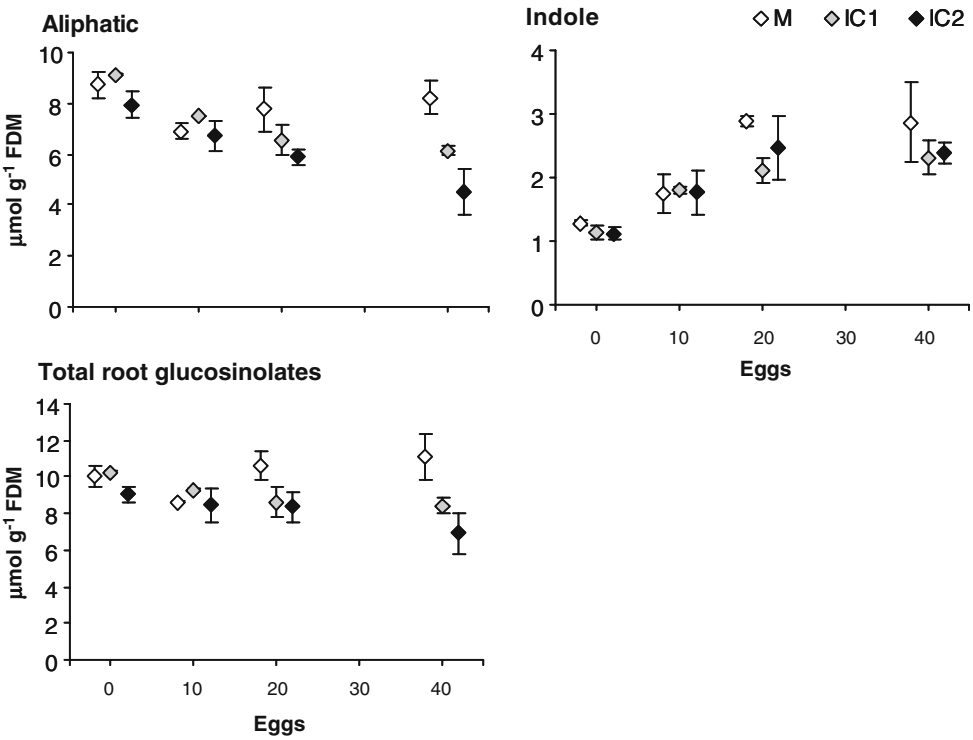

Fig. 3 Changes in concentration of aliphatic, indole, and total glucosinolates (μmol g^{-1} FDM) in cabbage roots caused by an increase in clover density (*IC1* and *IC2*) compared with monoculture (*M*), and increasing *D. floralis* egg density (0, 10, 20, and 40 eggs; *N*=2)

Additional increases did not occur in plants inoculated with 40 eggs, thus, resulting in a significant nonlinear response in monocultured plants (Table 2, Fig. 2). The concentration of hydroxyglucobrassicin had contrasting patterns in cabbage grown in monoculture vs. intercropping. As hydroxyglucobrassicin concentration decreased with egg density at both clover densities, it increased somewhat in the monoculture (Table 2, Fig. 2). The concentration of glucobrassicin was consistently higher when grown in monoculture (Table 2, Fig. 2). Methoxyglucobrassicin increased with egg density. In addition, the concentrations of this glucosinolate were higher in intercropped plants than in monocultured plants (Table 2, Fig. 2). Neoglucobrassicin and methoxyglucobrassicin were the only glucosinolates in roots to respond to egg inoculation with increased concentrations. This means that neoglucobrassicin had opposite reactions in shoots and roots as this glucosinolate tended to decrease with egg density in the foliage. The total concentration of indole glucosinolates increased in response to egg density similar to the neoglucobrassicin, the dominate glucosinolate (Table 2, Figs. 2 and 3).

Discussion

Earlier studies that examined glucosinolate levels in brassicaceous host plants following herbivory by root flies considered larval damage as the sole stress factor. The responses to larval feeding found previously correspond to herbivore-induced changes that occurred in the present study. Indole glucosinolate levels in roots, particularly neoglucobrassicin and glucobrassicin, tend to increase in response to root herbivory in most studies (Birch et al. 1992, 1996; Griffiths et al. 1994; Hopkins et al. 1998a; van Dam and Raaijmakers 2006). Whether or not these studies showed a net increase in the total amount of root glucosinolates seemed to depend on the relative size of the increase in indole glucosinolates vs. the decrease in aliphatic glucosinolates (Birch et al. 1992; Hopkins et al. 1998a). In our study, damage-induced increases in indole glucosinolates and the corresponding decrease in aliphatic glucosinolates did not balance each other out in intercropped roots (Table 2, Fig. 3).

The lack of response to root damage by total leaf glucosinolate content has previously been shown by Birch et al. (1992), although they reported decreases in foliar indole glucosinolates in several brassica cultivars, as also shown for cabbage in this study. It is clear that glucosinolate responses to root fly larval feeding in roots and leaves vary among plant species and genotype (Birch et al. 1992, 1996), as well as on a temporal scale (Birch et al. 1996). Our glucosinolate sampling was performed 6 weeks after egg inoculation at the time of pupation, when larval damage was completed. It is likely that the glucosinolate profile of both roots and leaves may have been different at earlier, or later, sampling dates (Bodnaryk 1992; Griffiths et al. 1994; Birch et al. 1996; van Dam and Raaijmakers 2006).

Besides herbivory, an additional stress factor was added in the present student, namely competition with red clover. The competitive environment within the intercropping is likely to have had consequences for the cabbage plants' ability to defend themselves against *D. floralis* larval feeding. The GDB hypothesis suggests that a plant can either grow or allocate resources to defense, depending on resource availability (Stamp et al. 2004). This should lead to reduced concentrations of defense compounds in competition-stressed plants. The ability of a plant to acquire resources for growth or defense is affected not only by competition but also by root damage, since such damage impairs the plant's ability to acquire resources. Decreased concentrations of several glucosinolates in aerial cabbage parts and the strong tendency towards an overall reduction in glucosinolates (Table 1) suggest that competing plants, as well as plants with root herbivory, do not allocate the same resources as unchallenged plants towards sustaining levels of foliar defense compounds. Total root glucosinolate levels were reduced in intercropped treatments but only at higher egg densities, while glucosinolate levels in monoculture treatments were fairly constant. This suggests that plants subjected to high *D. floralis* infestations are not able to allocate resources to maintain glucosinolate root levels if they are also competing with the clover for light and nutrients. Our findings on secondary compounds in relation to plant competition confirm the results of other studies. For example Stamp et al. (2004) found that foliar concentrations of chlorogenic acid, rutin, and tomatine in tomato (*Lycopersicon esculentum*) decreased with increasing competition. Furthermore, Cipollini and Bergelson (2001) reported decreasing nutrient availability through plant competition-mediated, density-dependent reductions in trypsin inhibitor levels of in *B. napus* seedlings. They later showed that this decrease in defense led to higher levels of leaf herbivory in a field situation (Cipollini and Bergelson 2002). From the results of this study, it is clear that within the usual division of glucosinolates into aliphatic, aromatic, and indole-based, that certain glucosinolates may not respond uniformly to herbivory or plant competition. Even if relevant to describe changes in different glucosinolate groups classified according to structure, this is likely to conceal the fact that individual glucosinolates within each group may respond in different manners. For cabbage roots, this was the case for methoxyglucobrassicin, which, in contrast to other indole glucosinolates, increased in intercropped treatments (see Fig. 2). It was also evident that the changes that occur within a glucosinolate group may be strongly influenced by changes in a single compound

(Griffiths et al. 1994; Hopkins et al. 1998a; van Dam and Raaijmakers 2006). In cabbage foliage, only indole glucosinolates responded to treatment with increasing clover density by decreasing the dominating glucobrassicin. The responses of aliphatic and indole glucosinolate groups in roots were dominated by sinigrin and neoglucobrassicin, respectively Our results confirm the importance of considering nonlinear responses, as they were observed to occur in several instances. Root gluconapin and neoglucobrassicin concentrations had the strongest nonlinear responses. In swede roots (Hopkins et al. 1998a), neoglucobrassicin and gluconapin had nearly identical nonlinear responses to increased egg load as found with cabbage in this study. A nonlinear response of glucobrassicin has also been shown for *B. napus* cotyledons wounded mechanically through an increasing number of needle punctures (Bodnaryk 1992). The additional stress from competition in this study also affected nonlinear responses to herbivory. The interaction between intercropping and egg density for gluconapin in roots could be explained by the nonlinear response to an increased herbivore load being more marked in intercropped roots than for monocultured cabbage.

Both root and leaf herbivories could have negative implications for the subsequent development of specialist leaf herbivores through systemic induced changes in the glucosinolate-myrosinase system in undamaged leaves (van Dam et al. 2005; Martin and Müller 2007). An indication of systemic induction of glucosinolate concentrations in response to larval damage in our study was the minor, but significant, decrease in foliar progoitrin and neoglucobrassicin. The effect of intercropping, which decreased concentrations of gluconapin, hydroxyglucobrassicin, and glucobrassicin in intercropped cabbage foliage, is likely to be a result of both above- and below-ground competition, as intercropped cabbage plants at the end of the experiment were almost overgrown by the clover. Glucobrassicin and gluconapin have been identified as oviposition stimulants for *D. radicum* and *D. floralis* (Roessingh et al. 1992; Simmonds et al. 1994; Gouinguené and Städler 2006), as well as other specialists, such as *Pieris brassicae* (van Loon et al. 1992). A decrease in the concentration of these compounds in aerial parts resulting from plant competition could lead to less attractive cabbage plants for specialized pest insects in intercropped systems. In contrast, lower leaf glucosinolate levels may have implications on the generalist herbivore community, as infestation levels may increase as defense levels decrease (Cipollini and Bergelson 2002). Changes in the glucosinolate profile of roots by competition and herbivory are most likely important for subsequent *D. floralis* and *D. radicum* females approaching plants for the purpose of oviposition. *D. radicum* females prefer to lay eggs on plants with moderate damage compared with undamaged or heavily infested plants (Baur et al. 1996a), and cues perceived from the roots of these plants are likely to be of importance for host selection by females (Baur et al. 1996b).

To evaluate the importance of the changes in this and other studies for host seeking and preference of brassica-specialized insects, one needs to investigate how the actual changes are perceived by herbivores. Evaluations of single factors in complex systems are far from easy, as other plant characteristics change at the same time as the concentrations of secondary compounds change, e.g., plant biomass, nutrient and fiber content (Björkman, unpublished data). Adding competition to the study of herbivore-induced glucosinolate responses has revealed complex relationships between responses and causal agents. This shows the importance of investigating the impact of multiple challenges on plant composition and the possible implications for herbivore host plant search and acceptance.

Acknowledgements This project was funded by the Swedish Research Council for Environment, Agricultural Sciences and Spatial Planning (FORMAS), and the Swedish University of Agricultural Sciences (SLU). Special thanks to Peter Hambäck, Department of Botany, Stockholm University, for help with the statistical analysis and comments on the manuscript. We would also like to thank Anna-Karin Borg-Karlsson, The Royal Institute of Technology, Sweden, for helpful comments on the manuscript.

illustrated by R-(+)-pulegone's ability to depolarize root membrane potentials (Maffei et al. 2001) and inhibit bacterial growth in low concentrations (<5 mg dm^{-3}; Oumzil et al. 2002). R-(+)-pulegone, known as a major constituent of pennyroyal, is hepatotoxic and pulmotoxic in rats, mice, and humans (Sullivan et al. 1979; Gordon et al. 1982; Thorup et al. 1983; Madsen et al. 1986; Anderson et al. 1996). Pennyroyal tea has been used by people against various ailments and as an abortifacient, sometimes leading to death because of the toxicity of R-(+)-pulegone (EMEA 2005).

Domestic goats and sheep have browsed and grazed the Mediterranean and Middle East for thousands of years. These animals have decimated many palatable plant species. The resulting "antipastoral vegetation" is dominated by plants with spines, thorns, leathery, or woolly leaves and stalks, and strongly aromatic or bitter compounds thought to act as chemical defenses against herbivores. Aromatic compounds, essential oils comprising mixtures of mono- and sesquiterpenoids, may deter herbivores either by immediate sensory experiences (i.e., taste or smell) or by causing negative postingestive consequences resulting in conditioned food aversions (Duncan et al. 2005). We studied monoterpene levels in thyme basil (*A. suaveolens*) growing in Greece under two environmental conditions: on rangeland heavily used by goats and sheep and on inaccessible rock pillars in the same area.

Methods and Materials

Study Site A unique group of rock pillars in Greece (Fig. 1) carries vegetation and is surrounded by heavily pastured livestock range with many plants of the same species as on the pillar. This permits a comparison of plant defenses in individuals of the same plant species that are inaccessible to goats and sheep (exclosure effect) to those that are exposed to browsing. The approximately 100 Metéora rock pillars consist of conglomerate and are located in central Greece's Plains of Thessaly in the valley of the Pinios River (approximately 21°30′ E and 39°30′ N), bounded by the Pindus Mountains in the West and the Khasia Range to the East. The Ambaria, Dupiani, and Aghia Apostoli (more commonly known as Grosse Heilige) pillars range between 150 and 300 m high (Stutte and Hasse 1986). In this study, DMS observed that local grazing sheep and goats ignore thyme basil, *A. suaveolens*, as they moved through stands of this plant.

Field Collection Terpenoid-based defenses show large between-individual variability (Sjödin et al. 2000; Latta et al. 2000, 2003; Langenheim 2003; Thoss et al. 2007) that makes detecting an environmental influence on overall production or composition in the field more challenging. In this study, we addressed inherent variability by taking nine samples per site and using six different sites, three of which were located on rock pillars and three in the rangeland surrounding these pillars.

The pillars are accessible only by technical rock climbing. On the summits of these pillars and on the livestock range below, DMS harvested at each location about ten nonflowering shoots from each of three–five plants during late April. Back at base, three shoots were randomly selected and five leaves plucked from each on the day of collection. The leaves were cut into thirds: leaf base, middle, and tip. Leaf bases of the five leaves were put

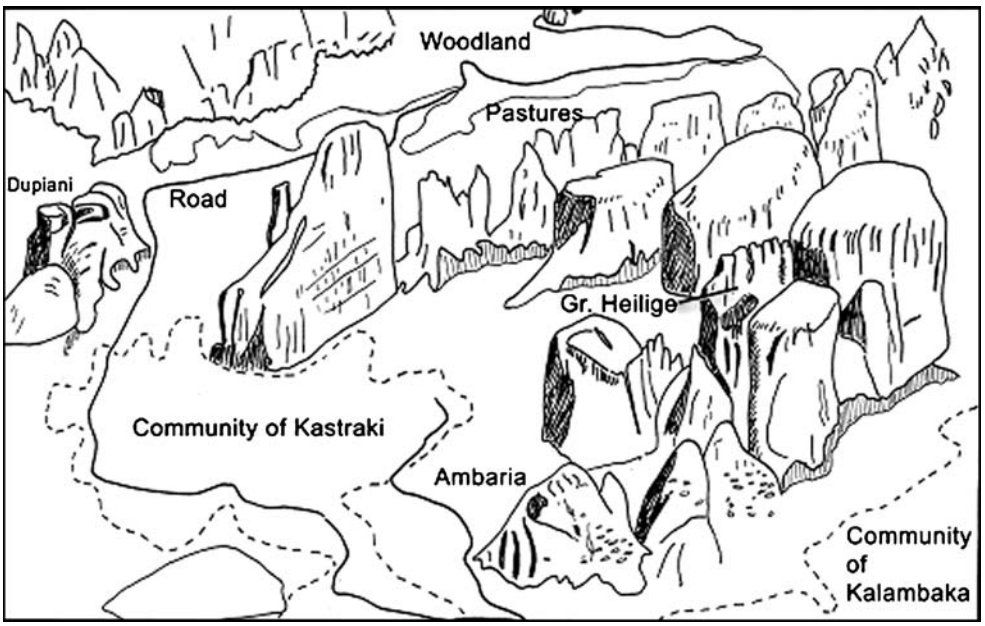

Fig. 1 Rock pillars at Meteora. The locations of the sampling sites Dupiani, Grosse Heilige (Aghia Apostoli), and Ambaria are shown. Approximate distance from *left* to *right* is 1.5 km. Redrawn with permission after Rohweder 1996

together in one screw cap vial (5 ml) with hexane (1 ml) and menthone (10 mg dm^{-3}) as procedural standard. The middle sections of five leaves were placed into another vial and the tips in a third vial. Upon completion of the collection, samples were air-shipped from Athens to Aberdeen.

Chemical Analysis The solvent extract was removed from the leaf sections and fenchone was added as internal standard to a final concentration of 20 mg dm^{-3}. The concentration of menthone (after subtraction of added procedural standard) and R-(+)-pulegone were determined on a Trace GC 2000 version 1.3 with a Trace DSQ version 1.3.0 SP4 mass spectrometer. The column was Sol Gel 10–25 (30 m length× 0.25 mm i.d. from SGE, UK). Injection volume was 1 µl with a 1:80 splitting ratio. The temperature program started at 70°C (held for 2 min), followed by a ramp of 10°C up to 130°C, followed by a 50°C ramp up to 200°C. The software for data capture and analysis was Xcalibur™ version 1.3. Identification and quantification was based on commercial R-(+)-pulegone (technical grade, 85% purity) and menthone (>99% purity) standards (from Sigma). The leaf material was dried at 50°C to obtain dry matter (DM).

Statistical Analyses Minitab Release 14 was used for statistical treatment of the data. At each location, for example "Range at Dupiani", 27 samples were taken, giving 162 samples in total. These samples related to nine different sets of plants, which had been split into top, middle, and bottom leaf sections. Since significant differences were not found between top, middle, and bottom sections (one-way analysis of variance (ANOVA)), the means for each sample derived from top, middle, and bottom sections were used for further calculation. The data was transformed by taking the square root of the concentration to achieve normality (Kolmogorov–Smirnov test). A two-way ANOVA was conducted for R-(+)-pulegone and for menthone, respectively. Factors used were "range or pillar" and "location" referring to the three different areas sampled.

Results

The average concentrations in *A. suaveolens* determined in this study were 8.4±1.4 mg R-(+)-pulegone, 3.7±0.14 mg menthone, and 12.1±1.4 mg total monoterpenoids (all per g DM). R-(+)-pulegone levels were higher ($P<0.001$) in plants growing on the range at the foot of the rock pillars where sheep and goats roamed freely than on the pillars, while the concentrations of menthone were similar (Table 1; Fig. 3). The results suggest that herbivory may be associated with higher absolute and relative concentrations of R-(+)-pulegone. This is true for all three pillars sampled (Fig. 2). Levels of R-(+)-pulegone and menthone did not differ significantly among tips, middle sections, and leaf bases, although there was a nonsignificant tendency for lower levels at the tips of the leaves than at their base or middle.

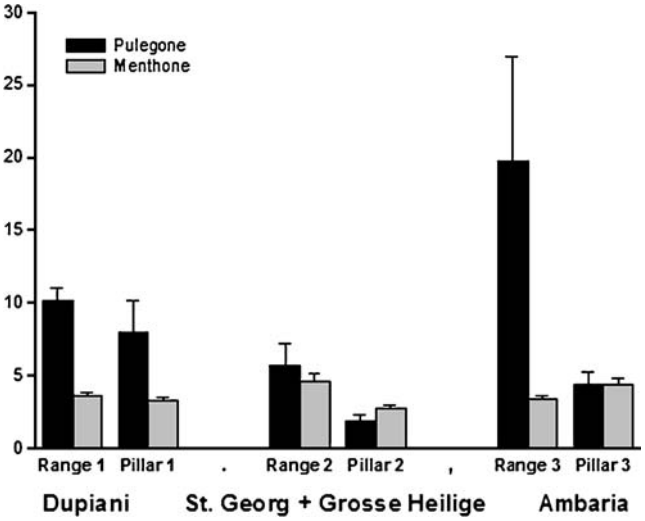

Fig. 2 The mean concentrations of R-(+)-pulegone and menthone in *A. suaveolens* leaves collected from three different pillar and range locations. *Error bars* are ±1 SE (N=9)

Discussion

The biosynthesis of menthone from R-(+)-pulegone via (+)-pulegone reductase in peppermint has been documented (Gershenzon et al. 2000; McConkey et al. 2000; Turner and Croteau 2004). Surprisingly, the genetic modification of peppermint to reduce menthofuran synthesis by down-regulating cytochrome P450 menthofuran synthases resulted in reduced R-(+)-pulegone content (Mahmoud and Croteau 2003). Despite elucidation of the genetic basis

Table 1 R-(+)-pulegone and menthone concentrations in thyme basil (*A. suaveolens*) from range vs. pillars (means±standard error (SE); *F*- and *P*-values from two-way ANOVA on square root transformed data)

	Range (N=27)	Pillar (N=27)	*P*-value	*F*-value
R-(+)-pulegone (mg (g DM)$^{-1}$)	11.72±2.38	4.73±0.92	<0.001	16.84
Menthone (mg (g DM)$^{-1}$)	3.89±0.19	3.45±0.22	0.076	3.29
(mg (g DM)$^{-1}$)	15.61±2.38	8.18±1.00	0.001	12.66
R-(+)-pulegone (%)	66.3±3.5	47.5±4.0	<0.001	12.52

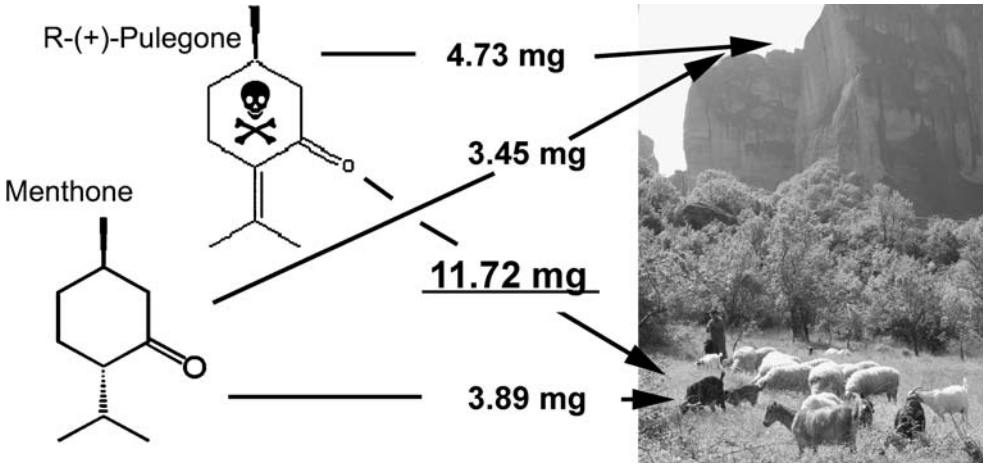

Fig. 3 Visual summary of the main results: concentrations of menthone and R-(+)-pulegone on *summits* and range *below summits*

for monoterpenoid production in peppermint, the actual content and composition seem to depend to a large extent on environmental conditions (Burbot and Loomis 1967; Voirin et al. 1990). Thyme basil produces two monoterpenoids and, therefore, its biosynthetic complexity is reduced compared to peppermint. In addition, the plasticity of (+)-pulegone reductase seems to support our findings of a significantly higher proportion and absolute concentration of R-(+)-pulegone in thyme basil plants accessible to herbivores. That environmental factors influence gene expression is further supported by significant differences among the three locations at Dupiani, Grosse Heilige, and Ambaria (P=0.001 and F=8.00; Fig. 2).

One difference between R-(+)-pulegone and menthone is the reported toxicity of either compound. For menthone, the no-observed-effect level orally for rats was <200 mg/kg body weight per day (Madsen et al. 1986), which is a magnitude higher than the 20 mg per kg body weigh per day for R-(+)-pulegone (Thorup et al. 1983). In addition, the mode of action of R-(+)-pulegone toxicity has been shown to involve covalent binding of the compound to liver proteins (McClanahan et al. 1989) through destruction of microsomal cytochrome P-450 (Moorthy et al. 1991). Our results show that, depending on the location and selective pressures it is exposed to, thyme basil responds by a selective increase in the more biologically active compound, requiring less energy to be expended for a similar level of protection.

Goats consume at least 3% of their body weight in dry plant matter every day. Assuming an adult goat weighing 50 kg, its daily consumption of dry plant matter is at least 1.5 kg. In the Metéora with its antipastoral vegetation, the intake is likely to be higher. In humans, at a concentration range between 90 to 150 mg per kg body weight, R-(+)-pulegone causes moderate to severe toxicity, while an estimated intake of about 130–215 mg R-(+)-pulegone per kg body weight in the form of pennyroyal essential oil is lethal due to centrilobular necrosis of the liver, pulmonary edema, and internal hemorrhage (EMEA/HMPWP/52/04). With the mean concentration of R-(+)-pulegone in the range plants studied, the consumption of 500 g DM of *A. suaveolens* is likely to be hepatotoxic for an adult goat. As goats are capable of associating negative postingestive consequences with a specific blend of volatile components (Duncan et al. 2005), their avoidance of *A. suaveolens* as observed in the field might be caused by previous experiences of R-(+)-pulegone toxicity.

This study adds further supportive evidence to the influence of mammalian browsing on plant chemical defense. Since plants on the pillars still face insect predation, they are expected to maintain certain levels of chemical defense. The studied system permits the separation of these two different herbivore pressures on plants. Absence of mammalian herbivores can affect plants in complex ways. For example, exclusion of large herbivores such as elephants and giraffes from stands of whistling thorn acacia trees (*Acacia drepanolobium*) leads to reduced secretion of "nectar" from leaf base glands. This makes the tree less attractive to a certain species of ant that defends the tree against mammals. Less defended by ants, the trees now succumb to other insects such as longhorn beetles (Palmer et al. 2008). In the case of *Acinos* at Metéora, other environmental factors such as water stress on the pillars with their thin soil cover cannot be ruled out at this point.

Of particular interest is the selective increase in the 'more toxic' R-(+)-pulegone in plants available to goats. Whether the measured concentrations and composition reflect a genetic difference among the plants, whether it occurred as induced response to browsing, or a combination of both, requires further study. Genetic isolation is unlikely, as seeds and pollen can travel between the pillars via wind, birds, and/or insects. Given individual variation between plants, livestock browsing may select for better defended specimens. Alternatively, browsing may phenotypically boost monoterpenoid levels in the same plant.

Acknowledgments We thank the rock climbers, notably Dietrich and Ursula Hasse, and Detlef Augustin for their guidance, both in locally facilitating the project and "hands on" leading on the rocks. The Macaulay Institute, Craigiebuckler, Aberdeen AB15 4QH, UK is acknowledged for access to analytical facilities.

of large-scale patterns of phenolic plant compounds. Factors that regulate carbon allocation to secondary compounds in plants are usually investigated by small-scale experiments, where one or two ecological factors are manipulated. It is poorly known how concentrations of phenolics vary with geographic or landscape changes. Earlier chemotaxonomic studies in conifers indicated that the concentrations of some flavonoids and monoterpenes vary in different latitudes (Hiltunen 1975; Laracine-Pittet and Lebreton 1988; Nerg et al. 1994). Latitudinal and regional variations in the concentrations of phenolics in naturally occurring white birch (*Betula pubescens* EHRH) populations have so far not been investigated. In birches, phenolics constitute a large fraction of foliar biomass. Concentrations vary with several different factors, such as soil nutrient availability (Ruohomäki et al. 1996; Mutikainen et al. 2000; Keski-Saari and Julkunen-Tiitto 2003; Stark et al. 2007), UV radiation (Tegelberg et al. 2001; Keski-Saari et al. 2005), and herbivory (Tuomi et al. 1990; Ruohomäki et al. 1996; Kaitaniemi et al. 1999; Mutikainen et al. 2000; Henriksson et al. 2003; Riipi et al. 2005).

In order to test whether variation in phenolic concentrations at the landscape level agree with the experimental evidence for the ecological factors that regulate phenolic concentrations in white birch, we conducted two separate investigations. First, we conducted a climatic transect of birch populations in boreal forests from south to north (from 60° to 70° north) in Finland and analyzed the concentrations of phenolics in birch populations along the transect. Second, we investigated the correlation between foliar phenolics and site characteristics, such as soil element concentrations, exposure on the sunny or shady slope in the landscape, temperature sum, and foliar biomass on a regional scale. Flavonoids in plants have beneficial properties for human health and, therefore, the potential for their use for antioxidative and anti-inflammatory purposes has received increasing attention (Rauha et al. 2000; Wojdylo et al. 2007). Our objective was also to examine whether the landscape variation in the concentration of phenolics could be used as a tool to select sites for gathering birch leaves with high concentrations of flavonoids.

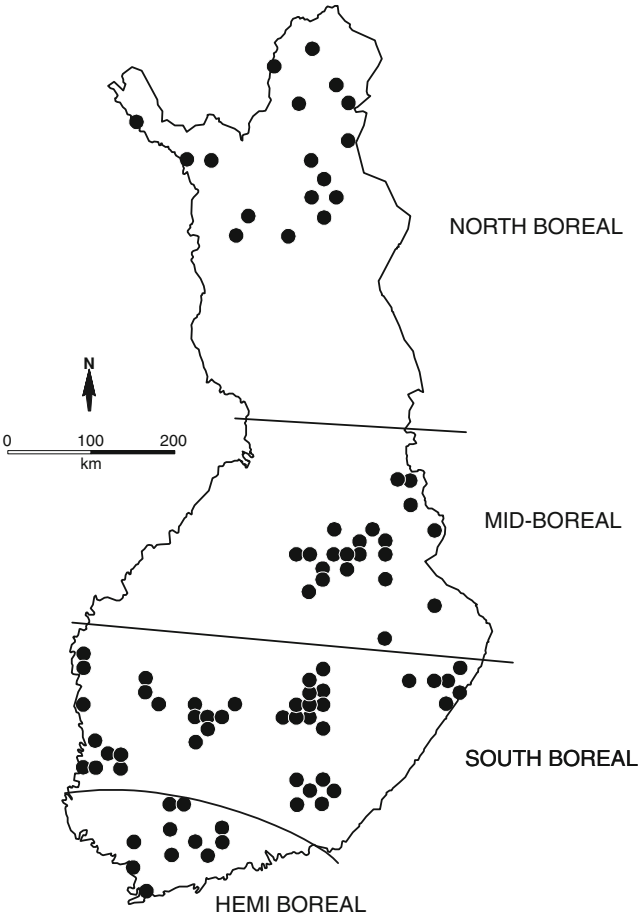

Fig. 1 Map of the study sites used in the north–south transect for investigating latitudinal variation and the effect of climatic zone on the concentration of flavonoids and condensed tannins in the white birch foliage (91 study sites)

Methods and Materials

The South–North Climatic Transect We collected leaf samples from *B. pubescens* in 91 study sites that belong to the National Forest Inventory network in Finland (Fig. 1). Following approximately the division of vegetation zones in Finland (Kalela 1958), we classified the study sites into the following four climatic zones: hemiboreal, southern boreal, midboreal, and northern boreal. Genetic variation among birch trees can sometimes override the effects of nutrient availability, simulated herbivory, or enhanced or excluded UVB radiation (Laitinen et al. 2000, 2004; Mutikainen et al. 2000; Keski-Saari et al. 2005). Our aim, however, was to identify differences between large areas and to cover the variation among the birch clones; we collected leaf samples randomly from at least ten different birch trees at each site. In the north, *B. pubescens* may hybridize with *Betula nana* and form the subspecies *B. pubescens* ssp. *czerepanovii*, the mountain birch. We did not distinguish between pure white birch and the mountain birch but collected random samples of trees. Our data thus represent the large-scale patterns of the concentration of phenolic compounds in birch that may result from either genotypic differences between birch populations, or phenotypic responses to environmental conditions.

Site Characteristics that Correlate with the Concentration of Flavonoids and Condensed Tannins In addition to the general investigation on the north–south gradient, we investigated factors that correlate with the concentrations

of flavonoids and condensed tannins on a regional scale. For this purpose, 38 sites were selected randomly in a study area in northern Finland (Fig. 2; latitude 65–68° north). These sites do not overlap with the sites used in the climatic gradient but constitute a selection of young forest sites. Therefore, data in this study represent a situation in which variation caused by the development stage of the forest is excluded. The following criteria were used in the selection of sites: (1) the sites represent young successional development stages and (2) the proportion of birch coverage is at least 50%. From each site, leaf samples were collected from ten trees. A forest inventory was conducted for birch density, height, and leaf biomass during June and early July, 2006. Mean birch leaf biomass was estimated by selecting a median tree, and the foliar biomass was removed and weighed. Leaf biomass (dry weight) then was used for scaling foliar analysis from a concentration basis into amounts per tree and per hectare.

Forest data for the analysis were provided by Metsähallitus (the government agency that manages state-owned forests in Finland). Geochemical data from the Geological Survey of Finland, which gave concentrations of 37 different elements, then was added to the data files. The following parameters were added to the data: (1) long-term *annual temperature sum*, obtained by a model (Ojansuu and Henttonen 1983); (2) *slope*, calculated by the differences in altitude; (3) *hill shade*, describing the sun exposure in each pixel in the digital elevation model and calculated by the angle of the sun, the direction of the slope, and the angulation of the slope; and (4) *topographic wetness index*, which combines local upslope contributing area and slope.

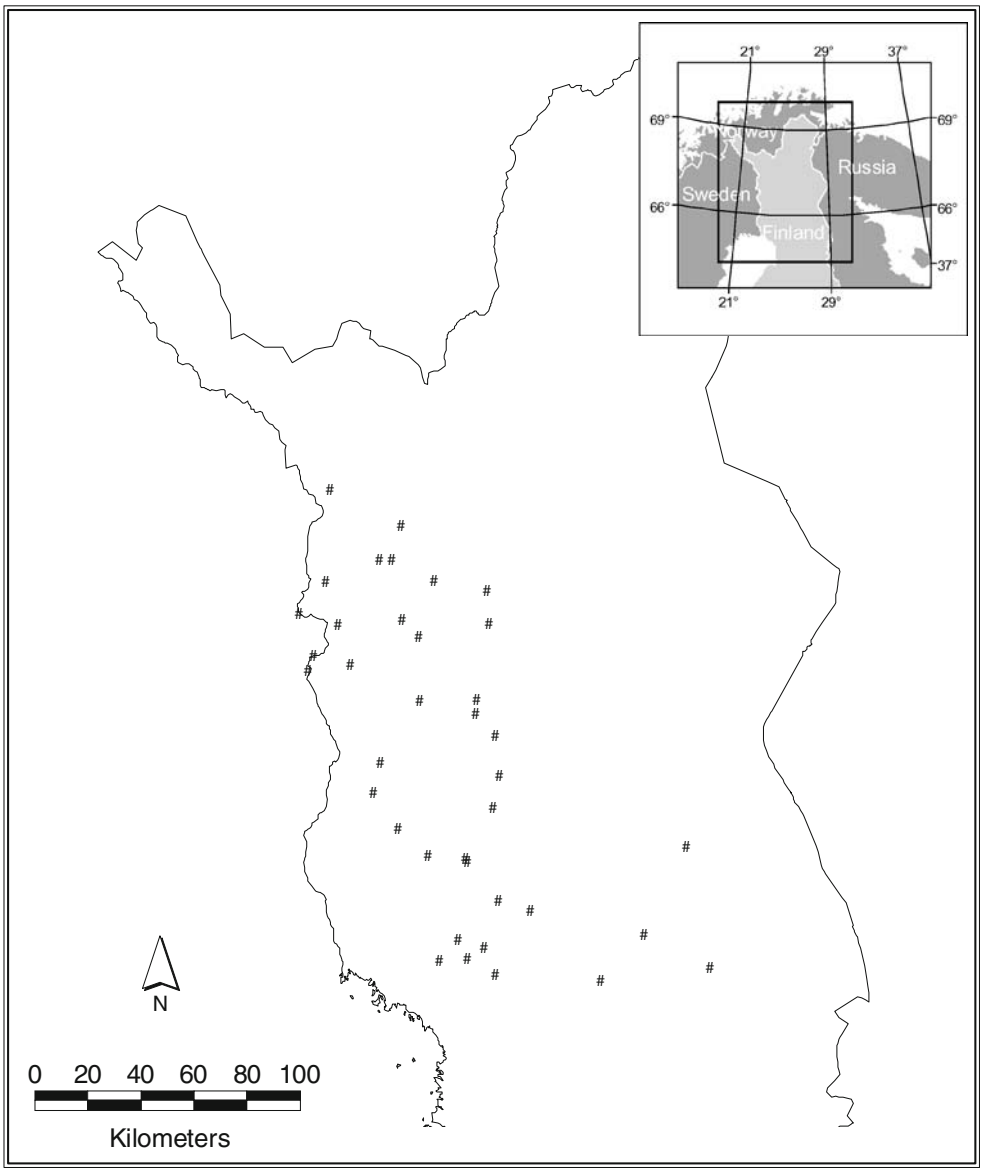

Fig. 2 Map of the study sites used to investigate factors that correlate with the concentration of flavonoids and condensed tannins on a regional basis (38 study sites)

Chemical Analysis of Birch Leaves Leaf samples were oven-dried at +48°C for 48 h and then milled to a fine powder, which was extracted with methanol for the high performance liquid chromatography (HPLC) analysis of phenolics (Julkunen-Tiitto 1985). Briefly, 8 mg of dried material were extracted three times in 400 µl of methanol. Methanol from the combined extracts (1.2 ml) was evaporated under a flow of nitrogen gas. Dried samples were redissolved in 200 µl of methanol and 200 µl of water and analyzed by HPLC with an RP C18 column and an injection volume of 10-µl HPLC conditions. Identification of the compounds was based on retention times, UV spectra, and HPLC–mass chromatography detection as described (Keski-Saari and Julkunen-Tiitto 2003). A wavelength of 320 nm was used for quantification of flavonoids. Concentrations were calculated with the following standards: kaempferol 3-glucoside for kaempferol derivatives, apigenin 7-glucoside for apigenin derivatives, quercetin 3-galactoside for quercetin derivatives, and myricetin 3-rhamnoside for myricetin derivatives. Condensed tannins were determined directly from dried and milled material by an acid butanol assay (Porter et al. 1986), which gives the total amount of condensed tannins (both soluble and cell-bound condensed tannins) in the leaves. Purified condensed tannin from *B. nana* leaves was used as the standard. All results were calculated as concentrations per unit leaf dry mass (mg g^{-1}). Results for the regional study were also calculated as amount per tree and per hectare.

Data Analysis Concentrations of birch flavonoids change with the age of leaves and are higher in young leaves compared to mature ones (Salminen et al. 2001; Laitinen et al. 2002; Riipi et al. 2002). Similarly, concentrations of condensed tannins are lower in young leaves compared to mature leaves (Riipi et al. 2002; Stark et al. 2007). For investigating latitudinal differences, it was crucial to collect leaf samples in exactly the same stage of development in different climatic zones. After conducting the analysis, phenological observations conducted regularly by the Finnish Forest Research Institute (http://www.metla.fi/metinfo/fenologia/index-en.htm) were used to standardize the leaf development stage in samples taken from the different climatic zones. The observations distinguish three stages of development: emergence of leaves, onset of leafing, and full growth of leaves. In each climatic zone, we used only samples collected at the onset of leafing for the statistical analysis. This reduced the total number of replicates from 91 to 54. Samples from the following dates were used: 29th May–4th June in the hemiboreal zone, 23rd May–4th June in the southern boreal zone, 5th June–15th June in the midboreal zone, and 8th June–19th June in northern boreal zone.

For testing the role of the climatic zone in concentrations of flavonoids, data were tested with one-way analysis of variance (ANOVA) with Tukey's multiple comparisons as a post hoc test. The effect of climatic zone on the concentrations of flavonoids was analyzed both for individual substances and substances pooled into the flavonoid groups (quercetin, myricetin, kaempferol, apigenin, and naringenin derivatives), and the pooled concentrations were used for data analysis. The sum of all flavonoids was calculated, and correlation between the phenolics and latitude was examined by using linear regression. Correlations with the site characteristics and concentrations of flavonoids on a regional basis were examined with stepwise linear regression. All statistical analyses were performed with SPSS 12.0 statistical software.

Results

Concentrations of Flavonoids and Condensed Tannins in a North–South Transect A total of 16 flavonoid substances were identified in the birch leaf samples, and the concentration of nine of these was influenced significantly by the climatic zone (Table 1; one-way ANOVA). When individual flavonoids were grouped into compound groups, there was a significant effect of climatic zone on the concentration of quercetin, apigenin, and naringenin derivatives and condensed tannins (Table 1; one-way ANOVA). The concentrations of quercetin derivatives in the northern boreal zone were significantly higher compared to other zones, whereas there were no differences between the hemiboreal, south boreal, and midboreal zones (Tukey's test; Fig. 3). By contrast, the concentrations of both apigenin and naringenin derivatives were significantly higher in the south boreal zone compared to the other zones. Concentrations of condensed tannins in the midboreal zone were significantly higher than in the other zones. There was no difference among the climatic zones in the concentration of kaempferol and myricetin derivatives, although some individual kaempferol derivatives differed by climate zone (Table 1). There was a significant influence of the climatic zone on the total sum of flavonoids (calculated as the sum of all identified substances), which was lower in the midboreal zone than in the other zones (Tukey's test, values not shown).

Analysis by linear regression showed that latitude correlated positively with concentrations of quercetin derivatives and negatively with the concentrations of apigenin and naringenin derivatives (Fig. 4). There was no correlation between latitude and concentrations of total flavonoids and condensed tannins. There was significant negative correlation between the concentration of total flavonoids and condensed tannins.

concentration of foliar flavonoids in the white birch populations was best explained by the temperature sum and the concentration of P in the geochemical mapping data, which together accounted for 53.1% of the variation in flavonoid concentrations (stepwise linear regression, $F=19.2$, $P<0.001$). The correlation coefficients in the analysis showed that the flavonoid concentration was correlated positively with the temperature sum, which explained a large proportion of the variation. However, flavonoid concentration correlated negatively with the P concentration (Fig. 5). When different compound groups were tested separately, the concentration of kaempferol derivatives ($F=12.4$, $P=0.001$, $R^2=25.7$), apigenin derivatives ($F=13.0$, $P=0.001$, $R^2=26.5$), and naringenin derivatives ($F=19.6$, $P<0.001$, $R^2=35.3$) were correlated positively with the temperature sum, whereas no correlation was observed for quercetin or myricetin derivatives (values not shown). Of the separate compound groups, only the concentration of apigenin derivatives was correlated negatively with soil P concentrations ($F=6.0$, $P=0.019$, $R^2=14.4$). The concentration of condensed tannins in birch leaves correlated negatively with slope, which explained 24.9% of the variation in the condensed tannin concentrations, but not with any other parameters used in the analysis (stepwise linear regression, $F=11.6$, $P=0.002$). There was no correlation between concentrations of flavonoids and condensed tannins.

When calculated as the amount of flavonoids per tree, flavonoids were best explained by leaf biomass and tree diameter together with temperature sum and slope ($F=76.8$, $P<0.001$, $R^2=0.903$, stepwise linear regression). The amount of flavonoids calculated per hectare was not correlated with any of the site characteristics other than the number of trees per hectare and the leaf biomass ($F=50.9$, $P<0.001$, $R^2=0.744$). Similarly, the amount of condensed tannins per tree was correlated with the leaf biomass and the slope ($F=172.1$, $P<0.001$, $R^2=0.902$), but the amount of condensed tannins per hectare was correlated only with the number of trees per hectare and the leaf biomass ($F=62.6$, $P<0.001$, $R^2=0.782$).

Discussion

In our investigation along a climatic transect from southern to northern Finland, we found that the concentrations of quercetin derivatives in the white birch foliage increased with latitude, while the concentrations of apigenin and naringenin derivatives decreased with latitude. The compound-specific latitudinal gradients compensated each other, resulting in no changes in the total concentration of flavonoids with latitude. Thus, our results demonstrate a qualitative, but not quantitative latitude-associated gradient in the foliar flavonoids of white birch. As the randomly selected study sites differed greatly in their properties, such as the successional state of the forest, the age of trees, and site fertility, the flavonoid concentrations varied to a great extent also within the climatic zones. In addition to the variation mediated by site characteristics, in our data of 53 study sites across Finland, the latitude explained 10–17% of the variation of the flavonoid groups.

The increasing concentrations of quercetin derivatives towards the north indicate higher need for protection against photooxidative stress there than in the south. White birch responds to enhanced UVB radiation with enhanced synthesis of quercetin derivatives (Keski-Saari et al. 2005). Excess light in relation to the photosynthetic capacity in plants causes formation of reactive chemicals that may cause oxidative damage in plant tissue (e.g., Asada 1994). Due to their chemical features, such as two hydroxyls in the B ring in an optimal location and 2,3-double bond with the 4-oxo function in the C ring, quercetin derivatives exert strong antioxidant activity (Larson 1988; Rice-Evans et al. 1996), and their antioxidant activity is many times higher (4.7 mM) than that of e.g., apigenin and naringenin (1.5 mM; Rice-Evans et al. 1997). Although the concentration of total flavonoids does not change with latitude, the change in the

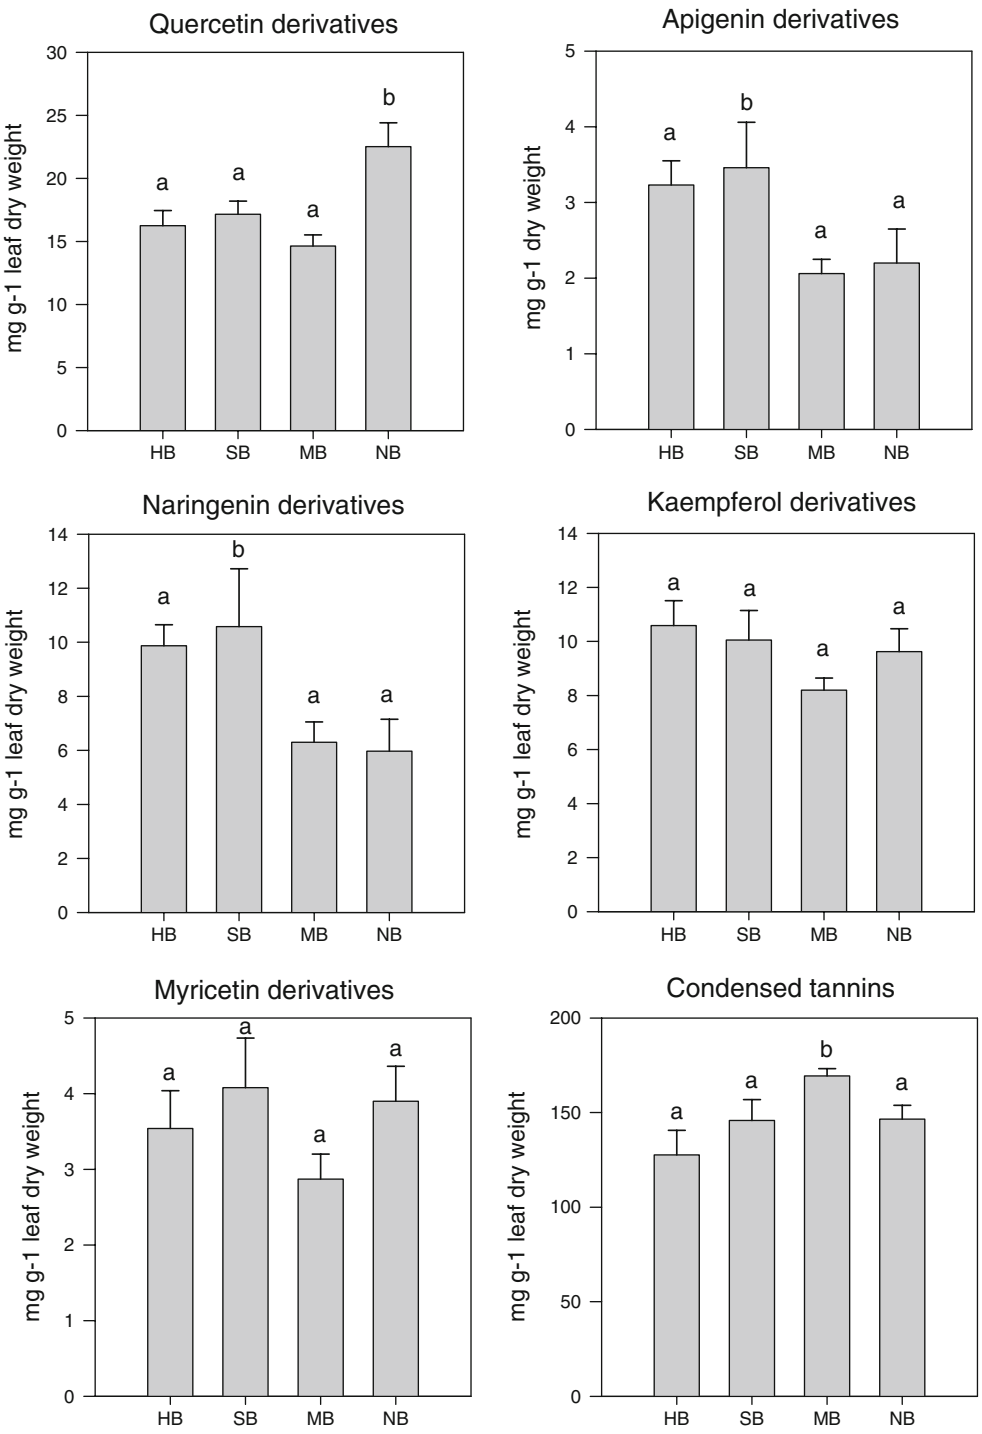

Fig. 3 The concentration of flavonoids in different compound groups in the different climatic zones. Values are mean + standard error, $N=54$ study sites. Significant differences ($P<0.05$) determined by Tukey's test are indicated by *different letters*. The climatic zones are: *HB* hemiboreal ($N=6$ study sites), *SB* south boreal ($N=16$ study sites), *MB* middle boreal ($N=17$ study sites), *NB* north boreal ($N=15$ study sites)

proportions of quercetin in relation to other flavonoids causes the antioxidant capacity in the leaves to be higher in the north than in the south. Low temperatures generally enhance photooxidative stress in relation to light intensity by limiting the capacity of photosynthetic enzymes (Close and McArthur 2002). In the north, continuous light during a large part of the growing season may require high concentrations of photoprotective compounds, because temperatures during the nights frequently drop extremely low at a time when light intensity remains high. The decrease in the concentrations of apigenin and naringenin derivatives indicates that there may be a trade-off between these compounds in flavonoid synthesis. In the plant flavonoid pathway, apigenin and naringenin are synthesized before quercetin. In the south, flavonoid synthesis ends more frequently with apigenin and naringenin derivatives than in the north where the precursors for apigenin and naringenin are used especially for the synthesis of quercetin.

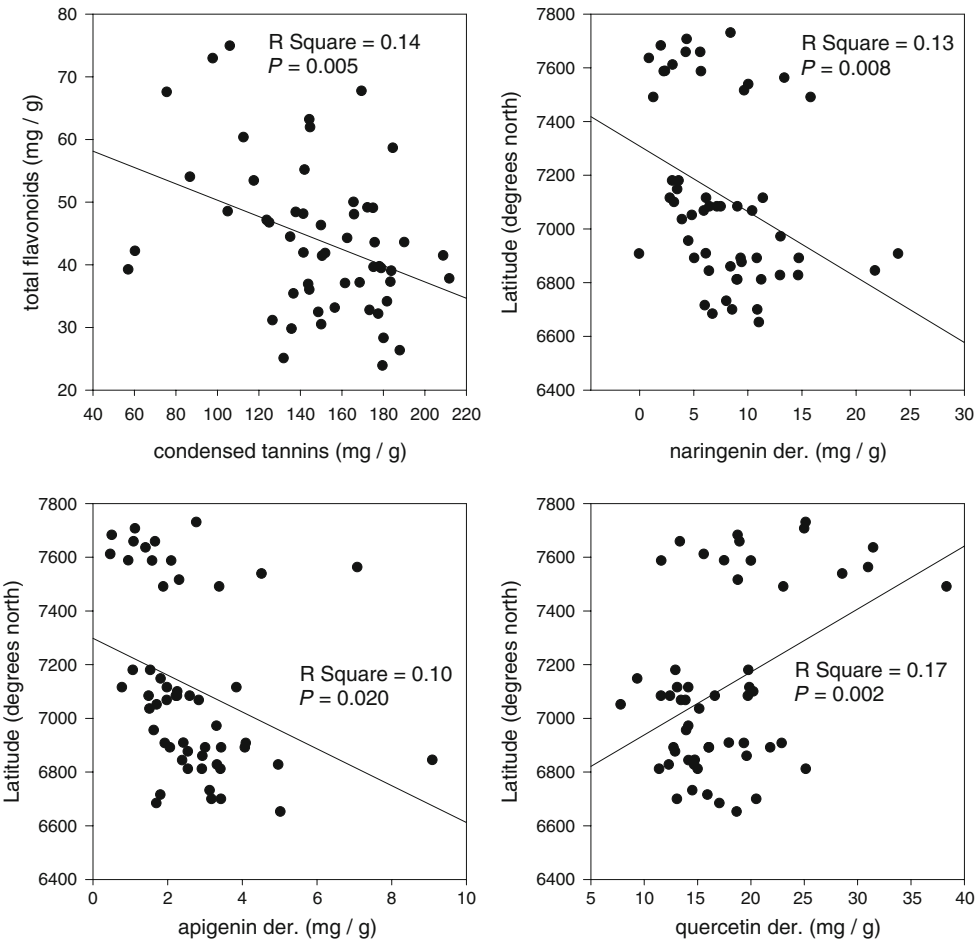

Fig. 4 The correlation between the concentration of quercetin, apigenin, and naringenin derivatives with latitude (degrees north) and the correlation between the total sum of flavonoids and condensed tannins in the north–south transect, *N*=54 study sites

There was no significant effect of latitude on the concentration of condensed tannins, which are considered to form the constitutive defense against herbivory in birch (Tuomi et al. 1990; Kaitaniemi et al. 1999; Mutikainen et al. 2000; Henriksson et al. 2003; Riipi et al. 2005). We are not aware of any study of latitudinal gradients in herbivory pressure on the white birch, but generally, invertebrate herbivory seems to increase (Tuomi et al. 1990). Mammalian browsing has been shown to reduce the concentrations of condensed tannins in birches (Danell et al. 1997; Lehtilä et al. 2000; Stark et al. 2007).

Despite the increase in photoprotective flavonoids towards high latitude and low temperature areas on a geographical scale, we found in our regional study that the sum of foliar flavonoids correlated positively with the temperature sum. In this area, the temperature sum is

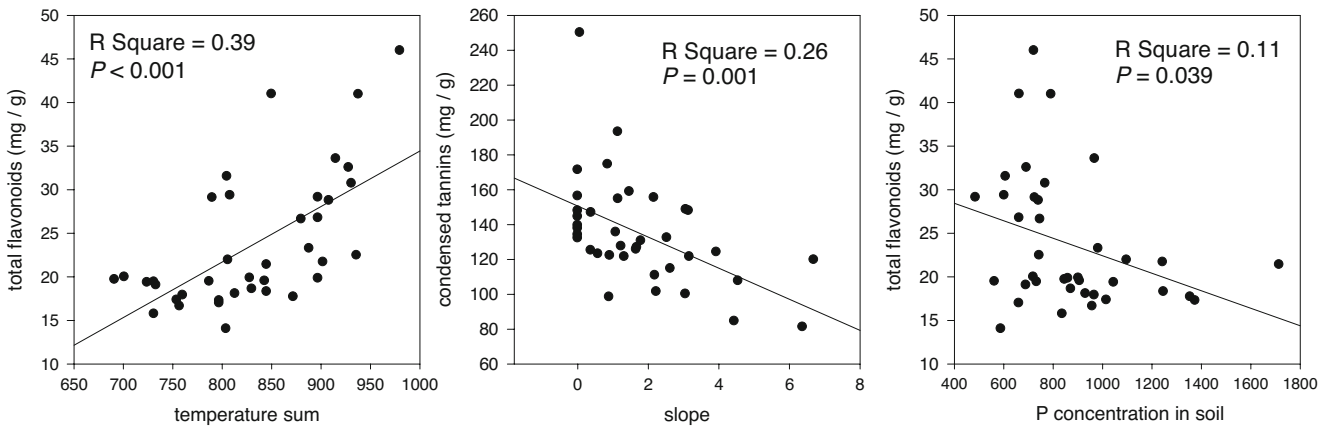

Fig. 5 The correlation between the concentration of total flavonoids and temperature sum and soil P concentration and the correlation between the concentration of condensed tannins and slope on a regional basis in the northern boreal zone, *N*=38 study sites

correlated strongly with altitude, which decreases towards the upland regions in northern and eastern Lapland. The positive correlation between flavonoid concentrations and the temperature sum in white birch is in line with an earlier study at high latitudes (Jonasson et al. 1986). The positive correlation is not necessarily in contrast with the latitudinal gradient with higher concentrations of quercetin derivatives in the north. The same substance group that showed higher concentrations in the north, and quercetin, did not respond positively to temperature, whereas the two substance groups that showed higher concentrations in the south, apigenin and naringenin, showed a positive correlation with the temperature sum on a regional basis and thus had parallel patterns with temperature on both geographical and regional scales.

The positive correlation between temperature and the concentration of phenolics agrees with experiments conducted at high latitudes (Graglia et al. 2001; Hansen et al. 2006). Jonasson et al. (1986) hypothesized that positive correlation between phenolic concentrations and temperature could be explained by the fact that the temperature effect on photosynthesis is proportionally higher than the temperature effect on nutrient supply rate. Therefore, availability of carbon for the synthesis of phenolic secondary compounds in northern ecosystems may increase with temperature, but due to limitation of available nutrients, only part of the surplus carbon can be allocated to new growth. Contrasting with areas in high latitudes, experimental warming in the south boreal areas has been shown to decrease the concentrations of phenolic compounds in birch and other boreal deciduous trees (Kuokkanen et al. 2001, 2003; Veteli et al. 2002). The role of temperature on the carbon allocation to phenolics under different light conditions is possibly a subject for future experimental investigations.

On a regional basis, we found a negative correlation between foliar phenolics and soil P concentrations in the geochemical database, which agrees with the inverse correlation between nutrient availability and leaf phenolic content shown by experimental fertilization (Mutikainen et al. 2000; Keski-Saari and Julkunen-Tiitto 2003). Antioxidative compounds have been shown to increase their turnover rates in conditions of high light (Polle and Rennenberg 1996) and nutrient limitation (Polle et al. 1992; Logan et al. 1999). When nutrient deficiency is limiting the synthesis of photosynthetic enzymes, the need for foliar photoprotection increases and thus, at any given light intensity, the degree of excess light at similar irradiance levels is relatively greater in nutrient-limited conditions (Close and McArthur 2002). Our study demonstrates that correlations between soil nutrient availability and plant phenolic concentrations can be observed at a landscape level.

Quercetin derivatives continue to be of great general interest because of their high antioxidant capacity and assumed effect of reducing the risk of oxidative stress-related chronic diseases in humans (Boots et al. 2007; Wach et al. 2007). Due to the high concentrations of quercetin, white birch foliage growing in the northern boreal zone would constitute a source of such natural products. On a regional basis, the total concentration of flavonoids was the highest in sites with a high temperature sum and a low P availability. Thus, our findings suggest that spatial data could be used as a tool for finding the optimal areas for collecting raw material for health-promoting natural products, thus bringing ecological knowledge to practice.

Acknowledgements We thank Pekka Välikangas and the entire Metla Biosoil group for organizing the collection of the birch leaf samples in the south–north gradient and to Outi Nousiainen for conducting the HPLC analysis of the birch leaves. We are grateful to Dr Sarita Keski-Saari for the inspiring discussions and two anonymous referees for the critical comments on the manuscript. We thank the Geological Survey of Finland and Metsähallitus for allowing the use of their inventory data for this study. This study was funded by the Tekes EU area development fund (to Mette project).

We have been studying such interactions using a *Pinus nigra–Diplodia pinea–Neodiprion sertifer* tripartite system (Bonello and Blodgett 2003; Eyles et al. 2007). *P. nigra* (Pinaceae; Austrian pine) are among the most commonly planted trees in North America where they suffer from *Diplodia* shoot blight and canker, which can kill stressed trees (Peterson 1977). *D. pinea* (Ascomycetes; formerly *Sphaeropsis sapinea*) inhabits the phloem of stems and branches. This pathogen will also infect other two- and three-needle pines, but *P. nigra* is the most susceptible pine in North America. *N. sertifer* (Hymenoptera; Diprionidae; European pine sawfly) feeds on 2-year-old needles of several pine species and readily defoliates *P. nigra* (D.A. Herms, personal observation). It is also an outbreak insect known to be sensitive to host quality (Larsson et al. 2000). In a given season, *P. nigra* can be attacked by both of these pests, indicating that host-mediated interactions between them may occur. Given their feeding locations, changes in host plant quality in response to one attacker that are systemic are more likely to impact the other than are local changes in quality. In a 2-year study, we showed that *D. pinea* infection of the stem of young *P. nigra* consistently induced systemic resistance against the same fungus in branches. Defoliation of branches by *N. sertifer* failed to systemically affect growth of this insect in undamaged branches in either year. In terms of cross-resistance, however, defoliation of branches by *N. sertifer* induced systemic resistance to *D. pinea* in an undamaged branch in one of the 2 years of the study. Conversely, *D. pinea* infection of the stem induced systemic resistance to *N. sertifer* growth on foliage from an undamaged branch in 1 year, while in the other year, systemic effects of both *D. pinea* infection and *N sertifer* feeding on *N. sertifer* survival on undamaged branches were significant, but depended upon soil fertility level (Eyles et al. 2007). These results indicated that systemic induced resistance to *D. pinea* in *P. nigra* by previous infection with the same fungus was consistent and, although reciprocal cross-resistance can occur in *P. nigra* in response to these attackers, the results can be asymmetric within a single year and variable among years.

Although regulatory mechanisms of defenses in conifers are poorly understood, conifers produce a suite of secondary metabolites in response to attack by insects and pathogens, notably phenolics and terpenoids (Franceschi et al. 2005). In a companion paper that focused on fungal resistance mechanisms in the phloem, we showed that, when examined as a group, phenolic glycosides and stilbenes increased systemically in the phloem of branches of young *P. nigra* in response to *D. pinea* infection of the stem and were positively correlated with resistance to *D. pinea* in those branches. On the other hand, terpenes were not inducible in the phloem by fungal infection as a group and were unrelated to fungal resistance. Only a single terpenoid, germacrene D, was systemically inducible in the phloem of branches by defoliation by *N. sertifer*, but it was unrelated to fungal resistance (Wallis et al. 2008). Less studied than secondary metabolites in conifers are pathogenesis-related (PR) and other defense-related proteins, which can be associated with insect and disease resistance in a variety of plants. In *Picea sitchensis*, a family of dirigent proteins that assist in lignan formation were locally induced by insect feeding, as were β-1,3-glucanases, chitinase, a protease inhibitor, and peroxidases (Ralph et al. 2006, 2007; Lippert et al. 2007). In *Pinus sylvestris*, chitinases were produced constitutively and were induced locally by endophytic microbes (Pirttilä et al. 2002), but not pathogenic fungi (Hodge et al. 1995). In *Pinus monticola*, chitinase was induced locally in needles by a pathogenic fungus (Liu et al. 2005), as was expression of a PR10 protein (Liu et al. 2003). In *P. sylvestris* and *Picea abies*, peroxidases and polyphenol oxidases were induced locally after attack by pathogenic fungi (e.g., Johansson et al. 2004). *P. abies* also produces chitinases, chitosanases, and glucanases locally after challenge with pathogenic fungi (e.g., Jøhnk et al. 2005). These studies revealed substantial variation in when and where induction of defense proteins may be expected to occur in conifers. However, these studies focused primarily on local induction. While certainly important in understanding local restrictions on disease spread or insect feeding, systemic changes in plant defenses have the potential to have broader effects on other interacting species. Despite mounting evidence of their importance, systemic induction of PR and other defense-related proteins has been little studied in conifers (but see Richard et al. 2000) and never in *P. nigra* in response to fungal or insect attack.

Environmental factors, such as soil fertility, are known to affect disease and insect resistance in plants. For example, resistance of red pine (*Pinus resinosa*) to *D. pinea* is decreased by high soil fertility (Blodgett et al. 2005), which can result in increased tree mortality (Stanosz et al. 2004). Such findings may relate to changes in host plant quality across soil environmental gradients. Although never studied in conifers, protein defenses in many herbaceous and woody plants can vary with soil fertility. Constitutive activity of trypsin inhibitors, peroxidases, chitinases, and β-1,3-glucanases increased in response to increased fertility in *Brassica napus*, *Arabidopsis thaliana*, and two *Citrus* species (Cipollini and Bergelson 2001; Cipollini 2002; Borowicz et al. 2003). Induced activity of trypsin inhibitors, papain inhibitors, and peroxidases were higher in plants with higher soil fertility (Bolter et al. 1998; Cipollini and Bergelson 2001; Cipollini 2002; Borowicz et al. 2003). In contrast, constitutive activities of trypsin inhibitors, chitinases, β-1,3-glucanases, and peroxidases in soybean

and tomato decreased with increasing fertility (Inbar et al. 2001; Vollmann et al. 2003). The equivocal nature of these results may be due to the different methods used to induce defenses (insect feeding, wounding, or exogenous hormone application). Furthermore, different methods of altering soil nutrients and different methods of sampling tissues may have yielded such varying results.

In this 3-year replicated study, we induced young Austrian pine trees with insect defoliation of branches or fungal inoculation of the main stem and monitored constitutive and induced activities of defensive proteins and levels of soluble proteins in both phloem and needles of uninfected or undefoliated branches. The effects of these treatments were examined across three soil fertility levels to examine the extent to which fertility modulated protein accumulation and the constitutive or inducible activities of defense proteins. We expected total protein levels and defense protein activities to increase with increasing fertility. In addition, we expected activities of defense proteins to be induced systemically by insect and fungal damage.

Methods and Materials

The *P. nigra–D. pinea–N. sertifer* system and our experimental design are described in detail in Eyles et al. (2007). Briefly, 4-year-old bare-root *P. nigra* saplings were grown outside in 21-L containers with a commercial nursery substrate (KB container mix, Kurtz Bros. Central Ohio, LLC) at the Ohio Agricultural Research and Development Center (Wooster, OH, USA). Plants were placed on a fertigation system at either low, intermediate, or high fertilization levels (30, 75, 150 ppm N; N/P/K 3:1:2) in the spring of 2004. Fertilization levels were chosen to represent recommended fertility regimes for containerized evergreen trees in forest nursery production (Eyles et al. 2007). After a year of conditioning on the fertilization regimes, four separate induction treatments were applied in the spring of 2005 (*D. pinea* infection, mock inoculation, defoliation by *N. sertifer*, and unwounded controls). The induction of fungal inoculations occurred 5 cm above the soil on the main stem where agar plugs containing *D. pinea* were placed in a 10-mm diameter wound made with a cork borer. Mock-inoculated trees received a 10-mm cork borer wound and a sterile agar plug. At the same time, a separate set of trees were induced by *N. sertifer* by allowing several third and fourth instar larvae to defoliate approximately 75% of the foliage on the tree (typically 2- and 3-year-old needles), while one branch in the top whorl of the tree remained protected by a mesh bag. This whorl was approximately 10 cm from the base of the trees, which averaged about 24 cm in height when induced. We replicated the study by growing a set of 6-year-old containerized trees grown under similar conditions and exposed to the same fertility treatments beginning in 2005 that were induced in the spring of 2006. The mock inoculation treatment was omitted in 2006 because it did not alter response variables significantly from those of control plants in 2005. The top whorl on trees used in the second study was about 40 cm from the base of the trees, which averaged about 63 cm in height. The fertility and induction treatments in both 2005 and 2006 were assigned to five spatial blocks with six to ten trees assigned to each fertility and induction treatment combination in each block. Further details on the induction procedure and our experimental design can be found in Eyles et al. (2007).

Foliage and branch phloem were sampled 16 days after induction treatments in 2005 and 21 days after induction treatments in 2006 (Eyles et al. 2007). While these timeframes are not necessarily optimal for capturing maximal increases in protein defenses after induction, they were timed to coincide with sampling for secondary metabolites (Wallis et al. 2008) and for challenge bioassays (Eyles et al. 2007). On trees induced by insect defoliation, foliage (second year needles) and branch phloem (hereafter phloem) were collected from a bagged branch from the top whorl. On trees induced by *D. pinea* infection of the stem, foliage and phloem were collected from a corresponding branch on the same whorl as that collected on insect-defoliated trees. Tissues were flash frozen immediately in liquid nitrogen and stored below −20°C until analysis. Tissues were first weighed, then ground with a mortar and pestle in liquid nitrogen. Needles were homogenized whole, while phloem was dissected from branch samples prior to homogenization. Soluble proteins were extracted from ground samples in ice-cold 0.01 M sodium phosphate buffer (pH 6.8) containing 5% *w*/*v* poly(vinylpolypyrrolidone). Guaiacol peroxidase (POD), polyphenol oxidase (PPO), chitinase (CHI), trypsin inhibitor (TI) activities, and total soluble protein content were assayed by using spectrophotometric and radial diffusion techniques as in Cipollini et al. (2004). β-1,3-glucanase (BGLU) activity was measured by following the hydrolysis of laminarin spectrophotometrically at 500 nm (modified from Abeles and Forrence 1970). Each sample for BGLU analysis was blanked twice, once with a blank containing extraction buffer and laminarin, and again with one containing extraction buffer and sample to account for color in the protein extracts. In 2005, activities of POD, PPO, and CHI were assessed in foliage and phloem, while TI and BGLU were only assessed in phloem due to limited amounts of available foliage. In 2006, activities of POD, PPO, CHI, and BGLU were measured in both tissues. Levels of TI were not assessed in 2006, since only very low levels were detected in phloem in 2005. Activities of the proteins were

expressed both per unit of extracted biomass and per unit extracted protein. Patterns were generally similar when expressed either way, so only activities expressed per unit extracted protein are reported. Total soluble protein contents were expressed per unit fresh weight of extracted biomass.

Data were transformed as necessary and analyzed for treatment effects using analysis of variance (SAS Version 9.1, SAS Institute). Factors in the model included fertility level, induction treatment, and their interactions. Block effects were examined and were negligible, so the degrees of freedom associated with this factor were included in the error degrees of freedom. Means were separated using Bonferroni comparisons. Only statistical results deemed significant at α=0.05 are presented in the descriptions below, although all data are shown in the figures.

Results

Interactions between fertility level and induction treatment were not significant for total protein content or for the activity of any protein. In no case did total soluble protein levels increase with increasing fertility or did activities of any defensive protein decrease with increasing fertility. We thus focus descriptions on the significant main effects of induction treatment and fertility, although nonsignificant patterns are also shown on the figures.

Across induction treatments, total soluble protein content of needles decreased with increasing fertility in both years of the study (Fig. 1a; 2005-fertility: $F_{2,169}$=6.10, P=0.003; 2006-fertility: $F_{2,111}$=7.47, P<0.001). Across induction treatments, total soluble protein contents in phloem were about ten times lower than in needles and tended to decrease with increasing fertility in 2005 (Fig. 1b; fertility: $F_{2,135}$=2.94, P=0.056). Across fertility levels in 2005, total soluble protein levels in phloem were 40% higher in trees induced with the fungus than in either control trees or those receiving a mock inoculation (Fig. 1b; induction: $F_{3,135}$= 5.05, P=0.002).

Across induction treatments, POD activity in needles increased with increasing fertility in 2005 (Fig. 2a; fertility: $F_{2,141}$=13.70, P<0.001). Across fertility levels, POD activity was almost 90% lower in needles of insect-induced trees than in control trees in 2006 (Fig. 2a; induction: $F_{2,100}$=6.72, P=0.002). In phloem, POD activities were about 400 times higher than in needles (Fig. 2). As in needles, POD activity in phloem in 2005 increased with increasing fertility across induction treatments, although differences were not as pronounced as those in needles (Fig. 2b; fertility: $F_{2,140}$= 4.65, P=0.011).

Across induction treatments, PPO activity in needles increased with increasing fertility in 2005 (Fig. 3a; 2005-needles-fertility: $F_{2,158}$=3.24, P=0.042). Activities in phloem were about ten times higher than in needles in 2005, but still lowest in the lowest fertility treatment with the effect nearly significant (Fig. 3b; 2005-phloem-fertility: $F_{2,138}$=3.03, P= 0.051). Across fertility levels, PPO levels in phloem were 40% higher in trees induced by insect feeding than in unwounded trees in 2005 (induction: $F_{3,133}$=4.28, P=0.006). Neither mock inoculation nor fungal attack affected PPO levels in phloem in 2005 (Fig. 3b).

Across induction treatments, CHI activity increased with increasing fertility in needles in 2006 and in phloem in both years (Fig. 4; 2006-needles-fertility: $F_{2,107}$=3.08, P=0.050; 2005-phloem-fertility: $F_{2,139}$=3.09, P=0.049; 2006-phloem-fertility: $F_{2,109}$=6.62, P=0.002). In 2005, CHI levels in phloem were about five times higher than in needles, and in 2006, levels in phloem were about ten times higher than in

needles (Fig. 4). Across fertility levels, no induction treatment altered CHI levels from those seen in controls in phloem in 2005, although levels were lower in trees induced by fungal attack than in trees receiving a mock inoculation (Fig. 4b; induction: $F_{3,139}$=3.07, P=0.030).

Activity of β-1,3-glucanase was very low in phloem in 2005 (Fig. 5). Across induction treatments, BGLU activity in needles in 2006 increased with increasing fertility (Fig. 5a; fertility: $F_{2,105}$=8.13, P<0.001). As for other defense proteins, BGLU activities were higher in phloem than in needles in 2006 (Fig. 5).

Trypsin inhibitor activity was only assessed in phloem in 2005 and was not significantly affected by any treatments. Levels detected were so low that TI was not measured in 2006 (Fig. 6).

Discussion

In 2005, we observed systemic induction of PPO in the phloem of undamaged branches of *P. nigra* trees that had been damaged by *N. sertifer* feeding on needles of other branches in the same whorl. Such systemic effects of insect feeding have never been demonstrated in conifer species, and they implicate long-distance signaling in the phloem. Systemic induction of PPO in upper leaves of poplar by damage to lower leaves has been demonstrated (Haruta et al. 2001), but systemic induction of this enzyme in the phloem of woody plants has not been studied to our knowledge. Despite systemic induction of PPO, defoliation by *N. sertifer* did not lead to systemic resistance to *N. sertifer* in the timeframe of our induction and challenge treatments (Eyles et al. 2007). In contrast, POD activity was

systemically suppressed in needles by insect feeding on other branches in 2006. Suppression of POD could be due to resource constraints or may reflect an ability of the insect to directly suppress the plant's defense response through signal interactions (Musser et al. 2005). Inoculation with *D. pinea* had surprisingly little effect on systemic defense protein activities during the timeframe of our study in either year, and aside from effects on PPO and POD, we saw little systemic response to induction treatments in the other defense proteins that we studied. Activities of rapidly induced defense proteins often increase within a matter of hours to days, typically followed by a return to basal levels sometime thereafter, so our relatively delayed sampling may have limited our ability to observe maximal changes in protein activities. In addition, changes in these proteins induced locally to the site of damage may have been more noticeable than systemic changes. Some of the variation in plant responses to treatments among years may reflect age differences of the trees used in each year.

Despite the lack of effect on insect growth, insect induction induced systemic resistance to fungal growth in 2006 (Eyles et al. 2007). Conversely, fungal induction induced systemic resistance to fungal growth in both 2005 and 2006, and it induced systemic resistance to insect growth in 2005 (Eyles et al. 2007). Since fungal inoculation did not induce systemically any of the defensive proteins that we measured, other defenses (protein or nonprotein) must have been responsible for the fungal-induced effects on resistance. In the same trees as the current study, Wallis et al. (2008) found that phenolic glycosides and stilbenes increased systemically in the phloem of uninoculated

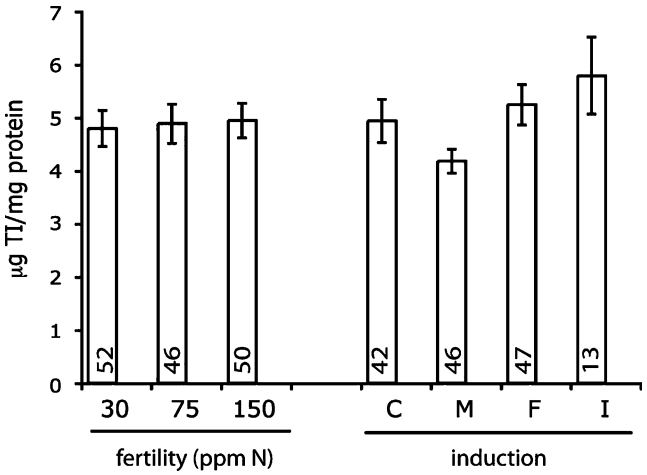

Fig. 6 Trypsin inhibitor levels in *P. nigra* phloem in 2005, means (micrograms trypsin inhibitor per milligram soluble protein)±1 SE. *Numbers in bars* indicate number of replicates. *C* control—untreated trees, *M* mock—trees challenged with a sterile agar plug, *F* fungus—trees inoculated with *D. pinea*, *I* insect—trees defoliated by *N. sertifer*

branches of *P. nigra* in response to infection of the stem and were positively correlated with resistance to *D. pinea* in those branches. In the current study, fungal inoculation induced systemic increases in total protein levels in the phloem, some of which with defensive roles may have contributed to resistance. Cross-resistance to pathogens induced by arthropod feeding has been observed in other studies, and in these examples, the inverse was also true (McIntyre et al. 1981; Karban et al. 1987; Inbar et al. 1998). These findings demonstrate that the outcome of host-mediated interactions between pests can be positive or negative and depends on environmental conditions as well as attacker identity.

More important than systemic induction, accumulation of total soluble proteins and the activity of most of the defense proteins studied here were mediated strongly by soil fertility. Declines in total soluble protein levels with increasing fertility contrasts with reports of either increases in total protein with increasing fertility (Borowicz et al. 2003; Vollmann et al. 2003) or constant total protein levels across fertility levels (Cipollini and Bergelson 2001). Although the results presented here were unexpected, they were consistent in both years of the study in trees of different ages and exposed to different ambient climatic conditions. Wallis et al. (2008) also documented decreases in total phenolics and concentrations of several individual phenolic metabolites in the trees in the high-fertility treatment in 2005. Assuming that our high-fertility treatment was not actually stressful to the plants, several factors may have contributed to this unexpected result. Protein concentrations were expressed per unit fresh weight of tissues, so if protein production rates stayed the same or declined as the trees grew, protein concentrations would decline due to dilution in greater amounts of tissue. Proteins may also have been present but less extractable for some reason in plants grown at high fertility. We also analyzed only soluble proteins, and insoluble structural proteins may respond differently to changes in fertility. In other studies, however, increases in protein levels with fertility were seen for total (soluble and insoluble) proteins (Vollmann et al. 2003), as well as for soluble proteins alone (Borowicz et al. 2003). This effect is unlikely to be due to the nature of the fertilizer, since Borowicz et al. (2003) also used a complete fertilizer and found increasing levels of total proteins with increasing fertility. Finally, the growth conditions used here may have been more conducive to production of certain metabolites that may have competed for substrate with nitrogen-rich proteins. Regardless of the mechanisms that control protein production in conifers, soil fertility clearly played an important role in this study.

In contrast to effects on total soluble protein levels, defense protein activities generally increased with increasing fertility, as has been seen in other studies (e.g., Bolter et al. 1998; Cipollini and Bergelson 2001). This was true whether the proteins were responsive to induction and whether their activities were expressed per unit protein or per unit biomass. This suggests that maintenance or increased production of some proteins is favored under increasing fertility levels, while levels of other proteins apparently decline. The finding that total protein levels declined while activities of some defense proteins increased suggests that, per unit biomass, tissues from plants in our high-fertility treatment should be of lower quality to herbivores and pathogens sensitive to such factors than tissues from our low-fertility treatment. However, in our studies, fertility had no direct effect on resistance to the fungus or the insect (Eyles et al. 2007, Wallis et al. 2008). This may be due to the fact that, as certain defenses increased with fertility, such as the activity of defensive proteins seen here, other defenses decreased with fertility, such as concentrations of total phenolics and individual phenolic metabolites shown by Wallis et al. (2008).

Trypsin inhibitors have been little studied in conifers, but are a well-known constitutive and inducible defense in many herbaceous and woody plants (e.g., Bolter et al. 1998; Cipollini and Bergelson 2001; Major and Constabel 2008). In 2005, we found only a low level of TI activity in phloem and we have found no activity in needles in other studies (D. Cipollini, unpublished data). While activities tended to increase with fertility in 2005, as with the other defensive proteins, TI activities were not affected significantly by any of our treatments. The restriction of TI activity in the phloem indicates that it could act against phloem feeding pests, probably wood boring insects or other phloem-inhabiting pathogens, but the low activity detected may limit its importance.

We have demonstrated systemic induction or suppression by insect feeding of PPO and POD in the phloem of branches of *P. nigra*. In contrast, *D. pinea* infection had no significant systemic effect on these proteins in needles or phloem, but it did induce systemic increases in total soluble protein accumulation in the phloem. Soil fertility strongly decreased concentrations of total soluble protein in needles and phloem, while it increased the activity of several defense proteins. Variation in concentration and activities of these proteins may be related to variation in pest attack and performance on *P. nigra* across natural fertility gradients in the field, but their impact on pests depends on correlated responses in other plant defenses.

Acknowledgments We thank Eusondia Arnett, Bryant Chambers, Alejandro Chiriboga, Ilka Gomez, Diane Hartzler, Anuprit Kaur, Cherissa Rainey, Matt Solensky, Duan Wang, and Justin Whitehill for the assistance in the field and in the laboratory and Kurtz Bros for the nursery supplies. The comments by two anonymous reviewers improved the manuscript. Funding was provided by the USDA National Research Initiative Competitive Grants Program No. 2004-35302-14667 and by the State and Federal funds appropriated to the Ohio Agricultural Research and Development Center, the Ohio State University. These experiments comply with the laws of the USA.

Say) is a member of the gall midge family (Diptera: Cecidomyiidae), which contains many gall-forming species. Feeding by virulent Hessian fly larvae does not result in the development of a typical gall structure. Instead, the larvae induce young unexpanded leaves to develop a gall-like nutritive tissue, similar to the inner lining of a gall that lacks an outer region of tissue called a covering gall. Harris et al. (2006) examined the ultrastructure of virulent Hessian fly-induced nutritive tissue cells in host wheat plants (*Triticum aestivum* L. em Thell) and reported an accumulation of cellular organelles (mitochondria, proplastids, Golgi, rough endoplasmic reticulum) and a decrease in size of the nucleus. Cell wall thinning leading to rupture of nutritive tissue cells was observed and is presumed to be the mechanism by which the cell contents are made available to virulent Hessian fly larvae.

Interactions between Hessian fly larvae and their host wheat plants are characterized as incompatible when avirulent larvae are detected by the plant in an *R*-gene-mediated gene-for-gene recognition event that blocks them from establishing permanent feeding sites, thus resulting in larval death (Flor 1955; Hatchett and Gallun 1970; Kaloshian 2004). Conversely, compatible wheat–Hessian fly interactions occur when virulent larvae infest the host plant and successfully establish feeding sites among the leaf sheaths near the base of the plant (the crown). Macroscopic changes observed in susceptible plants include a darkening of green leaf color (Robinson et al. 1960) and stunted plant growth compared to uninfested plants (Cartwright et al. 1959). These characteristics of susceptible wheat plants promote the survival of virulent Hessian fly larvae by providing access to nutrients in an area of the plant where larvae are protected from natural enemies.

It is unclear whether susceptible wheat plants (1) fail to mount a defense response against virulent Hessian fly larvae, (2) mount only a partial defense response, or (3) are subject to active suppression of defense mechanisms as a result of virulent larval feeding. Tooker and De Moraes (2007) reported that susceptible wheat plants attacked by virulent Hessian fly larvae failed to produce volatile chemicals (indirect defense response) that could attract insect natural enemies, whereas feeding by larvae of the tobacco budworm (*Heliothis virescens* Fabricius), a generalist herbivore, caused them to emit significantly higher amounts of volatile chemicals. The authors noted that prior feeding by Hessian fly larvae changed plant volatile emissions following subsequent feeding by *H. virescens*, suggesting that virulent Hessian fly larvae may exert some control over indirect defense responses in host wheat plants (Tooker and De Moraes 2007).

Recent research has identified biochemical pathways and physiological mechanisms in wheat conferring resistance and susceptibility to Hessian fly (Puthoff et al. 2005; Sardesai et al. 2005; Giovanini et al. 2006, 2007; Subramanyam et al. 2006, 2008; Liu et al. 2007; Tooker and De Moraes 2007). Zhu et al. (2008) examined the nutrient content of Hessian fly-infested wheat plants and reported changes in carbon and nitrogen metabolism in the wheat line *H9*-Molly (contains the *H13* resistance gene) infested with the Hessian fly line *vH13* (virulent on *H9*-Molly wheat). Changes included a 36% increase in free carbon-containing compounds and a 46% increase in free nitrogen-containing compounds. Wheat metabolic pathways reported to be associated with these changes included glycolysis, the tricarboxylic acid cycle, the pentose phosphate pathway, and amino acid synthesis (Zhu et al. 2008).

Bronner (1992) reported that nutritive tissues lining cecidomyiid-induced galls accumulate "soluble amino products", presumed to be amides or amino acids, which were proposed to arise from either proteolysis in gall tissues or transport from other parts of the host plant. Free amino acids (nonprotein-bound amino acids) ingested by an insect carry the advantage of being absorbed directly without processing in the gut, such as is required for polypeptides. Some species of aphid are known to alter the nutritional quality of host wheat plants by increasing the abundance of plant free amino acids in phloem (Telang et al. 1999; Eleftherianos et al. 2006). Two aphid species that attack wheat, the greenbug (*Schizaphis graminum* Rondani) and the Russian wheat aphid (*Diuraphis noxia* Mordvilko), manipulate wheat plant physiology and enhance the free amino acid composition of phloem sap that they ingest (Sandström et al. 2000).

In the present study, results support the hypothesis that crown tissues in Hessian fly-susceptible wheat plants contain increased levels of free amino acids following feeding by virulent Hessian fly larvae. Although the physiological function of elevated free amino acids in susceptible wheat plants remains unclear, we propose that this increase could improve the nutritional quality of plant fluids ingested by virulent larvae. Alternatively, increased levels of free amino acids may be associated with physiological processes in the plant and have no direct effect on larval nutrition. A possible link between elevated levels of free proline in susceptible plants and host plant energy requirements during compatible wheat–Hessian fly interactions is discussed.

Methods and Materials

Plant Growth and Hessian Fly Infestation Hessian fly Biotype L was maintained as a purified laboratory stock by the USDA-ARS Crop Production and Pest Control Research Unit in West Lafayette, IN, USA and was used for all infestations throughout the present study. Biotype L was collected as a wild population from an Indiana wheat field

and is virulent to four standard wheat differential lines, each containing one of the following Hessian fly-resistance genes: *H3*, *H5*, *H6*, and the two-gene combination *H7H8*. The laboratory Hessian fly line *vH13*, which is mentioned in association with other research, differs from Biotype L in that *vH13* was artificially selected in the lab, from an unrelated fly stock, to be virulent on wheat containing the *H13* resistance gene. Two near-isogenic winter wheat lines (Patterson et al. 1994), Newton (susceptible to Biotype L; compatible interaction) and *H9*-Iris (resistant to Biotype L due to the *H9* resistance gene; incompatible interaction), were used for all experiments. Ten wheat seeds were planted in each 10-cm plastic pot and infested at the two-leaf stage with Hessian fly Biotype L (five females and two males per pot) as previously described (Giovanini et al. 2006). Control plants were treated identically except that they received no flies. Following infestation, plants were dissected daily to determine when larvae reached the base of the crown (aerial portion of a seedling above the roots and below the ligule of the first leaf). To verify that the predicted interactions occurred, plants grown in parallel to those used for experimentation were compared 14 days after egg hatch, demonstrating that compatible interactions resulted in stunted plants containing living larvae and incompatible resulted in unstunted plants containing only dead first instars. The four wheat differential lines (resistance genes *H3*, *H5*, *H6*, and *H7H8*) were included as controls to verify the genotype of Biotype L. Two sets of tissue (biological replicates) were grown simultaneously with plants for free amino acid analysis and RNA isolation in each replicate.

Isolation, Identification, and Quantification of Wheat Free Amino Acids Crown tissues from infested and uninfested wheat seedlings were collected for free amino acid analysis 1, 4, and 7 days after Hessian fly egg hatch. Two biological replicates of each treatment (ten plants pooled per replicate) were harvested. Larvae were removed, from where they had settled at the base of leaf three, by washing with 0.2 µm filtered water after pealing back outer leaves. Then the basal 1 cm of crown tissue from each plant was collected and pooled to determine grams fresh weight (gfw) per sample. Samples were stored in liquid nitrogen until free amino acid isolation was carried out (on the same day) by using the methods of Lam et al. (2003).

Dried samples were stored at −80°C prior to shipment on dry ice to the Molecular Structure Facility at the University of California, Davis. Free amino acid analysis was conducted with a Beckman 6300 amino acid analyzer (Beckman Coulter, Fullerton, CA, USA) with a lithium citrate buffer system (Ozols 1990). Prior to analysis, samples were acidified with sulfosalicylic acid to remove intact proteins. Free amino acids were separated by ion-exchange chromatography (Rossomando 1990) and analyzed by using a post-column ninhydrin reaction detection system (Macchi et al. 2000). Samples for free amino acid analysis were dissolved in lithium citrate buffer containing aminoethylcysteine (AEcys) as an internal standard. AEcys was used to correct for any variation in the operating conditions of the Beckman 6300 amino acid analyzer. Authentic standards for amino acid identification were utilized (Pickering #012006P physiological standard mixture, Beckman Coulter). Amino acids were identified using Beckman 32 Karat software (version 5.0). In Table 2, ammonia refers to ammonia salts (detected as ammonium ion, NH_4^+) and ethanolamine is an organic chemical compound detected in our experiments because it is a primary amine and contains an amino group that reacts with ninhydrin (Macchi et al. 2000).

Concentration data for amino acids and other detected compounds were used to calculate nanomoles per gram fresh weight plant tissue (nmol/gfw) for each chemical. Based on the methods used to separate and identify free amino acids, cysteine and tryptophan could not be assayed. Quantification of these chemicals would have required different analytical methods. For each treatment, the fold-change in concentration for a given chemical (shown in Table 1) was calculated by dividing the concentration (nonlogarithm transformed) in the Hessian fly-infested treatment by the concentration in the corresponding uninfested controls (i.e., for each chemical and at each time point, average values for uninfested *H9*-Iris and Newton controls were used as divisors to calculate fold-change of corresponding infested samples). Reported fold-changes represent two biological replicates.

RNA Isolation and cDNA Synthesis The basal 1-cm of crown tissues from infested and uninfested wheat seedlings were collected into liquid nitrogen as two biological replicates per treatment (ten plants per replicate) for RNA extraction 1, 4, and 7 days after Hessian fly egg hatch. These collections were made at the same time as those used for amino acid analysis. Larvae were not removed from plants. RNA isolation and cDNA synthesis followed the methods of Giovanini et al. (2006).

Primers for Quantitative Real-time PCR Our interest in five of the nine wheat sequences used for qRT-PCR resulted from an Affymetrix GeneChip® Wheat Genome Array experiment recently carried out by our laboratory (C. Williams, unpublished). Probe sets corresponding to Hessian fly-responsive genes included histidine amino acid transporter (GenBank accession Ta.12339.1.S1_at), prephenate dehydratase (Ta.9122.1.S1_at), proline transporter (Ta.30603.1.S1_s_at), pyrroline-5-carboxylate synthetase (Ta.7091.1.S1_at), and transmembrane amino acid transporter (Ta.27343.1.S1_at). Annotation of the Affymetrix

		(R) 5′ TGCTCCACACCAGCAGAAGT

probe set sequences was carried out with HarvEST software (http://harvest.ucr.edu; Wheat 1 Array, version 1.52). Additional functional annotation was performed by using two web-based resources: the International Union of Biochemistry and Molecular Biology Enzyme Nomenclature website (www.chem.qmul.ac.uk/iubmb), and MetaCyc, a database of experimentally elucidated metabolic pathways (http://metacyc.org; Caspi et al. 2006). The Affymetrix target sequence was used to design qRT-PCR primers (Table 1) with Primer Express software (Applied Biosystems, Foster City, CA, USA). The protocol for qRT-PCR was as described in Giovanini et al. (2006). Following qRT-PCR, a melt curve analysis verified primer specificity by confirming the presence of a single PCR product. mRNA levels were calculated by using the standard curve serial dilution method described in the ABI "User Bulletin 2: ABI PRISM 7700 Sequence Detection System". The threshold cycle (C_T) for each dilution was plotted against its cDNA concentration (with an arbitrary starting quantity of 1 for the undiluted sample) and a regression equation generated Arbitrary Expression Values (AEV) for the experimental samples. Fold-changes reported in the text were calculated by dividing the AEV (nonlogarithm transformed) of a Hessian fly-infested treatment by the AEV of the corresponding uninfested control at the same time point. Fold-changes reported in the text and mRNA abundance data (AEV) shown in Fig. 2 represent two independent experiments (two biological replicates), and all samples were subjected to qRT-PCR × 3 (three technical replicates).

Statistical Analysis Experimental results were analyzed by using SAS software version 9.1.3 (SAS Institute Inc., Cary, NC, USA). Significance of the free amino acid concentration data and qRT-PCR data was determined by analysis of variance (ANOVA) using the PROC MIXED procedure of SAS. For analysis of free amino acid concentration data, the three main effects included in the analysis models were infestation status (Hessian fly-infested, -uninfested), interaction type (compatible, incompatible), and experimental time point. All interactions of main effects were included in the analysis models as predictor variables. Three-factor ANOVA models were fitted to the amino acid concentration data, with logarithm transformed concentration being the response variable for each type of amino acid. The LSMEANS statement for the three-way interaction was used to conduct pairwise comparisons of the mean amino acid concentration between Hessian fly-infested and -uninfested. For analysis of qRT-PCR data, two-factor ANOVA models were fitted with logarithm transformed qRT-PCR AEV data, which served as the response variable. ANOVA models were fitted to interaction type and gene type, and pairwise comparisons of the mean mRNA abundance levels were conducted using the LSMEANS statement for the two-way interaction. All P-values for amino acid and qRT-PCR data were adjusted by the Bonferroni correction procedure with respect to the total number of experimental time points and the total number of genes tested. The adjusted P values were considered statistically significant if $P<0.05$.

Results

Accumulation of Standard Free Amino Acids in Wheat Crown Tissues Although changes in free amino acid levels

were detected in both susceptible and resistant wheat plants as early as 1 day after egg hatch, these changes were not significantly different compared to uninfested controls (Table 2). Four days after egg hatch, significant increases in free amino acid abundance were observed in susceptible plants and included alanine (ala) (adjusted *P*-values from Bonferroni correction: $P=0.003$), glutamic acid (glu) ($P=0.009$), glycine (gly) ($P=0.046$), phenylalanine (phe) ($P=0.044$), proline (pro) ($P<0.001$), and serine (ser) ($P=0.046$). In resistant plants at the same time point, only ser ($P=0.002$) was significantly more abundant compared to uninfested controls. At the last time point assayed, 7 days after egg hatch, fewer significant changes in amino acid abundance were observed in susceptible plants compared to the previous 4-day time point, with only the aromatic amino acids phe ($P<0.001$) and tyrosine (tyr) ($P=0.001$) being more abundant compared to uninfested controls (Table 2).

Accumulation of Other Nitrogen-Containing Products in Wheat Crown Tissues Our study also quantified α-amino-*n*-butyric acid (AABA), ammonia, ethanolamine, γ-aminobutyric acid (GABA), 1-methylhistidine, and ornithine (orn). Compared to uninfested controls, no significant differences in the abundance of these chemicals were detected, but some trends were observed. For example, AABA was present at detectable levels only in control and resistant plants 1 and 4 days after egg hatch (Table 2). Ammonia, a normal product of amino acid metabolism,

showed a nonsignificant trend for decreased abundance over time in susceptible plants and increasing abundance in resistant plants. Both 1-methylhistidine and orn were present at relatively low levels in some samples but were not detectable in uninfested controls at the same time points (consequently fold-changes could not be calculated). 1-Methylhistidine was detected only in susceptible plants 4 days after egg hatch, and although orn was detected at low concentration in several treatments and time points tested, the only time it was detected in both replicates of a given treatment was 4 days after egg hatch in susceptible plants.

Concentration of Individual Free Amino Acids in Wheat Crown Tissues In addition to comparing fold-change of free amino acids, we ranked by concentration the amino acids that had significant fold-change increases (Table 2) to determine whether these changes were among the most abundant or among the less frequently occurring amino acids. We were particularly interested in glu and pro due to their proposed roles as an energy source for the plants during times of stress. In susceptible plants 4 days after egg hatch, glu was the most abundant of 18 standard amino acids measured (Table 3), and pro was the eighth most abundant but was present at a concentration lower than the treatment average. In resistant plants 4 days after egg hatch, ser was the only free amino acid with a significant increase in fold-change (Table 2), and it was the third most abundant, being present at a concentration higher than the treatment average (Table 3). The significant fold-change increases in phe and its precursor tyr in susceptible plants 7 days after egg hatch were of interest due to the role of these amino acids in hardening of insect cuticle; phe was present at a concentration slightly higher than the treatment average, while the concentration of tyr was less than the treatment average (Table 3).

Accumulation of mRNA Encoded by Wheat Genes Involved in Amino Acid Synthesis At the same time points used to assay free amino acid levels, quantitative real-time PCR (qRT-PCR) was used to measure the abundance of mRNA encoded by wheat genes involved in amino acid synthesis (Fig. 1). mRNA encoding alanine aminotransferase (synthesis of glu, a precursor of pro) was more abundant compared to controls one (1.81-fold, $P<0.001$), and 4 days (1.59-fold, $P=0.002$) after egg hatch in susceptible plants (Fig. 2A) and corresponded to increased free glu in susceptible plants 4 days after egg hatch (Table 2). mRNAs encoding ornithine aminotransferase (conversion of orn to glu) and glutamine-dependent asparagine synthetase (conversion of gln to glu) were each more abundant compared to controls 1 day after egg hatch in susceptible plants (ornithine aminotransferase: 1.54-fold, $P<0.001$; glutamine-dependent asparagine synthetase: 1.82-fold, $P=0.006$; data not shown) and preceded a significant increase in free glu in susceptible plants at the next time point tested (4 days after egg hatch; Table 2).

Wheat mRNA encoding pyrroline-5-carboxylate synthetase (catalyzes synthesis of pro from glu; Hare and Cress 1997) was more abundant in susceptible plants than in controls, 1 day (1.62-fold, $P<0.001$) and 4 days (2.58-fold, $P<0.001$) after egg hatch (Fig. 2B) and was associated with elevated free pro, which showed the largest fold-increase above control levels of any free amino acid measured 4 days after egg hatch (4.79-fold; Table 2). mRNA encoding prephenate dehydratase (synthesis of the aromatic amino acid phe) increased in susceptible plants compared to

Table 3 Concentration of amino acids found to be significantly more abundant in Hessian fly-infested wheat compared to uninfested controls

controls 4 days after egg hatch (1.79-fold, $P<0.001$; Fig. 2C) and corresponded to increased free phe in susceptible plants on days 4 and 7 (Table 2).

Accumulation of mRNA Encoded by Wheat Genes Involved in Amino Acid Transport In addition to de novo synthesis of free amino acids, the concentration of these chemicals may be increased at larval feeding sites by transport from other tissues. mRNA encoding a pro transporter was significantly more abundant in susceptible plants than in controls, 4 days (1.75-fold, $P<0.001$) and 7 days (2.05-fold, $P<0.001$) after egg hatch (Fig. 2D) and corresponded to increased free pro in susceptible plants 4 days after egg hatch (Table 2). In susceptible plants at all time points tested, mRNA encoding a transmembrane amino acid transporter was more abundant compared to uninfested controls (day 1: 2.92-fold, $P<0.001$; day 4: 7.03-fold, $P<0.001$; day 7: 3.53-fold, $P<0.001$; Fig. 2E). While mRNA encoding a histidine transporter was significantly more abundant than in controls, 4 days (6.74-fold, $P<0.001$) and 7 days (5.83-fold, $P<0.001$) after egg hatch in susceptible plants (Fig. 2F), free his levels were not significantly higher in susceptible plants compared to uninfested controls (Table 2).

Discussion

Biotype L larvae caused greater increases for susceptible than for resistant plants in wheat free amino acids and mRNAs that encode enzymes for amino acid synthesis or

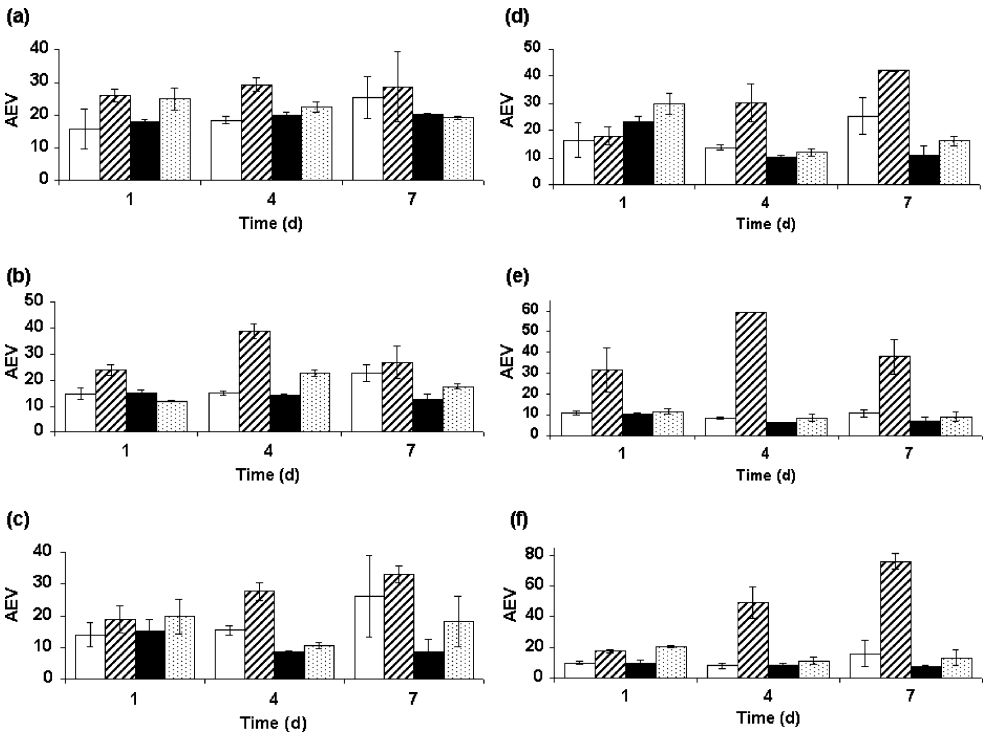

Fig. 2 mRNA levels for wheat genes involved in amino acid synthesis and transport. mRNA levels were quantified by qRT-PCR 1, 4, and 7 days after Hessian fly Biotype L egg hatch. *Bars* represent the mean arbitrary expression value (AEV)±SD (nonlogarithm transformed) from two independent experiments. AEV data are shown for Newton uninfested wheat (*white bar*), Biotype L-infested Newton susceptible wheat (*bar with diagonal lines*), *H9*-Iris uninfested wheat (*black bar*), and Biotype L-infested *H9*-Iris resistant wheat (*bar with dots*). Plants used for isolation of total RNA for qRT-PCR were grown in parallel to plants used for free amino acid analysis. **a** Alanine aminotransferase (glutamate synthesis). **b** Pyrroline-5-carboxylate synthetase (proline synthesis). **c** Prephenate dehydratase (phenylalanine synthesis). **d** Proline transporter. **e** Transmembrane amino acid transporter. **f** Histidine amino acid transporter

transport. This manipulation of free amino acid abundance may result in improved nutritional quality of plant fluids ingested by virulent larvae. Gall-forming insects are known to manipulate their host plants and produce new cell-types and structures as well as changes in source-sink relationships that are beneficial to larval development. Likewise, alterations in host plant gene expression and the production of chemicals, such as polyamines and leaf waxes, are among the responses of susceptible wheat when under attack by virulent Hessian fly larvae (Williams et al., unpublished). Alternatively, these increases in amino acid abundance may be a side effect that does not impact larval nutrition directly, but may be associated with the changing physiological processes in the susceptible plant as it adapts to accommodate the Hessian fly larvae.

Among the amino acids that became more abundant in susceptible plants were three essential amino acids [his, methionine (met), and phe] that insects cannot synthesize and must be received in their diet. Sandström et al. (2000) reported that feeding by the greenbug (*S. graminum*) caused an increase in host wheat plant production of these same three plus six additional essential free amino acids. Russian wheat aphid (*D. noxia*) feeding on wheat resulted in higher levels of the essential amino acids arginine (arg), his, and lysine (lys) (Sandström et al. 2000). Our studies with Hessian fly larvae on susceptible wheat detected significant increases in five nonessential amino acids [alanine (ala), aspartate (asp), glu, glycine (gly), and ser] that were not found to become more abundant following feeding by either *S. graminum* or *D. noxia*. Thus, wheat plants respond differently to attack by insects from diverse feeding guilds.

Once the wheat nutritive tissue was established and Hessian fly larvae were in their sessile second-instar, the greatest accumulation occurred for tyr, its precursor phe and mRNAs that encode enzymes involved in their synthesis. Tyrosine is important for immature insects because it is a precursor for formation of polyphenols and quinones that lead to darkening and hardening of insect cuticles (Heady et al. 1982) at pupation (Dindo et al. 2006). The high levels of phe and tyr that we observed 7 days after egg hatch occurred about 2 days before melanization would have started (McColloch 1923) just prior to pupation. In plants, plastids appear to be a primary site for synthesis of aromatic amino acids (Gruys and Sikorski 1999). Interestingly, Harris et al. (2006) noted an increased abundance of proplastids in Hessian fly-induced nutritive tissue cells.

Proline may be rapidly synthesized, transported, and degraded to provide energy for plant functions induced by Hessian fly larvae in susceptible wheat. Amino acids that can be converted into pro accumulated to high levels 4 days after egg hatch; glu (pro precursor, Fig. 1) was present in the highest concentration of any amino acid, and several amino acids capable of being converted to glu (ala, gln, his, and orn) were more abundant than in controls (Tables 2, 3). Increased abundance of mRNA encoding enzymes involved in synthesis of glu and pro (Fig. 2; alanine aminotransferase, pyrroline-5-carboxylate synthetase) suggested that increased free pro resulted from de novo amino acid synthesis and did not arise simply from proteolysis. At the same time, large fold-change increases in pro were detected, yet its concentration was relatively low suggesting that it was being transported or metabolized (4 days after egg hatch at the peak of nutritive tissue formation). Our qRT-PCR results showing increased abundance of mRNA encoding a proline transporter (Fig. 2) suggested translocation of accumulated pro, but the lack of high pro concentration suggested that it was being metabolized. In plants, biosynthetic routes that contribute to pro synthesis are regulated at both the gene expression and enzyme activity level (Verma and Zhang 1999).

Several published reports highlight possible functions for free pro in plants. Free pro accumulates in plants undergoing biotic or abiotic stress (Rhodes et al. 1999), followed poststress by rapid catabolism, which may support mitochondrial oxidative phosphorylation and generate ATP for repair of stress-induced damage (Hare and Cress 1997). Meon et al. (1978) reported that free pro levels increased in tomato roots (*Solanum lycopersicum* L.) following infection by *Agrobacterium tumefaciens*, suggesting that metabolic demands from giant cell and gall formation were met by translocating free pro. Oxidation of one molecule of pro yields approximately 30 ATP equivalents, making its accumulation an effective means by which to store energy that can be rapidly mobilized in the plant (Hare and Cress 1997). mRNAs associated with the tricarboxylic acid cycle become more abundant in Hessian fly-susceptible wheat (Zhu et al. 2008). Increased levels of tricarboxylic acid cycle intermediates could stimulate production of NADH and lead to greater production of ATP through the action of the electron transport chain, to meet energetic demands encountered during compatible wheat–Hessian fly interactions.

The possibility that free pro is ingested and used directly by virulent Hessian fly larvae cannot be ruled out. Plant pro can function as an insect-feeding stimulant (Behmer and Joern 1994; Carter et al. 2006) and also serves as an insect energy metabolite (Bursell 1981). Evidence suggests that oxidation of free pro in insect hemolymph leads to increased energy production through the formation of tricarboxylic acid cycle intermediates (Sacktor and Childress 1967; Bursell 1981; Gäde and Auerswald 2002). The involvement of biosynthetic pathways that lead to production of pro and a concomitant increase in free pro levels we observed in susceptible wheat could serve as a direct energy source for developing larvae and improve the nutritional quality of their diet.

The compatible interaction in which virulent Hessian fly larvae manipulate the development and physiology of susceptible wheat is only recently starting to be understood at the molecular level. However, we have demonstrated that larvae induce increased production of free amino acids that are essential for insect development. In addition, increased synthesis and transport of pro may provide energy directly to larvae as well as supporting plant processes such as nutritive tissue formation that deliver nutrients to developing larvae.

1992) and soil organic matter dynamics (Veen et al. 1989), so that changes in rhizodeposition patterns and amounts could have profound effects on overall soil properties and ultimately affect the survival of the plant (Widmer et al. 2001). Some workers (Klein et al. 1988, Grayston et al. 1996, Merbach et al. 1999) have suggested that there may be a release of C-rich exudates by some plants as an adaptation to stimulate microbial activity (Lynch and Whipps 1990, Mawdsley and Bardgett 1997).

Defoliation (removal of parts of the shoot) is a common feature in the life span of many pasture species with effects on both above-ground productivity and below-ground turnover of roots (Milchunas and Lauenroth 1993; McNaughton et al. 1998). In grasses such as *Lolium perenne* L., the ability to grow after cutting or grazing is important to persistence, although species differ in their responses to defoliation. Frequently, defoliation and grazing practices cause a change in both metabolism and the pattern of C allocation within grasses (Macduff and Jackson 1992; Johansson 1993; De Visser et al. 1997), resulting in a reduction of nutrient uptake and an increase in exudation of organic C from roots (Deane-Drummond 1986; Paterson and Sim 1999). Frequent defoliation of perennial ryegrass (*Lolium perenne* L.) resulted in lower water-soluble carbohydrate reserves and less developed root systems than in plants defoliated less frequently, with frequent defoliation in spring reducing survival over summer (Fulkerson and Slack 1994). There are also interactions between the carbon balance of the plant and that of other nutrients. For example, defoliation of *Lolium perenne* L. inhibited nitrate uptake, and absorption rates increased only after the whole plant carbon balance was re-established (Clement et al. 1978). Similarly Macduff and Jackson (1992) noted a three-fold increase in nitrate efflux from roots of defoliated plants compared to those of non-defoliated plants.

Several studies of root exudates have concentrated on the analysis of the individual monosaccharides and the more complex polysaccharide groups (Jones and Darrah 1992; Morvan-Bertrand et al. 1999; Osborn et al. 1999). Identification of individual sugars poses several analytical problems. Greenaway et al. (1987) developed an acetylation technique to allow the detection of small amounts of carbohydrates by gas chromatography-mass spectrometry (GC-MS). Jones and Darrah (1992) used this technique to analyze the sugars at the root tip and in root exudates of maize (*Zea mays* L.). Glucose, mannose, and galactose were the major sugars present, with traces of fructose and trehalose. Osborn et al. (1999) developed a more sensitive method for analyzing sugars in the mucilage of maize that involved the hydrolysis of the polysaccharides to their constituent monosaccharides followed by subsequent identification using GC. The major monosaccharide component identified was glucose but, as with earlier techniques (e.g., Oades 1967), some peaks remained unidentified.

The aims of this study were to collect and quantitatively analyze water soluble carbohydrates in root exudates of perennial ryegrass, and to investigate the effects of defoliation on their composition. A microlysimeter system was designed in which plants were grown from seed, and exudates were collected while the plants grew. Preliminary work demonstrated that the concentration of sugars in exudates was below the detection limit of liquid chromatography using Dionex columns, so GC-MS was employed for analysis (HPLC-MS being unavailable). The resulting study combined derivatization techniques developed by Osborn et al. (1999) with revised GC-MS procedures to analyze sugars in perennial ryegrass (*Lolium perenne* L.) exudates. Full details of the GC-MS analysis are given by Clayton (2003).

Methods and Materials

Growth of Plants and Collection of Exudates Seeds of *Lolium perenne* L. were sterilized in a petri dish containing 20 ml of sterile water, covered, and agitated for 1 min. The seeds were then soaked in 75% ethanol for 1 min, the excess solution decanted, and 20 ml 1% sodium hypochlorite solution was added for 5 min. Seeds were soaked again in 75% ethanol for 30 sec, drained, and rinsed immediately, twice with sterile water to remove any trace of the sodium hypochlorite solution. Seeds were then left to stand in sterile water to imbibe for a further 30 min before transfer to a second sterile petri dish. Five seeds from each petri dish were removed with the use of sterile tweezers, and planted into each of eight microlysimeters (50 ml syringe barrel) filled with sterilized sand (Murray et al. 1996). Each microlysimeter was housed in a separate growth chamber constructed from a Perspex cylinder (250 mm tall and 150 mm diam) with Perspex plates fitted to the top and bottom (Murray et al. 2002). The apparatus (all tubing, taps, and mycrolysimeters) was made with autoclavable materials. All items, even though packaged as sterile, were autoclaved before use. Nutrients (Hoagland and Arnon 1950) were pre-mixed, and frozen until required, and both the container and nutrient solution were autoclaved before use. Filters were fitted to both the "air in" and "nutrient out" tubes of the nutrient container to maintain sterility.

Individual growth chambers were placed inside a controlled temperature laboratory with a light/dark temperature of 18/14°C, a 16 hr photoperiod, and a photon flux density of approximately 350µmol m^{-2} sec^{-1} at the plant level. The five plants in each chamber were supplied with nutrient solution at a rate of 1 ml min^{-1} for 15 min, three times daily by using a peristaltic pump. Air, filtered through

a 500 μm filter, was pumped through the chambers at a rate of 250 ml min^{-1}. Plants were allowed to grow for 28 d to produce established plants, and then the drained nutrient solution containing exudates was collected from the individual chambers at 3 sampling times (08:00; 16:00; 24:00 hr) each day for a further 27 d period (referred to as days after establishment, dae). The solutions were immediately frozen to limit any microbial activity and subsequently freeze-dried and stored in a cool dry, dark environment for future analysis. At 8 dae, four chambers were randomly selected and all plants within them defoliated to 4 cm above the height of the sand; this height was chosen to leave some photosynthesizing leaf area after defoliation. Thereafter, the same plants were again defoliated at 10, 12, 15, 18, and 24 dae. As the experiment progressed, the time span increased between each cut as growth became less vigorous.

Analysis and Identification of Sugars The method developed by Osborn et al. (1999) that involves simultaneous hydrolysis and acetylation of the freeze-dried root exudate was used. Dulcitol (galactitol) was added at 2 μg as a standard to each flask before samples were acetylated. Dulcitol was chosen because preliminary studies showed that it was not present in any of the exudates, possessed a longer retention time than the other sugars present, and was identified easily. A mixture of acetic anhydride-glacial acetic acid-sulfuric acid (10:10:1) was refluxed with the freeze-dried exudate in a round bottom flask placed in a water bath at 40°C for 3 hr. The reaction mixture was then cooled in an ice bath before 5 ml of distilled water was added, drop wise, and 20 ml of diethyl ether was used to extract the resulting aqueous phase. The organic phases were then washed with saturated K_2CO_3 solution, dried over magnesium sulfate, and filtered. The solution was evaporated under reduced pressure at 60°C to give an oily product ready for GC-MS analysis.

Analyses were carried out on a Hewlett Packard 5890 GC (Hewlett Packard 5890) fitted with a Restek Rtx-50 column (15 m long, 0.25 mm i.d., 0.1 μm coating) with helium as the carrier gas at an inlet pressure of 34 kPa, coupled to a Hewlett Packard 5970 Mass Selective Detector. At injection, the initial column temperature was set to 50°C and held for three min before increasing to 250°C at a rate of 15°C min^{-1}, and the final temperature was held for 5 min. The temperature of the injection head was 260°C.

The monosaccharide carbohydrate groups were identified from their mass spectra and retention times. Detection was enhanced by running samples in selected-ion mode. The fragment ion at m/z 115 was a particularly useful marker, present in the mass spectra of all the various sugar types and, coupled with the retention time, made detection of monosaccharide sugars easier because peaks could be distinguished from background contaminants. Sugars such as the pentoses and deoxyhexoses had similar acetylated molecular weights because they had the same number of OH groups prior to acetylation. Analysis of the results was thus made easier when sugars were grouped according to the number of OH groups present prior to acetylation rather than the number of carbon atoms.

Commercially available sugars were used for comparison of retention times and mass spectra to the detected sugars. Samples of 15 sugars (including the dulcitol standard) were individually weighed to four decimal places, then dissolved in deionized water, freeze-dried and acetylated. This mixture of derivatized monosaccharide sugars produced an array of GC peaks with various retention times corresponding to the component sugars (see Clayton 2003). By examining the mass spectral fragmentation pattern and the retention time, it was possible to characterize and confirm the identity of each GC peak. Individual sugars found in exudates were identified by comparison of retention times and mass spectra with those of the individual, derivatized commercial sugars.

Quantification of Sugars Three replicate flasks, each containing known weights of the 15 standard sugars, were acetylated and injected into the GC-MS. The peak area for each sugar was determined. The ratios of peak areas and amounts of each sugar to the dulcitol standard were calculated. This allowed calculation of a calibration factor, which was used to convert areas of sugar peaks in the exudate samples to quantities. Individual sugars were grouped into six types, and a mean calibration factor for each group was used to calculate the quantity of each sugar present. The calibration factor was <1 for the 4 OH (erythritol and threitol) and 5 OH (arabitol and xylitol) alcohol sugars, but >1 for all other groups (see Clayton 2003).

Statistical Analysis Some of the data were analyzed with the statistical package GenStat Release 6.1 using the program Bartlett 3-group regression method (Sokal and Rohlf 1981) that was designed to predict functional relationships between two variables (X and Y) using only one sample. The procedure estimates the functional relationship by calculating the slope (b) of the X variate. Defoliated values were plotted against non-defoliated values, and the slope (b) and 95% confidence levels were calculated (b_1 5% standard error below the slope of regression line; and b_2 5% standard error above the slope of regression line). If b_1 and b_2 were both <1, the effect of defoliation was significant at the 5% confidence level and less sugar was produced, whereas if b_1 and b_2 were both >1, the effect of defoliation was to enhance sugar production significantly (5% confidence level). Our "null" hypothesis was that the slope of values from defoliated plants when plotted against values from non-defoliated

plants would be 1 if defoliation had no effect on sugar exudation.

Results

Detection of Sugars Preliminary analysis of individual microlysimeters produced chromatograms with only a few variable sugar peaks present, so solutions from all microlysimeters were combined (8 prior to defoliation and 4 each of defoliated and non-defoliated thereafter) at each sampling time to facilitate analysis. The gas chromatograms showed predominantly one anomer (one peak) for each monosaccharide. Although it was sometimes possible to identify both anomers (two peaks), this was rare because the background noise masked many smaller peaks. The technique of acetylating OH groups on the carbon rings of sugar or at the end of the molecule resulted in a longer retention time the greater the number of OH groups present (Table 1). By using a combination of retention times and the library of fragmentation ions, it was possible to detect six major sugar types based on the number of carbon atoms present and the number of OH groups present prior to acetylation. This permitted the identification of several aldehyde sugars and alcohol sugars not previously documented as being present in root exudates.

Early samples (1 and 2 dae) contained an array of sugars, but peak intensities were low compared to the dulcitol standard (Fig. 1, peak G), though by 6 dae, with increased plant growth, many of the peaks were larger than the standard. At 1 dae, there were few alcohol sugars present, but by 6 dae they were some of the major peaks found (Fig. 1). At this early stage of sampling, it was not possible to detect any differences among sugars collected in the light and dark phases.

Shortly after defoliation commenced (8–12 dae), there were no obvious differences between defoliated and non-defoliated plants; aldehyde and alcohol groups were present with gradually increasing intensity. At 13 dae, a rapid change in alcohol sugars occurred in both defoliated and non-defoliated plants, as the peaks associated with 4 C, 4 OH (Fig. 2a and b, peak A) and 6 C, 6 OH alcohol sugars (Fig. 2a and b, peak F) almost disappeared, while the 5 C, 5 OH alcohol peaks (Fig. 2a and b, peak D) also were greatly reduced in size. Between 13 and 27 dae, the 4 C, 4 OH alcohol sugar (Fig. 2c and d, peak A) never reappeared in either the non-defoliated or defoliated plants. However, there was a gradual recovery of both 5 C, 5 OH and 6 C, 6 OH, alcohol sugars in defoliated plants with time (Fig. 2d, peaks D and F).

In contrast to the alcohol sugars, there was no sudden decrease in peak intensity after 13 dae for the 5 C, 4 OH, 6 C 4 OH, and 6 C, 5 OH aldehyde sugars (Fig. 2, peaks B, C and E). The 5 C, 4 OH, and 6 C, 4 OH aldehyde sugars increased in both non-defoliated and defoliated exudates, and there was no obvious effect of defoliation. This was also the pattern for the more complex 6 C, 5 OH aldehyde sugars, so that for the first few weeks of sampling, peak intensities increased for both non-defoliated and defoliated plants. However, by 24 dae and thereafter, comparison of peak intensities with the internal dulcitol standard showed that defoliation caused an increase in 6 C, 5 OH aldehyde sugars released in root exudates (Fig. 2d, peak E), though not of 5 C, 4 OH and 6 C, 4 OH aldehyde sugars (Fig. 2d, peaks B and C). Over the 27 d period of defoliation, the aldehyde sugars became the major sugar components of the root exudates.

Identification and Quantification of Sugars By using the library of retention times and mass spectra prepared from derivatized, commercially available sugars, it was possible to name 11 of the individual peaks of the chromatograms. Peak areas were measured and normalized with respect to the dulcitol standard, and the previously determined calibration factor for groups of sugars was applied to give estimates of the quantities of each sugar in the exudates. Mass was recorded for each of 11 named peaks at each sampling point, and cumulative exudation recorded. To make the presentation of the results easier, sugars with similar cumulative patterns were consolidated into three groups. The first group, where defoliation enhanced sugar amounts; the second, where defoliation had no effect; and the third, where there was a detrimental effect.

The first group contains the 4 C, 4 OH alcohol ‘type’ 1 group sugars, erythritol and threitol, and the 5 C 5 OH alcohol ‘type’ 4 group sugar xylitol (Fig. 3). Clear differences between non-defoliated and defoliated plants were evident from the initial period of defoliation onwards. Changes occurred earliest in threitol (7 dae) but were more pronounced in the erythritol and xylitol sugars, especially at 11 dae, and resulted in enhanced exudation of these sugars in defoliated plants.

For the second group of sugars, although patterns were slightly different among the individual sugars, there was no overall enhancement or detrimental effect on sugar amounts resulting from defoliation. Of the two 5 C, 4 OH aldehyde ‘type’ 2 group sugars, xylose was present in much greater amounts than ribose (Fig. 3d and e). Cumulative amounts of xylose were slightly greater in non-defoliated plants, but followed a similar pattern for both treatments. This contrasted with ribose, which was cumulatively greater from the defoliated samples until the later stages of the 27 d period. The only identifiable sugar of the 6 C, 4 OH aldehyde ‘type’ 3 was fucose (Fig. 3f). Again, there was little evidence of an effect of defoliation over the 27 d period, but the pattern of production appeared slightly more

Table 1 Retention times for the six fragmentation types of sugars found in root exudates from *Lolium perenne*

9-10 min	4C, 4OH alcohols (e.g. erthritol, threitol)  Fragmentation Type 1.	Derivatize to tetracetates
11-12 min	5C, 4OH aldehydes (e.g. arabinose, xylose, ribose)  Fragmentation Type 2.	(pentoses) Derivatize to tetracetates
11-12 min	6C, 4OH aldehydes (e.g. rhamnose, fucose)  Fragmentation Type 3.	(deoxyhexoses) Derivatize to tetracetates
12-13 min	5C, 5OH alcohols (e.g. arabitol, xylotol)  Fragmentation Type 4.	Derivatize to pentacetates
14 min	6C, 5OH aldehydes (e.g. galactose, glucose, mannose)  Fragmentation Type 5.	(hexoses) Derivatize to pentacetates
15-16 min	6C, 6OH alcohols (e.g. galactitol, glucitol, mannitol)  Fragmentation Type 6.	Derivatize to hexacetates

erratic for the non-defoliated plants. Galactose (a 6 C, 5 OH aldehyde 'type' 5 group sugar) exudation also showed no overall effect of defoliation although cumulative release was higher in defoliated plants until 21 dae, after which the non-defoliated weight was slightly higher (Fig. 3g).

The third group, showed a detrimental effect of defoliation on the amounts of sugar exuded when compared to non-defoliated plants although the extent of the effect was different among sugars. For glucose (6 C, 5 OH alcohol 'type' 5 sugar), the quantity released from non-defoliated plants was considerably higher than that from defoliated plants from 17 dae onwards (Fig. 3h). Similar patterns were also found for arabitol (5 C 5 OH alcohol 'type' 4 sugar) and mannitol (6 C, 6 OH alcohol 'type' 6 sugar) where there was initially no influence of defoliation, but there was a sudden increase in amounts in the non-defoliated samples 22 dae (Fig. 3i and j).

Amounts of mannose were smaller compared with the other two named 6 C, 5 OH aldehyde 'Type' 5 group sugars (glucose and galactose). Cumulative weights followed a similar pattern of sugar exudation for both defoliated and non-defoliated plants until 16 dae, after which almost no more mannose was produced by defoliated plants. In non-defoliated plants, the cumulative weight of mannose was still increasing at the end of the 27 d period (Fig. 3k).

The bulking of samples meant the loss of replication, but the Bartlett 3-group regression method (Sokal and Rohlf 1981) allowed statistical testing of the responses of

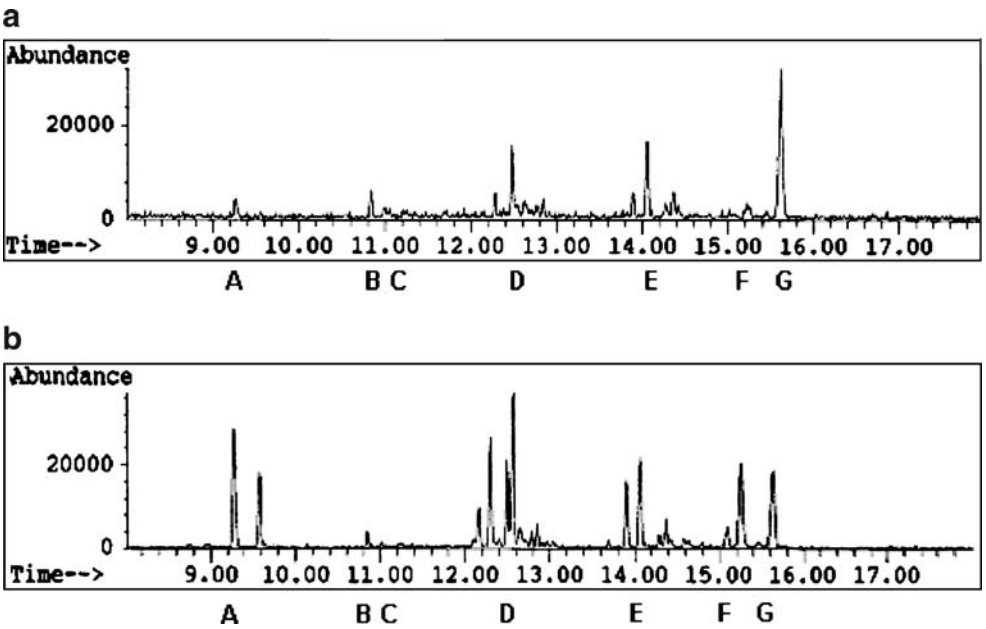

Fig. 1 Typical chromatograms showing the increase in alcohol sugars between 1 dae (a) and 6 dae (b). The letters on the x axes show: **A**, 4 C 4 OH alcohol sugars (MS fragmentation pattern type 1 – see Table 1 for a fuller description of fragmentation patterns); **B**, 5 C 4 OH aldehyde sugars (MS fragmentation pattern type 2); **C**, 6 C 4 OH aldehyde sugars (MS fragmentation pattern type 3); **D**, 5 C 5 OH alcohol sugars (MS fragmentation pattern type 4); **E**, 6 C 5 OH aldehyde sugars (MS fragmentation pattern type 5); **F**, 6 C 6 OH alcohol sugars (MS fragmentation pattern type 6); **G**, dulcitol standard (also MS fragmentation pattern type 6)

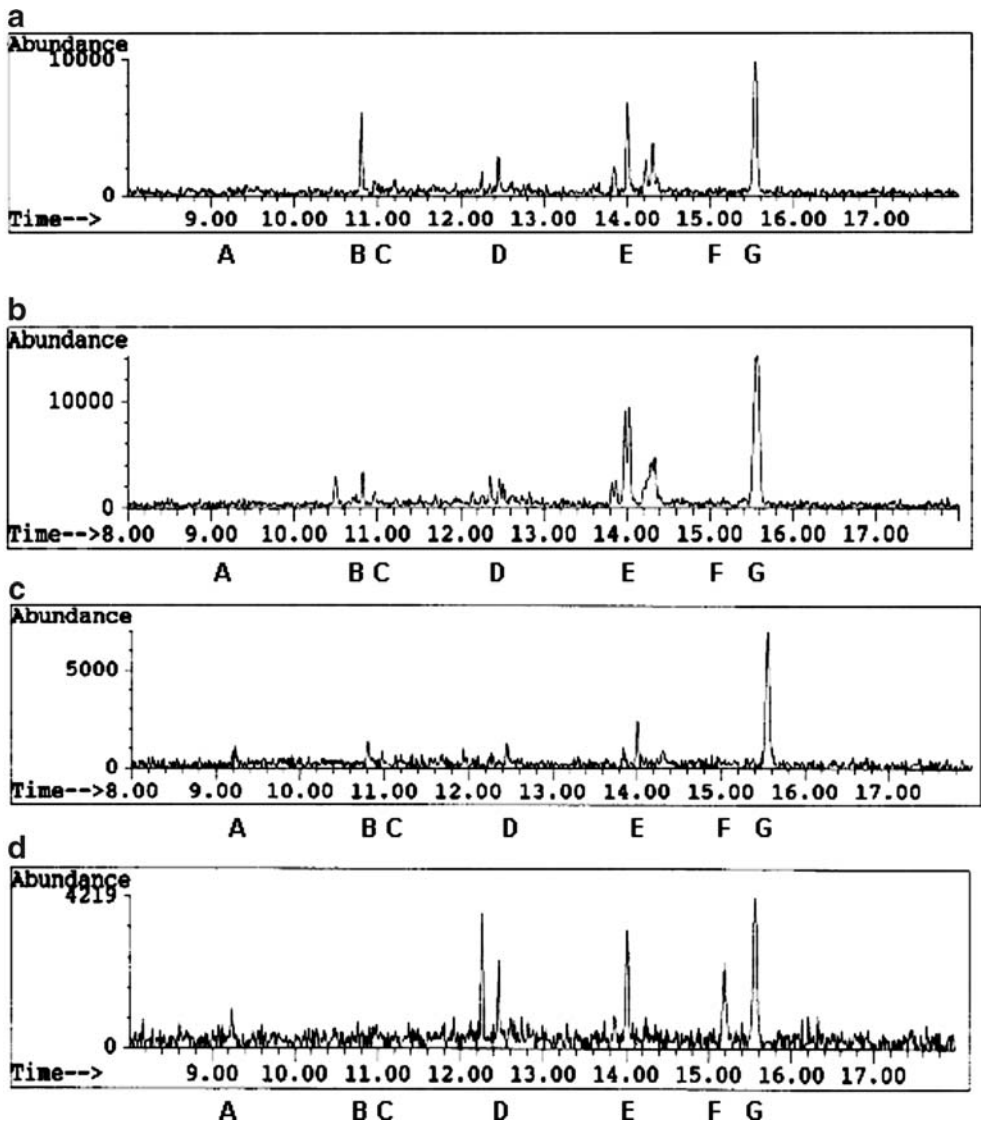

Fig. 2 Typical chromatograms showing the sugars recorded in root exudates at 13 dae (a, non-defoliated and b, defoliated plants) and 27 dae (c, non-defoliated and d, defoliated plants). The letters on the x axes are as in Fig. 1 and indicate where a peak would be expected if that sugar were present in the exudate

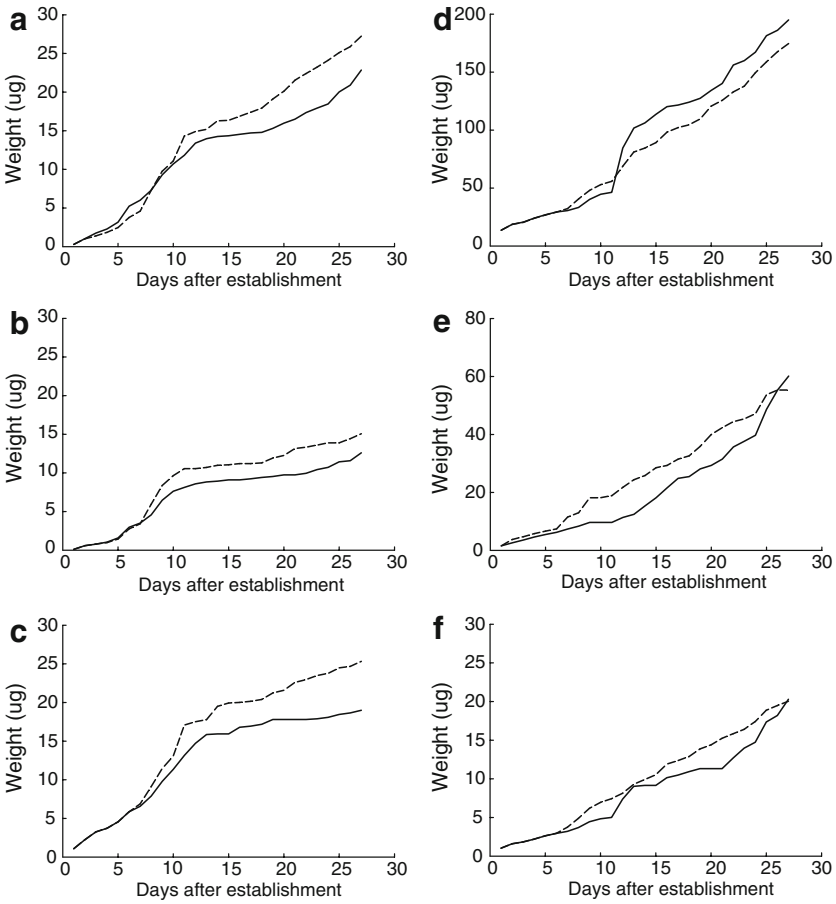

Fig. 3 Cumulative weights of sugars present in non-defoliated (solid line) and defoliated (dashed line) plant root exudates over the 27 d period: a) erythritol, b) threitol, c) xylitol, d) xylose, e) ribose, f) fucose, g) galactose, h) glucose, i) arabitol, j) mannitol, and k) mannose. The defoliation commenced at 8 dae and was repeated at 10, 12, 15, 18 and 24 dae

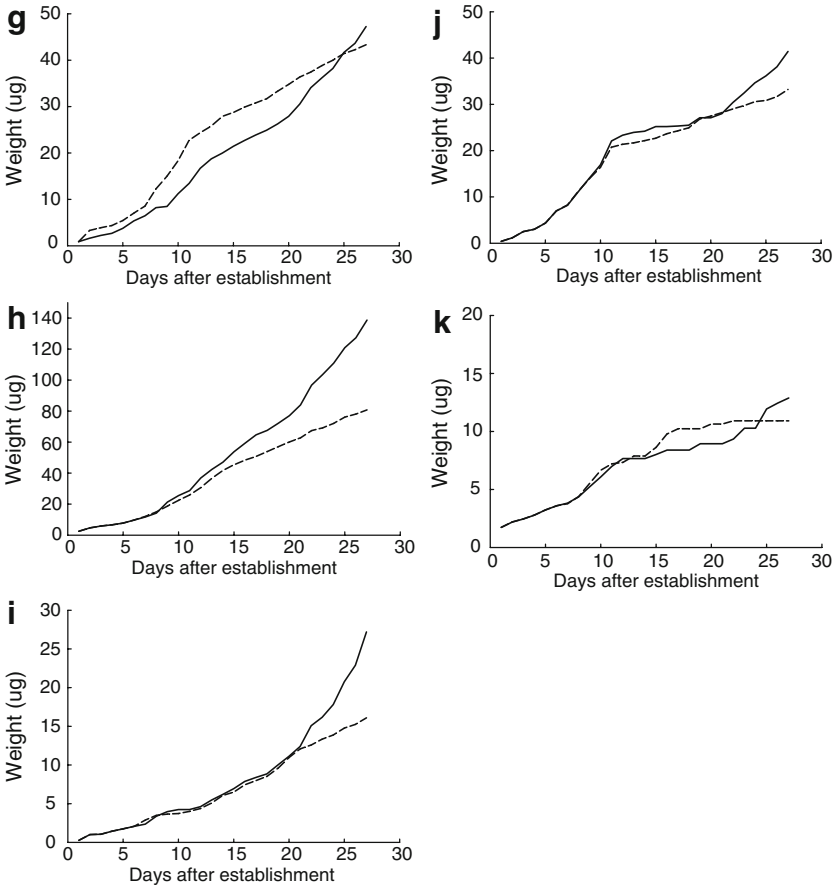
individual sugars to defoliation at each sampling time (08:00; 16:00; and 24:00 hr) over the period of defoliation (8 to 27 dae; Table 2). This analysis highlighted not only large variations in response to defoliation among individual sugars, but also variation within sugar groups. Defoliation reduced exudation of glucose at all sampling times (*b*: 0.6698; 0.5697; 0.6844), whereas for xylitol, amounts were enhanced at all sample times (*b*: 1.282; 1.780; 1.174). For all the other nine identifiable sugars, the effect of defoliation was more varied. For xylose, mannose, and mannitol, amounts were reduced in some of the defoliated exudate samples, but not at all sampling times. Ribose showed a similar but opposite pattern. At the 8:00 sample time, there were greater amounts of sugar from exudates of defoliated plants than from non-defoliated plants (b= 1.518), with no overall effects at 16:00 (b=1.111) and 24:00 (b=0.9023). For erythritol, threitol, fucose, and arabitol, there was a variable pattern of sugar exudation. While at one sampling time there was an enhancing effect due to defoliation, at another there was a detrimental effect. Because of these variable patterns, multiple testing corrections were not applied to the significance values.

Overall, xylose was the sugar exuded in the highest amount, and mannose the least, with glucose demonstrating the largest difference between non-defoliated and defoliated treatments and fucose the smallest difference. The 4 C, 4 OH alcohol group sugars (erythritol and threitol) was the only group present in exudates in greater amounts in defoliated samples than non-defoliated plants. There were differences within sugar groups, so that in the 5 C, 5 OH alcohol sugars, amounts of xylitol in exudates were slightly higher for defoliated plants, but the opposite was found for arabitol. For the aldehydes sugars, the amounts were generally greater in the non-defoliated plants.

Discussion

Root exudation is a key process in the transfer of C into the soil, and influences the composition and activities of soil microbial communities especially in processes of organic matter decomposition and nutrient cycling (Paterson 2003). The effect of defoliation of grasses has been found in some studies to increase the exudation of soluble compounds (Macduff and Jackson 1992, Morvan-Bertrand et al. 1999, Paterson and Sim 1999), and as a consequence, to enhance microbial activity over short periods, resulting in increased microbial biomass (Holland 1995, Mawdsley and Bardgett

Fig. 3 (continued)



1997) and culturable bacteria in the rhizosphere (Mawdsley and Bardgett 1997). However, other studies have indicated the opposite, with defoliation having little or no effect on overall microbial activity and microbial biomass (Wardle et al. 1997, Mikola et al. 2001).

In the present study, there was a slight increase in the total amount of sugars detected in the root exudates of defoliated compared to non-defoliated plants after the initial defoliation. This observation confirms those of Paterson and Sim (1999) who measured increased exudation of soluble compounds from *Lolium perenne* L. for periods of 3–5 d following cutting. Similarly, Paterson et al. (2005) measured enhanced C exudation from roots of *Festuca rubra* 0–2 d after defoliation but, as in the present study, this initial effect was subsequently reversed. The transient elevation of exudation following defoliation may reflect depletion of C and N storage compounds during this period (Paterson et al. 2005).

Mawdsley and Bardgett (1997) reported that continuous defoliation reduced C exudation by 14% in ryegrass and 4% in clover. Here, continual defoliation reduced the total quantity of sugars exuded by 16%, although the degree of change seemed to depend upon the type of sugar. The more complex 6 C, 5 OH aldehyde group sugars, especially glucose, showed changes in exudation patterns due to defoliation earlier and to a greater extent, than the 5 C, 4 OH (xlyose and ribose) and 6 C, 4 OH (fucose) aldehyde groups. Results showed that even sugars within the same group 'type' had different responses to defoliation. The overall amounts of arabitol and xylitol (5 C, 5 OH alcohol 'type' 4 group) sugars were approximately the same, although the cumulative patterns of sugar exudation were different. The 4 C, 4 OH alcohol sugars (erythritol and threitol) were the only group, along with xylitol (5 C 5 OH alcohol group), that was higher for defoliated plants than for non-defoliated plants throughout the 27 d experiment. Erythritol and threitol showed no sign of a detrimental effect of defoliation although the Bartlett 3-group regression method (Sokal and Rohlf, 1981) highlighted differences between the individual sugars. Both erythritol and threitol had a period where there was a significant effect of defoliation on sugar release that was not readily seen in the cumulative graphs.

Because sterile microcosms were used in this study, some care is required in the extrapolation of the results to field systems. The plants were grown in sterile sand (Hodge et al. 1996; Paterson et al. 1999), because under natural growth conditions in soil, root exudates are rapidly used by microbes and their chemical nature altered (Haller and Stolp 1985). The present study combined analysis that used

Table 2 Slope values of monosaccharide sugars generated using the bartlett 3-group regression method (Sokal and Rohlf 1981)

Values demonstrating that defoliation was detrimental to exudation are highlighted in dark grey while those demonstrating that defoliation enhanced exudation are highlighted in light grey. Values with no significant effect are not highlighted

GC-MS, a system used in previous studies (Svenningsson et al. 1990; Morvan-Bertrand et al. 1999), with an acetylation method (Osborn et al. 1999) to improve the range of sugars detectable in single-ion mode. Previous work identified several aldehyde sugars present in the root exudates of *Lolium perenne* plants (Jones and Darrah 1992; Morvan-Bertrand et al. 1999), although not the range detected by using the method developed in this work. Although it was not possible to identify every peak, 11 individual sugars were identified comprising 6 aldehyde sugars (consistent with earlier work reported by Jones and Darrah 1992) and 5 alcohol sugars not previously documented.

The acetylation technique could be used only to identify the monosaccharide components of root exudates. Although the majority of sugars were probably free monosaccharides, any polysaccharides present in the exudates would have been hydrolyzed to their constituent monosaccharide compounds (Osborn et al. 1999). For example, the disaccharide sucrose would have been acetylated to fructose (Guerrand et al. 1996; Morvan-Bertrand et al. 1999). However, as there was no evidence of fructose in any of the root exudate samples, it suggests that although sucrose is often a major transport sugar in grasses (Pollock et al. 2003), it was not exuded in any great amount from the roots of these *L. perenne* plants. These results agree with those of Jones and Darrah (1992) who also failed to detect sucrose and only 1.5% fructose in the total sugars exuded from root tips of *Zea mays*. Read and Gregory (1997) also found total sugars in the mucilage of *Zea mays* to be dominated by glucose.

The presence of a large number of monosaccharides in the exudate samples, especially glucose and xylose, has significant implications for the turnover of carbon in the rhizosphere, as such monosaccharides would be broken down rapidly in the presence of soil microbes (Killham 1994; Paterson 2003). Little is known about the effects of specific sugars on microbial communities and whether changes in the composition of sugars in exudates following defoliation would have differential effects on those communities. Moreover, soil microbes are likely to increase the net loss of root C through their activity as a C-sink (partially offset in the present study by the frequent flushing out of the exudates) and because of production of metabolites that increase root permeability (Meharg and Killham 1995).

elusive but may involve differences in innate immune responses (Woodhams et al. 2007a). An additional hypothesis is that a mutualism exists between the amphibian host and cutaneous antifungal bacteria symbionts and is effective on some individuals and species, but not in others (Fig. 1; Harris et al. 2006; Lauer et al. 2007, 2008; Woodhams et al. 2007b).

We suspected that the inhibitory effects of the antifungal symbionts are due to secondary bacterial metabolites as opposed to resource competition. Previously, we tested the hypothesis of inhibitory metabolite production with a strain of *Lysobacter gummosus* isolated from the skin of the salamander *P. cinereus*. The bacterium inhibited the fungus in challenge assays and produced the antifungal metabolite 2,4-diacetylphloroglucinol in vitro at concentrations that could inhibit the pathogen (Brucker et al. 2008).

Continuing our investigations of antifungal metabolites, a bacterium closely related to *Janthinobacterium lividum* based on DNA sequence similarity was also examined. This bacterium is commonly found on *P. cinereus* as well as the four-toed salamander, *Hemidactylium scutatum*, and it strongly inhibited pathogenic fungi in vitro (Lauer et al. 2007). We hypothesized that it, too, produces antifungal metabolites that act to reduce or prevent colonization of *B. dendrobatidis* on amphibians. Furthermore, we sampled the skins of wild salamanders to determine whether antifungal metabolites were present in inhibitory concentrations.

Methods and Materials

Isolation and Culturing of J. lividum As per published method (Harris et al. 2006; Lauer et al. 2007, 2008; Brucker et al. 2008), individuals of the salamander species *P. cinereus* were rinsed twice to remove transient bacteria and swabbed with sterile swabs. Pure bacterial cultures were obtained, genomic DNA was extracted, and a portion of the 16S rRNA gene was amplified by using 357F and 907R primers (Lauer et al. 2007). DNA obtained from the pure culture of *J. lividum* was sequenced by Agencourt (Beverly, MA, USA). A consensus sequence of approximately 1,400 bp was obtained by aligning the forward and reverse sequences' amplicons. The sequence was compared with the reference organisms by BLAST search (http://www.ncbi.nlm.nih.gov/blast) using the GenBank database in order to confirm the identification of *J. lividum* (99% match).

Co-cultures of *J. lividum* and *B. dendrobatidis* (JEL 215 strain) were grown on 1% tryptone agar plates and incubated for 48 h. The plates were checked for the presence of a zone of fungal inhibition around the bacterial colony to reconfirm the bacterium's antifungal properties (Lauer et al. 2007). Additionally, 100 ml co-cultures were made in liquid 1% tryptone medium to obtain adequate amounts of metabolites for chemical analysis (Brucker et al. 2008). Concurrently, co-cultures were compared to monocultures of the organisms to discriminate metabolites that are not produced by *J. lividum* (unpublished data). To inoculate the cultures, *J. lividum* was transferred from agar plates into 100 ml of 1% tryptone and

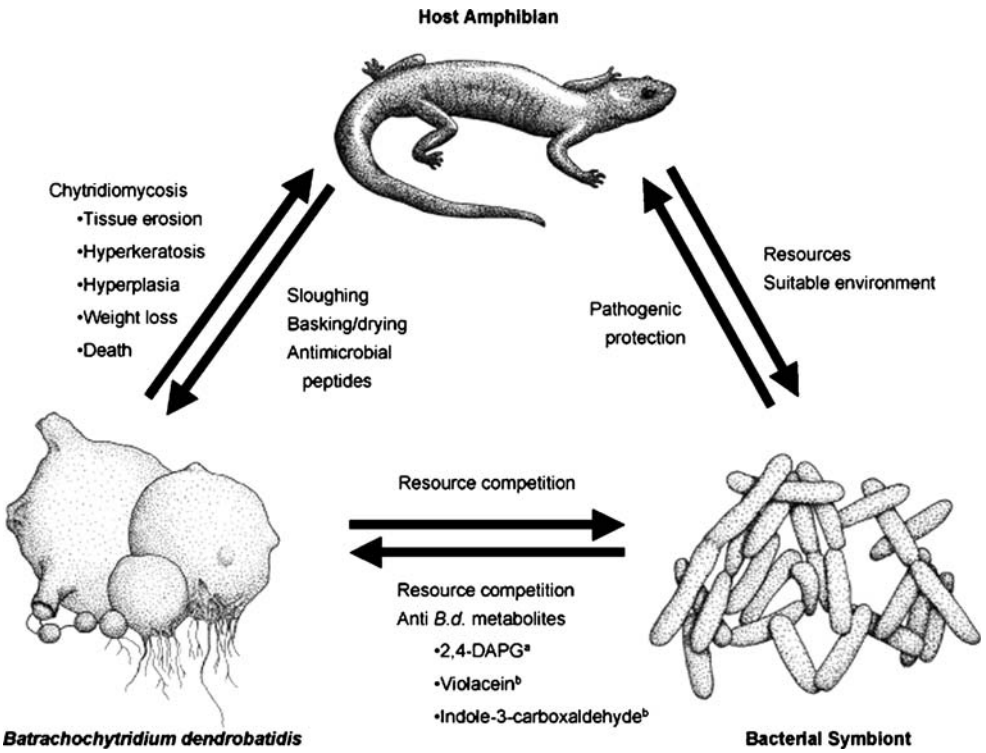

Fig. 1 Model of amphibian-bacteria-fungi interactions. The *arrows* indicate response or causation between the organisms. [a]Antifungal metabolite produced by *L. gummosus*. [b]Antifungal metabolite produced by *J. lividum*

1 ml of a solution containing zoospores (the motile infective stage of *B. dendrobatidis*; $1–2\times10^6$ zoospores/ml). All cultures were incubated for 72 h in a Lab-Line incubator shaker at room temperature (~23°C). After incubation, cultures were centrifuged at 5,000 rpm for 12 min. The supernatant was kept frozen until organic extraction; the pellet was discarded.

Organic Extraction and Antifungal Metabolite Isolation To extract organic metabolites from the cultures, the supernatant was thawed and extracted ×4 with a 1/3 volume of ethyl acetate (EtOAc). The combined organic layers were dried over Na_2SO_4, filtered, and evaporated in vacuo. The crude samples (3–15 mg) were kept frozen at −20°C, under nitrogen, until further analysis. A total of eight samples were extracted.

Each crude sample was dissolved in high performance liquid chromatography (HPLC)-grade methanol (2–3 ml). RP-HPLC analysis (Agilent Technologies, 1200 series, Wilmington, DE, USA) was then used to determine the retention times of the antifungal standards as well as to analyze the components of bacterial samples. The HPLC diode array detector was programmed to record absorbance at 220, 270, and 310 nm. Samples were injected (50 μl) into the HPLC equipped with a C18 reverse phase column (5 μm; 4.6×150 mm; Agilent Technologies, Wilmington, DE, USA) and eluted at 1 ml/min. The initial eluent, 10% acetonitrile/water (*v*/*v*, both acidified with 0.1% acetic acid), ran for 2 min. This was followed by a linear gradient to 100% acetonitrile (acidified with 0.1% acetic acid), over an 18-min period. This final solvent was eluted for another 3 min. Fractions were collected, and those that demonstrated antifungal activity were purified further and identified.

Nuclear Magnetic Resonance and High Resolution Mass Spectrometry Analysis of Antifungal Metabolites ^{1}H nuclear magnetic resonance (NMR) spectra were performed in $CDCl_3$ (indole-3-carboxaldehyde) and DMSO-d_6 with an aliquot of $CDCl_3$ (violacein) on a Bruker Advance 600 MHz NMR spectrophotometer. Samples were sent to the Mass Spectrometry Facility at Harvard University (Cambridge, MA, USA) for high resolution mass spectrometry (HR-MS) analysis (Agilent 6210 Time-of-flight LC/MS, ESI source, positive mode).

Confirmation of Antifungal Metabolites and Their Inhibitory Activity To determine the minimum inhibitory concentration (MIC) of the compounds required to inhibit the growth of *B. dendrobatidis*, an *in vitro* assay was performed according to the procedures previously detailed (Brucker et al. 2008). In brief, concentration of metabolites was varied in 96-well microtiter plates, and fungal growth was determined by measuring optical density. The positive control wells contained the fungus with the solvent DMSO; the negative control wells contained heat-killed zoospores. An exception to our previous published procedure was the reduction of the solvent DMSO to 1% by volume. Indole-3-carboxaldehyde treatments and controls were replicated 16 times, while the violacein assay treatments and controls were replicated eight times.

Statistical Analysis A Dunnett's *t* test was used to test the null hypothesis of "no inhibition" by comparing the amount of fungal growth in each metabolite concentration treatment to the positive control treatment that had fungi without metabolites. Pair-wise comparisons were made with Tukey's HSD procedure, which holds experiment-wide error at a maximum of 0.01.

Extraction of Metabolites from Skin Samples Seven wild-caught *P. cinereus* were collected from the James Madison University Arboretum (Harrisonburg, VA, USA) during the months of November and December of 2007. Each individual was handled separately with sterilized gloves and housed overnight, in separate sterile containers at 14° C. Salamanders were euthanized with gaseous CO_2. A 2.3–4.4-cm^2 portion of skin was excised from the shoulders to the hips, and the surface area of the skin was determined by using the program ImageTool 3.0 (distributed by the University of Texas Health Science Center at San Antonio, Texas. May 2002). The skin components were then extracted with HPLC-grade methanol (4×5 ml). The organic solvent was evaporated, and the resulting sample was then constituted with 200 μl of HPLC-grade methanol before being injected onto the HPLC, as per above. Approximate concentrations were determined by computing a standard curve of the metabolites. Animals were collected by permit from the Virginia Division of Game and Inland Fisheries. Our animal care protocol was approved by JMU's Animal Care and Use Committee.

Sampling for Naturally Occurring J. lividum Sampling and analysis of cutaneous bacteria follow methods published in detail by us elsewhere (Lauer et al. 2007). Briefly, transient bacteria were removed from salamander skin by rinsing them twice in sterile water and then swabbing their ventral and lateral sides with a wet sterile cotton swab (Harris et al. 2006; Lauer et al. 2007, 2008). The presence of *J. lividum* was tested by using polymerase chain reaction or denaturing gradient gel electrophoresis (DGGE; see published methods (Lauer et al. 2007)). Typically one bacterial species is indicated by one band (sequence type) on DGGE gels, although heterogeneity in ribosomal RNA copy number in some species can cause a species to appear as two or more bands. In one lane, we placed the amplification products from a

pure culture of *J. lividum*. Other lanes of the DGGE contained a culture-independent assay of bacterial diversity on salamander skins. If one band in these lanes migrated to the same position as the band from the pure culture of *J. lividum*, then we concluded that *J. lividum* was present on the skin.

Evaluating Mucus Depth of P. cinereus The mucous depth of *P. cinerus* was calculated by using three salamanders collected from local populations in order to determine metabolite concentration on salamander skins. The salamanders were sedated and euthanized using carbon dioxide. Skin samples were removed using a double-headed scalpel, which was assembled by using two size 10 scalpel blades taped parallel to each other. The resulting double-headed scalpel had a parallel 1–1.5 mm span between the blades and was used to cut and remove three 1–1.5-mm thick cross-sections, per salamander, at three locations: on the tail, above the hind legs, and below the fore limbs. Scalpel blades were replaced between each cut. Each cross-sectional sample was rotated 90° and immediately laid transversely onto a glass microscope slide.

To avoid distortion of the sample from the weight of the cover slip, two platforms were cemented on either side of the sample comprised of 7–10 cover slips, with a final cover slip spanning the sample field. Drops of a 1% saline solution were added to the sample to prevent dehydration of the sample. Two to three drops of methylene blue were added to the saline solution to provide contrast for the background and translucent mucus layer.

The slide was placed on an inverse microscope within half an hour of construction. Five out of the nine slides had undamaged, viable, cross-sectional samples. From these five samples, the depth of the mucus layer was measured at five random locations per sample, using microscopy measurement software (Nikon Imaging Systems Elements, Tokyo, Japan).

Results

Compounds in the culture medium produced by *J. lividum* that were fractioned around 9.07 min and 11.15 min via HPLC ("Electronic Supplementary Material" SI Fig. 1) inhibited fungal growth. Further HPLC purification of these bioactive fractions led to the isolation of two antifungal metabolites whose structures were identified as violacein and indole-3-carboxaldehyde (Fig. 2) via NMR and HR-MS analysis ("Electronic Supplementary Material" SI Table 1).

Optical density was used to assess fungal growth, and inhibitory growth assays against *B. dendrobatidis* were performed to determine the MIC for each of the metabolites. Increasing concentrations of violacein and indole-3-carboxaldehyde reduced fungal growth (violacein: $F=73.32$, $df=1$, 180, $P<0.001$; indole-3-carboxaldehyde: $F=211.59$, $df=1$, 84, $P<0.001$; Fig. 3). We determined MICs of 1.8 μM for violacein and 68.9 μM for indole-3-carboxaldehyde (Fig. 3).

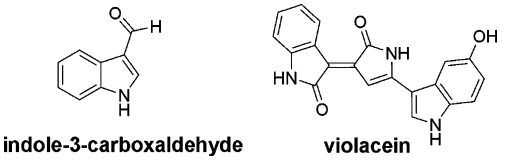

Fig. 2 Chemical structures of indole-3-carboxaldehyde and violacein, the two antifungal metabolites produced by *J. lividum* isolated from both the redbacked salamander (*P. cinereus*) and the four-toed salamander (*H. scutatum*)

We tested whether the metabolites identified from laboratory cultures of *J. lividum* could be detected directly on the salamanders in the wild and if their concentrations were sufficient to inhibit *B. dendrobatidis*. Of seven wild-caught salamanders, three housed the bacterium *J. lividum* as indicated by an analysis of DGGE ("Electronic Supplementary Material" SI Fig. 2). One individual had indole-3-carboxaldehyde on its skin, and three others had violacein. After determining an average depth of *P. cinereus* skin mucus (37 μm; see "Electronic Supplementary Material" SI Table 2), the volume of mucus on each individual and concentrations of the metabolites were calculated ("Electronic Supplementary Material" SI Table 2). The concentration of indole-3-carboxaldehyde on one wild-caught *P. cinereus* was estimated to be 51 μM (Table 1). The wild-caught salamanders displayed violacein exhibited concentrations of 207, 10, and 4 μM on their respective skins.

Discussion

A symbiotic relationship between cutaneous bacteria and a host amphibian is plausible; metazoans evolved with bacteria and mutualistic associations are common in animals (McFall-Ngai 1999). A fascinating example of cutaneous bacteria that benefit their host can be found in leaf cutter ants, *Acromyrmex* (Currie et al. 2006). The farming ants house bacteria, *Pseudonocardia*, which feed in the hosts' cuticle, and in return produce metabolites that deter an unwanted fungal species, *Escoviopsis*, from invading their subterranean garden (Currie et al. 2006). Our studies indicate that a similar mutualism might exist in amphibians, although whether associations will be found between specific amphibians species and specific bacterial species remains an open question (Harris et al. 2006; Lauer et al. 2007, 2008; Woodhams et al. 2007b; Brucker et al. 2008; Fig. 1).

The bacterium *J. lividum* is likely to be a mutualistic partner with red-backed salamanders. The two metabolites produced by *J. lividum* and found on salamander skin, indole-3-carboxaldehyde and violacein (Fig. 2; "Electronic

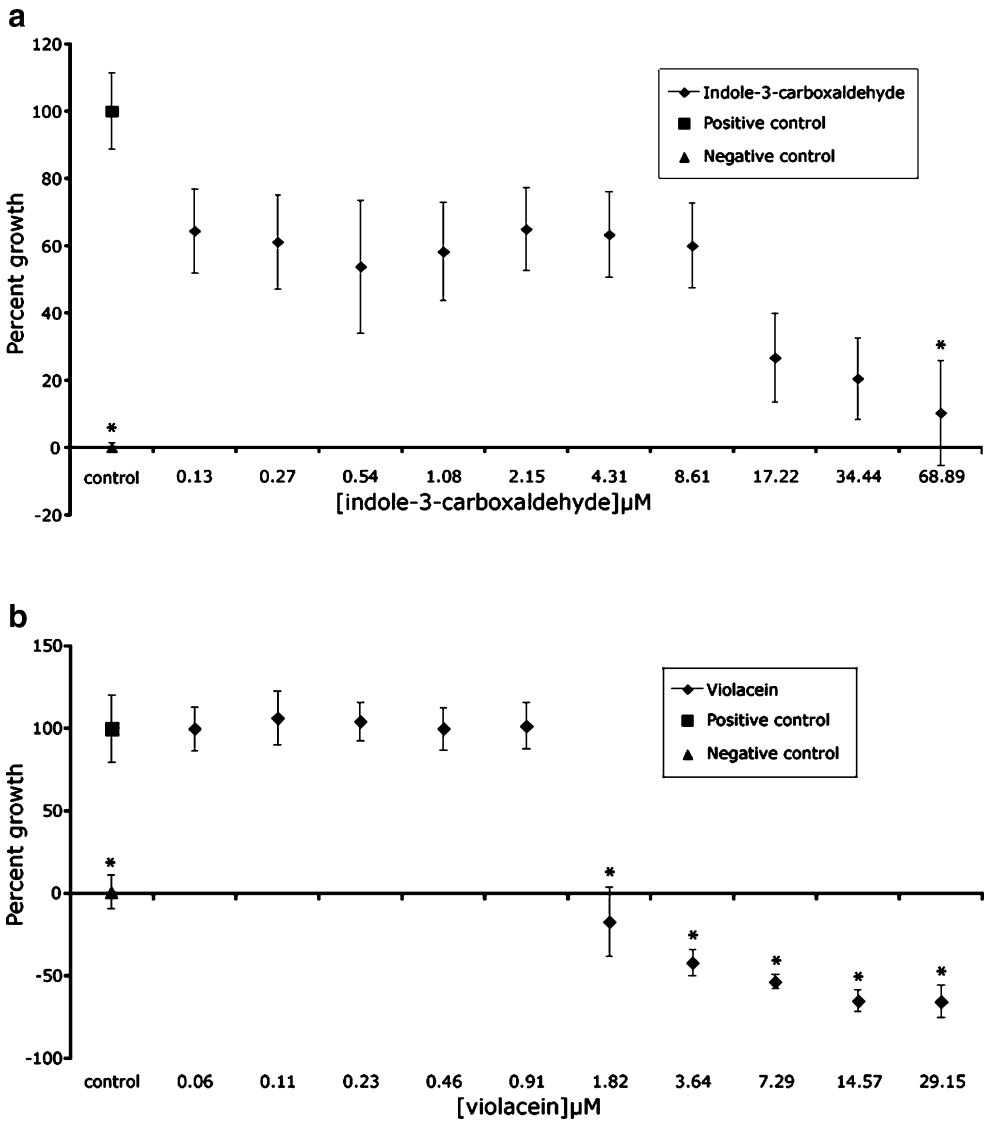

Fig. 3 Inhibition of growth in *B. dendrobatidis* due to the presence of **a** indole-3-carboxaldehyde or **b** violacein over a 7-day period. Percent growth is computed as difference in optical density between days 0 and 7 for each concentration compared to controls. *Error bars* indicate standard deviation of mean difference. *Asterisk* Significant difference from positive control, Dunnett's test

Supplementary Material" SI Table 1), are known agents of chemical defense although indole-3-carboxaldehyde is not a reported product of *J. lividum*. The fungus *Epichloë festucae* employs indole-3-carboxaldehyde in its endophytic relationship with many different host plants, defending the host against fungal pathogens (Yue et al. 2000). This metabolite also has antibacterial characteristics against several human pathogens in vitro (Gutierrez-Lugo et al. 2005). Violacein biosynthesis is a cell density-dependent factor, controlled via quorum sensing for the bacterial species *Chromobacterium violaceum.* Violacein is a known metabolite of *J. lividum* as well as several marine surface-associated bacteria (Durán and Menck 2001; Matz et al. 2008). Violacein has a broad bioactivity profile including antibacterial, antiviral, and antitumoral activity (Durán and Menck 2001). Neither compound, however, has been reported to protect vertebrates in the wild from an emerging infectious disease.

The concentrations of indole-3-carboxaldehyde and violacein on the skin of the salamanders (Table 1) approached or exceeded the MICs determined in vitro (Fig. 3). The concentration of indole-3-carboxaldehyde on the skin of one individual was just below the MIC required to completely inhibit *B. dendrobatidis* growth (51 vs. 68.9 μM). The violacein MIC was exceeded in all three salamanders that had violacein, with one individual having a concentration 114 times greater than the in vitro MIC. Comparatively, 2,4-diacetylphloroglucinol was not detected on the skin of the wild-caught salamanders, although there is a significant difference in concentrations required to inhibit *B. dendrobatidis* in vitro (MIC=136 μM; Brucker et al. 2008).

Concurrently, the bacterial diversity of the salamanders was examined with DGGE, specifically screening for *J. lividum* ("Electronic Supplementary Material" SI Fig. 1). Three of the four individuals that had indole-3-carboxaldehyde or violacein tested positive for *J. lividum.* This result

does not exclude the possibility of low densities of *J. lividum* on the fourth individual, nor does it exclude the presence of alternative symbionts playing a similar role. *J. lividum* was not detected on the individuals lacking these metabolites. Together, these data suggest that the metabolites are related directly to the bacterial symbiont and further support the hypothesis that symbiotic bacteria play a significant role in host resistance.

Host salamanders have variations in the diversity of bacteria, both antifungal and non-antifungal, on their skin (Lauer et al. 2007, 2008), and this variation in bacteria populations may determine the type and amount of antifungal compounds available. We have evidence from laboratory experiments that amphibians with adequate microbially produced antifungal metabolites on their skin persist with *B. dendrobatidis* infection while those with low concentrations die (unpublished data). It is an open question why some amphibians do not have adequate antifungal metabolites on their skin, but perhaps there are costs as well as benefits to maintaining skin bacteria that produce such metabolites.

The presence or absence of beneficial bacteria and the antifungal metabolites they produce could account for the variation in infection and decline among populations and amphibian species. Some species house beneficial bacteria on their skin due to their physiology, behavior, environment, or any combination of the three. Physiologically, it is likely that there are strong selective pressures, such as antimicrobial peptides (Simmaco et al. 1998; Rollins-Smith et al. 2002) and glycoproteins (Ducklow and Mitchell 1979; Brizzi et al. 2002) on the skins of amphibians that influence the type of bacteria that are found there. Behaviorally, some amphibian species congregate densely, perhaps aiding in the spread of beneficial and pathogenic microbes; similarly, some care for their eggs and may, therefore, impart microbes to their embryos and young (Harris et al. 2006). Environmentally, factors such as plants, soils, and water can determine the type of bacteria available to the amphibian. In addition, anthropogenic effects may alter microbial species compositions (Belden and Harris 2007). These factors likely contribute to the differences observed in amphibian vulnerability to chytridiomycosis.

Our research suggests two modalities for amphibians affected by chytridiomycosis: (a) application of antifungal metabolites onto infected amphibians in laboratory environments; (b) application of probiotic bacteria that already exist on amphibians and that produce antifungal metabolites in natural environments.

The use of chemical treatments for chytridiomycosis is precedented in amphibian husbandry (Young et al. 2007) although they cannot provide long-term protection from the disease. However, the application of *J. lividum* itself as a bio-augmentation or probiotic treatment is potentially self-

propagating and may provide long-term protection from the disease as seen in agriculture (Haas and Degafo 2005). Should the anti *B. dendrobatidis* properties of the bacteria be extended to susceptible species, then it is possible that species declines due to the pathogen could be avoided. A study focusing on the beneficial antifungal bacteria of *R. muscosa* populations that are persisting with *B. dendrobatidis* has suggested that the entire population does not need to have beneficial bacteria to allow persistence (Woodhams et al. 2007b). By inoculating probiotic bacteria onto the amphibian host, *B. dendrobatidis* resistance may be self-perpetuating in the species and perhaps other amphibians through communal interactions, for example in hibernacula. This method could prove superior to the continual application of antifungal chemicals, which could have a negative effect on nontarget species such as beneficial fungi, is not self-perpetuating, and is economically difficult to sustain.

Further studies of the metabolites being produced by other antifungal bacteria from amphibians should yield a diverse suite of antifungal metabolites, perhaps including novel antifungal compounds that could be used in amphibian husbandry as well for treatment of human pathogens. Additional research is needed to understand the microbial ecology of amphibian skin and to use that understanding to develop strategies to manage chytridiomycosis in nature.

of 1.5 larvae ml^{-1} in larval rearing water. Recently, Munga et al. (2006) compared oviposition choices of *An. gambiae* to (1) rainwater conditioned with different numbers (none, five or 50 in 200ml) of conspecific larvae but had been removed prior to assays and (2) rainwater with different densities of larvae (none, five, 40, 70 and 100 in 200ml). Fewer eggs were laid in rainwater conditioned with larvae than in unconditioned rainwater. In the presence of different densities of larvae, more eggs were laid in rainwater that had the fewest or no larvae. Additionally, the greatest number of eggs were laid in rainwater that contained the lowest concentration of larvae. These authors proposed that *An. gambiae* females were not influenced by the presence of conspecific larvae, but by other habitat characteristics associated with food quality and quantity, such as algal and microbial populations (Munga et al. 2006). In our previous studies on *An. gambiae*, we found that more eggs were laid in water from natural anopheline habitats than in distilled water or water from natural culicine habitats (Sumba et al. 2004a), and that volatile emissions associated with microbial populations from these habitats mediate this preference (Sumba et al. 2004b). We suggested that production of intra-specific cues from eggs or immature stages of the insect may occur only in habitats favorable for the optimal development of larvae and that rearing water (McCrae 1984) and rainwater (Munga et al. 2006) do not contain the full range of chemical signals present in natural anopheline larval habitats.

The present study was undertaken with two objectives in mind: (1) to compare *An. gambiae* oviposition levels in water collected from natural anopheline larval habitats with those in distilled water by using different densities of conspecific eggs or larvae and (2) to establish whether or not intra-specific olfactory signals mediate any of the observed effects.

Methods and Materials

Mosquitoes An. gambiae s.s. Mbita strain larvae were initially collected from anopheline pools at Mbita Point, Suba District, western Kenya, and reared in a screenhouse (11.5×7.1×4.4 m) (Seyoum et al. 2002) at a density of about 500 larvae in 3 l of water obtained from a natural ground pool containing predominantly anopheline larvae. Average temperature in the screenhouse was 29±2°C during the day and 24±2°C during the night, and RH ranged from 57±4% (day) to 72±5% (night). These conditions approximated the natural conditions prevailing in the Suba district in western Kenya. Larvae were fed daily on tetramin fish food (Seyoum et al. 2002). Adult mosquitoes were kept in standard 30×30×30 cm cages in an adult insectary at 27±2°C, 65–70% RH, a photoperiod of 12:12 h (L–D), and were offered 6% glucose solution on which to feed ad libitum. Three to four-days-old females were starved for 12 h and allowed to feed on human arms for a 10-min period on two consecutive evenings at 18:00 h. Unfed mosquitoes were removed from the cage after each blood meal. Fully engorged females were left in the cages until they were gravid and used in oviposition assays on the second night after their last blood meal. Approval for feeding mosquitoes on human subjects was obtained from the Kenya National Ethical Review Board (protocol number KEMRI/RES/7/3/1).

Collection of Anopheline Habitat Water Anopheline habitat water was collected at the start of the assays from natural ground pools around Mbita Point (Minakawa et al. 1999; Sumba et al. 2004a). Presence of anopheline larvae in these pools was confirmed by randomly sampling the water five times with a 350 ml standard dipper and inspecting it for larvae. Collected water was normally turbid with an average pH of 7.4±0.1 and was sieved to remove mosquito larvae or pupae.

Oviposition Response to Conspecific Larvae Oviposition assays were carried out in 25×25×25 cm Plexi®-glass cages under ambient conditions in the screenhouse. A gravid mosquito was placed in each cage and provided with a choice of two artificial oviposition sites, each in a black plastic cup (2 cm deep, 4 cm diameter), placed diagonally at opposite corners of the cage, 30 cm apart. One cup contained test water and the other control water. The test waters were prepared by placing different numbers (0, 1, 5, 10, 20, 30, or 40) of early (first and second) or late (third and fourth) instars in 20 ml of either (1) water taken from freshly collected natural ground pool colonized by anopheline larvae (pool water), or (2) distilled water. Larvae in distilled water were left in the cage for at least 24 h before the assay was started. Control water was either pool water or distilled water without larvae. Mosquitoes were released into the cages at about 17:00 h, and the number of eggs on each cup was counted the following morning. Two or three replicates of each treatment were performed on the same night and the experiment repeated on 10 different nights.

Oviposition Response to Conspecific Eggs Varying number of eggs (0, 1, 5, 10, 20, or 30 eggs) laid the previous night were placed in 20 ml of either a fresh batch of pool water or distilled water in a black plastic cup. Each was paired with another cup with control water (distilled or pool water) without eggs in a Plexi®-glass cage, and a gravid female was introduced into the cage 24 h later, as for the larval assays. The numbers of eggs laid in the two cups were recorded the following morning. Treatments were replicated from 22–27 times.

Nature of Signal(s) Mediating Larval Effects In the 2-choice assays, the greatest increase in oviposition occurred at a concentration of about 10 (early instar) larvae in 20 ml of pool water, and the greatest reduction in oviposition occurred at a concentration of about 40 (late instar) larvae in the same volume. These densities were used in 4-choice experiments carried out in 60×60×60 cm Plexi®-glass cages to determine whether the stimulus was olfactory or otherwise (tactile, contact chemical, or visual) in nature. 'Double cup' oviposition setups (Sumba et al. 2004b), placed at the corners of the cage, were used. Each setup consisted of an outer opaque plastic cup (8 cm deep, 6 cm diameter) containing 20 ml of either pool or distilled water, with or without larvae, and a smaller inner black plastic cup (2 cm deep, 4 cm diameter) containing 20 ml of distilled water that was floating on the water in the outer cup. In a setup designed to restrict exposure of gravid females to volatile chemicals from test substrates, a 6-cm diameter cone of white folded polyester cloth was placed so that it fit the inside of the plastic cup neatly and acted as a barrier against direct tarsal or visual contact of the test water in the outer cup by mosquitoes. This setup allowed olfactory perception of any volatile signal emanating from the test water. Four sets of 4-choice assays were carried out: (1) a choice of distilled water, distilled water with 10 early instars, pool water, and pool water with 10 early instars, with no cone barriers in any set-ups; (2) same as (1) with polyester cones in all setups; (3) same as in (1) but with 40 late instars; and (4) same as (3) with cone barriers. In a given replicate, the four treatments were randomly assigned to a corner of the Plexi®-glass cage. In all experiments, gravid mosquitoes were released into the cages in groups of five at about 17:00 h and the numbers of eggs laid on each treatment (outer and inner cups in treatments without cone barrier and cone in treatments with barrier) were counted the next morning. Fresh gravid mosquitoes and treatments were used on each experimental night. The assays were replicated from 16–22 times (Table 1).

Data Analysis An oviposition index (OI) for each replicate in the dual-choice assays was calculated according to the formula $OI=N_t-N_s/N_t+N_s$ (Kramer and Mulla 1979), with N_t=number of eggs on the test substrate (distilled water or pool water with larvae or eggs) and N_s=number of eggs on the control substrate (distilled water or pool water without larvae or eggs). Thus, OI indices can range from +1 to −1, with positive values indicating that more eggs were laid on the treatment than on the control and negative values the converse. Generally, a substance with an OI of +0.3 or above is considered attractive, whereas one of −0.3 or below is considered a deterrent or repellent (Hwang 1980; Poonam et al. 2002). In the present study, the statistical significance of the OI of each treatment (with larvae or eggs in one of the cup pairs) relative to the control (no larvae or eggs in a cup) was determined by a one-sample *t* test. In the 4-choice experiments, the number of eggs laid on each oviposition site was arcsine transformed (Gomez and Gomez 1984) and the angular values were subjected to ANOVA (SAS Institute Inc. 2003). Means were compared by a Student-Newman-Keuls (SNK) test at a 5% level of significance.

Results

Oviposition Responses to Different Densities of Conspecific Larvae Figure 1 shows OIs of treatments with different densities of early (Fig. 1a,c, and e) or late (Fig. 1b,d, and f) instars, in choices between pool water vs. distilled water control (Fig. 1a,b), pool water vs. pool water control (Fig. 1c,d), and distilled water vs. distilled water control (Fig. 1e, f). Water without larvae, obtained from a natural anopheline pool habitat was significantly more attractive (OI>+0.38; $P<0.05$, $N=27$, *t*-statistics) than the distilled water control (Fig 1a,b), confirming previous results (Sumba et al. 2004a, b). Irrespective of larval age, oviposition responses of gravid mosquitoes in the presence of conspecific larvae in pool

Table 1 Mean numbers of eggs (±SE) laid by gravid *Anopheles gambiae s.s.* given choices of four aqueous substrates: (1) using low density (10) early instars with no cone barriers; (2) same as (1) but with polyester cones preventing contact with aqueous substrate cues; (3) same as (1) but with high density (40) late instars; and (4) same as (3) with polyester cones

	Low larval density		High larval density

Means in the same column sharing a common letter are not significantly different at an alpha of P=0.05 level (SNK test)

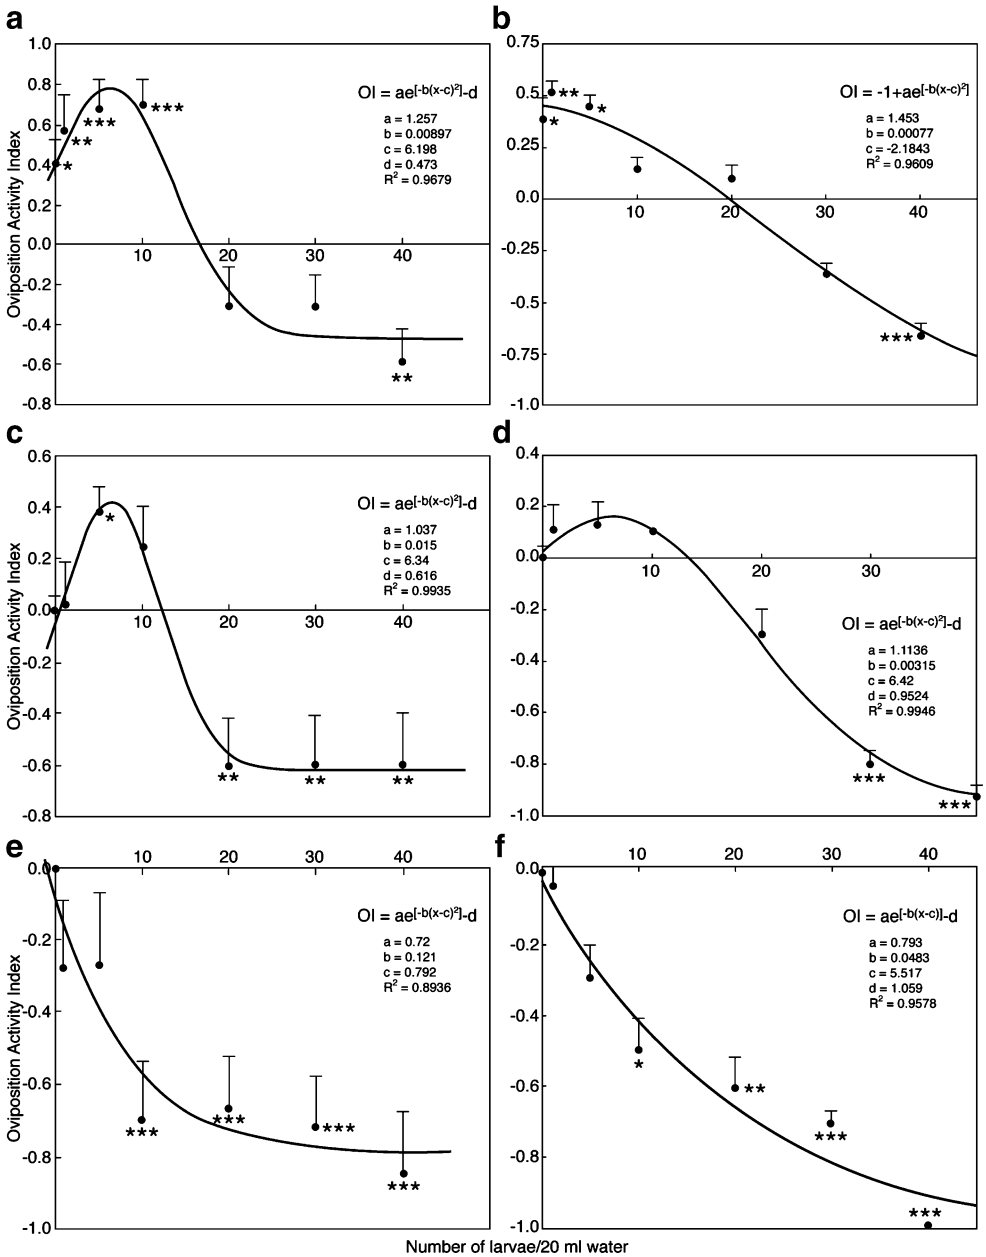

Fig. 1 Oviposition indices (OIs, mean±SE) and regression relationships showing oviposition responses of *Anopheles gambiae s.s.* to different densities of early (**a**, **c**, **e**) and late (**b**, **d**, **f**) conspecific larvae in: (1) pool water with distilled water control (**a** and **b**); (2) pool water with pool water control (**c** and **d**); and (3) distilled water with distilled water control (**e** and **f**). Starred OIs are significantly different from zero (one-sample *t* test) at **P*<0.05, ***P*<0.01 or ****P*<0.001

water were density-dependent, with test substrates with lower densities being preferred. Oviposition indices >+0.3 or <−0.3 were significantly different from zero (one sample *t*-test), indicating the test water was either stimulatory or deterrent, respectively, to females. The presence of larvae, particularly early instars (compare Fig. 1a and c with Fig. 1b and d), at relatively low density in pool water, stimulated oviposition by females (although not all increases were statistically significant). On the other hand, high larval densities, particularly late instars (compare Fig. 1b and d with Fig. 1a and c), deterred oviposition. Interestingly, the presence of larvae in distilled water deterred oviposition by gravid females at most densities (at low densities this was not significant) with late instars appearing particularly effective in this regard (Fig. 1e and f).

Oviposition Responses to Conspecific Eggs In choice assays between distilled water with eggs and a distilled water control, OIs (±SE) were (egg numbers in parentheses): 0.0±0 (0), 0.14±0.20 (1), 0.10±0.20 (5), −0.03±0.20 (10), 0.13±0.10 (20), and −0.12±0.10 (30). In assays involving a batch of pool water with eggs and pool water control, OIs were: 0.0±0 (0), 0.0±0.20 (1), 0.27±0.20 (5), 0.14±0.20 (10), 0.27±0.20 (20), and 0.06±0.10 (30). In assays with pool water with eggs and distilled water control, OIs were: 0.82±0.18 (0), 0.64±0.24 (1), 0.82±0.18 (5), 0.64±0.24 (10), 0.64±0.24 (20), and 0.82±0.18 (30). In all three sets of assays, the presence of 1-day-old eggs had no significant effect (*P*>0.05, *t*-test) on oviposition by *An. gambiae* females at any density tested. The high positive OIs (≥0.64) in the third set of assays between

natural pool and distilled water confirmed the preference for the former by *An. gambiae* females.

Roles of Olfactory and Non-olfactory Cues In all the 4-choice assays, pool water was significantly more attractive than distilled water (Table 1). The presence of larvae at low density (10 early instars in 20 ml) in pool water gave increased oviposition compared to pool water alone (Table 1 (1) and (2)), regardless of whether gravid females had contact with non-olfactory cues or not ($P<0.05$, SNK test). Distilled water showed no effect of low-density larvae (Table 1 (1) and (2)) for both situations. In assays involving the higher density of larvae (40 late instars in 20 ml), in which contact with non-olfactory cues was possible (Table 1 (3)), females laid significantly ($P<0.05$, SNK test) fewer eggs in water with, than in water without, larvae for both pool and distilled water. In contrast, in the situation in which only perception of volatile cues was possible (Table 1 (4)), the number of eggs laid in pool water with larvae was significantly ($P<0.05$, SNK test) greater than in pool water without larvae; there was no such difference observed with distilled water.

Discussion

Immatures of *An. gambiae* occur largely in fresh, sunlit, relatively small, and transient water pools with sparse vegetation (Muirhead-Thomson 1951; Gillies and De Meillon 1968; Service 1993; Minakawa et al. 1999, 2005a, b; Gimnig et al. 2001). Such pools are associated with lower levels of predation compared to large, long-lasting habitats (Service 1977; Washburn 1995; Sunahara et al. 2002). These pools are colonized rapidly within a few days of formation, suggesting that gravid females of this mosquito may actively search for and select such habitats for oviposition (Minakawa et al. 2005a). Laboratory studies have shown that volatile emissions associated with microbial activities in these habitats may partly mediate location of such habitats (Sumba et al. 2004b). Gravid females of two other anopheline species, *Anopheles albimanus* Wiedemann and *Anopheles vesttipennis* Dyar & Knab, are attracted similarly to volatile chemicals from their respective larval habitats (Rejmankova et al. 2005). The effect of the presence of *An. gambiae* larvae in the pools has been explored as an additional mechanism that influences attraction of conspecific females to a preferred oviposition site. Munga et al. (2006) compared oviposition levels of *An. gambiae* in rainwater with and without different numbers of larvae and found that, in all larval densities, the mosquito preferred to lay in clean rainwater over rainwater with larvae. This led the authors to suggest that conspecific larvae play no role in oviposition selection in this mosquito (Munga et al. 2006).

The results of our study demonstrate the role that conspecific larvae play in oviposition by *An. gambiae* and help to clarify some of the mechanisms that underlie the selection and spatial spread of larval habitats of this mosquito. First, the presence of conspecific larvae (but not eggs) influenced oviposition by gravid females. Preferences for ovipositing in water with larvae changed depending on the quality of the water and density of the larvae. In natural anopheline pool water, low densities of larvae (particularly early instars) resulted in increased oviposition, whereas higher densities resulted in decreased oviposition in a dose-dependent manner. Thus, contrary to previous work (Munga et al. 2006), our results show that, depending upon larval density, conspecific larvae of *An. gambiae* may play a dual role of augmenting the inter-specific signal emitted by preferred *An. gambiae* habitats and also of limiting the number of eggs laid in a particular habitat. Thus, conspecific larvae may fine-tune the balance between allowing exploitation of a healthy breeding site and avoiding intra-specific competition and other effects of overcrowding (Gimnig et al. 2002; Spencer et al. 2002; Kiflawi et al. 2003; Koenraadt and Takken 2003; Munga et al. 2006).

The 4-choice assays allowed us to clarify the roles played by inter- and intra-specific signals in oviposition by *An. gambiae*. At the lower larval density, with or without cone barriers, and the higher larval density with cone barriers, more eggs were laid on anopheline pool water substrates with larvae than on those without. This suggests that larvae in a favorable habitat emit a volatile intra-specific signal (pheromone) that augments the attraction to inter-specific volatiles (kairomone) associated with microbial activity in natural anopheline pools (Sumba et al. 2004b; Rejmankova et al. 2005). The presence of larvae, even at low density, in distilled water did not increase oviposition compared to distilled water alone, consistent with the observations made by Munga et al. (2006) in their study of the effects of different densities of larvae in rainwater. This suggests that either the larval pheromone is not stimulatory by itself (i.e., in the absence of the kairomone) or that production of the pheromone by larvae occurs only in *An. gambiae* preferred habitats with suitable organic matter, microbes, and algae (Merritt et al. 1992; Gimnig et al. 2001; Sumba et al. 2004b). The present study then represents the first demonstration of a larval pheromone on the oviposition behavior of *An. gambiae*. Chemical characterization of the pheromone and the kairomone associated with anopheline larval habitats will facilitate further studies on the relative roles of the two semiochemicals and possible manipulation of the oviposition behavior of this mosquito.

Our study of the effects of high larval density in assays with and without cone barriers suggests the presence of

intraspecific non-olfactory cues in addition to the olfactory signal. In the situation (no cone barriers) that allowed contact of females with the substrate, gravid *An. gambiae* females laid significantly fewer eggs in pool water with larvae than in that without larvae, suggesting an inhibitory effect. However, in the situation (with cone barriers) in which only olfactory cues could be perceived, the relative number of eggs laid in pool water with or without larvae resembled that with lower density of larvae. This suggests that gravid *An. gambiae* females are attracted to suitable pools with conspecific larvae, but that the intensity of non-olfactory, close range or contact cues, related to the density of larvae present, influences whether they oviposit or not. The nature of this cue, i.e., whether it is the physical disturbance of the water surface by the feeding larvae, contact with the larvae and/or visual effects, or a contact chemical from larval secretions, remains to be established. However, the work of Munga et al. (2006), who found that rainwater conditioned by different numbers of larvae deterred oviposition by gravid females, suggests the mediation of a chemical (non-volatile pheromone).

Finally, some differences between the effects of early and late instars on oviposition were apparent (Fig. 1). In anopheline pool water, in which gravid females were exposed to both olfactory and non-olfactory cues, comparison of OI values suggests that older instars appeared less effective in increasing oviposition at low density and more effective in deterring oviposition at high density (compare Fig. 1b,d and f with Fig. 1a,c and e). The results may indicate that ovipositing females are less inclined to lay in pools that have late instars compared with those with early instars. Follow-up field and laboratory studies will confirm whether these differences are real or not and, if so, elucidate the underlying factors.

In summary, the present study demonstrates the role that larvae of *An. gambiae* play in attracting and regulating oviposition by conspecific gravid females. Work is needed to elucidate the chemicals involved.

Acknowledgements We thank K. Okoth, E. Obudho, J. Wauna, and the staff of the malaria vector program at Thomas Odhiambo campus-ICIPE for their technical assistance. This research was partly supported by funds from the National Institutes of Health (NIH) grant U19 AI45511 and the ABC Fogarty through grant number D43TWØ1142. LS acknowledges a PhD scholarship from the German Academic Exchange Service (DAAD) (through the ICIPE African Regional Post-graduate Program in Insect Science, ARPPIS). CBO wishes to acknowledge the US William J. Fulbright Program and the Yale Institute for Biospheric Studies (YIBS) Field Ecology Award.

species secrete a sex pheromone that attracts males in a manner similar to many other nocturnal moths. Information about the sex pheromones of the diurnal arctiid species is limited, whereas pheromones of about 20 nocturnal species in the Arctiinae, another subfamily of Arctiidae, have been reported (Ando 2008). In the family Sesiidae, which also includes many diurnal moth species, 3,13-and 2,13-octadecadienyl compounds have been identified as sex pheromones of about 20 species and have been reported as sex attractants of more than 80 species (Naka et al. 2006; Ando 2008; El-Sayed 2008). Most of the known arctiid pheromones are composed of polyunsaturated hydrocarbons and their epoxy derivatives with a C_{17}–C_{23} straight chain. These compounds without a terminal functional group, which are also produced by females in the Geometridae, Noctuidae, and Lymantriidae, comprise a class of sex pheromones (Type II pheromones) that are differentiated from the compounds with a terminal functional group (Type I pheromones), such as the pheromones produced by the Sesiidae (Ando et al. 2004). For physiological and taxonomic reasons, we examined the pheromone components of *S. imaon* and revealed that the mating communication of the wasp moth is accomplished with a C_{21} 3,6,9-triene and 1,3,6,9-tetraene (i.e., a Type II pheromone).

In addition to characterizing the chemistry of Type II pheromone components, we studied their biosynthesis, mainly in the Japanese giant looper, *Ascotis selenaria cretacea* Butler (Geometridae). The female moths produce a C_{19} 3,6,9-triene and its epoxy derivative, as do females of the European strain, *Ascotis* (*Boarmia*) *selenaria* Denis & Schiffermüller (Becker et al. 1990). Both components are expected to be biosynthesized from dietary linolenic acid (C_{18} 9,12,15-trienoic acid) after its chain elongation to a C_{20} acid and decarboxylation. It has been confirmed that the epoxy pheromone was derived from the triene by monoepoxidation carried out in the pheromone gland (Miyamoto et al. 1999; Fujii et al. 2007). The triene is supplied to the pheromone gland via the hemolymph with the help of lipophorin after production outside of the pheromone gland, presumably in oenocytes and/or the fat body (Wei et. al. 2003; Matsuoka et al. 2006; Ando et al. 2008). However, the elongation and decarboxylation have not been demonstrated experimentally and the C_{20} acyl intermediate has not been identified. If the decarboxylation proceeds rapidly after the formation of the intermediate, trace amounts may be difficult to detect among an abundance of many common fatty acids. Since identification of the intermediate is an important essential step in a biosynthetic study, we purified and identified the hypothetical C_{20} acid intermediate from *A. s. cretacea* by high performance liquid chromatography (HPLC). In order to confirm this experiment with *A. s. cretacea*, we also analyzed fatty acids in *S. imaon* and identified not only C_{20} but also C_{22} trienoic acids. These acids have double bonds at the same positions as linolenic acid, relative to the terminal methyl group, i.e., they bear structures of intermediates of Type II pheromones. In addition to reporting the identification of the sex pheromone components secreted by *S. imaon* females, this paper deals with analyses of the fatty acids in abdominal integument tissues of *S. imaon* and *A. s. cretacea* to confirm the biosynthetic pathways of the pheromones.

Methods and Materials

Analytical Instruments The electroantennogram (EAG) activity of natural pheromonal components of *S. imaon* was measured with a gas chromatograph equipped with an electroantennographic detector (GC–EAD; Struble and Arn 1984). An HP-5890 Series II gas chromatograph (Hewlett-Packard, Wilmington, DE, USA) was equipped with a DB-23 column (0.25 mm i.d., 30 m length, 0.25 μm film thickness, J & W Scientific, Folsom, CA, USA). The column temperature was programmed for 50°C for 2 min, 10°C/min to 160°C, and 4°C/min to 220°C. The effluent from the column was split into two lines, which led to a flame ionization detector (FID) and EAD at a ratio of 1:1. An antenna was excised at the base from the male moth and a few distal segments were cut off. Each end of the antenna was attached to a droplet of a saline solution on an electrode of the EAD device such that the sensilla faced the airflow from the GC. Electron impact GC–mass spectrometry (GC–MS) was achieved by using an HP 5973 mass spectrometer system (quadrupole type, Hewlett Packard) equipped with the same DB-23 column operated at the same temperatures as the GC–EAD except for the analysis of the dimethyl disulfide (DMDS) derivatives, which were analyzed with an HP-5 column (0.25 mm i.d., 30 m length, 0.25 μm film thickness, Hewlett-Packard) and another program of 50°C for 2 min and 10°C/min to 320°C. For GC–MS analysis of fatty acid methyl esters (FAMEs) with the DB-23 column, the temperature program was 80°C for 1 min and 8°C/min to 220°C. The ionization voltage was 70 eV, and the flow rate of the carrier gas (He) was 1.0 ml/min. HPLC involved a Jasco PU-980 liquid chromatograph equipped with an integrator (System Instrument Chromatocorder 21J), a UV spectrometric detector (Jasco UV-970, 210 nm), and a reversed-phase column (Inertsil ODS, 4.6 mm i.d., 25 cm length; GL Sciences Inc., Tokyo, Japan). As the eluent, 5% water in methanol was used at a flow rate of 1.0 ml/min.

Insects and Pheromone Extraction Adults of *S. imaon* and larvae of *A. s. cretacea* were collected in a coppice in the Yonaguni-jima Islands and a tea garden in Mie Prefecture in

Japan, respectively. They were continuously reared on a semisynthetic diet for insects (Insecta LF(S), Nippon-Nosan-Kogyo Co., Yokohama, Japan) and sexed at the pupal stage. All insects were maintained under a 16:8 h, L–D cycle at 25°C. Since *S. imaon* virgin females showed a calling position during photophase, their abdominal ends were excised 4 h after the beginning of photophase to extract pheromone components. Each gland was separately immersed in hexane (100 μl) for 10 min to yield a crude extract.

Diimide Reduction and DMDS Derivatization Solvent of a crude pheromone extract of *S. imaon* (20 FE) was removed under a N_2 gas stream and the residue was successively treated with a N_2H_4 solution (0.3 ml of N_2H_4 in 10 ml of ethanol, 0.1 ml) and a H_2O_2 solution (0.04 ml of 30% H_2O_2 in 10 ml of ethanol, 0.1 ml) (Yamaoka et al. 1976). After warming at 65°C for 8 h, the reaction mixture was acidified with 1 N HCl and extracted with hexane (0.2 ml ×3). The hexane extract was passed through a short column with powdered Na_2SO_4 (0.1 g) and analyzed by GC–MS. The reduced products were subjected to DMDS derivatization (Buser et al. 1983) without any purification. After removing the solvent, residue was dissolved in DMDS (20 μl) that included a catalytic amount of iodine and kept at 40°C for 2 h. The DMDS adducts were extracted with hexane and analyzed by GC–MS. In the same manner, synthetic (*Z,Z,Z*)-1,3,6,9-henicosatetraene (1,*Z*3,*Z*6,*Z*9-21:H, 50 μg) also was treated with N_2H_4 and DMDS and the products of each reaction were analyzed by GC–MS to compare the results with those of the natural pheromone.

Field Test The synthetic lures for *S. imaon* were tested in 2007 in the Yonaguni-jima Islands. Rubber septa (white rubber, 8 mm o.d., Sigma-Aldrich, St. Louis, MO, USA) were used as dispensers, and synthetic compounds dissolved in hexane (100 μl) were applied to them. Each lure was placed at the center of a sticky board trap (30×27 cm bottom plate with a roof, Takeda Chem. Co., Tokyo, Japan). Two traps were used for each lure, and two other traps including the septa treated with only hexane (100 μl) were tested as control. The traps were placed at least 10 m apart at about 1.5 m above the ground in a coppice dominated by *Leucaena* trees, which are not the host plant of *S. imaon*, but were a convenient scaffold from which to hang the traps.

Chemicals (*Z,Z,Z*)-3,6,9-Trienes, which had been synthesized in our laboratory (Ando et al. 1993), were used as authentic standards for GC–MS analysis of a pheromone extract and as lures for a field test. (*Z,Z,Z*)-1,3,6,9-Tetraenes were newly synthesized by utilizing a one-pot double-Wittig approach (Pohnert and Boland 2000). The procedure and chemical data for the synthetic 1,*Z*3,*Z*6,*Z*9-21:H and other related polyenes have been reported (Yamamoto et al. 2008). The chemical structures of fatty acids and the methyl esters are abbreviated with the numbers before the colon, indicating the carbon number of a straight chain, and after the colon, indicating the degree of unsaturation.

Extraction and Methanolysis of Lipids in Integuments Abdomens from ten 0-day-old virgin females of *S. imaon* were isolated after elimination of their tips. Abdomens were incised along the midline, and their insides, including the ovaries, ovary-associated fat bodies, and digestive systems, were removed to yield integument tissues associated with oenocytes and peripheral fat bodies. Tissues were washed with cold saline (a 10 mM phosphate buffer, 150 mM NaCl, pH 6.5)×3, and then lipids included in the tissues were extracted with a mixed solvent (0.5 ml/tissue) of methanol and chloroform (Arima et al. 1991). Free acids, which were derived from the lipids by basic methanolysis, were converted further to methyl esters (FAMEs) by a reaction with diazomethane, and analyzed by GC–MS or subjected to HPLC fractionation. The quantities of common FAMEs were estimated by GC–MS analysis based on the peak areas in total ion chromatograms (TIC) of authentic standards (Sigma-Aldrich). The same experiment was carried out with ten virgin females of *A. s. cretacea* and the semisynthetic diet for insects (4.0 g) to yield their FAMEs.

Purification and Identification of Trace FAMEs The crude FAME mixture (1 FE) of each species was injected into an ODS column, and fractions were then collected every 1 min for 9–23 min and every 2 min for 23–61 min. This HPLC fractionation was repeated four more times, and fractions with the same fraction number were combined. After evaporation of methanol, the residues of each fraction were mixed with water (2 ml) and extracted with hexane (2 ml ×3). The extract was concentrated by evaporation and analyzed by GC–MS to identify the trace FAMEs included. Quantities were estimated by comparing peak areas with those of the authentic standards with a similar structure. Furthermore, two HPLC fractions (14–15 and 20–21 min) were separately collected from the FAME mixtures of *S. imaon* (10 FE) in order to confirm the structures of the esters with a trienyl moiety by micro chemical reactions, diimide reduction and DMDS derivatization, which was used to determine the double-bond positions of the *S. imaon* pheromone components.

Results

Identification of the S. imaon Pheromone In GC–EAD analysis with a pheromone gland extract from the *S. imaon* female, male antennae were constantly stimulated by two

components, Comp. I [retention time (Rt) 16.8 min] and Comp. II (Rt 17.9 min) (Fig. 1a). The structures of the two components were determined by GC–MS analysis of another crude pheromone extract. The mass spectrum of Comp. I (Rt 16.09 min) showed M^+ at *m/z* 290 (relative intensity, 2%), and characteristic fragment ions at *m/z* 234 (14%), 108 (63%), and 79 (100%) indicating a C_{21} 3,6,9-triene (Fig. 1b). The spectrum and Rt were closely coincident with those of synthetic (*Z,Z,Z*)-3,6,9-henicosatriene (*Z*3,*Z*6, *Z*9-21:H) (Ando et al. 1993). The mass spectrum of Comp. II (Rt 17.43 min) showed M^+ at *m/z* 288 (2%) and characteristic ions at *m/z* 234 (11%), 106 (33%), 91 (92%), and 79 (100%), indicating a C_{21} 1,3,6,9-tetraene (Fig. 1c). The spectrum and Rt were closely coincident with those of synthetic 1,*Z*3,*Z*6,*Z*9-21:H (Yamamoto et al. 2008). Moreover, the GC–MS analysis revealed a trace amount of the C_{20} triene and tetraene, (*Z,Z,Z*)-3,6,9-icosatriene (*Z*3,*Z*6, *Z*9-20:H, Rt 14.97 min, Comp. III) and (*Z,Z,Z*)-1,3,6,9-icosatetraene (1,*Z*3,*Z*6,*Z*9-20:H, Rt 16.28 min, Comp. IV), respectively. The C_{20} triene showed the spectrum with M^+ at *m/z* 276 (3%) and characteristic ions at *m/z* 220 (15%), 108 (65%), and 79 (100%), and the C_{20} tetraene showed the spectrum with M^+ at *m/z* 274 (2%) and characteristic ions at *m/z* 220 (11%), 106 (30%), 91 (87%), and 79 (100%). The average ratio of these four components (I–IV) analyzed with the extracts of seven individual females was 32:67:0.6:0.7. The content of the most abundant component (Comp. II, 1,*Z*3,*Z*6,*Z*9-21:H) was 1.5±0.2 μg/female.

Determination of Unsaturated Positions of the Tetraenyl Pheromone Component After the diimide reduction, the crude pheromone extract of *S. imaon* showed peaks of the following eight compounds (a–h) in a ratio of 10:7:7:5:4:4:4:1: a=icosane [Rt 14.85 min, *m/z* 296 (M^+, 2%) and 57 (100%)]; b=C_{21} monoene [Rt 15.00 min, *m/z* 294 (M^+, 13%) and 55 (100%)]; c=C_{21} monoene [Rt 15.14 min, *m/z* 294 (M^+, 13%) and 55 (100%)]; d=C_{21} monoene [Rt 15.35 min, *m/z* 294 (M^+, 11%) and 55 (100%)]; e=C_{21} diene [Rt 15.44 min, *m/z* 292 (M^+, 15%) and 67 (100%)]; f=C_{21} diene [Rt 15.55 min, *m/z* 292 (M^+, 2%) and 82 (100%)]; g=C_{21} diene [Rt 15.74 min, *m/z* 292 (M^+, 11%) and 82 (100%)]; and h=*Z*3,*Z*6,*Z*9-21:H [Rt 16.04 min, *m/z* 290 (M^+, 2%) and 79 (100%)]. Further treatment of the reduced products with DMDS yielded the following derivatives from the three monoenes: a DMDS adduct of 9-icosene (Rt 24.27 min, M^+ at *m/z* 388, diagnostic ions at *m/z* 215 and 173); a DMDS adduct of 6-icosene (Rt 25.37 min, M^+ at *m/z* 388, diagnostic ions at *m/z* 257 and 131); and a DMDS adduct of 3-icosene (Rt 24.88 min, M^+ at *m/z* 388, diagnostic ions at *m/z* 299 and 89). This result confirmed that the tetraenyl pheromone component (Comp. II) had three double bonds at the same positions as the trienyl component (Comp. I), i.e., the 3-, 6-, and 9-positions. The additional double bond in the tetraenes was estimated to be located at a terminal, which might be more easily attacked by N_2H_4 than the other bisubstituted double bonds. The experiment with synthetic, pure 1,*Z*3,*Z*6, *Z*9-21:H showed only the same products, indicating the selectivity of the diimide reduction.

Field Evaluation of the Synthetic S. imaon Pheromone Traps baited with a lure including a mixture of 1,*Z*3,*Z*6,*Z*9-21:H (1.0 mg/septum) and *Z*3,*Z*6,*Z*9-21:H (0.5 mg/septum) captured 31 male *S. imaon* from 28 June to 5 July, 2007, whereas no males were attracted by single component lures with each C_{21} polyene (1.0 mg/septum) and by the control traps.

GC–MS Analyses of Crude FAMEs In some lepidopteran insects, it has been reported that cuticular and pheromonal hydrocarbons are produced in the oenocytes located around the abdominal integument (Romer 1991; Jurenka et al. 2003). Therefore, the abdominal integument was dissected from female moths of *S. imaon* and *A. s. cretacea* to find

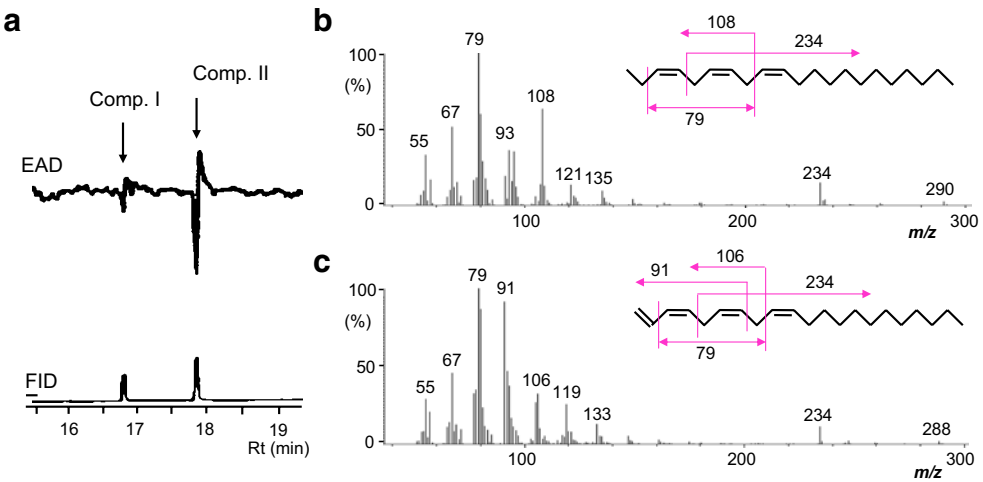

Fig. 1 Analyses of the sex pheromone components of *S. imaon* females by GC–EAD with the male antenna and GC–MS equipped with a DB-23 column. (**a**) Components I and II in a pheromone extract (0.5 FE) detected by a flame ionization detector (FID) and an electro-antennographic detector (EAD). (**b**) Mass spectrum of Comp. I (*Z*3,*Z*6,*Z*9-21:H) from the extract (1 FE). (**c**) Mass spectrum of Comp. II (1,*Z*3,*Z*6,*Z*9-21:H) from the extract (1 FE)

acyl intermediates involved in the pheromone biosynthesis. FAMEs prepared from extracts of one integument were dissolved in hexane (1 ml), and an aliquot (1 μl) was subjected to GC–MS analysis to reveal six common fatty acids (16:0, 16:1, 18:0, 18:1, 18:2, and 18:3) in *S. imaon* (Fig. 2a) and *A. s. cretacea* (Fig. 2b). The profiles of the FAMEs differed in the relative amounts of the two major components (peaks **1** and **4**). The 16:0 and 18:1 esters represented 40 and 25% of the total FAMEs in *S. imaon*, respectively, but 31 and 44% in *A. s. cretacea*. In these analyses, however, the proposed acyl intermediates of the type II pheromone components, such as 20:3, 22:3, 20:4, and 22:4 esters, could not be detected beyond a common 18:3 ester (peak **6**), which offered a mass spectrum with a base peak at *m/z* 79 (Fig. 2c). Even by using selected-ion monitoring, chromatograms at *m/z* 320 (M^+ of 20:3), 348 (M^+ of 22:3), 318 (M^+ of 20:4), 346 (M^+ of 22:4), and 79 showed no peaks around the Rts expected for the long-chain esters.

Analyses of the FAMEs after HPLC Fractionation From an ODS column, fatty alcohols and their derivatives with a shorter chain and a higher degree of unsaturation elute faster than the corresponding compounds with a longer chain and lower degree of unsaturation (Ando et al. 1986). Similar elution relationships hold for FAMEs of a series of authentic standards (C_{16} to C_{22}) (Fig. 3a). HPLC analyses of the esters from lipids of *S. imaon* (Fig. 3b) and *A. s. cretacea* (Fig. 3c) showed six peaks (**1**–**6**). With reference to the Rts of the standards, the chromatographic behaviors of the six FAMEs indicated that their chemical structures had a C_{16} or C_{18} chain, similar to those identified by GC–MS analysis (Fig. 2). On the other hand, GC–MS analyses of HPLC-fractionated elutants revealed the occurrence of FAMEs derived from other minor fatty acids with a C_{17}, C_{19}, C_{20}, C_{21}, or C_{22} chain. The chain length and degree of unsaturation of each ester were determined by M^+. While a 20:3 ester was recovered from the 14–15 min HPLC fraction of the FAMEs in both species, a 22:3 ester was detected only in the 20–21 min HPLC fraction of the *S. imaon* FAMEs. Together with the Rts of the authentic standards, the approximate Rts of trace FAMEs showed elution patterns that one might expect based on the chain length and degree of unsaturation (Fig. 3a). This analysis predicted that 20:4 and 22:4 esters might be recovered from the HPLC fractions of 9–12 and 16–19 min, respectively, but the GC–MS analysis of these fractions did not confirm the occurrence of these compounds.

Structure Determination of C_{20} and C_{22} Trienoates Trienoates were partially purified from an FAME mixture (1 FE) by using HPLC and were analyzed by GC–MS fractionation (Fig. 4) The FAMEs of *S. imaon* and *A. s. cretacea* included the same 20:3 ester (Rt 18.8 min), which showed a mass spectrum with M^+ at *m/z* 320 (6%) and fragment ions at *m/z* 289 (M-31, 4%), 277 (M-43, 2%), and 264 (M-56, 5%) (Fig. 4b). Each ion was larger than that of linolenate (18:3 ester, Fig. 2c) by 28 mass units (C_2H_4). Furthermore, the ion fragments lower than *m/z* 150 in the spectrum of the 20:3 ester were almost identical to that of 18:3 ester,

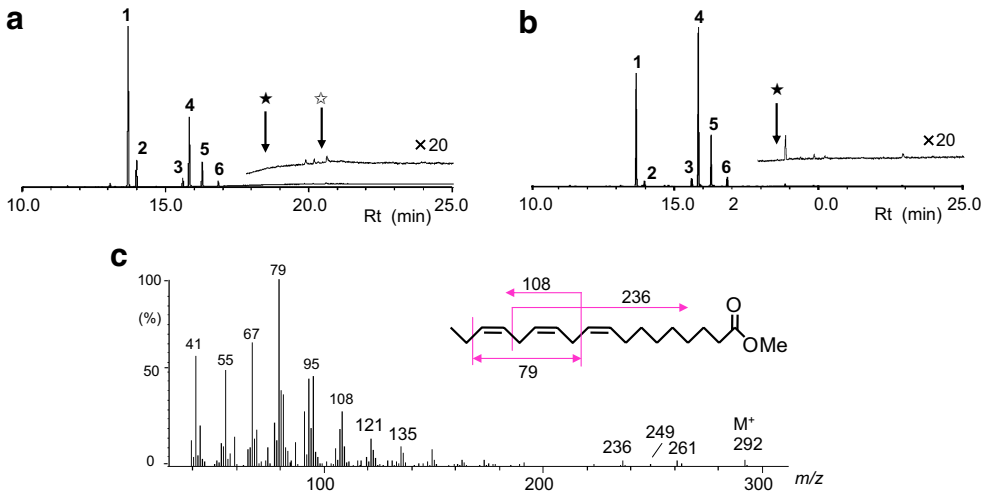

Fig. 2 Analyses of crude mixtures of fatty acid methyl esters (FAMEs), which were derived from the lipid extracts of abdominal integuments, by GC–MS equipped with a DB-23 column. (**a**) TIC (total ion chromatogram) of FAMEs from the *S. imaon* female (0.001 FE). (**b**) TIC of FAMEs from the *A. s. cretacea* female (0.001 FE). (**c**) Mass spectrum of the 18:3 ester of the *S. imaon* female (linolenate, peak **6**). Other esters: 16:0 (palmitate, peak **1**), 16:1 (peak **2**), 18:0 (stearate, peak **3**), 18:1 (oleate, peak **4**), and 18:2 (linoleate, peak **5**). The *arrows* in the amplified chromatograms show the expected Rts of 20:3 (*closed star*) and 22:3 (*open star*) esters, which could not be detected in these analyses

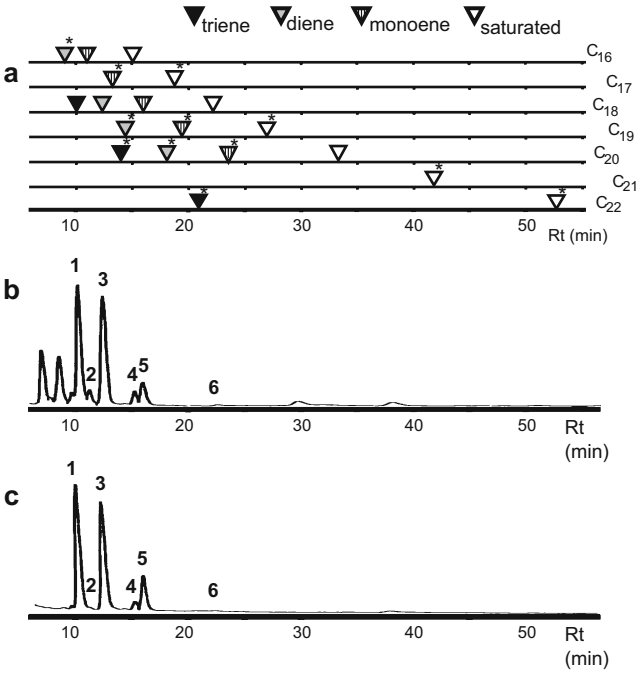

Fig. 3 Analyses of FAMEs, authentic standards and mixtures derived from the female abdominal integuments, by HPLC equipped with an ODS column. (**a**) Retention times (Rts) of saturated, monoenyl, dienyl, and trienyl FAMEs with a straight chain (C_{16}–C_{22}). The Rts of trace FAMEs with an *asterisk* were estimated by GC–MS analysis of the HPLC elutants, which were fractionated every one or 2 min after injection of insect FAMEs. (**b**) Chromatogram of FAMEs from the *S. imaon* female (1 FE). (**c**) Chromatogram of FAMEs from the *A. s. cretacea* female (1 FE). Upon injection of insect FAMEs, the following esters eluted with 5% water in methanol (flow rate, 1.0 ml/min; UV, 210 nm): 18:3 (linolenate, peak **1**), 16:1 (peak **2**), 18:2 (linoleate, peak **3**), 16:0 (palmitate, peak **4**), 18:1 (oleate, peak **5**), and 18:0 (stearate, peak **6**)

indicating the same trienoic structure. This characteristic spectrum suggests that the 20:3 ester is methyl (*Z,Z,Z*)-11,14,17-icosatrienoate derived from the predicted biosynthetic intermediate. This identification was confirmed by its partial reduction of the 20:3 ester, which yielded a mixture of three 20:1 esters. These monoenyl esters were treated with DMDS, and the GC–MS analysis of the reaction mixture revealed the production of the following three compounds: a DMDS adduct of 11-icosenoate (Rt 25.88 min, M^+ at *m/z* 418, diagnostic ions at *m/z* 245, 213, and 173); a DMDS adduct of 14-icosenoate (Rt 25.98 min, M^+ at *m/z* 418, diagnostic ions at *m/z* 287, 255, and 131); and a DMDS adduct of 17-icosenoate (Rt 26.45 min, M^+ at *m/z* 418, diagnostic ions at *m/z* 329, 297, and 89).

The 22:3 ester (Rt 20.5 min), which was detected only in the FAMEs of *S. imaon*, showed a mass spectrum with M^+ at *m/z* 348 (9%) and characteristic fragment ions at *m/z* 317 (M-31, 6%), 305 (M-43, 2%), and 292 (M-56, 5%) (Fig. 4d). Each ion was larger than that of linolenate by 56 mass units (C_4H_8). In the portion of the spectrum that was lower than *m/z* 150, the spectrum of the 22:3 ester was also identical to that of the 18:3 ester, indicating that the ester was methyl (*Z,Z,Z*)-13,16,19-docosatrienoate. Since the amount of the 22:3 ester purified from the FAME mixture was very low, the double-bond positions were not confirmed by the DMDS derivatization of monoenyl esters produced by its diimide reduction.

Relative Contents of Trace Fatty Acids In addition to 20:3 and 22:3 esters, the FAME mixtures of two species included many esters of the following trace fatty acids: 16:2, 17:0, 17:1, 19:0, 19:1, 19:2, 20:0, 20:1, 20:2, 21:0, and 22:0. While about 0.3 and 0.4 mg/female of the 16:0 ester were present in the crude FAME mixtures of *S. imaon* and *A. s. cretacea*, respectively, these trace esters were found at an ng range. Their relative contents based on the 16:0 ester were under 1% as shown in Table 1. Particularly, the amount of the 22:3 ester was quite low. In this study, 22:1 and 22:2 esters were not detected. If these esters are present in the mixtures, their contents are estimated to be

under 0.01%. In order to examine a possibility that the 20:3 and 22:3 acids were derived from the artificial diet, which was provided for larvae of both species, the FAMEs of the diet were also analyzed by the same procedure as insect integuments. The trienoates were not detected in the artificial diet.

Discussion

A pheromone extract of the *S. imaon* females included four poly-unsaturated hydrocarbons, *Z*3,*Z*6,*Z*9-21:H, 1,*Z*3,*Z*6,*Z*9-21:H, *Z*3,*Z*6,*Z*9-20:H, and 1,*Z*3,*Z*6,*Z*9-20:H, at a ratio of 32:67:0.6:0.7. The former two C_{21} components showed strong EAG activities (Fig. 1), while the latter C_{20} components were not detected on GC–EAD analysis of the pheromone extract because of their low contents. In a coppice in the Yonaguni-jima Islands, we confirmed that the traps baited with a lure that included a 1:2 mixture of *Z*3,*Z*6,*Z*9-21:H and 1,*Z*3,*Z*6,*Z*9-21:H could capture males. After a preliminary field test in 2007, violent typhoons hit the islands and caused serious damage everywhere. Since the larvae and adults of *S. imaon* were not observed on the islands after the storm, the optimum mixing ratio and the roles of two minor components in the synthetic lures were not evaluated. However, the trapping revealed that the pheromone is the most significant cue in the searching behavior of the male moths around the females of this diurnal species. On the other hand, visual cues may play a role in final recognition of the partner because the adults have colorful species-specific striped bodies. By using a wind tunnel, we are examining exactly how the shape of the *S. imaon* female is recognized by the males attracted by the synthetic pheromone.

To date, sex pheromones have been reported for two other species in the Syntominae, *Empyreuma mucro* and *Syntomeida epilais* (Descoins et al. 1989). Although the identified components have not been evaluated in the field, the pheromones were composed of Type II pheromone components, *Z*3,*Z*6,*Z*9-21:H and the epoxy derivative. Our study with *S. imaon* confirmed that females of diurnal arctiid species secrete Type II pheromones, as the nocturnal arctiid species do. Species in the Syntominae evolved in the tropics, and only three other species are distributed throughout Japan. We also identified the Type II pheromone from another wasp moth, *Amata fortunei fortunei* (Kondo et al., unpublished). Sex pheromones of species in another subfamily, Lithosiinae, have not been reported, with the exception of female *Lyclene dharma dharma* (Ando 2008). We recently identified novel EAG-active compounds (methyl-branched 2-ketones) from this species, and the compounds were not classified into Types I or II (Yamamoto et al. 2007). The sex pheromones of arctiid moths are taxonomically interesting, and these results will be reported elsewhere.

To add to the above two Syntominae species, *Z*3,*Z*6,*Z*9-21:H has been identified as a pheromone component from more than 20 species in Geometridae, Noctuidae, Lymantriidae, and Arctiidae (Ando 2008). 1,*Z*3,*Z*6,*Z*9-21:H has been identified from the following three species: *Epirrita autumnata* (Geometridae) (Zhu et al. 1995), *Arctia villica* (Arctiidae) (Einhorn et al. 1984), and *Utetheisa ornatrix* (Arctiidae) (Jain et al. 1983; Choi et al. 2007). Similar to *S. imaon*, the latter two arctiid species produced a mixture of *Z*3,*Z*6,*Z*9-21:H and 1,*Z*3,*Z*6,*Z*9-21:H, but field tests of the synthetic mixture have not been reported for them. The preliminary field data from our study with *S. imaon* is the first case where the mixture identified from females was attractive to conspecific males.

In addition to the pheromone components, the lipid extracted from abdominal integuments, which were associated with oenocytes and peripheral fat bodies, was examined. A direct GC–MS analysis of FAMEs derived from the lipid of the *S. imaon* females was fruitless (Fig. 2). However, after HPLC fractionation of the FAMEs (Fig. 3, Table 1), methyl (*Z,Z,Z*)-11,14,17-icosatrienoate and (*Z,Z,Z*)-13,16,19-docosatrienoate were identified by GC–MS analysis (Fig. 4). These novel 20:3 and 22:3 acid moieties

might be biosynthesized by chain elongation of linolenic (18:3) acid, and are presumed to be biosynthetic precursors of the trienyl component (*Z*3,*Z*6,*Z*9-21:H) of the *S. imaon* pheromone. The C_{21} triene can be produced by decarboxylation of the 22:3 acid, which has the double bonds at the same positions counting from the terminal methyl group. On the other hand, only the 20:3 ester was found in FAMEs of *A. s. cretacea* females (Table 1), which secreted C_{19} pheromone components, (*Z,Z,Z*)-3,6,9-nonadecatriene and *cis*-3,4-epoxy-(*Z,Z*)-6,9-nonadecadiene. The difference of acid composition in these two species reflects the different chain lengths of the pheromones, indicating that the biosyntheses of Type II pheromones are strictly regulated by a species-specific system of the chain elongation. This result concurred with biosynthetic experiments of cuticle hydrocarbon pheromones in cockroaches and houseflies (Vaz et al. 1988; Tillman-Wall et al. 1992; Chertemps et al. 2007). It has been reported that the chain lengths of the pheromones are regulated by the step of fatty acyl-CoA elongation.

Studies on the biosynthetic pathways of Type II pheromones began from research with females of two arctiid species, *Estigmene acrea* and *Phragmatobia fuliginosa*, which secreted (*Z,Z*)-*cis*-9,10-epoxy-3,6-henicosadiene (Rule and Roelofs 1989). Since the females injected with ^{14}C-labeled 18:3, 20:3, or 22:3 acids produced the radioactivity-incorporated pheromones, the pathway via chain elongation of 18:3 acid was proposed. The 20:3 and 22:3 acids, however, could not be detected in the females. Moreover, no unsaturated fatty acids with a C_{20} or longer chain have been chemically determined from any insects, including the species that produce unsaturated hydrocarbons with a long chain (Blomquist et al.1987; Jurenka et al.1987). Our identification of the acyl intermediates in Type II pheromone biosynthesis is the first example that confirms the occurrence of long-chain unsaturated fatty acids in insects, to the best of our knowledge.

It is well known that cuticle hydrocarbons are produced in oenocytes associated with either epidermal tissue or fat body cells in insects (Romer 1991; Fan et al. 2003). In the case of insects that secrete a Type II pheromone, polyunsaturated hydrocarbons characterized as a pheromone component or biosynthetic precursor are also expected to be biosynthesized there and transported to the pheromone gland via the hemolymph after association with lipophorin (Matsuoka et al. 2006). From the *S. imaon* females, the triene and tetraene were detected in the hemolymph (data not shown), as other polyunsaturated hydrocarbons of *A. s. cretacea*, *Hemerophila artilineata* (Geometridae), and *Spilosoma imparilis* (Arctiidae) were (Wei et al. 2003). Although the contents of the 20:3 and 22:3 acids in *S. imaon* and *A. s. cretacea* were very low (Table 1), they were detected only in the lipids derived from the abdominal integuments and not from any other regions, such as the hemolymph and a pheromone gland (data not shown). This confirmed the site for the production and decarboxylation of 20:3 and 22:3 acids.

Recently, the biosynthetic pathway of the 1,*Z*3,*Z*6,*Z*9-21:H was examined with *U. ornatrix* (Choi et al. 2007). Deuterated *Z*3,*Z*6,*Z*9-21:H injected into female pupae was not incorporated into 1,*Z*3,*Z*6,*Z*9-21:H, indicating that the triene was not a biosynthetic precursor of the tetraene and that the terminal double bond was introduced at an early step in the biosynthetic pathway. With female *S. imaon*, we tried to identify the tetraenyl acids corresponding to the tetraene, but none of the hypothetical tetraenyl acids, i.e., 18:4, 20:4, and 22:4, was detected in FAMEs. If the tetraene is biosynthesized via desaturation of the acyl intermediate starting from dietary linolenic (18:3) acid, we can speculate that the desaturation step is linked effectively with decarboxylation and the tetraenyl acid does not accumulate. Further studies are necessary to determine the biosynthetic pathway of the tetraene. While conversion of deuterated 19:3 acid into a C_{18} trienyl pheromone was reported recently in *Erannis bajaria* (Goller et al. 2007), the biosynthetic steps that produce polyenyl hydrocarbons with an odd-numbered chain (not only tetraenes, but also trienes and dienes) have not been confirmed experimentally with labeled compounds. The *S. imaon* female seems to be a desirable insect for biosynthetic experiments, since the pheromone content is higher than 1 μg/female. Based on the structures determined in this study, we are synthesizing labeled candidates of precursors of the *S. imaon* pheromone to confirm the biosynthesis.

Fig. 1 Crown-like arrangement boring dust (frass) surrounding the entrance hole constructed by male *M. mutatus* in *P. canadensis*. Volatiles emitted from the frass and entrance hole attract individuals of the opposite sex

Santoro (1963) reported that *M. mutatus* emerge primarily at sunrise. Observations (Gatti Liguori, unpublished results) suggested that newly emerged *M. mutatus* are susceptible to dehydration once they are outside their gallery system in the xylem. Therefore, it would be reasonable to expect that, immediately after emergence, female flight is orientated to locate males *via* the volatile plume emitted early in the morning. The response is necessary to initiate courtship and copulation.

Here, we report an analysis of the frequency profile of diurnal and nocturnal female emergence. Furthermore, volatile emission was analyzed during the morning hours when female emergence and courtship and mating occur at high frequency. Finally, the behavioral activities of candidate compounds from the volatile blend were evaluated by using the female response in a walking behavioral assay.

Methods and Materials

Biological Material Insects were collected from our Institute's plantation of *Populus canadensis* Moench and *Quercus palustris* Muenchh. located in Villa Martelli, Province of Buenos Aires, Argentina (34°22′ S, 58°30′W). Beetles were collected during emergence by using plastic traps that were specially designed to avoid antagonistic interactions (Gatti Liguori et al. 2007) and immediately sexed. Only females that emerged within a period of 3 h or less were used in laboratory experiments.

Temporal Pattern of Female Emergence The number of emerged females was recorded every 2 h from 7–23 h, between 1 and 20 October, 2006. A relative frequency chart was made based on the data collected. The times of day with the highest frequency of emergence were used to select the time to collect and analyze male volatiles.

Collection and Analysis of Male Volatiles Live *Populus alba* L., *Q. palustris* Munchh, and *Casuarina stricta* L. trees that were at least 10 years old and had a diameter at breast height (dbh) of 20 cm were artificially infested with 59, 15, and 94 virgin males, respectively. Each insect was confined in a transparent plastic jar (60×30 mm) to ensure its interaction with the tree bark surface. The date and time at which tunneling activity began was recorded.

At times during maximal female emergence, males were collected from the frass crown arrangement with entomological forceps and immediately placed in a 20-ml glass vial (Scientific Specialties Service, Inc., Baltimore, MD, and Reno, NV, USA) with a teflon-coated cap (teflon septum with glass-reinforced polypropylene resin open cap). The physical integrity of each male was checked, and the volatiles from the headspace were collected at 30°C for 30 min by using a Solid Phase Microextraction (SPME) holder and fiber covered with a Carbowax®/divinylbenzene polar phase (Supelco Inc., Bellefonte, PA, USA). This coating is specific for low-molecular weight alcohols and ketones. Samples were analyzed immediately by GC-MS (see below), yielding a volatile emission profile for each insect.

Synthetic Chemicals Sulcatone (6-methyl-5-hepten-2-one) and 3-pentanol were analytical grade (Sigma-Aldrich Co., St. Louis, MO, USA); (+)-sulcatol [(+)-6-methyl-5-hepten-2-ol] 99% chemical purity, was purchased from Pherotech Inc., Delta, B.C., Canada.

Linked Gas Chromatography–Mass Spectrometry (GC-MS) Analyses SPME fibers were analyzed by GC-MS with a Shimadzu QP 5050A instrument equipped with a non-polar, fused silica HP-1 capillary column with crossed linked methyl silicone (50 m length, 0.32 mm diameter, and 0.52 μm thickness) (Hewlett Packard, Santa Clara, CA, USA). Samples were injected in the splitless mode. Volatiles from the SPME fibers were desorbed in the injection port at 190°C for 1.5 min. The GC column was held at 60°C for 1 min, after which the temperature was programmed to increase 3°C/min up to 105°C, and then 40°C/min to 250°C where it was maintained for 5 min. The carrier gas was helium with a head pressure of 30 kPa. The MS detector was set on electron impact mode at 70 eV.

Behavioral Bioassays Walking behavior of female *M. mutatus* was evaluated in an experimental arena with a video-tracking technique (Alzogaray et al. 2000). The floor of the test arena was covered with a round piece of Whatman No. 1 filter paper (125 mm diameter; Whatman Ltd., Maidstone, UK), and a glass cover (20×20 mm) was placed in the center of the paper. Next, the filter paper and glass cover were both covered with a rectangular piece of wire mesh (100×100 mm; 1 mm mesh size). A colorless

glass ring (100 mm diameter; 50 mm high) was used to confine the insects. The glass ring and wire mesh were washed previously with 96% ethanol and kept at 250-300°C for at least 1 week. A new glass cover and filter paper were used in each replicate.

A closed-circuit video camera that provided black and white images (VC 1910; Sanyo Electrical Co., Tokyo, Japan) was suspended 22 cm over the center of the test arena. A circular fluorescent tube (22 W, OSRAM, Buenos Aires, AR) was placed 64 cm above the video camera.

An image analyzer (Videomex V, Columbus, OH, USA) received input from the video camera, converting the analog signal into digital data. The resolution was 256×192 pixels, and the acquisition and processing speed was 30 fps. The video signal colors were inverted in the monitor, therefore white objects appeared black and vice versa. The presence of insects in the arena was determined by visual contrast between the individuals (white) and the arena background (dark), and scored as the number of "ON" pixels. The area occupied by the insects was recorded by using the Multiple Zone Motion Monitor for Videomex software.

The arena image was divided into a central square (4 cm^2, 5% of the total area) and a circular outer area. The center of the glass cover was located in the center of the virtual central square. A female *M. mutatus* was placed on the wire mesh and allowed to acclimatize for 5 min before starting the bioassay. During this time, the insect moved all around the arena. Insect movement was recorded for 60 min. During the first 30 min, 20 µl of carbon dioxide-free distilled water were placed on the glass cover. Then, 20 µl of the test solution were placed on the cover by using carbon dioxide-free distilled water as carrier. Temperature varied between 25 and 30°C. Water took about 30 min to evaporate within this temperature range. The first 30 min of each test was the control, and the remaining 30 min was the experimental treatment. Thus, the occupation level of the central circle during the first 30 min (control) was compared to the occupation level during second 30 min (following the introduction of the test substance).

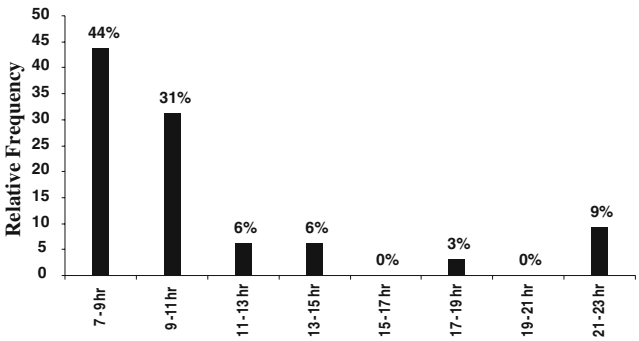

Fig. 2 Relative frequencies, expressed as percentages, of emerging female *M. mutatus* during each 2-h time interval, from 7–23 h. Samples were taken between 1 and 20, October, 2006. Total number of females was 31

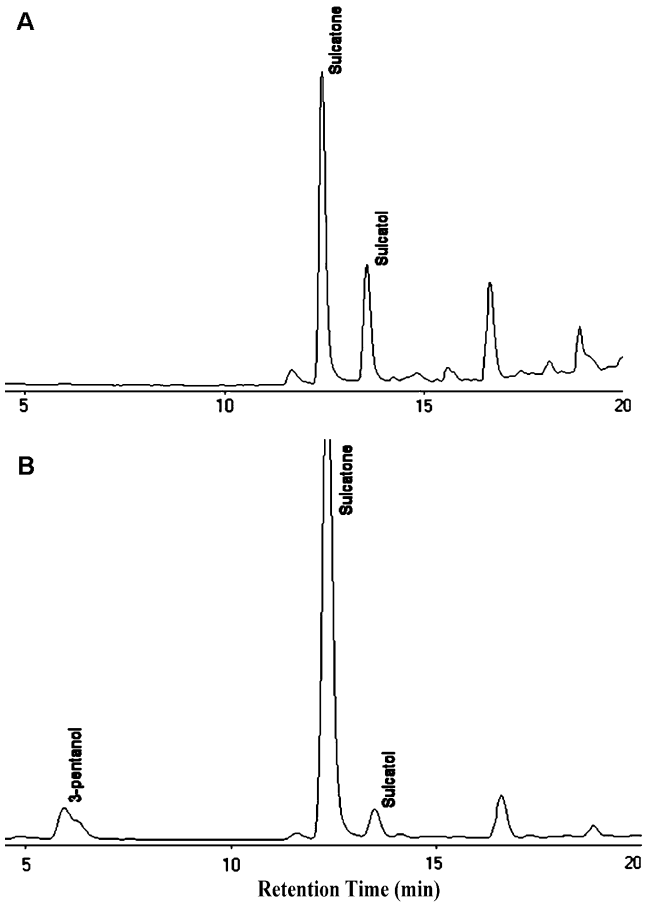

Fig. 3 GC trace of volatiles collected by SPME above a male *M. mutatus* boring in *C. stricta*. **a** GC trace representative of 91.7% of samples. **b** GC trace representative of 8.3% of the samples showing the presence of 3-pentanol in the volatile emission

For preparation of test solutions, sulcatol, sulcatone, and 3-pentanol were weighed and added to carbon dioxide free distilled water (100 ml total volume). Concentrations of stock solutions were chosen in order to obtain the required amounts of test substance in the 20 or 40 µl test aliquots. Solutions were sonicated and stored at 5°C until 1 h before they were used in the behavioral assays. At least four different concentrations of each compound were assayed. Carbon dioxide-free distilled water alone was used to evaluate the behavior of the control group. Each experiment was repeated at least eight times.

To assay the comparative responses to (+)-sulcatol and sulcatone (binary mixture) versus (+)-sulcatol, sulcatone, and 3-pentanol (ternary mixture), 40 µl of solution containing 22 µg of each component were tested in the same conditions. Each experiment was replicated al least 16 times.

We used the Central Area Occupation (CAO) parameter, defined as the total number of "ON" pixels in the central circle (where the test compound is placed) during a

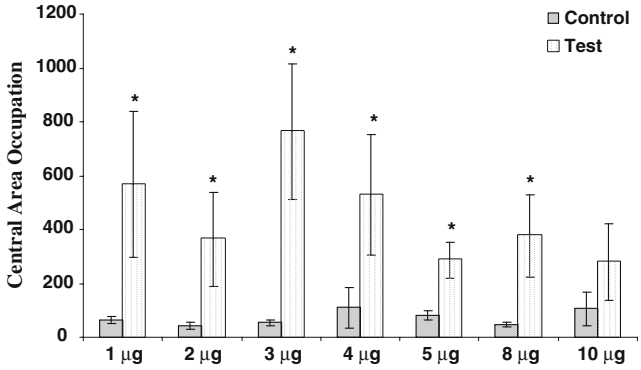

Fig. 4 Response of female *M. mutatus* (mean±SE) measured as the Central Area Occupation (=number of *on* pixels) for each dose of 3-pentanol compared to its respective control. Each test was replicated at least eight times. *Indicates significant difference compared to control values ($P \leq 0.05$)

replicate (Fontán et al. 2002), to quantify insect behavior. A mean CAO value was obtained for each treatment and compared to its respective control.

Statistical Analysis Data from the behavioral assay were analyzed by non-parametric Kruskal–Wallis ANOVA (STATISTICA'99 1999). Edition software by StatSoft, Inc (Kernel Release 5.5 A ©1984–1999).

Results

Temporal Pattern of Female Emergence Analyses of female emergence with time of day showed that 75% of the females left the gallery between 7 and 11 h (Fig. 2). Based on these results, we performed our analysis of male volatiles by using males collected during the first hours of this interval, hypothesizing that pheromone emission would be in progress at this time.

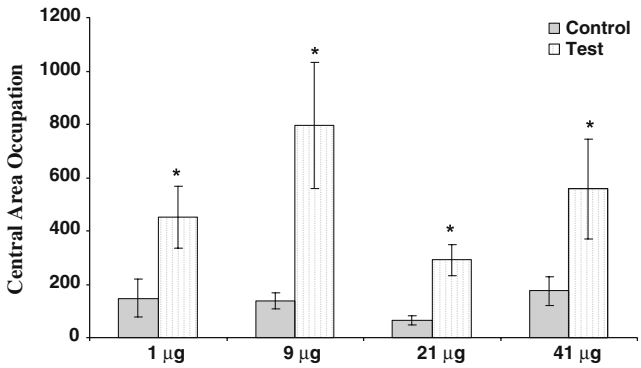

Fig. 5 Response of female *M. mutatus* (mean ± SE) measured as the Central Area Occupation (=number of *on* pixels) for each dose of (+)-sulcatol compared to its respective control. Each test was replicated at least eight times. *Indicates significant difference compared to control values ($P \leq 0.05$)

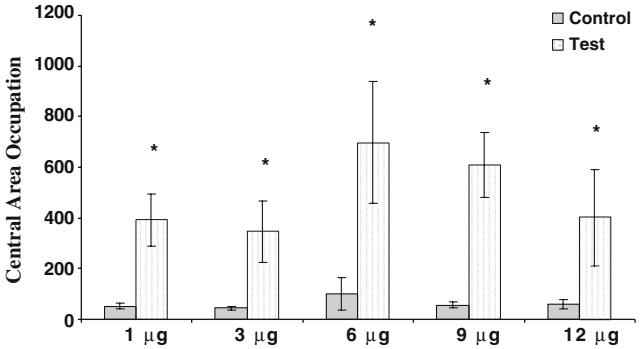

Fig. 6 Response of female *M. mutatus* (mean±SE) measured as the Central Area Occupation (=number of *on* pixels) for each dose of sulcatone compared to its respective control. Each test was replicated at least eight times. *Indicates significant difference compared to control values ($P \leq 0.05$)

Collection and Analysis of Male Volatiles GC-traces showed that (+)-sulcatol and sulcatone were found in 91.7% of the male samples collected on *P. alba*, *Q. palustris*, and *C. stricta* trees between 7 and 11 AM. However, an additional peak was detected in 8.3% of the samples (Fig. 3). This peak was identified as 3-pentanol by comparison of its retention time and mass spectrum with an authentic standard. Although there was considerable variability among insects, we estimated a mean relative amount of 3-pentanol as 13.9±6.4%, whereas sulcatone and sulcatol were 34.9±9.3% and 51.2±10.7%, respectively. 3-Pentanol was not found in any of the system blanks.

Behavioral Bioassays Results were analyzed based on the Central Area Occupation (CAO) parameter. Significant occupation of the central area can be interpreted as an effective attraction to the source followed by an arrestment in the area (Fontán et al. 2002).

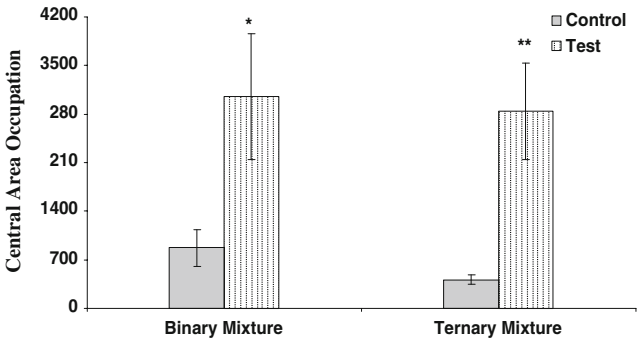

Fig. 7 Response of female *M. mutatus* (mean±SE) measured as the Central Area Occupation (=number of *on* pixels) for the binary mixture and the ternary mixture compared to their respective controls. The binary mixture contained 22 µg each of (+)-sulcatol and sulcatone. The ternary mixture contained 22 µg each of (+)-sulcatol, sulcatone, and 3-pentanol. *Indicates significant difference compared to control values ($P \leq 0.05$). **Indicates significant difference compared to control values ($P \leq 0.001$). Controls were not significantly different

CAO values of female *M. mutatus* exposed to different concentrations of 3-pentanol revealed that doses between 1 and 8 μg elicited a significant behavioral response ($P \leq 0.05$) when compared with their respective controls (Fig. 4). Thus, females were attracted to the stimulus source. Only the highest concentration (10 μg) failed to elicit any significant response from females. In this case, the value of CAO was not significant differently from its control ($P = 0.07$). This can be interpreted as a repellence or saturation phenomenon that attracts the insects to the plume, but then repels them when they get closer.

The values of CAO for (+)-sulcatol were different from their respective controls for all doses tested ($P \leq 0.05$). Therefore, a significant attraction to the source was observed whenever the insects were exposed to (+)-sulcatol (Fig. 5). There were no differences among the different concentrations ($P > 0.05$).

The values of CAO for sulcatone were different from their respective controls ($P \leq 0.05$) at all doses tested. Thus, the insects were significantly attracted to the source in all cases of exposure to sulcatone (Fig. 6). No differences were observed among the different concentrations ($P > 0.05$).

In the assay to evaluate the role of 3-pentanol in the pheromone blend, the values for CAO for the binary mixture [(+)-sulcatol+sulcatone] were not significantly different from those of the ternary mixture [(+)-sulcatol+ sulcatone+3-pentanol] (Fig. 7).

Discussion

Our results showed that during the assay period (1 to 20 October), female *M. mutatus* emerge preferably between 7 and 11 AM. This preference could be due to this insect's particular susceptibility to dehydration (Gatti Liguori, unpublished results).

Chemical analyses of volatiles emitted by male *M. mutatus* between 7 and 11 AM showed that the extracts were composed primarily of sulcatone and (+)-sulcatol. However, an additional compound, 3-pentanol, was identified in a small percentage of samples. Walking behavioral bioassays with video image analysis showed that at the doses tested, 3-pentanol, (+)-sulcatol, and sulcatone each elicited an attractive response from female *M. mutatus*. As no significant differences in response were observed among the different concentrations, we cannot conclude whether one of the concentrations was more attractive than the others under the current the experimental conditions. The assay to compare the attractiveness of the two vs. three component mixtures did not show significant differences in their behavioral activity. So, although we have demonstrated that 3-pentanol is attractive to *M. mutatus* females, we were not able to address its role in the sex pheromone blend.

3-Pentanol has been described as a minor pheromonal component in West Indian sugarcane weevils, *Metamasius hemipterus sericeus* (Oliv.) (Perez et al. 1994), an insect pest of bananas, pineapples, palms, and sugarcane in Central and South America, the Caribbean, and Africa (Vaurie 1966). It has also been described in volatile emissions from the metasternal glands of *Triatoma infestans* (Klug), the etiological agent of Chagas disease (Manrique et al. 2006). For *M. mutatus*, we hypothesize based on the superior response to the ternary mixture with respect to its control ($P < 0.001$ vs. $P = 0.01$ for the binary mixture with the same test), that 3-pentanol could diminish the uncertainty in the process of location of the pheromone source (Witzgall and Arn 1990) and/or arrest the *M. mutatus* female at the point of origin of the plume (i.e., the male in the natural system).

Our efforts are now aimed at testing the role of 3-pentanol combined with (+)-sulcatol and sulcatone in the attraction of female *M. mutatus* in the field. We are also investigating whether the male proctodeum is the site of pheromone storage and/or production. We are evaluating the attractant activity of this male tissue compared to a blend of synthetic pheromone components, and are conducting an exhaustive chemical analysis of this tissue for minor pheromonal components.

Nelson et al. 2001; Copren et al. 2005). Finally, it is difficult to distinguish *Reticulitermes* taxa solely on the basis of morphology, particularly if only workers are available.

Given this problem, numerous investigators have employed chemical characters, such as cuticular hydrocarbons (CHCs) and soldier defense secretions (SDSs), for distinguishing taxa of *Reticulitermes* (Howard et al. 1978, 1982; Parton et al. 1981; Zalkow et al. 1981; Baker et al. 1982; Clément et al. 1985, 1986, 1988; Bagnères et al. 1988, 1990, 1991; Lemaire et al. 1990; Haverty et al. 1996a, 1999b; Haverty and Nelson 1997; Clément and Bagnères 1998; Takematsu 1999; Takematsu and Yamaoka 1999; Nelson et al. 2001; Page et al. 2002; Quintana et al. 2003). Studies that correlate mitochondrial DNA sequences with CHC phenotypes of *Reticulitermes* give additional credibility to the value of CHCs as taxonomic characters (Jenkins et al. 2000; Clément et al. 2001; Copren et al. 2005).

We have successfully used CHCs and SDSs to separate taxa in studies on the foraging ecology of *Reticulitermes* in northern California (Getty et al. 1999a; Haverty et al. 1999c, 2000) and to evaluate baiting technology for control of *Reticulitermes* in structures (Getty et al. 1999b, 2000b). This chemotaxonomic information has also been critical for studies of behavior of *Reticulitermes* (Haverty et al. 1999a, 2003; Getty et al. 2000a; Delphia et al. 2003; Copren 2004; Copren et al. 2005).

Recently, we expanded our studies to locations in southern California to fill in gaps in the biogeography of *Reticulitermes* and to facilitate evaluation of bait technology. The study reported here includes more extensive collections and a complete description of the phenotypic differences first reported in Haverty and Nelson (1997), Nelson et al. (2001), and Copren et al. (2005). We also characterized SDSs for the CHC phenotypes found in southern California, and we discuss the state of current taxonomic research on *Reticulitermes*.

Methods and Materials

Insects Termites were collected from monitoring stations or naturally infested wood at locations in Los Angeles, Orange, Riverside, San Bernardino, San Diego, and Santa Barbara counties in southern California (Table 1). In San Bernardino County, we collected at the type locality of *R. hesperus*, Little Bear Lake, San Bernardino Mountains, CA (Snyder 1949). This area is now known as Lake Arrowhead (Robinson 1989). In addition, we include information from collections used in our study of the CHCs of *Reticulitermes* from northern California (Table 1) (Haverty and Nelson 1997).

Once separated from wood and debris, samples of up to 200 termite workers were placed in 20-ml scintillation vials and kept at −15°C until extraction of CHCs. Termite soldiers (1–10) were placed in *n*-pentane (ca 200–600 µl) in 4-ml vials and stored at −15°C until analysis of SDSs. Voucher specimens for each colony were placed in 70% ethanol and are maintained by the authors.

Cuticular Hydrocarbons Frozen termite workers were thawed, dried at ca 60°C, and immersed in 10 ml of *n*-hexane for 10 min. After extraction, hydrocarbons were separated from other compounds by pipetting the extract through 4 cm of activated silica gel (70–230 mesh), in Pasteur pipet mini-columns, followed by elution with 5 ml of *n*-hexane. The solvent was removed under a stream of nitrogen, and the residue was redissolved in 60 µl of *n*-hexane for gas chromatography-mass spectrometry (GC-MS) analysis.

GC-MS analyses were performed on a Hewlett-Packard (HP) 5890 gas chromatograph interfaced with an HP 5970B Mass Selective Detector. The GC-MS was equipped with an HP-1 fused silica capillary column (25 m×0.2 mm ID). Split injection (split ratio of 8:1) and a temperature program of 200–320°C at 3°C min^{-1} were used in the analysis. Electron impact (EI) mass spectra were obtained at 70 eV. Samples collected in 2001 and 2002, numbered SC-182-244 (Table 1), were analyzed under the same conditions with an Agilent 6890 GC coupled with a 5973 MSD.

n-Alkanes and methyl-branched alkanes were identified by mass spectral fragmentation patterns (Blomquist et al. 1987; Nelson 1993; Page et al. 1997). Alkenes, alkadienes, and alkatrienes were identified by mass spectra, but double bond positions were not determined (see Haverty and Nelson 1997). Equivalent chain lengths (ECL) were calculated for some of the unsaturated compounds, so as to distinguish isomers.

In the text and tables, we use shorthand nomenclature to identify individual hydrocarbons or mixtures of hydrocarbons. This shorthand uses a descriptor for the total number of carbons (CXX) in the hydrocarbon component, excluding the methyl branch(es), the location of methyl groups (X-me), and the number of double bonds following a colon (CXX:Y). Thus, normal pentacosane is *n*-C25; 5-methylpentacosane is 5-meC25; 5,17-dimethylheptacosane is 5,17-dimeC27; and pentacosatriene is C25:3. Integration of the total ion chromatogram was performed by using HP Chemstation data analysis software. GC-MS peak areas were converted to percentages of the total hydrocarbon fraction. A summary of the relative amounts of each peak is presented in table form using all samples of each phenotype.

CHC phenotypes are identified by a prefix that indicates geographic region from where specimens were collected, and a suffix indicating the distinct phenotype for that geographic region. In Haverty and Nelson (1997), northern California phenotypes were labeled with a single letter to

[a] Sequences of the cytochrome oxidase II region of mtDNA for these collections were reported in Copren et al. 2005.
[b] The cuticular hydrocarbon phenotypes for these samples are reported in Haverty and Nelson 1997, excluding samples SC-115–118.
[c] The soldier defense secretion phenotypes for these samples are reported in Nelson et al. 2001, excluding samples SC-115–118.

indicate the phenotype (e.g., A, A′, B, C, D). However, in subsequent publications, we added the prefix CA- to distinguish these phenotypes from those characterized from other regions, such as Arizona (AZ-) and Georgia (GA-). Here, we use the prefix SC- for southern California collections.

Soldier Defense Secretions Monoterpenes, sesquiterpenes, and diterpenes were identified and quantified by GC-MS (Nelson et al. 2001). GC-MS analysis was carried out with splitless injection, a 0.25 mm ID×30 m 5% phenyl–95% methylpolysiloxane capillary column, helium as carrier gas, and a temperature program of 35°C (held for 0.7 min) to 280°C at 6°C min^{-1}. Most compounds were identified by retention time and MS comparison with authentic material or components of well-characterized essential oils. In some cases, identification was by comparison with published GC-MS data only and is considered tentative (compound name in parentheses). Terpenoids in bold characters in the tables are novel reports for termite soldiers. Unknowns are designated by apparent molecular weight and an identifying suffix letter. The suffix designations for the unknowns correspond to the same unknowns reported in Nelson et al. (2001).

Quantities of each terpenoid are calculated as a percentage of total peak area from the total ion chromatogram without correction for response factors. Germacrene A, which gradually rearranges to β-elemene under GC conditions, appeared as a broad hump following the β-elemene peak. Its quantity was determined as the sum of the areas of the β-elemene peak plus the hump, minus the areas of the other peaks superimposed on the hump. Germacrene B behaved similarly (rearranging to γ-elemene) and was quantified by the same approach.

(+)-γ-Cadinene from pooled samples of various collections was purified by silica gel LC and preparative GC as described elsewhere (Kim et al. 1994) and positively identified by diffuse-reflectance Fourier-transform infrared spectroscopy by using ca 50 μg of the neat material on powdered KBr in a microcup. Its optical rotation (α_D) was measured in hexane at 20°C.

Enantiomeric identity of a number of the monoterpenes and sesquiterpenes was determined by enantioselective GC (EGC). Conditions were: 10% permethylated β-cyclodextrin-90% OV-1701 capillary column, 0.25 mm ID×30 m; temperature program of 60–80°C for monoterpenes, 90–140°C for sesquiterpenes, with a 1-°C min^{-1} temperature increase; splitless injection (0.7 min); flame-ionization detection; internal standards of *n*-undecane for monoterpenes, and *n*-tetradecane or *n*-hexadecane for sesquiterpenes. EGC analysis was done on one soldier collection from the CHC phenotype that was richest in the relevant terpene(s). Before analysis, oxygenated components were removed by passing the pentane extract through activated alumina. Enantiomer identification was by retention time comparison with authentic materials. In the case of (−)-germacrene A, pooled samples were purified as for γ-cadinene, although under preparative GC conditions only β-elemene was recovered. This was then analyzed by EGC and compared to authentic (−)-β-elemene. For brevity, enantiomeric designations are not specified in the text, although they are given in the tables.

Cluster Analysis of CHC Mixtures From Termites The percentage of each hydrocarbon peak was used as the response variable. The presence of co-eluting compounds precluded exact quantification of many individual hydrocarbons. Several samples of each of the five northern California phenotypes described by Haverty and Nelson (1997) were included in the cluster analysis (Table 1).

Cluster analysis was first performed with all the samples listed in Table 1. There was a definite division between samples that lacked 5-methylalkanes and 5,17-dimethylalkanes and those that contained these compounds. Thus, in order to simplify the analysis, samples were divided into two groups based on this distinction, which corresponds to the lineage designations of Page et al. (2002). The first group included collections that lacked 5-methylalkanes and 5,17-dimethylalkanes. The predominant compounds in these samples were internally branched monomethyl- and dimethylalkanes, which place this group in lineage I. Phenotypes in lineage I were CA-A/A′ and SC-A. The second group, lineage II, was composed of collections with abundant 5-methylalkanes and 5,17-dimethylalkanes in the CHCs. Phenotypes in this lineage were CA-B, CA-D, and SC-B/B′. We also included four samples designated as CA-C from Placerville, CA (Haverty and Nelson 1997); although this phenotype did not neatly fit into lineage I or II, these samples were grouped with the former because of the absence of 5-methylalkanes and 5,17-dimethylalkanes.

The standardized Euclidean distances were calculated separately for the samples in lineages I and II by using all hydrocarbon peaks (Takematsu and Yamaoka 1999; Haverty et al. 2005; Baker and Haverty 2007; Haverty and Nelson 2007) using R Statistical Language (R Development Core Team 2004). Results are displayed as dendrograms. Euclidean distances of 15.0 were used to define clusters that we infer represent discrete taxa within each of the two lineages.

Results

Cuticular Hydrocarbons As reported in Copren et al. (2005), the two CHC phenotypes found in southern California were designated SC-A and SC-B. These pheno-

types belong to lineages I and II, respectively (Page et al. 2002). Samples representing each phenotype often were found at the same sites, indicating sympatry. For example, at study sites in Goleta (Santa Barbara Co.) and Burbank (Los Angeles Co.), we collected samples of SC-A and SC-B from nearby monitoring stations on the same day (Table 1: SC-231 and SC-236; SC-209 and SC-212).

Figure 1 shows the dendrogram based on cluster analysis of Californian *Reticulitermes* samples belonging to lineage I. There were three main clusters. One, SC-A, is composed of 18 samples from southern California ranging from Goleta to Alpine in San Diego County (Fig. 1; Tables 1 and 2). A second cluster is composed of CA-A and CA-A′ samples from northern California, as well as the two *R. hesperus* topotype samples from Lake Arrowhead (SC-115 and SC-117), and one sample from Los Angeles (SC-241; Fig. 1; Tables 1 and 2). Three samples (CA-Yt2, CA-Zn11, and CA-Wi74), previously designated as phenotype CA-C (Haverty and Nelson 1997), clustered together (Fig. 1; Tables 1 and 2), and a fourth sample (CA-PV), also previously included in CA-C, fell out by itself in the cluster analysis, despite the fact that the predominant compounds present (C27:2; 11,15-dimeC27) were typical of phenotype CA-C. For this reason, this sample is considered phenotype CA-C.

Phenotype SC-A closely resembles phenotypes CA-A and CA-A′ from northern California (Table 2), with a few quantitative and qualitative differences. All three of these phenotypes were dominated by internally branched monomethylalkanes and dimethylalkanes, with the methyl branches usually on carbons 11 or 13. SC-A produced several monomethylene-interrupted dimethylalkanes, 9,11-dimeCXX, in small amounts; these were not seen in CA-A, CA-A′, nor in the *R. hesperus* topotype samples from Lake Arrowhead (Fig. 2; Table 2).

SC-A profiles contained the same pair of pentacosatrienes (C25:3, ECL 25.98 and 26.07) as CA-A′, although the relative proportions differed (Table 2). Most samples from southern California produced more of the later eluting isomer (ca 1:7; Fig. 2a), whereas CA-A′ produced approximately equal amounts of both (Fig. 2b). Topotype samples from Lake Arrowhead had more of the earlier eluting isomer (ca 4:1; Fig. 2c). CA-A lacked these two compounds (Fig. 2d).

The one sample (SC-241) from Los Angeles that clustered with the northern California phenotypes had very small amounts of 9,11-dimethylalkanes, which may have caused it to cluster as it did (Fig. 1). However, we designate this sample as SC-A based on the presence of these compounds and the proportion of pentacosatrienes.

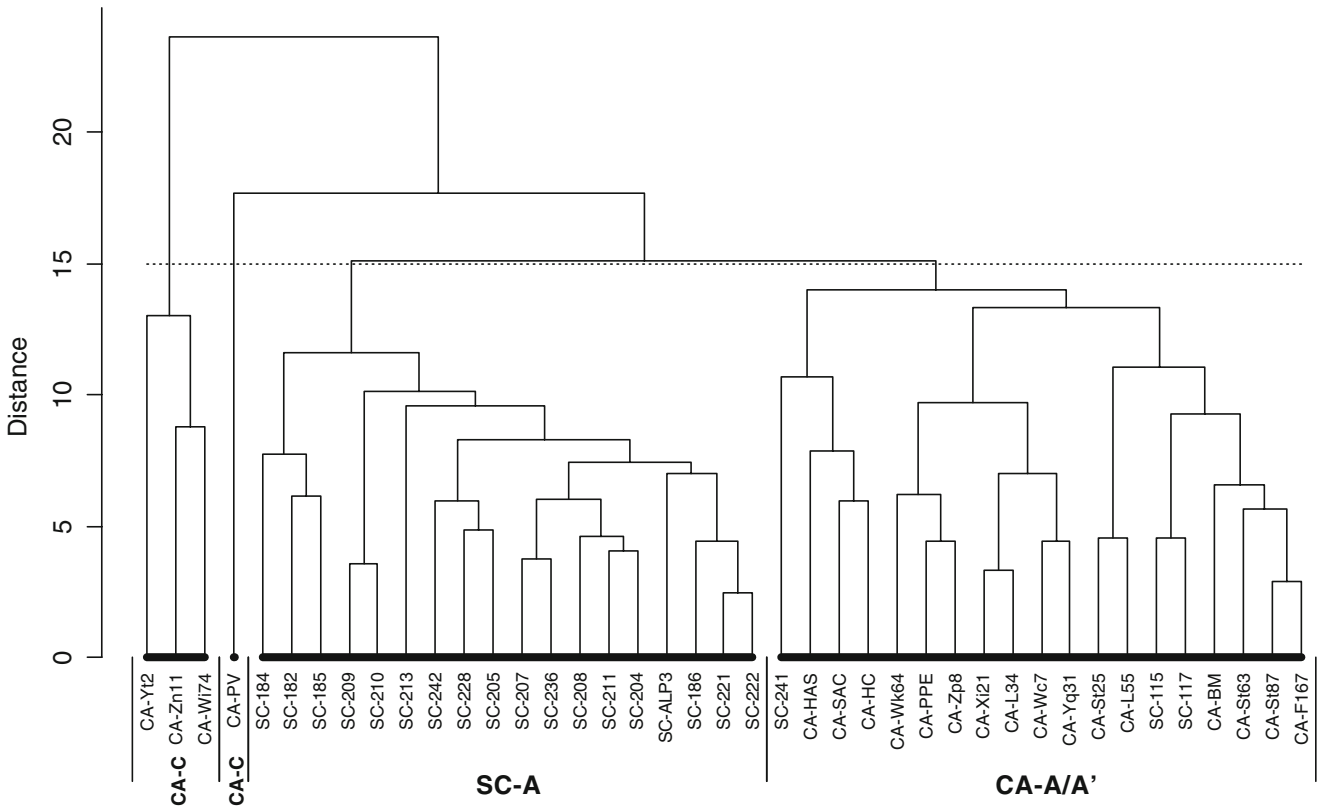

Fig. 1 Dendrograms from cluster analyses based on Euclidean distance of cuticular hydrocarbons extracted from samples of *Reticulitermes* workers from California. These samples lack 5-methylalkanes and 5,X-dimethylalkanes. See Tables 1 and 2 for data pertaining to individuals and phenotypes

[a] Presented in order of elution. Co-eluting compounds are listed together. *ECL* equivalent chain length (approximate). **Bold type** indicates diagnostic peaks.
[b] 9,13-dimeC23 is only present in SC-A and CA-D.
[c] 9,13-dimeC24 is present only in SC-A, CA-A/A', CA-D; only 2-meC24 is present in CA-B.
[d] C25:2 is absent in CA-C and CA-B.
[e] 11,13-dimeC25 is present only in CA-C.
[f] Only 2-meC25 is present in CA-C, SC-B and CA-B.
[g] These trienes are not found in CA-A; their absence is diagnostic for this phenotype.
[h] 9,13-dimeC26 is present only in SC-A and CA-A/A'; C27:2 and C27:1 are present only in CA-C.
[i] C27:2 is present only in CA-A/A', CA-C, and CA-D; 11,13-dimeC27 is present only in CA-C.
[j] 11,15-dimeC27 is present only in CA-A/A' and CA-C.
[k] C29:2 is present only in CA-C.
[l] 5,19-dimeC33 is present with 5,17-dimeC33 only in CA-B.

Phenotype CA-C is distinguished from phenotypes CA-A/A′ and SC-A by the presence of large quantities of C27:1, C27:2, 11-; 13-meC27, and 11,15-dimeC27 (Fig. 2e; Table 2). A phylogenetic analysis based on the COII mtDNA gene also separated this phenotype from all others reported in this paper (Copren et al. 2005). Thus far, this phenotype appears to be rare and has been found only at our site in Placerville, CA.

Cluster analysis of the lineage II *Reticulitermes* resulted in four clusters (Fig. 3), two with all the southern California samples and two with all the northern California samples. Twenty-three samples from southern California comprise phenotype SC-B, while the smaller cluster is composed of four samples we designated as SC-B′ (Table 2). The two remaining clusters included one with five samples from northern California that had been previously designated as CA-B, and one with six samples that had been previously designated as CA-D (Table 2) (Haverty and Nelson 1997).

CHC phenotype SC-B is similar to phenotypes CA-B and CA-D from northern California (Fig. 4a-c; Table 2). The most abundant compound in the majority of phenotype SC-B samples was 5,17-dimeC27, and there was a homologous series of similar compounds, with carbon chain length from 33 to 43. This pattern is comparable to that of CA-B and CA-D. However, several monomethylalkanes present in CA-B and CA-D, such as 11-meC35 and 11-; 13-meC37, were absent in most samples of SC-B (Fig. 4a–c; Table 2). CA-D produced less 5,17-dimeC27 than SC-B or CA-B, and more internally branched monomethylalkanes, such as 11- and 13-meC25 and 11- and 13-meC37 (Fig. 4a-c; Table 2).

Two variants of SC-B were seen in San Diego County. In one variant, which included samples SC-SF1 and SC-SF2, 5,17-dimeC27 was less abundant, and 5,17-dimeC33 was absent (Fig. 4d; Table 2). These two samples grouped together with another, SC-TP, within the main SC-B cluster. Closer examination of the profile of SC-TP indicated that it is more similar to the other SC-B samples in the main cluster than to the two SC-SF samples, as it contained a large amount of 5,17-dimeC27 (19.2%), and 5,17-dimeC33 was present (3.4%).

The other variant (samples SC-MR2, -3, -4, and SC-PTF) had significant quantities of internally branched mono- and dimethylalkanes with chain lengths of 35 to 39 carbons, and smaller amounts of 5,17-dimeC27 (Fig. 4e; Table 2). Because the four samples formed a separate cluster and had other distinguishing features in common, they were designated as SC-B′ and are possibly a separate taxon.

We indicate in bold type the diagnostic CHCs that distinguish the phenotype clusters in Table 2. It is noted

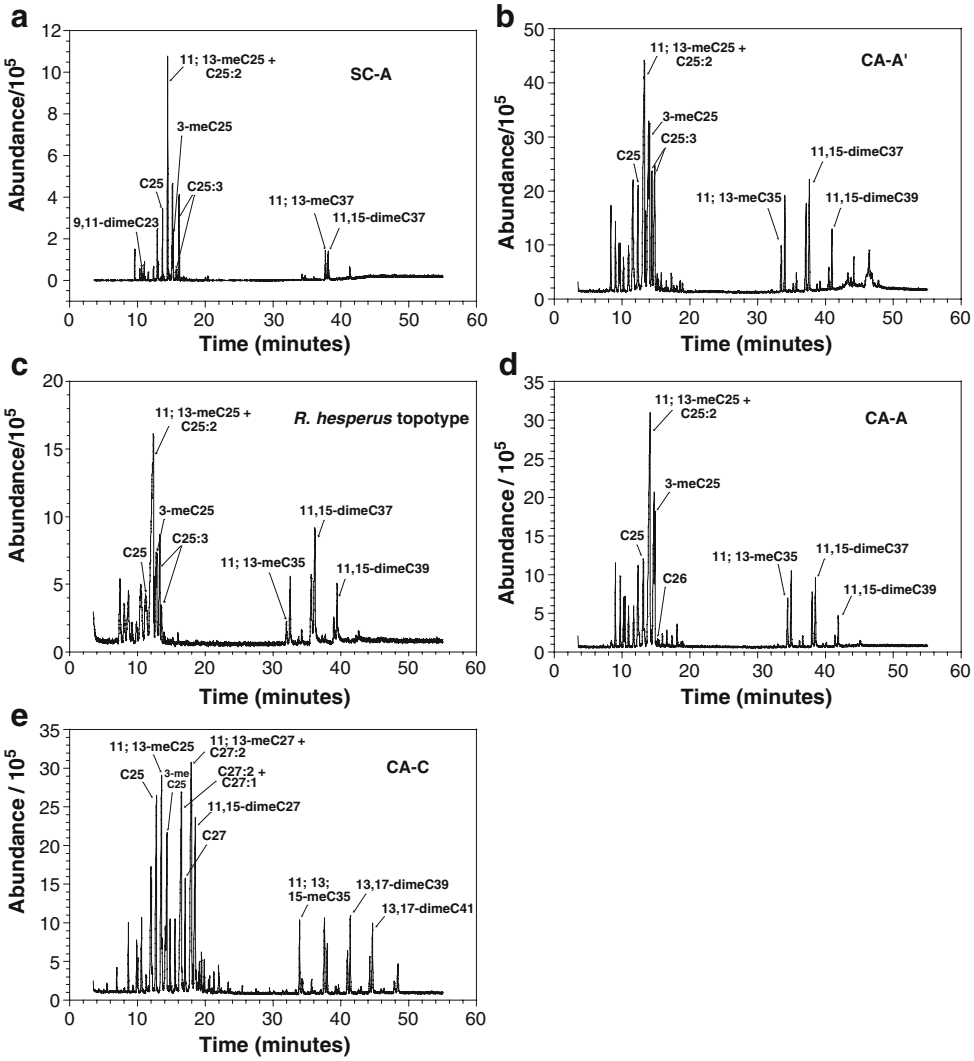

Fig. 2 Total ion chromatograms of cuticular hydrocarbons from *Reticulitermes* workers collected from **a** Goleta, Santa Barbara Co., CA (SC-A); **b** Novato, Marin Co., CA (CA-A′); **c** Lake Arrowhead, San Bernardino Co., CA (*R. hesperus* topotype); **d** Placerville, El Dorado Co., CA (CA-A); **e** Placerville, El Dorado Co., CA (CA-C)

that since phenotypes CA-A and CA-A′ clustered together, their hydrocarbon data were combined in Table 2. However, they can be distinguished easily from each other by the absence of the two isomers of C25:3 in CA-A, which is not apparent in the table, but can be seen in Fig. 2b and d. Haverty et al. (1991) proposed that if CHCs are to be reliable as taxonomic characters, they should be abundant components (at least 1%, but preferably 5% or more of the total hydrocarbon mixture). They should also be unique or present in only a few of the species, or conversely, they should be common in most of the species yet completely absent or in insignificant quantities in one or a few species. These are the criteria that we used to select the diagnostic CHCs listed in bold in Table 2.

Soldier Defense Secretions Soldiers of CHC phenotypes from southern California generally produced substantial amounts of germacrene A in the SDS (Table 3). The defense secretions of soldiers taken from colonies with CHC phenotype SC-A consisted almost entirely of germacrene A (>95%), except for one sample (SC-111) that had 79.0% germacrene A and greater amounts of γ-cadinene (15.0%) than the rest. Soldiers from the Lake Arrowhead collections (SC-115, -116, -117, and -118) produced mainly γ-cadinene (>78%) in their SDS, similar to the samples of CA-A and CA-A′ (Nelson et al. 2001). Other compounds, such as 3-octanol, *Z,E*-germacrene A, and δ-amorphene, were present in the Lake Arrowhead samples in significant amounts (0.5–9.9%, 5.0–11.5%, 1.2–2.9%, respectively), but were either absent or present in trace quantities in CA-A and CA-A′. The latter two compounds were previously identified in the SDS of CA-B soldiers (Table 3; Nelson et al. 2001).

The SDS of phenotype SC-B also contained significant amounts of germacrene A; however, there was variation in the relative quantities, ranging from 16.2% to 97.2%. Most of the samples had >62% germacrene A, along with moderate amounts of γ-cadinene (Table 3). Two collections

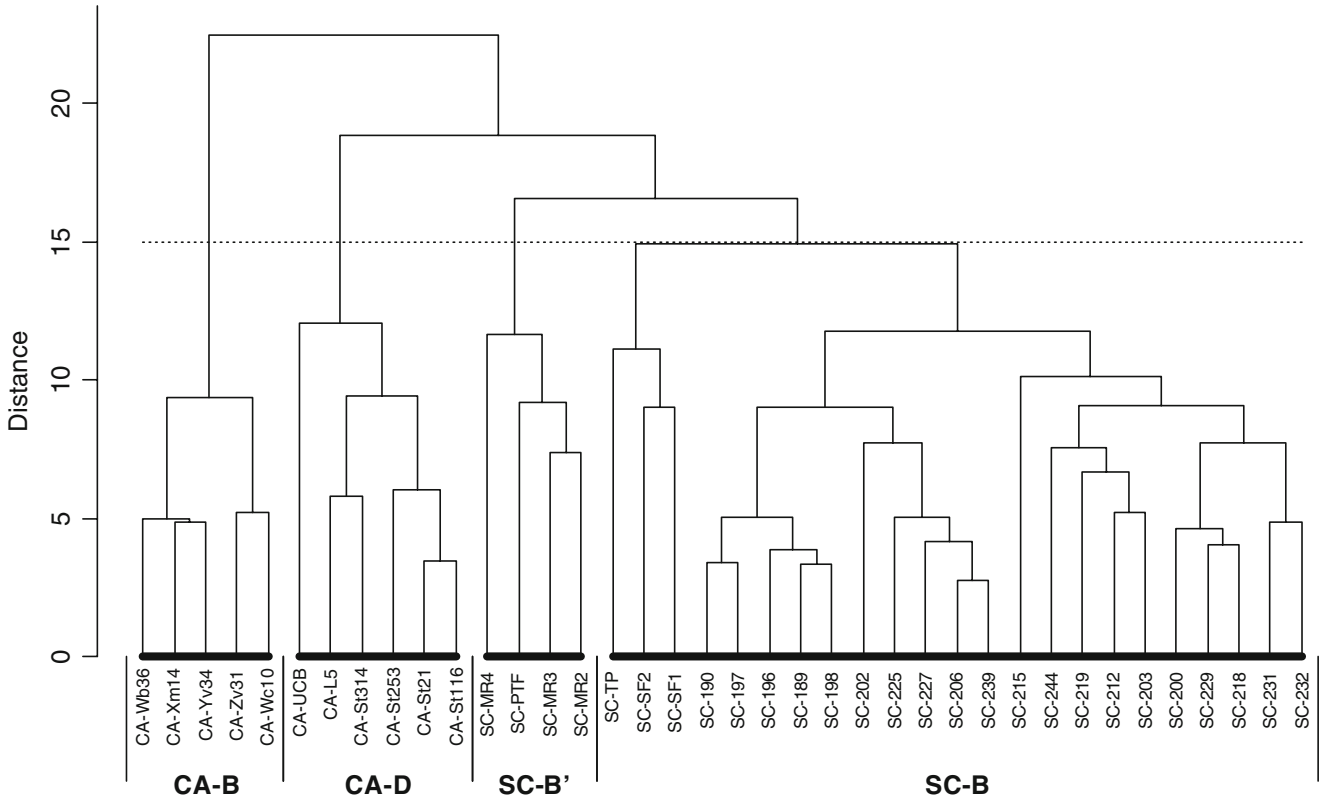

Fig. 3 Dendrograms from cluster analyses based on Euclidean distance of cuticular hydrocarbons extracted from samples of *Reticulitermes* workers from California. These samples contain 5-methylalkanes and 5,X-dimethylalkanes. See Tables 1 and 2 for data pertaining to individuals and phenotypes

from San Diego County (SC-SF1 and SC-SF2) contained much less germacrene A and substantially more geranyl linalool (Table 3). These same samples had notable differences in their hydrocarbon mixture when compared with other SC-B samples (Fig. 4a,d).

Collections from Riverside County, which were designated as hydrocarbon phenotype SC-B′, contained predominantly germacrene A (56.7–98.7%), and γ-cadinene (0.8–16.6%; Table 3). Samples MR2, MR4, and PTF1 contained modest amounts of dauca-8,11-diene and dauca-4(11),8-diene (1.4 to 5.8% and 0.3 to 2.2%, respectively). These compounds have not been reported before from *Reticulitermes* soldiers. A small amount of dauca-8,11-diene (0.6%) was observed also in SC-SF1, and dauca-4(11),8-diene was found in SC-SF1 and SC-TP. Several other components (daucene, β-santalene, zingiberene, β-sesquiphellandrene) were found in these samples as well. Small amounts of unknowns designated as 204f and 204g were seen in SC-SF1, SC-MR2, SC-MR4, SC-PTF1, and 204g was also found in SC-TP from San Diego Co. (Table 3).

Zingiberene was reported in trace amounts in *Reticulitermes* phenotype AZ-C(I) from Arizona (Nelson et al. 2001). Daucene, 3-octanol, β-santalene, (*Z*,*E*)-α-farnesene, and β-sesquiphellandrene also have not been reported previously from *Reticulitermes* soldiers, although 3-octanol was reported in pentane extracts from workers of four European *Reticulitermes* species (Reinhard et al. 2003). Nerolidol was found in one sample of SC-A (0.4%) and two samples of SC-B (<0.03%). This compound was reported previously, by Quintana et al. (2003), in soldiers of *R. lucifugus* and *R. lucifugus corsicus*.

Discussion

Before addressing the particular results of the current study, it is helpful to review the current state of taxonomic research on *Reticulitermes*.

We are troubled by several things in the literature on termite taxonomy: exclusive reliance on morphological determination of species, with use (or misuse) of inadequate keys; use of samples from the GenBank sequence database that may or may not be correctly identified to species; and misrepresentation of the value of chemical characters in delimiting species in termites. We also agree with Uva et al. (2004) who, in a study of *Reticulitermes* from southern Europe, warned against the following assumptions: (1) the classification of termites is definitive, and (2) that identification of termites can be made based on geographic origin alone. Unfortunately, these cautions, and other difficulties

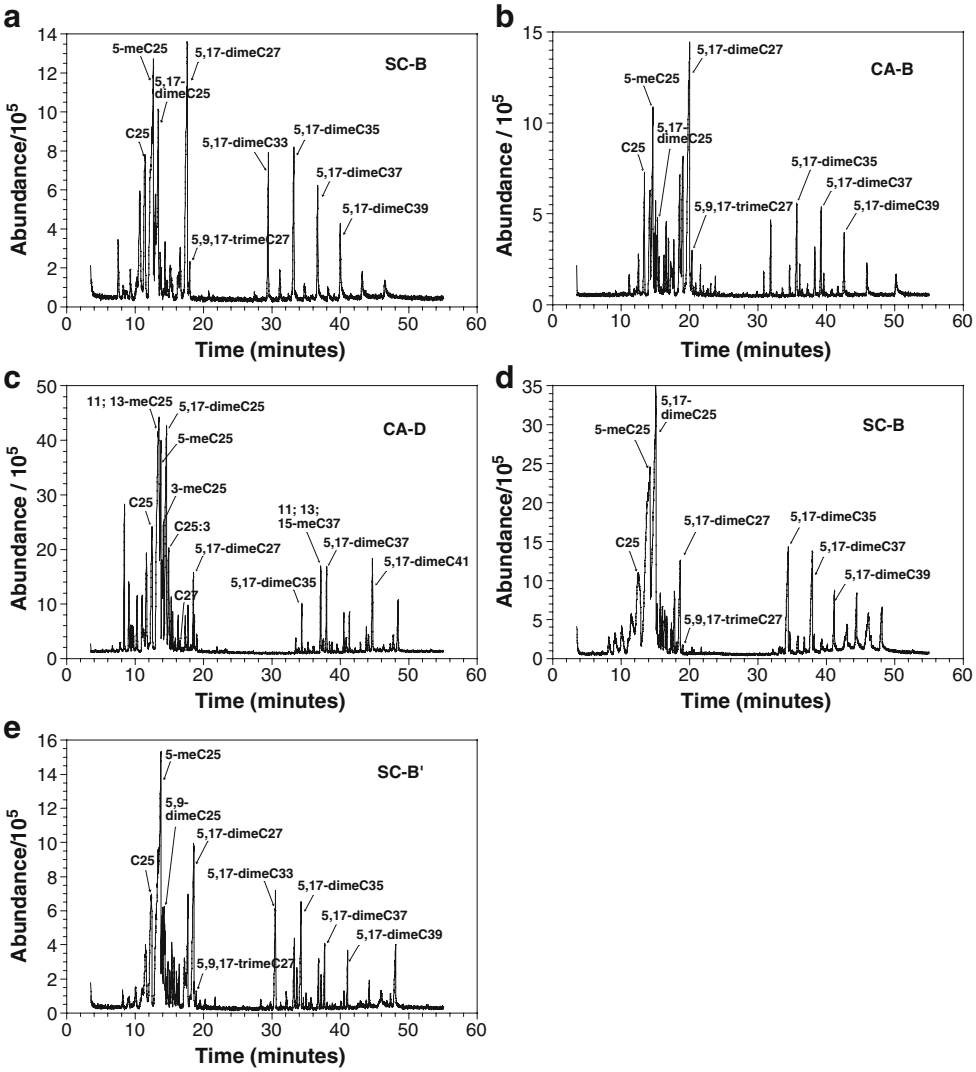

Fig. 4 Total ion chromatograms of cuticular hydrocarbons from *Reticulitermes* workers collected from **a** Carpinteria, Santa Barbara Co., CA (SC-B); **b** Placerville, El Dorado Co., CA (CA-B); **c** Novato, Marin Co., CA (CA-D); **d** Scissors Crossing, San Diego Co., CA (SC-B); **e** Motte Rimrock Reserve, Riverside Co., CA (SC-B′)

inherent in the taxonomic study of *Reticulitermes*, often have been overlooked.

Taxonomy of North American Reticulitermes Much of the biogeographical and taxonomic information on *Reticulitermes* was developed in the first half of the past century (Banks and Snyder 1920; Light 1934; Pickens 1934a, b; Banks 1946; Miller 1949; Snyder 1954). Banks and Snyder (1920) provided the first "descriptions" of species within this genus, and Snyder (1949) established the number of species of *Reticulitermes* in North America at six: *R. arenincola* Goellner, *R. flavipes* (Kollar), *R. hageni* Banks, *R. hesperus* Banks, *R. tibialis* Banks, and *R. virginicus* (Banks). Snyder (1954) reiterated that there are only six species of *Reticulitermes* in North America, and this has been affirmed by Weesner (1965, 1970) and Nutting (1990) and assumed by most termite biologists (Haverty et al. 1999b). However, the growing body of literature on the diversity of *Reticulitermes* suggests that there are more species than the six currently recognized. Our own chemotaxonomic analyses (Haverty et al. 1996a, 1999b; Haverty and Nelson 1997, 2007; Jenkins et al. 2000; Nelson et al. 2001; Copren et al. 2005) and ethological studies (Haverty et al. 1999a, 2003; Delphia et al. 2003) indicated that undescribed species of *Reticulitermes* occur in the United States. Su et al. (2006) reported two undescribed species from California, based on mtDNA sequences, as did Tripodi et al. (2006). Szalanski et al. (2006) named a new species, *R. okanaganensis*, from the western United States and Canada, based on the mtDNA 16S gene. Austin et al. (2007) provided genetic and other evidence to confirm the existence of *R. malletei*, first described by Clément et al. (1986), in Georgia and several other states. Correspondence of genetic data with those from CHC, biometric, and ethological analyses support resurrecting this species name, which had never been formally accepted. Taken together, studies like these underscore the outdated and incomplete nature of North

American *Reticulitermes* taxonomy. As Weesner (1970) put it, "...this genus is woefully in need of a critical taxonomic study..."

Identification of Reticulitermes *Specimens* Assigning insect specimens to the correct species has been done traditionally by using dichotomous keys and/or surmised by the geographic location of the collection. In practice, there are serious problems and pitfalls with both methods.

The morphological keys most commonly used and cited for identification of *Reticulitermes* species are those by Snyder (1954), Weesner (1965), and Nutting (1990). These keys are based on the original keys in Banks and Snyder (1920), with additional characters added and the acceptance of the synonomies presented by Snyder (1949). The keys developed by Scheffrahn and Su (1994) and Hostettler et al. (1995) were intended for identifying termites only from Florida, but have been cited in numerous papers as useful for identifying specimens of *Reticulitermes* from Arkansas, Louisiana, Missouri, and Virginia (Szalanski et al. 2003), Texas (Austin et al. 2004b; Foster et al. 2004), Oklahoma (Austin et al. 2004c), California (Tripodi et al. 2006), Oregon (McKern et al. 2006, 2007), and Delaware (King et al. 2007). In their genetic analysis of *Reticulitermes*, including samples from Europe, Asia, and North America, Austin et al. (2002) stated that they identified species in their study by using keys by Krishna and Weesner (1969), Scheffrahn and Su (1994), and Donovan et al. (2000). There are no keys for identification of species in Krishna and Weesner (1969), nor in Donovan et al. (2000). Furthermore, Scheffrahn and Su (1994) only have keys to three species: *R. flavipes*, *R. virginicus*, and *R. hageni*, and they restrict their focus to Florida specimens. It is unclear how specimens from China, Israel, Japan, South Korea, Arizona, or California can be identified by using these references.

In their phylogenetic analyses of the family Rhinotermitidae, Austin et al. (2004a) claimed to have identified termites collected from North America and the Caribbean by applying keys by Goellner et al. [sic] (1931), Scheffrahn and Su (1994), and Hostettler et al. (1995). Again, the last two references include termite species known to occur only in Florida. It appears that all but three samples [*R. arenicola* (sic), *Coptotermes formosanus* Shiraki, and *Heterotermes cardini*] were gathered from GenBank and not collected by the authors. It is questionable how the *H. cardini* sample was identified by using any of these keys.

In their study of the phylogeography of *Reticulitermes* in California, Tripodi et al. (2006) claim that "*R. flavipes* and *R. tibialis* were morphologically identified when alates were available by using the keys of Krishna and Weesner (1969), Banks and Snyder (1920), and Hostettler et al. (1995)." As mentioned earlier, there is no key in Krishna and Weesner (1969). The key in Banks and Snyder (1920) is timeworn, and if it is agreed that the genus needs revision, reliance on such a key is inherently problematic. The keys to *Reticulitermes* of Florida in Hostettler et al. (1995) do not include *R. tibialis*. We have serious reservations about morphological identifications of *Reticulitermes* species by using geographically inappropriate keys, i.e., that do not include all the species. Equally suspect are identifications that claim to use sources (such as Krishna and Weesner 1969 or Donovan et al. 2000) that do not contain keys to species (Austin et al. 2002, 2004b, c, 2005a; Szalanski et al. 2003; Tripodi et al. 2006, McKern et al. 2007).

A major problem with existing morphological keys to *Reticulitermes* species is the complication of the caste used for identification. If only workers of *Reticulitermes* are collected, identification to species is all but impossible, as there are no morphological keys to workers available. For imagoes (alates) and soldiers, the most common approach is to have separate keys (see Snyder 1954; Weesner 1965; Nutting 1990; Scheffrahn and Su 1994). However, the great majority of *Reticulitermes* collections involve either foraging groups, which rarely contain imagoes, or flights of imagoes (alates) without the associated soldiers. Weesner (1965) lacks a key to the soldiers for *Reticulitermes* from the Pacific Coastal region, and thus makes species identification of *Reticulitermes* foraging groups impossible. The problem is exacerbated when both castes are present in the same sample, and keys to alates indicate a species different from that indicated by the keys to soldiers (Haverty et al. 1999b; King et al. 2007).

While ignoring geography can lead to dubious identifications of specimens, uncritical reliance on the location of a collection in its identification is also hazardous. In their discussion of phylogeography of *Reticulitermes* in California, Tripodi et al. (2006) stated that their "... experience with this group shows that it consistently has been misidentified because of prejudices or assumptions about their respective distributions (Austin et al. 2002, 2005b)." Weesner (1970) gave detailed geographic information on the distribution of *Reticulitermes* species that could lead to erroneous conclusions. For example, if one collected a *Reticulitermes* sample anywhere in Arizona, USA, and referred to Weesner (1970) or Nutting (1990), the conclusion would be that it could only be *R. tibialis*. Now, we know that there are at least four CHC phenotypes of *Reticulitermes* in Arizona, that we believe represent four different species, only one (or none) of which could actually be *R. tibialis* (Haverty and Nelson 2007). Identification of *Reticulitermes* in California has proven difficult (Haverty and Nelson 1997; Tripodi et al. 2006), especially considering the possible occurrence of exotic species, such as *R. flavipes* (Kollar), or undescribed species (Haverty and Nelson 1997; Su et al. 2006; Tripodi et al. 2006). The assumed species distributions in extant keys for California would allow only two choices, *R. hesperus* or *R. tibialis*.

[a] Values of 0.0 indicate the compound was detected, but at a level <0.05% of the total SDS.
[b] Terpenoids are listed in GC elution order. Terpenoids in **bold type** have not previously been reported for termite soldiers. Compound name in parentheses or brackets indicates identification is tentative. Unknowns are designated by an apparent molecular weight and an identifying suffix letter.
[c] The terpene phenotypes for these samples are reported in Nelson et al. 2001.

All these difficulties have led us, as well as other researchers, to investigate chemical or molecular characters as a better means of distinguishing termite taxa based on soldiers or workers (pseudergates; (Haverty and Nelson 1997; Takematsu 1999; Takematsu and Yamaoka 1999; Jenkins et al. 2000, 2001; Nelson et al. 2001; Austin et al. 2002, 2004a, b, c, 2005a, b, 2007; Szalanski et al. 2003, 2006; Foster et al. 2004; Uva et al. 2004; Ye et al. 2004; Copren et al. 2005; Su et al. 2006; Tripodi et al. 2006; King et al. 2007).

Chemical Taxonomy of Reticulitermes Howard and Blomquist pioneered the use of CHCs as taxonomic characters for delimiting species or taxa of *Reticulitermes* (Howard et al.

1978, 1982; Howard and Blomquist 1982). With a few exceptions, most termites have species-specific mixtures of CHCs (Kaib et al. 1991; Howard 1993; Page et al. 2002). CHCs are homologous characters; they represent hierarchical distributions of shared characters and are independent characters with discrete states (Page et al. 2002). Termites synthesize most, if not all, of their complement of CHCs de novo (Blomquist and Dillwith 1985). As such, hydrocarbon composition is an expression of a taxon's genotype, and therefore, we can assume there is a genetic basis for different hydrocarbon composition among species (Page et al. 2002).

Use of CHCs to sort specimens has led to identification of new species and has resulted in morphological descriptions supplemented by chemical data (Takematsu 1999; Takematsu

and Yamaoka 1999). These studies examined the CHCs of six species of *Reticulitermes* from Japan, Korea, and Taiwan, observed nine different hydrocarbon phenotypes, and recommended that four subspecies be elevated to species status. They concluded that the nine species had unique compounds that can be used to separate species and that hydrocarbons are of value for classification of *Reticulitermes* species. These studies demonstrated that *R. speratus* is a complex of three species, and the investigators found new morphological characters for separating species. Similarly, important phenotypic differences in CHC profiles (Bagnères et al. 1988, 1991) and SDS composition (Parton et al. 1981; Bagnères et al. 1990; Quintana et al. 2003) were found between the different species of *Reticulitermes* in Europe.

Two recent studies (Szalanski et al. 2006; Tripodi et al. 2006)[1] have, in our opinion, misrepresented the value of CHCs for taxonomy, even though two of the authors used CHCs (data from *P. Uva*) in an earlier study to validate the species status of *R. lucifugus* from Turkey (Austin et al. 2002) and to confirm the identity of samples of *R. malletei* in the eastern United States (Austin et al. 2007). Szalanski et al. (2006) stated "Recently, Copren et al. (2005) found evidence for as many as seven new species of *Reticulitermes* from the western United States based upon cuticular hydrocarbon phenotypes, but resolved to designate them as putative new species after attempting to corroborate their relationship with molecular phylogenetics and reproductive flight dates. These discrepancies likely are attributable to the environmental plasticity of cuticular hydrocarbons and stresses (sic) the need for fixed character states for species identification such as mtDNA sequences." Tripodi et al. (2006) echoed this line of thought. Actually, there were no discrepancies; this is a misinterpretation of Copren et al. (2005) as she and her colleagues corroborated the species groups based on CHCs and COII mtDNA sequences. Thus, taxa determined by CHC analyses agreed with taxa determined by mtDNA sequences. The "environmental plasticity" caveat has been carefully considered, and the references provided by Szalanski et al. (2006) and Tripodi et al. (2006) are not relevant to this analysis. Our phenotype designations are based on numerous, repeatable qualitatively different profiles. There can be minor quantitative variation among collections of the same phenotype, in which case, we do not distinguish them as separate phenotypes (Haverty et al. 1991, 1996b).

Tripodi et al. (2006) state "The application of cuticular hydrocarbons for chemotaxonomy requires fixed patterns of hydrocarbons within taxa (Kaib et al. 1991). This approach is inherently problematic because of the plastic nature of hydrocarbon composition. Although hydrocarbon compositions are assumed to be species-specific (Kaib et al. 1991), variation between groups may be more greatly attributable to environmental differences and available food sources (Liang and Silverman 2000)." The study by Liang and Silverman (2000) involved colonies, not of termites but of the Argentine ant, *Linepithema humile* (Mayr), which were feeding on and mixing with various species of cockroaches. It is clear that predatory insects feeding on waxy organisms, such as laboratory-reared cockroaches, will acquire foreign hydrocarbons that could easily affect kin recognition. This study, however, has no relevance with regard to the alleged "plastic nature" of termite CHC mixtures.

In their discussion on the effects of diet on aggression in *Coptotermes formosanus* Shiraki, Tripodi et al. (2006) claim that "differences in diet can influence hydrocarbon composition and intercolonial aggression (Florane et al. 2004). Therefore, although cuticular hydrocarbons probably play a key role in nestmate recognition among colonies of termites, considerable variation of hydrocarbons across small spatial distances within an apparently single morphological species may occur and should alert taxonomists to interpret cuticular hydrocarbon patterns with care." Florane et al. (2004) do not show effects of diet on CHC composition, but rather on volatile compounds (collected by headspace solid-phase microextraction of workers) that possibly affected kin recognition and intercolonial aggression.

In summary, we find no valid objections to the use of CHC profiles in *Reticulitermes* taxonomy. The extensive body of knowledge demonstrating the taxonomic value of termite CHCs allows us to accept distinct, repeatable CHC profiles as descriptive of distinct taxa.

Reticulitermes soldiers, like soldiers from other termite genera, synthesize their defense secretions *de novo* (Prestwich 1979, 1983). It follows that these SDS mixtures, like CHCs, could be useful as taxonomic characters. Several studies have characterized and compared SDSs from *Reticulitermes* species. Parton et al. (1981) compared SDS mixtures from populations of *R. lucifugus* and *R. santonensis* in Europe, finding geographic variation in the *lucifugus* complex, while *R. santonensis* was homogeneous. In the southeastern United States, Clément et al. (1985) identified two SDS phenotypes in *R. flavipes*, one in *R. virginicus* and another in *R. malletei*. Bagnères et al. (1990) examined chemical characters from *R. flavipes* in the southeastern United States and *R. santonensis* in Europe, and reported six SDS phenotypes in *R. flavipes*, while *R. santonensis* was, again, homogeneous. In a study of the same characters from *Reticulitermes* samples from Georgia, Arizona, and northern California, Nelson et al. (2001) reported that some SDS phenotypes pair with more than one CHC phenotype; however, with two exceptions, each hydrocarbon phenotype is associated with only one SDS phenotype. Samples that keyed to *R. flavipes* were represented by three SDS phenotypes, similar to ones previously reported by Clément et al. (1985) and Bagnères et al. (1990). Quintana et al. (2003) described species-

[1] There are several incorrect references in these papers. Szalanski et al. (2006) acknowledged the "identification of new species from northern California ...reported by Haverty and Nelson (1997), Haverty et al. (1999) [our Haverty et al. 1999b] applying CHCs, and further investigated with ethological data (Getty et al. 2000a, b)." However, there was no new information on species of *Reticulitermes* from northern California reported in the cited Haverty et al. (1999) reference. This paper (Haverty et al. 1999b) reported a number of new CHC phenotypes from Georgia, New Mexico, Arizona, and Nevada. Furthermore, the ethological information that supports species designations is not found in the Getty et al. (2000a, b) papers, but in Haverty et al. (1999a) and Delphia et al. (2003) in which we examined agonistic behavior; and in Haverty et al. (2003) we studied flight phenology as a reproductive isolating mechanism. This same referencing error was repeated by Tripodi et al. (2006).

specific SDS phenotypes for seven European *Reticulitermes* species.

Our findings for *Reticulitermes* from southern California show that the two primary CHC phenotypes (SC-A and SC-B) have qualitatively similar SDS mixtures, although they are quantitatively dissimilar (Table 3). Possible explanations for this lack of correspondence include (a) different rates of evolution among the character sets and/or (b) this particular SDS phenotype is adaptive to the conditions of southern California. However, the samples collected at Lake Arrowhead, which is the type locality for *R. hesperus*, had the same SDS profile as CA-A/A′ from northern California.

Taken together, CHC and SDS profiles appear to be complementary character sets that have similar, although not always identical, sensitivity in discriminating putative *Reticulitermes* taxa.

Genetics of Reticulitermes Within the past decade, numerous genetic analyses have been published that indicate additional species or taxa, potential synonymies, and the degree of genetic variation within a species. Copren et al. (2005) used the COII gene in a phylogenetic analysis that indicated at least six clades or species of *Reticulitermes* in California, including the two CHC phenotypes presented here from southern California. Szalanski et al. (2006) and Tripodi et al. (2006) provided genetic evidence of an undescribed species in western North America and a phylogenetic analysis of *Reticulitermes* by applying the 16S mtDNA gene, and validated the prior genetic analysis by Copren et al. (2005). Furthermore, Tripodi et al. (2006) and Su et al. (2006) identified an apparent exotic species, *R. flavipes*, in California via genetic analyses. McKern et al. (2006, 2007) identified *R. flavipes* and *R. hageni* in Oregon by using the 16S mtDNA, which is the first report of these species in that state.

Recent genetic evaluations of North American, European, and Chilean *Reticulitermes* have resulted in intriguing conclusions: (1) North American *R. flavipes* and *R. arenincola*, and European *R. santonensis* are likely conspecific (Ye et al. 2004), and (2) the invasive *Reticulitermes* in Chile and Uruguay is *R. flavipes* (Austin et al. 2005b; Su et al. 2006). One Indiana population of *R. arenincola* shares identical DNA sequences with one *R. santonensis* population from France and one *R. flavipes* population from Indiana (Ye et al. 2004). Even though *R. flavipes* = *R. arenincola* by DNA sequence, there appeared to be morphological differences between the respective soldier castes, and the authors decided that the synonymy of these two species would be premature (Ye et al. 2004). Su et al. (2006) demonstrated that all 13 samples of Chilean *Reticulitermes* termites collected from four cities were *R. flavipes* and had identical gene sequences for all loci examined, thus suggesting a single geographic introduction. A similar conclusion was reached by Austin et al. (2005b).

As an adjunct to population studies of *Reticulitermes* in northern California, Copren (2007) found that three microsatellite loci, specifically developed for *R. hesperus*, did not amplify with the three other species of *Reticulitermes* from northern California. Finding fixed genetic differences among cryptic species that result in reciprocal monophyly, particularly among sympatric species, provides information useful for taxonomic studies (Copren 2007).

We think that GenBank is an important tool for phylogenetic analyses, but its use is not without problems. The use of GenBank data submitted by others requires one to accept the submitter's species designations as accurate or authoritative. With refractory genera, such as *Reticulitermes* or *Heterotermes*, GenBank sequences should be used with caution.

Use of Multiple Characters in Reticulitermes *Taxonomy* In a difficult genus like *Reticulitermes*, taxonomic conclusions are greatly strengthened when two or more features, CHC mixtures, SDS mixtures, genetic markers, morphology, behavioral characteristics (such as agonism or flight times), etc., correlate. The more differences that exist among groups of organisms, the greater the likelihood of their being separate species (Futuyma 1998). Jenkins et al. (2000) and Copren et al. (2005) demonstrated the association of CHC phenotypes and mtDNA haplotypes, illustrating that CHCs are useful in separating known species, determining new species, and understanding termite evolution, and adding robustness to the phylogenetic analyses (Jenkins et al. 2000; Page et al. 2002). Additional examples of multiple, independent data sets for determining species of *Reticulitermes* include the CHC and morphological work of Takematsu and Yamaoka (1999), the CHC and SDS study of Nelson et al. (2001), and the use of microsatellites to assess sympatric populations of *R. hesperus* and cryptic species of *Reticulitermes* in northern California (Copren 2007).

In contrast to this approach, Ye et al. (2004) relied heavily on morphological information and did not address contradictory genetic information. Genetic data gathered from three mitochondrial DNA genes (COII, 16S, and 12S) indicated that *R. flavipes*, *R. santonensis*, and *R. arenincola* are conspecific. Others reached the same conclusion about *R. flavipes* and *R. santonensis* (Austin et al. 2005b; Su et al. 2006). However, Ye et al. (2004) felt it was premature to synonymize *R. arenincola* and *R. flavipes* due to the morphological separation of *R. arenincola* and *R. flavipes* by soldier characteristics.

Reticulitermes *in Southern California: the Current Study* In early studies of Californian termites, *Reticulitermes* was

determined by various authors as consisting of just two species, *R. hesperus* and *R. tibialis* (Light and Pickens 1934; Pickens 1934a, b; Snyder 1949, 1954). There is a persistent assumption that these are the only *Reticulitermes* species in California and that they have distributions that are allopatric over most of their ranges (Weesner 1970).

We were among the first to question the number of species of *Reticulitermes* in California, and we reported five CHC phenotypes of *Reticulitermes* (CA-A, CA-A′, CA-B, CA-C, and CA-D) in northern California (Haverty and Nelson 1997). In the current study, we report a wider distribution of previously described phenotypes SC-A and SC-B and a variant of one of them (SC-B′) that occurs in Riverside County. Correlation of CHC phenotypes with mtDNA (COII) genotypes supported elevating phenotypes CA-B, CA-C, CA-D, and SC-B to the status of new species, but suggested that CA-A, CA-A′, and SC-A represent one species, which we postulated to be *R. hesperus*, with the CA and SC phenotypes comprising geographic subspecies (Copren et al. 2005).

Banks and Snyder (1920) originally described *R. hesperus* based on samples from California, Nevada, Oregon, and Washington and designated the type locality as Little Bear Lake, San Bernardino Mountains, California (Snyder 1949). Many of these sites are distant from the Pacific Coast and east of the Cascade Range and Sierra Nevada. In a case like this, with an old species designation based on morphology of a limited number of specimens (Banks and Snyder 1920), it is difficult to associate chemical or genetic determinations of taxa with the species in question. We collected at the type locality of *R. hesperus* so that we could associate one of our CHC phenotypes with a species name. The type specimen of *R. hesperus* (winged, Cat. No. 21864, U.S.N.M.) was reported from Little Bear Lake, CA, now known as Lake Arrowhead (Robinson 1989), in the San Bernardino Mountains (see Banks and Snyder 1920; Snyder 1949). Haverty et al. (2003) and Copren et al. (2005) reported that topotype samples from Lake Arrowhead all had one CHC phenotype, CA-A′. Copren et al. (2005) used the geographic nomenclature SC-A to describe this phenotype, but the lack of 9,11-dimethylalkanes, the presence of C25:3, and γ-cadinene in the SDSs puts it in the same group as CA-A′ from northern California. Thus, this phenotype was postulated to represent *R. hesperus*.

Studies by Szalanski et al. (2006) and Tripodi et al. (2006) that used 16S mtDNA, have identified a genetically distinct species in the western United States, which they have named *R.* n. sp. "*R. okanaganensis*." We contend that is incorrect, and the collections designated as *R.* n. sp. "*R. okanaganensis*" are actually the common, and widely distributed, *R. hesperus*. Austin et al. (2002) were likely correct, and the revision by Szalanski et al. (2006) and Tripodi et al. (2006) simply confused the status of *Reticulitermes* in California. Szalanski et al. (2006) and Tripodi et al. (2006) apparently disregarded the value of collections at the type locality. Instead, they designated a sample from Lake Arrowhead as their putative new species, *R. okanaganensis*, but did not find what they now consider to be *R. hesperus* at the type locality. Actually, the distribution presented for *R. okanaganensis* (Szalanski et al. 2006) closely resembles the original distribution map of *R. hesperus* reported by Banks and Snyder (1920) and reinforced by Weesner (1970) and Nutting (1990).

One particular mitochondrial DNA sequence is key to our study, especially as it relates to Tripodi et al. (2006): a fragment of the mtDNA cytochrome oxidase (COII) from *R. hesperus* [GenBank AF525329] (Austin et al. 2002, 2004a; Copren et al. 2005). The sequence for *R. hesperus* from Los Angeles, California [GenBank AF525329] was useful for the demonstration of the correlation of species determinations based on CHCs and COII sequences, as this sequence was similar to that of the collections from the type locality for *R. hesperus* (Copren et al. 2005). Now, based on the mtDNA 16S sequence, Tripodi et al. (2006) state that the sample identified by Austin et al. (2002) as *R. hesperus* [GenBank AF525329] was a mistake, and it truly represents a new species, "*R. okanaganensis*." We think that Tripodi et al. (2006) are wrong and that Austin et al. (2002) attached the correct species name to sequence AF525329, possibly relying on location to assign the species name since the references they cited did not have keys or had keys that were inappropriate for specimens from California. The confusion would be compounded if, based on Tripodi et al. (2006), someone "corrected" the species name associated with AF525329.

If our analysis is correct, *R. hesperus* is the most common subterranean termite throughout California. It is found sympatrically in northern California with three unnamed species: *R.* sp. CA-B, *R.* sp. CA-C, and *R.* sp. CA-D. *R.* sp. CA-B and *R.* sp. CA-C are rare compared to *R. hesperus* and *R.* sp. CA-D (Copren 2007). In southern California, *R. hesperus* (SC-A) occurs sympatrically with *R.* sp. SC-B over most of their distributions. Furthermore, in Arizona and Nevada, we collected samples (phenotype AZ-D) that resemble specimens (designated CA-A′) from the type locality of *R. hesperus*. Therefore, it is likely that *R. hesperus* also occurs in northwestern Arizona and mountainous areas of southern Nevada, but is somewhat rare (Haverty and Nelson 2007). The CA-A/A′, SC-A, and AZ-D phenotypes may each represent a geographic subspecies of *R. hesperus*, as the CHCs are similar, but the SDSs are dissimilar, with AZ-D having SDSs consisting of mostly geranyl linalool (Haverty and Nelson 2007).

Today, the distribution, or even presence, of *R. tibialis* in California is not as clear as it apparently was to early researchers (Banks and Snyder 1920; Light and Pickens 1934; Pickens 1934b; Snyder 1954). Tripodi et al. (2006) only reported samples of *R. tibialis* in the southern portion of California in areas that border the Mojave Desert. Likewise, Copren et al. (2005) found specimens in Inyo County, California, on the xeric east side of the Sierra Nevada in the northern portion of the Mohave Desert that closely resembled (by COII mtDNA) the sample of "*R. tibialis*" from Cochise County, Arizona, USA, (GenBank AF525355) reported by Austin et al. (2002).

The type specimen for *R. tibialis* (winged, Cat. No. 21861 U.S.N.M.) was collected in Beeville, Texas (Banks and Snyder 1920; Snyder 1949). This species is purported to be the most widely distributed species, covering diverse habitats in North America (Banks and Snyder 1920; Snyder 1934; Weesner 1970). However, Weesner (1970) recognized that many of the alate specimens collected from the range of the species (Colorado, Illinois, Kansas, Missouri, Oklahoma, and Texas) were "typical" for *R. tibialis*, yet additional collections from the same area, particularly Texas, were extremely variable and could not be designated as *R. tibialis*. This suggests that there is more than one species in this distribution.

One of the GenBank COII sequences assigned to *R. tibialis* [AF525355] has been used in many studies (Austin et al. 2002, 2004a; Szalanski et al. 2003; Copren et al. 2005) and was collected from Cochise County, Arizona. This specimen was collected from an area that is likely to be the same as the species designated as our CHC phenotype AZ-B because only this phenotype has been found at the lower elevations in this region of Arizona. AZ-B is the most common CHC phenotype/species found in Arizona from Fairbank in Cochise County (≈1,200 m) to the North Rim of the Grand Canyon in Coconino County (≈2,500 m; Haverty and Nelson 2007). Using this sequence, *R. tibialis* [AF525355] is similar to, yet significantly different from, other *Reticulitermes* taxa in California (Copren et al. 2005).

Other COII sequences assigned to *R. tibialis* [GenBank AY168206 & AY168207, see Ye et al. 2004; GenBank AY808094, see Su et al. 2006] have not been used together with AF525355 in a comparative study and have likely been assigned to *R. tibialis* based on the location of the collection, as neither present a source for identification of any species (Ye et al. 2004) or the *R. tibialis* samples (Su et al. 2006). Furthermore, none of the samples identified as *R. tibialis* have been collected within 1500 km of the type locality of this species or in habitats resembling the type locality. As we see it, the actual genotype(s) or CHC phenotype of *R. tibialis* remains unknown.

Other Reticulitermes *Taxa in California* Su et al. (2006) and Tripodi et al. (2006) reported finding *R. flavipes* in California on the basis of mtDNA. We, too, have found *R. flavipes* in California based on CHC and SDS composition (Haverty and Nelson, unpublished), as have Ripa et al. (2002). Tripodi et al. (2006) were not able to confirm this based on morphology, whereas Su et al. (2006) identified their California population from Sacramento as *R. flavipes* by using the key in Snyder (1954). One unexpected finding was that the *R. flavipes* sample collected from Sacramento, California, closely resembled the introduced Chilean *R. flavipes* in combined mitochondrial DNA (COII, 16S, and 12S) sequences (Su et al. 2006). Su et al. (2006) hypothesized that the Chilean *R. flavipes* may have been introduced from California, or vice versa, or that both Chilean and Californian *R. flavipes* populations may have the same origin in North America. The well-established *R. flavipes* infestation in Sacramento suggests the ability of this east coast species to survive in a Mediterranean climate and that it could be more widespread in California than is known (Su et al. 2006). Tripodi et al. (2006) opined that the establishment of *R. flavipes* in Sacramento and El Cajon probably represents either extreme western distributions of the species or accidental introductions from anthropogenic sources. We believe the latter explanation is more likely.

Additional exotic or undescribed species of *Reticulitermes* are likely present in southern California given the numerous coastal, montane, and desert habitats. Based on mtDNA sequences, Su et al. (2006) found two populations of *Reticulitermes* from California (US27 and US42) that were similar to a sample labeled *R. tibialis* (US5), but one (US27) differed from it by 61 bp, the other (US42) by 52 bp, and they differed from each other by 34 bp. These samples may thus represent two undescribed species. Furthermore, Tripodi et al. (2006) also reported two undescribed species from southern California; one from Arrowbear, San Bernardino County, and another from Mission Gorge, San Diego County.

To summarize, the total count of probable species of *Reticulitermes* in California is at least seven: (1) *R. hesperus* (our hydrocarbon phenotypes CA-A, CA-A′, and SC-A); (2) *R.* sp. CA-B; (3) *R.* sp. CA-C; (4) *R.* sp. CA-D; (5) *R.* sp. SC-B [and SC-B′]; (6) "*R. tibialis*" = *R.* unknown sp. (Copren et al. 2005); (7) *R. flavipes* (Su et al. 2006, Tripodi et al. 2006); as well as *R.* unknown I (Su et al. 2006) and *R.* unknown II (Su et al. 2006). It is possible that the two unknown species identified by Tripodi et al. (2006) are the same as those found by Su et al. (2006). Genetic comparison of these samples will resolve this question. It is also possible that one of the unknown species of Su et al. (2006) and Tripodi et al. (2006) equates with our SC-B/B′.

Reproductive isolation is the most convincing if populations are sympatric (Freeman and Herron 1998). Exam-

ples of valid species of *Reticulitermes* with sympatric distributions have been reported numerous times for *R. flavipes*, *R. virginicus*, and *R. hageni* (Weesner 1970 and others), as well as *R. banyulensis* and *R. grassei* (Uva et al. 2004). Haverty et al. (2003) provided evidence of reproductive isolation in sympatric populations of different CHC phenotypes of *Reticulitermes* in northern California. Alates of phenotype CA-A/A′ (identified here as *R. hesperus*) take flight in the spring, whereas alates of phenotype CA-D fly only in the fall. These disparate flight times make reproductive isolation, and thus species status, complete. In our sampling of *Reticulitermes* in southern California, alates with the hydrocarbon phenotype SC-A were collected in March 2001 and 2002, while SC-B alates were collected in September and November 2001. This sampling is not extensive and warrants further corroboration, but the trend matches earlier reports for *Reticulitermes* species in northern California.

We (MIH and LJN) and our colleagues have been cautious, perhaps too cautious, in delineating and naming new termite species. We have taken this approach in order to avoid further confusing the taxonomy of *Reticulitermes* in North America before appropriate suites of taxonomic characters are agreed upon, and the status of previously published species is resolved. We do not propose naming species based on CHC phenotypes alone, but once taxa are sorted by this method, we can corroborate or refute the groupings with other evidence, such as morphological, chemical, behavioral, and genetic data. When there is agreement of two or more character sets, we can be more confident assigning species status to the phenotypes. The evidence for two predominant species, *R. hesperus* and *R.* sp. SC-B, in southern California is strong, and we believe our inference regarding *R. hesperus* and its type locality is correct. Finally, we urge researchers in this field to be cautious in applying species names based on inappropriate, unspecified, or incorrectly cited reference sources, and to take care in accurately describing both their own methodology and research performed by others.

Acknowledgments We thank Brian Forschler, Barbara Thorne, J. Kenneth Grace, Vernard Lewis, and Srini Kambhampati for their helpful comments on an earlier draft of this manuscript. Gail Getty, Kirsten Copren, and Casey Delphia assisted in collecting and preparing many samples used in this study. The number of samples collected was increased by the cooperation of Dow AgroSciences personnel in their extensive evaluation of the Sentricon® Termite Colony Elimination System in southern California. Jim Baldwin assisted with the cluster analyses.

Sympatric species with similar pheromone blends and conspecific male preference functions are hypothesized to be the major evolutionary forces acting on female signal traits (i.e., the amount and ratio of components emitted; Cardé and Haynes 2004). The former could impose directional selection on the pheromone signal and result in either reproductive character displacement via communication interference or reinforcement if hybridization is possible, but at a fitness cost (sensu Butlin 1987; Cardé and Haynes 2004). The evolutionary forces associated with male preference functions depend on preference function shape, which can be open ended, flat, or unimodal (Bentsen et al. 2006). Open-ended and flat preference functions result in directional and no selection, respectively. The type of selection that results from a unimodal preference function depends on the relationship between the preference function maximum and mean signal value (Bentsen et al. 2006). If the maximum and mean are coincident, selection will be stabilizing. If there is an asymmetry, selection will be directional or directional and stabilizing depending on whether or not the maximum occurs within the range of signal phenotypes produced. Open-ended, flat, and unimodal male preference functions for pheromone signal traits all have been documented (Allison and Cardé 2008).

In the short term, the potential for a trait to respond to selection will be determined by the amount of heritable variation. Empirical studies of the genetics of moth pheromones suggest the existence of both polygenic (Collins and Cardé 1985; Hunt et al. 1990; Gemeno et al. 2001; Svensson et al. 2002; Allison and Cardé 2006; Schek et al. 2006) and major gene effects (Klun and Maini 1979; Roelofs et al. 1987; Haynes and Hunt 1990) on female pheromone signaling traits in several species. Selection experiments have observed predictable changes in both the relative and absolute amounts of components (Sreng et al. 1989; Collins and Cardé 1989; Collins et al. 1990; Allison and Cardé 2007). A genetic basis for male response traits has been demonstrated in several lepidopteran species, including the European corn borer, *Ostrinia nubilalis* (Hübner) (Hansson et al. 1987; Roelofs et al. 1987); the brownheaded leafroller, *Ctenopseustis obliquana* (Walker) (Hansson et al. 1989); the pink bollworm, *Pectinophora gossypiella* (Saunders) (Collins and Cardé 1990); and the cabbage looper, *Trichoplusia ni* (Hübner) (Liu and Haynes 1994; Evenden et al. 2002). These studies suggest that both female signaling and male response traits have the potential to respond to selection.

Traits are often associated with each other and as a consequence, are seldom inherited independently (Lande 1979; Lande and Arnold 1983). Positive and negative genetic correlations can result in unexpected phenotypic changes. Negative correlations indicate trade-offs among traits and are a fundamental assumption underlying some evolutionary theory [e.g., life history theory (Roff 1992; Stearns 1992; Reznick et al. 2000)]. Few studies have examined the genetic architecture of moth pheromone signals. Significant genetic correlations were documented among the pheromone components of the cabbage looper, *T. ni* (both positive and negative, Gemeno et al. 2001) and the almond moth, *Cadra cautella* (Walker) (positive, Allison and Cardé 2006). These correlations suggest that the potential evolutionary trajectories of the female pheromone blend are genetically constrained. Variation among males in breadth of response and sensitivity to female pheromone blends has been hypothesized to be one potential source of variation in male mating success (Cardé and Charlton 1984). Negative correlations between the male response traits sensitivity and breadth of response have been the subject of speculation for over 20 years (see Cardé 1986). For example, it has been suggested that a negative correlation between sensitivity and the breadth of response profile may be a common feature of the insect peripheral nervous system and may explain the rarity of generalist natural enemies able to use moth sex pheromones as foraging cues (Cardé and Haynes 2004). This hypothesis is an extension of the extraordinary sensitivity and high specificity observed for moth pheromone signals.

The objective of this study was to examine empirically the relationship between two male pheromone response traits: sensitivity and breadth of response. The cabbage looper, *T. ni* is a model system for examination of this relationship because: (1) studies of variation in the female pheromone blend led to the discovery of a single gene mutation with major effects on the female pheromone blend but no effects on male preference (Haynes and Hunt 1990); and (2) after 49 generations of rearing pure mutant cultures, mutant male response levels to the mutant and wild-type pheromone blends were equivalent (Liu and Haynes 1994). The existence of mutant males with an increased breadth of response provides an opportunity to test for a trade-off between sensitivity and breadth of response.

Methods and Materials

Insect Rearing The wild-type colony of *T. ni* was initiated with insects obtained from a colony maintained at the USDA-ARS Insect Attractants, Behavior, and Basic Biology Research Laboratory in Gainesville, FL, USA and were maintained without further introductions for about 3 years until the time of these experiments. The mutant colony of *T. ni* was established from a rare pheromone phenotype discovered in a laboratory colony that originated from a field population in Riverside, CA, USA (Haynes and Hunt 1990). The pure mutant colony had been maintained in the laboratory for approximately 10 years at the time of

experimentation. Both colonies were reared on a pinto bean-based diet (Shorey and Hale 1965) at ambient room temperature, humidity, and light conditions. Pupae were sexed and males were transferred to 3.8 l paper cartons. The cartons were placed in an environmental chamber with a photoperiod of L/D 14:10 h and temperature regime of 27:25°C (photophase/scotophase). Eclosed males were collected daily and maintained on a 10% sugar solution until they were bioassayed.

Wind Tunnel Bioassays The wind tunnel used for male flight bioassays was designed based on the wind tunnel described by Miller and Roelofs (1978). Air was pushed through the tunnel with a variable speed fan controlled with a rheostat to 50 cm/s for all experiments. The pheromone plume was exhausted out of the assay room by a second fan at the downwind end of the wind tunnel. The flight section of the wind tunnel was approximately 1.5 m long by 1 m high at its center and was illuminated by overhead red and white lights at an intensity of 0.4 lx (measured 20 cm above the wind tunnel floor at its longitudinal center). A pheromone-loaded septum was suspended from a hook attached to the front of a 15×15 cm metal plate on top of a 20-cm tall metal platform located 50 cm from the upwind end of the tunnel. At the beginning of the fourth hour of the scotophase, males 3–4 days old were placed individually in 4 cm diam×8 cm high hardware cloth cages with aluminum foil lids and allowed to acclimate to the conditions of the wind tunnel room for 1 h. During the fifth to eighth hour of scotophase, caged males were placed on another 20 cm tall metal platform 150 cm downwind from the pheromone source. The lid was removed and the male was given 1 min to respond to the pheromone and scored (+ or −) for the following behaviors: wing fanning, taking flight (leaving the wire cage), locking on (zigzag flight in the pheromone plume), upwind flight, flying within 10 cm of the source, and source contact. Males were discarded after being assayed. If any males failed to respond after 1 min, they were tested to make sure they were capable of flight. Males incapable of flight were removed from the analysis.

Dose–Response Experiment Stock solutions of wild-type and mutant pheromone blends were formulated in HPLC grade hexane with synthetic pheromone components. These solutions consisted of a mixture of 12:Ac, *Z*5-12:Ac, *Z*7-12:Ac, 11-12:Ac, *Z*7-14:Ac, and *Z*9-14:Ac (see Table 1 for emission ratios). Blends were checked for accuracy by using a Hewlett Packard Series II Plus Gas Chromatograph connected to a Hewlett Packard 5972 Series Mass Selective Detector (Palo Alto, CA, USA) with a 30-m DB-Wax capillary column (0.25 mm ID, J&W Scientific, Folsom, CA, USA). Serial dilutions of both blends were prepared from this stock solution. Fifty microliters of each blend was loaded onto a hexane-extracted rubber septa (Thomas Scientific, Swedesboro, NJ, USA; 5×9 mm, red). Blends differed in the amount of the major pheromone component *Z*7-12:Ac with either 100 μg, 33 μg, 10 μg, 1 μg, or 100 ng of *Z*7-12:Ac per septum. After loading, septa were left in a fume hood overnight to allow solvent evaporation and then stored at −10°C until use. Loaded septa were treated in the same way in all subsequent experiments. Volatiles emitted from the highest dose septa of both blends were determined following the procedure of Haynes and Hunt (1990). These emission rates given in Table 1 are similar to that of wild-type and mutant females (Haynes and Hunt 1990).

Each day that moths were bioassayed, one or two males of each type (mutant or wild type) were flown individually to each blend/concentration combination, resulting in 20–40 males flown each day. A total of 67 mutant and 71 wild-type males were tested to each blend–concentration combination, with the exception that 65 mutant and 69 wild-type males were flown to the mutant blend at the 0.1-μg dose because of equipment malfunction. Results were analyzed with logistic regression (SAS Institute 1996) with moth–blend combination, concentration, and the interaction as model variables. This linear model allowed

Table 1 Targeted (and measured) emitted blend ratios of *Trichoplusia ni* sex pheromone components from septa

	Wild-type blend (measured)	Intermediate blends			Mutant blend (measured)
	W	WWM	WM	WMM	M
12:Ac	15 (12.4)	15	15	15	15 (18.6)
*Z*5-12:Ac	12 (14.5)	5.7	2.7	1.3	0.6 (0.7)
*Z*7-12:Ac	100 (100)	100	100	100	100 (100)
11-12:Ac	6 (8.9)	6	6	6	6 (8.2)
*Z*7-14:Ac	1.4 (2.1)	1.4	1.4	1.4	1.4 (1.5)
*Z*9-14:Ac	0.6 (0.6)	2.1	7.6	27	100 (101.9)

*Z*7-12:Ac is set at 100 for each blend. In order to achieve the desired emitted blend ratio 7-fold excess, *Z*7-14:Ac and *Z*9-14:Ac were loaded onto the septa. Measurements were made once (i.e., no replication) on the aged septa

treatments to be compared in terms of their overall level of response (tests for similar intercepts) and rates of response increase (tests for similar slope).

Intermediate Blend Response Experiment Five artificial blends were formulated: a wild-type, a mutant, and three intermediate blends (ratios of compounds are given in Table 1). For all five blends, the amounts of 12:Ac, 11-12:Ac, and *Z*7-14:Ac relative to *Z*7-12:Ac was 15:6:1.4:100. The amount of *Z*5-12:Ac gradually decreased from an optimum relative amount of 12 to 100 parts *Z*7-12:Ac in the wild-type blend through three intermediate blends to a minimum of 0.6 to 100 parts *Z*7-12:Ac in the mutant blend. Conversely, the amount of *Z*9-14:Ac gradually increased from a minimum of 0.6 to 100 parts *Z*7-12:Ac in the wild-type blend through three intermediate blends to a maximum of 100 to 100 parts *Z*7-12:Ac in the mutant blend. Fifty microliters of a blend was loaded onto a hexane-extracted rubber septum (Thomas Scientific, 5×9 mm, red) resulting in 33 μg of *Z*7-12:Ac.

During each day bioassays were run, three or four males of each type (mutant or wild type) were flown to each blend, resulting in 30 or 40 males flown each day. Sixty-six wild-type and mutant moths were flown to each blend. Results for mutant and wild-type males were analyzed separately by using logistic regression (SAS Institute 1996) looking for effects of blend. After these analyses, mutant and wild-type male responses were compared. This was done by combining data sets and adding moth-type and moth-type × blend interaction terms into the model.

Hybrid Response Experiment Male and female moths from the pure wild-type and mutant colonies were used to generate the F1 hybrid experimental moths. The rearing protocol was the same as outlined above. The following crosses were made (male × female): a pure wild-type line, W × W; a pure mutant line, M × M; and two hybrid lines, W × M, and M × W. Crosses were created by placing one male and female (each 2–5 days old) in 0.47 l cartons lined with blotter paper. Eggs were collected 3, 5, and 7 days after pairing. Male pupae were separated from females and kept in styrofoam containers. Upon emergence, males were transferred to 0.47 l cartons with access to a 10% sucrose solution until testing. A total of 23 W × W families were tested, 24 M × M families, 26 W × M families, and 30 M × W families.

Four of the blends from the intermediate blend response experiment above were used: the wild-type blend, the mutant blend, the WM blend, and the WMM blend (see Table 1 for emission ratios). Thirty-three micrograms of *Z*7-12:Ac (with other compounds in the corresponding amounts) was loaded onto a hexane-extracted rubber septum (Thomas Scientific, 5×9 mm, red). During each day of testing, one to three males of each cross were flown to each blend. Fifty W × W, 51 M × M, 55 W × M, and 55 M × W moths were flown to each blend. Results for each cross were compared by using logistic regression (SAS Institute 1996) comparing treatments in terms of their overall level of response (tests of intercepts) and blend preference (tests for slope). Linear model variables included the amount of *Z*9-14:Ac (to test for blend effect), the effect of cross type, and *Z*9-14:Ac by cross-type interactions.

Results

Dose–Response Experiment: Mutant Males Overall, mutant males did not respond differently to the wild-type or mutant pheromone blend at any behavior category (Fig. 1). For the behaviors wing fanning and taking flight, there were no significant concentration effects ($P=0.092$ and $P=0.056$, respectively; data not shown). For all other behaviors, strong concentration effects were observed ($P<0.001$; Fig. 1). For mutant males, there were no significant differences among blend types in terms of level of response (i.e., intercept), or rate of response increase with concentration (i.e., slope) for any of the behaviors measured: wing fanning ($P=0.643$ for a test of similar intercept and $P=0.165$ for a test of similar slope), taking flight ($P=0.815$ for a test of similar intercept and $P=0.323$ for a test of similar slope), locking on ($P=0.056$ for a test of similar intercept and $P=0.355$ for a test of similar slope), flying upwind ($P=0.067$ for a test of similar intercept and $P=0.150$ for a test of similar slope), coming within 10 cm of the source ($P=0.311$ for a test of similar intercept and $P=0.699$ for a test of similar slope), and source contact ($P=0.330$ for a test of similar intercept and $P=0.475$ for a test of similar slope; Fig. 1). These results indicate that there is no discrimination by the mutant males between the wild-type and mutant pheromone blends and that the effects of concentration on response level were parallel. Because the behavioral responses of the mutant males to the mutant and wild-type blends did not differ, their responses to these two treatments were combined for comparison to the wild-type male responses to the wild-type and mutant pheromone blends.

Wild-Type Males The response level of wild-type males to the mutant pheromone blend was lower compared to the level of response of wild-type males to the wild-type pheromone blend, or when compared to the mutant response to either blend across all behaviors ($P<0.001$ for all tests of similar intercept; Fig. 1). The rate of response increase of wild-type males to the mutant pheromone blend was greater than the combined mutant male responses for the behaviors of flying upwind and coming within 10 cm of the pheromone source ($P=0.031$ and $P=0.038$, respectively,

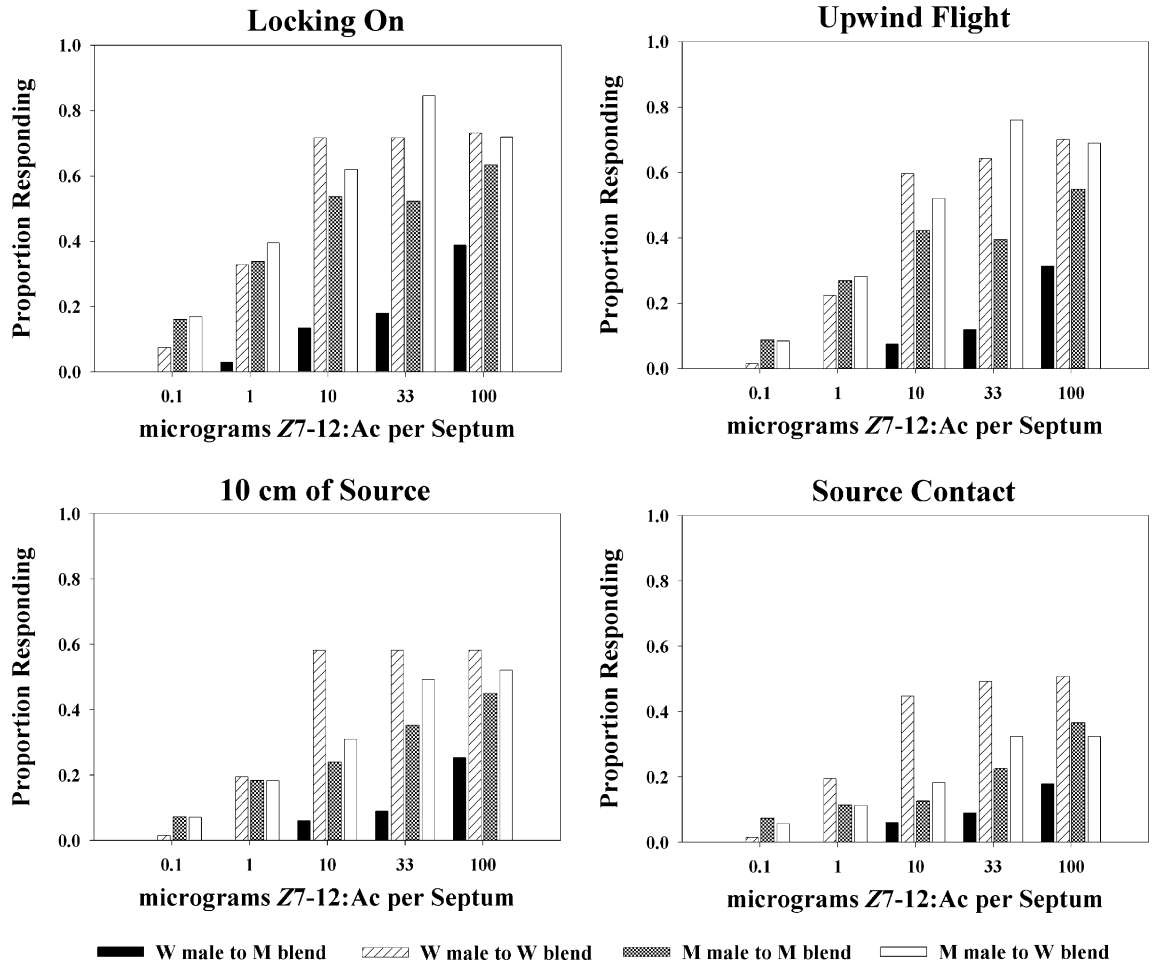

Fig. 1 The effect of pheromone dose on the proportion of male *Trichoplusia ni* engaging in the behaviors of "locking on", "upwind flight", "coming within 10 cm of the source", and "source contact" in response to synthetic pheromone sources. Wild-type male responses to the mutant (*solid black bars*) and wild-type (*hatched bars*) pheromone blends and mutant male responses to the mutant (*stippled bars*) and wild-type (*open bars*) pheromone blends are shown

for tests of similar slope; Fig. 1). For all other behaviors, the slopes were not significantly different ($P>0.05$ for tests of similar slope; Fig. 1). When the wild-type male response to the wild-type blend was compared to the mutant male responses to both blends, there were no significant differences in the rate of increase of response [tests for similar slope: $P=0.090$ for wing fanning; $P=0.212$ for taking flight; $P=0.306$ for locking on; $P=0.188$ for upwind flight; $P=0.853$ for coming within 10 cm of the source; and $P=0.940$ for source contact (Fig. 1)]. When the overall level of response was examined, there were differences between mutant male and wild-type male responses to the wild-type pheromone blend. Wild-type males had lower levels of response than mutant males for the behaviors wing fanning and taking flight ($P<0.001$ and $P=0.001$, respectively, for tests of similar intercept). There were no significant differences between wild-type and mutant male responses for the behaviors locking on and upwind flight ($P=0.909$ and $P=0.948$, respectively, tests of similar intercept; Fig. 1). Wild-type males were more likely to fly within 10 cm and contact the wild-type pheromone source than mutant males ($P=0.011$ and $P<0.001$, respectively, test of similar intercept; Fig. 1).

Intermediate Blend Response Experiment: Mutant Males Mutant male moths did not discriminate among blends. For none of the behaviors observed did blend variation explain the variation seen [wing fanning ($P=0.624$), taking flight ($P=0.382$), locking on ($P=0.115$), upwind flight ($P=0.238$), coming within 10 cm of the source ($P=0.116$), and source contact ($P=0.775$)] (Fig. 2; data for the behaviors wing fanning and taking flight not shown). These results indicate that mutant males do not discriminate among the mutant, wild-type, or intermediate pheromone blends at any behavioral category.

Wild-Type Males Wild-type males showed the highest response to the wild-type blend. Their responses decreased

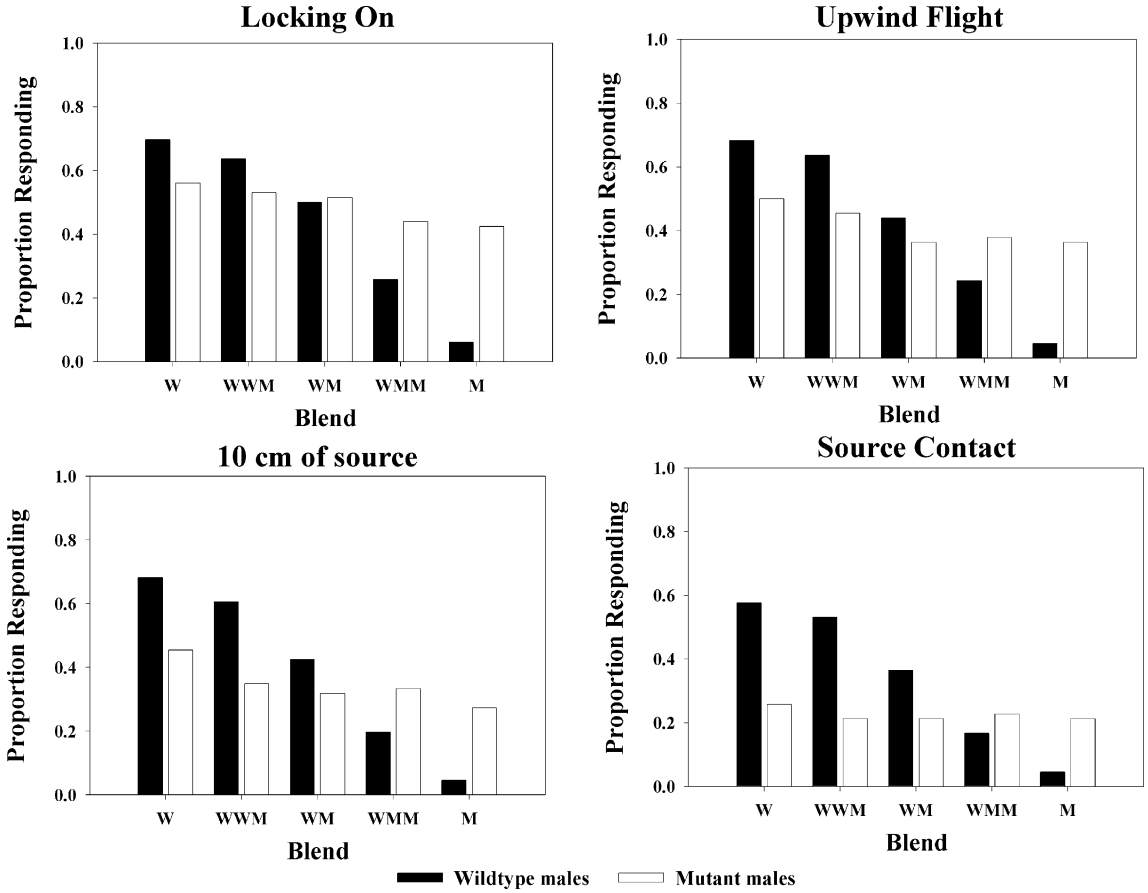

Fig. 2 The effect of pheromone blend on the proportion of male *Trichoplusia ni* engaging in the behaviors of "locking on", "upwind flight", "coming within 10 cm of the source", and "source contact" in response to synthetic pheromone sources. Wild-type and mutant male responses are shown by the *solid black* and *open bars*, respectively. For all five blends (see Table 1), the amounts of 12:Ac, 11-12:Ac, and *Z*7-14:Ac relative to *Z*7-12:Ac were 15:6:1.4:100. The amount of *Z*5-12:Ac gradually decreased from an optimum in the wild-type blend through three intermediate blends to a minimum in the mutant blend. Conversely, the amount of *Z*9-14:Ac gradually increased from a minimum in the wild-type blend through three intermediate blends to a maximum in the mutant blend

as the blend gradually changed to that of mutant females. For the behaviors wing fanning (P=0.002), taking flight (P=0.005), locking on (P<0.001), upwind flight (P< 0.001), coming within 10 cm of source (P<0.001), and source contact (P<0.001), blend had a significant effect (Fig. 2). For all behaviors, wild-type males were most responsive to the wild-type blend, and response decreased progressively through the WWM, WM, and WMM and reached a minimum for the mutant blend. These results illustrate the discrimination of wild-type males for the wild-type blend over the mutant blend, and that this discrimination is graded becoming more evident as the blend diverges from the wild type.

The responses of the wild-type and mutant males to the five pheromone blends were also compared directly. No differences in the responses of the wild-type and mutant males were observed for the behavioral categories wing fanning (P=0.503 for a test of similar intercept and P= 0.242 for a test of similar slope) or taking flight (P=0.302 for a test of similar intercept and P=0.220 for a test of similar slope). There was no difference among wild-type and mutant males in the level of response (P=0.056 for a test of similar intercept) for the behavior locking on, but there was a significant difference in blend preference (P< 0.001 for a test of similar slope; Fig. 2). For the behaviors upwind flight, coming within 10 cm, and source contact, there was a difference in blend preference (P<0.001 for all three behaviors for a test of similar slope) with wild-type males showing a preference for the wild-type blend. Similarly, wild-type males had higher levels of response to the wild-type blend for the behaviors upwind flight (P< 0.001 for a test of similar intercept), coming within 10 cm (P<0.001 for a test of similar slope), and source contact (P<0.001 for a test of similar slope; Fig. 2).

Hybrid Response Experiment: Hybrid Males Offspring of both types of hybrid crosses, W × M and M × W (male × female), behaved similarly across behavioral categories

(Fig. 3). For the behaviors wing fanning and taking flight, there was no blend effect (P=0.864 and P=0.300). For the behavior wing fanning, there were no significance differences between crosses (P=0.790 for a test of similar intercept and P=0.212 for a test of similar slope). At the next behavioral category, taking flight, there were no significant differences in the level of response (P=0.090 for a test of similar intercept), but there was a difference in how the crosses reacted to the different blends (P=0.024 for a test of similar slopes). For the behavior locking on, there was a strong and significant blend effect (P<0.001) with hybrids showing a preference for the wild-type blend (Fig. 3). There was no significant hybrid-type (maternal wild-type or mutant crosses) effect (P=0.334 for a test of similar intercept and P=0.602 for a test of similar slope). For the remaining behaviors, significant preferences for the wild-type blend and no hybrid effects were observed [upwind flight (P<0.001 for a blend effect, P=0.322 for a test of similar intercept, and P=0.858 for a test of similar slope); approach within 10 cm (P<0.001 for a blend effect, P=0.876 for a test of similar intercept, and P=0.285 for a test of similar slope); and source contact (P=0.022 for a blend effect, P=0.676 for a test of similar intercept, and P=0.656 for a test of similar slope)].

Hybrid vs. Parental Males For those behaviors where there were no significant differences between the responses of the two hybrid strains, the two strains were combined and compared to the pure wild-type and mutant lines. For the behavior taking flight, the W × M and M × W (male × female) hybrid offspring were tested separately. No significant differences between the combined hybrid treatment and either of the pure wild-type or mutant crosses (hybrids vs. pure wild-type males, P=0.066 for a test of similar

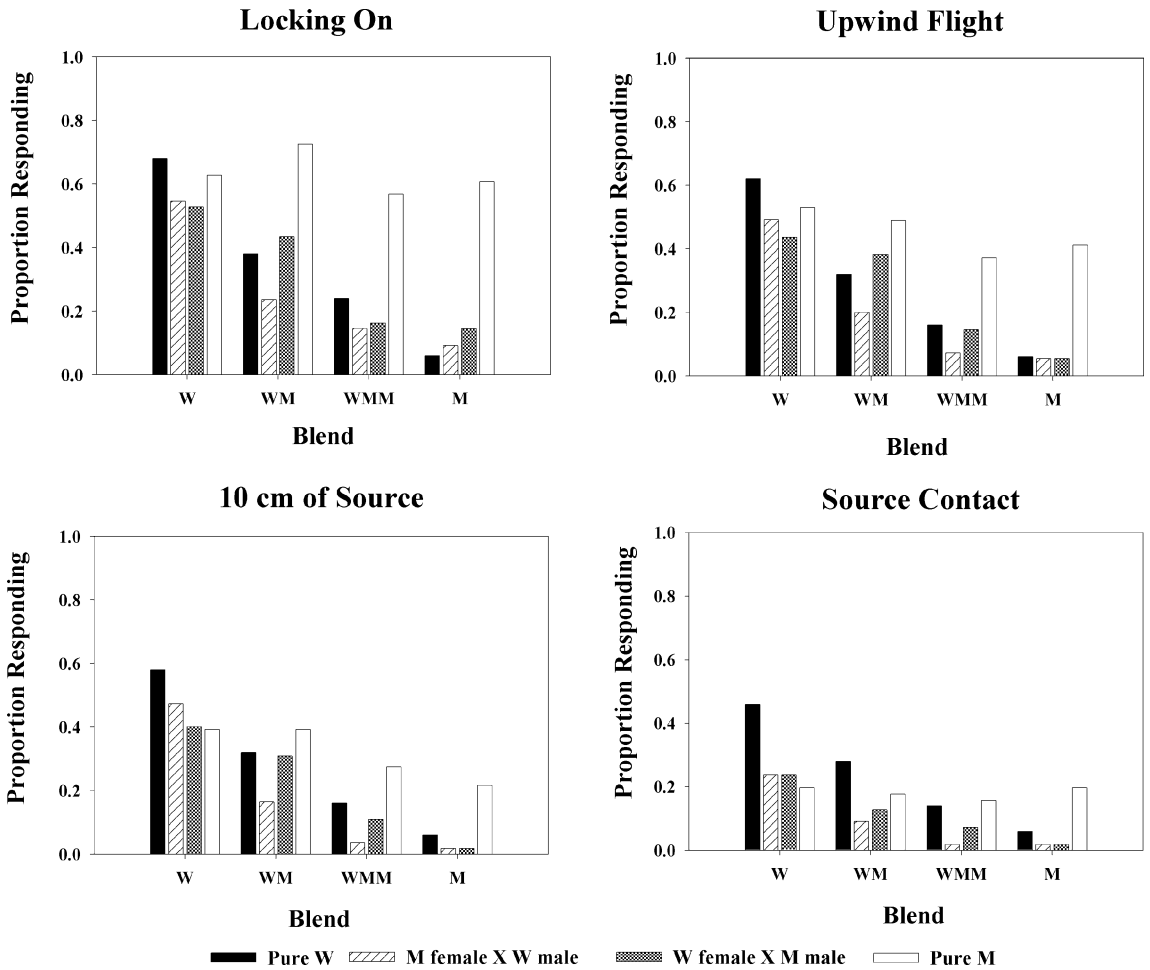

Fig. 3 The effect of pheromone blend on the proportion of male *Trichoplusia ni* engaging in the behaviors of "locking on", "upwind flight", "coming within 10 cm of the source", and "source contact" in response to synthetic pheromone sources. Pure wild-type (*solid black bars*), mutant female × wild-type male hybrid (*hatched bars*), wild-type female × mutant male (*stippled bars*), and pure mutant (*open bars*) male responses to the differing pheromone blends are shown. For all four blends, see Table 1

intercept and $P=0.190$ for a test of similar slope; hybrids vs. pure mutant males, $P=0.946$ for a test of similar intercept and $P=0.950$ for a test of similar slope) were observed for the behavior wing fanning. Similarly, for the behavior taking flight, no differences were observed between the M × W hybrid males and the pure wild-type ($P=0.558$ for a test of similar intercept and $P=0.198$ for a test of similar slope) and mutant ($P=0.600$ for a test of similar intercept and $P=0.519$ for a test of similar slope) males. There were no differences between the W × M hybrid males and the pure mutant males ($P=0.208$ for a test of similar intercept and $P=0.060$ for a test of similar slope). The W × M males were less sensitive than wild-type males ($P=0.031$ for a test of similar intercept), but there was no significant difference in blend preference ($P=0.087$ for a test of similar slope). For all subsequent behavioral categories, both hybrid strains were combined for statistical analysis as in the wing fanning behavioral category. Hybrid males did not differ from the pure wild-type moths in blend discrimination ($P=0.092$ for a test of similar slope), both hybrids and pure wild-type males preferred the wild-type blend over the mutant blend. The hybrids did show a decreased level of response compared to wild-type moths ($P=0.027$ for a test of similar intercept). Hybrid and pure mutant moths differed in both blend discrimination and level of response ($P<0.001$ for a test of similar intercept and $P<0.001$ for a test of similar slope). For the behavior upwind flight, the hybrid male response did not differ from the pure wild-type male response ($P=0.099$ for a test of similar intercept and $P=0.697$ for a test of similar slope) indicating similar levels of response and blend discrimination. The hybrid males did differ from the pure mutant males in blend discrimination ($P<0.001$ for a test of similar slope), and there was a borderline non-significant difference in the level of response ($P=0.052$ for a test of similar intercept). For the behavior coming within 10 cm of the source, there was no difference in the blend preference or level of response of the hybrid and pure wild-type males ($P=0.194$ for a test of similar intercept and $P=0.124$ for a test of similar slope). Although there was no difference in the level of response of hybrid and pure mutant males ($P=0.846$ for a test of similar intercept), there was a difference in blend discrimination ($P<0.001$ for a test of similar slope). Hybrid males exhibited a preference for the normal blend, while pure mutant males did not. For the final behavior, source contact, there was no difference in the blend discrimination of hybrid and pure wild-type males ($P=0.550$ for a test of similar intercept); both had a preference for the wild-type over the mutant blend. Hybrids did have a reduced level of response compared to wild-type males ($P<0.001$ for a test of similar intercept). The level of hybrid male response was more similar to the level of response of pure mutant males ($P=0.930$ for a test of similar intercept). Hybrid males did show greater blend discrimination than pure mutant males ($P=0.001$ for a test of similar slope). These results indicate that hybrid males have wild-type male preferences for the wild-type over the mutant pheromone blend, but like mutant males have reduced pheromone sensitivity.

Discussion

Because the adaptive value of pheromone communication is mate location, selection should favor male preferences for (Butlin and Ritchie 1989; Groot et al. 2006; Allison and Cardé 2008) and maximum male sensitivity to (Roelofs 1978; Linn et al. 1987) the most common blend emitted by females. As a result, variation in the presence and relative amounts of components in the pheromone blend may contribute to variation in female mating success. The resultant variation in mating success is hypothesized to impose stabilizing selection on the pheromone signal and ultimately constrain signal evolution (Butlin and Ritchie 1989). This paradigm is the basis for a model of moth sex pheromone evolution that has been referred to as the "stasis" model (Allison and Cardé 2008). An alternate model, asymmetric tracking, emphasizes an expected asymmetry in the strength of sexual selection that acts on female signal and male response traits due to differential investment in the zygote (Phelan 1997). Accordingly, males are predicted to optimize individual fitness by rapidly locating females and mating multiply, whereas females are not expected to be limited in mating opportunities. As a consequence, this model predicts that the female pheromone blend is free to change via non-adaptive evolutionary processes (i.e., drift) and that male response traits (e.g., breadth of response and sensitivity) will be selected simultaneously to track changes in the female pheromone blend.

The primary difference between the two models involves the predicted shape of the male preference function. The stasis model emphasizes unimodal male preference functions that constrain signal evolution, whereas the asymmetric tracking hypothesis does not (see Butlin and Ritchie 1989; Phelan 1997). The stasis model predicts a male response phenotype with maximal sensitivity to the most common blend and a narrow preference function with an optimum coincident with the most common pheromone blend. Similarly, the asymmetric tracking hypothesis predicts maximal sensitivity to, and an optimum coincident with, the most common blend. It differs from the stasis model in that it predicts a broad male preference function. Implicit to the prediction of maximal sensitivity to the most common pheromone blend is a trade-off in sensitivity among blends

(i.e., high sensitivity to one signal comes at the expense of reduced sensitivity to other signals). In the absence of this trade-off, the optimal male phenotype would appear to be high sensitivity to the complete range of signals defined by the male preference function.

Little empirical data on the relationship between the traits breadth of response and sensitivity in male moths to pheromone blends exist. The two traits are hypothesized to be negatively correlated, and the optimization of male response phenotypes limited (i.e., increases in sensitivity to one or more blends results in reduced sensitivity to other blends; Cardé 1986; Cardé and Haynes 2004). Independent studies have documented that mutant males have a broader response profile (Liu and Haynes 1994) and are less sensitive at the peripheral level (Baker and Domingue, pers. comm.) than wild-type males. Simulations of a population genetics model predict that if changes in sensitivity are not associated with trade-offs in breadth of male response, that selection will favor males with broad response phenotypes (Butlin and Trickett 1997). When a negative correlation between breadth of response and sensitivity was included in the model, the simulations predicted that selection would favor males with narrow response phenotypes and high sensitivity.

In this study, mutant male sensitivity and rate of response increase to increasing pheromone concentrations were independent of the pheromone blend. In contrast, wild-type males were more responsive to the wild-type than the mutant pheromone blend (Figs. 1 and 2). When the responses of wild-type males to the wild-type pheromone blend were compared to the combined mutant male responses, the level of response sensitivity differed among strains (Fig. 1). These results are consistent with the results of earlier wind tunnel and field trapping studies (Liu and Haynes 1994; Zhu et al. 1997) and suggest a trade-off between sensitivity and breadth of response.

The terminal behaviors in the mate location sequence (coming within 10 cm and source contact) are likely the best indicator of the ability of an individual male to locate a mate. For both of the behaviors, coming within 10 cm and source contact, wild-type males were more likely to complete the behaviors to the wild-type blend than mutant males to either blend (Fig. 1). Similar results have been reported for *Grapholita molesta* (Baker et al. 1981) and *P. gossypiella* (Linn and Roelofs 1985) in which males were most sensitive to the female produced pheromone blend. Because wild-type males are more sensitive to the wild-type pheromone, mutant males may be at a competitive disadvantage when competing with wild-type males for mating opportunities with wild-type females [an argument supported empirically by Evenden and Haynes (2001)]. Conversely, wild-type males do not respond well to mutant pheromone and may be at a disadvantage when competing with mutant males for mutant females. Interestingly, although wild-type and mutant hybrid males and pure wild-type males have similar blend preferences at the level of source contact, wild-type males are more sensitive than hybrid males (Fig. 3). These data suggest that assortative mating could occur in mixed populations (Zhu et al. 1997) and provide a mechanism for reinforcement and diversification of pheromone signals that could ultimately result in speciation.

The mutant males did not show a preference for any blend at any behavioral category. They responded equally to the normal, intermediate, and mutant blends. This lends support to the hypothesis that the mutant males underwent a general broadening of response as they became equally responsive to the normal and mutant pheromone blends.

Overall, it appears that at the same time that mutant males experienced a broadening of response, they simultaneously experienced a reduction in sensitivity. This documents a trade-off between sensitivity and breadth of response in *T. ni*. Population genetic simulations run by Butlin and Trickett (1997) suggest that when a trade-off between sensitivity and breadth of response exists, selection should favor a narrower, more sensitive response profile. It remains to be seen if this trade-off between sensitivity and breadth of response is present in other moth pheromone systems. The trade-off in sensitivity was observed with lures releasing up to 2 ng/min of *Z*7-12:Ac; the mean amount of *Z*7-12:Ac emitted by calling females has been estimated to range from 2 to 11 ng/min of *Z*7-12:Ac (see Hunt and Haynes 1990; Liu and Haynes 1994). If trade-offs are a general phenomenon, it could mean that the evolution of novel pheromone signals could involve an intermediate step during which some individuals have a broad response, but lower sensitivity. Presumably, selection could then act on the male response phenotype, narrowing the response peak and increasing sensitivity to the new pheromone blend. For now, our ability to make such generalizations is limited by a lack of data for other species.

Acknowledgments We are grateful to B. Chastain for reliable and invaluable technical assistance and to Drs. C. Gemeno and M. Evenden for comments and discussions. The research was supported by the Kentucky Agricultural Experiment Station and a competitive grant from the USDA, Cooperative State Research and Extension Service (97-35302-4324).

Aquatic animals often use chemical alarm cues to signal the risks associated with predation (Chivers and Smith 1998; Wisenden 2000). In many teleost fishes, olfactory cues are released following mechanical damage to the skin, which in turn stimulates a stereotypic avoidance behavior; the fright reaction (von Frisch 1938; Schutz 1956; Mathis and Smith 1993; Brown and Smith 1997). Specialized epidermal cells, club cells, are believed to contain the alarm substances responsible for eliciting this behavior (Pfeiffer 1963). In several species, the number of club cells decreases in sexually mature or testosterone-treated male fish (Smith 1973, 1976). This was suggested to be an adaptive mechanism to prevent the release of alarm substances during abrasive male–male interactions that commonly occur during the breeding season. In this way, the display of aggressive spawning behaviors such as abrasive contact and fighting would not result in the release of false alarm signals. Although less pronounced than in males, females may also experience physical abrasion during the breeding season as a result of active courtship behavior and nest-building. Taken together, this indicates that the potential to display chemical alarm cues is suppressed during the breeding season in fishes. However, to our knowledge the effect of sexual maturation on the response to olfactory cues from damaged conspecifics has not been reported previously.

The present study reports the occurrence of a suppressed olfactory induced fright reaction in late stages of sexual maturation in crucian carp, *Carassius carassius* (L.) (Cypriniformes: Cyprinidae). Maturation of gonads and plasma levels of gonadal steroids suggest that this suppression occurs around the time of ovulation in females.

Methods and Materials

Experimental Animals In May 2005, crucian carp were caught in a fishing pot with corn and bread as bait in a small lake on the outskirts of the city of Oslo, Norway, and transported to the aquaria facilities at the Department of Molecular Biosciences, University of Oslo. The fish were kept in 1,000 l aquaria supplied with through-flowing freshwater, and maintained under a photoperiod of light–dark (L–D) 12:12 h and a temperature of 10°C. The fish were fed three times a week with commercial pelleted feed (Modulfôr, Ewos, Norway). All experimental procedures were made in accordance with national legislation and institutional guidelines at the University of Oslo.

Skin Extract Three specimens of crucian carp were killed by decapitation and flayed. Skin samples were immediately homogenized manually in cold distilled water (50 g/l). The homogenate was centrifuged, and the supernatant frozen immediately at –20°C in 1 ml aliquots.

Experimental Procedure In June 2006, 24 female and 18 male specimens (body weight, 6–12 g) were transferred from the holding tank to a 25 l observation aquarium at approximately 4 PM, where they were kept singly. The photoperiod was set to L–D 13:11 h and the temperature was changed gradually to room temperature (approximately 18°C), in order to induce the onset of ovulation and increase milt volume (Dulka et al. 1987). Between 9:30 AM and 12:00 PM on the following day, the fish were exposed to 0.2 ml of skin extract, injected into the water through a polyethylene tube. The subsequent reaction to the skin extract was categorized as either a fright reaction or no fright reaction, by using behavioral characteristics previously reported for this species (Hamdani et al. 2000; Höglund et al. 2005). In short, the fright response in crucian carp is characterized by fish displaying rapid tail movements and swimming to the bottom floor of the aquaria. After 12 min of skin extract exposure, the fish were netted and blood samples taken for the measurement of plasma levels of sex steroid hormones. Gonadal maturation of these fish was characterized as either strippable or non-strippable, depending on whether milt/eggs could be readily stripped following gentle abdominal pressure. This showed that 18 of 24 females had strippable eggs (ovulation) and 12 of 18 males had strippable milt.

Measurement of Sex Steroid Hormones The major sex steroid hormones in mature male and female teleost fish are 11-ketotestosterone (11-KT) and testosterone (T), and T and 17β-estradiol (E_2), respectively (Borg 1994). The plasma levels of 11-KT, T, and E_2 were measured by specific radioimmunoassay (RIA) according to Pall et al. (2002), a method validated for the use of small volumes of plasma. In brief, individual plasma samples (15–50 µl) were diluted to 300 µl with RIA buffer and heated at 80°C for 60 min. The samples were centrifuged at 3,400×*g* (Hettich bench centrifuge, Model Rotanta 46 R, Hettich Instruments, Tuttlingen, Germany) for 15 min, after which the supernatant was removed and stored at 4°C until assay. Fifty µl aliquots of the sample, followed by 50 µl of RIA buffer were added first to incubation tubes. Fifty µl of the radio-labelled steroid were added to each tube (^{3}H-T and ^{3}H-E_2 was purchased from Amersham International and ^{3}H 11-KT was a gift from Dr. A.P. Scott, CEFAS, UK) (30,000–35,000 dpm/50 µl). Two hundred µl of steroid antiserum were also added to the tube (a gift from Dr. Helge Tveiten, University of Tromsø). All samples were run in duplicate and a mean plasma level of steroid was calculated for each fish and used in further statistical analyses (see below). The vials were vortexed and incubated overnight at 4°C. Free, unbound steroid was separated from bound steroid with dextran charcoal suspension (activated charcoal, acid-washed, 100–400 mesh (Product No. C.5385) and Dextran T-70

(average molecular weight 64,000–76,000; Product No. D.4751) both purchased from Sigma-Aldrich Sweden AB, Stockholm, Sweden). Following a 5-min centrifugation, the supernatant was poured into scintillation vials that contained 4 ml scintillation fluid (OptiPhase Hi Safe II, LKB Wallac) and run for 5 min in the counter (1214 Rackbeta liquid scintillation counter, LKB Wallac). The detection limit for the assay was approximately 2 ng/ml and the intra- and interassay coefficients of variance were 5.4 and 7.0%, respectively.

Statistical Analyses Fisher's exact probability test (two-tailed) was applied (http://statpages.org/ctab2x2.html) to analyze for significant differences in the number of males or females with and without strippable gonads performing or not performing a fright reaction. An unpaired Student's *t* test (two-tailed) was applied to analyze the differences in the mean levels of plasma sex hormones (Excel, Microsoft Office 2003). Individuals responding with a fright reaction to skin extract were compared to those not responding for each gender separately. A critical value of $\alpha=0.05$ was used for all comparisons.

Results

Maturation of Gonads, Females Following exposure to skin extract, female crucian carp could be divided into two groups, those performing (10) and those not performing (14) a fright reaction. As judged by the presence or absence of strippable eggs, maturation status was more advanced in females not performing a fright reaction (Fig. 1). In this group, 13 out of 14 females had strippable eggs. In the group performing a fright reaction, this ratio was five out of 10. This difference in relative frequency of fully mature individuals between the two groups is significant ($P=0.05$).

Maturation of Gonads, Males Following exposure to skin extract, only six out of 18 males displayed the fright reaction. Among males not performing a fright reaction, nine of 12 had running milt. In the group performing a fright reaction, three of six had running milt (Fig. 1). Hence, in contrast to the situation in females, among males the occurrence of mature individuals was not significantly different between the responding and not responding groups ($P=0.34$).

Steroid Hormones, Females The mean plasma levels of E_2 (Fig. 2) were significantly higher in those females performing a fright reaction (54.3±22.5 ng/ml) compared to those that did not (34.3±14.8 ng/ml; $P=0.03$). The same was observed with plasma T levels, where means were significantly higher in the individuals performing a fright reaction (7.1±2.2 ng/ml) compared to those that did not (4.8±1.3 ng/ml; $P=0.01$).

Steroid Hormones, Males In contrast to the females, there were no significant differences in steroid hormone levels between those males that performed a fright reaction and those that did not perform a fright reaction. Plasma T levels were not significantly different between responders (7.2±3.3 ng/ml) compared to non-responders (6.4±1.7 ng/ml; $P=0.32$). Similarly, plasma 11-KT levels (Fig. 2) were not significantly different in responders (5.0±4.0 ng/ml), compared to non-responders (7.0±2.3 ng/ml; $P=0.38$).

Discussion

We report a suppression of the fright reaction in female crucian carp during the final stages of sexual maturation. That is, among the females failing to perform a fright reaction, a large majority had ovulated, as indicated by the presence of strippable eggs. In contrast, in mature male fish, the failure to respond to alarm substances was not associated with the presence of strippable milt.

Steroid measurements showed that the group of females displaying a fright reaction had significantly higher mean plasma levels of both E_2 and T compared to the females without fright reaction. The relatively low levels of E_2 and T observed in females not performing a fright reaction are in accordance with the endocrine changes that occur just

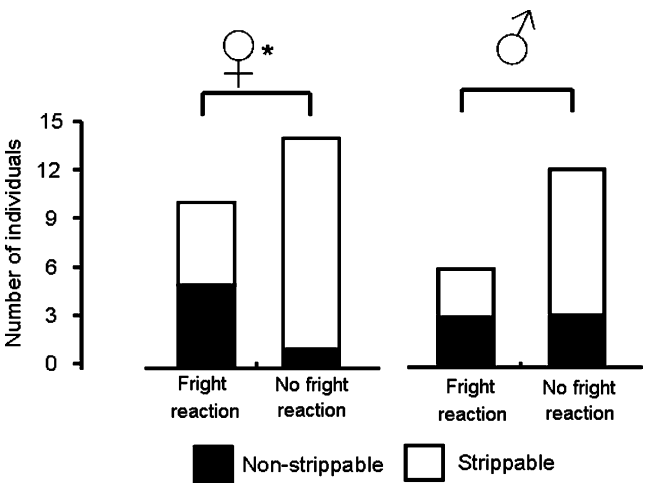

Fig. 1 Number of individuals grouped by behavioral response to skin extract as either a fright reaction or no fright reaction. Maturation of gonads was characterized as either strippable or non-strippable, depending on whether milt/eggs could be stripped following gentle abdominal pressure. The *asterisk* indicates a significant difference in the status of gonad maturation ($P=0.05$) between the two behavioral response groups of females (Fisher's exact probability test)

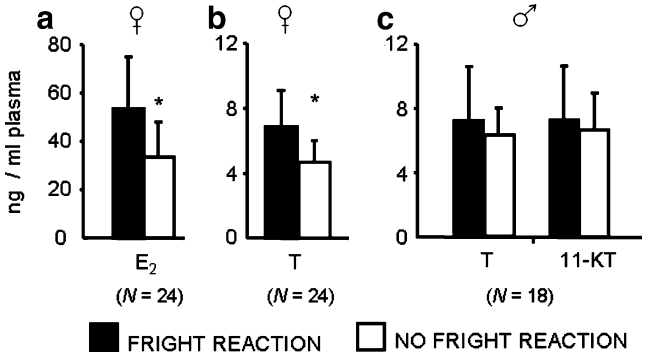

Fig. 2 Mean plasma levels+SD of gonadal steroids in individuals performing and individuals not performing a fright reaction upon skin extract exposure. **a** *E_2* 17*β*-estradiol, **b** *T* testosterone in females (*N*=24) and **c** *T* testosterone and *11-KT* 11-ketotestosterone in males (*N*=18). Note that the scale for E_2 values differs from that of the androgens (T and 11-KT). The *asterisks* indicate significant differences in E_2 values (*P*=0.03) and T values (*P*=0.01) between the two behavioral response groups of females (Student's *t* test)

before ovulation in the goldfish, *Carassius auratus*, a close relative of the crucian carp (Kobayashi et al. 2002). These results are in accordance with a suppression of the alarm response during final oocyte maturation and ovulation, a time when plasma levels of the sex steroid hormones E_2 and T are declining.

The majority of all males, 12 of 18, did not show an alarm response. Still, there were no significant differences among males responding or not responding with a fright reaction to skin extract, both with respect to strippable milt, and mean plasma levels of those androgens (T and 11-KT) that influence both male sexual behavior and spermatogenesis (Borg 1994). Unfortunately, the low sample-size could potentially make the comparisons between responding and non-responding individuals problematic. There may be a suppressed alarm response induced by factors not taken into account in this study. In male fish, spermatogenesis as well as courtship behavior are dependent on socio-sexual cues from conspecifics (Poling et al. 2001; Stacey et al. 2001; Kobayashi et al. 2002), and it is possible that a suppression of a fright reaction is affected by the same socio-sexual cues, which were not taken into account in the present study. Female preovulatory steroids, such as 17α, 20β-dihydroxypregnenone, and postovulatory pheromones such as prostaglandins are possible candidates.

By presenting the steroid levels as we have, we attempted to highlight the reproductive state of the fish, rather than to show the role of these hormones in the suppression of the behavioral response. However, we feel that our data are robust enough to suggest the possible involvement of gonadal hormones in the modulation of the fright reaction in female crucian carp. This assumption is strengthened when we compare responding and non-responding females in the ovulated group; the mean T level in the group with fright reaction is higher when compared to the group without the reaction. There is also a strong trend for higher mean E_2 level in the group with fright reaction when compared to the group without the reaction (data not shown). Thus, we hypothesize that endocrine variation may account for the loss of predator avoidance.

Previous studies have demonstrated the absence or reduction of alarm substance cells in the skin of sexually mature fish, where it was suggested that this could prevent the release of false alarm signals that result from fighting and abrasive contact (courtship, nest building) that commonly occurs during spawning behavior (Smith 1976). Our results demonstrate that female crucian carp lose the behavioral response to these predation cues during the final stages of sexual maturation, which may have the same ultimate function, i.e., to prevent interruption of spawning. To reduce predator avoidance in favor of reproduction may be necessary, since the fright reaction includes hiding and freezing (Hamdani et al. 2000; Höglund et al. 2005); behaviors that are incompatible with typical spawning behavior (Stacey and Liley 1974; Bjerselius et al. 1995; Weltzien et al. 2003). The suppression of either sending or responding to information about potential predators may seem risky from an evolutionary point of view. Predation eliminates all future reproductive opportunities, and animals have been suggested to maximize lifetime and reproductive success by attaining an optimal balance between reproduction and predator avoidance (Lima and Dill 1990; Magnhagen 1991). In the present study, the loss of the fright reaction seems to occur during a relatively short time window in relation to the release of gametes, thus indicating that the increased risk-taking is minimized.

Mechanisms involved in suppression of a behavioral response may be related to modification of the olfactory organ and/or the central mechanisms involved in processing received information. Interestingly, there is plasticity in the olfactory organ in crucian carp, showing seasonal variation in the number of sensory cells that are believed to be involved in the detection of sex pheromones (Hamdani and Døving 2006; Lastein et al. 2006; Hamdani et al. 2008). However, such a mechanism might be too slow to account for the suppression of the fright reaction. Central modifications induced by endocrine alterations are more likely to be involved.

In summary, we have demonstrated that the fright reaction is suppressed during the final stages of sexual maturation in female crucian carp. This seems to occur during a relatively short time window corresponding to ovulation and the release of gametes. Having only a short window during which the fright reaction is suppressed would minimize the overall risk of predation. Since the fright reaction in crucian carp consists of behavior incompatible with spawning behavior, we hypothesize that

this short-term suppression has evolved to enable spawning to occur uninterrupted.

diterpenoids (approximately 400) are the main natural products in this genus and are especially abundant in fresh branches and leaves (Sun et al. 2001). Some of these compounds possess diverse bioactivities that include among other properties: antitumor activity (Tengchaisri et al. 1998), induction of apoptosis (Suzuki et al. 2004), and cytotoxicity (Jiang et al. 1999; Han et al. 2004). Being perennial deciduous herbs, shrubs, or sub-shrubs, the aerial parts of *Isodon* plants wilt, fall to the ground, and are incorporated into the rhizosphere via degradative processes on an annual basis. However, whether these chemical components mediate interactions in natural surroundings is still unknown.

Leukamenin E (Fig. 1) was first isolated from the leaves of *Isodon umbrosa* var. *leucantha* f. *Kameba* (Takeda et al. 1981); however, little information is available concerning its bioactivity. Our investigation of *Isodon racemosa* (Hemsl) Hara obtained from Gansu, China, led to the isolation of leukamenin E from branches and leaves (Ding et al. 2006). Leukamenin E is abundant, and yields can reach as high as 0.13% DW. Preliminary screening of several *ent*-kaurene diterpenoids (e.g., leukamenin E, weisinensin B, rabdosin B, and epinodosin; data not shown) confirmed that leukamenin E is most phytotoxic toward the growth of lettuce, radish, ryegrass, and wheat seedlings. Consequently, it was selected to probe for possible modes of action.

Plant root systems are most likely to be affected by certain allelochemicals because they have direct contact with soil and can absorb many compounds. Mitotic activity can be used to evaluate root growth resulting from cell division of meristematic cells and cell expansion in the elongation zone of roots. Root hairs, projections from root epidermal cells that increase the effective surface area available for nutrient and water uptake, can be used to evaluate the influence of compounds on root development.

The purpose of our experiments was: (1) to determine the phytotoxic effects of leukamenin E on root growth and root hair development in lettuce seedlings and (2) to probe possible modes of action. Lettuce has been used extensively as a test organism because of its fast germination and high sensitivity (Rasmussen and Einhellig 1979) and, thus, was selected as the target plant species in our study.

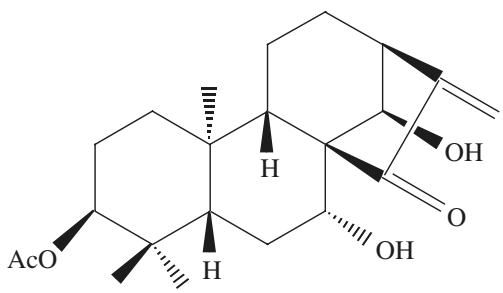

Fig. 1 Chemical structure of leukamenin E, an *ent*-kaurene diterpenoid from species of *Isodon*

Methods and Materials

Plant Materials and Chemicals Lettuce (*Lactuca sativa* L.) seeds were obtained from Dadi Seed Service (Lanzhou, China). Leukamenin E was isolated previously in our laboratory from *I. racemosa* (Hemsl) Hara (Ding et al. 2006). Ethephon was purchased from BBI, USA. Silver thiosulfate solutions were prepared by mixing $AgNO_3$ with $Na_2S_2O_3$ in a 1:4 molar ratio (Kamaluddin and Zwiazek 2002). All other chemicals were from Sango Biological Engineering Technology and Service Co., Ltd. (Shanghai, China).

Culture Conditions and Treatments Lettuce seeds were rinsed in tap water (×3), surface-sterilized with 0.1% mercuric chloride (8 min), followed by rinsing in distilled water. Seeds were placed into Petri dishes that contained two sheets of filter paper soaked with distilled water and allowed to germinate for 48 h at 22±2°C and a photoperiod of 16:8 h L:D. Uniform, 2-day-old seedlings (ten per treatment) were transferred into Petri dishes containing different concentrations of treatment solutions and incubated for 48 h under the same conditions.

Leukamenin E was dissolved in DMSO and diluted to the desired concentrations with distilled water. The amount of DMSO varied for each treatment but never exceeded 0.1%—i.e., below a level where root growth and root hair developments were affected (data not shown). Net growth rates (NGR) were measured to evaluate the influence of leukamenin E and Ag^+ on root growth according to the method of Pan et al. (2001). The seminal root lengths of the seedlings in each treatment were measured before and after treatment. NGR was calculated as follows: (final length-initial length)/initial length.

Mitotic Activity and Aberrations Squash techniques were modified from Akinboro and Bakare (2007). Primary roots of lettuce seedlings after leukamenin E treatments were fixed in freshly prepared 3:1 (*v*/*v*) ethanol–acetic acid for 24 h, transferred into 70% EtOH, and stored at 4°C until use. Roots were hydrolyzed in 1 M HCl for 8–10 min at 60°C followed by rinsing in distilled water (3–4 rinses). Root tips (approximately 1–2 mm) were excised, stained with carbol fuchsin (10 min), and squashed onto slides. Five slides were prepared for each treatment, and at least 1,000 cells were randomly counted per slide. The mitotic index was calculated as the number of dividing cells per 1,000 observed cells. All slides were examined for aberrant

mitosis with a Nikon Eclipse E400 optical microscope. Digital images were captured with a Canon A460 digital camera.

Measurements of Root Hairs Root hairs were evaluated with slight modifications according to the method of Yang et al. (2004). Seedlings (ten) were randomly selected from each treatment. Root segments (1 cm) were excised from each seedling at 0.5 cm behind the root tip, fixed in 70% EtOH, and placed onto microscope slides for microscopic observation. The number and length of root hairs present in certain regions (424 μm root segment) were measured (×3) from the ends and the middle of root segments with an ocular micrometer. Measurements for each treatment were determined from the ten root segments, and mean values were calculated.

Statistical Analysis All data are presented as means ± SD. Data were subjected to analysis of variance (ANOVA) with significant differences among means identified by LSD multiple range tests using SPSS 11.0. Differences were considered significant at $P \leq 0.05$. To verify the relationship between pairs of data (root NGR/mitotic index; mitotic index/prophase index) at the same leukamenin E concentrations, linear regression analysis was calculated, and the coefficient of regression (r) and its level of significance was determined.

Results

Leukamenin E Effects on Root Growth The inhibitory effect of increasing concentrations of leukamenin E on lettuce seedling roots is evident in Fig. 2A. NGR over 48 h were calculated to quantify the effects of leukamenin E on root growth. The NGR resulting from treatment with a low concentration of leukamenin E (10 μM) was no different from control seedlings exposed to DMSO. However, the inhibitory effects of higher concentrations of leukamenin E (50–200 μM) were significantly different. At all concentrations above 50 μM, the NGR of lettuce seedlings decreased, but the inhibitory effects at 100 and 200 μM leukamenin E resulted in similar levels of inhibition. When seedlings were treated with the highest concentration of leukamenin E, the NGR remained at about 37% of the control (Fig. 2B).

Effects of Leukamenin E on Mitotic Activity Leukamenin E affected the mitotic index in a pattern that was similar to the NGR (Fig. 3A). The mitotic index for root tip cells treated with 10 μM leukamenin E did not differ from controls. At higher concentrations (i.e., 50–200 μM), the mitotic index

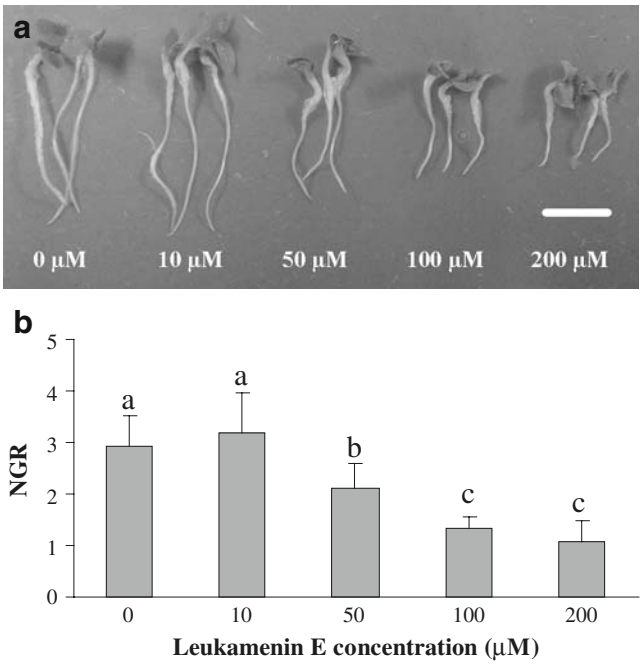

Fig. 2 **A** Effect of increasing concentrations of leukamenin E on the root growth of lettuce seedlings 48 h after treatment. **B** Root NGR in lettuce seedlings calculated after 48 h of treatment. *Different letters* indicate significant differences at $P \leq 0.05$. *Bars* indicate SD. *Bar*= 1 cm

decreased, and the inhibition was positively correlated with leukamenin E concentration. The mitotic index of root cells treated with 200 μM was approximately 62% of the control value. Regression analysis revealed a positive correlation between NGR and mitotic index (r=0.97, P=0.006). In addition, leukamenin E affected the relative proportion of the various stages of mitosis in meristematic cells with different stages showing different sensitivity to leukamenin E (Fig. 3B). The decrease in the number of meristematic cells in prophase was analogous to the mitotic index (r= 0.98, P=0.004), while the percentages of other phases were less affected.

The distribution of mitotic phases relative to mitotic cells was also influenced (Fig. 3C). After treatment with higher concentrations of leukamenin E (100 and 200 μM), the percentage of cells in metaphase increased compared to cells in other mitotic phases while the number of cells in prophase decreased. Finally, a low incidence of aberrant mitosis, (e.g., chromosome stickiness, C-colchicine metaphase, chromosome bridges, multipolar division, lagging chromosome, etc.) was observed in plants treated with 100 and 200 μM leukamenin E (Fig. 4). These phenomena were not observed in control seedling cells or cells treated with lower concentrations of leukamenin E.

Inhibition of Root Hair Development by Leukamenin E Root hair development in lettuce seedlings (i.e., length

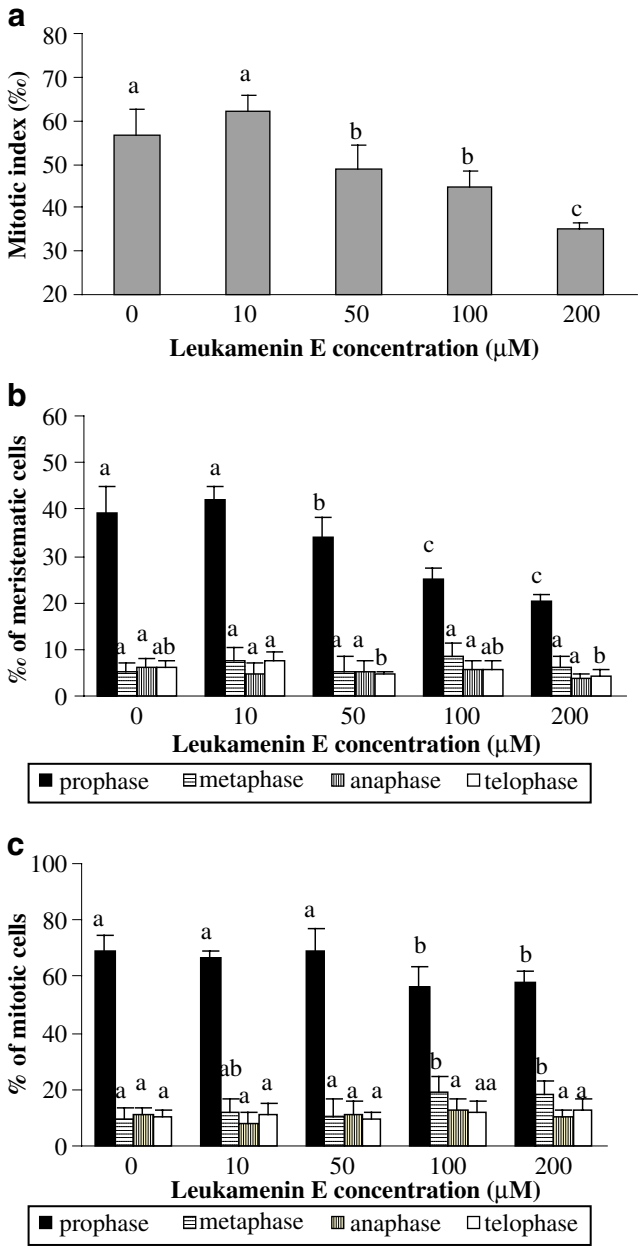

Fig. 3 Effect of leukamenin E on the mitotic activity of lettuce seedling root apical meristem cells after treatment (48 h). **A** The mitotic index of root apical cells; **B** percentage of mitotic phases calculated relative to the total number of meristematic cells; and **C** the distribution of mitotic phases calculated relative to mitotic cells. *Different letters* indicate significant differences at $P \leq 0.05$. *Bars* indicate SD

and density) was inhibited by leukamenin E (Fig. 5). Concentrations between 10–80 μM curbed root hair elongation and decreased the average root hair length in a dose-dependent manner (Fig. 5A). In contrast, root hair density remained stable up to 20 μM and only declined at concentrations above 40 μM (Fig. 5B). A few bulges were observed on root surfaces when leukamenin E concentrations were raised to 40 μM; at 80 μM, the roots were rendered smooth and hairless. The effect of leukamenin E on root hair length in lettuce seedlings compared to control root hairs is shown in (Fig. 6).

Effects of Ag^+ on Lettuce Seedling Roots The effects of Ag^+ on root growth and root hair development are shown in Fig. 7. Lower levels of Ag^+ (0.5–2 mM) promoted root growth, and the root NGR reached a maximum at 1 mM (Fig. 7A). Inhibitory effects were not observed at the Ag^+ concentrations tested. Significant inhibitory effects on root hair length were found at all Ag^+ concentrations at or above 0.5 mM, but the inhibition did not increase linearly at the higher concentrations (Fig. 7B). The density of root hairs remained constant at all concentration tested (Fig. 7C).

Reversion of Ethephon Enhanced Root Hairs by Leukamenin E Lettuce seedlings were treated simultaneously with ethephon (40 μM), an ethylene-releasing agent, and different concentrations of either leukamenin E or Ag^+ to determine whether leukamenin E might act as an ethylene antagonist similar to Ag^+. Treatment of lettuce seedlings with ethephon alone stimulated root hair growth (Fig. 8). Simultaneous treatment of seedlings with ethephon and Ag^+ (0.5 and 4 mM) inhibited the stimulatory effect of ethephon on root hair growth. Increasing concentrations of leukamenin E and simultaneous treatment with ethephon also inhibited the stimulatory effect of ethephon on root hair growth.

Treatment of lettuce seedlings with ethephon resulted in a significant reduction in the NGR of control seedlings. Increasing concentrations of Ag^+ were able to reverse this effect. The NGRs of lettuce seedlings simultaneously treated with ethephon and leukamenin E were significantly lower than seedlings treated with Ag^+—i.e., leukamenin E was not able to reverse the inhibitory effect of ethephon (Fig. 9).

Discusssion

For the first time, we have demonstrated that leukamenin E is phytotoxic toward root growth and root hair development in lettuce seedlings. Parker et al. (2000) reported that root hairs contribute as much as 77% to the total root surface area in cultivated crops, being the major point of contact between plants and the rhizosphere. Among other physiological functions, plant roots are important in water and nutrient uptake, growth regulation, and anchoring in soil (Ryan et al. 2001; Bibikova and Gilroy 2003). Root length is important in the exploitation of soil resources (Aerts et al. 1991). Short, hairless roots that result from exposure to leukamenin E would undoubtedly hamper a plant's ability

to compete for resources and, as a result, could lead to decreased shoot growth. This suggests that this abundant *ent*-kaurene diterpenoid may play a role in mediating ecological interactions between *Isodon* and other species in nature.

Root growth arises from the proliferation of meristematic cells followed by cell expansion that results in root elongation. Our results demonstrate that lettuce seedlings treated with leukamenin E experience a reduction in root NGR and that this is correlated with the mitotic index of root meristematic cells. This suggests that inhibition of root growth may result from suppressed mitotic activity. Along with a reduction in the number of mitotic cells, leukamenin E alters the percentage of cells in the various phases of mitosis calculated relative to meristematic cells. A reduction in the number of cells in prophase (Fig. 3B) follows a pattern that is similar to the mitotic index (Fig. 3A); however, the percentage of cells in other mitotic phases did not change. Romagni et al. (2000) reported that treatment with a monoterpene—1,4-cineole—caused similar decreases in the number of cells in prophase. It is hypothesized that such a phenomenon depends on the general mechanism responsible for arresting the mitotic cycle in cells (Fusconi et al. 2007). Upon induction of DNA damage or after alteration of the intracellular redox homeostasis, the cell cycle slows down at the G_1/S and G_2/M transition points (Den Boer and Murray 2000). This may reduce the percentage of prophases and eventually the

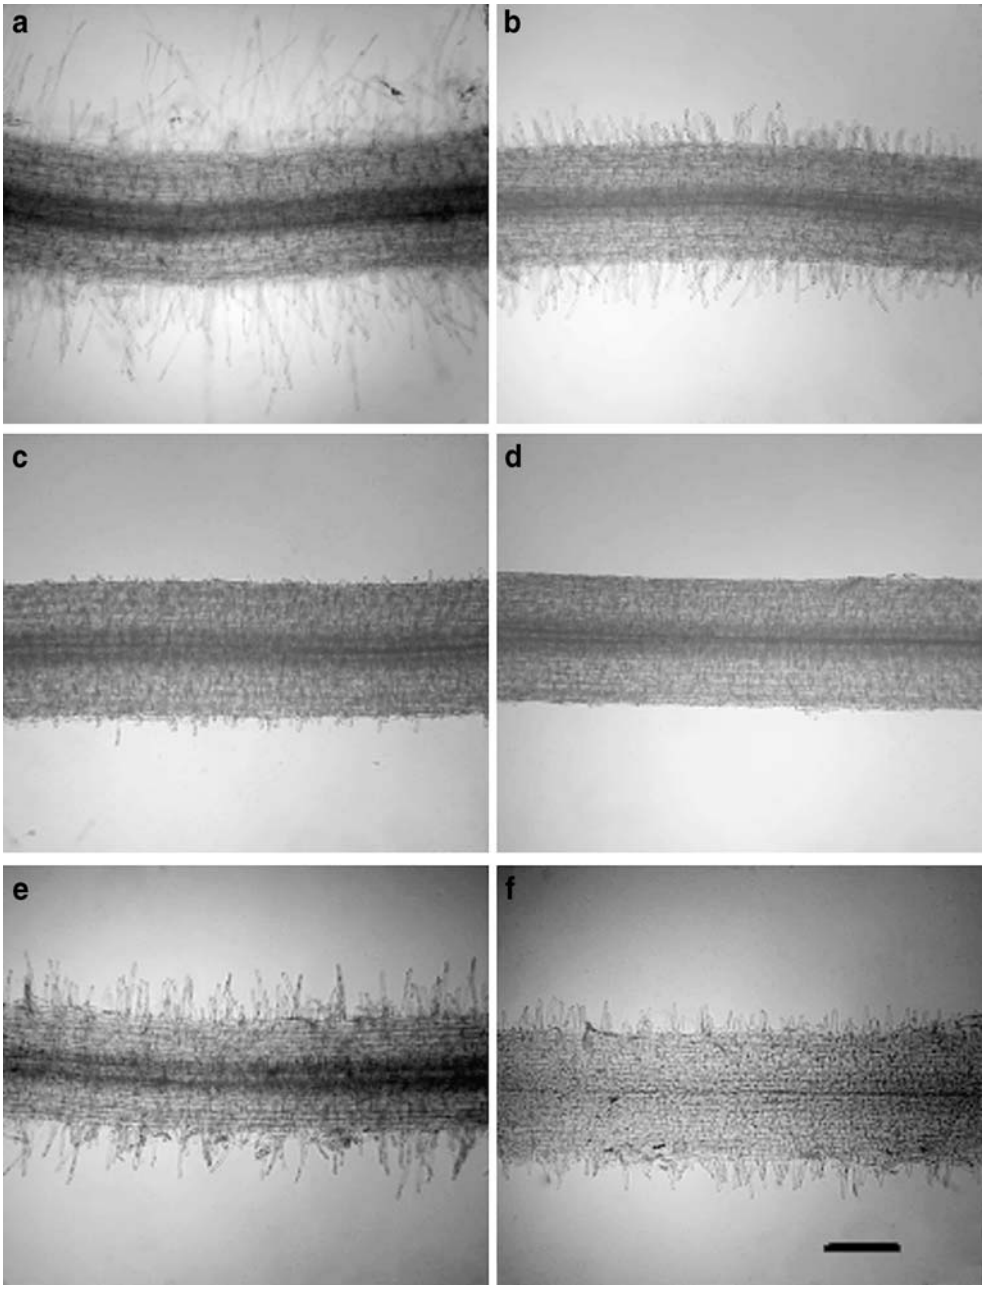

Fig. 6 Representative images showing the inhibitory effects of leukamenin E and Ag^{+} on root hair development in lettuce seedlings 48 h after treatment. **A** Control; **B**–**D** treatments with 20, 40, and 80 μM leukamenin E, respectively; **E** and **F** treatments with 0.5 and 4 mM Ag^{+}, respectively. *Bar*=200 μm

mitotic index. However, according to Borboa and De La Torre (2000), plant cells with unrepaired chromosomal damage can overcome the G_2/M-checkpoint pathway and enter mitosis, giving rise to chromosomal aberrations (e.g., chromosome bridges in anaphase). Our results support this since a low incidence of aberrant mitosis was observed following leukamenin E treatments (at 100 and 200 μM), some of which may be related to DNA damage. In plants treated with the two highest concentrations of leukamenin E (100 and 200 μM), the percentage of cells in metaphase relative to the number of mitotic cells increased, while the percentage of cells in prophase decreased compared with controls. Such a phenomenon might be accounted for by alterations in mitotic spindle microtubules, which could delay chromosome segregation and increase the percentage of metaphases (Fusconi et al. 2007). However, interference with tubulin or microtubules in general often causes a large increase in metaphase that was not observed. This may be explained by speculation that higher concentrations of leukamenin E (100 and 200 μM) are insufficient to induce large increases in metaphase, since aberrant mitosis that may arise from abnormal microtubule pattern did not occur in higher percentage at these two concentrations. In short, root growth inhibition caused by leukamenin E was mainly

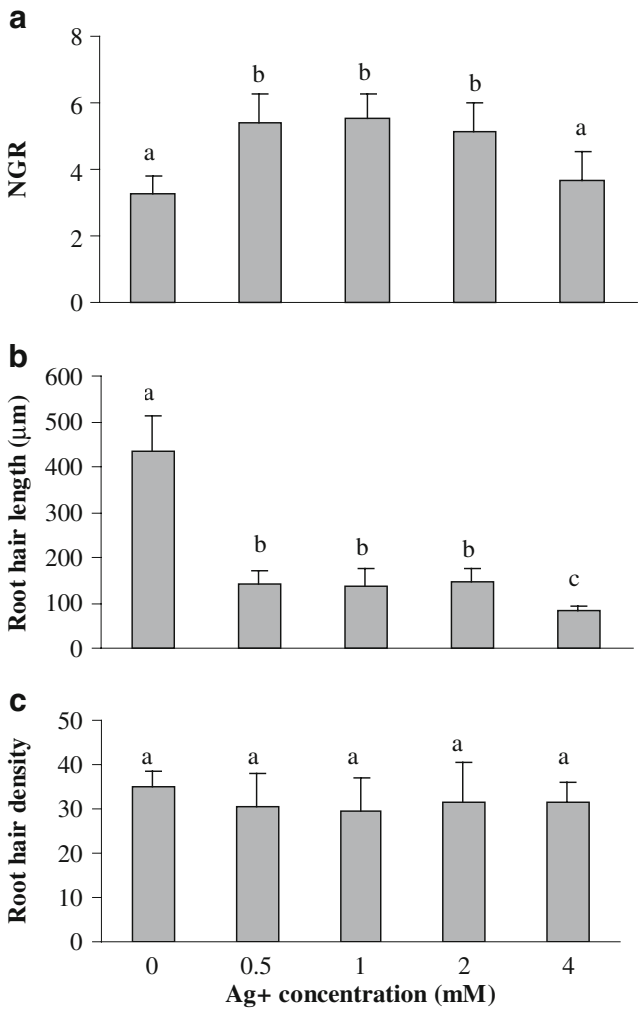

Fig. 7 Effect of Ag^+ on root growth and root hair development in lettuce seedlings 48 h after treatment. NGR were calculated to evaluate the effects on root growth (**A**); root hair development was evaluated in terms of root hair length (**B**) and root hair density (**C**). Root hair density was measured as the number of root hairs per 424 μm of root segment. *Different letters* indicate significant differences at $P \leq 0.05$. *Bars* indicate SD

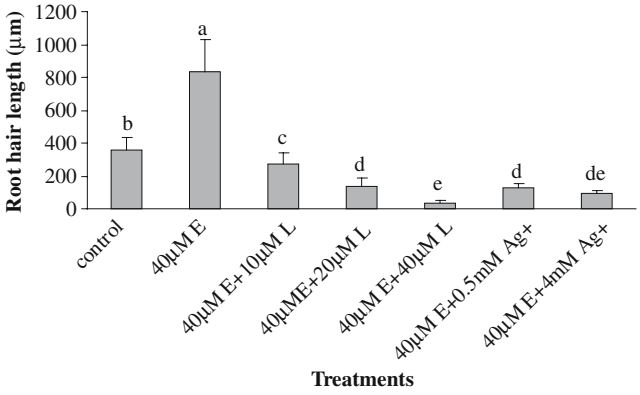

Fig. 8 Enhanced root hair length caused by 40 μM ethephon could be counteracted by addition of both leukamenin E and Ag^+. Ethephon (40 μM) and different concentrations of leukamenin E or Ag^+ were applied simultaneously to lettuce seedlings; the average root hair length was evaluated after 48 h. *E* represents ethephon and L leukamenin E. *Different letters* indicate significant differences at $P \leq 0.05$. *Bars* indicate SD

the result of a decreased mitotic index, possibly by arresting the cell cycle.

Many terpenes are antagonistic to ethylene action (Sisler et al. 2006). Consequently, we investigated whether leukamenin E could act as an ethylene antagonist and inhibit root hair development. Our results suggest that the diterpene may be an ethylene antagonist. Experiments that involve the simultaneous addition of ethephon and leukamenin E or ethephon and Ag^+ confirmed that enhanced root hair length induced by ethephon could be reversed by addition of either Ag^+ or leukamenin E. Seedlings with suppressed root hairs that were treated with leukamenin E (40 or 80 μM) could not be reversed by exogenous application of ethephon (10–80 μM; data not shown), suggesting that leukamenin E may interfere with the ethylene response pathway instead of ethylene biosynthesis as with Ag^+. Leukamenin E inhibited root hair elongation in a dose-dependent manner and completely blocked root hair initiation at 80 μM. In contrast, the inhibitory effect of Ag^+ on root hairs length was not dose-dependent. Leukamenin E (above 40 μM) decreased root hair density while remaining stable with increasing concentrations of Ag^+. Differences between the interfering mechanism of Ag^+ and leukamenin E are apparent even though both inhibit root hair length by interfering with ethylene action.

Inhibition of root growth is a characteristic ethylene response. A simple explanation for ethylene-triggered root inhibition is that ethylene induces *WEI2/7* expression

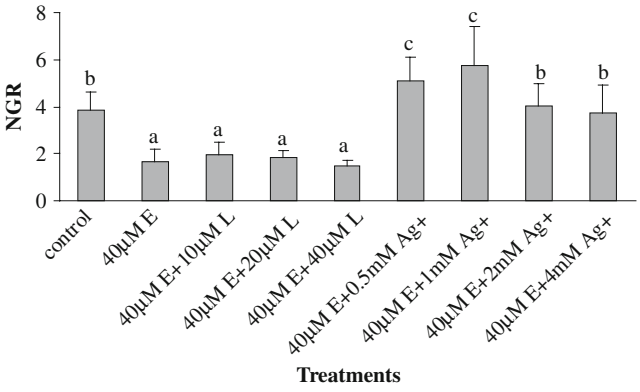

Fig. 9 Effects of leukamenin E and Ag^+ on root growth caused by ethephon. Ethephon (40 μM) and different concentrations of leukamenin E or Ag^+ were applied simultaneously to lettuce seedlings. Root NGR were calculated 48 h after treatment; *E* represents ethephon and L leukamenin E. *Different letters* indicate significant differences at $P \leq 0.05$. *Bars* indicate SD

specifically in root tips, which in turn accelerates auxin biosynthesis and consequently inhibits root elongation (Li and Guo 2007). Investigations with Ag^+, a specific ethylene action inhibitor, showed that lower concentrations of Ag^+ (0.5–2 mM) promoted root growth. Since ethylene generally inhibits root growth, it is reasonable to suspect that interference of ethylene action by Ag^+ could result in root elongation, which is supported by our finding that ethephon-shortened roots were reversed by simultaneous application of Ag^+. In contrast, root growth in lettuce seedlings was significantly reduced when treated with leukamenin E through the suppression of mitotic activity. Stimulatory effects on root growth were not detected at lower concentrations, indicating that the diterpenoid may affect root growth by a mechanism different from Ag^+. Moreover, addition of leukamenin E did not overcome the inhibitory effect on root growth caused by ethephon as Ag^+ did. It is possible that leukamenin E interferes with the downstream portion of the ethylene pathway, thus, specifically controlling root hair development instead of affecting root growth. Its inhibitory effects on root growth are largely attributed to the decreased mitotic index, while Ag^+ may interact with an ethylene receptor (Rodríguez et al. 1999) at a point upstream in the ethylene pathway, thus, both affecting root hair development and root growth.

In summary, our research demonstrates the potential phytotoxic effects of leukamenin E on root growth and root hair development in lettuce seedlings and offers a plausible mechanism for this action. Studies are needed to confirm the role of leukamenin E in mediating ecological interactions. In addition, further investigation is necessary to determine whether leukamenin E possesses activity that is antagonistic to other ethylene responses. If so, it is possible that such research may have commercial relevance, such as prevention of fruit ripening and flower senescence.

serious impacts on plant communities, but the extent of the effect is largely unknown (Ro et al. 2001; Pagel Brown et al. 2007).

Acid rain, as a result of atmospheric pollution, can have detrimental effects on terrestrial and aquatic ecosystems (US-NAPAP 1991). For example, in forest ecosystems, soil acidification is thought to be responsible for a decline in plant health (Aber et al. 1982; Xin et al. 2007). Acidification of soil causes damage to the fine roots of plants that results in leakage of nutrients and directly impacts the soil microbial communities required for plant health and maintenance (Malinowski et al. 1998; Illmer et al. 2003). For example, studies have shown that mycorrhizal associations present in healthy forest trees are poorly developed or absent in unhealthy trees exposed to acid rain (Dighton and Skeffington 1987).

Industrial pollution is pervasive and may comprise organic and inorganic chemicals that may be toxic to plants and their supporting microbes (Kasurinen et al. 2007). Acidification of soils, a byproduct of industrial pollution, increases metal bioavailability (Bergholm et al. 2003; Wang et al. 2006) and exacerbates the detrimental effects of metal pollutants on plants and microbes. All plants have the ability to perceive stresses such as high CO_2, soil acidification, and heavy metal exposure and can initiate complex physiological responses that mitigate impacts of these stresses (Bohnert et al. 1995; Kasurinen et al. 2007). However, few plants are capable of thriving in high stress habitats. The adaptation to stressful habitats is considered to involve changes in the genome (Robe and Griffiths 2000; Schurr et al. 2006) as well as associations with various microbes that are important for health and maintenance of plant systems (Petrini 1996; Rodriguez et al. 2008). Over the last half century, researchers have become concerned about hyperaccumulation of heavy metals in plants due to the alarming increase in industry induced heavy metal contamination and soil acidification (Wang et al. 2005). These metals are easily taken up by roots and translocated to different plant organs (Baker et al. 1994), and high accumulation generally causes growth inhibition and even plant death (Khan and Khan 1983).

The aim of this study was to compare the stress tolerance ability of one plant species growing in industrially contaminated and noncontaminated soils. In South Korea, the invasive weed *Phytolacca americana* has become established in both contaminated and noncontaminated areas (Park et al. 1999, Kim et al. 2005a, b). Here, we present the first chemical studies of *P. americana* plants from two different locales: industrially contaminated soils of Ulsan (acidified soil, metals, and heavy metals) and noncontaminated soils from Suwon, South Korea. Collectively, field and laboratory-generated plants were analyzed and compared for chemical composition and plant response to abiotic stresses associated with global warming (elevated temperature and CO_2) and acid rain (soil pH).

Methods and Materials

Plant and Soil Collection P. americana plants and seeds were collected from contaminated Ulsan (Kyunnam Province) and noncontaminated Suwon (Kyunggi Province) soils, South Korea. The organic plant debris layer surrounding the plants was removed and discarded, and the upper 5 cm of soil (approximately 200 g) was collected in plastic baggies and maintained at 4°C until processed.

Endophyte Profile Analysis of Plants and Soil Greenhouse studies were conducted by propagation of PaU and PaS plants generated from seeds collected from Ulsan and Suwon sites, respectively. For endophyte profile analysis, seeds with their seed coats and plant tissues were surface sterilized in 2% sodium hypochlorite for 10–30 min and rinsed in ten volumes of sterile distilled water. Seeds (N=100) and plant tissues (N=6; cut into roots, stem, and leaf sections) were placed on 0.1× potato dextrose agar (PDA) medium supplemented with antibiotics (100 ug/ml ampicillin and streptomycin, 50 μg/ml tetracycline; Redman et al. 2002a). Soils and plant tissues were processed for endophyte colony forming units (CFU) and percentage colonization of plant tissues, respectively. Soil was homogenized in plastic baggies, passed through a 2-mm soil sieve, 3 g resuspended in 30 ml of sterile water, and 100 μg/ml plated onto 0.1× PDA plates. One gram of surface sterilized plant tissues (Redman et al. 2002a) was homogenized, resuspended in 3 ml of STC (1.2 M Sorbitol, 10 mM TRIS pH 8.0, 10 mM $CaCl_2$) and 500 μg/ml were plated onto 0.1× PDA medium. All plates were maintained at 28°C with a 12-h light regime for 10 days and assessed for fungal colonization. Fungi were identified by using standard taxonomic, microscopic, and molecular techniques (Barnett and Hunter 1998; Redman et al. 2002a). CFU analysis was repeated a minimum of three times.

Soil and Plant Chemical Analysis Soil from Ulsan and Suwon were air-dried and passed through a 2-mm soil sieve. Root and leaf samples of PaU and PaS field plants were oven-dried at 60°C for 48 h and then ground and passed through a 2-mm sieve. Soil and plant tissues were analyzed by using standard protocols for pH, total nitrogen, Cl (Piper 1966), various compounds and metals (B, Al, Co, Cd, Cu, Fe, Mn, Ni, Pb, Zn, As; Agricultural Improving Institute 1988), available phosphate, (Agricultural Improving Institute 1988), suggested exchangeable ions ($(Na^+$, K^+, Mg^{++}, $NO3^-$) Page et al. 1982), and total phenolic compounds (Swain and Hillis 1959) see below.

Total Phenolic Compounds Two hundred grams of fresh PaU and PaS leaf and root tissues were extracted in 1 L of distilled water at room temperature for 48 h and centrifuged at 15,000 rpm for 30 min (Centrikon T-1045, Kontron Co). For soil sampling, the upper 5 cm of soil was collected under a patch of *P. americana* after removing the organic layer. Ten g of PaU and PaS soils were resuspended in 50 ml of sterile water. The supernatant was collected and stored at 4°C (Inderjit 1996). Total phenolic compounds in plant materials (leaves and roots) and soils were analyzed by the Folin–Denis reagent method (Swain and Hillis 1959). All assays were repeated a minimum of three times.

Chlorophyll Content The total chlorophyll content (chlorophyll a and b) of leaves was determined by using standard protocols (MacKinney 1941). Four mature leaves that were 15 cm above the pot soil base for each treatment were measured for chlorophyll content. A minimum of ten measurements per leaf was taken and recorded.

Simulated Acid Rain Stress Uniformly sized PaU and PaS seeds were sterilized for 3 min in 5% sodium hypochlorite solution, and then rinsed with 7–10-fold volume of distilled water. Using a modified bioassay of Lodhi (1976), 30 seeds were sown in a petri dish (diameter of 90 mm) and treated with simulated acid rain (pH 2 to 8) solutions (Park et al. 1999). Seeds were placed in an incubator at 28°C under 400 μmol/m^2/s fluorescent lighting with 16/8 h L/D period for 6 days. Seed germination, growth, and biomass were assessed daily. All assays were replicated a minimum of three times.

Statistical Analysis Data were normally distributed, and significant differences between treatments and controls were calculated with Duncan's mean separation test for the measured parameters (SAS INSTITUTE 2000). The data given in tables and figures are the mean ± SE.

Results

Chemical analysis of the soils and plants (roots and leaves) from contaminated Ulsan and noncontaminated Suwon sites was performed to measure various elements and metals, pH, and total phenolics (Table 1). Statistical analysis revealed that all of the elements analyzed and total phenolics were significantly higher in Ulsan soils. In addition, Ulsan soil pH (3.84) was significantly more acidic than Suwon soil pH (5.82). Of the metals analyzed, Al, Fe, and Mn were in highest abundance (approximately 3, 129, and 14 times, respectively) in Ulsan soils compared to Suwon soils. A similar pattern was observed in the plant leaf tissues with elevated levels of Al, Fe, and Mn at 50.41, 18.30, and 69.45 mg/l in Ulsan plants (PaU) compared to 1.49, 2.80, and 3.11 mg/l in Suwon plants (PaS). Overall levels of these compounds in roots was lower than in leaf tissues; however, differences between PaU and PaS root

Values represent mean ± SE (N=4) and mean values with the same letter are not significantly different (Duncan's multiple range test, P<0.001). Values in bold indicate significant differences between Ulsan and Suwon soils or *P. americana* plants (roots and leaves) harvested from Ulsan (PaU) and Suwon (PaS) field sites

TP total phenolic compound levels, *ND* not detected

tissues were not significant (Table 1). The pH of leaves and plant tissues were similar in both PaS and PaU plants with the pH ranging from 5.92–5.42 and 7.55–7.47 in the leaf and root tissues, respectively (Table 1). Analysis of total phenolic compunds indicated that they were more than three times higher in Ulsan soils compared to Suwon soils. Similarly, total phenolic compounds were approximately twice as high in both the plant leaf and root tissues of PaU plants compared to PaS plants (Table 1).

Nutrient composition of PaU and PaS plant tissues were also analyzed (Table 2). PaU leaf tissues had elevated levels of Cl, NH_4, N, P, and S compared to PaS plants with N, Cl and S being 846, 11.8, and 1.98 times higher in PaU leaves, respectively. In contrast, PaS plant leaves had elevated levels of K, Na, Ca, and Mg compared to PaU leaf tissues. With the exception of Ca, Na, Mg, and K, all elements tested were higher in PaU roots compared to PaS root tissues. Of these elements, Cl, N, P, and S were notably higher in PaU roots compared to PaS roots (Table 2).

The effects of simulated acid rain (pH 2–6.4) on PaU and PaS plants was measured by determining the percentage seed germination, total phenolic compounds, and chlorophyll levels in plants, as well as plant growth and biomass (Fig. 1). With the exception of chlorophyll content, the overall pattern in each of these assays was similar: PaU plants had higher seed germination ($P<0.001$), plant growth, and biomass compared to PaS plants for all simulated acid rain treatments ($P<0.001$). The highest seed germination of 100% and 78% and chlorophyll content of 37 and 22 mg/m^3 occurred at simulated acid rain pH 2.0 for both PaU and PaS plants, respectively (Fig. 1A and B). The same pattern was observed with plant growth and biomass of shoot at simulated acid rain pH 2.0, with the highest plant growth of 45 and 38 cm, and plant biomass of 5.4 and 4.2 mg occurred in PaU and PaS plants, respectively (Fig. 1C and D). Assessment of plant seed germination, chlorophyll content, plant growth and biomass over a simulated acid rain pH range (2.0–6.4) showed a similar pattern in that the highest levels were achieved at pH 2.0 followed by a marked decrease at pH 3.0–5.0 and a slight increase at pH 6.4 (Fig. 1A–D) for both PaU and PaS plants. In general, an inverse relationship was observed with total phenolic compounds and pH compared to other parameters (% seed germination, plant growth and biomass), with a general increase in total phenolic compounds occurring from pH 2.0 to 5.0 followed by a slight decrease at pH 6.4 for both PaU and PaS plants (Fig. 1B). In contrast, PaS plants exhibited statistically lower total phenolic compound levels than PaU plants but higher chlorophyll content at pH 2–5 (Fig. 1B).

The effects of varying temperature and CO_2 levels on PaU and PaS plant health was assessed (Fig. 2). The overall effect of the treatments (I–IV) on growth rates of PaU plants was III > I > IV > II, and PaS plants was I > III > IV > II, with PaU plants being larger ($P<0.001$) and maturing faster (onset of flowers and mature leaves; recorded observation; data not shown) than PaS plants. PaU and PaS plants were compared and analyzed for chlorophyll content, plant growth, and total phenolic levels when exposed to treatments I–IV; PaU plants were statistically higher for plant growth and total phenolics compared to PaS plants (Fig. 2A and C). In contrast, PaU plants exhibited statistically lower chlorophyll levels when compared to PaS plants (Fig. 2B). Although PaU and PaS plants were the same age, PaU plants were larger, and tissues were more mature when compared to PaS plants (personal observation, Yong Ok Kim). Leaves were broader and more mature and, as such, exhibited a lighter green color and subsequent decrease in chlorophyll content. The reverse was true for total phenolics with levels in PaU higher when compared to PaS plants.

Six PaU and PaS field plants and 100 seeds from both field sites were surface sterilized and plated on microbial

growth media to determine the plant and seed endophyte profiles. The surrounding rhizosphere soil was collected and analyzed to determine the composition of the soil microbial community. All six of the PaU plants had a fungal endophyte (*Glomeralla acutata*) associated with the leaf and root tissue, as did 97.25% of seeds. No such fungal associations were found in PaS plants and seeds. Analysis of the soils surrounding the plants indicated that the same fungal endophyte was present in Ulsan and absent in Suwon soils (Table 3, $P<0.01$).

Discussion

In 1979, *P. americana* was introduced into South Korea and became an important ecological problem by 1993 when it had spread throughout the country, displacing many native species (Park 1995). *P. americana* is widely distributed in contaminated areas of Korea, and a correlation between plant distribution and pollution absorption from soils has been reported (Park et al. 1999). Little is known about Phytolaccaceae ecology with the exception of a few papers that deal with the invasive threat of *P. americana* in Korea (Kim et al. 2005a, b). The extent of the effects of pollution on plants and the time frame for adaptation to stressful habitats in unknown but thought to involve a combination of plant genome changes and associations with microbes that can hasten the adaptation (within a growing season) in a non-Darwinian manner (Rodriguez et al. 2008). Our studies are the first to address the effects of pollution and global warming related stresses of *P. americana* via plant chemical analysis and the surrounding rhizosphere soils from two different habitats. Interestingly, PaU plants growing in the Ulsan contaminated site were larger (overall height, leaf size and number), more robust, and growing more densely than PaS plants growing in noncontaminated Suwon soils (personal observation, Yong Ok Kim).

It is not surprising that PaU plants had higher concentrations of phenolic compounds in the leaves and roots when compared to PaS plants, since plants exposed to metal or acid stress often produce secondary metabolites that are thought to play roles in plant health and survival (Inderjit 1996; Kasurinen et al. 2007). Terpenoids, flavonoids, alkaloids, and phenolics are the most common allelochemicals, with the latter allelochemical being abundant under field conditions (Seneviratne and Jayasinghearachchi 2003). Phenolic compounds are known to affect seed germination, seedling growth, cell division, fungal activity, protein synthesis, and enzyme activity (Callaway et al. 2004; Vivanco et al. 2004). It has been reported that phenolic-induced oxidative damage is mediated by heavy metals (Sakihama and Yamasaki 2002) and that accumulation of

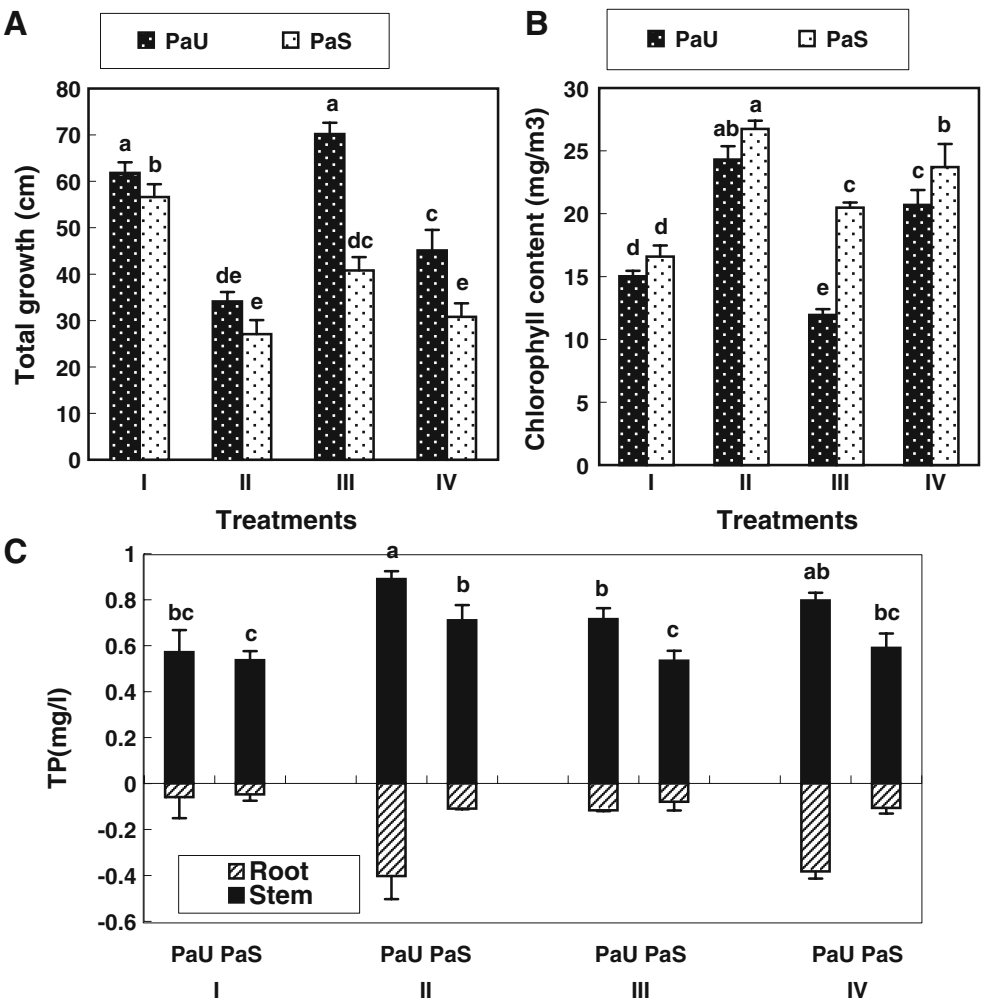

Fig. 2 Comparison of **A** Total growth; **B** Chlorophyll content; **C** Phenolic compound levels of plants grown from seed harvested from Ulsan (contaminated soils) and Suwon (noncontaminated soils) field sites. PaS and PaU plants were exposed to treatments *I* ambient CO_2 (360 µmol mol^{-1} CO_2) and temperature (25°C); *II* double ambient CO_2 (650 µmol mol^{-1} CO_2) and ambient temperature (25°C); *III* increased temperature (30°C) with ambient CO_2; and *IV* increased temperature (30°C) and double ambient CO_2. *TP* total phenolic compound levels; means with the *same letter* are not significantly different (Duncan's multiple range test, **A** and **B**=$P<0.001$, **C**=$P<0.01$), ±SE of $N=10$ measurements each are given

these metals occurs by conjugation with phenolics in various plant organs (Santiago et al. 2000; Lavid et al. 2001). Loponen et al. (2001) studied foliar concentrations of phenolics in contaminated and control areas to detect early symptoms of heavy-metal pollution in birch trees. They found that in heavily polluted areas, atmospheric stress factors appear to be correlated with the accumulation of phenolics in birch leaves (Andrea et al. 2006). In addition, exposure of plants to simulated low-pH acid rain (pH 3.0) conditions resulted in the appearance of necrotic spots on the leaf blades and subsequent accumulation of phenolics in necrotic areas (Sant'Anna-Santos et al. 2006).

Table 3 Comparison of Ulsan and Suwon soils and plant tissues for presence of *Glomerella acutata*

	Ulsan	Suwon

Numbers denote percentage colonization of 100 seeds and colony forming units (CFU) equivalent to 0.17 g of plant tissues ($N=6$) and 10 mg of soil ($N=6$), respectively
ND not detected

Our studies showed that *P. americana* preferentially accumulates metals in leaf tissues compared to root tissues. This was not expected since several studies indicate that plants preferentially accumulate metals in root tissues (Rauser and Meuwly 1995). For example, Nishizono et al. (1987) reported the heavy metals, Cd, Cu, and Zn, accumulated in roots of *Athyrium yokoscense* compared with other organs. Lubben and Sauerbeck (1991) also suggested that roots are the first site of accumulation of heavy metals and subsequent tolerance to heavy metals (Wu and Bradshaw 1972).

Seed germination of both PaU and PaS plants decreased when exposed to simulated acid rain with the lowest germination rates occurring at pH 5.0 and 4.0, respectively. Although seed germination of PaU and PaS increased at pH 6.4, the highest percentage germination occurred at the lowest pH (2.0), and germination rates for PaU were higher

than PaS at all pH levels tested. The growth length, dry weight, and overall health of PaU and PaS were also highest at pH 2.0, with all values greater for PaU. These results are in contrast to those of others (Fan and Wang 2000) that showed simulated acid rain conditions of pH 2.0 caused foliar damage, reduced chlorophyll content, and reduced seedling growth; while seedling growth was simulated at pH levels between pH 3.5 and 5. Regardless, increased germination and growth of PaU plants at pH 2.0 suggests that PaU plants have more tolerance to acid rain than PaS plants.

The phenolic levels of both PaU and PaS plants significantly increased with pH under simulated acid rain conditions, and the phenolic content of PaU plants was higher than that of PaS plants (Fig. 1). Interestingly, in other plants species (*Mimosa artemisiana*, *Gallesia integrifolia*, and Norway spruce), enhanced accumulation of phenolics and development of necrotic spots on leaves occurred upon exposure to acidic pH (3.0; Sant'Anna-Santos et al. 2006). Although phenolic accumulation was directly proportional to pH in *P. americana*, plant growth was inversely proportional to pH, and lesions did not develop at low pH. Therefore, we surmise that the acidic nature of soils and enhanced bioavailability of compounds do not have a negative impact on growth or disease symptom development on PaU plants.

Exposure of plants to different environmental treatments (altered CO_2, temperature, and soil pH) resulted in altered growth rates (Fig. 2). PaU plants grew larger and matured faster in all treatments compared to PaS plants. In addition, the treatments affected plant growth differently with PaU plants having highest growth in treatment III (ambient CO_2 and increased temperature) while PaS plants had the greatest growth in treatment I (ambient CO_2 and temperature). Although the significance of this is not yet known, it demonstrates that PaU and PaS plants are physiologically different.

The chlorophyll content of leaves was greater for PaS plants than PaU plants in every treatment. A contributing factor to the observed overall decrease in plant chlorophyll content in PaU plants growing in contaminated soils is that they grew more quickly (both overall plant height and overall size and number of leaves), and the leaves measured were physiologically more mature than PaS plants. Chlorophyll levels in both plants were highest when the ambient CO_2 levels were doubled. However, measurements of the growth, chlorophyll content, and phenolic levels did not show a significant difference between treatment I of PaU plants when compared to PaS plants. Mature flowers and aging leaves in PaU plants appeared earlier than in PaS plants and, as such, is reflected as a decrease in chlorophyll content in PaU plants. Similarly, Loponen et al. (2001) and Peltonen et al. (2005) reported that elevated CO_2 increased phenolic compound levels by 25%, with phenolic compound levels 21% higher in samples from heavily contaminated smelter areas than from noncontaminated areas. We observed a similar phenomenon with higher levels of phenolics in PaU plants than PaS plants, especially in the roots of plants exposed to treatment II (25°C, 650 ppm CO_2) and IV (30°C, 650 ppm CO_2).

Total phenolic levels in the leaves and roots of treatment I were less than that of the other treatments, and the growth rates decreased, while chlorophyll content increased for treatments II and IV. This suggests that there may be a relationship between growth rates, total phenolic levels, and chlorophyll content.

Microbial analysis showed that a single dominant fungal endophyte (>97%) was present in the contaminated (PaU) and absent in the noncontaminated (PaS) site samples. The endophyte was identified as *G. acutata*, which was isolated from leaves, roots, and seeds, and was also abundant in the surrounding soils (Table 3). Interestingly, the endophyte was in highest abundance (84.53 CFU) in PaU leaves where the highest accumulation of metals was found. The abundance of the endophyte in Ulsan soils, and the variance in abundance levels in the different plant tissue types, suggest that this endophyte may have an ecologically significant role in PaU plants. Recent studies have shown that symbiotic fungi impart habitat-specific stress tolerances and are responsible for the survival of some plants in high-stress habitats (Redman et al. 2002a; Rodriguez et al. 2008). In addition, fungal endophytes are known to promote plant growth (Redman et al. 2002b; Varma et al. 2006). However, the ecological role of endophytes in contaminated habitats has not been well defined. Studies have shown that fungal symbionts have the ability to confer heavy metal tolerance to plants (Monnet et al. 2001). Some fungi produce siderophore and siderophore-like compounds and are able to sequester iron in the surrounding rhizosphere (Wilhite et al. 2001), while other fungi increase translocation of metals to leaf tissues (Al-Karaki et al. 2001).

Although the mechanism is yet unknown, collectively, these studies provide evidence to support the hypothesis that PaU plants have adapted to and are able to thrive in this industrially contaminated high stress habitat. The PaU plants represent acid-rain and heavy-metal-tolerant ecotypes, while PaS plants do not. Although additional work is required, the results presented here are promising and demonstrate the ability of PaU pokeweed plants to absorb and translocate metals to leaf tissues. As such, the results suggest that this system may be developed as a potential useful phyto-remediation tool to clean-up contaminated soils.

via lolines as "exogenous resistance" since it originates from the symbiont rather than the grass itself.

Plants, particularly dicotyledonous ones, often can respond directly to damage by producing their own defensive chemicals (Karban and Myers 1989). We refer to this as "endogenous resistance." The response involves signaling pathways within the plant that are activated and which lead to the synthesis of many different secondary metabolites (McConn et al. 1997). The induced response is thought to be a tactic that allows plants to produce defensive compounds only when they are needed.

One signaling molecule used by many plants is jasmonic acid (JA), a ubiquitous phytohormone, synthesized through the octadecanoid pathway (Gols et al. 2003). Following herbivore feeding, endogenous concentrations of JA rapidly increase and lead to activation of numerous genes (Farmer and Ryan 1992; Reinbothe et al. 1994). Methyl jasmonate (MJ) and JA are known to regulate a number of physiological processes in plants that include the induction of proteinase inhibitors, meristematic growth, senescence, vegetative storage proteins, and interplant signals (de Bruxelles and Roberts 2001). Jasmonates also are involved in signal transduction, especially in relation to defense gene activation (Gunlach et al. 1992; Wasternack 2007).

Interactions between the endogenous inducible defenses of grasses and those provided through symbiotic endophytes (exogenous) have not been studied previously. By examining two inducible systems of defense, loline synthesis by *Neotyphodium* and tall fescue defense gene activation by jasmonates, we can learn more about their interactions and possible antagonistic or synergistic relationships. Additionally, the study of these defense systems may lead to a better understanding of the signaling that takes place between fungus and its host plant. We formulated two competing hypotheses: (a) *Neotyphodium coenophialum* responds to MJ by upregulating loline synthesis (either by responding directly to MJ or to biochemical signals produced by the plant in response to MJ), and (b) the plant responds to MJ by upregulating its own defensive chemicals and this response compromises the ability of *N. coenophialum* to produce lolines.

Methods and Materials

Plant Growth Tall fescue K-31 (*Lolium arundinaceum)* was planted in April 2007 into Sungrow Sunshine LC1 professional potting soil topped with vermiculite in 15.3-cm-diameter pots. Seeds were provided by H. Fribourg at the University of Tennessee (Knoxville, TN, USA) in 2001 and stored at −10°C until use. Infected seeds were obtained from infected plants (*N. coenophialum* is naturally transmitted through host seed) while plants free of endophyte infection were produced by heat treatment of seeds (Nott and Latch 1993) in the 1980s followed by subsequent annual cultivation of plants for seed production. Our plants were grown in a greenhouse with natural light [supplemental light (14-h L:10-h D) was also used for the first 6 weeks of growth]. Temperature varied from 15°C to 40°C. Seeds containing the fungal endophyte *N. coenophialum* were planted into 72 pots, while endophyte-free seeds were planted into 96 pots. After plants emerged from the soil, they were thinned to one plant per pot. Plants were fertilized every 1–2 weeks for the first 5 weeks with1.5-g/l solution of 5% NH_4, 10% NO_3, 16% P_2O_5, and 17% K_2O (Pro Sol Ozark, AR, USA). Plants were subsequently fertilized consistently on a weekly basis.

Plant Treatment

Experiment I. Eight weeks after germination, 31 infected and 58 infection-free plants were placed randomly into a controlled environmental chamber (185 cm L×77 cm W×178 cm H; 1.7-m^2 growth capacity; 22°C) with continuous airflow (0.15 m^3/min) for MJ exposure. Five cotton swabs were first submerged in MJ (95%, Sigma-Aldrich) and then suspended in the headspace. Plants were exposed for 3 h. Similar exposures to gaseous MJ have been used (Farmer and Ryan 1990; Hall and Horton 1994; Matsui et al. 1999); yet, generally, these are done in relatively small sealed containers, whereas ours was conducted in a large chamber with mixing of air from the outside. More commonly, MJ is applied directly to leaves as a spray (e.g., Thaler 1999). We did not quantify the amount of MJ applied to swabs, and the level we used may have been higher than what might occur in the headspace of grasses in nature, yet, since our primary goal was to determine if and how the fungus responds to MJ exposure, we wanted to provide a sufficiently strong signal to elicit a possible fungal response. It is possible that the MJ concentration we used was toxic to *N. coenophialum*, but this seems unlikely since the fungus lives within the intercellular spaces within the plant. At the conclusion of the exposure, plants were removed from the chamber and returned to the greenhouse. Nonexposed plants (N=79) were not placed into controlled environmental chambers due to the short duration of the treatment (3 h) and because all controlled environment chambers are in the same room, thus leading to the possibility that aromatic MJ from the treatment cham-

bers would contaminate chambers in which control plants would have been placed. In sum, four treatment combinations were produced in the two-way design: infection free–MJ free, infection free–MJ-exposed, infected–MJ free, and infected–MJ-exposed.

Experiment II. A second experiment was conducted to determine if MJ exposure would compromise the ability of *Neotyphodium* to mount a wound-inducible response of loline biosynthesis (as had been shown by Bultman et al. 2004 and Sullivan et al. 2007). Ten weeks after germination, all 28 plants (14 endophyte-infected and 14 endophyte free) were cut with scissors to 15.3 cm above the soil surface to simulate vertebrate grazing. At 10.5 weeks of age, all 28 plants were placed in a controlled environment chamber for MJ exposure. Plants then were returned to the greenhouse. Hence, Experiment II had the same design as Experiment I except that plants in Experiment II had been mechanically damaged prior to MJ exposure.

Herbivore Resistance

Experiment I. Three days after exposure to MJ and 9 weeks after germination, a bioassay was performed with *R. padi* (bird cherry oat aphid). Aphids were obtained from S. Clement (ARS-USDA, Pullman, WA, USA) and were reared on barley at 20°C prior to use in the experiment. Four aphids (second- and third-instar nymphs) were placed in a mesh clip bag that was secured to the newest fully expanded leaf blade of the largest tiller. Plants (N=20–26 per treatment combination) were placed on lighted plant stands (14:10 h, L:D) for 7 days at 21°C. *R. padi* reproduces parthenogenetically while feeding on grass host plants (Leather et al. 1989) and has been used extensively in grass–endophyte research (Eichenseer et al. 1991; Siegel et al. 1990; Breen 1994; Bultman et al. 2004). After 7 days, clip bags were removed from the plants, and the apterous aphids were counted.

Experiment II. Three days after exposure to MJ and 1 week after damage, an aphid bioassay identical to that described for Experiment I was performed.

Loline Extraction and Analysis Samples were taken 10 days after MJ exposure for loline analysis from four endophyte-infected control (not exposed to MJ) plants and four infected plants exposed to MJ. Three to four tillers of fresh material were cut from each plant. Plant material was freeze-dried and finely ground with a Wiley mill and then stored at −20°C. Analysis of lolines followed that of Bush et al. (1982). Briefly, 100 mg of ground plant tissue were added to 95:5 dichloromethane–ethanol and 100 ml saturated sodium bicarbonate. The plant mixture was vortexed and centrifuged, and the liquid layer was pipetted into a test tube. Nitrogen gas was blown onto the surface of the liquid layer to concentrate the solution. The solution was filtered with a syringe and placed into a gas chromatograph (GC)–mass spectrometer (MS) vial for analysis. Samples were inspected for retention times at 5.68 min for *N*-formyl loline and 5.94 min for *N*-acetyl loline with mass peaks at 82. Standards for comparison were obtained from L. Bush (University of Kentucky). Samples that were prepared and not immediately run were refrigerated for no more than 24 h before analysis on GC–MS.

RNA Extraction and Quantification of LolC Samples for analysis with real-time reverse transcriptase (RT)-polymerase chain reaction (PCR) were obtained at both 0.5 and 1.5 weeks after MJ exposure (we sampled at two dates to determine if fungal response varied over that time frame). Fresh tissue (150 mg) was harvested from the base of the youngest fully expanded leaves from two tillers per plant (N=4 plants per treatment combination per date), as in Sullivan et al. (2007). The tissue was stored at −80°C. Samples were prepared by grinding them in liquid nitrogen into a powder with mortar and pestle. RNA was extracted by using the RNAeasy minikit (Qiagen). Purified RNA was quantified by using a Hitachi U-2000 spectrophotometer (Sullivan et al. 2007). Probes, primers, and conditions described by Spiering et al. (2005) were used for the quantitative real-time RT-PCR. Primers specific for one of the loline biosynthesis genes, *LolC*, were used in the assay (Spiering et al. 2005). The amount of β-tubulin mRNA was used as a reference for the amount of fungal RNA in the sample. The reaction was performed by using the Brilliant II QRT-PCR Master Mix Kit (Stratagene) on a Smart Cycler II (Chepheid; Sullivan et al. 2007). One-hundred nanograms of total RNA were used in each reaction, and all reactions were run in triplicate. All runs included a negative control (H_2O) to ensure that no contamination was present, and a no-reverse-transcriptase control was run for every sample to ensure that there was no contaminating genomic DNA. RT-PCR can have significant variability among individual reactions as a result of stochastic variation (Keilholz et al. 1998); for this reason, replicate samples were not considered valid if the coefficient of variation in cycle threshold values varied by >5%. Plants used in the

RNA samplings were not used in any subsequent experiments to ensure that damage caused by the sampling was not causing a defense response (Sullivan et al. 2007).

Statistical Analysis Statistical analysis was performed with Systat (Systat 2004). Analysis of bioassay data (number of aphids per plant) was carried out with a two-way analysis of variance (ANOVA) to compare the effects of MJ and infection on the performance of *R. padi.* Aphid number was ranked prior to analysis to correct for departures from normality (Conover and Iman 1981). Loline data and mRNA data were analyzed by using a two-sample *T* test or its nonparametric equivalent where appropriate.

Results

Effects of Methyl Jasmonate Exposure on Herbivore Resistance

Experiment I. We tested whether or not the alkaloid-mediated insect resistance that *N. coenophialum* provides its host plant is influenced by MJ exposure. We found that fungal infection reduced aphid numbers (Fig. 1; $F_{1,\ 96}$=199.4, P<0.001). In contrast, there was no difference in aphid numbers between plants treated with MJ and those left untreated ($F_{1,\ 96}$=0.04, P=0.84). Interestingly, there was an interaction between endophyte infection and MJ exposure ($F_{1,\ 96}$=13.15, P<0.001). Endophyte-free plants treated with MJ showed increased resistance to aphids compared to endophyte-free unexposed (control) plants, while endophyte-infected plants exposed to MJ were less resistant to aphids than unexposed (control) plants (Fig. 1).

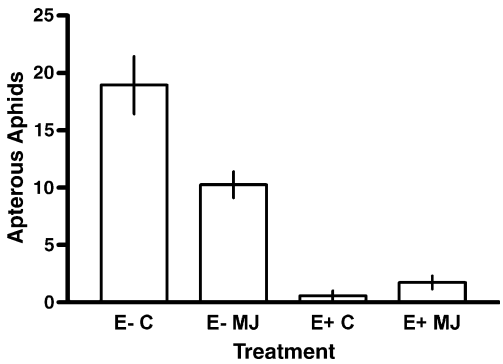

Fig. 1 Effects of methyl jasmonate (*MJ*) exposure to tall fescue plants in Experiment I on *R. padi* aphid performance. The experiment was a two-way ANOVA design with main effects of MJ exposure and endophyte infection. The two main effects interacted to affect aphid numbers ($F_{1,\ 96}$ =13.15, P<0.001). Sample sizes varied from 20 to 26 plants for each treatment combination. *Error bars* are mean+1 SEM throughout. Labeling: *E+* = endophyte-infected plants; *E−* = endophyte-free plants; *C* = control (no MJ exposure); *MJ*=methyl jasmonate exposure

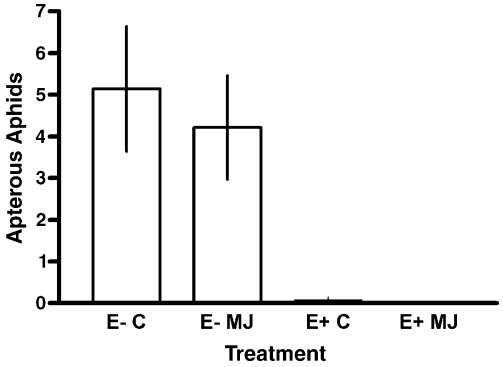

Fig. 2 Effect of main effects methyl jasmonate (*MJ*) exposure and endophyte infection on aphid performance in a two-way ANOVA design experiment. In contrast to Experiment I, all plants in Experiment II were mechanically damaged prior to MJ exposure. Samples sizes were 14 plants per treatment combination. The main effect of endophyte infection reduced aphid numbers ($F_{1,\ 52}$=80.4, P< 0.001), while MJ exposure did not (see text). Labeling as in Fig. 1

Experiment II. After mechanical wounding and exposure to MJ, a bioassay for herbivore performance was performed at 11 weeks postgermination. Analysis of variance showed that aphid numbers were lower on infected plants (Fig. 2; $F_{1,\ 52}$=80.4, P<0.001). There was no effect of MJ on aphid numbers ($F_{1,\ 52}$= 0.8, P=0.37) nor was there an interaction between endophyte infection and treatment ($F_{1,\ 52}$=0.13, P=0.72).

Loline Analysis

Experiment I. The quantity of total lolines (*N*-acetyl loline and *N*-formyl loline) produced by *N. coenophialum* in plants treated with MJ appeared to be lower than in control plants at 10 weeks postgermination, yet the trend was not significant (Fig. 3, Mann Whitney U=12.0, df=1, P=0.25).

Experiment II. Having found in Experiment I that MJ compromised endophyte-mediated constitutive resistance to aphids, we tested whether or not exposure also compromises inducible resistance provided by *N. coenophialum*. Endophyte-infected plants that had been mechanically damaged were subsequently exposed to MJ to determine if exposure would compromise the normal wound-induced response of elevated loline

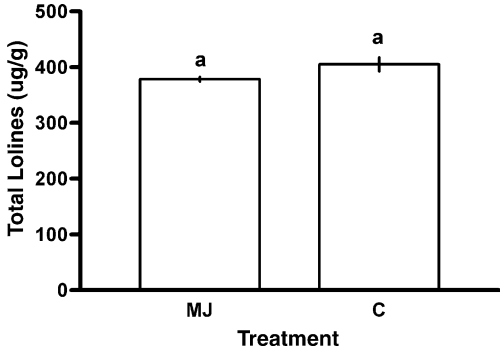

Fig. 3 Effect of methyl jasmonate exposure on total loline production by endophyte-infected tall fescue in Experiment I (Mann Whitney U=12.0, df=1, P=0.25). Labeling: C=control (no MJ exposure); MJ=methyl jasmonate exposure. *Common letters* over histograms represent lack of significant difference between means

production (Bultman et al. 2004). We found that total loline concentration at 2 weeks after mechanical wounding was lower in MJ-exposed compared to unexposed plants (Fig. 4; T=4.47, df=5, P<0.01).

Quantification of Loline Biosynthesis Gene

Experiment I. Samples for real-time RT-PCR analysis were taken at 8.5 and 9.5 weeks after germination to determine if MJ exposure influenced the regulation of the loline biosynthesis gene. The trends in the data were the same from both sampling times, and as such they were combined. We found that infected plants exposed to MJ had significantly lower levels of mRNA for the *LolC* gene compared to unexposed plants (Fig. 5; T=3.2, df=5, P<0.05).

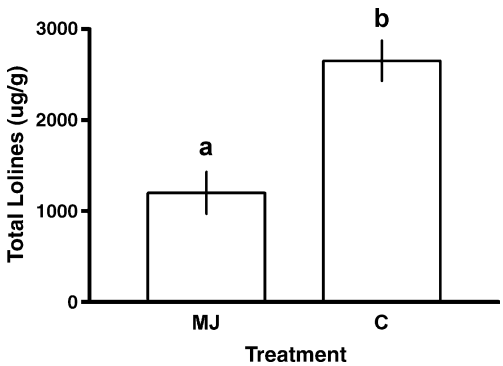

Fig. 4 Effect of methyl jasmonate (MJ) exposure on total loline production by endophyte-infected tall fescue following cutting. Significant differences between means denoted by histograms with *different letters*. Labeling as in Fig. 3

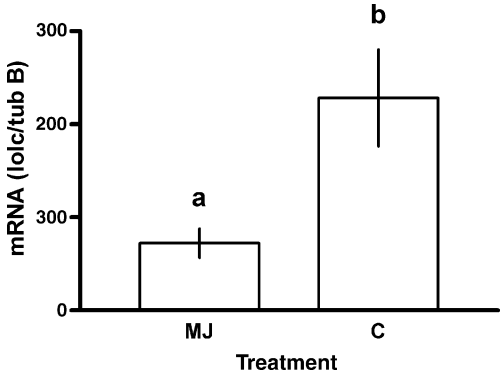

Fig. 5 Effects of methyl jasmonate (MJ) exposure on *LolC* mRNA production by *N. coenophialum* growing within tall fescue plants in Experiment I (T=3.2, df=5, P<0.05). Sample size was four plants per treatment combination. Significant differences between means denoted by histograms with *different letters*. Labeling as in Fig. 4

Discussion

Both exposure to MJ and infection by *N. coenophialum* heightened resistance to aphids in tall fescue plants, although the latter provided substantially stronger protection. While grasses are known to produce some antiherbivore compounds, like DIMBOA (Klun et al. 1967; Russel et al. 1975), which may even be wound inducible (Gutierrez et al. 1988), compared to other angiosperms, grasses are generally thought to be poorly defended. Instead of investing in defense, they appear to opt for herbivore tolerance. They have meristematic tissues close to the ground, which makes them more tolerant of herbivore damage, and they rapidly grow back tissue lost to herbivores (Barnard and Frankel 1964; Stebbins 1981). The discovery that fungal endophytes produce toxins suggests that many grasses utilize these symbionts, thus providing defense against herbivores that they would otherwise lack (Cheplick and Clay 1988; Bultman et al. 2004). Our study shows that exposure to MJ stimulates tall fescue to mount its own defense (in the absence of the endophyte) against *R. padi* aphids (Fig. 1). The defensive compounds responsible for this result are unknown but apparently are produced by the plant through an MJ-initiated biochemical cascade. While the role of jasmonates in monocotyledonous plants has not received a great deal of attention, they have been shown to play an important role in activation of pathogen defense genes (Mei et al. 2006) and to induce volatile emission that enhances parasitism of planthopper pests in rice (Lou et al. 2006). Interestingly, naturally uninfected tall fescue is more resistant to aphids than manipulatively endophyte-free plants (Lehtonen et al. 2005), suggesting that plants lacking a history of endophyte

infection are more able to mount an endogenous defense than those that have been recently disinfected.

Our results suggest that, even though tall fescue can mount an endogenous defensive response, plants that are infected with *N. coenophialum* should be at a selective advantage due to the heightened herbivore resistance that the fungus provides (Fig. 1). Indeed, this expectation has been repeatedly demonstrated by investigators (Clay 1991; Latch 1993; Breen 1994; Clement et al. 1994; Bush et al. 1997; Saikkonen et al. 1998; Faeth and Bultman 2002; Lehtonen et al. 2005). Most populations (whether managed or not) of tall fescue in the USA are highly infected with *N. coenophialum*, suggesting a selective advantage (Clay 1990).

We found that MJ exposure hindered the ability of *Neotyphodium* to produce lolines, alkaloids that reduce aphid performance (Fig. 4), and that MJ-treated infected plants were more susceptible to aphids than infected plants not exposed to MJ (Fig. 1). This is a noteworthy finding as it tells us about the signaling between fungus and plant. The fungus does not use MJ [which normally would be produced by the plant in response to stresses, like herbivory (see Creelman and Mullet 1997)] as a signal for production of lolines. In fact, just the opposite occurs. The presence of MJ compromises the fungus' ability to provide exogenous resistance to its host through the synthesis of lolines. Thus, we can rule out our hypothesis that the fungus uses MJ as a signal for loline synthesis. Rather, the competing hypothesis that MJ stimulates biochemical pathways within tall fescue that are antagonistic to loline production is supported. Moreover, the biochemical cascade that MJ initiates also inhibits the transcription of a loline biosynthesis gene in *N. coenophialum* (Fig. 5). These molecular data reveal that the effect of MJ on fungal loline production is not a result of drawing away resources that the fungus needs to produce lolines but rather an active inhibition of fungal gene transcription. The details of these biochemical signals between fungus and plant await further study.

In light of the finding that MJ suppresses the *LolC* gene, we conducted the second experiment to determine if MJ exposure could compromise the previously documented wound-induced response of endophyte-infected tall fescue (Bultman et al. 2004). Based on the results of Experiment I, we predicted that the exposure of plants to MJ 3 days after inflicting mechanical damage would reduce the accumulation of lolines and the aphid resistance that normally occurs following wounding (Bultman et al. 2004; Sullivan et al. 2007). Our results did not match our predictions. While loline concentration was lower in MJ-treated plants (Fig. 4), aphid performance did not differ among MJ-treated and untreated plants (Fig. 2). We think this is best explained by the high levels of lolines found in the infected plants after they were cut. Even with some reduction in loline concentration in MJ-treated plants, the levels were still high (>3× higher than in undamaged infected plants—compare Figs. 3 and 4), high enough to kill most of the aphids in the clip bags (Fig. 2). It may be that, once the plant is cut, upregulation of the fungal *LolC* gene occurs and application of MJ 3 days later can depress this response only slightly. Simultaneous exposure to MJ and plant damage would reveal if the timing of the two events affects the outcome.

Acknowledgements Several undergraduate students helped in counting aphids: T. Boman, A. Dreyer, D. Fraker, R. Johnson, N. Marra, B. McMahon, and J. Molenhouse. The Departments of Biology and Chemistry provided facilities. 'witches brooms' and tasteless dwarf fruits, for which no curative approaches are available (Seemüller et al. 2002).

The univoltine psyllid species *C. picta* (Foerster) (Hemiptera: Psyllidae) was discovered recently as the vector of this phytoplasma in Central Europe (Frisinghelli et al. 2000; Mayer et al. 2008b); the phytoplasma infects both its host plant and the vector insect. Our previous study provided evidence that apple plants infected by this phytoplasma released higher amounts of the sesquiterpene ß-caryophyllene than uninfected plants and that newly hatched adults of *C. picta* were attracted by the odor of infected apple trees (Mayer et al. 2008a). Hence, we established the hypothesis that *Ca.* P. mali may manipulate both the odor of infected plants and the behavior of its vector insect, thus promoting its propagation. In this follow-up study, we confirm this hypothesis by both laboratory and field bioassays, and we highlight the applied aspect of our findings.

Methods and materials

Maintaining Insects for Bioassays Adults of *C. picta* were collected from apple trees (*Malus domestica*) in early spring after having returned from their overwintering host plants. They were maintained in rearing cages (60×60×90 cm) either on uninfected or *Ca.* P. mali-infected apple plants on which they could feed and oviposit. The rearing cages were located in a greenhouse chamber under natural light conditions and a day–night temperature program (D:N= 20:15°C). For behavioral trials, test insects were collected from the boxes 1 day before testing in groups of ten in Eppendorf vials at 4°C. All insects were tested within 2 weeks after emergence.

Behavioral Bioassays Behavioral tests were carried out by using a dynamic Y-shaped olfactometer consisting of a glass tube (entrance arm 12.5 cm, test arms 21.0 cm, inner diameter 0.6 cm) mounted on an angular board. Charcoal-cleaned air (granulated 4–8 mm, Applichem GmbH, Darmstadt, Germany) was pumped (75 ml/min) through two glass jars (2 l) containing the volatile sources. For testing the behavior of uninfected and inexperienced females, a twig of uninfected apple plants (length 10–15 cm, phenology stage 69–71) was placed together with a water-filled glass vial in each of the jars. One microliter of ß-caryophyllene (80%, FEMA 2252, Sigma-Aldrich, Steinheim, Germany) was pipetted onto a filter paper disk (diameter 5 mm), which was set into the inflow of one olfactometer arm. In all other experiments (Fig. 1B–D), a filter paper disk treated with 1 µl ß-caryophyllene was offered against an untreated disk. According to Mayer et al. (2008a), for each test, ten females were placed into the entrance arm at one time. Every individual passing a final marking (10.0 cm after the branching) on one of the test arms after 15 min was recorded and transferred to a vial filled with ethanol (70%) for later analysis of their infection status (see below). All experiments were repeated 20 times. Data were analyzed statistically after log (x+0.5) transformation by *dependent paired t-test* using the Statistica 5.5 scientific software package.

DNA Extraction from Insect Material and PCR Analysis Psyllids used in biotests (see above) were subjected to DNA extraction by using the methods described in Mayer et al. (2008a). Insect DNA was purified by using the primer pair fAT/rAS specific for *Ca.* P. mali, amplifying a 400-bp sequence in the 16S-23S rRNA spacer region. Polymerase chain reactions (PCRs) were performed in a thermal cycler (Robocycler 96, Stratagene, La Jolla, CA, USA) according to Mayer et al. (2008a).

Field study ß-caryophyllene (purity >80%, SAFC Supply Solutions, USA; 2 ml) was added to a membrane dispenser (Langlock type Do 48, Wilhelm, Germany). The dispenser consisted of a 4-ml glass vial with an open lid (diameter 12 mm) containing four layers of permeable rubber membranes. The dispenser was mounted in the center of a transparent plastic cup (Polarcup 500 ml, Huhtamaki GmbH, Germany) that was sealed by a respective lid. ß-caryophyllene could evaporate through 20 openings (diameter 10 mm) evenly distributed over the sticky cup surface. The dispensers were refilled with ß-caryophyllene depending on weather conditions. Cups with empty dispensers were used as negative controls. Cups with empty dispensers, which were wrapped by collars of yellow plastic foil (32×5 cm), were used as positive controls. The traps were placed randomly in ten blocks, each consisting of one trap per treatment in an apple orchard close to Heidelberg (Germany) from April 24, 2008 to May 13, 2008. The traps were controlled every 2–5 days, and the captured psyllids determined. The data were analyzed by a nonparametric *Friedman-analysis of variance* followed by *Wilcoxon matched pairs tests* after sequential Bonferroni correction using the Statistica 5.5 scientific software package.

Results

Adult *C. picta* females reared on uninfected plants without any previous contact to *C.* P. mali during their ontogenesis (inexperienced) significantly preferred the olfactometer arm supplied with ß-caryophyllene both when offered simultaneously with uninfected apple odor (71.1%, Fig. 1A) and without apple odor (73.3%, Fig. 1B; *dependent paired t test*, $P<0.001$). Adult *C. picta* females, which were reared

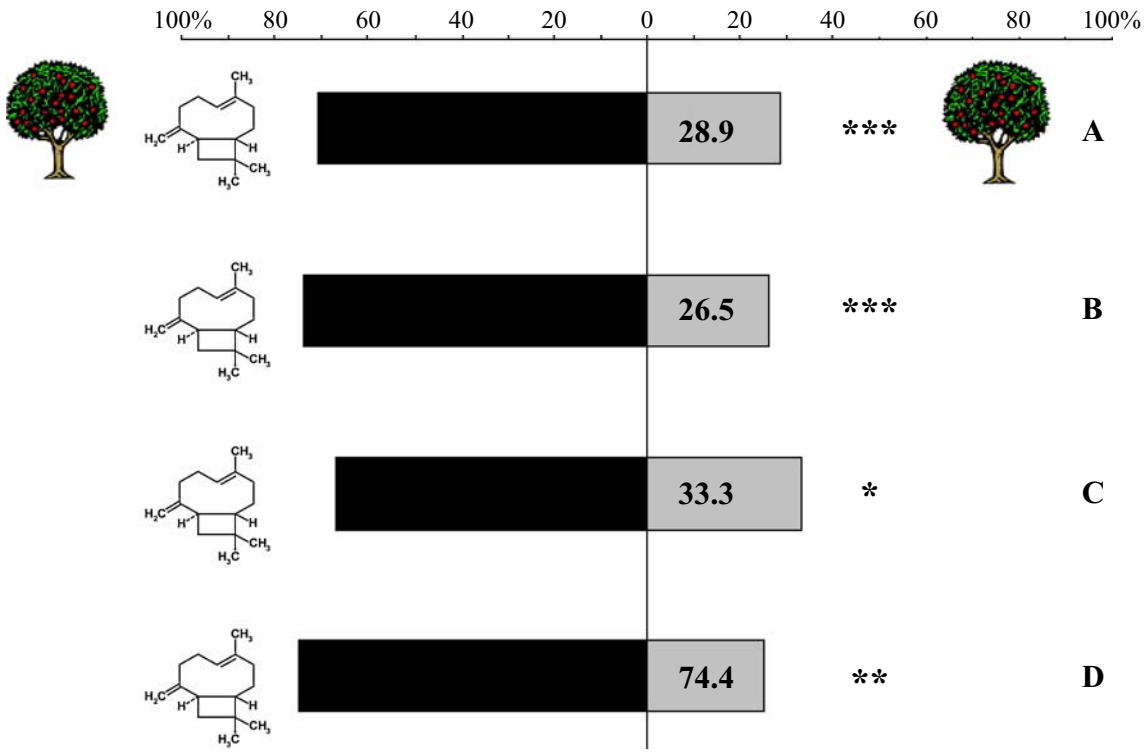

Fig. 1 Results of olfactometer-bioassays with newly hatched adults (emigrants) of *Cacopsylla picta*. *A* Apple odor + ß-caryophyllene (*left*) vs. apple odor (*right*): inexperienced and uninfected emigrants developed on healthy plants (N=149; motivation 74.5%). *B–D* ß-caryophyllene (*left*) vs. empty control (*right*) *B* inexperienced and uninfected emigrants developed on healthy plants (N=132; mot. 66.0%). *C* Experienced and uninfected emigrants developed on infected plants (N=42; mot. 42.5%). *D* Experienced and infected emigrants developed on infected plants (N=43; mot. 42.5%). *T test for dependent samples*: *P<0.05, **P<0.01, ***P<0.001

during their entire ontogenesis on infected plants (experienced), also significantly preferred the olfactometer arm supplied with ß-caryophyllene when offered against an empty control (70.6%). No differences were observed between the behavior of phytoplasma-infected (66.7%, *dependent paired t test*, P<0.05; Fig 1C) or uninfected psyllids (74.4%, *dependent paired t test*, P<0.01; Fig. 1D). Less than half (42.5%) of the experienced *C. picta* females were motivated to enter an olfactometer arm, whereas 74.5% of inexperienced individuals made a decision when ß-caryophyllene was offered together with apple odor and 66.0% when ß-caryophyllene was offered alone. Interestingly, rearing of *C. picta* on infected apple trees resulted only in 50.6% infection of the potential vectors by the phytoplasma, as was shown by PCR analysis of whole body extracts using specific primers for detection of *Ca.* P. mali.

Sticky traps equipped with a dispenser filled with ß-caryophyllene captured significantly more adults (both males and females) of *C. picta* than the negative control trap containing an empty dispenser (Table 1). Compared to the positive control equipped with yellow foil, no significant difference was detected. However, the captures of traps baited with ß-caryophyllene contained mainly *C. picta*

Table 1 Mean captures/trap and standard error of *Cacopsylla picta* remigrants with infochemical-baited (ß-caryophyllene) or yellow sticky traps

Dispenser content	Mean captures/trap	Statistical comparison	*N*
ß-Caryophyllene	0.38±0.09	A (**)	50
Empty	0.04±0.03	B	50
Yellow foil	0.34±0.08	A (*)	50

Sticky traps without visual or chemical baits (empty dispenser) were used as controls. *Wilcoxon matched pairs test* followed by *sequential Bonferroni correction*. Different capital letters indicate significant differences between captures in traps with different dispenser contents
n.s. not significant
*P<0.05
** P<0.01

(90.5% of the captures are *C. picta*), whereas yellow traps also captured many other psyllid species (69% *C. picta*).

Discussion

The interactions between the pathogen *Ca.* P. mali, the host plants, and the vector insect *C. picta* are complex and summarized in Fig. 2. After overwintering on an alternate host plant [conifers like *Picea abies* and others (unpublished results)], brown colored *C. picta* remigrate into apple orchards for reproduction. For only 2–3 months per year, they live exclusively on their reproduction host plant *M. domestica* for mating, oviposition, and juvenile development (Mayer et al. 2008a). Other plants are not attractive to this highly specialized herbivore. Soon after adult emergence (phenology stages 69–71), the young adults (colored green) are able to ingest *Ca.* P. mali from infected plant phloem (acquisition feeding). Attracted by ß-caryophyllene, which is only produced by infected apples during this time, both males and females are lured to infected plants, irrespective of whether they developed on healthy (Fig. 2, white dot) or infected plants (black dot) (Mayer et al. 2008a). Psyllids that developed from the egg to the adult stage on phytoplasma-infected plants (experienced psyllids) showed a lower inclination to move in the olfactometer bioassays than inexperienced individuals that developed on healthy apple plants (Fig. 1). As shown recently, the pathogen impaired at least indirectly the juvenile development of its vector (unpublished results). Hence, it is possible that these effects influence the activity of the psyllids, and as a consequence, the motivation of the experienced psyllids may decrease.

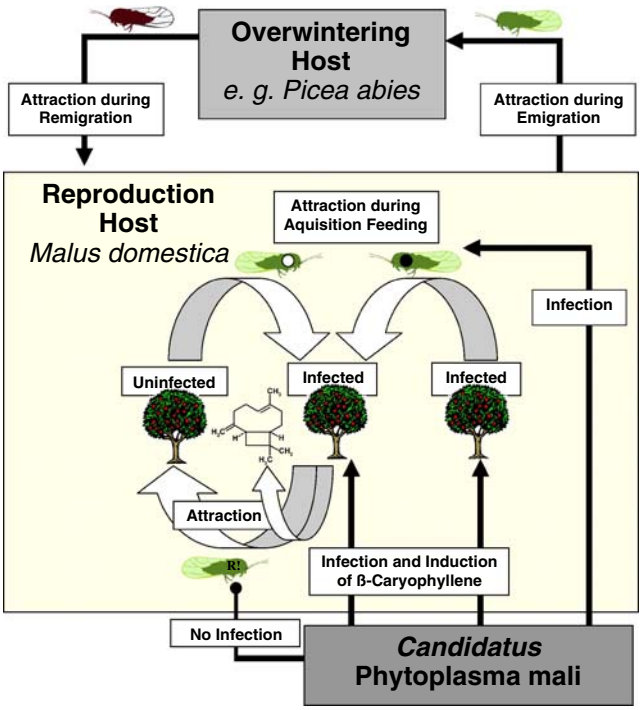

Fig. 2 Multitrophic interactions between *C. picta*, its reproduction, overwintering and nonhost plants, and the pathogen *Ca.* P. mali. Active processes (infection, attraction, induction) are indicated by an *arrow*, otherwise by a *dot*. The structure of ß-caryophyllene is given. The *black dot* indicates an infected psyllid, the white dot an uninfected one and "R!" potentially resistant individuals. For further description please refer to text

Witches' brooms produced exclusively by infected plants increase their leaf surface and may support the emission of volatile ß-caryophyllene. Psyllids that had developed on infected plants but did not get infected (R!) were attracted by ß-caryophyllene (Fig. 1D), but not by the odor of infected plants (Mayer et al. 2008a). Thus, either healthy plant odors may contain more attractive components, or infected plant odors may contain additional substances that mask the attractiveness of ß-caryophyllene to this psyllid phenotype. However, shortly after feeding on apple, the adults emigrate to conifers where they stay until spring (Fig. 2). During this time, the phytoplasma can replicate within its vector and invade its salivary glands.

The sesquiterpene ß-caryophyllene has multifaceted functions in different systems. It was detected in the odor of leaves, flowers, and fruits, and it is known to be attractive to several herbivore species (Khalilova et al. 1998). Furthermore, maize plants attacked by root-feeding larvae of the leaf beetle *Diabrotica virgifera virgifera*, emit ß-caryophyllene as a belowground signal, which attracts entomopathogenic nematodes (Rasmann et al. 2005). The production of ß-caryophyllene aboveground in the infected apple plant is induced by the phytoplasma just at the time of acquisition feeding, thus resulting in increased attractiveness of infected plants to their insect vector (Mayer et al. 2008a). Thus, this infochemical is detrimental for both its producer and its vector insect because attracted phloem-feeding insects cause more damage to the plant, and the psyllids themselves may get infected by the phytoplasma, respectively. At least during their ontogenesis, the infection of the vector insect has detrimental effects on its own fitness, resulting in, e.g., smaller body size and a higher mortality (unpublished results). Consequently, only the phytoplasma appears to have a benefit in this multitrophic system. According to the widely accepted terminology (after Dicke and Sabelis 1988), the costs and benefits for involved organisms are assessed to describe the ecological function of an infochemical without consideration of its origin. Thus, ß-caryophyllene emitted by infected apple plants is not a plant kairomone but a pathogen-induced allomone because it is beneficial for the phytoplasma and detrimental for the psyllid.

Our field studies that used sticky traps equipped with dispensers containing this infochemical implicate for the

first time that an allomone can represent a promising compound to develop new traps for monitoring or maybe even mass trapping of *C. picta*, the most important vector of apple proliferation disease!

permanent production and storage of defense metabolites, and resources required for their biosynthesis are invested only in times of increased herbivore or pathogen pressure (Karban and Baldwin 1997).

Despite several observations of induced defense in brown algae (Cronin and Hay 1996; Pavia and Toth 2000; Hemmi et al. 2004; Macaya et al. 2005; Molis et al. 2006), there is an ongoing debate about how the induction of the de novo biosynthesis of defensive metabolites is regulated (Tarakhovskaya et al. 2007). In higher plants, hormones such as jasmonic acid (JA) and methyl jasmonate (MeJA), as well as external elicitors and continuous mechanical tissue disruption, can orchestrate the induction of chemical defenses after mechanical wounding, herbivore damage, or pathogen attack (Karban and Baldwin 1997; Baldwin et al. 2002; Wittstock and Gershenzon 2002; Mithöfer et al. 2005; Garcia-Brugger et al. 2006; Wasternack 2007). JA and MeJA have been identified in red algae (Rhodophyta) as well (Krupina and Dathe 1991; Bouarab et al. 2004; Tarakhovskaya et al. 2007). JA influences growth and development in the green microalga *Chlorella vulgaris* (Czerpak et al. 2006). Moreover, JA and MeJA have a positive effect on the tolerance of the green microalga *Scenedesmus incrassulatus* to stress temperatures and infections (Christov et al. 2001), but the occurrence of these metabolites in both algae has not been verified. The question whether JA and its derivatives play a role in the induced defense reactions of the red macroalga *Chondrus crispus* was addressed by Bouarab et al. (2004). They suggested a role of this metabolite as a hormone comparable to that found in higher plants. However, JA and MeJA seem not to be ubiquitous in red algae since *Gracilaria chilensis* does not contain detectable amounts even when heavily challenged with pathogens (Wiesemeier and Pohnert, personal observation).

While several reports on the potential hormonal role of JA and MeJA in red and green algae are available, the occurrence and significance in brown algae has been poorly addressed. Arnold et al. (2001) reported that exposure of the common rockweed *Fucus vesiculosus* to MeJA during periods of tidal emergence causes induction of polyphenolic chemical defenses. Since timing and magnitude of this induced increase in phlorotannin concentration was similar to that caused by herbivory, the question arose whether jasmonates or their oxylipin relatives are natural elements of antiherbivore responses in *Fucus*.

In this study, we report a series of experiments on the occurrence and potential influence of JA and its derivative MeJA on the formation of medium- and non-polar secondary metabolites in different brown alga species. In addition, the JA mimic coronalone (Schüler et al. 2004) was investigated to exclude artefacts due to metabolization of JA in the medium. Special attention was given to the brown alga *Dictyota dichotoma* for two reasons: (a) this alga is known to exhibit induced defense (Cronin and Hay, 1996), and (b) it is rich in bioactive terpenoids (Fattorusso et al. 1976; Teixeira et al. 2001; Barbosa et al. 2004; Kim et al. 2006), a compound class often involved in induced defense of higher plants. The chemical profiling was paired with bioassays that used herbivores of algae; these assays were conducted to study the role of JA and MeJA as hormones involved in the production of medium- and non-polar antiherbivore metabolites of brown algae.

Methods and Materials

Test Organisms The brown algae *D. dichotoma*, *Colpomenia peregrina*, *Ectocarpus fasciculatus*, *F. vesiculosus*, *Himanthalia elongata*, *Saccharina latissima* (formerly *Laminaria saccharina*), and *Sargassum muticum* were collected on the Atlantic coast in Roscoff, France and transferred to the laboratory within 2 days. *D. dichotoma* was collected from June until August 2004 as well as in March 2006. All other brown algae were collected exclusively on the later date. Algae were kept at 16°C under a 14:10 h L/D regime in artificial seawater. Artificial seawater was prepared by dissolving 33 g l^{-1} Instant Ocean (Aquarium Systems, Sarrebourg, France) in distilled water.

The amphipod *Ampithoe longimana* and the isopod *Paracerceis caudata* are widely distributed along the Atlantic coast of North America. Test animals for these assays were collected in Morehead City, NC (USA) and air-shipped to the laboratory, where they were kept in artificial seawater under identical culture conditions as the brown algae.

Induction Experiments Racemic MeJA was provided by R. Kaiser, Givaudan-Roure, Dübendorf, Switzerland; racemic JA was synthesized by base-mediated saponification of MeJA and subsequently purified by column chromatography. Coronalone (Schüler et al. 2004) was provided by W. Boland, Max-Planck-Institute for Chemical Ecology, Jena, Germany. Linolenic acid (LEA) was obtained from Sigma/Aldrich, Düren, Germany. For induction experiments, defined pieces of freshly collected algae (*D. dichotoma*, *C. peregrina*, *E. fasciculatus*, *F. vesiculosus*, *H. elongata*, *S. latissima*, and *S. muticum*, 80–400 mg) were kept in 20 ml filtered seawater that contained different amounts of potential elicitors (added from 100 mg ml^{-1} stock solutions in methanol). Solvent controls were run in parallel. *D. dichotoma* was treated with 0.1, 0.5, and 1 mg ml^{-1} JA and LEA, respectively, and with 0.1 and 0.5 mg ml^{-1} MeJA, where solubility problems occurred at higher concentration. Incubations were performed for 2, 24, and 48 h. The other algae were treated with 0.5 mg JA and MeJA, respectively,

for 12 and 48 h. All treatments were performed at least in triplicate. After the induction period, algal pieces were rinsed carefully with seawater, blotted dry with a paper towel, weighed, wrapped in aluminum foil, shock-frozen in liquid nitrogen, and kept at −20°C until further workup.

For bioassays, *D. dichotoma* was induced with 0.5 mg ml^{-1} JA, MeJA, or LEA (added from 100 mg ml^{-1} stock solutions in methanol) in seawater for 30 h. A solvent control was run in parallel. After the incubation period, the algae were rinsed carefully with seawater, blotted dry with a paper towel, and used for the preparation of artificial food as described below.

Profiling of Acidic Oxylipins Bearing Aldehyde or Ketone Structural Elements and Screening for Jasmonic Acid Profiling of oxylipins in *D. dichotoma* was accomplished by using a solid phase extraction protocol optimized by Schulze et al. (2006). Briefly, alga pieces (1–3 g) were covered with 5 ml MeOH that contained 0.05% 2,6-di-*tert*-butyl-4-methylphenol, followed by the addition of *O*-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine hydrochloride (3 ml, 0.05 M in methanol). To monitor extraction efficiency, [9,10-$^2H_2$]-dihydrojasmonic acid (150 ng) was added. The mixture was homogenized for 5 min under an inert argon atmosphere with a high-performance dispenser at 24,000 rpm (Ultra-Turrax T 25, IKA-Werk, Staufen, Germany). Subsequent acidification with diluted HCl (pH 3) was followed by extraction of the MeOH/water phase with hexane (3×10 ml). The remaining polar phase was acidified again by the addition of 4 ml of diluted HCl (pH 3) to enhance phase separation and extracted with dichloromethane (3×10 ml). The organic fractions were passed separately through preconditioned Chromabond NH_2 cartridges (0.5 g, aminopropyl, Macherey-Nagel, Düren, Germany). After sample loading, the cartridges were washed with 2-propanol/CH_2Cl_2 (5 ml, 2:1, *v*/*v*) and eluted with diethyl ether/formic acid (10 ml, 98:2, *v*/*v*). The solvent was removed at RT by a stream of argon. For derivatization of the carboxyl groups, samples were treated with an ethereal solution of diazomethane (1 ml). After 2 min, excess of diazomethane and the solvent was removed by a stream of argon, and the residue was dissolved in dichloromethane (30 µl). Samples were analyzed by using a Finnigan TraceMS coupled to a Finnigan GCQ gas chromatograph/mass spectrometer (Thermo-Finnigan, Waltham, MA, USA) equipped with an Alltech EC5 capillary column (15 m×0.25 mm, 0.25 µm, Alltech, Hamburg, Germany). The ions at m/z=399 were used to monitor JA and m/z=481 to monitor 12-oxophytodienoic acid (OPDA).

Profiling of Terpenoids and Other (Semi)volatiles For metabolic profiling of terpenoids and other (semi)volatiles, frozen samples of the seven brown algal species were ground in a mortar and extracted directly with dichloromethane (3×0.5–1 ml). The combined organic phases were dried over Na_2SO_4, and the solvent was removed under a stream of nitrogen. Samples were taken up with dichloromethane containing 20 µg ml^{-1} laurylaldehyde as standard to give a final volume corresponding to 2 ml solvent per gram alga. These samples were submitted directly in split mode to a Finnigan TraceMS coupled to a Finnigan ITS gas chromatograph equipped with an Alltech EC5 capillary column (15 m×0.25 mm, 0.25 µm, Alltech, Hamburg, Germany). The temperature program was 50°C (2 min) then ramped at 10°C min^{-1} to 280°C (2 min). Peaks were assigned by retention time and verified by mass spectra. In cases of poor chromatographic resolution, characteristic ion traces were used for the relative quantification.

Metabolic Profiling of Methylated Extracts Frozen samples were ground and extracted as described above. [$^2H_{27}$]-myristic acid (0.1 µl of a 10 mg ml^{-1} stock solution in MeOH per milligram alga) was added as standard prior to extraction. After removal of the solvents under a stream of nitrogen, an excess of trimethylsilyldiazomethane solution (1 ml of a 2M solution in diethylether, Sigma/Aldrich, Buchs, Switzerland) and 10 µl MeOH was used for derivatization. After 1 h, the excess derivatization reagent was removed under a stream of nitrogen, and 500 µl dichloromethane was added. These samples were submitted directly in split mode for gas chromatography (GC)/mass spectroscopy (MS) analysis. Profiling of derivatized samples was performed as described above (temperature program of the GC, 60°C (2 min), then ramped at 20°C min^{-1} to 140°C, then at 5°C min^{-1} to 250°C and at 20°C min^{-1} to 300°C (2 min)). Fatty acid methyl esters were identified by comparison of retention time and mass spectra with commercially available standards.

LC/MS Profiling For metabolic profiling of more polar metabolites, frozen samples were ground in a mortar and extracted directly with methanol or a 1:1 mixture of methanol and water (3 ml per 400 mg alga). Samples were centrifuged and the supernatant was submitted directly to liquid chromatography (LC)/MS analysis. HPLC/MS profiling was done on a Finnigan LCQ connected to an Agilent 1100 System equipped with a Grom-Sil 120 ODS-3 CP column (125×2 mm, particle size 3 µm, Grom, Rottenburg-Hailfingen, Germany). Samples were run twice with APCI and ESI ionization, respectively. A gradient of water/0.5% acetic acid (solvent A) and acetonitrile/0.5% acetic acid (solvent B) was used at a total flow rate of 0.2 ml min^{-1}: solvent B 10% (7 min), 27–37 min 100% B, and 38.50 min 10% B (9.5 min).

Peaks were assigned by retention time in the base peak monitoring mode and verified by mass spectra. In cases of

poor chromatographic resolution, characteristic ion traces were used for relative quantification.

Evaluation of Profiling Experiments Each treatment was replicated at least in triplicate. For profiling, all peaks >5% were quantified and normalized to the internal standard. Differences between induced and uninduced samples were evaluated after calculating the standard deviation using Microsoft Excel. If ambiguous results were observed, additional control/induction pairs were generated and consistency was verified. Minor peaks were evaluated by visual pattern comparison. Quantification was done by using peak areas of characteristic ion traces (LC/MS) or TIC (GC/MS). Peaks were considered different in control and treatment when >10% difference of the respective integrals was observed in all three measurements of the control and of the treated sample. For major peaks, differences were evaluated additionally based on standard deviation.

Bioassays Agar (Aldrich, Seelze, Germany)-based food was prepared by using the methods described in detail by Wiesemeier et al. (2007). Freshly collected *D. dichotoma* were put into 200 ml culture containers and either treated with 500 μg ml^{-1} of JA, MeJA, or LEA for 30 h, or kept as solvent control. Subsequently, the algae were washed carefully with excess seawater to avoid contamination of the food with inducing reagents. These algae were freeze-dried, finely powdered, and subsequently incorporated into an agar matrix prepared by mixing 0.72 g of agar with 36 ml distilled water and dissolving the mixture by heating in a microwave. Subsequently, 2 g of powdered alga was added, and the mixture was shaken vigorously to homogenize. This mixture was poured into 25 ml plastic centrifuge tubes (Falcon, Franklin Lakes, NY, USA). The tubes were inverted and cooled to room temperature. After agar solidification, the falcon tube was opened and the agar was cut to give pieces of a quarter of a ca. 2-mm-thick agar disc.

We tested responses of *A. longimana* and *P. caudata* to agar-based food with induced and uninduced *D. dichotoma*. Feeding assays were performed in 12-well ice cube containers, each well filled with 20 ml of sea water (18°C). One amphipod per vessel could choose between one control and one induced food pellet that were arranged on specified sides of the assay container. During 25 min, we noted every 5 min on which type of food each test animal was present. This behavioral association assay is a valid surrogate for feeding assays because these test animals tend to live on, and thus associate spatially with the foods that they consume (Cruz-Rivera and Hay 2003). To statistically evaluate food choice, we used the Wilcoxon test for paired samples.

Results

Oxylipin Profiling The oxylipin profiling method used allows the detection of JA in concentrations down to 20 ng g^{-1} fresh material. Nevertheless, JA was not found in the brown alga *D. dichotoma* (Fig. 1). Moreover, the

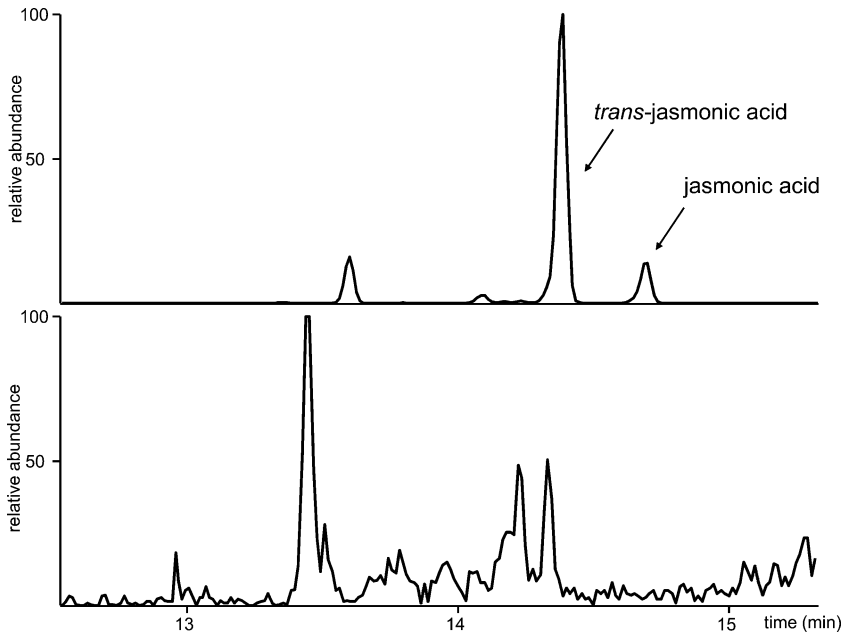

Fig. 1 GC/MS (extracted single ion chromatogram *m*/*z*=399 corresponding to M-20 due to a loss of HF) separation of derivatized jasmonic acid (*upper trace*) and the oxylipin extract of *Dictyota dichotoma* (*lower trace*). Spectra were recorded by using chemical ionization with methane as reagent gas in the negative mode

biosynthetic precursor 12-oxophytodienoic acid also could not be detected (data not shown). In parallel experiments, samples from higher plants (*Phaseolus lunatus*) were run as positive control. As expected, JA and OPDA were detected in these controls (Schulze et al., 2006).

Metabolic Profiling Induction experiments with JA, MeJA, and LEA (control) were run with freshly collected samples to verify whether significant changes of the metabolic profile of the algae occur in response to the putative hormones. Metabolites with a broad biosynthetic spectrum that included terpenes, phenolics, lipids, and fatty acids were covered by using general methods of metabolic profiling (Weckwerth et al. 2005).

No significant metabolic response was observed when the putative hormones were administered in the seawater in concentrations below 500 μg ml^{-1} to the algae *D. dichotoma*, *C. peregrina*, *E. fasciculatus*, *F. vesiculosus*, *H. elongata*, *S. latissima*, or *S. muticum*. In similar experiments with higher plants, significant up-regulation of secondary metabolites can be detected (Boland et al. 1995). In Fig. 2, a GC/MS comparison of trimethylsilyl-diazomethane-methylated organic extracts of *D. dichotoma* is shown. Similar chromatograms were used for the evaluation of metabolic differences of terpenoids and other (semi)volatiles. Peak lists were generated from these chromatograms. If inconsistent results were obtained, re-evaluation of the peaks was performed by using single ion monitoring, or a second set of replicates was generated. None of the carefully evaluated peak lists of all seven algal species showed significant differences between treatment and control. LC/MS profiling of JA-treated samples was evaluated by comparison of extracts from JA-treated and untreated algae. Peaks were evaluated in base peak monitoring mode and verified with single ion monitoring. In no evaluated case (peaks with more than 5% intensity) could a statistical significant up- or down-regulation of signals be observed.

Only if high amounts ≥500 μg ml^{-1} of potential elicitors added over a prolonged period of more than 24 h was a metabolic response observed (Fig. 2). With the exception of *S. muticum*, all investigated algae released fatty acids, but their nature and amount varied strongly between experiments. In the experiments with *D. dichotoma*, up to 500-fold up-regulation of free palmitic acid, palmitoleic acid, and oleic acid was observed. Besides these metabolites, strongly varying amounts of saturated fatty acids, such as lauric (C12:0), myristic (C14:0), stearic (C18:0), arachidic (C20:0), and behenic acid (C22:0), as well as unsaturated fatty acids, such as stearidonic (C18:4), α-linolenic (C18:3), arachidonic (C20:4), and eicosapentaenoic acid (C20:5) were released by all investigated algae with the exception of *S. muticum*. This metabolic response was unspecific and could be triggered with high concentrations of JA, MeJA, and LEA. During these treatments, algae were heavily stressed and depigmentation was observed after more than 48 h. The solvent control did not lead to comparable metabolic and stress reactions.

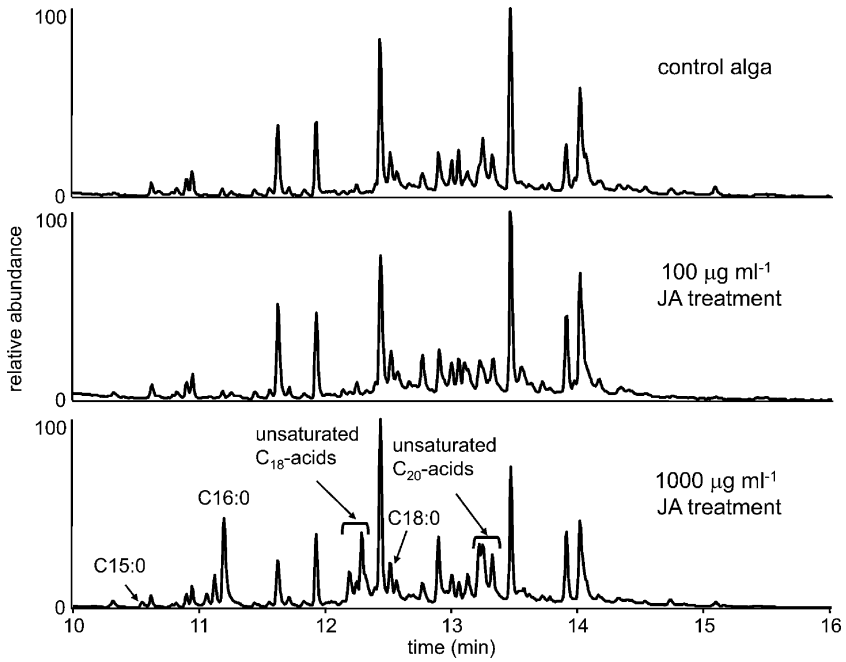

Fig. 2 GC/MS profiling (total ion current) of methylated *Dictyota dichotoma* extracts. *Upper trace*: untreated control; *middle trace*: after incubation with 100 μg ml^{-1} JA; *lower trace*: after incubation with 1,000 μg mL^{-1} JA. The respective up-regulated fatty acids are indicated. C16:0 palmitic acid, C18:0 stearic acid

Additional profiling of terpenoids and other semivolatiles of *D. dichotoma* after challenging the algae with coronalone (10, 100, and 1,000 μg ml^{-1}) for 24 h also did not reveal any specific induction of secondary metabolites (data not shown).

Bioassays on the Induction of Chemical Defense Bioassays were performed with two model herbivores, the amphipod *A. longimana* and the isopod *P. caudata* (Wiesemeier et al. 2007). Food from control algae was compared with food from algae treated with 500 μg ml^{-1} of the inducing reagents, which corresponds to the lowest concentrations at which a metabolic response was observed. *P. caudata* associated unselectively with both types of food offered; no preference was detectable for control food nor for JA-, MeJA-, or LEA-treated *D. dichotoma*. In contrast, *A. longimana* selected preferentially (P=0.01) food from algae pre-treated with 500 μg ml^{-1} JA, MeJA, or LEA for 30 h (Fig. 3).

Discussion

The brown alga *D. dichotoma* was submitted to a robust metabolic profiling method of oxylipins based on derivatization and detection with gas chromatography/mass spectrometry (Wichard et al. 2005; Schulze et al. 2006). Despite a detection limit well below 20 ng g^{-1} plant material (Schulze et al. 2006), no traces of JA were found in this algal species (Fig. 1). Given the resting level of JA in plant tissue (around 50 ng g^{-1}) and the amounts above 1,300 ng g^{-1} of JA that can be reached during active induction (Schulze et al. 2006; Adra et al. 2006), it can be excluded that JA concentrations in the investigated brown algae were high enough to induce defense responses triggered by mechanisms that are comparable to those in higher plants. Moreover, 12-oxophytodienoic acid, a biosynthetic precursor of JA that is present in considerable amounts in higher plants, could not be detected in algal extracts (Feussner and Wasternack 2002). Samples from higher plants were run in parallel as positive controls. In these samples, JA and OPDA were detected, thereby providing proof of suitability of the method employed (data on higher plants shown in Schulze et al. 2006). This finding suggests that brown algae lack a higher plant-like pathway towards JA. Nevertheless, it cannot be excluded that some algal species may contain JA or related metabolites.

Because we studied only freshly collected material with unknown grazing history, it is possible that only non-stressed algae with low resting levels of JA were surveyed. These resting levels might have been below the detection limit of our analytical method. Therefore, we performed a series of experiments where metabolic profiles of JA-,

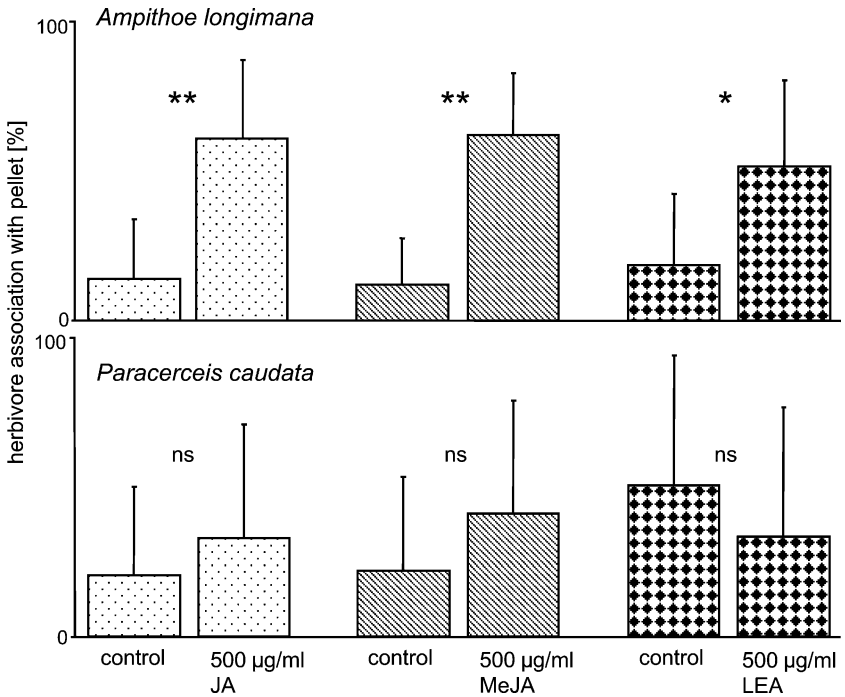

Fig. 3 Food selection by the amphipod *Ampithoe longimana* (*top*) and the isopod *Paracerceis caudata* (*bottom*). Mean percentage (+SD) of individuals present on food items. Choice assays were performed with artificial food derived from control alga (*Dictyota dichotoma*) and *Dictyota dichotoma* after jasmonic acid (*JA*) incubation, methyl jasmonate (*MeJA*) incubation, and linolenic acid (*LEA*) incubation. Number of replicates N=21 *Ampithoe longimana*/JA, N=22 *Ampithoe longimana*/MeJA, N=24 *Ampithoe longimana*/LEA, N=24 for all *Paracerceis caudata* experiments. **P=0.01, *P=0.05, *ns* not significant

MeJA-, and LEA-treated algae were compared to control samples. We selected a concentration range of these potential inducing reagents starting with amounts similar to those used for the induction of higher plants (1,000 μg ml^{-1}; Boland et al. 1995). This comprehensive metabolic profiling enabled us to monitor changes of most volatiles, semivolatiles, acids, labile aldehydes, lipids, and other compound classes detectable by GC/MS and LC/MS. We did not aim to characterize all detected metabolites but rather we followed protocols established for the metabolic profiling of plant tissues that reveal global changes in metabolic profiles (Weckwerth et al. 2005; Shulaev et al. 2008). Accordingly, we did not bias towards specific compound classes but rather surveyed all accessible metabolites of the algae. Due to methodological limitations, we did not focus on phlorotannins, a dominant compound class in brown algae, often associated with chemical defense (e.g., Pavia and Toth 2000; Koivikko et al. 2008). In cases where a regulation of metabolite production was observed in response to the treatment, we verified the structures. In other cases, we relied on MS libraries to characterize compound classes but not exact structures.

This procedure gave no evidence for an induced up- or down-regulation of biosynthetic pathways with levels of inducing agents below 500 μg ml^{-1} of the potential hormones. This lack of secondary metabolite induction was found consistently in all investigated brown algal species. In similar induction experiments with higher plants as a positive control, identical analytical methods can be routinely used to monitor metabolic changes that manifest as dramatic change of metabolic profiles (see, e.g., Boland et al. 1995; Schüler et al. 2004). Since we did not observe any increase of amounts of JA in the tissue of brown algae, this value of 500 μg ml^{-1} medium is high and should be sufficient for induction if hormone-mediated processes were involved.

The employed hormone concentrations definitely exceed those required to trigger plant responses (Heil 2004), but we selected them to overcome dilution effects, since in the case of algae it is impossible to apply the inducing agents via vascular transport as is often the practice with higher plants. To avoid potential interferences of artificially elevated concentrations of putative hormones, a series of experiments also was run with 10 μg $ml^{-1}$of JA, MeJA, and LEA, respectively. These treatments did also not result in any change of the metabolic profile (data not shown).

The role of JA in the induction of terpene biosynthesis is well established for higher plants (Hopke et al. 1994; Keinanen et al. 2001), but similar processes were not observed in *D. dichotoma* as no change in the terpene profile was observed after treatments with the potential elicitors. The group of *D. dichotoma* metabolites that belong to diterpenes was identified by comparison with characteristic EI mass spectra from the literature, but no exact structures were assigned (Fattorusso et al. 1976; Teixeira et al. 2001; Barbosa et al. 2004; Kim et al. 2006). Additional experiments were performed with this alga by using coronalone as a JA analogue (Schüler et al. 2004). Coronalone mimics the action of coronatine, which is known to induce JA-like up-regulation of the production of terpenes in higher plants (Boland et al. 1995). We used coronalone in an additional bioassay to elucidate whether JA-responsive induction of secondary metabolites can be observed with a non-natural elicitor. It might be possible that coronalone is taken up more readily by the algae than JA. In addition, coronalone may not be subjected to the same (bacterial) transformation as JA if administered in the culture medium (Schüler et al. 2004). This JA analogue, which proved to be even more active than the hormone in experiments with higher plants, also had no effect on the absolute and relative concentration of *D. dichotoma* terpenoids.

Unspecific stress on the algae due to exposure to higher concentrations of the elicitors (500–1,000 μg elicitor ml^{-1} seawater) over prolonged time spans led to the release of free fatty acids (Fig. 2). This was found for all investigated species with the exception of *S. muticum*. The metabolic responses were unspecific and were observed with the JA and MeJA treatments as well as with the LEA control. It is likely that increased stress causes activation of lipases, thus releasing fatty acids from (storage) lipids. Whereas saturated fatty acids, such as lauric (C12:0), myristic (C14:0), stearic (C18:0), arachidic (C20:0), and behenic acid (C22:0), and unsaturated fatty acids, such as stearidonic (C18:4), linolenic (C18:3), arachidonic (C20:4), and eicosapentaenoic acid (C20:5), were up-regulated occasionally, and only palmitic (C16:0), palmitoleic (C16:1), and oleic acid (C18:1) were found in all induction experiments with elevated amounts of phytohormones (Fig. 2). Because release of fatty acids was observed after all treatments (JA, MeJA, and LEA), we exclude this result as a specific hormonal action.

Comparative bioassays with induced and non-induced (control) *D. dichotoma* were performed to verify whether—despite the lack of a detectable metabolic reaction—a more subtle up-regulation of chemical defense can be triggered by JA, MeJA, or the control treatment with LEA. The amphipod *A. longimana* and the isopod *P. caudata* served as model herbivores that are widely distributed along the Atlantic coast and that can be monitored closely under controlled conditions in the lab. Bioassay procedures to monitor defense reactions of brown algae that are due to medium- and non-polar metabolites as well as to volatiles are suitable, but they have not been verified for phlorotannins (results in Wiesemeier et al. 2007). No significant food preference was detected in assays where *P. caudata* had the choice between artificial foods derived from an

induced or uninduced algae. In contrast, *A. longimana* preferred food from JA-, MeJA-, and LEA-treated algae, thereby contradicting the concept of induced defense. Interestingly, all three treatments (JA, MeJA, and LEA) led to weakly significant but comparable responses (Fig. 3). The lack of a specific induction of JA or MeJA and the fact that algae were highly stressed due to the elevated concentrations of the inducing reagents suggests that an unspecific stress response that weakens the algae might be detected by the herbivores. Since feeding by *A. longimana* is known to induce chemical defense in the closely related algal species *Dictyota menstrualis* (Cronin and Hay 1996), it thus has been documented that this amphipod is susceptible to induced brown algal chemical defense. Our results show that treatment with test compounds did not trigger the same chemical defense induction as feeding by the herbivore itself. Hormones or regulative principles other than JA and MeJA must, therefore, be responsible for the observed reaction (Cronin and Hay 1996).

The preference of treated, heavily stressed food by *A. longimana* might be due to the amphipod's ability to detect chemical cues of stressed algae that do not invest in chemical defense. Interestingly, the up-regulation of free fatty acids did not result in reduced food palatability, as has been observed in the interactions of grazers on epilithic biofilms (Jüttner 2001), thus indicating a resistance of these herbivores against free fatty acids that are lipolytic or deterrent in other alga–herbivore interactions (Fu et al. 2004).

In summary, we could not detect any indication for a role of JA and related metabolites in induced chemical defense of brown algae. The study covered a broad range of possible metabolic responses, but did not focus on the regulation of polyphenolics, which do play documented roles in induced chemical defense of some brown algae (Pavia and Toth 2000). We suggest that for the classes of metabolites investigated in our study, fundamentally different mechanisms for induction may have developed in higher plants and brown algae. Whether these mechanisms rely on structurally different hormones or on other regulative principles can currently not be ascertained.

Acknowledgments We thank Akira Peters and Florian Weinberger for their help with algal collection and identification. We are grateful to Marc Hay, who provided us with test animals and introduced us to the techniques for bioassays. Paulina Dabrowska and Birgit Schulze are acknowledged for help with analysis of phytohormones. We acknowledge the helpful support from Wilhelm Boland and funding from the Volkswagenstiftung.

tiveness. We report here on the attractiveness of blends and hybrid molecules of isophorone/isophorol and α-ionone/α-ionol to evaluate their potency for practical use as lure compounds in an eradication program against *B. latifrons*.

Materials and Methods

Chemicals (Fig. 1) (±)-α-Ionone (**1**), isophorone (**3**), and (±)-isophorol (**4**) were obtained from Sigma–Aldrich (Fluka) (St. Louis, MO, USA). (±)-α-Ionol (**2**, a mixture of racemic diastereomeric isomers) was obtained from Sankei Chemical Co., Ltd. (Kagoshima, Japan). (±)-3-Oxo-α-ionone (**5**), (±)-3-oxo-α-ionol (**6**) (a diastereomeric mixture) and (±)-3-hydroxy-α-ionol (**8**) (a diastereomeric mixture) were obtained from NARD Institute, Ltd. (Hyogo, Japan). (−)-*trans*-3-Hydroxy-α-ionone (**7**, $[\alpha]_D=-46.0°$, $c=0.30$, methanol) was prepared by microbial oxidation of racemic α-ionone (Wako Pure Chemical Industries, Ltd., Japan) using *Aspergillus niger* (Yamazaki et al. 1988) (Fig. 1). The identities of compounds **5**–**8** were confirmed by their ^{1}H NMR spectra (400 MHz) and mass spectra.

Insects A culture of *B. latifrons*, obtained from the Okinawa Prefectural Agricultural Research Center (originally collected in Yonaguni Island), was reared at 26–27°C and 60–70% RH under a photoperiod of 14 L:10D at the Naha Plant Protection Station in Okinawa, Japan. Adults were provided with water and a diet of four parts sucrose and one part dry yeast AY-65 (Asahi Food & Healthcare, Ltd., Tokyo, Japan). Sexually mature, mated flies (21–27-day-old) were used for the behavioral tests in a bioassay chamber under the same environmental conditions.

Laboratory Bioassays Fifty sexually mature adults of each sex were transferred into a meshed cage (30×30×45 cm) in the morning (09:00–11:00) and acclimatized with food and water until the bioassay was started 1 h after the lights came on at 8:45 the following morning. A piece of filter paper (a diameter of 90 mm, Advantec No. 2), impregnated with 100 μg of one of the test compounds in ethanol applied to the center (approximately 10 mm diam) and dried at ambient temperature, was placed on a plastic cup (45 mm high) at the center of the cage. Filter paper treated with ethanol alone served as an experimental control. The number of males and females (1) "attracted" (on the filter paper) and (2) licking the sample area ("feeding") were recorded during 10 s every 10 min for 60 min (i.e., six times). We tested every compound (100 μg) [**1**–**8**], and some two compound blends [**1**+**3**; **1**+**4**; **2**+**3**; **2**+**4**] at a 1:1 ratio (*w*/*w*, total 100 μg). A minimum of 15 replicates were carried out for each compound/blend tested.

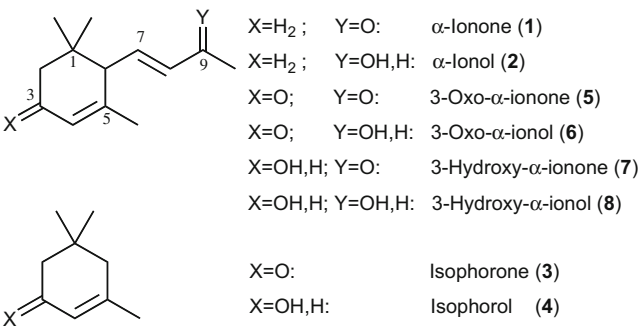

Fig. 1 Structures of the compounds tested as attractants and phagostimulants for *Bactrocera latifrons*

Fig. 2 Males of *Bactrocera latifrons* attracted to, and voraciously feeding on, filter paper treated with 3-oxo-α-ionone (**5**) (100 μg applied to the center as an approximately 10 mm diameter spot)

Statistical Analysis Within a given replicate, the data collected at 10-min intervals were summed to yield a grand total, and these were square root transformed [sq rt (x+0.5)] to normalize the distribution before analysis. Means of the transformed values were compared by Tukey–Kramer HSD multiple comparison test (α=0.05) with the statistical package JMP (ver. 5.0.1J, SAS Institute Inc. 2001).

Results

There were two distinct male behavioral responses: attraction and feeding (directly licking the chemical source) (Fig. 2). 3-Oxo-α-ionone (**5**) and 3-oxo-α-ionol (**6**) elicited similar levels of both attraction and feeding, and were significantly greater than those recorded for any other compound or mixture (Table 1). Once attracted to compounds **5** and **6**, most males persistently licked the chemical source for >10 min, leaving clear salivation marks on the filter paper. The corresponding 3-hydroxy analogs (**7** and **8**) were not as attractive as the 3-oxo derivatives (**5** and **6**),

Table 1 Mean total number (±SD) of males and females of *Bactrocera latifrons* attracted to and feeding on the chemical source

Test chemicals	Number of males attracted		Number of males feeding		Number of females attracted		Number of females feeding		*N*

The values with different letters indicate significant differences within the same column by Tukey–Kramer HSD test of the square-root transformed data ($P<0.05$)

eliciting responses similar to α-ionol (**2**), isophorone (**3**), and isophorol (**4**) (Table 1). However, some of the blends of α-ionone/α-ionol and isophorone/isophorol elicited higher responses than any of the individual components (**1**, **2**, **3**, or **4**) within the subsets (Table 1).

Females did not display a strong response towards any of the test compounds, although the 3-oxo analogs **5** and **6** elicited weak but significantly higher responses (both as attractants and feeding stimulants) than the other compounds or mixtures (Table 1).

Discussion

Within the series of 3-oxygenated α-ionone/α-ionol analogs tested, 3-oxo-α-ionone (**5**) and 3-oxo-α-ionol (**6**) were the most effective both as attractants and phagostimulants for *B. latifrons*, and significantly better than the corresponding 3-hydroxy compounds **7** and **8** or the known attractants α-ionone (**1**) and α-ionol (**2**) (Flath et al. 1994). However, there was a higher proportion of males that fed on all four 3-oxygenated analogs [number of feeding males/number of attracted males: **5** (87%), **6** (85%), **7** (80%), and **8** (84%)] than on α-ionone and α-ionol [**1** (48%) and **2** (59%)].

3-Oxygenated α-ionone analogs have been reported from many plants, including tomato, grape, and blackberry, although the compounds are found mostly as glycosidically bound aroma in various fruit tissues (Strauss et al. 1987; Humpf and Schreier 1991; Marlatt et al. 1992). Interestingly, a small quantity of 3-hydroxy-α-ionone was detected in the tissues of eggplant fruit, one of the favorite hosts of *B. latifrons* (Nishida et al., unpublished). Furthermore, males that fed voraciously on eggplant incorporated a series of 3-oxygenated α-ionone derivatives in the rectal gland, which is presumed to be a pheromone reservoir organ in *B. latifrons* (Little 1992). This suggests that these male attractants may act as sex pheromones, or their precursors, to attract females during the crepuscular courtship period, in a manner similar to the case of methyl eugenol for the oriental fruit fly, *B. dorsalis* (Tan and Nishida 1998).

Isophorone (**3**) and isophorol (**4**), which conform to the partial structures of compounds **5**–**8**, also elicited responses in males, although not significantly different from those of compounds **7** and **8**. However, when either **3** or **4** were combined with α-ionol (**2**), the resulting mixtures gave significantly higher attractancy than any of the three compounds individually. While we do not understand how this synergism actually works, these artificial blends may be used as effective long-range attractants for *B. latifrons* males, as **3** and **4** are much more volatile than compounds **5**–**8**. Clearly, under laboratory conditions in small cages, 3-oxygenated α-ionones/α-ionols are attractants for *B. latifrons* males, but further research is required to determine over what range they and/or blends that incorporate **3** and **4** would be effective under field conditions.

Acknowledgments We thank Dr. Kohji Yamamura (Laboratory of Population Ecology, National Institute for Agro-Environmental Sciences, Tsukuba, Japan) and Hajime Katsumata (Yokohama Plant Protection Station, Yokohama, Japan) for assistance with data analysis, Okinawa Prefectural Agricultural Research Center for transferring *B. latifrons* to us, and Isao Miyazaki, Shinobu Sukenari, Takuji Yamamoto, and other staff members of Naha Plant Protection Station (Okinawa, Japan) for assistance with laboratory tests. We are also grateful to Dr. Keng Hong Tan (Penang, Malaysia) and Dr. Todd E. Shelly (USDA–APHIS, Waimanalo, HI, USA) for useful discussions on this study. This work was partially supported by a Grant-in-Aid for the 21st Century COE Program for Innovative Food and

Environmental Studies Pioneered by Entomomimetic Sciences from the Ministry of Education, Culture, Sports, Science and Technology of Japan.

locate inflorescences for efficient pollination. Worldwide, there are about 750 fig species (*Ficus*, Moraceae; Berg 1989), and figs generally are pollinated by female fig wasps (Agaonidae: Hymenoptera) that are specific for each *Ficus* species, and they oviposit in the fig syconium (Wiebes 1979; Ware and Compton 1992). Although visual factors may be involved (Ramirez 1974; Janzen 1979; Verkerke 1989), several studies have shown that the pollinating wasps are attracted by olfactory cues (Bronstein 1987; Van Noort 1989; Ware et al. 1993; Hossaert-McKey et al. 1994; Gibernau et al. 1998; Grison et al. 1999). However, in the five stages of fig development [i.e., prefemale floral stage, female floral stage, interfloral stage (time period between female floral stage and male floral stage), male floral stage, and post-floral stage], only the female stage is receptive to pollinators (Galil and Eisikowitch 1968; Bronstein 1987). Ware and Compton (1994) concluded that figs should either cease to produce attractive signals after being pollinated or that new compounds should be produced (or specific components increased) that repel pollinators. This provides an alternate explanation for the pollinators' indifference to post-pollination flowers (Schiestl and Ayasse 2001; Song et al. 2001). Recent studies of *Ficus hispida* L. volatiles did not detect new compounds after pollination, but the quantity of volatile emission decreased quickly after 24 h (Proffit et al. 2008). Some compounds present only in small amounts disappeared when checked by gas chromatography-mass spectrometry, but the abundant compounds β-ocimene, (*E*)-β-farnesene, and linalool still existed 2 weeks after pollination (Proffit et al. 2008).

It is clear that pollinators can distinguish between receptive and non-receptive figs (Van Noort et al. 1989; Ware and Compton 1994; Song et al. 2001). However, few bioassays have been conducted to test the pollinators' responses to figs at different developmental stages (Grision-Pigé et al. 2002a). Because floral odors are complex mixtures of volatiles (Knudsen et al. 1993, 2006), it is difficult to determine how alterations in the composition, proportion, and concentration of floral odor components influence pollinator behavior (Patt et al. 1995). Nonetheless, tests of individual volatile compounds and combinations may shed light on the chemical mechanism involved in post-pollination volatile changes.

In this study, we used a Y-tube olfactometer to test fig wasp, *Ceratosolen solmsi marchali* Mayr, behavior to volatile compounds from *F. hispida* and preferences of pollinators to receptive and interfloral figs from their dioecious host. Based on previous studies (Song et al. 2001; Proffit et al. 2008), we also chose three monoterpene compounds from receptive figs, one abundant compound (linalool) and two minor ones (limonene and β-pinene), to test the response of the pollinator. All of these volatile compounds are found in the odor of receptive figs of *F. hispida*, and their quantities have decreased by the interfloral fig stage. The specific purpose of our study was to (1) determine experimentally whether the pollinator was sensitive to floral scent changes between receptive and interfloral figs of *F. hispida*; (2) investigate whether quantity or quality of fig volatiles play an important role in attracting fig pollinators; (3) examine whether linalool, the main constituent of the receptive fig odor of *F. hispida*, plays an important role in attracting pollinators; and (4) whether the minor constituents of fig odor enhance attractiveness.

Methods and Materials

Plants and Insects F. hispida, growing naturally at Xishuangbanna Tropical Botanical Garden (101°15′ E, 21°55′ N) in southwest China, was used to obtain both plant and insect materials. *C. solmsi marchali*, the pollinator of *F. hispida*, develops in syconia of this species. Both the fig and its pollinator have been studied and described in earlier publications (Hill 1967; Abdurahiman and Joseph 1976; Patel et al. 1995; Patel 1996; Patel and Hossaert-McKey 2000; Moore et al. 2003; Peng et al. 2005; Proffit et al. 2008). Pre-receptive figs were isolated from pollinators by using mesh bags. Fresh figs with their branches were cut in the morning, placed into a vase containing water, and used for bioassays of volatiles. When a fig is nearly mature, fertilized female wasps will leave via a channel bored by males (Galil and Eisikowitch 1968). Pre-mature male figs without holes were collected at dusk and put into mesh bags. The next morning, wasps came out of those figs and were selected for olfactometer studies. Fig floral stages were estimated by their physical characteristics: loose obstacle, heavy-sweet scent, and pollinators being attracted outside the bag are signals of a receptive fig; interfloral figs have a hard, solid feel and a deeply colored surface, while a mature fig has a soft, white and smooth surface.

Chemicals Previous studies indicate that linalool is the most abundant compound in the odor of receptive *F. hispida* (Song et al. 2001; Proffit et al. 2008). For this reason, the response of *C. solmsi marchali* was tested against (*R*)-(+)-linalool (Linke Reagent Co., Ltd., China, ≥93%), (*S*)-(−)-linalool (Juhua Reagent Co., Ltd., China, ≥98%) and a 1:1 mixture of these two enantiomers. Limonene and β-pinene are minor volatiles in the odor of receptive *F. hispida* and numerous other receptive *Ficus* species (Grison-Pigé et al. 2002b). Enantiomers of limonene were tested against *C. somisi marchali* by using (*R*)-(+)-limonene (Fluka, ≥98%), (*S*)-(−)-limonene (Fluka, ≥97%) and a 1:1 mixture of these two enantiomers. The levoisomer of β-pinene [(−)-β-pinene (Cole-Parmer, ≥98%)] was also tested against *C. somisi marchali*.

Olfactometer Methodology All experiments were conducted in a Y-tube olfactometer (stem, 8 cm; arms, 9 cm; at 55° angle; ID 1.5 cm) with each of the two arms connected to a glass container or a polyethylene terephtalate (Nalophan) bag (Kalle Nalo GmbH, Wursthüllen, Germany) that contained an odor source. This small dimension olfactometer was adopted to test small wasps that respond to attractants by walking. It is similar to the one described by Tooker et al. (2005). Air is drawn through Teflon tubing by an air pump and passed through a charcoal filter and distilled water. The cleaned and humidified air stream, regulated to a flow rate of 0.2 L/min with two flowmeters, was split via a "Y" hose junction to create two equal air streams. To limit visual distractions for the insects, the olfactometer was placed in the center of a flat, white table illuminated with three 40-W cool white fluorescent tubes placed above the arms of the Y tube. The windows of the bioassay room were covered by black fabric curtains, and the air temperature was monitored and maintained at ~26°C.

Each wasp was allowed 5 min to respond to odors, and a choice of the left or right arm of the olfactometer was noted when the insect went 1 cm (decision line) past the Y junction and stayed for at least 1 min. Wasps not reaching the decision line within 5 min were removed and recorded as "no choice". Every four to five bioassays, the treatment arm was switched between the two arms of Y-tube to avoid any influence of unforeseen asymmetries in the setup. The olfactometer was rinsed with absolute alcohol and then dried by an air blower after every bioassay.

Bioassays of Odors of Receptive and Interfloral Fig Sources (Experiment A) In order to compare responses of *C. solmsi marchali* to receptive and non-receptive floral scents, experiments (Table 1, Exp. A1, A2, A3, and A4) were conducted with four different types of *F. hispida* scents vs. clean air.

Table 1 Response of the pollinator wasp *Ceratosolen solmsi marchali* to odors of receptive and interfloral fig(s) of *Ficus hispida* (Experiment A)

Experiment	Type and (number of figs) in the arms of the Y tube	
	Arm 1	Arm 2
A1	Male receptive fig (1)	Clean air
A2	Male interfloral fig (1)	Clean air
A3	Female receptive fig (1)	Clean air
A4	Female interfloral fig (1)	Clean air
A5	Male receptive fig (1)	Male interfloral fig (1)
A6	Male receptive fig (1)	Male interfloral fig (9)
A7	Male receptive fig (1)	Male interfloral fig (25)
A8	Female receptive fig (1)	Female interfloral fig (1)
A9	Female receptive fig (1)	Female interfloral fig (9)
A10	Female receptive fig (1)	Female interfloral fig (25)

Grison-pigé et al. (2001) reported that figs have a higher quantity of volatile emission in their receptive stage. The ratios of scent quantity emitted by one fig between receptive fig vs. interfloral fig were about 13:1 for male *F. hispida* and 17:1 for female *F. hispida* (Proffit et al. 2008). In six subsequent experiments (Table 1, Exp. A5, A6, A7, A8, A9, and A10), we set 1:1, 1:9, and 1:25 ratios for the number of receptive figs vs. interfloral figs to balance the higher quantity of odor emission from receptive figs.

Fresh figs were packed into a polyethylene terephtalate bag and used as a sample odor source. A similar sized bag was used as a control for supplying clean air in the first four experiments. Fig sources were changed every 1–2 h. Trials were replicated until there were at least 24 wasps responding to one of the odor sources in the Y-tube. In each experiment, all replicates were tested over 3 days. All bioassays of fresh fig sources were conducted between 08:30 to 11:30 during November and December 2005.

Bioassay of Fig Volatiles (Experiment B) The olfactory responses of *C. solmsi marchali* to three fig volatiles emitted from receptive *F. hipida* (e.g., linalool, limonene, β-pinene, and blends of linalool and limonene and β-pinene). This experiment examined whether a major or a minor constituent of volatiles attracts the pollinator at different quantities and determined whether these compounds could enhance the attraction of pollinators.

The concentrations of volatiles in the blends were set according to the amount emitted by the receptive figs. In the case of *F. hispida*, linalool, limonene, and β-pinene comprise 13.57%, 1.23%, and 0.24% of the total volatiles emitted by the receptive figs of male trees, and 15.74%, 2.90%, and 1.21% of the volatiles emitted by the receptive figs of female trees, respectively (Proffit et al. 2008). The compounds were diluted separately in dichloromethane (10^{-6} μl ~ 1 μl/100 μl). Cellulose sponge pieces (1×1×0.2 cm) were impregnated with 100 μl of diluted compounds. In the same way, a piece of cellulose sponge with pure solvent (100 μl of dichloromethane) was prepared as the control. After 20 min of solvent evaporation (to get rid of dichloromethane completely), each piece of sponge was stored in a pipette tube, the tube was put into a 30 ml glass container, and the container was connected with one arm of the Y-tube. The compound put into the pipette tube was used as a sample odor source and tested individually on one wasp. Each pipette tube was made from a 7 cm long, 1 ml polypropylene pipette tip, from which 3 cm of the bottom and 1.5 cm of the tip were removed. Trials were replicated until there were at least 40 wasps responding to either of the odor sources in the Y-tube.

Seven experiments (Table 2, Exp. B1-1, B1-2, B1-3, B2-1, B2-2, B2-3, and B3) were conducted to test single compounds. Based on the results of single compound tests,

the attractive enantiomers of linalool were mixed with the other two compounds (Table 2, Exp. B4 and B5). Each blend was tested respectively in four doses.

All the bioassays on compounds were conducted between 07:30 to 11:30 from February to May 2006 and from May to July 2007.

Statistical Analyses The results from each bioassay experiment were subjected to a chi-square (χ^2) test. The null hypothesis was that wasps had a 50:50 distribution between the two odor sources in two arms, respectively. Given the sample sizes in the experiments, statistical analyses were not needed when all the responding wasps entered one of the arms.

Results

Before testing all odor sources, a series of control tests were performed with arms of the olfactometer permeated with clean air. There was no observed difference in the responses of wasps to the two arms of the Y-tube: 20 directed to the right and 20 to the left when the arms were switched by turning the Y-tube over every five tests ($\chi^2=0$, $df=1$, $P=1.000$).

Bioassays of Odors from Receptive and Interfloral Fig Sources (Experiment A) In the treatment of fig odor vs. clean air, wasps chose the arm of the olefactometer with fig odor over the control, even when odors were emitted from interfloral figs (Fig. 1a). Subsequent experiments investigated the choices of *C. solmsi marchali* made between receptive and interfloral fig odors. Pollinators always showed a strong preference to the receptive fig odor, regardless of increases in interfloral fig numbers (Fig. 1b).

Bioassay of Fig Volatile Compounds (Experiment B) In the assays with single volatile compounds, all were tested with less than 1 μl. Among them, the highest doses of enantiomers of linalool were presented as 0.1 μl because the pollinators reacted in a confused, disordered way to it at a dose of 0.25 μl. At all tested doses, (*R*)-(+)-linalool, (*R*)-(+)-and (*S*)-(−)-limonene were never active (Fig. 2a,d,e). However, the other four compounds all evoked dose-dependent responses from *C. solmsi marchali*, although the threshold doses at which each first induced a significant response were markedly different. The wasp pollinators showed a strong preference for (*S*)-(−)-linalool when offered at amounts of 0.01 or 0.1 μl (Fig. 2b). The mixture of (*R*)-(+)- and (*S*)-(−)-linalool was attractive to wasps at doses of 0.001, 0.01, and 0.1 μl (Fig. 2c). No response was observed at lower doses for (*S*)-(−)-linalool or (±)-linalool. At the higher doses, (±)-limonene and (−)-β-pinene both evoked a significant wasp avoidance response, while they were neutral at the lower doses (Fig. 2f,g). Compared with either enantiomer of linalool and limonene, the mixture of *(R)*-(+)- and *(S)*-(-)-linalool enhanced pollinator attraction, while *(R)*-(+)-linalool and (*S*)-(−)-limonene enhanced wasp avoidance.

Subsequent experiments with volatile blends utilized a 10:1 ratio of (*S*)-(−)-linalool or (±)-linalool vs. (±)-limonene, or a 20:1 ratio of (*S*)-(−)-linalool or (±)-linalool vs. (−)-β-pinene. The (±)-limonene and (*S*)-(−)-linalool

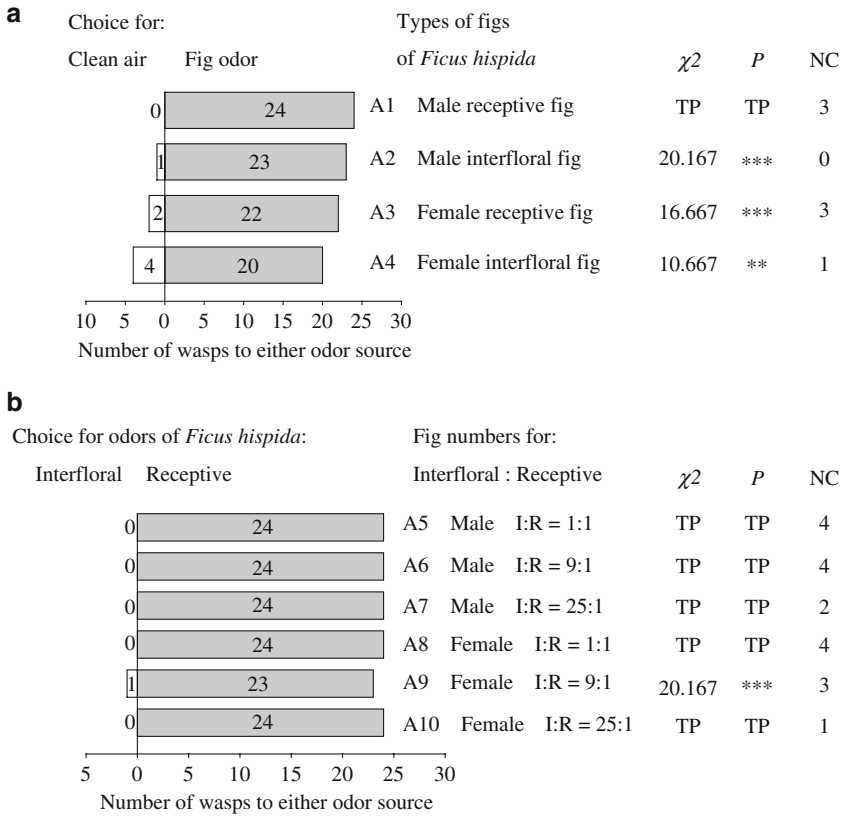

Fig. 1 Responses of females of *Ceratosolen solmsi marchali* to (**a**) volatiles of male or female figs of *Ficus hispida* at receptive or interfloral stages compared with clean air. The volatiles tested were emitted by one fig; (**b**) volatiles of male or female figs of *F. hispida* compared between receptive and interfloral stages. The ratios of number of interfloral vs. receptive figs (I:R) were set as 1:1, 9:1 and 25:1. Numbers in the bars are the number of wasps responded to the arms of the Y-tube. χ^2 test was used to evaluate whether the number of responding wasps differed from a 50:50 distribution between the two olfactometer arms (TP: there was no χ^2 test performed because one of the odor sources in either arm had a total preference (TP) of pollinators; ***$P<0.001$; **$P<0.01$). Wasps that did not response within 5 min [no choice (NC)] were excluded from statistical analysis

mixture was attractive to pollinators at the two higher doses (Fig. 2h). (±)-Limonene plus (±)-linalool was attractive at the three higher doses (Fig. 2i); however, at lower doses, pollinators did not respond to either of the two blends (Fig. 2h,i). The 20:1 ratio mixtures of both (*S*)-(−)-linalool and (±)-linalool to (−)-β-pinene were attractive to pollinators at the three higher doses but were neutral at the lower doses (Fig. 2j,k).

At higher doses, (*S*)-(−)-linalool and (±)-linalool actively attracted *C. solmsi marchali*, but a blend of (−)-β-pinene and (±)-limonene was repellent. (*R*)-(+)-Linalool, (*R*)-(+)-limonene, and (*S*)-(−)-limonene did not induce any response from the wasps. The non-active compounds (*R*)-(+)-linalool and (−)-β-pinene enhanced the attractiveness of (*S*)-(−)-linalool, while enantiomers of limonene did not.

Discussion

Post-pollination changes in floral characteristics, which include shape and color changes, cessation of nectar production, and scent alteration, can be detected by pollinators (Arditti 1979). The structure of inflorescences and specificity of the association make pollinator attraction by *Ficus* species unique. Both tactile and olfactory cues have been suggested to be involved in fig wasp's localization (Ramírez 1974; Janzen 1979; Ware and Compton 1992). Long-distance olfactory cues are used by wasps to find host trees that bear receptive figs. Tactile cues are used once the insect has landed on the fig surface to determine whether it is suitable (Gibernau et al. 1998). However, in this study, without any visual or tactile cues, fig wasps were attracted to host fig volatiles in the Y-tube. Thus, at short distances, tactile cues may not be indispensable for the pollinator to locate a receptive fig.

Few studies have tested directly pollinator responses to pollination-induced floral changes. (Gori 1983; Primack 1985; van Doorn 1997). The behavior of pollinating wasps at the receptive stage compared with that at the interfloral stage has not been studied, probably because the wasps are rarely observed on figs at the interfloral stage (van Noort et al. 1989; Ware and Compton 1994). Our findings showed

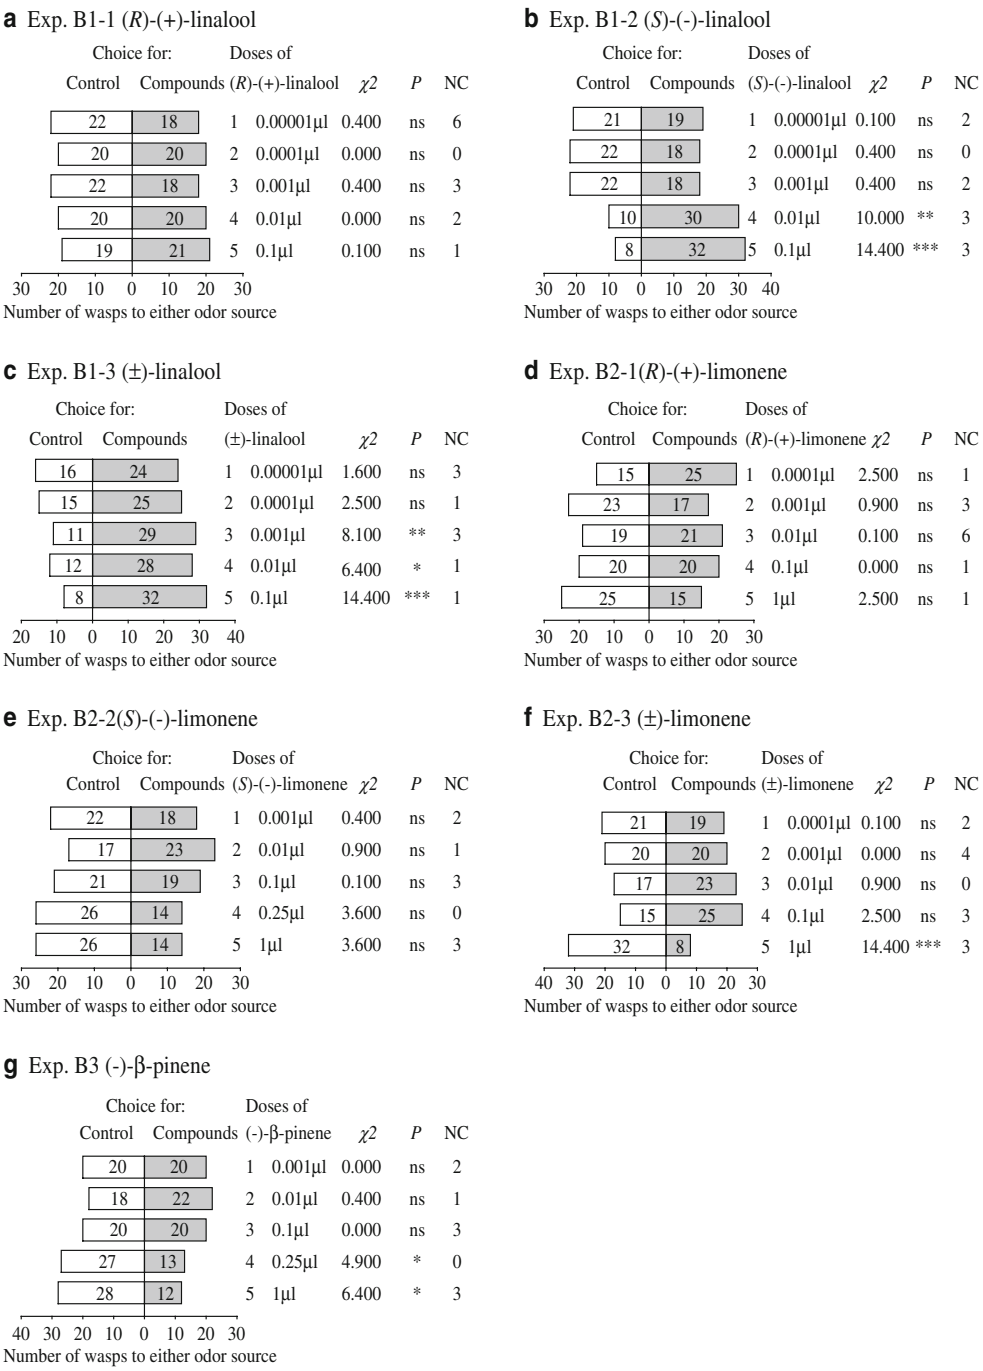

Fig. 2 Responses of females of *Ceratosolen solmsi marchali* to: (**a**–**g**) single volatile component mainly found in receptive figs of *F. hispida*, (**h**–**k**) blends mixed by a 10:1 ratio of *(S)*-(−)-linalool or (±)-linalool to (±)-limonene, and a 20:1 ratio of (*S*)-(−)-linalool or (±)-linalool to (−)-β-pinene. Each blend was tested respectively in four doses. The doses labeled in the figure belong to (*S*)-(−)-linalool or (±)-linalool in blends. Numbers in the bars are the number of wasps responded to the arms of the Y-tube. χ^2-test was used to evaluate whether the results differed from a 50:50 distribution between the two olfactometer arms (***$P<0.001$; **$P<0.01$; *$P<0.05$; ns: $P\geq0.05$). Wasps that did not response within 5 min [no choice (NC)] were excluded from the statistic analysis

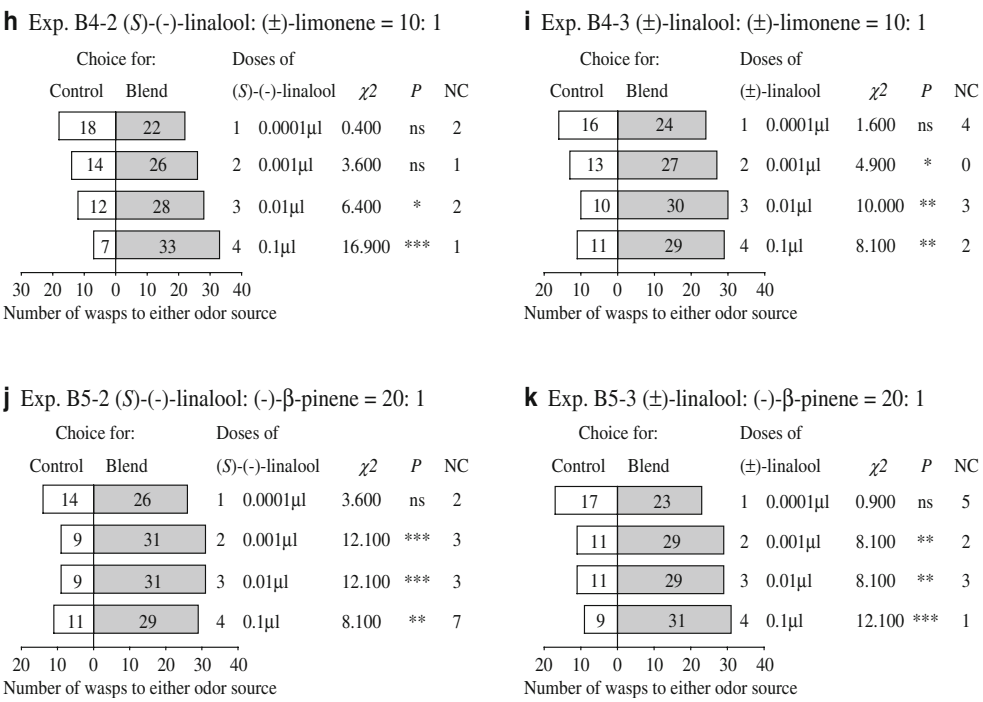
that two odor sources emitted from receptive figs and interfloral figs of *F. hispida* caused different behavioral responses of *C. solmsi marchali*. These results parallel previous studies in which pollinators were found to be attracted only to receptive figs (Ware and Compton 1994; Gibernau et al. 1998; Song et al. 2001). All previous studies were carried out under conditions when non-receptive figs coexisted with receptive figs. In the present study, we found unexpectedly that pollinators were attracted also to interfloral figs in the absence of receptive figs.

Raguso (2001) has summarized the three roles of post-pollination volatile emission in pollinator attraction as follows: distance attraction, futile visits prevention, and promotion of learned avoidance of reward-depleted flowers. It seems that the attractive effect of *F. hispida* interfloral figs cannot be explained by the above. We suggest that the similarity of odor composition in the two stages may be responsible for the wasps' tendency for futile attraction to interfloral inflorescences in the Y-tube olfactometer. Nearly all volatiles found in *F. hispida* interfloral figs occur also in

Fig. 2 (continued)



receptive figs. Linalool, the major volatile, continued to be emitted from the interfloral figs and was a strong attraction to pollinators in our tests. There might be an adaptive advantage to having pollinated figs that still draw wasps to a tree. In situations where pollinators are limiting, any extra attraction to trees could be advantageous—i.e., as long as wasps are drawn to figs that need to be pollinated, in preference to pollinated ones. In particular, this might be valuable for female trees where relatively few figs are attractive at any one time. Although pollinated figs are still attractive, wasps cannot get into them because the figs tightened obstacles after pollination. However, not all interfloral figs of *Ficus* species are attractive to their respective pollinators. In other studies, the interfloral figs of dioecious *Ficus semicordata* were not attractive to their pollinator *C. gravelyi*, (Chen and Song, unpublished data), probably because of differences in the volatile composition compared with receptive figs). The fig–fig wasp mutualism is a complex and diverse system, so conclusions deduced from one species should be carefully applied to another species.

Numerous studies have focused on whether quantity or quality plays a more important role in plant–insect chemical attraction (e.g., Visser 1986; Hoballah et al. 2002). Since *F. hispida* has lower volatile emission following the receptive stage, another aim of our study was to elucidate whether the quantity of odor in this fig species influenced the cognitive behavior of its pollinator. Our results indicate that higher quantities of interfloral fig odor were less attractive to pollinators than receptive fig odor. Although receptive figs may emit higher levels of volatiles, the stage-dependent host localization behavior of wasps is regulated by the composition and proportion of the compounds (i.e., quality), not just the quantity of volatiles. Moreover, all of the volatiles studied induced a behavioral response in wasps that was dose-dependent. All compounds tested at the lower concentrations were neutral, even those that were attractive to pollinators at higher concentrations. There is little doubt that compounds termed "attractants" can also act as neutrals or repellents at high concentrations. Single compound tests indicated that some compounds are more important than others in attracting wasps. Attractive compounds that were identified in this study, e.g., linalool, are common in many floral fragrances (Gibernau et al. 1997). In simulating changes in fig odors from the receptive to interfloral stage, we set four concentration degrees in the blend tests. Just as the interfloral figs with smaller volatile quantities were less attractive to pollinators, the attractive compounds were not attractive to the pollinator when their concentrations were comparatively low. At high concentrations, all blends of (*S*)-(−)-linalool or (±)-linalool with one of the minor components attracted pollinator wasps. However, at low concentrations, all blends were neutral. In addition to host quality odor, i.e., volatile composition, the quantity of active volatiles is also important.

Our mixture experiments confirmed synergistic effects of volatiles in plant odors (Visser 1986). In several cases, blends of active and non-active compounds are more attractive to parasites or pollinators than single compounds (Visser and Avé 1978; Dariusz and Stephen 1999). In this study, neither (±)-limonene nor (−)-β-pinene were attractive to *C. solmsi marchali* when applied singly; however, blends

of either of those compounds with linalool were more attractive. The attractiveness of (*S*)-(−)-linalool to *C. solmsi marchali* was enhanced by decreasing the active threshold dose from 0.01 to 0.001 μl when mixed with non-active (*R*)-(+)-linalool, (±)-limonene, or (−)-β-pinene.

The fig–fig wasp mutualism is a complex system, with variation among *Ficus* species and fig wasp species, volatile compounds, and volatile emission rhythms (Wiebes 1979; Berg 1989; Grison et al. 1999; Grison-Pigé 2001, 2002b). Our experiment is an initial exploration of pollinating fig wasp responses to pollination-induced changes. In the future, comprehensive studies should be undertaken to investigate further the chemical interaction in this specialized insect–plant mutualism.

Acknowledgments The authors thank Dr. Magali Proffit, Prof. Martine Hosseart-McKey (Centre d'Ecologie Fonctionnelle et Evolutive, France), and Dr. Susan M. Owen (Lancaster University, UK) for help in chemical analysis of the fig odor and Prof. Jean-Yves Rasplus (Centre de Biologie et de Gestion des Populations, France) for identifying wasps. We also thank Profs. Yang Darong and Li Qingjun (Xishuangbanna Tropical Botanical Garden, CAS, China) for support. The comments of Prof. Stephen G. A. Compton (University of Leeds, UK) and Dr. Magali Proffit improved the manuscript. This research was supported by the *Knowledge Innovation Project* and the special support of the Chinese Academy of Sciences (STZ-01-18).

The impact of herbivory is dependent on the relative density and species composition of browsers (Mysterud 2006). Both herbivore density and plant damage can be either site-specific or change seasonally, and even spatially. Larger-bodied mammals mostly affect the vegetation around farms and corrals where overgrazing is common (Wezel and Bender 2004). Large-scale variation in plant damage is correlated with herbivore density (Tsujino and Yumoto 2004). Herbivores that live in certain patch types may cause extensive damage in nearby plant associations as rabbits do in grasslands that surround junipers (Villafuerte and Moreno 1997), thus resulting in short-scale patchiness.

In previous studies, we focused on the juniper–poplar forests of a sandy region of Hungary. The differences in vegetation was attributed partly to local and seasonal changes in browsing pressure (Kertesz et al. 1993) by either the European rabbit (*Oryctolagus cuniculus*) or domestic sheep (*Ovis aries*), as the density of other browsers was negligible in the juniper forests (Katona and Altbacker 2002). Earlier studies had shown that browsing habits of the main herbivores differed by sites, as junipers (*Juniperus communis*) were browsed by rabbits at the Bugac site during the winter period exclusively (Matrai et al. 1998) and by sheep but not rabbits at the Orgovány site. Junipers were seemingly intact at the Bócsa site, even though both rabbits and sheep were present in the area. Traditional sheep grazing, mostly occurring from pens surrounding the forest, was restricted to the spring and autumn periods, and sheep grazing was discontinued by the authorities of Kiskunság National Park in 2001. This change in the management and recent collapse of the rabbit population (Katona and Altbacker 2002) resulted in reduced browsing pressure. As juniper shrubs regenerate slowly, comparison of the herbivory signs in local juniper stands has enabled us to evaluate the distribution of PSMs without current confounding impacts, such as induced responses in damaged branches (Nagy et al. 2000; Miller et al. 2005). Assuming that present plant damage still reflects previous browsing pressure, we describe the spatial and temporal pattern of the morphological and chemical constituents. The following hypotheses were tested: (1) the level of juniper damage should correlate negatively with essential oil yield; (2) oil yield should change by season in accordance with browsing pressure; (3) heavily browsed and nonbrowsed junipers should differ in their chemical composition; (4) browsing damage will reveal the main browser: it should be lowest in the middle of the forest if junipers were eaten by sheep or highest if rabbits were the main agents shaping the shrubs; and (5) long-term differences in local browsing pressure will be reflected in site-specific age distributions of juniper populations.

Methods and Materials

Study Area

This study was conducted in the sand dunes of the Kiskunság National Park in central Hungary (Fig. 1). Mosaics of juniper patches and intermittent sandy grasslands form the semidesert vegetation were categorized as juniper–poplar forests (Kertesz et al. 1993). The focus area of Orgovány (46°47′30″ N; 19°27′34″ E) was chosen for analyzing herbivore–juniper interactions. For a broader-scale analysis, we selected two additional shrubland areas: Bugac (46°38′58″ N; 19°36′38″ E) and Bócsa (46°38′56″ N; 19°27′31″ E) where the age distribution of juniper stands was analyzed for a comparison (see below).

Classification of Browsing Damage Level

The shape of damaged junipers was studied at the area of Orgovány (see Fig. 1). Browsing damage was classified from the ground to a height of 100 cm on a scale of 1–5 from nonbrowsed to heavily browsed (Fig. 2). Junipers were labeled as nonbrowsed when damage (shape distortion) was between 0% and 20%; mildly browsed when damaged ranged between 21% and 40%; medium-browsed when damage was between 41% and 60%; well-browsed when damage was between 61% and 80%; and heavily browsed

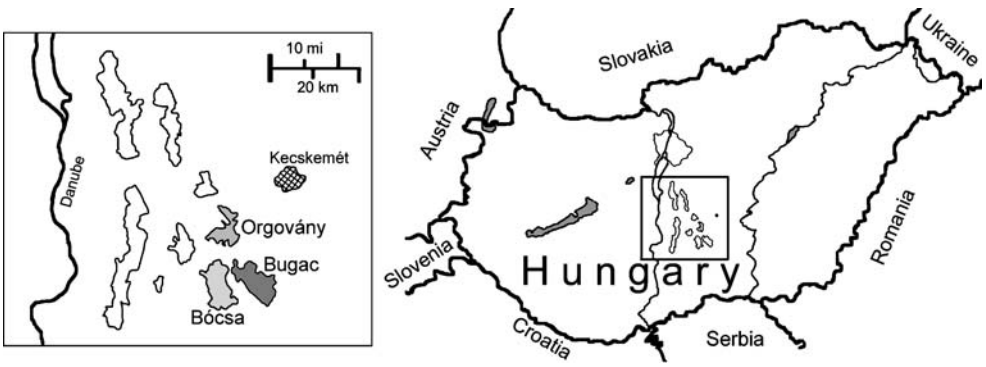

Fig. 1 Studies were conducted in the Orgovány, Bugac, and Bócsa areas of Kiskunság National Park, Hungary

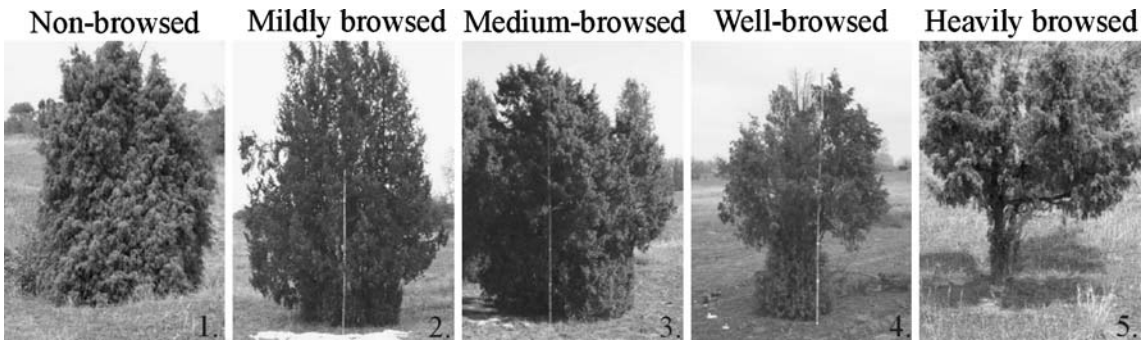

Fig. 2 Classification of browsing damage level of junipers. Pictures show *1* nonbrowsed (damage between 0% and 20%); *2* mildly browsed (damage between 21% and 40%); *3* medium-browsed (damage between 41% and 60%); *4* well-browsed (damage between 61% and 80%); *5* heavily browsed (damage between 81% and 100%) shrubs

if damage were between 81% and 100% of the bottom part of the shrub.

Seasonal Pattern of Essential Oil Yield

Ten randomly chosen, independent juniper shrubs were chosen in July and October of 2003 and February and May of 2004. Two nonadjacent shrubs were selected per damage level category. The height of these shrubs (2–2.5 m) and their gender (female) were similar. Samples consisting of 10 cm long tips of new branches were collected from the same height (about 1 m) from each shrub (100–120 g of foliage after removal of berries). Plant material was placed into plastic bags, stored in a cooler (5°C) for transport, and then oven dried at 37±3°C (Memmert U-type oven). The method described by Pharmacopoea Hungarica (Vegh 1986) was used to extract the essential oil except that the steam distillation time was reduced to 1.5 h because of the negligible (less than 5% of the total) additional yield afterwards (Bernath, unpublished data). Dried plant material (40–50 g), chopped into 2–3 cm pieces, was distilled with a Clevenger apparatus constructed according to Vegh (1986). Statistical analysis consisted of two-way repeated-measures analysis of variance (ANOVA) with damage level as a fixed factor and season as a repeated factor.

Essential Oil Composition

Plant material was collected during February 2004 from the Orgovány area. Heavily browsed and nonbrowsed shrubs (N=10 and 10, respectively) were selected randomly from the most browsed part of the forest. The terminal 10–15 cm of foliage was clipped from several branches between ground level and 2 m height. Sample preparation and extraction of essential oil was as described above. The chemical composition of essential oils extracted from the above 10 heavily browsed and 10 nonbrowsed shrubs was analyzed with a Shimadzu 14B gas chromatograph equipped with a FID detector and SE-30 capillary column (30 m×0.25 mm and 0.25 mm film thickness). The carrier gas was nitrogen (1 mL min^{-1}), and the split ratio was 75/1. The oven temperature program was as follows: 110°C for 3 min, up to 220°C at 8°C min^{-1} (5 min), 21.75 min analysis time, IB 220°C, and detection 250°C. Data were analyzed using the Shimadzu Class VP Chromatography Data System (Shimadzu, Japan) software. The area normalization method (Novak et al. 2001, 2003) was used to determine the relative percentage of oil constituents. Identification of compounds was performed by peak enrichment with gas chromatography (GC) standards by (Carl Roth; Karlsruhe, Germany). Student's t tests were used to test the statistical differences in essential oil components of heavily browsed and nonbrowsed samples.

Effect of Grazing Pressure

The spatial distribution of grazing damage was analyzed at the Orgovány site (see Fig. 1) where rabbits disappeared in 1995 and traditional sheep grazing was discontinued in 2001. Three plots (approximately 100 m in diameter) were defined along a transect running between the last active sheep pen found at the border of the juniper forest (N=100) and the middle of the juniper forest (N=100). Within each plot, the shape of junipers was classified by using a spiral sampling from the center point. We expected a decreasing trend if sheep were the most important agents shaping the shrubs, an opposite trend if rabbits browsed most intensively, or an inverse U-shaped spatial pattern if both species contributed to browsing damage. The Mantel–Haenszel χ^2 test was used to analyze data.

Long-Term Consequences of Juniper Browsing

The age distribution of juniper shrubs was evaluated in three separate forests (Bugac, Bócsa, and Orgovány) in May 2003. The basal diameter of the stems from plants at the border of the juniper forest (N=100) and the middle of

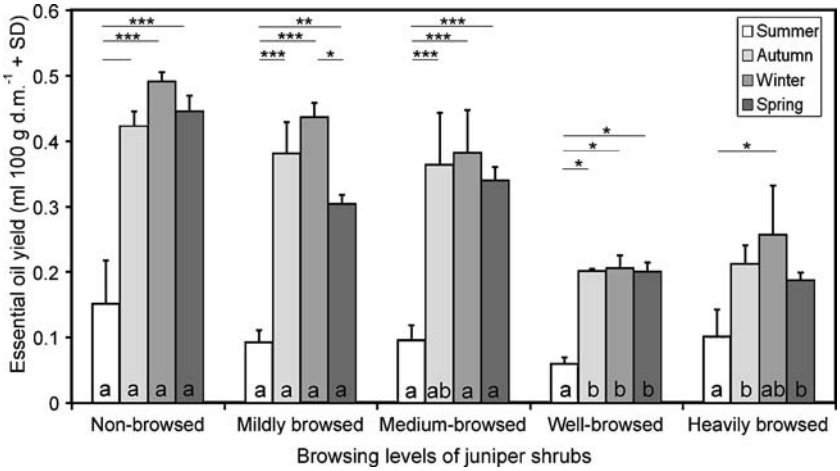

Fig. 3 Seasonal pattern of juniper essential oil yield (N=2–2) belonging to different browsing damage levels. Mean values were tested for significant differences (P<0.05) by two-way repeated-measures ANOVA followed by Duncan's post hoc tests for all pairwise comparisons. *Different letters* indicate significant differences among damage level categories, while *P<0.05; **P<0.01; ***P<0.001 are significant differences among seasons

the juniper forest (N=100) was measured at each site around 5–5 randomly chosen points by using spiral sampling (altogether 500 individuals per area). Stem diameter was measured with a slide caliper (MEBA, Croatia) at a height of 10 cm. Polished cross-sections of dead junipers (N=13) of different diameters were prepared to count annual rings for age determination. Data were compared by site as a fixed factor and age categories as a repeated factor with two-way repeated-measures ANOVA followed by Duncan's post hoc tests.

Results

Seasonal Pattern of Essential Oil Yield of Differently Browsed Junipers

The relationship between oil yield, damage level, and seasonal pattern is shown in Fig. 3. Damage level was inversely proportional to essential oil yield. Analysis of oil yield, done with a two-way repeated-measures ANOVA and Duncan's post hoc test, indicated a significant effect of browsing level (F(4,5)=5.64, P=0.027) and season (F(3,15)=48.24, P<0.001) without indication of a significant interaction (F(12,15)=1.70, P=0.164). This suggests a similar seasonal change in the different browsing level categories. Oil yield was lower in the summer period than in the other seasons.

Essential Oil Components of Heavily Browsed and Nonbrowsed Juniper Shrubs

Essential oil components of heavily browsed and non-browsed juniper shrubs (Fig. 4) were tested with Student's t tests using the Welch correction). Significant differences were found between the following chemical constituents of the essential oil: α-pinene (t(10)=2.187, P=0.05); δ-3-carene (t(9)=3.061, P=0.01); β-myrcene (t(17)=2.111, P=0.04); and other unidentified components designated by their retention time 11.14 (t(12)=2.488, P=0.02) and 12.22 (t(12)=2.405, P=0.03). The concentration of some chemicals was lower (δ-3-carene and β-myrcene) in the browsed shrubs than in the undamaged junipers. In some cases, they were higher (α-pinene).

Browsed Shrubs and Herbivore Pressure

The frequency of browsed shrubs was compared among three plots (Fig. 5). There was a decrease in the ratio of heavily browsed shrubs toward the center of the shrubland (Mantel–Haenszel χ^2 test for linear trend: $\chi^2(2)=46.143$; P<0.001). The majority of shrubs was browsed on the plot closest to the formerly active sheep pen, indicating a high browsing pressure by sheep. Deep in the forest, damage was less evident, suggesting that it was mainly sheep browsing rather than rabbits that contributed to the shaping of the junipers at Orgovány.

Long-Term Consequences of Juniper Browsing

We estimated the age of junipers by measuring their stem diameter. The linear regression equation (y=0.386x+4.97) describes a significant stem–age function (R^2=0.87, P<0.001) and was used to estimate age in Fig. 6. We compared the frequency distributions by using a two-way repeated-measures ANOVA followed by Duncan's post hoc tests for all pairwise comparisons and found that age distributions were different among the areas (F(2,12)=0.42, P<0.001), age classes (F(7,84)=0.28, P<0.001), and areas×age classes (F(14,84)=0.11, P<0.001). Further analyses of site differences within age classes showed that the juniper stand at Bugac is different from the other two populations. There was a smaller proportion of age classes of juniper less than 20 years, indicating that Bugac lacks young individuals.

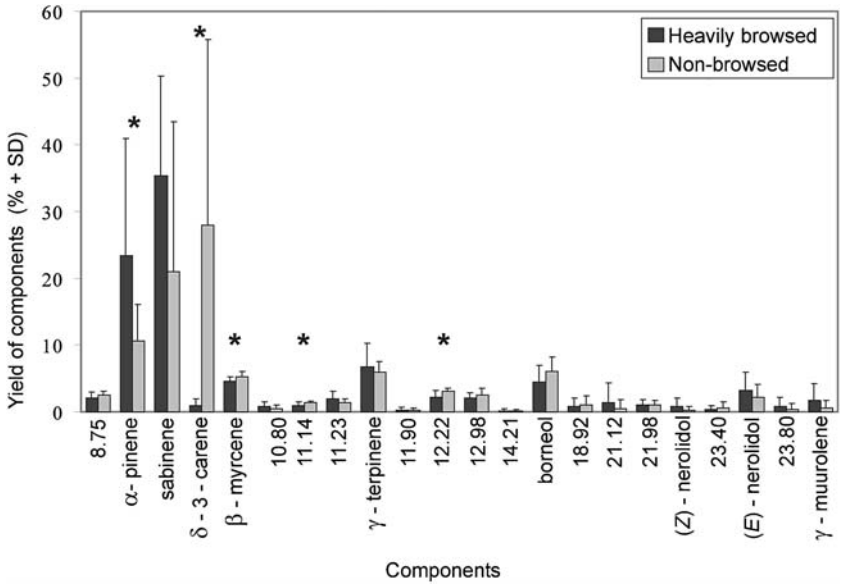

Fig. 4 Quantification of essential oil components of heavily browsed ($N=10$) and non-browsed juniper ($N=10$) shrubs from the Orgovány area as determined by GC. The identification of the oil components was based on a comparison of GC standards (Carl Roth; Karlsruhe, Germany). Component percentages were computed from GC (FID) peak areas by using the area normalization method. *Bars* represent the mean values+SD. Statistical difference of essential oil components of heavily browsed and nonbrowsed samples was verified by Student's *t* tests with Welch correction. *$P<0.05$, significant differences

This indicates that junipers at Bugac are older than the other two stands. Junipers at Bócsa and Orgovány seem to form stable populations with a linear decrease by age.

Discussion

It has been assumed that plant damage investigated at different temporal and spatial scales reflects selective herbivory for juniper forests in Hungary. The level of juniper damage was tested for a possible correlation with PSM concentration and the seasonal changes in browsing pressure, as plant damage can influence PSM concentrations in response to herbivore density (Tsujino and Yumoto 2004). Assuming that both the appearance and chemical composition of shrubs reflects grazing pressure, we found support for several predictions of plant–animal interaction. A diminishing impact toward the middle of the forests was expected in areas of sheep browsing damage. In contrast, an opposite spatial distribution of grazing damage should be found in rabbit-dense areas where damage is concentrated deep in the forest, as rabbits feed around their warrens to avoid open areas (Moreno et al. 1996). The level of damage was highest near a sheep pen (the activity center for the pastoral grazing system). There was no evidence of rabbit browsing in this location (Fig. 5).

Variation in the shape of juniper shrubs corresponded to their chemical composition (Fig. 4) with truncated shrubs containing the lowest oil yield. This indicates that PSMs might have led to avoidance of the undamaged shrubs (Provenza et al. 2003). Concentrations of volatile oils varied among junipers and seasons (Fig. 3). Even though our simplified method of essential oil extraction could underestimate the total oil yield (Venskutonis 1997;

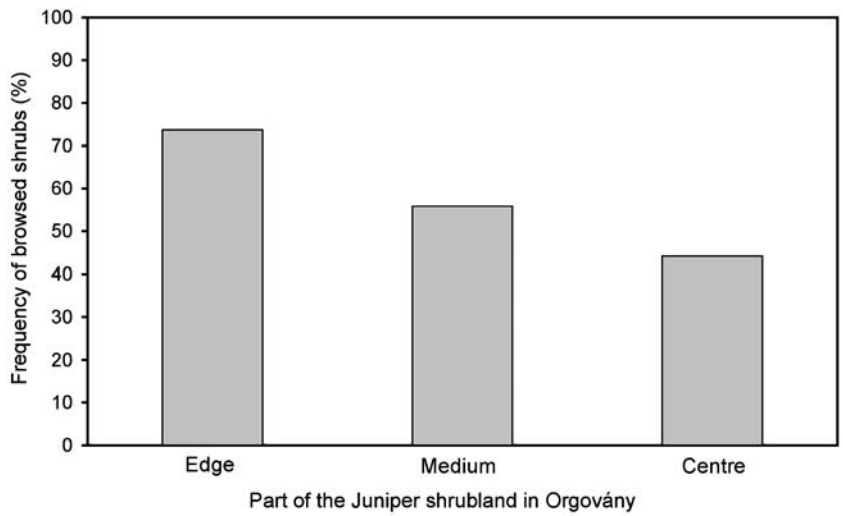

Fig. 5 Spatial distribution of damaged junipers along an axis from the edge to center of the juniper shrubland at Orgovány. *Bars* represent the frequency of juniper shrubs with any signs of browsing determined in 1 ha plots. In each plot, 100 individuals were classified. Mantel–Haenszel χ^2 test for linear trends showed damage frequency to decrease from edge to center, indicating that distance from the sheep fold was more important than presence of rabbits in determining browsing damage

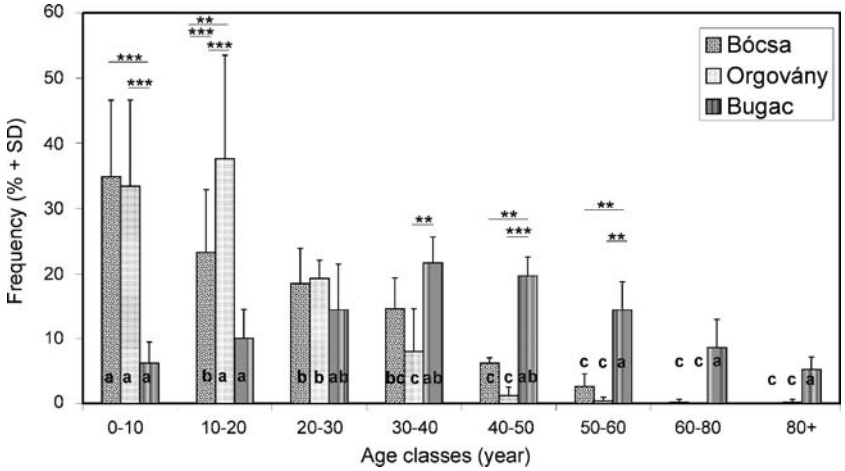

Fig. 6 Age structure of *J. communis* populations in the three study areas (Bócsa, Orgovány, and Bugac) of Kiskunság National Park, represented as the percentage of individuals belonging to the corresponding age class. In each area, the age distribution was determined from five different plots where stem diameter of the individuals at the border of the juniper forest (N=100) and the middle of the juniper forest (N=100) was measured. Age was determined by using the regression equation y=0.386x+4.97 based on counting age rings for 13 reference stems collected in the same locality. Mean values were tested for significant differences (P<0.05) by two-way repeated-measures ANOVA followed by Duncan's post hoc tests for all pairwise comparisons. Different letters indicate significant differences among age classes, while *P<0.05; **P<0.01; ***P<0.001 are significant differences among areas

Milojevic et al. 2008), differences among shrubs that show high or low damage levels are still meaningful. Certain chemicals might have contributed to reduced consumption, as browsed junipers contained essential oil with elevated levels of terpenoids (Fig. 4) similar to conifers (Vourc'h et al. 2001, 2002). In our case, the most frequent constituents, α-pinene and sabinene, were even more concentrated in the damaged plants than in those that were avoided. It should be noted that plants with low levels of α-pinene were rich (i.e., had high levels) of δ-3-carene, β-myrcene, and borneol, and whose concentration was high in damaged shrubs. This suggests that the complex composition of the oil, and not the concentration of a single component, may explain the variation in herbivore damage. Sheep avoid food when exposed to α-pinene or a mixture of monoterpenes (Narjisse et al. 1996), and lambs exposed to camphor and α-pinene reduced their food intake (Estell et al. 2005). The strong selective pressure exerted by black-tailed deer (*Odocoileus hemionus sitkensis*) contributed to the persistence of individual seedlings with high concentrations of chemical defenses (Vourc'h et al. 2001). In semiarid environments similar to our study site, aromatic plants often contain high monoterpenoid levels that can interfere with digestion (Carpenter et al. 1979). A tenfold increase in δ-3-carene was found in nonbrowsed junipers of Orgovány. In other studies, monoterpenes were either positively (e.g., cymene) or negatively (e.g., α-pinene, sabinene, β-pinene, myrcene, terpineol) correlated with goats' willingness to ingest juniper (Riddle et al. 1996). Black-tailed deer were repelled by α-pinene, myrcene, and sabinene (Vourc'h et al. 2002). The antiherbivore defense of red cedar (*Thuja plicata*) was directly proportional to the level of herbivory, as the essential oil yield and quality were adapted to the feeding pressure (Vourc'h et al. 2001).

PSM production may be seasonally coupled with herbivore browsing. Seasonal changes in essential oils have been documented for many coniferous species (Nerg et al. 1994; Riddle et al. 1996). Owens et al. (1998) reported a strong seasonal influence on volatile oil concentration in the leaves of ashe juniper (*Juniperus ashei*) and redberry juniper (*Juniperus pinchottii*). Essential oil concentrations were highest during the winter and spring months (January through May) and lowest in summer and fall. Similarly, the essential oil in thyme (*Thymus vulgaris*) was highest in midsummer (Badi et al. 2004) when browsing by goats is most intensive (Riddle et al. 1996). Production of volatile terpenoids (e.g., monoterpenes, sesquiterpenes, and homoterpenes) can be induced by herbivore feeding (Arimura et al. 2005), a mechanism that is well-studied in conifers (Trapp and Croteau 2001; Martin et al. 2003; McKay et al. 2003; Miller et al. 2005). In the present study, juniper oil had the lowest concentration during the summer period. The high concentration of essential oils in other seasons was remarkable. Due to management practices, sheep were present in the spring and autumn periods. Based on fecal analyses, rabbits most likely browsed junipers in winter (Matrai et al. 1998). As browsing by the main browsers were no longer present in the study area in the present sampling period, the induced plant protection system known for conifers was unlikely to be responsible for the seasonal changes observed. It is more likely that preexisting individual differences in PSMs production resulted in various levels of browsing damage, and that was still obvious at the time of sampling due to slow growth of junipers.

Differences in age distribution of junipers were expected among the areas due to local herbivores that affect the survival of shrubs. The difference in age distributions of compared stands might stem from herbivore species composition and foraging behavior of local herbivores. The foraging habits of European rabbits resulted in a high mortality of young shrubs at Bugac (Matrai et al. 1998), and age distribution of juniper stands reflects that impact (see Fig. 6). In spite of the recent browsing by sheep, the age distribution of the juniper population in Orgovány has remained the same as in Bócsa where neither sheep nor rabbits consumed juniper. Sheep forage mainly in the grassy patches and only start eating juniper when grass becomes scarce. The occasional browsing of tall junipers from the side did not affect the survival of junipers, but did modify their morphology. Rabbits, on the contrary, forage in well-hidden places close to shrubs and not only browse the bottom twigs of older plants, but can destroy young junipers as well, as our former field experiment proved (Matrai et al. 1998). For renewal of the juniper stands, it is essential that seedlings survive, especially as *J. communis* becomes fertile only after several years, and aging results in reduced fertility (Ward 2007). The long-term accumulation of such impacts could have resulted in the distorted age distribution of junipers at Bugac.

Herbivores may circumvent the negative effects of plants by physiological (Dearing et al. 2000) or behavioral means (Provenza 1995). The effect of plant metabolites can be reduced by several strategies; for example, certain herbivores can avoid tannin-containing plants by learned avoidance (Provenza 1995), and selective browsing minimizes the intake of harmful plants (Launchbaugh et al. 2001). Therefore, within the same plant population, individuals with a higher concentration of PSMs may enjoy better protection (Bryant et al. 1985). Juniper browsing by mule deer (*Odocoileus hemionus*) was inversely correlated to the essential oil yield (Schwartz et al. 1980a). This may be attributed to the oxygenated monoterpenes and sesquiterpenes in the oil that inhibit the microbial activity in the deer's rumen after ingestion of a certain number of branches (Schwartz et al. 1980b). As Welch et al. (1983) showed, PSM concentration was not the only determinant of food intake. More detailed studies are necessary.

Signs of a varying amount of juniper consumption were found by site and season. Such differences might stem either from plant toxicity, feeding responses of animals, or an interaction of both (Iason and Villalba 2006). Thyme was one of the main components of the summer diet of the Bugac rabbits (Matrai et al. 1998) and naive animals in captivity consumed small amounts if their mother was forced to eat thyme despite its toxicity (Altbacker et al. 1995). Rabbits could adjust their diet both by individual and social learning (Bilko et al. 1994). With a mixed diet, the accumulation of certain PSMs can be avoided and consumption increased (Marsh et al. 2006), and thereby the energy and toxin intake optimized (Bryant et al. 1985, 1992; Provenza et al. 2003) as can be observed in several generalist vertebrates. Nevertheless, some specialists are physiologically better adapted to ecological constraints and have a more efficient detoxification system than generalists (Dearing et al. 2000). Experimental manipulation of juniper chemical composition in food choice tests are currently underway in order to reveal how oil content and carene concentration reduce juniper consumption. Further studies that use different herbivore species and manipulate experience levels when alternative food sources are present would be valuable (Dearing et al. 2000; Villalba and Provenza 2005). Substantial changes in the grazing regime are considered as the major force of succession in semidesert shrub lands (Evans et al. 2006). Understanding the mechanisms that contribute to the interaction of plant defenses and browsing behavior of local herbivores is increasingly important.

Acknowledgments We thank István Németh for his contribution to the fieldwork and the Kiskunság National Park for their support of our field surveys. The suggestions from two anonymous reviewers is acknowledged for strengthening this manuscript. This study was supported by the Hungarian Scientific Research Foundation (OTKA T 29703) and the National Research and Development Program (NKFP 3B-0008/2002).

functions have been categorized as direct and indirect resistance mechanisms, respectively.

Nitrogen (N) application is an important practice in crop production. It can exert a variety of bottom-up effects and may significantly alter tritrophic interactions through qualitative and quantitative alteration of plant direct and indirect defensive compounds (McNeil and Southwood 1978; Stiling and Moon 2005). Soil nitrogen availability affects the expression of constitutive and induced plant defenses in a wide range of plant species (Stout et al. 1998; Cipollini and Bergelson 2001; Coviella et al. 2002). The level of expression of secondary metabolites may correlate positively (Cipollini and Bergelson 2001; Lou and Baldwin 2004), negatively (Stout et al. 1998; Hemming and Lindroth 1999), or not at all (Dudt and Shure 1994) with nitrogen availability among systems examined, but surprisingly few crop species have been examined in detail.

Nitrogen levels affect the release of plant volatile organic compounds (VOCs), which serve as cues for natural enemies to locate potential hosts/prey (Dicke et al. 1990; Choh et al. 2004). For example, in maize (*Zea mays* var Delprim), the maximal-induced volatile emission was detected after both mechanical wounding and addition of an elicitor from oral secretions of the noctuid *Spodoptera exigua* (Schmelz et al. 2003a) when N fertilization was the lowest. Similarly, celery with additional N had a lower quantity of constitutively emitted volatiles (Van Wassenhove et al. 1990). In contrast, Gouinguené and Turlings (2002) found that unfertilized maize plants (*Z. mays* var Delprim) emitted less volatiles following application of crude *Spodoptera littoralis* oral secretions when compared with those that had received a complete nutrient solution. Unfortunately, the role of N alone was unclear in this study because all the nutrient amounts were varied. In tobacco (*Nicotiana attenuata*), volatile emission levels were not affected by N, although low N availability attenuated the jasmonate and salicylate levels and reduced two N-containing antiherbivore defensive compounds, namely nicotine and trypsin proteinase inhibitors (Lou and Baldwin 2004). Based on this documented variability, the responses of any given plant species or crop cannot yet be readily predicted.

Changes in insect-induced phytohormone production or sensitivity mediated by nutrient availability may provide a mechanism for regulating the magnitude of plant defense responses. With jasmonates established as key regulators of plant responses to insect herbivores (Browse and Howe 2008), jasmonic acid (JA) serves as a useful marker in probing interactions between nutrients and induced defenses. In maize, direct positive relationships have been established between *S. exigua*-induced JA accumulation in the leaves and subsequent induced volatile emission (Schmelz et al. 2003b). In this system, low N availability resulted in higher levels of sustained JA accumulation and subsequent induced volatile emission, following treatment with insect-derived elicitors, than identically treated plants grown under medium N availability (Schmelz et al. 2003a). Despite some advances, few studies have considered the interactions between N fertilization, herbivore-induced JA, and defense in agronomically significant crops (Schmelz et al. 2003a; Lou and Baldwin 2004).

In this study, we investigated the defense response of cotton plants in relation to nitrogen fertilization. Specifically, we tested three hypotheses: (1) increased N fertilization will result in a reduced production of carbon-rich herbivore-induced defense responses, specifically JA and terpenoid aldehydes, in cotton leaves; (2) production of volatile organic compounds will be affected by N fertilization; and (3) the parasitoid *Cotesia marginiventris* will inflict higher mortality on sentinel beet armyworm larvae feeding on plants emitting higher VOC levels.

Methods and Material

Plants Cotton (*Gossypium hirsutum* cv. FiberMax 989) plants were grown using methods and nutrient solutions described by Chen et al. (2008), except as otherwise noted. Plants were fertilized with 100 ml of 112 ppm N nutrient solution daily for approximately 2 weeks, at which time they were of the same height and with leaves of similar size at the same leaf position were randomly assigned to different N treatments. Cotton plants were subsequently fertilized with respective N nutrient treatment solutions (42, 112, 196, and 280 ppm N) for approximately 2 weeks until experimentation. Leaching (watering without nutrients) followed every fourth N nutrient solution application to limit soil salinity. All experimental plants had three–five mature true leaves.

Insects Beet armyworm (*S. exigua*) larvae (reared on modified Pinto bean diet; Chen et al. 2008) and their parasitoids (*C. marginiventris*) were from laboratory colonies maintained in the Biological Control Laboratory at the University of Georgia in Tifton, GA, USA.

Plant Hormone and Volatile Production in Relation to N Fertilization To examine the effects of N fertilization on production of phytohormones and volatiles, a 2 (leaf position—local and systemic)×3 (N fertilization—42, 112, and 196 ppm N)×2 (herbivore infestation—control and 20 *S. exigua* larvae/plant) factorial experiment was designed. For the herbivore damage treatments, 20 3-day-old *S. exigua* larvae were caged on the third true leaf on the main stem for 48 h (see Chen et al. 2006 for cage description). In control treatments, a cage with no larvae was placed on the third true leaf to account for possible physiological changes caused by cages. The cages were checked twice daily for

larval escape and availability of leaf tissue for caterpillars. If all the leaf tissue within the cages were eaten, then the cages were moved to an undamaged location on the same leaf. Immediately following continuous feeding for 48 h, the insect-damaged leaves of all treatments were briefly and gently cleaned with a fine brush to remove larvae and debris. Damaged leaves were photographed digitally for herbivory assessment immediately following removal of larvae and debris, and approximately 150–200 mg fresh leaf tissue from each sample leaf were collected, weighed, stored in FastPrep® tubes containing approximately 1 g Zirmil beads (1.1 mm; SEPR Ceramic Beads and Powders, Mountainside, NJ, USA), and frozen in liquid N as described in Schmelz et al. (2004). Leaf damage was quantified by using the digital images as described in Chen et al. (2006). Samples were collected from leaf 3 (local, damaged, mature leaf) and leaf 6 (systemic; expanding at the time of experiment) and stored at −80°C until analysis. Each treatment was replicated four times.

Terpenoid Aldehyde Production in Relation to N Fertilization To examine the effects of N fertilization on terpenoid aldehyde production, the same 2 (leaf position)×3 (N fertilization)×2 (herbivore infestation) factorial experiment as phytohormone and volatile assessment was designed. At the beginning of the experiment, 20 3-day-old *S. exigua* larvae were caged on the third true leaf of the treatment plants to induce production of the terpenoid aldehydes (see Chen et al. 2006 for cage description). A cage with no larvae was placed on the third true leaf of control plants (zero larvae) to account for possible physiological changes caused by cages. Similarly, cages were checked twice daily for escape of larvae and availability of leaf tissue. Cages and *S. exigua* larvae were removed after 48 h of continuous feeding. The insect-damaged leaves of all treatments were briefly and gently cleaned with a fine brush to remove larvae and debris. A photo of the damaged leaves was taken immediately following removal of larvae and debris and excised at the distal end of the petiole and stored at −80°C until lyophilization. The leaf damage was quantified as in the previous experiment. The sixth true leaves (young and expanding leaves) of all treatment plants were also collected to quantify the effects of N fertilization on systemic production of terpenoid aldehydes. Each treatment was replicated four times.

C. marginiventris Foraging Tests To examine the effects of N fertilization on short-range host location by parasitoids, three cotton plants of one N treatment were placed in one end of 2×2×2 m cages covered with fine mesh. The mesh has square holes with 1 mm openings. Three plants of the other N treatment were placed in the opposite side of the cage. Plants were so arranged that the same N treatments were touching each other but were separated from the other treatment by at least 50 cm. N pairings tested were 42 vs. 196 and 112 vs. 280 ppm N. Forty (42 vs. 196 ppm N trial) or 30 (112 vs. 280 ppm N trial) neonate *S. exigua* larvae were placed on the top leaves of each cotton plant (a total of 120 and 90 larvae/treatment for 42 vs. 196 and 112 vs. 280 ppm N trials, respectively) and allowed to feed for 24 h before five *C. marginiventris* females were released into the center of the cage. *C. marginiventris* females were prepared as follows: 1-day-old male and female wasps were placed together in a plastic cage and 2-day-old *S. exigua* larvae were provided for 24 h for oviposition experience of females; the 2-day-old male and female wasps were then transferred to a new cage without *S. exigua* larvae but supplied with a cotton ball soaked in 5% honey solution for 24 h before experimentation. Remaining *S. exigua* larvae were recovered 24 h after parasitoid release and placed in groups of five in 5-ml plastic cups filled with 3 ml of modified Pinto bean diet. Parasitoid offspring emergence was checked daily. Recovery rate was calculated as the total number of *S. exigua* larvae recovered divided by 120 (42 vs. 196 ppm N trial) or 90 (112 vs. 280 ppm N trial). Parasitism rate was calculated as the number of *C. marginiventris* offspring that emerged from hosts, regardless of cocoon construction, divided by the total number of *S. exigua* larvae recovered. Total mortality was calculated as the total number of dead *S. exigua* larvae divided by the total number of larvae recovered.

Chemical Analyses The high performance liquid chromatography (HPLC) procedure outlined by Stipanovic et al (1988) was used to analyze terpenoid concentrations. Samples (100 mg of freeze-dried ground plant material) were shaken for 30 min in a capped 125-ml Erlenmeyer flask with 15 ml of glass beads, 10 ml of 3:1 hexane:ethyl acetate (HEA), and 100 μl of 10% HCL. The solution was filtered over a glass-fritted filter funnel into a 50-ml pear-shaped flask, and the beads and residue were rinsed three times with 3 ml of HEA. The solvent was left to evaporate in a 90°C water bath, and the residue in the flask was redissolved with four 150-μl HEA washes. Each wash was transferred to a Maxi-clean silica cartridge (Alltech, Breda, The Netherlands). The silica cartridges were dried with compressed air, and terpenoid compounds were eluted with 5 ml of isopropyl alcohol, acetonitrile, water, and ethyl acetate (35:21:39:5). The eluent was filtered through a 45-μm nylon filter and transferred to a crimp top vial. Twenty microliters of each sample were analyzed by an HPLC system (DIONEX Corp., Sunnyvale, CA, USA), using a single wavelength UV absorbance detector (λ= 272 nm) and a 250-mm long, 4.6-mm (*id*) Alltima C-18 column (Alltech, Breda, The Netherlands). The column was eluted with ethanol/methanol/isopropyl/alcohol/acetonitrile/water/ethylacetate/dimethylformamide/phosphoric acid

(16.7:4.6:12.1:20.2:37.4:3.8:5.1:0.1) at a flow rate of 1.25 ml per min and kept at 55°C during analysis (Stipanovic et al. 1988). Standard of gossypol (G) was purchased from Sigma Aldrich (UK), and standards of hemigossypolone (HGQ), heliocides 1 and 4 (H_1 + H_4), and heliocides 2 (H_2) and 3 (H_3) were kindly provided by Dr. R.D. Stipanovic. These standards were used to assess retention times of the individual terpenoids. Terpenoids were calculated as microgram per gram dried plant material.

Vapor phase extraction was used to estimate acidic phytohormones and herbivore-induced VOCs simultaneously, with analyses following those of Schmelz et al. (2004). Briefly, the plant metabolites were extracted with 300 µl of H_2O/1-propanol/HCl (1:2:0.005) and 1 ml dichloromethane ($MeCl_2$). The $MeCl_2$/1-propanol layer into which plant metabolites were extracted was then transferred to a glass vial, and 2 µl of 2.0 M trimethylsilyldiazomethane solution were added to form methyl esters of carboxylic acid containing analytes. Residual trimethylsilyldiazomethane was neutralized with excess acetic acid. Plant volatiles were trapped on filters containing 30 mg Super Q (Alltech Associates, Inc., Deerfield, IL, USA) at 200°C and eluted with $MeCl_2$. Samples were later analyzed with chemical ionization-gas chromatography/mass spectrometry (CI-GC/MS) profiling method. The settings of the CI-GC/MS profiling method are described elsewhere (Engelberth et al. 2003; Schmelz et al. 2004). Estimates of total JA and salicylic acid (SA) represent combined pools of endogenous methyl esters and free acids. Plant volatiles analyzed were (*Z*)-3-hexenal, (*E*)-2-hexenal, (*Z*)-3-hexenyl acetate, indole, α-pinene, β-pinene, myrcene, (*E*)-β-ocimene, β-caryophyllene, (*E*)-β-farnesene, (*E*)-4,8-dimethyl-1,3,7-nonatriene (DMNT), (*E*,*E*)-4,8,12-trimethyl-1,3,7,11-trideca-tetraene (TMTT), α-bergamotene, α-humulene, γ-bisabolene, bisabolol, and limonene. Unless otherwise noted, quantification was based on the slopes of external standard calibration curves derived from the peak areas of $[M + H]^+$ parent molecular ions generated for each compound. Authentic standards for α-bergamotene and bisabolol were not available; thus, tentative identifications based on electron ionization spectra were made by using a National Institute of Standards and Technology database. To estimate quantities, the slopes generated for β-caryophyllene and γ-bisabolene were applied to the tentative α-bergamotene and bisabolol peak areas, respectively. All reagents and solvents used in the experiments were acquired from Sigma-Aldrich (St Louis, MO, USA) or previously established research standards.

Statistical Analyses The experimental design for phytohormone and volatile production assessment was a 2 (leaf position—young and mature)×3 (nitrogen levels—42, 112, and 196 ppm N)×2 (herbivore infestation—0 and 20 *S. exigua* larvae) factorial, so the amounts of chemical compounds were analyzed by a three-way analysis of variance (ANOVA). The data were square root (x+3/8) transformed for heteroscedasticity before analysis. The experimental design and analysis for terpenoid aldehyde production was the same as for phytohormone and volatile production assessment, except that untransformed data were analyzed. Leaf damage inflicted by *S. exigua* was analyzed by one-way ANOVA with data untransformed. Recovery rate, parasitism, and total mortality of *S. exigua* larvae were arcsine (square-root) transformed before being subjected to one-way ANOVA. All ANOVAs were conducted with PROC GLM in SAS (SAS Institute 1999), and means were separated by Bonferroni's t tests if the null hypothesis was rejected.

Results

Increased N Fertilization Decreased Herbivore-Induced JA Accumulation and Volatile Pools Nitrogen fertilization did not significantly influence feeding damage inflicted by inducing *S. exigua* larvae (P=0.38). The average leaf areas consumed on damaged leaves receiving 42, 112, and 196 ppm N were 13.93±1.30, 15.62±0.87, and 15.64±0.50 cm^2, respectively.

Leaf position marginally affected JA concentration (P=0.057). As expected, all herbivore-damaged leaves (local leaves) had higher JA content than undamaged leaves in the same position (P<0.001); however, the magnitude of herbivore-induced JA accumulation sharply and significantly decreased with increasing N levels (Fig. 1 (1)). After 48 h of herbivory, herbivore-damaged local leaves from 42 ppm N plants displayed 11-fold increases in JA while those from 196 ppm N plants were increased by only 1.5-fold. JA levels in the systemic leaves did not exhibit the sharp positive response to herbivory observed in the local leaves, but like the local leaves, the mean JA concentrations of the systemic leaves were highest in plants receiving the least N (Fig. 1 (2)).

Unlike JA, SA was either not significantly different by leaf position or was significantly reduced in herbivore-damaged local leaves compared to controls (Fig. 1 (3)). Herbivory resulted in a significant decrease in SA levels in the 112 ppm N group, while the lowest average concentrations of constitutive SA in local leaves were observed in the highest fertilization treatment (196 ppm N) (Fig. 1 (3)). Increasing plant N levels tended to decrease SA concentrations in systemic leaves of damaged and undamaged plants, although statistically significant differences were observed only in the damaged plants (P<0.05 or 0.001; Fig. 1 (4)).

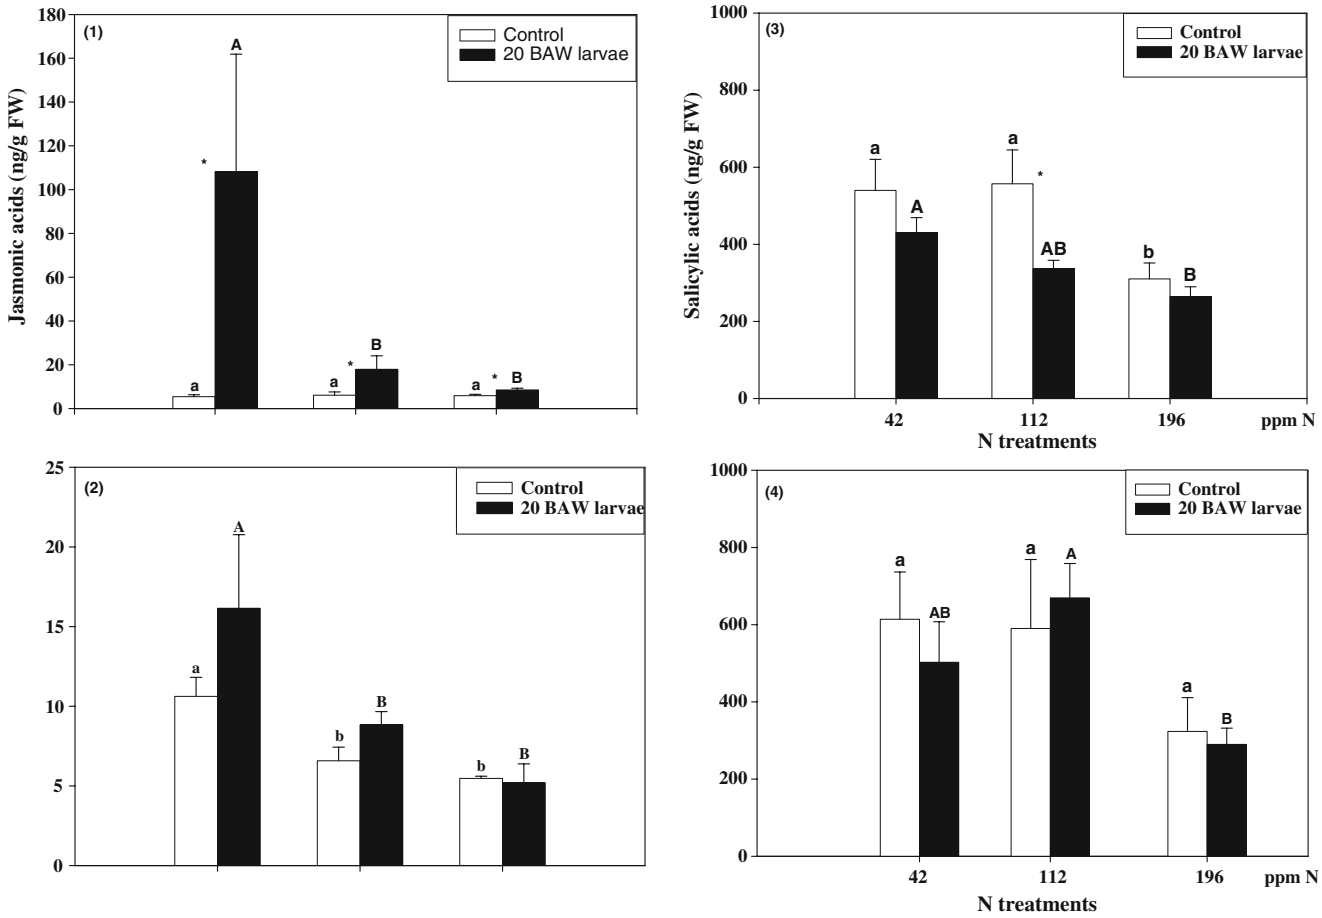

Fig. 1 Plant hormone production (mean ± SE ng g^{-1} fresh weight plant tissue) in response to nitrogen fertilization. *1* total jasmonic acid—local leaf (true leaf 3), *2* total JA—systemic leaf (true leaf 6), *3* total salicylic acid (SA)—local leaf, *4* total SA—systemic leaf. *Different lowercase letters above mean bars* denote significant difference between N treatments of control plants at α=0.05. *Different uppercase letters above mean bars* denote significant difference between N treatments of damaged plants at α=0.05; * Denotes significant difference between control and damaged plants of the same N treatment at α=0.05; damage induced by 20 3-day-old *S. exigua* (*BAW*) larvae

Effects of N on local production of volatiles are summarized in Table 1. Increasing N fertilization constrained leaf tissue concentrations of herbivore-induced volatiles. In plants grown under 42 ppm N, *S. exigua* herbivory significantly increased the local leaf tissue concentrations of seven volatile chemicals including (*Z*)-3-hexenal, (*E*)-2-hexenal, (*E*)-β-farnesene, DMNT, α-bergamotene, γ-bisabolene, and β-bisabolol (Table 1). As N fertilization increased to 112 ppm, only (*Z*)-3-hexenal and (*E*)-2-hexenal remained significantly different and increased in herbivore-attacked leaf tissues. At 196 ppm N, plants displayed an opposite pattern, with herbivory resulting in significantly lower levels of six predominant volatiles: β-caryophyllene, (*E*)-β-farnesene, α-bergamotene, α-humulene, γ-bisabolene, and β-bisabolol. DMNT, a widely occurring herbivore-induced plant volatile, exemplifies the above trend by exhibiting a significant 3.2-fold concentration increase in herbivore-damaged plants at the lowest N level, yet a steady decline in average fold induction under increasing N fertilization. Plant N addition increased constitutive levels of the lipoxygenase products (*Z*)-3-hexenal and (*E*)-2-hexenal (P<0.01 and P<0.001, respectively) in leaf extracts of undamaged control tissues (Table 1). Constitutive levels of (*Z*)-3-hexenyl acetate displayed the opposite trend, significantly decreasing in plants receiving 196 ppm N compared to those receiving 42 ppm N (P< 0.05). Aside from these lipoxygenase pathway products, N fertilization did not significantly influence the constitutive levels of volatiles in undamaged control leaves but instead demonstrated strong effects on the inducibility of volatiles in herbivore-attacked leaves.

Effects of N on systemic volatile production are summarized in Table 2. Increasing N fertilization decreased systemic production of six volatiles in undamaged mature leaves, while decreasing systemic production of nine volatiles in upper leaves of damaged plants (Table 2). Under 42 ppm N, herbivory in local leaves significantly increased systemic production of the volatiles (*Z*)-3-

hexenal, (*Z*)-3-hexenyl acetate, myrcene, and bisabolol (all $P<0.05$). Under 112 ppm N, systemic production of the volatiles (*Z*)-3-hexenal, (E)-2-hexenal, and DMNT was increased by herbivory (all $P<0.05$). However, at 196 ppm systemic production of none of the volatiles examined was affected by herbivory.

Constitutive and Herbivore-Induced Terpenoid Aldehyde Production Decreased Under Increased N Fertilization The effects of N fertilization and herbivory on production of nonvolatile terpenoid aldehydes of the local mature leaf (leaf 3) and the systemic young leaf (leaf 6) are summarized in Table 3. N fertilization did not significantly affect feeding damage caused by beet armyworm larvae ($P=0.50$).

The main terpenoids in the leaves were HGQ and heliocides (H_1, H_2, H_3, and H_4). Leaf position significantly affected production of HGQ, $H_1 + H_4$, H_2, H_3, and total terpenoids, and as expected, young leaves had greater terpenoids than mature leaves (HGQ: $P<0.001$; $H_1 + H_4$: $P<0.05$; H_2: $P<0.001$; H_3: $P<0.001$; total: $P<0.001$). Increased N fertilization decreased production of HGQ, H_2, H_3, and total terpenoid aldehydes (HGQ: $P<0.001$; H_2: $P<0.001$; H_3: $P<0.001$; total: $P<0.001$). *S. exigua* infestation increased HGQ and marginally elevated total terpenoid levels when all N treatments were pooled (HGQ: $P<0.05$; total: $P=0.06$). The interactions between leaf position and N were significant for HGQ, H_3, and total terpenoids (HGQ: $P<0.001$; H_3: $P<0.01$; and total: $P<0.05$, respectively). The interactions between leaf position and *S. exigua* infestation were significant for HGQ and total terpenoids (HGQ: $P<0.01$; total: $P<0.05$). The interactions between N and herbivore infestation were significant for HGQ ($P<0.01$). No other two-way and three-way interactions were observed ($P>0.05$).

N addition to control plants reduced constitutive expression of HGQ, H2, H3, and total terpenoid aldehydes in local leaves (all $P<0.01$) but did not affect terpenoid aldehydes of systemic leaves to the same degree. In contrast, increased N fertilization significantly decreased production of HGQ, H_2, H_3, and total terpenoid aldehydes

in systemic leaves of damaged plants (HGQ: $P<0.001$; H_2: $P<0.01$; H_3: $P<0.001$; total: $P<0.0001$). Under low N fertilization (42 ppm) HGQ, the predominant leaf terpenoid aldehyde displayed a 2.1-fold increase in the systemic leaves of herbivore-damaged plants (Table 3). With the exception of HGQ under 112 ppm N where herbivory diminished the concentration, no significant herbivore-induced terpenoid aldehyde production was detected at N fertilization levels above 42 ppm.

C. marginiventris Short-Range Foraging Not Affected by Plant N Fertilization N treatment did not significantly affect the recovery rate, parasitism rate, or total mortality of sentinel *S. exigua* larvae in the caged preference studies (Table 4).

Discussion

In this commercial variety of cotton, increased N fertilization dramatically impaired the herbivore-induced accumulation of plant defense markers, including JA, volatile pools, and also terpenoid aldehydes in systemic leaves. Consistent with the established role of JA as a positive regulator of herbivore-induced defenses (Reinbothe et al. 1994; Schmelz et al. 2003a; Browse and Howe 2008), low N (42 ppm) plants that exhibited the highest induced JA levels also exhibited robust increases in leaf tissue concentrations of volatiles in local and systemic leaves and terpenoid aldehydes in systemic leaves. At N fertilization levels above 42 ppm, the induction of most biochemical defense markers examined greatly declined or disappeared altogether. However, despite the large differences in herbivore-induced leaf-tissue volatile concentrations among the N fertilization regimes, parasitism of *S. exigua* larvae by adult female *C. marginiventris* did not differ among N fertilization regimes.

In this study, we considered JA, terpenoid aldehydes, and concentrations of leaf volatiles as markers for herbivore-induced defenses. Significant induced biochemical responses were demonstrable only at low N fertilization levels. In the local herbivore-damaged leaves

of 42 ppm N plants, concentrations of volatiles in induced tissue undoubtedly relate to actual volatile emission at the larval feeding sites. In corn (*Z. mays*) leaves, herbivore-induced volatiles are readily detected in leaf tissue extracts (Schmelz et al. 2003c). In contrast, under higher fertilization levels (196 ppm N), we detected significant decreases in the volatile concentrations of herbivore-attacked leaves. This result makes projections of volatile emission more complex. Actual emission of constitutive volatiles at the feeding sites still would likely be substantial. However, if low levels of herbivore-induced JA fail to stimulate new volatile synthesis, low volatile concentrations in damaged leaf tissue may be the result of increased emission and eventual depletion of leaf volatile pools. In support of this hypothesis, Loughrin et al. (1994) found decreased emission of many constitutive and herbivore-inducible volatiles after the third day of continuous *S. exigua* feeding on cotton plants. One anomaly is the presence of significant amounts of (*Z*)-3-hexenal and (*E*)-2-hexenal in undamaged control tissue. Production of these C6 volatiles from C18 fatty acids proceeds through the sequential activity of C13 lipoxygenase and hydroperoxide lyase enzymes (Matsui 2006). Artificially increased levels of C6 volatiles in control tissue may have occurred during leaf harvesting or initial sample extraction. Despite this potentially elevated background, clear differences in (*Z*)-3-hexenal and (*Z*)-2-hexenal at both 42 and 112 ppm are indicative of herbivore-induced enzyme activity.

Table 4 Influence of host plant N fertilization on survival (mean ± SE %) of *S. exigua* and parasitism (mean ± SE %) by *C. marginiventris* in outdoor-cage choice tests

S. exigua herbivory significantly increased JA production in local leaves. While increased N fertilization had no significant effects on the constitutive JA levels in local leaves, it was inversely related to the induced JA in herbivore-damaged local leaves. As with many insect-inducible defenses, applications of JA on cotton similarly promoted terpenoid aldehyde accumulation (Opitz et al. 2008). What has not been previously explored is the relationship between insect-induced endogenous JA levels and the systemic induction of terpenoid aldehydes. While precise N availability was not specifically examined in

previous cotton studies, a strong reduction in herbivore-induced JA and systemic terpenoid aldehyde accumulation at higher N fertilization levels was unexpected. However, this N-mediated reduction in herbivore-induced JA, terpenoid aldehydes, and volatiles in cotton is surprisingly consistent with short-term responses described in corn following application of the *S. exigua* elicitor, volicitin (Schmelz et al. 2003a). In hydroponically grown corn seedlings, volicitin-induced levels of JA, and sesquiterpene volatiles dramatically increase as N availability decreases. In contrast, low N availability in tobacco (*Nicotiana attenuata*) suppresses the levels of JA and SA induced by insect oral secretions and likewise results in lower induced accumulation of nonvolatile defenses (Lou and Baldwin 2004). SA is a plant hormone widely considered to be induced in response to pathogen attack or pathogen-like damage caused by phloem-feeding insects, such as whiteflies and aphids (Walling 2000). N addition to cotton plants significantly decreased SA content of both control and damaged local leaves. However, in contrast to JA, insect herbivory generally reduced SA levels. This result is consistent with antagonistic interactions of JA and SA observed in tomato (Pena-Cortés et al. 1993) and tobacco plants (Niki et al. 1998) with respect to wound- and pathogen-induced defenses.

Herbivory by *S. exigua* larvae had no significant effects on the induction of terpenoid aldehydes under high (112 and 196 ppm) N conditions in this study but significantly increased induced terpenoid aldehydes of young leaves under low (42 ppm) N conditions. The lack of induction of terpenoid aldehydes by insect feeding in mature cotton leaves has been shown in another cotton variety (cv. Deltapine 90; McAuslane et al. 1997); however, the lack of systemic terpenoid aldehyde production under high N conditions contrasts with previous research (Alborn et al. 1996; McAuslane et al. 1997; McAuslane and Alborn 1998; Bezemer et al. 2003). We do not yet know if this is a specific response to N fertilization in *G. hirsutum* cv. FiberMax 989 or a more generalized pattern common to cotton cultivars. Many plants, including corn, tobacco, and cotton, exhibit significant cultivar or genetic variation in the production of both direct and indirect herbivore-induced defenses (Loughrin et al. 1995; Gouinguené and Turlings 2002; Wu et al. 2008).

Foliar terpenoid aldehydes in cotton function as dietary toxins for numerous lepidopteran insects and are typically dominated by HGQ, while heliocides (H_1, H_2, H_3, H_4) also occur at significant levels (Elliger et al. 1978; Stipanovic et al. 1988; Bezemer et al. 2003). N fertilization significantly reduced the constitutive (local mature leaves) and induced (systemic young leaves) accumulation of HGQ and most heliocides in this study. Plants with higher N may be more capable of compensating for biomass loss and therefore need not invest as much in defense as is the case for lower N plants. As shown by Chen et al. (2008), both *S. exigua* larvae and adult females preferred cotton leaves receiving high N fertilization for feeding and oviposition, respectively. Higher N content or weaker constitutive and inducible defenses of plants grown with high N fertilization or a combination of the two may contribute to this preference.

Young expanding leaves of plants with no previous herbivore damage had higher terpenoid aldehyde contents than mature leaves, which is consistent with predictions of the optimal defense (OD) theory (McKey 1974). The significance of defending the young leaves is underscored by our observation that terpenoid aldehyde titers in young leaves of control plants were not significantly affected by changing N levels, whereas increasing N led to significantly reduced terpenoid aldehyde content of mature leaves. OD theory predicts that plant parts having higher fitness value should be better defended. The greater fitness value of young expanding leaves over older leaves has been experimentally demonstrated in some plants (McKey 1979; Krischik and Denno 1983), as has the elevated accumulation of chemical defenses in these leaves (Ohnmeiss and Baldwin 2000; Bezemer et al. 2004). The general applicability of our results must be tempered by the extensive domestication of the cotton variety used in the present study. Nevertheless, the patterns observed tend to conform to adaptive theory and suggest that defensive responses may be intensified under nutrient deficiency.

For herbivore-induced indirect defenses, large differences in leaf-tissue volatile concentrations were found among the N fertilization regimes; however, parasitism of *S. exigua* larvae by adult female *C. marginiventris* was not different in caged choice tests with neonate larvae feeding on host plants grown under 42 and 196 ppm N. *C. marginiventris* females are known to exploit insect-induced volatiles for long-range attraction to hosts (Turlings et al. 1991a; Loughrin et al. 1995; Hoballah et al. 2002; Gouinguené et al. 2005), and both qualitative and quantitative differences in VOC blend are suggested to affect this attraction (Pickett 1999; Hoballah et al. 2002). At first glance, the lack of dose-dependent responses of the parasitoid to overall VOC levels is surprising, since attractiveness has been shown to increase at higher VOC release rates in some systems (Turlings et al. 1991b; Weissbecker et al. 1999; Hoballah et al. 2002). Unlike the commonly studied corn model, cotton foliage contains large preexisting pools of volatiles which are released immediately upon feeding damage (Elzen et al. 1985; Loughrin et al. 1994). In a short-range attraction assay, rankings for the total number of flights completed by female *C. marginiventris* suggested wasps preferred cotton plants systemically releasing herbivore-induced volatiles, followed by artificially damaged cotton plants, and lastly undamaged

control plants (Röse et al. 1998). While these results indicate that *C. marginiventris* has a strong attraction to herbivore-induced cotton volatiles, it also demonstrates an innate attraction to the volatiles from wounded cotton plants.

The lack of N effects on observed parasitism rates may be a result of the experimental arena. As parasitoids were exposed to plants in a closed field cage, they were unable to leave the plant patch. Under open-field conditions, they might have been more likely to ignore or abandon patches where plants release lower levels of VOCs. Parasitoid success is hierarchically divided into host habitat location, host location, host acceptance, and host suitability (Nordlund et al. 1981). In cages, the cues involved in host habitat location might be obscured, mixed, or even concentrated, thereby possibly rendering the results of limited ecological significance. Once parasitoids locate the plant–herbivore complex, additional cues including those associated with host frass can also be significant (Eller et al. 1988). Thus, the degree of difference in host searching cues between the treatments may have been insufficient to significantly modify parasitoid behaviors over the 24-h assay period. In the field, qualitative and quantitative differences of individual VOCs in the herbivore-induced blend are believed to significantly affect host searching behavior of parasitoids (De Moraes et al. 1998). The apparent disparity of VOC levels and parasitoid host finding also might be attributable to limitations of chemical analytical methods. VOCs of leaf extracts analyzed in the study may not necessarily reflect the parasitoid-orienting VOCs released into the air. Nevertheless, it is possible that the relatively large preexisting pools of plant volatiles (known to be emitted during larval herbivory) across all N fertilization treatments overshadow weak vs. strong herbivore-induced biochemical defenses and impair the ability of *C. marginiventris* to discriminate, at short range, host *S. exigua* larvae on these physiologically different host plants.

In summary, N fertilization rates and herbivory exerted variable effects on cotton plant chemistry, with low N input (42 ppm N) and herbivore damage inducing significant increases in JA, volatiles, and in systemic accumulation of terpenoid aldehydes relative to higher N rates. However, increased N fertilization of cotton plants suppressed *S. exigua*-induced plant hormones and led to reduced production of various terpenoid aldehydes in undamaged mature leaves and systemic young leaves above mature leaves that had been fed on by *S. exigua* larvae. However, although increased N fertilization significantly diminished herbivore-induced leaf volatile concentrations, parasitism of *S. exigua* larvae by *C. marginiventris* in field cages did not differ among N treatments. This suggests that parasitoids were unable to differentiate in the field cages among the varying VOC titers induced by different N treatments.

2004; Pawlik et al. 2007). In addition, competition can be avoided or limited by upward growth or by inward burrowing into the substratum (Jackson 1979; Woodin and Jackson 1979).

Allelopathic agents may allow sessile species to compete effectively for space. These agents can inhibit adjacent organisms through direct contact or by releasing mucus or exudations into the water (Becerro et al. 1997). Allelopathy often can be inferred from the presence of chemical substances (Uriz et al. 1996; Becerro et al. 1997; Hay et al. 1998). As a first step, the chemical properties of the suspected allelopathic organism need to be segregated from other physical and biological characteristics (shape, color, texture). Crude organic extracts are fractionated to give the corresponding fractions and pure compounds. Chemical substances are then delivered to the target organism at natural concentrations through an assumedly inert carrier medium. The potential existence of allelopathy is inferred if the chemical substances are active and if there is a plausible mechanism for their natural delivery, e.g., direct contact, through mucus, by exudation (Sullivan et al. 1983; Targett and Schmahl 1984; Porter and Targett 1988; de Nys et al. 1991; Miyamoto et al. 1994; Thacker et al. 1998; Nishiyama and Bakus 1999; Engel and Pawlik 2000; Nishiyama et al. 2004; Chaves-Fonnegra et al. 2005; Pawlik et al. 2007). The exact mechanism by which allelopathy occurs is not clearly elucidated in most cases.

Water-soluble (polar) compounds can diffuse in water and act relatively far from their source (Hadfield and Scheuer 1985; Woodin 1993; Slattery et al. 1997). However, such compounds need to be continuously produced to maintain minimally active concentrations (Woodin 1993). Water-insoluble (non-polar) compounds or compounds with mixed polarity can act when competitors are in direct contact or at close range (Schmitt et al. 1995; Turon et al. 1996). Such compounds may be deployed through mucus and have longer residence times (Sullivan et al. 1983; Miyamoto et al. 1994). Bioactive compounds are often stored in specialized cells and then released by exocytosis (Thompson et al. 1983; Walker et al. 1985; Uriz et al. 1996; Turon et al. 2000). In some cases, there must be a tactile stimulus for release to occur (de Nys et al. 1991).

Some sponges induce bleaching and death of underlying or adjacent coral polyps, thus attaching onto and spreading over the dead areas (Jackson and Buss 1975; Sullivan et al. 1983; Target and Schmahl 1984; Sullivan and Faulkner 1985; Porter and Targett 1988). However, few studies have shown that marine sponges produce allelopathic compounds that may be used in the competition for space. Siphonodictidine, isolated from the coral excavating sponge *Aka* (= *Siphonodictyon*) sp., was the first example of a potentially allelopathic substance produced by a marine sponge (Sullivan et al. 1983). This compound decreased respiration rates and was lethal at high concentrations to the coral *Acropora formosa*. Siphonodictidine, along with siphonodictyals from *Aka coralliphaga*, was presumed to be present in the abundant mucus that these sponges secrete that kills surrounding coral (Sullivan et al. 1983; Sullivan and Faulkner 1985). However, bioassays used pure compound solutions in sea water, and they did not directly address allelopathy. Subsequent studies are more ecologically relevant. For example, the regeneration of holes experimentally made in the sponge *Scopalina lophyropoda* was inhibited when rubbed with the co-occurring sponge *Crambe crambe*, which is known to possess an array of bioactive metabolites (Turon et al. 1996). The use of allelopathy by *C. crambe* revealed a significant trend for other sponges to be distributed away from this sponge (Turon et al. 1996). 7-Deacetoxyolepupuane from the sponge *Dysidea* sp. caused necrosis by contact with the sponge *Cacospongia* sp. when incorporated into agar strips (Thacker et al. 1998). Engel and Pawlik (2000) recorded lateral growth inhibition in fast growing sponges when they grew on gels containing crude extracts of other sponges. Pawlik et al. (2007) also demonstrated a decrease in photosynthetic activity of coral zooxanthellae when sponge extracts included in gels are brought into contact with live coral tissue in the field.

In coral reefs, sponges that simultaneously excavate and encrust the calcareous substratum are strong competitors for space (Pang 1973; Rützler 2002; López-Victoria et al. 2006). These sponges are able to displace and kill live coral tissue, apparently by undermining the polyp's skeletal support through excavating tissue filaments and fronts (Schönberg and Wilkinson 2001; Rützler 2002; López-Victoria et al. 2003, 2006; Chaves-Fonnegra and Zea 2007). Among these sponges, Caribbean *Cliona tenuis* is one of the fastest in displacing and killing coral tissue (López-Victoria et al. 2003, 2006). It currently occupies up to 10% of the hard reef substratum in some wave-exposed reef zones (Williams et al. 1999; Rützler 2002; López-Victoria and Zea 2004, 2005). Furthermore, the crude extracts and some fractions of *C. tenuis* included in gels and brought into contact with live coral are able to kill tissue (Chaves-Fonnegra et al. 2005) and decrease the photosynthetic yield of associated zooxanthellae (Pawlik et al. 2007, e.g., *Cliona langae*).

The aim of this study was to examine whether an allelopathic process—through external contact or at a distance—is involved in coral death by *C. tenuis*. The following investigations were carried out: (1) We tested whether experimentally induced proximity or contact of sponge tissue with coral tissue is deleterious to coral; (2) we searched for the substance(s) responsible through bioassay-guided fractionation; (3) we tested the toxic

effects of extracts, fractions, and pure substances against live corals. The chemical structure and the total synthesis of compound **1** (Fig. 1, herein named clionapyrrolidine A), which were isolated from a fraction that showed a potent allelopathic effect of *C. tenuis* against corals, have been published (Castellanos et al. 2006a). For comparison, we included in this study the recently synthesized *N*-acetylhomoagmatine (compound **2**, Fig. 1; Castellanos et al. 2006b). This compound is a suspected allelopathic agent originally isolated from the polar fraction of the excavating sponge *Cliona celata* from the Northeastern Atlantic (Lenis et al. 1996).

Methods and Materials

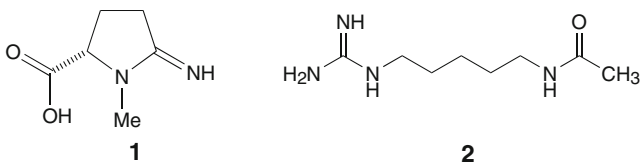
Source of Studied Material and Locations The sponge *C. tenuis* was collected at a depth of 3–6 m in the northern windward fringing fore-reef of the Islas del Rosario, Pajarales sector, SW of the city of Cartagena, Colombian Caribbean (for description of the sites, see López-Victoria and Zea 2004). Field and laboratory bases were the Oceanarium of Islas del Rosario and INVEMAR at Santa Marta, in NE Colombia. Extraction and chemical studies were carried out at the Universidad Nacional de Colombia in Bogotá and Universidade da Coruña, Spain.

Allelopathy by Contact or by Proximity of Live Sponge Tissue to Coral Tissue Fragments of *C. tenuis* of approximately 10×10 cm were cut from sponge-colonized dead branches of the coral *Acropora palmata*. The fragments were allowed to heal inside a basket for 2 days. To determine the effect of direct contact of sponge tissue on coral tissue, fragments were placed on each of ten hemispherical colonies of the coral *Siderastrea siderea*. Each fragment was strapped in place with a piece of plastic netting tied to surrounding nails with cable ties. Fragments of the same dead coral branches wrapped in cotton fabric (to prevent grinding of the live coral) previously soaked in sea water for 2 days were employed as controls. Live fragments and controls were lifted after 24 h, and coral and sponge tissue were compared for the presence/absence of tissue death in the contact zones. Significance of the treatment effects was established by Fisher's exact test (Siegel and Castellan 1988; see details below) from the number of cases in which the coral–sponge contact elicited coral or sponge death but the controls did not.

To determine whether there may be an allelopathic effect at distance by exudation, a healed sponge fragment was placed at a distance of up to 2 cm from the side of each of six colonies of *S. siderea*. Fragments were mounted and tightly tied onto a bed of plastic netting held by two adjacent 3-in. steel nails. Beds were placed horizontally to prevent fragments from shading adjacent coral tissue. A control fragment (as above, but cleaned in bleach and not covered with fabric) was also positioned in each colony in the same way. After 6 months, fragments were removed, and the presence/absence of coral or sponge tissue death was recorded.

Bioassay-Guided Fractionation of C. tenuis Organic Extract The sponge and its excavated substratum (which extends 2 cm below the surface) were collected by using a hammer and chisel, broken further into small fragments, frozen, and sent to Bogotá by air. Fragments were extracted exhaustively first with MeOH and then with CH_2Cl_2 (2:1 sample/solvent volume ratio). The displaced volume of each sample was measured when it was immersed in MeOH. Extracts were filtered, concentrated under reduced pressure, and combined to give the total extract. Five subsamples of fragments were used to determine the volumetric equivalent of the extract (weight of extract per volume of sponge tissue) without substratum. The displaced volume of each subsample was measured first. Subsamples were then extracted as described above, and the dried extract was weighed. Extracted sponge tissue + substratum were digested in 15% HCl to dissolve carbonates, and the displaced volume of the sponge tissue was measured (26.0±5.6% of the total volume). The volumetric equivalent referred to this value, whose mean was 0.082±0.007 g ml^{-1} of sponge. This mean value was used subsequently as the natural concentration of the crude extract.

The total extract (93 g) was partitioned between CH_2Cl_2 and H_2O (Fig. 2). The CH_2Cl_2 partition was evaporated under reduced pressure (non-polar fraction, 29%) and partitioned between 10% aqueous MeOH (400 ml) and hexane (2×400 ml). The hexane partition was evaporated to obtain the hexane fraction (12%). Water was added to the MeOH partition until the mixture became 50% aqueous MeOH. This material was partitioned with CH_2Cl_2 (3×400 ml) to give the methanol (7%) and dichloromethane (10%) fractions after removal of the solvent under reduced pressure. The initial aqueous partition was evaporated and further partitioned between 1:1 water and *n*-BuOH saturated



1 2

Fig. 1 Structure of (**1**) Clionapyrrolidine A [(−)-(5*S*)-2-imino-1-methylpyrrolidine-5-carboxylic acid], isolated from the most active water fraction of the sponge *C. tenuis* from the Caribbean, and of (**2**) *N*-acetylhomoagmatine, obtained from a polar fraction of the sponge *C. celata* from the Northeastern Atlantic

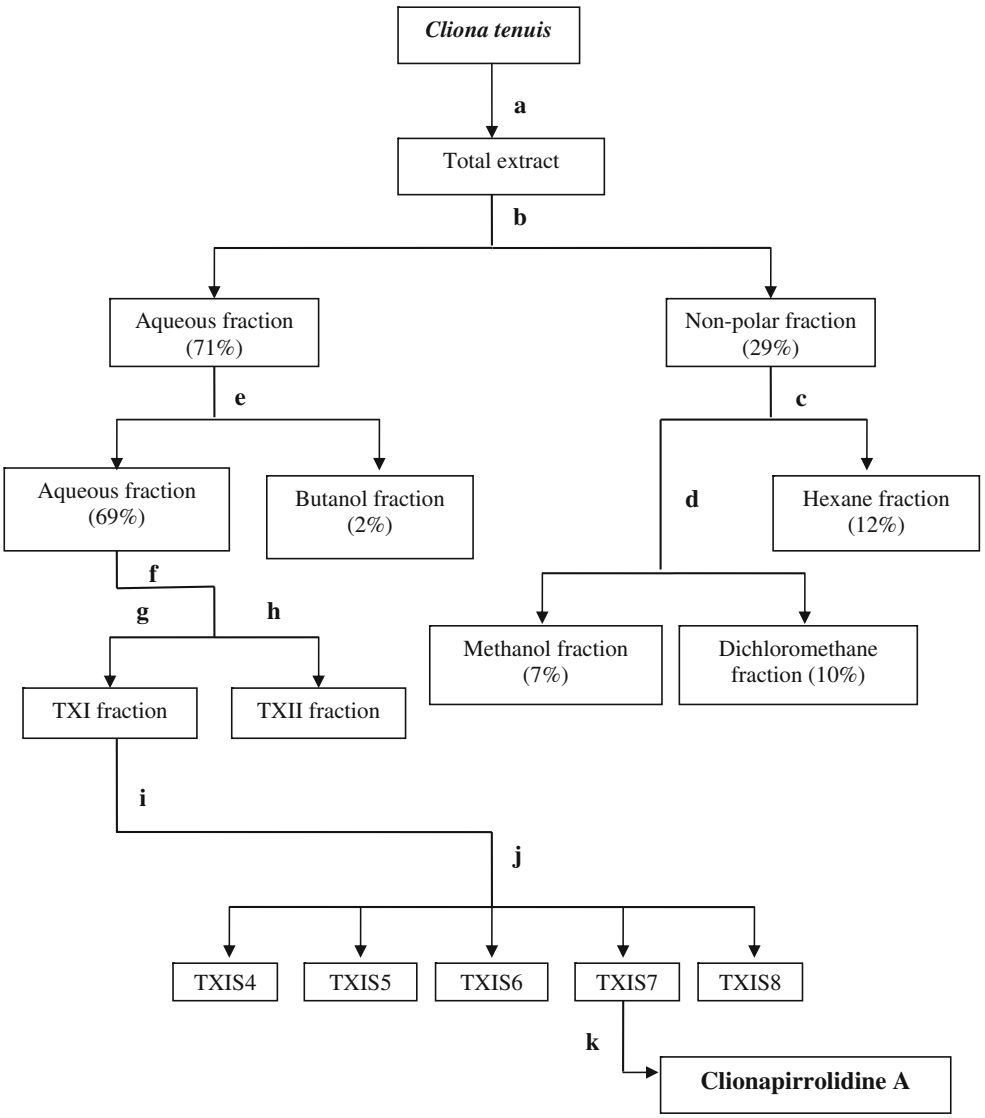


Fig. 2 *C. tenuis* bioassay-guided fractionation protocol. *a* MeOH and CH_2Cl_2 extraction (2:1 sample/solvent volume ratio). *b* Partition between CH_2Cl_2 and H_2O. *c* Partition between 10% aqueous MeOH and hexane. *d* Addition of water to obtain a 50% aqueous MeOH mixture and then partition with CH_2Cl_2. *e* Partition between water and *n*-BuOH saturated with water. *f* Column chromatography on XAD-4 resin. *g* Washing with distilled water. *h* Washing with methanol and with acetone. *i* Addition of methanol to achieve sequential precipitation of inorganic components, which were removed. *j* Column chromatography on Sephadex LH-20 (10% MeOH/H_2O). *k* RP-HPLC purification on a Discovery® HS F5 column [using acetonitrile/water (8:2) and 0.05% formic acid]

with water to afford the aqueous (69%) and butanol (2%) fractions after evaporation.

The total extract and fractions were assayed for activity by contact against corals (see below). This enabled us to identify an active fraction (aqueous), further fractionated and assayed. The active fraction was loaded onto XAD-4 resin, washed with distilled water (fraction TXI), then with methanol, and finally acetone (fraction TXII). Fraction (TXI) was further fractionated by slow addition of methanol in order to achieve sequential precipitation of inorganic components, which were removed. Filtration and evaporation of the methanol filtrate to dryness yielded a residue (14 g) that was chromatographed on Sephadex LH-20 (10% MeOH/H_2O) to afford 12 fractions (TXIS1-S12). The most active fraction (TXI-S7, 80 mg) was purified by RP-HPLC on a Discovery® HS F5 column, using acetonitrile/water (8:2) and 0.05% formic acid, to yield 3.5 mg of clionapyrrolidine A (Fig. 1). Natural concentration of this compound was calculated to be 0.1056 mg ml^{-1}. This compound was characterized by NMR and MS-ESI techniques, and its structure was confirmed by total synthesis of a 100 mg sample (Castellanos et al. 2006a). Spectroscopic data for clionapyrrolidine A are as follows: (+)-HRMS-ESI *m/z*: 143.0815 $[M + H]^+$ (calculated 143.0815). ^1H NMR (500 MHz, D_2O) δ (parts per million): 2.95 (H-2, m, 2H), 2.51 (H-3, m, 1H), 2.12 (H-3′, m, 1H), 4.37 (H-4, dd, J=9.5, 4.2, 1H), 3.04 (H_3-6, s, 3H). ^{13}C NMR (125 MHz, D_2O) δ (parts per million): 169.55 (C-1, C), 30.12 (C-2, CH_2), 24.29 (C-3, CH_2), 70.36 (C-4, CH), 31.74 (C-6, CH_3), 177.43 (C-7, C).

Allelopathy by Contact Against Live Coral Using Gels - Following the method of Pawlik et al. (2007), gels made of Phytagel™ were used as carrier media in which extracts,

fractions, and pure compounds were included. These agar-based gels are made of complex sugars that do not have active functional groups, and they slowly release the extract contents when exposed to sea water (Henrikson and Pawlik 1995). Treatment gels were prepared by adding 0.37 g of Phytagel powder to 35 ml of deionized water at room temperature. Once the powder was completely wet, it was heated with constant stirring until it boiled—at which point it became translucent. Subsequently, 1 ml of a solution (or dispersion) of the extract, fraction, or compound in solvent (CH_2Cl_2 for non-polar fractions, H_2O for the aqueous fractions, MeOH for all others) was added to the gel. The gel, still hot to avoid bubble formation, was poured into opaque plastic caps (28 mm diam, 5 mm high, approx. volume 3 ml) of 35-mm commercial photographic film canisters. These caps had been mounted previously on strips of duct tape assembled to resemble a wristwatch for subsequent attachment onto the coral. Gels were allowed to cool and solidify at room temperature and were kept refrigerated in sealed plastic bags for use within 24 h. When solidified gels had an elevated convex surface; they were leveled to a flat surface with a razor blade to prevent excessive smothering when placed on the coral.

Assays were carried out at Santa Marta Bay (8–10 m in depth) and the Islas del Rosario (5–6 m in depth). Gels in their mounts were placed on live corals and tied with cable ties (through holes made in the tape) to nails driven into the coral head (where possible in the dead periphery). Mounts were stretched with enough force to avoid free movement but loose enough to minimize gel pressure on the coral. As pressure and shading by gels always produced coral tissue bleaching beneath them, several alternative approaches were tried for gel placement to reduce pressure and smothering. In the first, three small supporting "legs" were added to the caps that contained gels in order to keep them at a distance 1–2 mm above the surface. In this way, the coral tissue would touch the gel only at night when polyps extended to feed. In a second approach, gels were placed loosely on coral tissue in such a way that the only pressure exerted involved the weight of the caps and the gels. This was done by holding the supporting caps (without duct tape mountings) with two nails placed directly on each side of the caps by means of copper wire rings. Finally, we also prepared strips of gel (6×2 cm, 2–3 mm thick) in the manner described by Thacker et al. (1998), placing them between two sewn pieces of soft plastic mosquito netting (as described by Gochfeld et al. 2006). The netting was then loosely tied onto the coral tissue surface for a few days. The lack of pressure and smothering in these experiments did not elicit coral death with active extracts and fractions, so we carried out the bioassay-guided fractionation as described above. It was assumed that in competition for space, direct contact between sponges and neighbors also entails some degree of pressure, abrasion, and smothering.

Gels with total extract and the first round of fractions were prepared at concentrations between two and three times the natural concentration in order to enhance any effect. Two different control gels were prepared. The first control was prepared as described previously, without substances from the sponge but with the addition of the maximum amount of solvent used to dissolve substances in each assay. In the second control gel, marine salt (evaporated from local sea water) was added at the volumetric equivalent concentration. This sample was used as a control for assays with the complete aqueous fraction (which had not yet been obtained in a salt-free form).

In each experiment, one set of each of the various treatment and control gels was placed in each of four to ten coral colonies. Gels were left in place for 1–4 days, after which they were lifted, and the presence/absence of dead coral tissue was recorded. As coral tissue under control gels always bleached, it often was difficult to distinguish bleaching from coral tissue death. Further observations were carried out at 3 to 93 days thereafter in order to confirm coral death or recovery under treatment gels or recovery from bleaching under control gels. Fisher's exact test (Siegel and Castellan 1988) was used to determine whether differences were statistically significant. This process involved counting the number of cases in which treatment gels elicited coral tissue death out of the number of control gels that recovered. The null hypothesis was that compounds contained in *C. tenuis* did not produce a deleterious effect on coral tissue beyond the physical effect of shading and transient smothering produced by the gel itself. Different coral species were used at various stages, with the major fractions tested initially on *Montastraea cavernosa*, the most abundant coral around Santa Marta. However, thereafter, the coral *S. siderea* was used because it has smaller polyps and a smoother and more level surface, thus allowing the placement of gels with lower pressure. Pure synthetic clionapyrrolidine A (**1**) was tested against the latter coral at a concentration of 0.19 mg ml^{-1}, which is 1.8 times its natural concentration.

Synthetic *N*-acetylhomoagmatine (**2**) from *C. celata* also was tested in this assay in order to compare its effect to that of clionapyrrolidine A. Compound **2** also was tested because of its structural similarity—a guanidine residue bound to an aliphatic chain—to the compound siphonodictidine, which is known to be lethal to corals (Sullivan et al. 1983). As an approximation to the natural concentration, a level of 0.042 mg ml^{-1} of **2** was used as the reference, a value calculated from its known weight per gram of crude extract (Lenis et al. 1996). In this calculation, we assumed *C. celata* to have the same proportion of

sponge tissue to un-eroded substratum volume and weight of total extract to tissue volume as *Cliona delitrix*. The latter is a Caribbean sponge with a similar excavation pattern to that of *C. celata* and has been previously studied by us (unpublished data).

Toxicity Against Live Coral The non-polar CH_2Cl_2 partition, the aqueous-butanol, and aqueous fractions of *C. tenuis* were evaluated in this assay along with clionapyrrolidine A and *N*-acetylhomoagmatine. Fragments of the branching coral *Madracis auretenra* (=*Madracis mirabilis*; see Locke et al. 2007) were collected in the Santa Marta area and brought to continuous flow aquaria at INVEMAR. Specimens were broken into similarly sized branches (up to 5 cm tall, often being bifurcated at the tip) and kept in a vertical position on plastic mesh. Specimens were allowed to acclimate for 3 days and fed with live plankton or nauplii of the brine shrimp, *Artemia salina*. In the assay, three branches were placed separately in glass bottles with 70 ml of sea water and constant aeration and then fed with nauplii (added in 5 ml of sea water). In this way, the polyps would extend out of their calices to feed and thus confirm the good health of the specimens. Within 2 h, solutions of the fractions and test substances in 5 ml of the corresponding solvent were added to each bottle to give a total volume of 80 ml, in amounts according to the required final concentration. Solvents were CH_2Cl_2/MeOH for the CH_2Cl_2 partition, MeOH for the butanol fraction, distilled water for the aqueous fraction and clionapyrrolidine A, and EtOH for *N*-acetylhomoagmatine. Final concentrations were the natural ones for fractions, 0.1372 mg ml^{-1} for clionapyrrolidine A (1.3 times the natural concentration) and 0.1 mg ml^{-1} for *N*-acetylhomoagmatine. The latter concentration was that used in respiration inhibition assays with siphonodictidine from the excavating sponge *Aka* sp. (see Sullivan et al. 1983). Three replicate bottles were used for each treatment and control. The maximum amount of solvent used in the controls was added to the water. Assays were carried out separately for fractions and for pure compounds. After 2 h, coral branches were moved back to the aquaria with clean circulating water and again fed with nauplii. The behavior of the polyps was observed between 1 and 24 h later. The retracted percentage was quantified over an area of approximately 1 cm^2 in the middle of the branch, usually below the apical bifurcation. Branches were monitored for up to 1 week to confirm whether retracted polyps remained so and thus were dead. The percentage polyp retraction (taken as percentage lethality) at 24 h was used as the analysis variable. Differences in percent lethality between treatments and controls were compared separately for each assay by using the Kruskal–Wallis test (Sokal and Rohlf 1981).

Results

Allelopathy by Contact or Proximity of Live Sponge Tissue None of the ten *C. tenuis* fragments produced tissue death on live tissue of *S. siderea* when both were in contact for 24 h (Fisher's exact test, $P=1$). Coral tissue underneath both sponge and control fragments with cloth showed only a few scratches. In contrast, the area of sponge fragments that had been in close proximity or in contact with the coral had dermal tissue digested in all ten cases (as evidenced by the lack of a brown color and uneven surface). Sponge tissue away from coral contact was normal. Thus, the external defenses of the coral prevented any possible sponge allelopathy by quickly killing sponge tissue that was in contact or in close proximity. In contrast, the six *C. tenuis* and six control fragments placed within 2 cm of *S. siderea* tissue for 6 months did not have any discernible effect on coral tissue (Fisher's exact test, $P=1$), nor was sponge tissue affected. Hence, allelopathy did not occur over this distance by release of substances into the medium.

Allelopathy by Contact with Extract, Fractions, and Pure Compounds Included in Gels Despite initial bleaching and in a few cases some small patches of necrosis, coral tissue under all control gels recovered within days to weeks after the experiments. In cases where fractions were active, after gel retrieval, coral tissue was bleached and necrotic under the entire area of the gels. Coral tissue was thereafter completely lost under gels, and the dead area was colonized by turf algae and filled with sediment. Gels with the total extract of *C. tenuis* had a significant deleterious effect against *M. cavernosa* after 4 days of contact (Fig. 3, tissue killed under gels in all four cases and in five out of six cases, respectively, in two separate experiments, Fisher's exact test, $P<0.05$). Of the five major fractions, only the aqueous one had a significant effect (Fig. 3, tissue killed under all four gels, $P<0.05$; in the other fractions, tissue was killed under up to two out of four gels, $p>0.05$). Further experiments with the most polar fractions (butanol, aqueous) on the coral *S. siderea* confirmed that the aqueous fraction had the highest level of activity (nine out of ten cases after 1 day of contact; nine out of nine cases after 4 days of contact (both $P<0.05$) vs. two out of ten cases after 1 day of contact for the butanol fraction, $P>0.05$; Fig. 3).

Further fractionation of the aqueous fraction in XAD-4 resin produced two fractions, one eluted with water (TXI) and another with organic solvent (TXII). Although both fractions showed a significant effect on the coral *S. siderea* after 1 day of contact (Fisher's exact test, $P<0.05$, $N=10$), TXI was the most active (nine of ten vs. five of ten; Fig. 3). Only five (S4–S8) out of 12 fractions obtained from TXI after chromatography on a Sephadex LH-20 column had

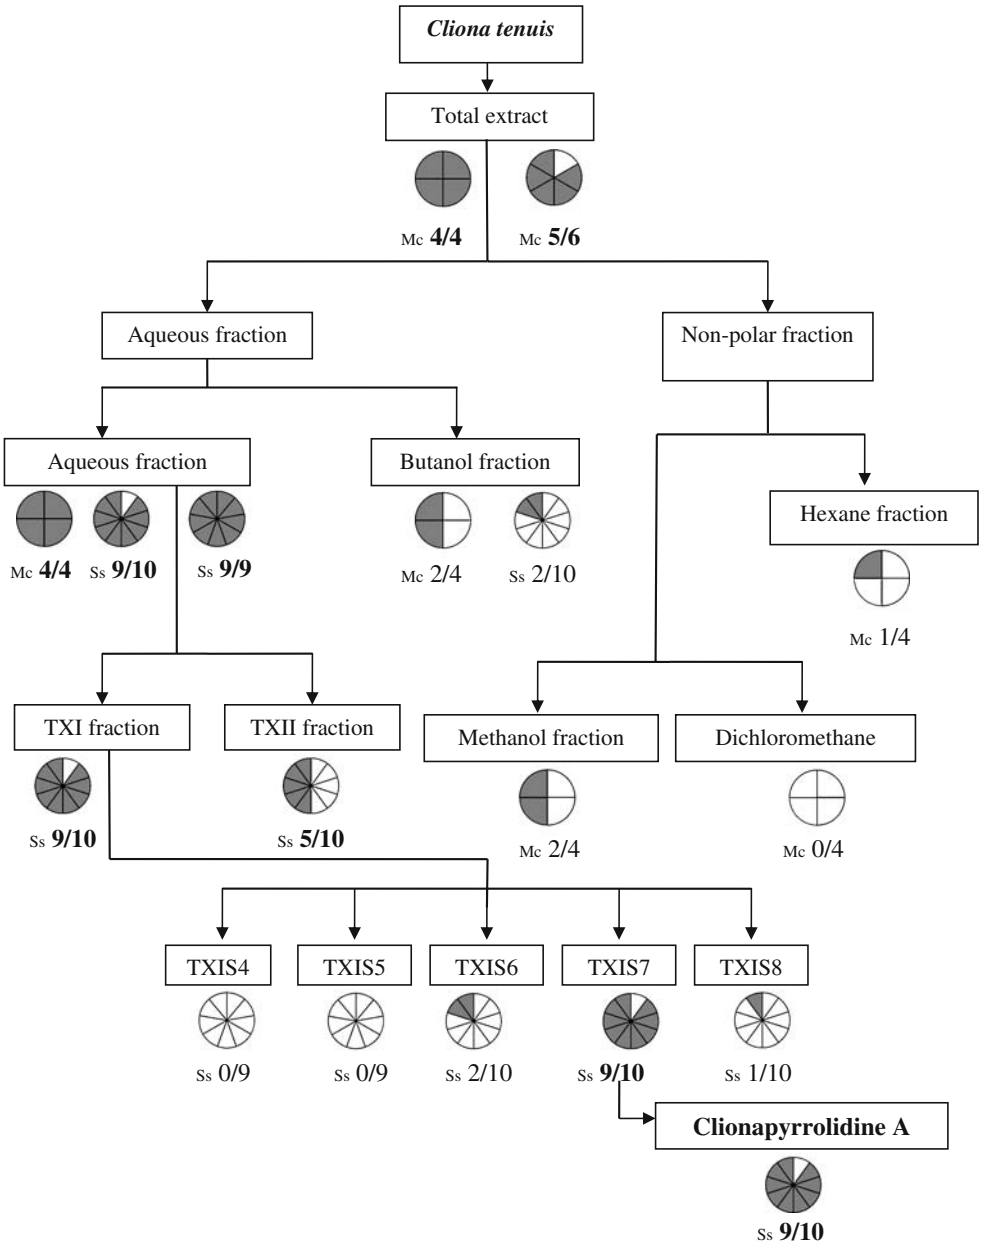

Fig. 3 Bioassay-guided fractionation of *C. tenuis* extract using the allelopathy by gel contact assay. Pie charts and numbers below show the number of cases in which there was coral tissue mortality over the total number of replicate coral colonies (controls recovered in all cases). For the values shown in *bold*, there is a statistically significant effect of tissue mortality (Fisher's exact test, $P<0.05$). *Mc M. cavernosa*, *Ss S. siderea*. Concentrations used in *M. cavernosa* and *S. siderea* were, respectively, three and two times the natural volumetric concentrations. Gels were placed on coral tissue for 4 days in *M. cavernosa* and for 1 day in *S. siderea* (excepting the repeated assay with the aqueous fraction and final assay with pure clionapyrrolidine A, in which contact lasted 4 days). Effects were verified from 2 days to 2.5 months after gel retrieval

sufficient material (50 mg) for testing. From those fractions, the allelopathic activity after 1 day of contact on *S. siderea* was significant only in fraction S7 (nine out of ten cases, $P<0.05$, Fig. 3). HPLC purification on a Discovery® HS F5 column of the active fraction S7 led to the isolation of clionapyrrolidine A (**1**), the major organic component of the fraction. This fraction also contained inorganic salts and unidentified sugars, which were not tested for activity.

Bioassays with synthetic clionapyrrolidine A in contact with *S. siderea* for 4 days, with monitoring over the next 23 days, resulted in a significant effect (nine out of ten gels killed coral tissue after 4 days of contact, Fisher's exact test, $P<0.05$, Fig. 3). These results show clearly that clionapyrrolidine A is responsible for the activity displayed by the crude extract. In contrast, *N*-acetylhomoagmatine (**2**) from *C. celata*, when placed against *M. cavernosa* for 4 days and monitored for up to 1 month later, did not have a deleterious effect on the coral tissue (zero of ten cases, $P>0.05$). This experiment ruled out the suspected allelopathy of this compound.

Toxicity Against Live Coral In the toxicity assays with the non-polar CH_2Cl_2 partition, as well as those with the butanol and aqueous fractions of *C. tenuis* at natural volumetric concentrations, all polyps of the coral *M. auretenra* remained retracted throughout the 2-h exposure

period. Controls remained extended and fed on *Artemia* nauplii during the first 2 h and throughout the experiment. After 24 h and thereafter, however, there was a great deal of polyp recovery on treated corals (polyp lethality at 24 h; aqueous fraction 37.0±23%; butanol fraction 18.9±12%; non-polar partition 7.0±7.0%). A significant difference was not observed among these treatments, and the controls had zero polyp lethality (Kruskal–Wallis test, KW=1.9, $P>0.05$, $N=3$). Pure clionapyrrolodine A at 1.3 times the natural concentration (0.1372 mg ml^{-1}) and *N*-acetylhomoagmatine (0.1 mg ml^{-1}), tested in a separate assay, also caused 100% of polyps of all three replicates to retract during the 2 h of exposure. However, all polyps had relaxed in clean water after a further 2 to 24 h and were out feeding, thus showing zero lethality. Hence, even though there may exist a partial lethal effect at the fraction level (not significant because of the low replication of the assay), pure clionapyrrolidine A and *N*-acetylhomoagmatine are non-lethal in a 2-h exposure period.

Discussion

The use of bioassay-guided fractionation enabled us to show that *C. tenuis* produces a substance (clionapyrrolidine A) that, at concentrations similar to the natural level within the sponge tissue, kills coral tissue upon forced contact, i.e., in combination with pressure and smothering. This is the first report of a pure chemical substance produced by a sponge that kills coral tissue upon direct contact. One of the major tasks of chemical ecology in general and of sponge ecology in particular is to identify ecological roles associated with the diverse production of secondary metabolites (Becerro 2008). However, the mechanisms by which *C. tenuis* actually uses clionapyrrolidine A to kill coral, while displacing it in competition for space, is not known. As *C. tenuis* does not directly overgrow or smother corals, other mechanisms must be sought. The discussion below concerns the possible ways in which allelopathy may or may not occur in *C. tenuis*–coral interactions.

In portions of *C. tenuis*–coral borders that have not been bitten by corallivorous fish (López-Victoria et al. 2003, 2006), there are unhealthy signs in the coral polyps that confront advancing *C. tenuis*. These include paling, partial bleaching, and half polyps. The latter are the result of partial death or partial detachment from the skeleton (Chaves-Fonnegra et al. 2005). However, these signs do not seem to be the result of the release by *C. tenuis* of clionapyrrolidine A or any other allelopathic substances to the external medium. Our experiments showed that coral tissue was not affected on placing sponge fragments less than 2 cm from the coral for 6 months. Siphonodictidine from the excavating sponge *Aka* (=*Siphonodictyon*) sp. inhibits coral respiration when dissolved in the medium at low concentration (0.0001 mg ml^{-1}) and kills corals through cell lyses at higher concentration (0.1 mg ml^{-1}; Sullivan et al. 1983; Sullivan and Faulkner 1985). In contrast, clionapyrrolidine A is only slightly toxic (non-lethal, eliciting temporary polyp contraction during 2-h exposure) to coral polyps at close to its natural concentration (1.3 times, 0.14 mg ml^{-1}). Even if allelopathic compounds are released, substances such as water-soluble clionapyrrolidine A are probably washed away too quickly by currents for any allelopathic effect to occur (see also Pawlik et al. 2007). Indeed, only through HPLC purification on a Discovery® HS F5 column was it possible to separate clionapyrrolidine A from the aqueous partition (see also Castellanos et al. 2006a). This may explain why a deleterious effect was not observed with the *C. tenuis* extract and active fractions when gels were used in caps slightly elevated from the coral surface or when loosely tied gel strips were tested. In a natural situation, a carrier medium such as mucus would be required to deliver a water-soluble compound to the neighboring coral tissue. Mucus production in *C. tenuis* was not observed. In this context, siphonodictidine previously had been assumed, although not yet proven, to kill coral upon contact when delivered in the abundant mucus produced by the sponge (Sullivan et al. 1983; Sullivan and Faulkner 1985). Unhealthy signs observed in coral tissue that confront *C. tenuis* may thus be the result of processes occurring below the coral polyps, where the sponge is excavating and undermining the polypar skeletal support. Mechanisms that involve the use of clionapyrrolidine A in these processes should be explored.

Allelopathy by *C. tenuis*–coral external tissue contact cannot occur because the external defense mechanisms of the coral kill the contacting sponge tissue, as shown by our experiments. We previously observed that healed cores of *C. tenuis* (López-Victoria and Zea 2004) and *Cliona varians* (unpublished results) implanted in holes surrounded by live coral tissue were killed by the coral defensive appendages within 24 h. It appears that in the normal situation, the undermining by excavating tissue guarantees the weakening of the border polyps or enough separation of the external tissues, thus limiting coral defense. However, there is one natural situation in which forced *C. tenuis*–coral contact occurs. During heavy surge, loose dead coral branches colonized by *C. tenuis* are thrown onto massive live corals. The sponge subsequently is able to invade the massive coral, and then it advances and displaces live tissue by undermining (López-Victoria and Zea 2004). Presumably, the initial crush damages both coral and sponge tissue. Allelopathic compounds may be liberated when producer cells lyse. This release, in combination with smothering by

the fallen branch, could elicit coral tissue weakening and death. This process occurs in a manner similar to allelopathy by contact experiments with gels carried out in this study. The sponge tissue leaning against the coral could then reach down to the now polyp-free coral skeleton and start a new colonization (López-Victoria and Zea 2004). Predator deterrent compounds also are thought to be released when predators bite and crush sponge tissue (Pawlik 1997). Similarly, abrasion and smothering of coral tissue by a non-excavating erect sponge growing close by could elicit release of allelochemicals by the sponge and aid in its subsequent attachment to the dead or dying portion of the coral. Rubbing fragments of a sponge known to have strong bioactive compounds against holes made in another non/toxic sponge inhibited regeneration and regrowth of the hole (Turon et al. 1996). A red alga is known to release chloromertensene, a toxic chlorinated terpene, when abrading neighboring octocorals and sponges, inducing local tissue necrosis (de Nys et al. 1991).

In summary, *C. tenuis* contains clionapyrrolidine A, and this substance, when included in gels, kills coral tissue upon forced contact. This is the first report of a pure chemical substance produced by a sponge that kills coral tissue upon direct contact. Natural forced *C. tenuis*–coral contact occurs during storms, and this process results in local coral death and new colonization by the sponge. However, under normal circumstances, in which *C. tenuis* encrusts and excavates a coral colony and approaches live coral tissue sideward and from underneath, coral death neither occurs through natural external tissue contact nor at distance through mucus or exudation of allelochemicals. Clionapyrrolidine A, however, could be used to kill coral tissue when *C. tenuis* excavating tissue reaches coral polyps from below.

In contrast to clionapyrrolidine A, *N*-acetylhomoagmatine from *C. celata*, when incorporated into gels, did not produce coral death upon forced contact. At concentrations similar to the natural level of clionapyrrolidine A, a solution of *N*-acetylhomoagmatine was only temporality toxic to live coral. These results suggest that the guanidine moiety, which is also present in siphonodictidine, is not a sufficiently strong structural motif to explain the strong deleterious effect of this compound on corals.

Acknowledgments This research was supported by the Colombian Science Fund—COLCIENCIAS (grant 110109-13544 to C. Duque and S. Zea), Universidad Nacional de Colombia (DIB), the Xunta de Galicia from Spain (PGIDIT05RMA10302PR), and Instituto de Investigaciones Marinas y Costeras—INVEMAR. We are grateful to J. C. Márquez, CEINER, Diving Planet and Dolphin Dive Shop for their logistical support and help during field work. Two anonymous reviewers greatly helped to improve the manuscript. behavioral response is greater with the ratio identified from conspecific oviparae (Dawson et al. 1990; Hardie et al. 1990; Lilley and Hardie 1996; Boo et al. 2000). However, some experiments have suggested that the two iridoids do not always convey species integrity. For example, the ratio of (4a*SR*,7*SR*,7a*RS*)-nepetalactone/(1*RS*,4a*SR*,7*SR*,7a*RS*)-nepetalactol released from different species of *Cryptomyzus* oviparae were similar, but *Cryptomyzus galeopsidis* (European blackcurrant aphid) males could distinguish between the sex pheromone released by conspecific oviparae and the sex pheromone from other species of *Cryptomyzus* (Guldemond et al. 1992). Male *C. galeopsidis* also could discriminate between a synthetic pheromone blend 30:1 (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (1)/(4a*S*,7*S*,7a*R*)-nepetalactone (2) and volatiles from conspecific oviparae (Guldemond et al. 1993). A stronger, positive behavioral response to the conspecific oviparae occurred, suggesting that the sex pheromone of some aphids is likely to comprise more than two components.

The holocyclic heteroecious aphid *Dysaphis plantaginea* (rosy apple aphid) is the second most important pest of apples in Europe and North America after the codling moth (*Cydia pomonella*) (Graf 1999; Wyss et al. 1999; Blommers et al. 2004). It colonizes apple (*Malus domestica*) as its primary host and plantain (*Plantago* spp.) as the secondary host (Blackman and Eastop 2000). In apple, *D. plantaginea* impairs shoot growth, reduces the formation of flowers over winter, gives rise to leaf curl, and causes malformation and reduction in size of the fruit (Forrest and Dixon 1975; Blommers et al. 2004). Apple yield can be reduced by as much as 45% (De Berardinis et al. 1994; Blommers et al. 2004). Stewart-Jones et al. (2007) determined that *D. plantaginea* oviparae release (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (1) and (4a*S*,7*S*,7a*R*)-nepetalactone (2) in a 4:1 ratio.

In this paper, we investigate whether chemicals in addition to the nepetalactone and nepetalactols are released from oviparae as part of the aphid sex pheromone. The identification of other chemicals that may play a role in species integrity will add a new dimension to our understanding of aphid sex pheromones, and additional chemicals could be exploited as part of integrated pest management systems. To investigate the role of other components, *D. plantaginea* is used as a model.

Methods and Materials

Insects *Dysaphis plantaginea* oviparae were collected from an apple (*Malus silvestris* c.v. Braburn) orchard (Leckford Fruit Farm, Leckford Estate, Hampshire, UK). Male *D. plantaginea* were obtained by rearing on apple (*M. silvestris* c.v. Braburn) in a controlled environment room (12L/12D regime; photophase 16±0.5°C; scotophase 12±0.5°C).

The aphid parasitoid *Aphidius ervi* was purchased as mummies from Koppert Biological Systems (Product: Ervipar). The mummies were placed into a Petri dish (9-cm diameter, Scientific Laboratory Supplies), and the adult parasitoids emerged into a ventilated polypropylene breeding cage (30×30×30 cm, Bugdorm 1, Watkins & Doncaster, Kent, UK). Honey solution (1:1 honey/water) on cotton wool was provided as a food source. Emergence cages were kept in a controlled environment room (20°C, 25–40% RH, 16L/8D regime). All parasitoids used in laboratory experiments were naïve-mated females, 1–3 d old.

Isolation of Volatiles The base of an excised apple (*M. silvestris* c.v. Braburn) branch, bearing leaves infested with *D. plantaginea* oviparae (various adult ages), was placed in a glass vessel (500 ml) containing water. The branch was then placed into a glass entrainment vessel (1.5 L). A metal plate containing a hole for the apple branch was clipped to the base of the glass vessel. As a hole was present in the entrainment set-up (an open system), air that had been purified by passage through an activated charcoal filter (BDH, 10–14 mesh, 50 g) was pushed into (700 ml min^{-1}) and pulled out of (600 ml min^{-1}) the vessel. Excised leaves heavily infested with *D. plantaginea* oviparae (various adult ages) were also placed in a glass vessel (500 ml). Air that had been purified by passage through an activated charcoal filter (BDH, 10–14 mesh, 50 g) was

pulled (600 ml min^{-1}) out of the vessels. Volatiles were also collected from uninfested apple leaves and an uninfested apple branch with leaves as controls.

Volatiles were trapped onto Porapak Q 50/80 (50 mg; Supelco, Bellefonte, PA, USA) held in glass tubing (5 mm outer diameter) by two plugs of silanized glass wool. The Porapak Q was conditioned by washing with redistilled diethyl ether (5 ml) and heating at 132°C for 2 hr under a stream of purified N_2. After the air entrainment, volatiles were eluted from the Porapak with redistilled diethyl ether (750 µl), and samples were stored in a freezer (−22°C). Because preliminary tests showed that the quantities of pheromone released were low, subsequent entrainment using Porapak Q was carried out over a 4-d period. The procedure was repeated for two additional 4-d periods.

Analysis of Volatiles Air entrainment samples were analyzed by gas chromatography (GC) on both polar (DB-wax, 30 m×0.32 mm inner diameter × 0.5 µm film thickness) and non-polar (HP-1, 50 m×0.32 mm inner diameter×0.5-µm film thickness) capillary columns with a HP5890 GC (Agilent Technologies, UK) fitted with a cool-on-column injector, a deactivated retention gap (1 m×0.53 mm inner diameter), and a flame ionization detector (FID). The GC oven temperature was maintained at 30°C for 1 min after sample injection and then raised by 5°C min^{-1} to 150°C, then 10°C min^{-1} to 240°C. The carrier gas was hydrogen. Peak enhancement by co-injection with a chemical standard was done to confirm tentative identification of the chemicals present. A multiple-point external standard method was used to quantify the amount of identified chemical components present in the air entrainment samples. Coupled gas chromatography-mass spectrometry (GC-MS) analysis was performed on a Thermofinnigan Instrument MAT95 XP double-focusing magnetic sector mass spectrometer coupled to a TRACE GC fitted with an HP-1 column and integrated data system (Fisons Instruments, Manchester, UK). The GC oven temperature was maintained at 30°C for 5 min and then programmed at 5°C min^{-1} to 250°C. Ionization was by electron impact at 70 eV, 250°C (source temperature).

Electrophysiology The air entrainment sample collected from *D. plantaginea* oviparae was tested by using coupled gas chromatography-electroantennography (GC-EAG) with male *D. plantaginea*. Two Ag–AgCl glass electrodes were filled with saline solution [composition as in Maddrell (1969), but without glucose]. The head was excised and placed into the indifferent electrode, and the tips of the antennae were severed and inserted into the recording electrode. The signals were passed through a high impedance amplifier (UN-06, Syntech®, The Netherlands) and analyzed by using a customized software package (EAG 2000 and GC-EAG 2000, Syntech®, The Netherlands). Preparations were held in a humidified, charcoal filtered air stream (1 l min^{-1}) coming from a glass tube outlet positioned 0.5 cm from the preparation.

Separation of the volatiles was achieved by GC on a non-polar (HP-1, 50 m×0.32 mm inner diameter×0.52-µm film thickness) capillary column using an HP5890 GC (Agilent Technologies, UK) fitted with a cold on-column injector and a FID. The oven temperature was maintained at 30°C for 2 min and then programmed at 5°C min^{-1} to 100° C and then at 10°C min^{-1} to 250°C. The carrier gas was hydrogen. The outputs from the EAG amplifier and the FID were monitored simultaneously and analyzed with the software package (EAG 2000, Syntech®, The Netherlands). Chromatograms were compared visually by overlaying traces on a light box and matching corresponding EAG peaks. Six replicates were done.

EAG recordings were also made from male and gynoparous *D. plantaginea* with three of the identified chemicals (10 µg). The delivery system employed a filter paper in a disposable Pasteur pipette cartridge. The stimulus (2 sec duration, 100 ml min^{-1}) was delivered into a purified air stream (900 ml min^{-1} during stimulus delivery, 1 l min^{-1} before and after stimulus delivery) flowing continuously over the preparation. Solutions of synthetic compounds were made in distilled hexane and applied to a filter paper strip. The solvent was allowed to evaporate for 30 sec before the strip was placed in the cartridge. The control stimulus was hexane. Fresh cartridges were prepared immediately prior to each experiment. Responses were compared for significant differences by using Student's *t* test. Six replicates were done.

Chemical Standards (1*R*,4a*S*,7*S*,7a*R*)-Nepetalactol (**1**) and (4a*S*,7*S*,7a*R*)-nepetalactone (**2**) were synthesized as stated in Dawson et al. (1996). Phenylacetonitrile (benzyl cyanide, **5**) was obtained from Sigma-Aldrich, UK (99% purity).

(1*S*,2*R*,3*S*)-Dolichodial (**3**) (Fig. 1) was extracted from cat thyme, *Teucrium marum* (Jekka's Herb Farm, Bristol, UK). The aerial parts of *T. marum* (102.58 g) were extracted with chloroform (2×800 ml) for 24 hr at ambient temperature. The solvent was removed under reduced pressure to yield a golden-brown gum (2.97 g). The extract was subjected to liquid chromatography over Florisil (100–200 mesh, Sigma-Aldrich) with hexane/diethyl ether (1:1) to yield a pale oil (912 mg). Bulb-to-bulb distillation using a Kugelrohr apparatus (90°C, 2 mmHg) yielded four fractions, one of which was shown by comparison of MS, ^{1}H and ^{13}C NMR data with literature values (Pagnoni et al. 1976) to contain (1*S*,2*R*,3*S*)-dolichodial (**3**) and (1*S*,2*S*,3*S*)-dolichodial (**4**) (Fig. 1) in a 9:1 ratio (Bellesia et al. 1983a).

Four-Way Olfactometer Aphid behavioral assays were done by using a Perspex four-way olfactometer [modified from Pettersson (1970), 120 mm diameter]. Air was removed from the center of the olfactometer by a vacuum pump, buffered by a 2-l jar and adjusted with a flow meter to 400 ml min^{-1}. Air was thus pulled through each of the four side arms at 100 ml min^{-1}, and again verified with airflow meters. Teflon tubing was used to attach a glass vessel (25 ml) and a flow meter to each of the four side arms. Polytetrafluoroethylene tape was used to ensure airtight seals between the olfactometer and the Teflon tubing. All five holes were covered with a layer of muslin to prevent access by the aphid during bioassays. To remove any visual stimuli, the olfactometer was placed in the center of a black-walled box with an observation opening at the front and lit from above with diffuse uniform lighting.

Two experiments were conducted. First, the response of male *D. plantaginea* to different amounts of (1*S*,2*R*,3*S*)-dolichodial (**3**) (10, 1, 0.1, and 0.01 µg) and hexane (control) was tested. Second, two ratios, 4:1:0 (40:10:0 µg) and a 4:1:0.05 (40:10:0.5 µg) of (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)/(1*S*,2*R*,3*S*)-dolichodial (**3**) and hexane (control) were tested. An aliquot of the test solution was applied with a micropipette (Drummond "microcaps," Drummond Scientific Co., USA) to a filter paper strip (solvent allowed to evaporate for 30 sec). The filter paper was placed into one of the glass vessels (25 ml). The three control vessels were similarly treated with the same volume of solvent on the filter paper. Sixteen replicates were done. All treatments were tested in a randomized block experimental design.

The four-way olfactometer arena was split into five areas (four areas by each arm and a central area). A single aphid was introduced into the central area. The time spent and number of entries into each area was recorded by using specialist software (OLFA, Udine, Italy) over a 16-min period. The apparatus was rotated 90° every 4 min to eliminate bias. The proportion of time spent in each of the four side areas was logit-transformed with a correction factor in order to avoid extreme values (Rawlings et al. 1998). The proportion of entries into each of the four areas out of the total number of entries was also calculated. The data were compared by analysis of variance (ANOVA) with randomized blocking (Montgomery 1997), as implemented in Genstat 8.0 (Payne et al. 2005). The analysis was used to look at two parameters: (1) the difference between the treated and control arms and (2) the difference between the three control arms.

Four-Choice Olfactometer A four-choice olfactometer (Vamvatsikos 2006) [modified from Douloumpaka and van Emden (2003)] was used to test the behavioral response of naïve female *A. ervi* to (1*S*,2*R*,3*S*)-dolichodial (**3**). The olfactometer was made from four cylindrical Perspex tubes (test-odor chambers, 9.5×2.5 cm internal diameter) each connected to a flow meter by Teflon tubing and a central arena by four smaller pieces of Perspex tubing (4×0.5 cm internal diameter). These small tubes protruded 2 cm into the cylindrical Perspex tubes but were flush with the internal surface of the central arena. The central arena comprised a Perspex tube (4.5 cm internal diameter×2.5 cm height) and a Perspex lid covered the pot firmly, forming an air-tight central arena. The lid was fitted with a small tube connecter (0.5 cm internal diameter) by Teflon tubing to a flow meter and a vacuum pump, buffered by a 2-l jar.

Two experiments were conducted. First, the response of *A. ervi* to different amounts of (1*S*,2*R*,3*S*)-dolichodial (**3**) (10, 1, 0.1, and 0.01 µg), a control (hexane), and a positive control [1:1 (10:10 µg) (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)] was tested. Second, two ratios 1:1:0 (10:10:0 µg) and a 1:1:0.05 (10:10:0.5 µg) of (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)/(1*S*,2*R*,3*S*)-dolichodial (**3**), a control (hexane), and a positive control [1:1 (10:10 µg) (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)] were tested. Glinwood (1998) showed that, in a four-way olfactometer, mated naïve female *A. ervi* spent significantly more time in the test arm containing 1:1 (10:10 µg) (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**) compared to the control arms (10 µl of hexane), hence the use of this ratio.

An aliquot of the test solution was applied with a micropipette (Drummond "microcaps," Drummond Scientific Co., USA) to a filter paper strip (solvent allowed to evaporate for 30 sec). The filter paper was placed into two of the cylindrical, Perspex test-odor chambers. The two control test-odor chambers were similarly treated with the same volume of solvent on the filter paper. Sixteen replicates were done. All treatments were tested in a randomized block experimental design.

Twelve mated naïve female *A. ervi* were drawn into the central arena of the olfactometer by using a pooter. The insects were left to acclimatize for 15 min before the experiment commenced. To remove any visual stimuli, the olfactometer was placed in the center of a black-walled box. Air was removed from the center of the olfactometer at a flow rate of 1.6 l min^{-1}. Air was thus pulled through each of the four side arms at 400 ml min^{-1}. After 30 min, parasitoids that had entered the odor chambers were counted. The whole system (central arena and side arms) was rotated 90° clockwise after each replicate to cancel out any directional bias in the apparatus.

Chi-square analysis was performed on the results from the four-choice olfactometer. The choice chi (which tests

the significance of variation between choices) and the heterogeneity chi (which tests the significance of variation between the replicates) were taken into consideration (Gomez 1984).

Results

Electrophysiology Coupled GC-EAG analysis with male *D. plantaginea* revealed four EAG-active compounds in the air entrainment sample collected from *D. plantaginea* oviparae (Fig. 2). Gas chromatography-mass spectrometry and peak enhancement by co-injection using non-polar (HP-1) and polar (DB-Wax) columns confirmed that the peaks were phenylacetonitrile (**5**), (1*SR*,2*RS*,3*SR*)-dolichodial (**3**), (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**), and (4a*S*,7*S*,7a*R*)-nepetalactone (**2**). (1*R*,4a*S*,7*S*,7a*R*)-Nepetalactol (**1**), (4a*S*,7*S*,7a*R*)-nepetalactone (**2**), and (1*SR*,2*RS*,3*SR*)-dolichodial (**3**) were present in a 4:1:0.05 ratio. These compounds were not detected in the air entrainment samples of apple leaves without *D. plantaginea*.

Male and gynoparous *D. plantaginea* showed a significantly greater EAG response to (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**), (4a*S*,7*S*,7a*R*)-nepetalactone (**2**), and (1*S*,2*R*,3*S*)-dolichodial (**3**) compared with the control (hexane) (Fig. 3).

Behavioral Response of Male Dysaphis plantaginea Male *D. plantaginea* spent more time in (P=0.025) and made a higher proportion of entries (P=0.012) into the arm containing 1 µg (1*S*,2*R*,3*S*)-dolichodial (**3**) compared to the control arms (Fig. 4). Male *D. plantaginea* also spent more time (P=0.016) in the arm containing 0.1 µg (1*S*,2*R*,3*S*)-dolichodial (**3**) compared to the control arms. The time male *D. plantaginea* spent in and the proportion of entries into the arms containing 10 µg and 0.01 µg of (1*S*,2*R*,3*S*)-dolichodial (**3**) were not significantly different compared to the control arms. A significant difference was not seen between any of the control arms.

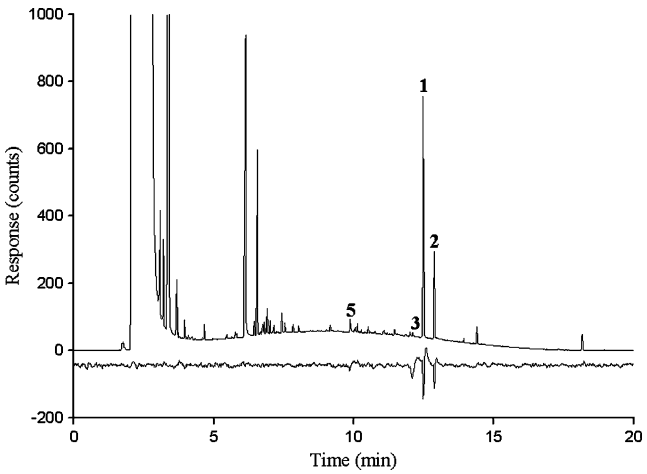

Fig. 2 Example of a coupled GC-EAG trace of male *Dysaphis plantaginea* responses to an air entrainment sample from conspecific oviparae. Top trace corresponds to the FID detector on the GC, and the bottom trace corresponds to the antennal response of the insect preparation. *Numbers* refer to chemicals *1* (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**), *2* (4a*S*,7*S*,7a*R*)-nepetalactone (**2**), *3* (1*S*,2*R*,3*S*)-dolichodial (**3**) and *5* phenylacetonitrile (**5**)

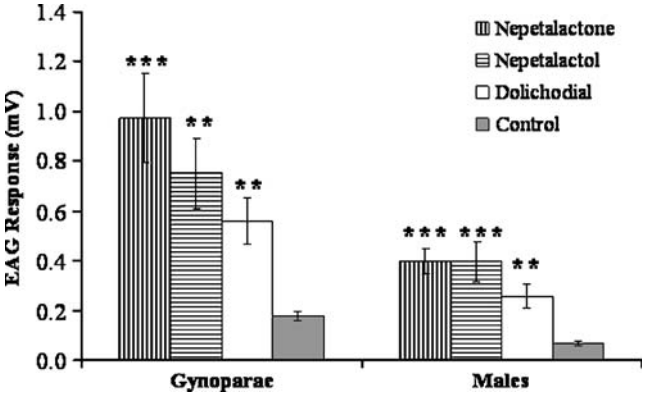

Fig. 3 Electrophysiological response (mean±SE) of male and gynoparous *Dysaphis plantaginea* to (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**), (4a*S*,7*S*,7a*R*)-nepetalactone (**2**), and (1*S*,2*R*,3*S*)-dolichodial (**3**) standards. *Asterisks* indicate significant differences from the control (solvent) determined using Student's *t* test (see text) (**P<0.01, ***P<0.001, N=6)

Male *D. plantaginea* spent a greater proportion of time in (P=0.014) and made a higher proportion of entries (P< 0.001) into the arm of the olfactometer where the three-component mixture [4:1:0.05 (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)/(1*S*,2*R*,3*S*)-dolichodial (**3**)] was present compared to the control arms (Fig. 5). The proportion of time spent in and the proportion of entries into the arms containing the two-component mixture [4:1 (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)] compared to the control arms were not significantly different. A significant difference was not observed between any of the control arms.

Behavioral Response of Aphidius ervi More naïve-mated female *A. ervi* were counted in the arms containing the positive control (P<0.001), 10 µg (P<0.001), and 1 µg (P< 0.01) of (1*S*,2*R*,3*S*)-dolichodial (**3**) compared to the control arms (Fig. 6). The number of naïve-mated female *A. ervi* counted in the arms containing 0.1 and 0.01 µg (1*S*,2*R*,3*S*)-dolichodial (**3**) was not significantly different compared to the control arms.

The number of naïve-mated female *A. ervi* counted in arms containing 1:1:0.05 (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)/(1*S*,2*R*,3*S*)-dolichodial (**3**) was not significantly different compared to the arms containing 1:1 (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**) (Fig. 7).

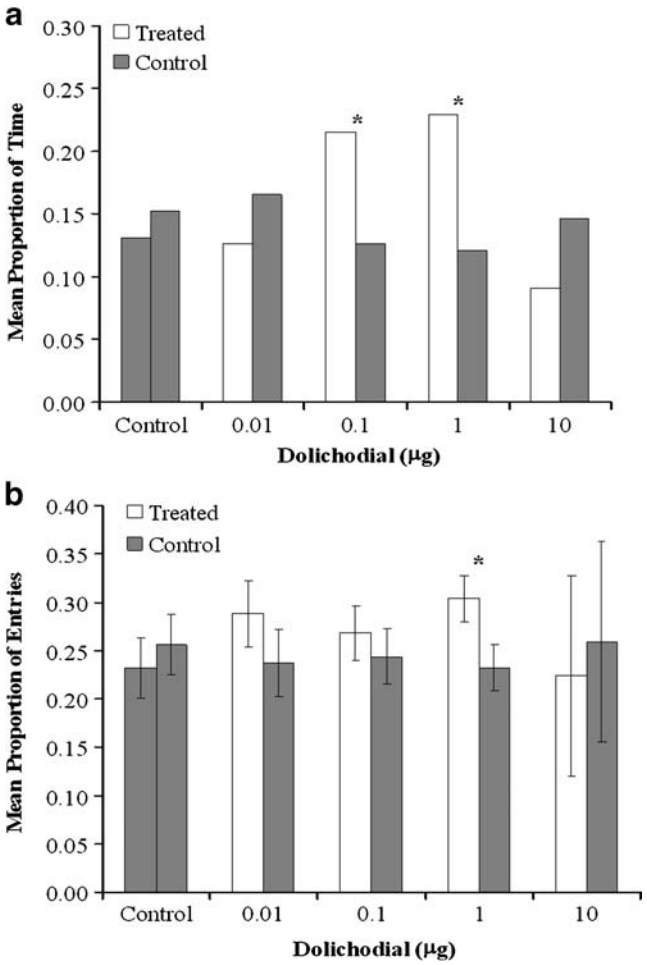

Fig. 4 The response, **a** back-transformed mean proportion of time spent and **b** mean proportion of entries±SE, by male *Dysaphis plantaginea* to different amounts of (1*S*,2*R*,3*S*)-dolichodial (**3**) in the four-way olfactometer. *Asterisks* indicate significant differences from the control (solvent) determined using ANOVA (see text) (**P*<0.05, ***P*<0.01, ****P*<0.001, *N*=16)

Discussion

Electrophysiological responses by male *D. plantaginea* to four chemicals present in volatiles collected from *D. plantaginea* oviparae were recorded. The EAG-active chemicals were identified as (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**), (4a*S*,7*S*,7a*R*)-nepetalactone (**2**), (1*S*,2*R*,3*S*)-dolichodial (**3**), and phenylacetonitrile (**5**). These four compounds were not detected in the air entrainment sample collected from the host plant, suggesting that they are either released by oviparae or by the plant in response to oviparae feeding. As previously discussed, (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**) and (4a*S*,7*S*,7a*R*)-nepetalactone (**2**) may be components of *D. plantaginea* sex pheromone (Stewart-Jones et al. 2007).

Past research has identified phenylacetonitrile (**5**) as an insect and a plant volatile, involved in insect–plant (Leal et al. 1994; Bartlet et al. 1997) and insect–insect (Norris and Pener 1965; Obeng-Ofori et al. 1993; Torto et al. 1994; Loughrin et al. 1995) interactions. With regard to plant volatiles, phenylacetonitrile (**5**) has been identified from leaf tissue (Macleod et al. 1981; Loughrin et al. 1995) and flowers (Tatsuka et al. 1990; Knudsen et al. 1993; Leal et al. 1994) but, relevant to this study, occurs as a major volatile from apple fruit (Boeve et al. 1996). This may suggest that phenylacetonitrile (**5**) present in the air entrainment sample of *D. plantaginea* oviparae originated from the aphid/plant complex. Thus, phenylacetonitrile (**5**) is most likely not a component of the aphid sex pheromone, but male *D. plantaginea* may utilize it synergistically with the sex pheromone components to locate conspecific oviparae (Powell and Hardie 2001). As phenylacetonitrile (**5**) is thought not to be a component of the aphid sex pheromone, no behavioral studies were conducted.

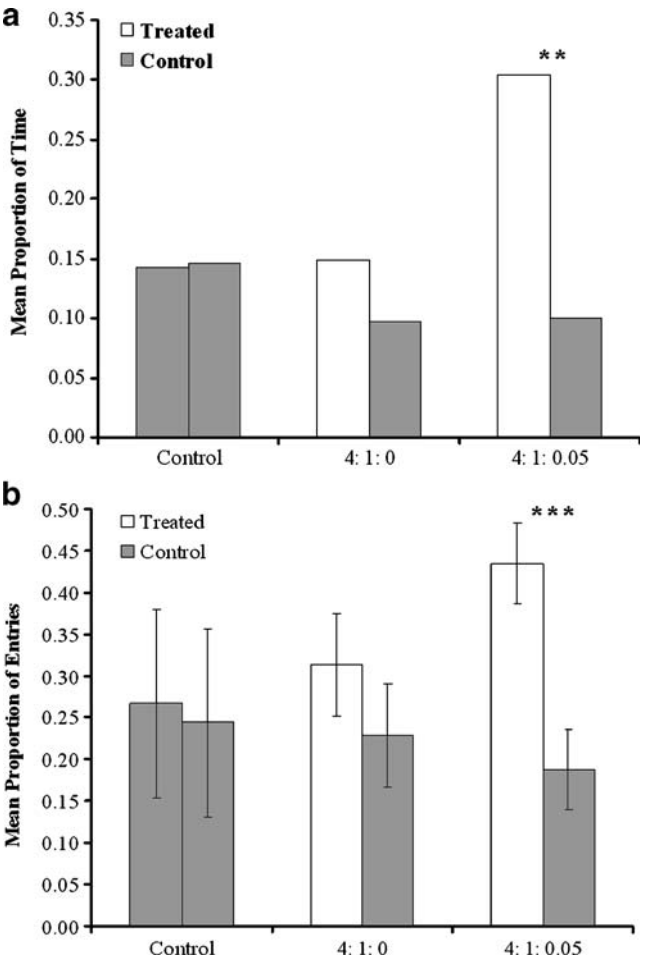

Fig. 5 The response (back-transformed mean proportion of time-spent) by male *Dysaphis plantaginea* to different ratios of (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)/(1*S*,2*R*,3*S*)-dolichodial (**3**) in a four-way olfactometer. *Asterisks* indicate statistically significant differences from the control (solvent) determined using ANOVA (see text) (****P*<0.001, *N*=16)

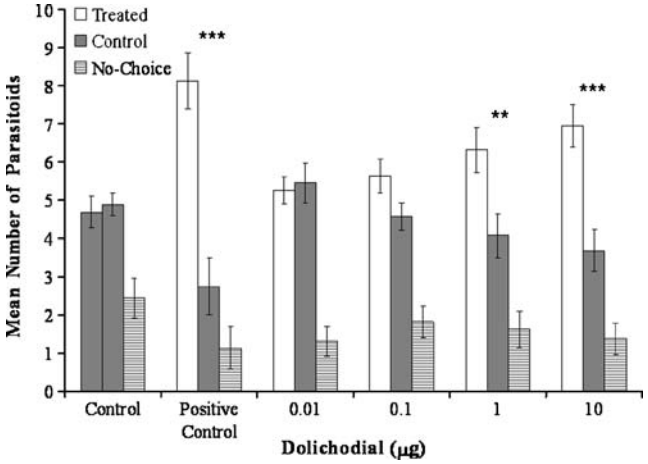

Fig. 6 The response (mean number±SE) of naïve-mated female *Aphidius ervi* to different amounts of (1*S*,2*R*,3*S*)-dolichodial (**3**) in a four-choice olfactometer. *Asterisks* indicate statistically significant differences from the control (solvent) determined using χ^2-test (see text) (**P<0.01, ***P<0.001, N=16)

The fourth compound, (1*S*,2*R*,3*S*)-dolichodial (**3**), is released by insects. *Dolichoderus* and *Iridomyrmex* species of ants release (1*S*,2*R*,3*S*)-dolichodial (**3**), and it may play a defense or trail role (Cavill and Hinterberger 1960; Cavill and Houghton 1974; Cavill et al. 1982). The diastereoisomer anisomorphal [(1*S*,2*S*,3*S*)-dolichodial (**4**) (Pagnoni et al. 1976)] is a major component of the defense secretion of the Southern walking stick insect, *Anisomorpha buprestoides* (Meinwald et al. 1962). In addition, (1*S*,2*R*,3*S*)-dolichodial (**3**) is structurally related to (4a*S*,7*S*,7a*R*)-nepetalactone (**2**), a known component of the aphid sex pheromone. Both are methylcyclopentanoid terpenes thought to originate biosynthetically from citronellol. Dawson et al. (1996) suggested that citronellol may be a precursor for the cyclopentanoids biosynthesized in aphids, as during studies on the composition of the sex pheromone of several species of aphid, including *D. plantaginea*, citronellol accompanied the cylcopentanoid sex pheromone components but was electrophysiologically and behaviorally inactive. Although the biosynthetic pathways from citronellol to (4a*S*,7*S*,7a*R*)-nepetalactone (**2**) in *Nepeta cataria* (Lamiaceae=Labiatae) (Bellesia et al. 1984) and (1*S*,2*R*,3*S*)-dolichodial (**3**) in cat thyme, *T. marum* (Bellesia et al. 1983b), are thought to be different, when [10–^{3}H](1*S*,2*R*,3*S*)-dolichodial was fed to cut stalks of *N. cataria*, partial incorporation into (4a*S*,7*S*,7a*R*)-nepetalactone (**2**) was observed (Bellesia et al. 1984). This suggests that the (1*SR*,2*RS*,3*SR*)-dolichodial (3) present in the air entrainment sample of *D. plantaginea* oviparae may originate from the oviparae and may be a third component of the sex pheromone.

In behavioral assays, (1*S*,2*R*,3*S*)-dolichodial (**3**) elicited a response by male *D. plantaginea*. This suggests that (1*S*,2*R*,3*S*)-dolichodial (**3**) may be an attractant or an arrestant. This is the first time that electrophysiological and behavioral responses by any aphid morph to (1*S*,2*R*,3*S*)-dolichodial (**3**) have been reported. Behavioral responses were not recorded when the two-component mixture [4:1 (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)] was present in the bioassay. However, when (1*S*,2*R*,3*S*)-dolichodial (**3**) was present in a three component mixture [4:1:0.05 (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)/(1*S*,2*R*,3*S*)-dolichodial (**3**)] with a ratio equivalent to the ratio in the air entrainment sample, a behavioral response by male *D. plantaginea* was recorded.

These behavioral data add weight to the possibility that (1*S*,2*R*,3*S*)-dolichodial (**3**) is a component of the aphid sex pheromone. In addition, mass spectrometric analysis on air entrainment samples collected at Rothamsted Research from *Rhopalosiphum padi* (bird-cherry-oat aphid), *Aphis fabae* (black bean aphid), *Cryptomyzus maudamanti*, and *Cryptomyzus ribis* (redcurrent blister aphid) oviparae all contain a chemical with the same mass spectra as (1*S*,2*R*,3*S*)-dolichodial (**3**) (Pickett, Wadhams and Woodcock, unpublished data). As discussed, biological evidence suggests that the sex pheromone of the *Cryptomyzus* species is likely to comprise more than just the (4a*SR*,7*SR*,7a*RS*)-nepetalactone and (1*RS*,4a*SR*,7*SR*,7a*RS*)-nepetalactol. As (1*S*,2*R*,3*S*)-dolichodial (**3**) elicits a behavioral response in male *D. plantaginea*, this chemical may also be a component of the sex pheromone of *Cryptomyzus* species and play a role in species integrity.

(1*S*,2*R*,3*S*)-Dolichodial (**3**) not only elicits a behavioral response by male *D. plantaginea* but also an

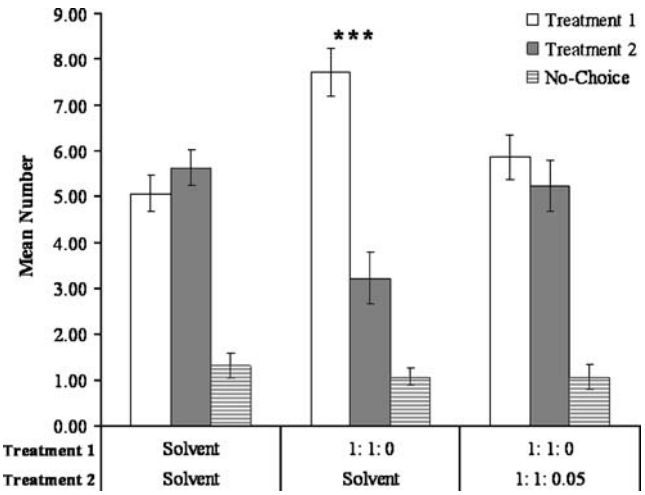

Fig. 7 The response (mean number±SE) of naïve-mated female *Aphidius ervi* to different ratios of (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**)/(1*S*,2*R*,3*S*)-dolichodial (**3**) in a four-choice olfactometer. *Asterisks* indicate statistically significant differences between treatments 1 and 2 determined using a χ^2-test (see text) (***P<0.001, N=16)

electrophysiological response by gynoparous *D. plantaginea*. Electrophysiological and behavioral responses by gynoparae to (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**) and (4a*S*,7*S*,7a*R*)-nepetalactone (**2**) have been reported previously (Hardie et al. 1994; Lösel et al. 1996; Park et al. 2000; Zhu et al. 2006). It was suggested that the aphid sex pheromone may act as an aggregation pheromone for gynoparae in order to locate conspecific oviparae on suitable host plants (Lilley and Hardie 1996; Powell and Hardie 2001; Zhu et al. 2006). Therefore, if (1*S*,2*R*,3*S*)-dolichodial (**3**) is part of the aphid sex pheromone, an EAG response in gynoparae would be expected. Behavioral assays are required to determine whether this compound elicits a behavioral response by gynoparae.

Aphid pheromones provide an ideal method for parasitoids to locate hosts, as they are specific to aphids. If (1*S*,2*R*,3*S*)-dolichodial (**3**) is part of the sex pheromone of certain aphid species, it may be perceived by *A. ervi* as a pheromone component and, therefore, should elicit a behavioral response. In this paper, a behavioral response by naïve-mated female *A. ervi* to (1*S*,2*R*,3*S*)-dolichodial (**3**) was indeed recorded. However, when a choice was available between the two-component mixture and the three-component mixture, no significant differences were recorded in a four-choice olfactometer. A behavioral response of naïve-mated female *A. ervi* toward a 1:1 (1*R*,4a*S*,7*S*,7a*R*)-nepetalactol (**1**)/(4a*S*,7*S*,7a*R*)-nepetalactone (**2**) mixture and to (4a*S*,7*S*,7a*R*)-nepetalactone (**2**) alone has already been reported (Glinwood 1998). This suggests that the presence of (4a*S*,7*S*,7a*R*)-nepetalactone (**2**) may be needed only to elicit a strong behavioral response by *A. ervi*.

Air entrainments with oviparae on artificial diets and radio-labeling studies could be conducted to assess whether (1*SR*,2*RS*,3*SR*)-dolichodial (**3**) is released from the oviparae or from the host/aphid complex. In addition, enantiomeric studies need to be conducted to determine whether (1*S*,2*R*,3*S*)-dolichodial (**3**) or its enantiomer (1*R*,2*S*,3*R*)-dolichodial is present in the air entrainment sample. The absolute stereochemical configuration is presumed to be (1*R*,2*S*,3*R*)-dolichodial (**3**), as this enantiomer is behaviorally active and is structurally related to (4a*S*,7*S*,7a*R*)-nepetalactone (**2**). If (1*SR*,2*RS*,3*SR*)-dolichodial (**3**) is a third component of the aphid sex pheromone, it will add a new dimension to the ratios of sex pheromone components and may play an important role in species integrity.

sized de novo via the mevalonate pathway (Seybold et al. 1995) in the anterior midguts of male *I. pini* (Hall et al. 2002), *Ips confusus* (Ginzel et al., unpublished data), and probably also in other *Ips* spp. Although early steps in the pathway are well understood in *I. pini*, final steps are still being characterized. The ipsdienol biosynthetic pathway branches from the main mevalonate pathway via the activity of a dual function enzyme, geranyldiphosphate synthase/myrcene synthase (GPPS/MS) (Gilg et al. 2005, Unpublished data). Achiral myrcene, whether produced endogenously (Martin et al. 2003) or ingested with the phloem, is then hydroxylated to ipsdienol by CYP9T2 (Sandstrom et al. 2006). Since CYP9T2 from a western *I. pini* population produces ipsdienol in vitro in a ~4:1 (*R*)-(−):(*S*)-(+) ratio, other enzymes must act to increase the proportion of (*R*)-(−)-ipsdienol before it is released. Indeed, Vanderwel (unpublished data) proposed that an oxidoreductase system oxidizes ipsdienol to ipsdienone and then stereo-selectively reduces it to (*R*)-(−)-ipsdienol, and a similar mechanism was proposed to determine the final enantiomeric composition of ipsdienol in *Ips paraconfusus* (Fish et al. 1984) (Fig. 1). Genetic analyses of eastern and western *I. pini* populations suggest that, while a single locus contributes significantly to the observed distribution of enantiomers (Domingue et al. 2006), other factors are involved, and the stereoselectivity of the cytochrome P450 may be important in some instances (Domingue and Teale 2008).

Although significant progress has been made in understanding pheromone biosynthesis and regulation in *I. pini*, studies that involve species with different pheromone ratios would be useful to investigate the mechanism(s) determining pheromonal ipsdienol composition, and to provide insight into the evolution of pheromone systems. To this end, we have begun studies of pheromone biosynthesis in the pinyon ips, *I. confusus*. *I. confusus* is reproductively isolated from *I. pini* by both its host preference and pheromone system. *I. confusus* infests and kills pinyon pines (*Pinus monophylla* and *Pinus edulis*) (Furniss and Carolin 1977), whereas *I. pini* in the southwestern USA largely infests weakened or fallen trees and branches of *Pinus ponderosa* (ponderosa pine), *Pinus contorta* (lodgepole pine), and *Pinus jeffreyi* (Jeffery pine) (Kegley et al. 2002). The aggregation pheromone blend emitted by *I. confusus* consists of about 99%-(S)-(−)-ipsenol and 95%-(*S*)-(+)-ipsdienol (Young et al. 1973), very different from the approximately 95%-(*R*)-(−)-ipsdienol produced by the western North American *I. pini* (Miller et al. 1997).

Here, we report the isolation and characterization of a CYP9T2 ortholog, IcCYP9T1, from *I. confusus* in order to assess its role in pheromone biosynthesis and in determining the enantiomeric ratio of the key pheromone component, ipsdienol.

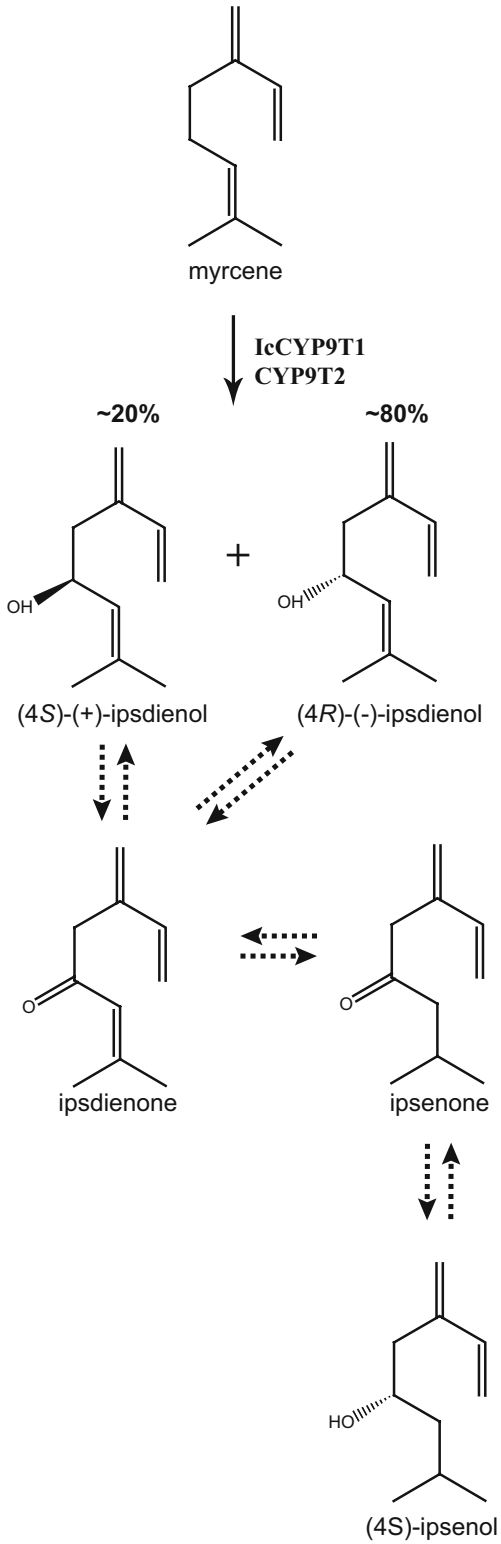

Fig. 1 Pheromone production in *Ips pini* and *Ips confusus*. Recombinant IcCYP9T1 and CYP9T2 are able to convert myrcene, which is ingested in the diet and produced de novo, to a ~5:1 mixture of (*R*)-(−):(*S*)-(+)-ipsdienol. Hypothesized pheromone-biosynthetic reactions, to achieve the crucial enantiomeric compositions of mostly (−)-ipsdienol for western North American *I. pini* populations and mostly (−)-ipsenol and (+)-ipsdienol for *I. confusus*, are shown as *dashed lines*

Methods and Materials

Insects Immature *I. confusus* were obtained from infested *P. edulis* bolts collected from the Bureau of Land Management (BLM), land east of Carson City, Nevada, USA. The insects were reared in a greenhouse to adults as per Browne (1972) and emerged adults (i.e., those that exited the brood tree) were collected daily. Adults were separated by sex according to Lanier and Cameron (1969) and were stored for up to 2 weeks at 4°C in moist paper towels.

Experimental All reagents and chemicals, cloning procedures, cell culture, recombinant protein production, microsome preparation, and enzyme assays were performed essentially as described previously (Sandstrom et al. 2006), with the following modifications:

cDNA isolation Two male *I. confusus* were inserted into separate small holes drilled into the phloem of fresh *P. edulis* bolts, secured with wire mesh, and allowed to feed for 23 h before their midguts were dissected and flash frozen in liquid nitrogen. The midguts were kept overnight at −80°C, and RNA was isolated by using the RNeasy Plant Mini Kit (Qiagen). To obtain a cDNA homologous to CYP9T2, first-strand cDNA synthesis and 3′ and 5′-Rapid amplification of cDNA ends (RACE) was achieved with the Clontech SMART™ RACE cDNA amplification kit (Clontech, Mountain View, CA, USA). *CYP9T2*-specific primers ("Ic9T2F1", GTGGCAAAAACTAACACCGCTGAAGAC; "Ic9T2R1", GTCTTCAGCGGTGTTAGTTTTTGCCAC, and "Ic9T2R2", CCGATTCATAGGTGACTTTGTTCCC), and the provided anchor primer (10× Universal Primer A Mix) were used as described in the manufacturer's instructions. Amplified products from the RACE PCR reactions were visualized on agarose gels, cloned into pST-Blue-1 AccepTor™ Vector (Novagen, San Diego, CA, USA), and transformed in *E. coli* NovaBlue Singles™ Competent Cells (Novagen). Recombinants were identified by colony PCR as described by the AccepTor™ Vector Kit protocol. Purified PCR products were sequenced by primer walking by using the ABI BigDye Terminator Cycle Sequencing Ready Reaction Kit v3.1 on an ABI3730 DNA Analyzer at the Nevada Genomics Center (UNR). All sequence analysis was done with Vector NTIv.9 software (Informax, N. Bethesda, MD, USA). The full-length cDNA was assembled from the overlapping RACE products and confirmed by PCR amplification of first strand cDNA with primers flanking the putative open reading frame (ORF). The complete deduced amino acid sequence was submitted to the P450 Nomenclature Committee (David Nelson, personal communication) and was given the name *Ips confusus CYP9T1* (IcCYP9T1).

Expression Analysis mRNA levels were determined by quantitative Real Time RT-PCR (qRT-PCR). cDNA templates for the fed male and female anterior midgut time-course studies were prepared previously (J. Bearfield, unpublished). Briefly, beetles were fed for 4, 8, 16, or 32 h, while unfed controls were held in plastic cups in the dark. There were six biological replicates that each included five beetles. For the tissue-distribution study, males and females were either allowed to feed on the phloem of *P. edulis* bolts or kept as unfed controls in plastic cups in the dark for 26 h and then dissected in water under a stereomicroscope. Tissues from the head, anterior midgut, posterior midgut, hindgut, fat body, and carcasses of eight insects were pooled and frozen in N_2(l). There were four male and female biological replicates.

Real time PCR primers with minimal potential for primer–dimer formation were identified by using Vector NTI (Version 7.1, Invitrogen) among primers suggested by Primer Express software (Applied Biosystems, Foster City, CA, USA). Relative gene expression was determined with the ΔΔCT method (Livak and Schmittgen 2001). The results were normalized with an internal control gene, *cytoplasmic actin*, which is unaffected by feeding in *I. confusus* (J. Bearfield, unpublished).

Cloning The *IcCYP9T1* ORF was amplified by PCR by using Ic9T1F1 (GCACCATGGTGGTCGGGTTGGTT) and IcCYP9T1R1 (tagged; GCCTCGAGGGTTCAAATG CAAGGT) primers, directionally cloned into the *NcoI* and *Xho*I sites of pENTR4 (Invitrogen) by standard methods (Sambrook et al. 1989), and transformed into DH5α cells. The reverse primer ensured that the construct would have a C-terminal extension containing a V5 epitope and the polyhistidine tag (encoded by the vector). An untagged version was not constructed because products and their relative abundance were statistically identical in assays of both the untagged and tagged versions of CYP9T2 (Sandstrom et al. 2006). The recombinant plasmid, pENTR4-IcCYP9T1V5H6, was confirmed by sequencing.

Recombinant IcCYP9T1 Protein Detection IcCYP9T1 production was determined by western blotting using 1:10,000 Anti-V5 primary antibody (Invitrogen), 1:20,000 Goat Anti-Mouse secondary antibody (Biorad, Hercules, CA, USA), and SuperSignal West Pico Chemiluminescent Substrate (Pierce, Rockford, IL, USA).

Enzyme Assays Recombinant IcCYP9T1 assays were performed as described by Sandstrom et al. (2006).

Gas Chromatography–Mass Spectrometry A Thermo Finnigan Polaris Q ion trap coupled with a Trace gas chromatograph was used for the gas chromatography–

mass spectrometry (GC-MS) analyses. The GC was fitted with a 60 m×0.25 mm i.d. DB-5 capillary column (J&W Scientific, Palo Alto, CA, USA) and was programmed from 50 (1 min hold) to 200°C at 5°C min^{-1}, and then to 320°C at 10°C min^{-1}. Split injection (100:1 ratio) with a constant column flow of 1.5 ml min^{-1} of helium was used. The enantiomeric composition of ipsdienol was determined by chiral separation by using the same instruments with a CycloSil-B (30 m×0.25 mm i.d., 0.25 μm film thickness) column (J&W Scientific) at 100°C and with a helium flow rate of 1.3 ml min^{-1}.

Results

DNA Isolation and Expression The cDNA for the CYP9T2 ortholog from *I. confusus* was isolated by PCR techniques. The 1,699 bp cDNA contained a 1,596 nt ORF encoding a 532 amino acid (a.a.) protein flanked by 74 nt and 26 nt 5′ and 3′ UTRs, respectively, and is therefore likely full-length. The predicted translation product has a molecular mass of 61 kDa and a pI of 8.9 (Gasteiger et al., 2003). It was designated *I. confuses* CYP9T1 (IcCYP9T1) by the P450 Nomenclature Committee (David Nelson, personal communication). The primary structure has an N-terminal membrane anchor and typical P450 conserved residues, including the WxxxR, ExxR, and PxxFxPERF ('PERF') motifs, and the canonical heme-binding domain (PFxxGxRxCxG) surrounding the heme-cysteine ligand (Cys475; Fig. 2) (Feyereisen 2005). BLAST searches (Altschul et al. 1990) indicated IcCYP9T1 is most similar to coleopteran CYP9s (not shown). It has a 98% a.a. identity (7 a.a. different) with the functionally uncharacterized partial length CYP9T1 from *I. paraconfusus* (IpCYP9T1) (Huber et al. 2007) and is 94% identical (34 a.a. different) to the *I. pini* myrcene hydroxylase CYP9T2 (Sandstrom et al. 2006) (Fig. 2).

Message levels were determined by qRT-PCR by using *cytoplasmic actin* as a normalizing gene. *IcCYP9T1* mRNA levels in males increased substantially over time upon feeding, with a maximal induction of approximately 400-fold at 32 h (Fig. 3a). In contrast, *IcCYP9T1* mRNA levels in females were repressed at 4, 8, and 16 h and only minimally induced at 32 h by feeding (Fig. 3a). *IcCYP9T1* mRNA localized predominantly to the anterior midgut of fed males (Fig. 3b). Levels in females were substantially lower than those in males, with no clear induction in any tissue upon feeding (Fig. 3b).

Fig. 2 Alignment of the deduced a.a. sequences of IcCYP9T1, IpCYP9T1 (ABF06554) and CYP9T2 (ABG74909). Conserved residues are indicated by a *dash*. The missing portion of IpCYP9T1 is indicated by a *gap* (a.a. 1–20). The membrane anchor domain is *underlined*. Conserved WxxxR, ExxR, and PxxF motifs are *boxed*. The heme-binding domain (PFxxGxRxCxG) is *shaded*

Enzyme Assays and Product Formation A baculoviral system was used to produce sufficient enzyme to analyze IcCYP9T1 functionally. The V5-epitope was used to follow recombinant protein production, as an antibody for IcCYP9T1 was unavailable. Western blot analysis indicated high expression of an approximately 65 kDa protein at 4 and 5 days post-infection (not shown). CO-difference absorption spectra of microsomes from Sf9 cells producing IcCYP9T1 had the characteristic peak at 450 nm, while microsomes from Sf9 cells without recombinant protein did not (not shown).

Assays with microsomes from Sf9 cells that co-express recombinant IcCYP9T1 and housefly P450 reductase were analyzed by GC-MS for myrcene hydroxylation products. Selective ion monitoring (SIM) analysis at *m/z*=85 (for ipsdienol) of microsomes incubated with unlabeled myrcene yielded a product with a retention time and mass spectrum identical to an ipsdienol standard (Fig. 4a). Products from reactions incubated with deuterium-labeled myrcene had the same retention time (not shown), but with a mass spectrum of appropriate *m/z* diagnostic fragments that was 1 amu larger. A time course of 5, 10, and 15-min reactions with unlabeled myrcene showed a linear increase in ipsdienol production relative to the *n*-octanol standard (not shown). Ipsdienol was not detectable by SIM analysis of products from reactions run in the absence of substrate (not shown), boiled microsomes (Fig. 4b), or microsomes infected with housefly P450 reductase baculovirus construct only (not shown). No other hydroxylated versions of myrcene (amitinol, *E*-myrcenol (2-methyl-6-methylene-2,7-octadien-1-ol), linalool (2,6-dimethylocta-2,7-dien-6-ol), or geraniol (2,6-dimethyl-2,6-octadien-8-ol)) were detected in any sample.

GC-MS analysis with a CycloSil-B column, of extracts of recombinant IcCYP9T1/P450 reductase, incubated with either unlabeled or deuterium-labeled myrcene, produced two major peaks with retention times corresponding to (*R*)-(−)-ipsdienol and (*S*)-(+)-ipsdienol. Reactions using unlabeled myrcene as substrate yielded enantiomeric percentages that averaged 85%-(*R*)-(−)-ipsdienol (Fig. 4c).

Selected ion monitoring (*m/z*=85 for ipsdienol) using a DB-5 column for reactions containing **a** unlabeled myrcene (identical to the ipsdienol standard, not shown) or **b** boiled microsomes (negative control). **c** Enantiomeric ratio of reaction products, determined by chiral GC-MS

Discussion

We report the isolation and functional expression of a monoterpene-oxidizing cytochrome P450 cDNA, IcCYP9T1, which produces the pheromone component, (*R*)-(−)-ipsdienol. The predicted translation product has a hydrophobic N-terminal target sequence and many motifs, including the classic heme-binding domain, common to P450s (Fig. 2). A CYP9T1 partial cDNA was first isolated and characterized from the California five-spined ips, *I. paraconfusus*, although its biochemical function was not determined (Huber et al. 2007). *I. paraconfusus* and *I. confusus* are sibling species, and once were considered a single species. It is, therefore, not surprising that the IcCYP9T1 and IpCYP9T1 orthologs share such high (98%) sequence identity (Fig. 2). The seven non-identical amino acids are nevertheless conserved, and appear located in positions that do not contribute to the active site (not shown), suggesting that the activities of the two enzymes should be similar.

Bark beetle pheromone-biosynthetic genes are typically up-regulated by feeding (Keeling et al. 2004), transcribed predominantly in the anterior midgut (Tillman et al. 2004; Gilg et al. 2005; Bearfield et al. 2006), and have basal expression levels that are higher in the pheromone-producing sex (Keeling et al. 2004, 2006). IcCYP9T1 mRNA levels increased substantially in male, but not in female, anterior midguts in response to feeding (Fig. 3a,b). *IcCYP9T1* mRNA was predominantly localized to the anterior midgut of pheromone-producing male *I. confusus* (Fig. 3b), and there was a fivefold basal level difference between male and female expression. These data correlate well with expression patterns of other *I. confusus* (Bearfield et al., unpublished), *I. paraconfusus* (Ivarsson et al. 1998; Tittiger et al. 1999; Huber et al. 2007) and *I. pini* pheromone-biosynthetic genes (Keeling et al. 2006), and strongly support a role for *IcCYP9T1* in male-specific aggregation pheromone biosynthesis.

Interesting differences in transcript accumulation patterns exist between *CYP9T2, IcCYP9T1*, and *IpCYP9T1*. Feeding induced an approximately 28-fold *CYP9T2* mRNA expression in male *I. pini* midguts (Sandstrom et al. 2006), over 400-fold expression in male *I. confusus* midguts (Fig. 3a,b), and an astonishing 85,000-fold expression in male *I. paraconfusus* whole bodies (Huber et al. 2007).

There are also differences in the timing of the up-regulation, with male *I. paraconfusus* achieving high levels within only 8 h of feeding (Huber et al. 2007), while the highest expression in *I. confusus* (Fig. 3a) and *I. pini* (Sandstrom et al. 2006) occurred by 32 h. Finally, while the difference between male and female basal levels of expression was not reported for *I. paraconfusus*, male *I. confusus* had an approximately five-fold higher expression level than females (not shown), which was much less than the ~500-fold difference in basal CYP9T2 mRNA levels in observed in male and female *I. pini* (Keeling et al. 2006). It should be emphasized that the study by Huber et al. (2007) investigated whole bodies, and the tissue distribution of IpCYP9T1 is unknown. Furthermore, IpCYP9T1 levels in that study were normalized to *CYP4G27*, rather than *cytoplasmic actin*. We analyzed the stability of expression of four candidate normalizing genes, *CYP4G27*, *cytoplasmic actin*, *β-tubulin*, and *ubiquitin C* in *I. confusus* by using qBase (Hellemans et al. 2007) and found that *CYP4G27* and *cytoplasmic actin* were similarly stable (A. Griffith, unpublished data). We chose to continue to use *cytoplasmic actin* as a normalizing gene in order to maintain continuity with previous studies. Thus, while quantitative comparisons between our studies and that of Huber et al. (2007) may have reduced value, the general trends among the three species appear qualitatively similar.

Similarities in sequence and expression patterns with the myrcene hydroxylase CYP9T2 (Sandstrom et al. 2006) suggested myrcene as a logical IcCYP9T1 substrate. A baculovirus system was used to produce sufficient enzyme for functional assays. Sf9 microsomes that contain recombinant IcCYP9T1 readily hydroxylated myrcene to ipsdienol (Fig. 4). The amount of ipsdienol produced increased linearly with incubation time, and myrcene hydroxylation activity was abolished when microsomes were heat-denatured prior to the reaction (Fig. 4b), confirming that ipsdienol is an enzymatic product. Furthermore, microsomes from cells that were infected with recombinant housefly P450 reductase baculovirus (without recombinant IcCYP9T1) did not hydroxylate myrcene (not shown). Thus, ipsdienol production was due to IcCYP9T1 and not to an endogenous activity of Sf9 cells. Other possible myrcene hydroxylation products were not detected, suggesting high product specificity.

Recombinant IcCYP9T1 produced ~85%-(−)-ipsdienol, similar to the ~81%-(−)-ipsdienol produced by recombinant CYP9T2 (Sandstrom et al. 2006). This enantiomeric excess is nearly antipodal to the ~90%-(+)-ipsdienol found in the *I. confusus* pheromone blend. While the enantiomeric ratios of ipsdienol from recombinant enzyme assays may be affected by experimental conditions (i.e., the reactions were done with Sf9 microsomes, not purified recombinant enzyme), the observed excess of (*R*)-(−)-ipsdienol is assumed to be biologically relevant. Our data strengthen the observation that myrcene hydroxylases contribute little to the final enantiomeric blend of pheromonal ipsdienol (Sandstrom et al. 2006), and further support the suggestion that enzymes downstream from myrcene hydroxylation are required to achieve the crucial enantiomeric compositions of pheromone used by different species. The terminal steps in ipsenol and ipsdienol pheromone biosynthesis in scolytids likely involve oxidases and/or reductases that catalyze the interconversion between ipsdienol, ipsdienone, ipsenone, and ipsenol (Fish et al. 1979; Ivarsson 1997; Vanderwel, personal communication). There may be situations, such as those that can occur in hybrid zones, in which downstream enzymes with different product profiles may compete, or not be active, and the enantiomeric composition would then be determined by the P450 (Domingue and Teale 2008).

Functional expression of IcCYP9T1 provides insight into P450 evolution and control of *Ips* spp. pheromone production. The enantiomeric ratios of ipsdienol produced by IcCYP9T1 and CYP9T2 are similar and apparently unrelated to the final pheromone blend. Even though a single a.a. change can alter P450 activity (Feyereisen 2005), the 94% a.a. identity between IcCYP9T1 and CYP9T2 appears to be sufficient to confer similar activity. The conservation of activities can be taken to indicate a common ancestral function, most likely host-resin detoxification. However, both genes appear to have acquired, or else inherited from a common ancestor, regulatory motifs that coordinate their transcription with other pheromone-biosynthetic genes. Indeed, co-ordinate regulation would almost be necessary given the large amounts of toxic myrcene produced endogenously during pheromone biosynthesis. In this respect, these P450s still function as detoxification enzymes in pheromone-biosynthetic midguts. Thus, they may serve as an example of how enzymes acquire new biological roles by variations in their corresponding gene expression, despite retaining their original activities. This is consistent with the application of pre-existing metabolic activities to conserve resources and develop regulated pheromone component production. Future investigation will determine the substrate specificity of IcCYP9T1 and CYP9T2. The study of these proteins and additional homologues in different *Ips spp*. or populations will lead to a better understanding of the origin and regulation of bark beetle pheromone biosynthesis, thus allowing for the development of new pest management tools.

Acknowledgements We thank D. Vanderwel for deuterium-labeled myrcene and for sharing unpublished data, M. Schuler for the housefly P450 reductase baculoviral clone, C. Oehlschlager for the ipsdienol standard, D. Nelson for the naming of *Ips confusus CYP9T1* in accordance with current P450 nomenclature, the Nevada Genomics

Center for assistance with sequencing and qRT-PCR, D. Quilici at the Nevada Proteomics Center for GC-MS analysis, H. Damke for help with baculovirus expression, A. Griffith for studies of potential housekeeping genes, other members of the laboratories of GJB and CT for assistance with collecting beetles, dissections, assays, and helpful advice, and the Bureau of Land Management and US Forest Service for permission to collect beetle-infested trees. This work was supported by USDA-NRI (2006-35604-16727), NSF (IBN 0316370), and a HATCH grant from the Nevada Agriculture Experiment Station (NAES) (NEV00339). This paper is a contribution of the NAES, publication # 03087107.

with intraspecific pheromone reception, but rather with the perception of nonpheromonal odorants.

Proteins with characteristics of OBPs also have been identified in many orders of insects, such as in Lepidoptera (Vogt et al. 1991b; Maleszka and Stange 1997; Scaloni et al. 1999; Wang et al. 2003; Maida et al. 2005; Xiu and Dong 2007), Diptera (Ozaki et al. 1995; Hekmat-Scafe et al. 1997; Biessmann et al. 2002; Ishida et al. 2002a, 2004; Xu et al. 2003), Heteroptera (Dickens et al. 1995), Coleoptera (Graham et al. 2003; Nagnan-Le Meillour et al. 2004), Orthoptera (Ban et al. 2003), Isoptera (Ishida et al. 2002b), and Hymenoptera (Lu et al. 2007). Twenty-one OBP-like genes have been characterized from the whole genome sequences of the honey bee, *Apis mellifera* L. (Forêt and Maleszka 2006). Proteins corresponding to specific OBP family member genes from *A. mellifera* include ASP1 (Danty et al. 1999), ASP2 (Briand et al. 2001), ASP4: AAL60417 (GenBank accession number), ASP5: AAL60422, and ASP6: AAL60421. These have been characterized from the antennae and legs of workers and drones according to their precise molar weights determined by mass spectrometry and N-terminal sequencing (Danty et al. 1998). The antennal specific water-soluble protein, ASP2 (Mr 13,695.2±1.6), was purified and characterized as the first Hymenoptera putative GOBP, based on its specific expression in olfactory areas and higher expression in the worker than in the drone (Danty et al. 1997). Briand et al. (2001) reported that it interacted with a wide range of volatile odorant molecules, but not with the major components of the queen pheromone.

The Asian honey bee, *Apis cerana cerana* Fabricius (Hymenoptera: Apidae), is an economically important indigenous species with about two million colonies being bred in China. *A. cerana cerana* has many unique characters, such as the resistance to ectoparasitic mites by a specific grooming behavior and tolerance for low environmental temperatures. The latter quality makes *A. cerana cerana* an important pollinator of flowering plants at high altitudes (Peng et al. 1987; Chen 2001). Biochemically, OBPs are thought to act as solubilizers and carriers of the lipophilic odorants in the sensillar lymph, as peripheral filters in odor discrimination by selectively binding certain kinds of odorants, as stimulus molecules to the receptor to facilitate signal transduction, as rapid deactivators of odorants after stimulation, and as cleaners to remove unwanted or toxic compounds from the perireceptor space (Vogt and Riddiford 1981; Steinbrecht 1998; Pelosi et al. 2006). Thus, we hypothesize that OBPs may play an important role in the olfactory system of *A. cerana cerana* related to the search for nectar and pollen and in detection of odorants from ectoparasitic mites.

In this study, we cloned a new OBP-encoding gene (*Acer-ASP2*) from *A. cerana cerana* and then expressed the corresponding protein in *Escherichia coli*. With polyclonal anti-(Acer-ASP2)-serum from purified recombinant Acer-ASP2 antigen, we investigated immunolocalization in the antennae of *A. cerana cerana* workers, and with real-time polymerase chain reaction (PCR), we characterized the spatiotemporal expression pattern of *Acer-ASP2*.

Methods and Materials

Insects Larval, pupal, and adult workers from *A. cerana cerana* colonies were bred at the Experimental Apiary at Zhejiang University, Hangzhou, China. Bees of known ages were obtained by marking the newly emerged bees from a frame of capped broods kept in an incubator; bees were returned to the hive and collected when required. The developmental stages of workers were classified according to the criteria of Rachinsky et al. (1990) and Michelette and Soares (1993).

Amplification of cDNA Encoding Acer-ASP2 From 100 antennae of adult worker bees of *A. cerana cerana*, total RNA was isolated with Trizol reagent (Invitrogen, Carlsbad, CA, USA). cDNA was synthesized by using SuperScript™ II Reverse Transcriptase system (Invitrogen). The DNA encoding *Acer-ASP2* was amplified by PCR from cDNA with primer pairs (Table 1) designed from ASP2 sequence from *A. mellifera* (GenBank no. AF393493). The amplification conditions were 4 min at 94°C, followed by 35 cycles of 45 s at 94°C, 45 s at 50°C, 1 min at 72°C, and final extension for 10 min at 72°C. Amplified DNA purified with a gel extraction kit (Qiagen, Valencia, CA, USA) was inserted into pGEM-T vector (Promega, Madison, WI, USA) and was transformed into *E. coli* TG1 competent cells. Positive colonies, screened for the presence of the insert by restriction analysis by using *Bam*H I and *Hin*d III, were sequenced (Center of Analysis &

Production and Purification of Recombinant Acer-ASP2 The 450-bp fragment excised with *Bam*H I and *Hin*d III from the pGEM-Acer-ASP2 plasmid, was purified with the gel extraction kit (Qiagen) and cloned into pET-30a (+) vector (Novagen, Darmstadt, Germany) digested with the same restriction enzyme, and the recombinant expressed plasmid pET-Acer-ASP2 was transformed into *E. coli* BL21 (DE3) competent cells. Single colonies were grown overnight in 10 ml Luria–Bertani broth (including 30 μg/ml kanamycin). The culture was diluted 1:100 with fresh medium and grown at 37°C until absorbance at OD_{600} reached 0.4, at which point isopropyl-β-D-thiogalactopyranoside (Merck, Darmstadt, Germany) was added to the culture to a final concentration of 1.5 mM to induce expression of the target products. After 5 h at 28°C, the bacterial cells, harvested by centrifugation and resuspended in lysis buffer [50 mM Tris/HCl (pH 8.0), 100 mM NaCl, TritonX-100 (0.5%), 2 mM ethylenediaminetetraacetic acid], were lysed by sonication and centrifuged again. The inclusion body of recombinant protein Acer-ASP2 was severely precipitated in 1.5 M urea in ddH_2O and finally freeze-dried and resuspended (1 mg/ml) in phosphate buffered saline (PBS; pH 7.4) for injection into rabbit for producing antisera.

Preparation of Antisera Antisera were obtained by injecting an adult male rabbit subcutaneously and intramuscularly with purified inclusion body of recombinant protein of Acer-ASP2 (1 mg/time). The interval between the first and second injection was 21 days, whereas two additional injections were performed at 14-day intervals. The protein was emulsified with an equal volume of Freund's complete adjuvant for the first injection and incomplete adjuvant for further injections. For 10 days after the final injection, the rabbit was bled and the serum was collected for further application.

Western Blot Analysis After electrophoretic separation under denaturing conditions (12.5% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE)), purified Acer-ASP2 was electroblotted on a nitrocellulose membrane by using a Bio-Rad Transblot (Bio-Rad Laboratories, Hercules, CA, USA). After treatment in TBS (containing 3% BSA and 0.05% Tween 20) at 4°C overnight, the membrane was incubated with the crude antiserum against Acer-ASP2 (dilution 1:500) and then with goat antirabbit IgG horse radish peroxidase conjugate (dilution 1:1,000). Immunoreacting bands were treated with the color development solution (2 mg diaminobenzidine in 10 ml TBS, 10 μl 30% H_2O_2).

Scanning Electron Microscopy For scanning electron microscopy (SEM), the antennae of worker bees were immersed in osmic acid (1%) for 30 min and in a concentration series of ethanol (50%, 70%, 80%, 90%, 95%, and 100%) for 15 min each. After air drying, samples were mounted on holders and examined by using a SEM of XL30-ESEM (Philips Research, Eindhoven, The Netherlands) after gold coating with K500X sputter coater (Emitech Ltd., Ashford, Kent, UK).

Immunocytochemical Localization Antennae of worker bees were chemically fixed in a mixture of formaldehyde (2%) and glutaraldehyde (1%) in 0.1 M PBS (pH 7.4) at 4°C for 2–3 h, then dehydrated in an ethanol series and polymerized embedded in K4 M (Sigma, St. Louis, MO, USA) and irradiated with UV at −20°C for 72 h. Ultrathin sections (50–100 nm) were cut with a glass knife on an Ultracut E ultramicrotome (Reichert-Jung, Austria). For immunocytochemistry, the nickel grids adhering to ultrathin sections were floated on droplets of the following solutions on parafilm with sequential steps: ddH_2O, BL (50 mM PBS containing 1% bovine serum albumin and 0.02% PEG2000, 10 mM NaCl, and 1% NaN_3), primary antiserum diluted with BL (dilution 1:50), twice each on ddH_2O, BL, secondary antibody that goat anti-rabbit IgG coupled to 10-nm colloidal gold (AuroProbe EM, GAR G10, Amersham Biosciences, Piscataway, NJ, USA) diluted with BL (dilution 1:20), and three–five times on ddH_2O. The results of immunolocalization of Acer-ASP2 were observed and photographed through the transmission electron microscope of JEM-1230 (JEOL Ltd., Tokyo, Japan).

Expression Profiling of Acer-ASP2 with Real-Time PCR For spatial expression profiling, antennae (A), heads (H), thoraces (Th), abdomens (Ab), wings (W), and legs (L) were dissected from 50 adult worker bees. For expression profiling across ages of worker bees, 7-day-old larvae and pupae, and the antennae of 1, 4, 6, 9, 12, 15, 18, 21, 24, 27, and 30-day-old adult worker bees were prepared. Total RNA of all above material from individual honeybee colonies was extracted separately and cDNA was synthesized as described above. Specific primer pairs were designed based on the primers used for cloning Acer-ASP2 (Table 1) and *A. cerana* β-actin (GenBank accession no. AB072495). For real-time quantitative RT-PCR, primers for *A. cerana* β-actin were designed such that the paired primers (Table 1) were expected to amplify a 301-bp fragment. An iCycler iQ™ real-time PCR detection system (Bio-Rad) was used to detect the spatiotemporal transcriptional profiling of *Acer-ASP2* mRNA of *A. cerana cerana*. The total 20-μl reaction system consisted of 1 μl cDNA (about 20 ng), 10 μl iQ™ SYBR® Green Supermix (Bio-Rad), and 10 μM of each primer. The thermal cycling

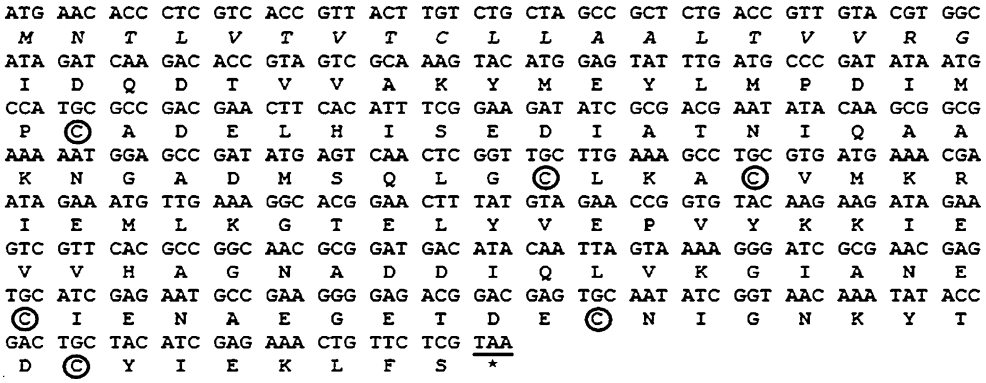

Fig. 1 Full cDNA sequence of the open reading frame and deduced amino acid sequence of Acer-ASP2 from an Asian honey bee, *A. cerana cerana*. The *asterisk* marks the stop codon, six conserved Cys residues are *circled*, and the 19 amino acid residues in *italicized font* represent the N-terminal signal peptide sequence

conditions for real-time PCR were 5 min at 94°C, followed by 40 cycles of 30 s at 94°C, 30 s at 50°C, and 30 s at 72°C. PCR reactions were performed in triplicate, and data were processed by using the relative quantification $2^{-\Delta\Delta Ct}$ method (Livak and Schmittgen 2001).

Results

cDNA Sequence of Acer-ASP2 To characterize the *Acer-ASP2* cDNA, we designed specific primers and obtained a 393-bp open reading frame (ORF; Fig. 1). After cloning and sequencing, we obtained the cDNA sequence and submitted it to GenBank (accession number DQ449667). The ORF encodes 142 amino acids and contains a hydrophobic signal peptide with 19 amino acids at the N terminus (predicted by the software SignalP 3.0; Bendtsen et al. 2004). By using the proteomics server ExPASy (Gasteiger et al. 2003), the theoretical isoelectric point and molar weight of mature Acer-ASP2 were computed as 4.36 and 15,656.16, respectively, in agreement with other OBPs. The protein has the typical six-cysteine signature of OBPs and has low similarity (14.9–24.4% of identical residues) with OBPs from other insect species (Fig. 2). However, it does have high similarity (98.6%) with *Amel*-ASP2

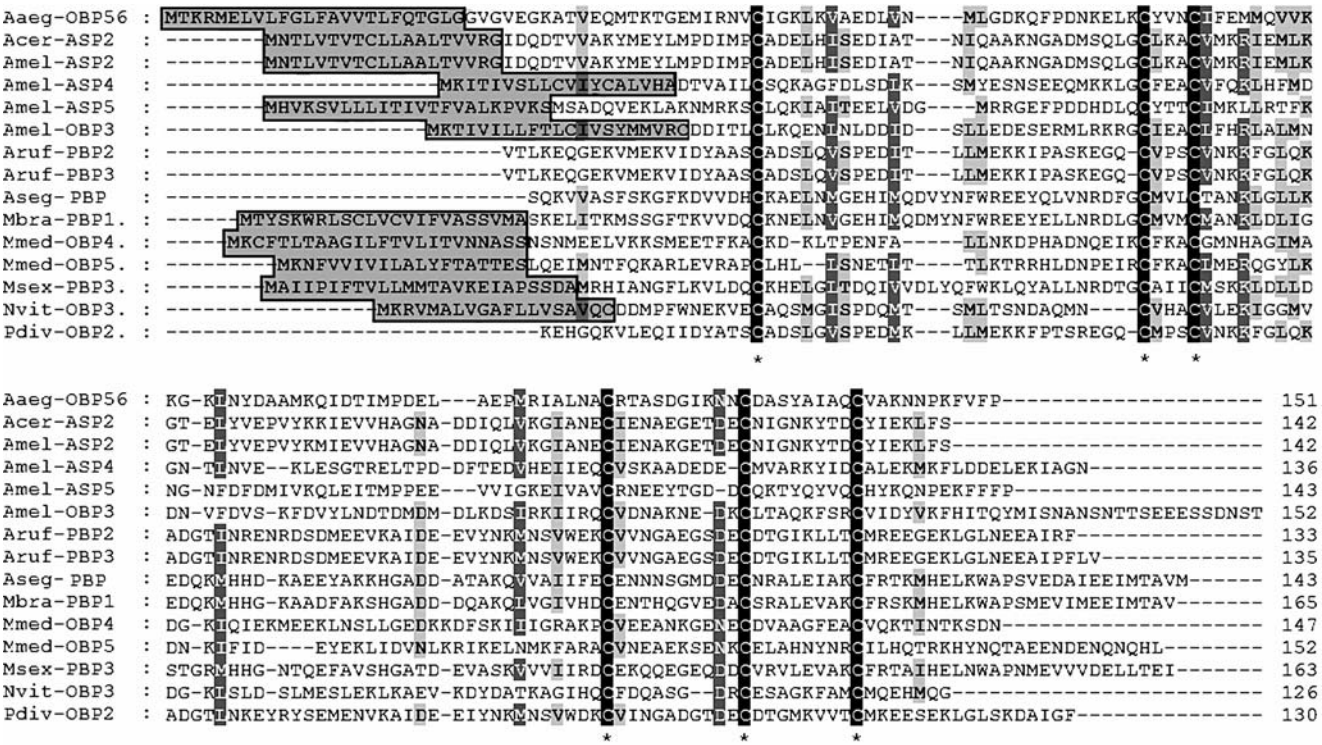

Fig. 2 Alignment of deduced amino acid sequence of Acer-ASP2 with homologous proteins from other insect species (GenBank BLASTP). Sequences used in alignment are indicated by the following species abbreviations: *Acer Apis cerana cerana*, *Aaeg Aedes aegypti*, *Amel Apis mellifera*, *Asch Anomala schonfeldti*, *Aruf Anomala rufocuprea*, *Pdiv Phyllopertha diversa*, *Nvit Nasonia vitripennis*, and *Mmed Microplitis mediator*. Residues common to most sequences are *shaded*. Six conserved Cys residues are labeled by *asterisks*. Signal peptide sequences are highlighted by enclosing them in *shaded rectangles*

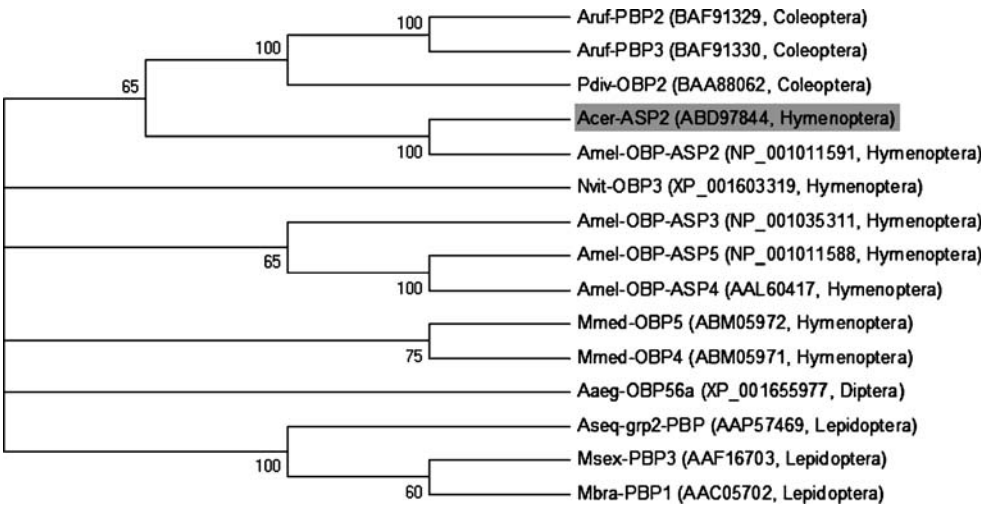

Fig. 3 Neighbor-joining (NJ) tree (condensed tree, cutoff value is 50%) of sequences similar to Acer-ASP2. All OBPs from the alignment analysis (Fig. 2) were included in the NJ tree. Bootstrap support values (%) based on 1,000 replicates are indicated

(Fig. 2). These results were emphasized in the evolutionary tree from the neighbor-joining analysis (Fig. 3).

Production and Purification of Acer-ASP2 and Western Blot Analysis with Antisera To obtain the amounts of recombinant protein Acer-ASP2 suitable for preparation of antisera, we digested the pGEM-Acer-ASP2 plasmid with *Bam*H I and *Hin*d III and the resultant purified DNA was inserted into the expression vector pET-30a (+) and transformed into *E. coli* BL21(DE3) competent cells. Electrophoretic analysis of the crude cell extracts (pellet and supernatant) under denaturing conditions (12.5% SDS-PAGE) revealed that the recombinant protein Acer-ASP2 migrated as an intense band of 23 kDa (Fig. 4). The protein was recovered almost entirely in the form of an insoluble inclusion body and in high yields (generally, 1 l of culture yielded 50 mg of protein at final purification). Recombinant Acer-ASP2 was purified by precipitation in urea, freeze-dried, and injected into a rabbit as described above. The polyclonal anti-(Acer-ASP2)-serum obtained was applied to detect Acer-ASP2 by Western blot analysis (Fig. 4, WB).

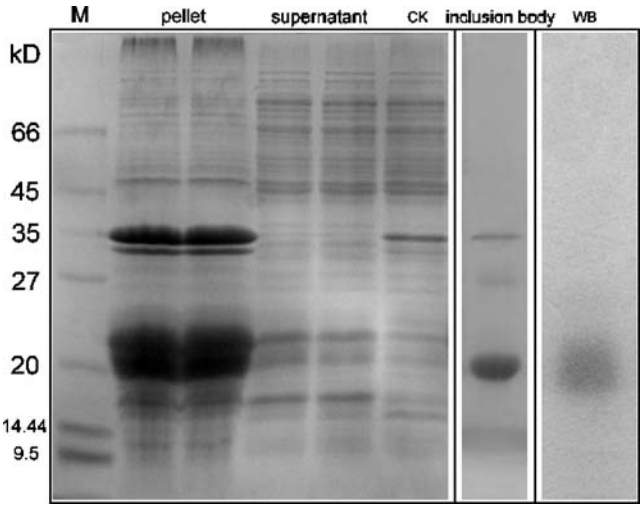

Fig. 4 Electrophoretic analysis (12.5% SDS-PAGE) of expression products from *E. coli* BL21(DE3) cells. The inclusion body protein of Acer-ASP2 was purified by urea with differing concentrations, showing an intense band of 23 kDa, present almost entirely in the pellet. Western blot analysis showed the specificity of anti-(Acer-ASP2)-serum with antigen Acer-ASP2. The low molecular weight protein markers are shown in the *lane furthest to the left*

Immunocytochemical Localization Imaging of *A. cerana cerana* worker antennae by scanning electron microscopy revealed at least six different types chemosensilla: sensilla placodea (sp), sensilla basiconica (sb), sensilla campaniform (scf), and sensilla trichoidea A,B,CD (Fig. 5, which shows only sp and stA). Sensilla placodea, the most numerous type on worker bee antennae, are oval discs. As observed in other honey bees (Ågren 1977, 1978), the plate is raised and resembles a hemispherical dome separated from the surrounding surface by a crevice. These clefts may either result from air drying during sample processing (i.e., an artifact) or may correspond to a lower point at which the plate rim is fastened to the cuticle and the outer rim of the

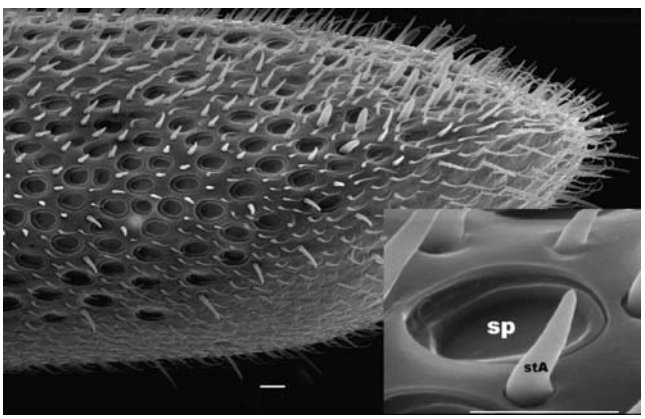

Fig. 5 Scanning electron micrograph of the sensilla on the tip of the flagellar segment of the antennae of *A. cerana cerana*. The *magnified figure* illustrates the two main olfactory sensilla: s. placodea (*sp*) and s. trichoidea A (*st A*). *Scale bar* is 10 μm

sensillum is raised (Fig. 5, sp). Sensilla trichodea A, which are more numerous than the remaining types listed above, appear slender, glabrous, and bent distally with the tip pointed slightly up. They are characterized by a thick cuticular wall with unbranched outer dendritic segments in the lumen (Fig. 5, stA).

The polyclonal antiserum against Acer-ASP2 was used for immunocytochemical analysis of the antennae. In sections of tarsal segments of antennae, significant gold particles only labeled the sp and the stA. With the sp, gold particles accumulated on the dendrites in the sensillar lymph, but not in the narrow pore areas on the top of the wide brim of the oval discs of the sp (Fig. 6, A1,A2). With the stA, more gold particles accumulated on the dendrites in the trichogen cell; fewer particles accumulated in the outer and inner sensillar lymph in the cell (Fig. 6, B1,B2).

Expression Profiling of Acer-ASP2 Based on the normalized relative quantification $2^{-\Delta\Delta Ct}$ method (Livak and Schmittgen 2001) for real-time PCR with SYBR I, spatial expression profiling of *Acer-ASP2* revealed that the transcript was specifically expressed on antennal tissue, but never in other anatomical regions tested (based on the final melt curve of real-time PCR; Fig. 7a). On the other hand, the developmental and temporal expression analysis indicated no expression in larvae or pupae, and then two ages in the adult worker bee antenna during which expression was elevated: (1) highest expression between 9 and 15 days (although it declined at the 12 days measurement) and (2) relatively high expression between 27 and 30 days (Fig. 7b). Transcript abundance was calculated based on the difference in threshold cycle (C_t) values between *Acer-ASP2* and β-actin transcripts.

Discussion

In this study, we cloned and identified a novel gene encoding Acer-ASP2, an OBP from the Asian honey bee, *A. cerana cerana*. The protein has typical hexapod OBP characteristics, e.g., conserved residues of six cysteines, and a similar isoelectric point and molecular weight. When compared with Amel-ASP2 of *A. mellifera*, the amino acid

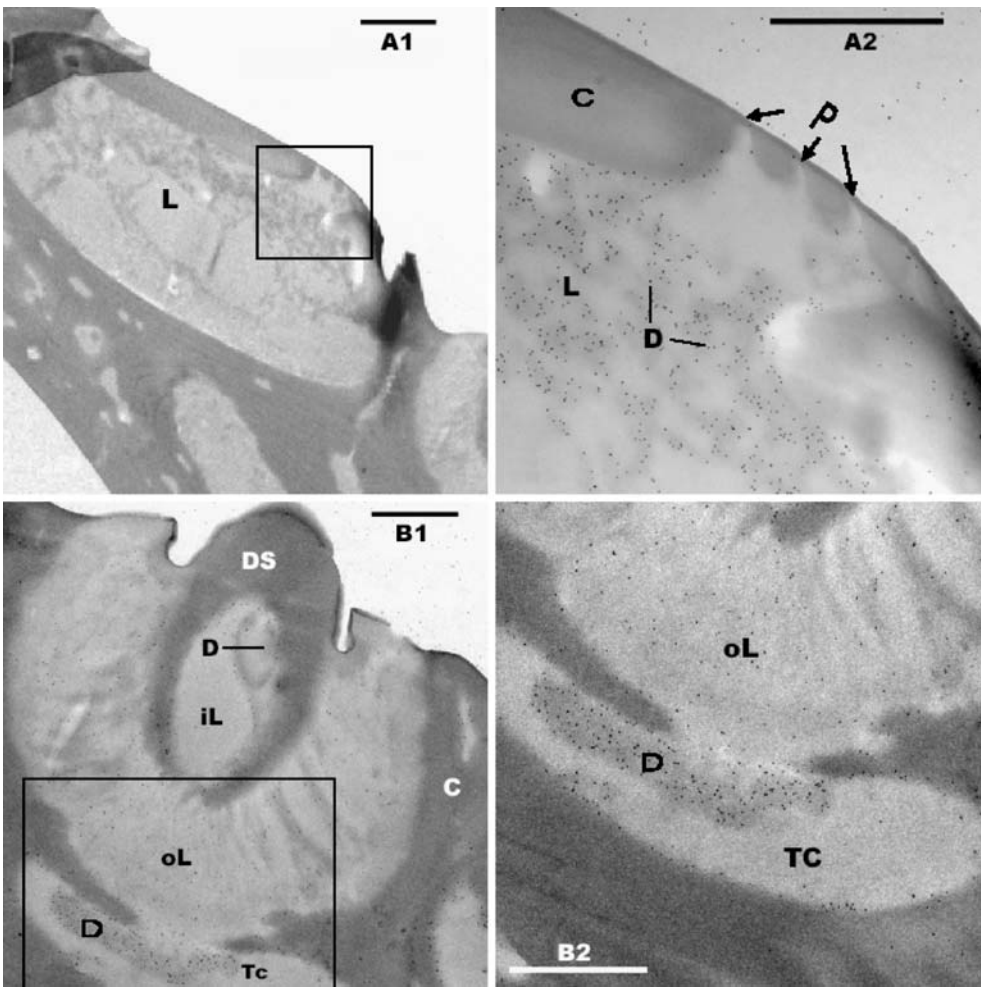

Fig. 6 Immunocytochemical localization of OBP in the antennal sensilla of *A. cerana cerana*. Acer-ASP2 was specifically expressed on the s. placodea (*A1* and *A2*, *A2* is an enlargement of the square section in *A1*) and the s. trichodea A (*B1* and *B2*, B2 is an enlargement of the square section in *B1*). In this image of the s. placodea, the gold particles were labeled on the dendrites (*D*) and the sensillar lymph (*L*), but not in the narrow pore areas (*P*) on the top of the olfactory sensilla (*A2*). In this image of the s. trichodea A, more gold particles were labeled on the dendrites in trichogen cell (*TC*) and fewer particles were labeled in the outer (*oL*) and inner (*iL*) sensillar lymph, the cuticular hair wall (*C*), or the dendritic sheath (*DS*). *Scale bar* is 1 μm

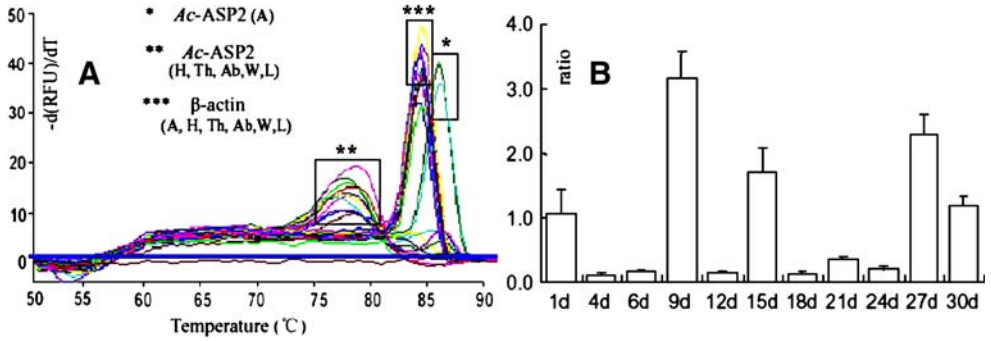

Fig. 7 Relative spatial and developmental quantification of Acer-ASP2 transcripts from various honey bee organs by real-time PCR. In spatial expression profiles (**a**), the melting curve within real-time PCR showed that Acer-ASP2 was specifically expressed on antennae (*A*; the high peak at 85–90°C labeled with *one asterisk*) but was never detected (except as primer dimers) in other organs: heads (*H*), thoraces (*Th*), abdomens (*Ab*), wings (*W*), and legs (*L*; the lowest peak at 75–80°C labeled with *two asterisks*). Another peak representing amplified products of β-actin present in all organs was labeled with *three asterisks*. In temporal expression profiles (**b**), Acer-ASP2 was not expressed in larvae and pupae (data not shown in the figure). However, in some adults, the highest levels of relative expression in the antennae occurred at 9 and 27 days (ratio>2.0), the next highest levels occurred at 1, 15, and 30 days (2.0>ratio>1.0), and the lowest levels occurred at 4, 6, 12, 18, 21, and 24 days (ratio<1.0)

sequence of Acer-ASP2 is highly similar (98.6%), but less similar (14.9–24.4%) to 13 other OBPs or PBPs (Fig. 2) from more distantly related species of insects.

Immunocytochemistry experiments have shown that OBPs are always localized in the diverse olfactory sensilla in many insects. For example, in Lepidoptera, the GOBPs of *Antheraea polyphemus* and *Bombyx mori* were localized only in s. trichodea and s. basiconica and principally in the sensillar lymph around the sensory dendrites (Steinbrecht et al. 1995). Similar anatomical patterns were also described for OBPs from two species of Orthoptera, *Schistocerca gregaria* and *Locusta migratoria* (Jin et al. 2005). In male *Helicoverpa armigera* (Lepidoptera), GOBP2*Harm* was mainly expressed in the s. basiconica, whereas in females, it was expressed abundantly in the s. trichodea (Wang et al. 2003). In the noctuid moths, *Agrotis segetum*, *Autographa gamma*, *H. armigera*, *Heliothis virescens*, and *Spodoptera littoralis*, PBPs were localized predominantly in s. trichodea and GOBP2 in s. basiconica (Zhang et al. 2001). In that study, interspecific immunolocalization utilized antisera raised against the PBP and GOBP2 of *A. polyphemus*, but the result reflected a good correlation with the stimulus specificity of the receptor cells in these types of sensilla.

Summarizing the immunochemical studies, we can conclude that PBPs of moths always have been localized predominantly in the s. trichodea, which respond to pheromones, whereas the GOBPs have been localized predominantly in the s. basiconica, which are generally involved in detecting plant odors. However, Acer-ASP2 was not found in the s. basiconica of *A. cerana cerana* (considered to be involved in taste and mechanoreception in *A. mellfera*; Esslen and Kaissling 1976), but in the s. placodea and s. trichodea A. This suggests that the latter sensillar types may be involved in detecting plant odors in bees. Although the allocation of function to the various types of sensilla in moths and bees is not completely identical, the anatomical placement of OBPs is consistent with their role in detecting general odors in both higher taxonomic groups. Perhaps this is a result of differences in classification of the antennal morphology of moths and bees or in the function of the sensilla in the two species. OBPs are synthesized in the trichogen cells along typical pathways for protein biosynthesis (Steinbrecht et al. 1992). In our study, the heavy labeling of Acer-ASP2 in the trichogen cells of the s. trichodea A supports this concept.

In most insect species, the prevailing model is that OBPs are expressed specifically in the antennae. Our real-time PCR data support this because the *Acer-ASP2* mRNA was present in abundance in antennae, but never in other anatomical tissues (e.g., heads, thoraces, abdomens, wings, or legs; Fig. 7a). The anatomical patterns of expression of Acer-ASP2 were similar to those of Amel-ASP2, which has been detected exclusively in the antennae of *A. mellifera* (Danty et al. 1997). Other OBPs of *A. mellifera* (e.g., Amel-ASP1, 4, 5, 6) have been reported as antennal specific in workers and drones, but with some localization in legs of drones (ASP1; Danty et al. 1998), equally expressed in the antennae, wings, and legs of various castes and age groups (ASP4 and ASP5) or detected in antennae and legs of both workers and drones (ASP6; Calvello et al. 2005). Furthermore, OBPs have been expressed equally in antennae, wings, and legs of all castes and ages of the paper wasp, *Polistes dominulus* (Calvello et al. 2003), and in legs and wings of another wasp, *Vespa crabro*.

From the developmental and temporal expression profiles of *Acer-ASP2*, we learned that it is not expressed in larvae and pupae, and in adults, there are two periods of elevated expression. The first period occurs at 9 and 27 days (mean expression ratio was 2.7±0.4) and the second occurred at 1, 15, and 30 days (mean ratio was 1.3±0.3).

Throughout the remaining times that we assayed for expression, the mean ratio was 0.2±0.03 (Fig. 7b). Because the expression ratios during the first two periods are tenfold greater than that of the lowest period, Acer-ASP2 may play an important functional role in adults during the two periods. At the 9-day timepoint (the highest expression of *Acer-ASP2*), worker bees are making the transition in maturation and are starting to secrete plentiful beeswax to construct their comb (Yang 1998). After 15 days, maturing bees begin to fly out and forage for nectar and pollen. Their highest level of foraging activity occurs around the 27-day timepoint, which coincides with the second highest level of *Acer-ASP2* expression that we recorded. We do not understand why transcript amounts were lower in the intervening periods of 18, 21, and 24 days. However, taken together, our results suggest that Acer-ASP2 may play an important role in the processes of producing beeswax and acquiring the odorant molecules related to foraging for nectar and pollen, or other general odorants.

As a native Chinese bee species, the habitat of *A. cerana cerana* is threatened by the invasion of exotic bees as well as deteriorating environmental conditions (Tan 2006). Future research necessary to protect this species might involve the molecular mechanism of the unique characteristics of the olfactory system. Recently, the genomic sequencing project of *A. mellifera* was completed (The Honeybee Genome Sequencing Consortium 2006), and examination of genes related to signal transduction suggested that *A. mellifera* has fewer genes for gustatory reception and more genes for odorant reception, which is consistent with its ecology and social organization. *A. cerana cerana* appears to have greater olfactory sensitivity when compared with *A. mellifera*, so elucidating the biochemical mechanism of the olfactory process in *A. cerana cerana* should be a high priority in the future.

al. 2006), and many containerized baits are not practical for landscape scale applications. Poison baits also may carry non-target risks to pets and wildlife. In natural areas, particularly those sensitive to perturbation or of high ecological value, impacts on native invertebrates can be considerable (Balança and de Visscher 1997; Zhakharov and Thompson 1998). Thus, effective and environmentally benign control tactics are needed for management and control of these invasive ants.

Wright (1964) proposed that if sufficient synthetic sex pheromone were distributed in the air, the normal pheromone communication systems of certain species would be disrupted, and the sexes might be incapable of locating each other. The feasibility of the disruption approach by using pheromones was demonstrated for the cabbage looper (Gaston et al. 1967), and "mating disruption" is now an effective direct control option against certain pests (Suckling and Karg 2000; El-Sayed 2008).

The development of more environmentally benign treatments based on semiochemicals could be used for managing invasive ants in sensitive natural ecosystems. Despite the discovery and characterization of a variety of ant pheromones, relatively little work has been undertaken using them for management (Robinson and Cherrett 1978; Shorey et al. 1992).

The Argentine ant uses (*Z*)-9-hexadecenal (Cavill et al. 1979) as its trail pheromone to orient and communicate the location of food, and it is probably critical to successful mass recruitment to ephemeral food resources. Van Vorhis Key et al. (1981) and Van Vorhis Key and Baker (1982a, b, c) studied this system and recognized that it might be possible, without elaborating how, to modify trail-following behavior with synthetic compounds. Shorey et al. (1992) tested other volatile compounds as barrier treatments for disruption of Argentine ant trails, but these were not very effective.

The recent demonstration of partial disruption of Argentine ant trails by using polyethylene tubing dispensers that release (*Z*)-9-hexadecenal in orchards (Tatsuki et al. 2005) raises the possibility of development of a new control tactic against this species in different environments, including sensitive ecosystems, by using formulations that could be applied at landscape level. Trail disruption could have a potential as a stand-alone pest management tactic or in combination with others.

In this study, we first examined close-range disruption of trail-following behaviors on different substrates when a single point source was placed near a trail. Second, we carried out small plot field tests to examine foraging at bait cards in areas by using a widely dispersed point source strategy. In both cases, the pheromone was placed within the boundary layer of the foraging ants, which was not the case in the study by Tatsuki et al. (2005).

Methods and Materials

Chemicals The Argentine ant trail pheromone (*Z*)-9-hexadecenal (94% purity; Bedoukian Research, Danbury, CT, USA) was loaded in micronized carnuba wax (Eggar & Co. Ltd. (Reading, UK), as plant wax is an effective carrier for pheromones (Karg et al. 1994). In single point source tests at close range, the pheromone source was prepared either as (a) 0.1 g pheromone in hexane (10% by vol.) steeped in 1 g of carnuba wax in a closed 1-ml glass screw cap vial at room temperature for 2 h, and then the solvent was evaporated off, or (b) by coating particles of white quartz sand (−50 + 70 mesh, Sigma Aldrich, Saint Louis, MO, USA) with melted wax (20% wax by weight) in a rotary evaporator, and then adding pheromone to give a mixture consisting of 1 g quartz sand/200 mg wax/1 mg pheromone.

Disrupting Trail Following from a Point Source Ant density and trail walking behaviors, before and after treatment, were used to characterize disruption from a single point source on a range of vertical and horizontal substrates in and around a wooden office building located at ca 1,200 m altitude in Hawaii Volcanoes National Park, Hawaii. A Logitech webcam (640×480 pixels, Notebook Pro, Logitech, Freemont, CA, USA) recorded avi files at rate of 15 frames/s onto a laptop computer (actual screen size 10×12 cm at 480×640 pixels). A plastic ruler was used for frame calibration before treatment. All experimental data were collected between 10 A.M. and 3 P.M.

Video Recording and Statistical Analysis The position of ants in the frame, number of ants per frame, and walking track angle were measured in the first trial, but only the position of ants was analyzed for the subsequent three experiments. The position and movement of individual ants was analyzed with MaxTraq v1.92 trial edition (Innovision Systems, Lapeer, MI, USA). The *x*–*y* positions of the ants were either recorded continuously (15 frames/s) or from individual frames at 5-s intervals, as this was sufficient time for the ants to leave the video frame under control conditions, thus rendering the samples independent. Walking angles of individual ants were analyzed from sequential frames and were calculated as: $\theta\,^{\circ} = \text{Arctan}\,\Delta X/\Delta Y \times 180/\pi$, where $\theta\,^{\circ}$ is the walking angle, and ΔX and ΔY are the distance traveled between two consecutive frames on the *X*–*Y* axes, respectively. Values generated when an ant apparently did not move in two consecutive frames were discarded, as these rare cases would be erroneous. Regression statistics for trail integrity (r^2) were calculated

from the position of digitized ants, before and after treatment. A *t* test was used to determine the significance of trail integrity in each of the tests, following Shapiro and Wilk tests for normality (Zar 1984). For experiment 1, the number of ants present in the video frame on the wall before and after the vial was introduced was analyzed by regression of count over time over 40 min. Sampling of the avi file at 5-s intervals was undertaken at the beginning and end of the time series to improve precision. The walking track angles of individual ants walking on a painted internal wall at high traffic density were compiled into histograms, and the track angle distributions were compared by two-sample *F* test for variance for before and after exposure to the pheromone.

Test 1.1 Ants (between 20 and 40 per frame) on a vertical interior wall were recorded as in a continuous stream, diagonally across the frame for 2 min at 300 and 120 s before the experiment, and confirmed that the foraging trail was linear. Activity was recorded continuously for 60 s before the glass vial with pheromone was opened within the camera view (2 cm to the right of the lower left corner) and after a 20-s behavior was recorded for another 60 s. Recordings were made continuously over the next 30 min, at which time the vial was removed and activity was recorded for an additional 7 min. The same experimental procedure was carried out on a painted outdoor wall (*Test 1:2*) at low to moderate density (range one to 13 ants per frame), but in this case, the ant positions were digitized for 100 s following treatment.

Test 1.3 and 1.4 Ant walking tracks, on an interior wooden floor (five to 30 ants per frame) or on an outdoor concrete step covered by a roof eave (four to 13 ants per frame), were recorded as above, before and after a 10-mg sample of carnuba wax containing 1 mg trail pheromone was placed in the view, ca. 4 cm from the trail. Ants were recorded, and positions were digitized for up to 340 s post-treatment.

Experiment 2.1: Small Plot Disruption (1 m^2) Semi-field plots (>3 m between plots) were established under the eaves of the office building (to avoid rainfall). There were four treatments (a sand alone control or 2.5, 7.5, and 25 mg of pheromone), and in each case, the ant sand was mixed with local Kilauea cinder soil to give a final amount of 50 g that was applied to each 1 m^2 plot by using a hand-held rotary spreader (Handy Green II, Scott's, Mayville, OH, USA).

A plastic-coated 3×5 cm card was baited with a small dab of 1:1 macerated tuna (chunky light tuna in water, Bumblebee Foods, San Diego, CA, USA) and Karo light corn syrup (ACH Food Companies, Memphis TN, USA) and placed in the center of a white sheet of paper taped to a firm backing in the center of each plot for 1 h before treatment. The number of ants at the bait card and the presence of the trails (a 1-min visual assessment) were recorded pre-treatment and then at 1, 2, 3, 24, 48, 72, 120, 144, and 196 h after treatment. Baits were covered each night with inverted plastic bins to protect them against vermins. The experiment was replicated three times, and fresh baits were used for each assessment in each replicate. Video files (15 frames/s) were also recorded in the sand control and the high rate (25 mg/m^2) plots, 24 h post-treatment, so that walking track angles could be calculated as with the single point experiment above.

Experiment 2.2: Trail Disruption Impacts on Ant Foraging Twenty-four plots (4 m^2), at least 10 m apart, were established in the Broomsedge Burn (19°25′59.6″ N, 155° 17′35.2″ W) of Hawaii Volcanoes National Park (1,200 m elevation), an area with few trees but dominated by clumps (1–3/m^2) of about 1-m-high broomsedge bluestem (*Andropogon virginicus*). Thus, the study site was exposed to prevailing trade winds, making it a challenging natural ecosystem to test rigorously the concept of trail disruption.

Sand samples were mixed with Kilauea cinder soil to give 200 g lots of soil containing 0, 10, 30, and 100 mg of pheromone, and at the start, each of the six replicates were applied to the plots by using a hand-held rotary spreader. Bait cards were placed directly on the ground at the center of each plot and protected from the direct rays of the sun by inverted plastic plates (25 cm diam.) suspended 15 cm above ground level. New baits were used for each observation period, except between the pre-treatment and first post-treatment ones.

Measurements of ant density at the bait card and visual assessment of the presence/absence of visible trails ants in 1-m^2 core of each plot were carried out just before treatment and then 1, 2, 3, 24, and 48 h after treatment. Wind speeds at ground level (2 cm), as well as at 1 and 2 m height, and shaded ground temperature were recorded at the time of application and toward the end of the observation period each day (2–3 P.M.).

In both field trials, analyses of variance were conducted on log-transformed counts of ants for each time interval, with Tukey tests to separate treatment effects.

Pheromone Release Rate Ant sand was aged in a laboratory fume hood (ca. 20°C) with an airflow (0.5 m/s) at Lincoln, New Zealand so that pheromone release rates could be estimated. The pheromones in three subsamples were extracted by adding 1,800 μl ethanol with 200 μl of 1 mg/ml decanal as the internal standard, vortexed, sonicated at 25°C for 30 min, centrifuged at 3,000 rpm for 10 min, and then filtered through 0.45-μm PTFE filter. Samples were analyzed by gas chromatography with a GC-

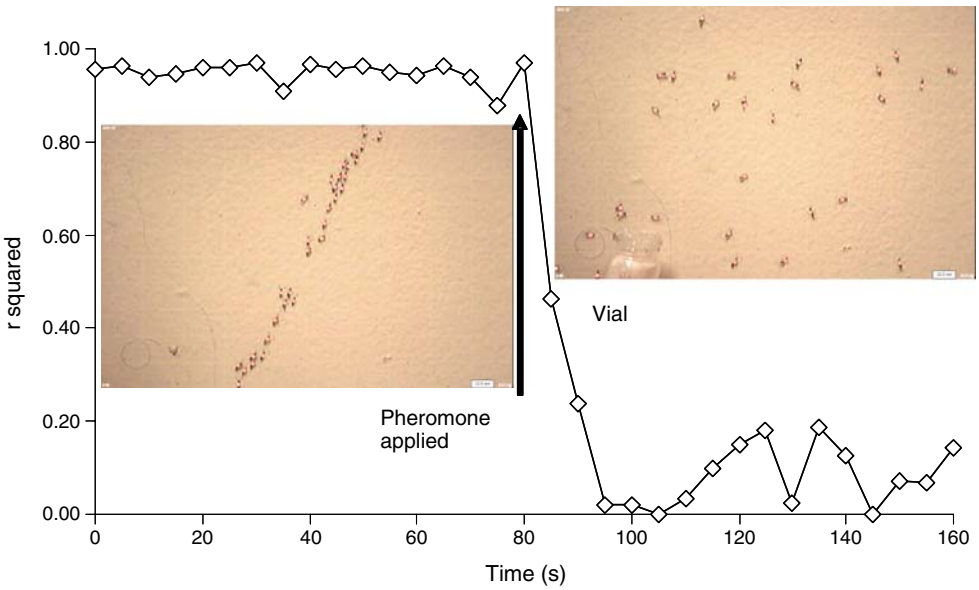

Fig. 1 Disruption of trail integrity (r^2) of high-density foraging trails of Argentine ant after the introduction of a vial at 80 s, containing a slow release formulation of carnuba wax with 100 mg of the trail pheromone, (*Z*)-9-hexedecenal. Ants are shown with *numbered dots*, before and after treatment

FID BPX-70 polar column, splitless, injector 220°C, flow 1 ml/min He, with a temperature program of 80°C for 1 min then ramped up to 220°C at 5°C/min and held for 1 min (total 30 min). The entire procedure was repeated twice.

Results

Disrupting Trail Following from a Point Source Ant trails at high traffic density on the wall (between 20 and 40 ants in the field of view) were <1 cm wide and linear. Upon introduction of the synthetic trail pheromone, the integrity of the trail was disrupted completely within seconds (Fig. 1; Test 1.1, Table 1; supplementary material, video A), as evidenced by an immediate drop in the value of the r^2 statistic. Trail-following behavior was disrupted for 30 min that the vial was present and for at least 7 min after its removal. Inspection the next day showed some evidence of disruption, although this was not quantified, possibly due to absorption of pheromone in the wall paint.

The number of ants increased significantly over time at the site (Fig. 2), probably due to ants arriving for both the food source and the nest but unable to leave by using the normal trail because of the pheromone treatment.

Ants initially showed a unimodal distribution of walking angles (with a SE 7.18 from 560 observations), but after presentation of the trail pheromone, there was no clear peak (an SE of 2.94 from 340 observations; Fig. 3; $F_{18,18}=5.94$, $P<0.001$).

Experiment 2.1: Small Plot Disruption (1 m^2) There was no difference in bait card visitation between bait cards before treatment and after 1 h in the sand control ($F_{3,8}=0.34$, $P=0.798$), but there was a significant decline in visitation in all pheromone-treated plots (Fig. 4). There was an overall difference in the number of foraging workers at bait cards between pheromone and control over 24 h (1 h, $F_{3,8}=4.71$, $P=0.035$; 2 h, $F_{3,8}=10.05$, $P=0.004$; 3 h, $F_{3,8}=12.62$, $P=0.002$; 4 h, $F_{3,8}=13.20$, $P=0.002$; 24 h, $F_{3,8}=11.05$, $P=0.003$). The disruption effect was marginally significant

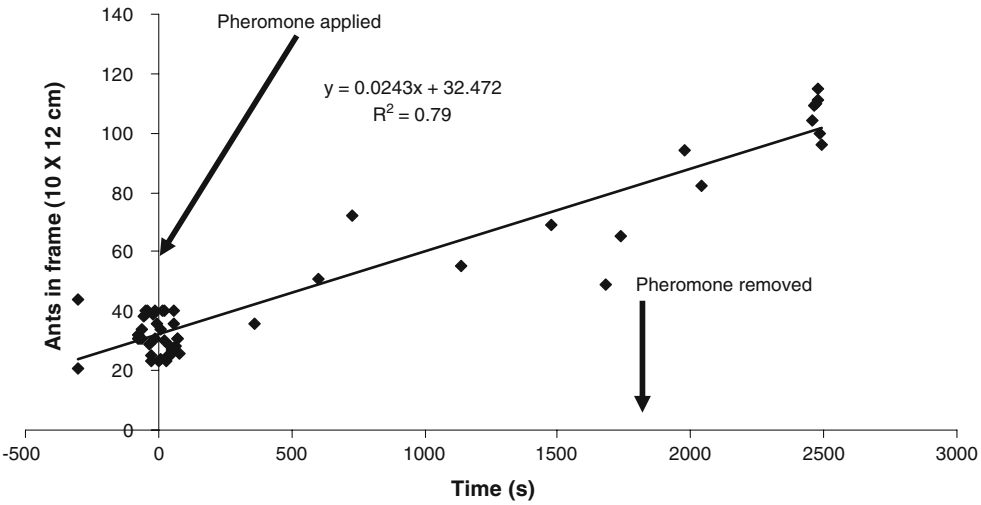

Fig. 2 Increase in the number of Argentine ants in the video frame after the introduction of a vial containing a slow release formulation of carnuba wax with 100 mg of the trail pheromone (*Z*)-9-hexedecenal

after 48 h ($F_{3,8}$=0.041) but not at any later times (Fig. 4). Tukey tests indicated significant differences (P<0.05) between the control and all pheromone treatments at 1, 2, 3, and 4 h, while at 24 h, only the 2.5- and 7.5-mg/m^2 application rates differed from the control. By 48 h, this effect had started to decline in these treatments. The absence of evident trails lasted 72 h in all three treated plots (Supplementary material, Fig. A).

Ants in the three sand controls all showed unimodal distributions of walking track angles, which was not the case in the 25 mg/m^2 pheromone treatment (Fig. 5). The difference in walking track angles between the treatment and controls was significant (P<0.05, t=4.06, df=3).

Experiment 2.2: Trail Disruption Impacts on Ant Foraging There was no difference in the number of foraging ants in the different plots before treatment ($F_{3,\ 20}$=0.53, P=0.66). However, there was a decline in the number of visiting bait cards for 2 h (1 h, $F_{3,\ 20}$=8.61, P<0.001; 2 h, $F_{3,\ 20}$=4.63, P=0.013, Fig. 6) when comparing treated vs. control plots, but after that, there were no significant differences (3 h, $F_{3,\ 20}$=2.92, P=0.059; 24 h, $F_{3,\ 20}$=0.66, P=0.59). The significant differences observed were due to the two higher concentrations of pheromone (Tukeys tests, P<0.05). There was evidence of trail-following behaviors in control plots for the duration of each trial but none for 24 h after treatment in the pheromone ones (Supplementary material, Fig. B). There was a correlation (r^2=0.36, P< 0.05) between the methods assessing disruption of counts at bait cards and disruption of trails in this experiment.

Pheromone Release Rate The experimental wax formulation had a high first-order release rate with ca. 30% loss of the applied material in 2 days at 20°C under laboratory conditions, giving an estimated half-life of 30 h for the ant sand preparation (Supplementary material, Fig. C). Using this laboratory data, the estimated release rates for the 25 mg/m^2 treatment in the field, where temperatures averaged about 22°C, were 260 and 200 μg/h/m^2 1 and 4 h after treatment (Figs. 4 and 6).

Discussion

The results of this study demonstrate the proof of concept of trail disruption against the Argentine ant indoors, as well as in small semi-field and field plots. Close-range trail orientation behaviors were significantly disrupted when the ants were exposed to an excess of their trail pheromone, resulting in a virtually instantaneous increase in turning behavior and a complete lack of orientation to the natural foraging trail. Furthermore, the deployment of a dispersible formulation, such as the ant sand used here, would have a natural advantage over a few large emission rate point sources for trail disruption (Suckling and Angerilli 1996). When applied, the material would fall within the boundary layer of the pest species, thus ensuring maximum atmospheric concentrations at the most suitable site (Suckling et al. 1999).

However, the effects observed were of quite short duration, especially in field plots where a variety of abiotic conditions (such as temperature, UV, and wind; Supplementary material, Fig. D) could markedly affect both release rates and persistence of the pheromone. Clearly, more research is required to determine the feasibility of this technique at a practical level. The fact that the highest concentration tested varied in efficacy in the field trials underlines the need to develop new formulations to provide longer and more consistent pheromone release under a range of different climatic conditions.

One also needs to find the minimum dose that would effectively disrupt trail-following behavior for an extended period of time. (*Z*)-9-Hexadecenal, being a lepidopteran sex pheromone (Nesbitt et al. 1975; Piccardi et al. 1977; Mayer and McLaughlin 1991), is more readily available than many other ant trail pheromones, but if the concentration required is too high, then trail disruption may not be economically

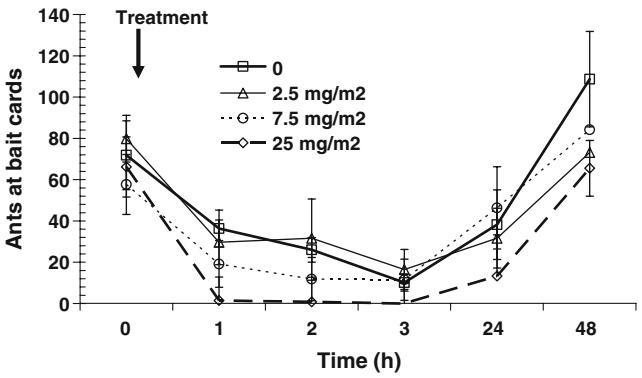

Fig. 6 Mean (±SEM) number of Argentine ants present at bait cards before and after treatment with three rates (milligrams per square meter) in 4-m^2 plots of a trail pheromone-laden wax and sand formulation at the Broomsedge Burn area of Hawaii Volcanoes National Park

viable as a stand-alone management tool, even for sensitive ecosystems. Cavill et al. (1979) reported many other compounds from the Argentine ant, and these merit investigation, as some of these minor compounds might improve both trail following and its disruption. Even if this were not the case, the integration of trail disruption with other control tactics warrants investigation.

Additional work on the trail-following behavior of the ants also is required, including further evaluation of the proposed trail integrity statistic, r^2. Van Vorhis Key and Baker (1986) reported that workers are more likely to follow trails if they meet an engorged con-specific, and they have other complex behaviors that may render trail disruption unsuccessful. For example, ants crossing an uninterrupted portion of the trail deposit more pheromone than those crossing "odor" gaps. Thus, if workers respond by increasing the concentration they release, this could reduce the duration of trail disruption.

Our results suggest that it would be worth trying a similar approach for the disruption of trail following in the Red Imported Fire Ant since they are an even more significant ecological problem in urban and sensitive environments world wide, causing billions of dollars of loss every year (Pimentel et al. 2000). Successful application of trail pheromones to tackle such pest ants may have significant environmental and social benefits.
